Comparison studies involving laboratories engaged in water and wastewater analysis have been made regularly for many years by various overseas organizations, for example, the U.S. Environmental Protection Agency, the Canada Centre for Inland Waters, the U.K. Water Research Centre and the National Swedish Environment Protection Board. Similar studies for southern African water-analysis laboratories, however, were not established until 1976, when the National Institute for Water Research introduced a series of six studies, in which 16 invited laboratories participated (Table 1).[1-7]

On completion of this programme in 1978, it was decided to continue the studies on a larger scale, to include any laboratory engaged in water or wastewater analysis in South Africa, Namibia, or Zimbabwe, and interested in taking part. A second series, consisting of ten studies, involving 46 laboratories from industry, government and statutory organizations, and various municipalities, was commenced in 1979 and completed in 1982 (Table 2).[8-18]

This paper describes the organization of the vari-

Table 1. Programme of studies (1976–78)

Study No.	Title	Determinands	No. of participants
76/A,B	Introductory study	Chemical oxygen demand, total organic carbon, Kjeldahl, ammonia, nitrate and nitrite nitrogen, total and orthophosphate, chloride, sulphate, fluoride, silicon, total alkalinity, pH, electrical conductivity, sodium, potassium, calcium, magnesium, cadmium, chromium, cobalt, copper, iron, lead, manganese, nickel, strontium, zinc, arsenic, mercury	15
77/A	COD, pH and electrical conductivity analysis	Chemical oxygen demand, pH, electrical conductivity	18
77/B	Nutrient analysis	Kjeldahl, ammonia, nitrate and nitrite nitrogen, total and orthophosphate	16
77/C	Mineral analysis	Sodium, potassium, calcium, magnesium, chloride, sulphate, fluoride, total alkalinity	16
78/A	Trace metal analysis	(1) Mercury, cadmium, chromium, cobalt, copper, iron, lead, manganese, nickel (2) Zinc, aluminium, arsenic, selenium, beryllium, lithium, strontium, vanadium, barium, silver	14
78/B	Boron, silicon, MBAS, cyanide, phenol, sulphide, BOD, colour and turbidity analyses	Boron, silicon, Methylene Blue active substances, cyanide, phenol, sulphide, biochemical oxygen demand, colour, turbidity	14

ous studies and the statistical evaluation of the results obtained, and summarizes the findings and recommendations arising from these studies.

ORGANIZATION OF THE STUDIES

For an interlaboratory comparison study to produce meaningful results, a number of important factors must be taken into consideration with regard to the organization of the study.

(1) To be able to evaluate satisfactorily the methods and data and prepare comprehensive written reports on the results, the originator (or co-ordinator) of the study should be well-qualified and experienced in analytical chemistry, especially in water analysis, and

Table 2. Programme of studies (1979–1982)

Study No.	Title	Determinands	No. of participants
79/A	Analysis of a surface water and a sewage effluent	pH, electrical conductivity, colour, turbidity, chemical oxygen demand, Methylene Blue active substances, Kjeldahl, ammonia, nitrate and nitrite nitrogen, total phosphorus, orthophosphate, chloride, sulphate, fluoride, total alkalinity, total filterable residue, silica, boron, cyanide, phenols, calcium, magnesium, potassium, sodium, copper, iron, manganese, zinc, aluminium, mercury	44
79/B	Evaluation of the comparative reliability of the COD determination	Chemical oxygen demand	37
80/A	Analysis of major cations and anions	Calcium, magnesium, potassium, sodium, chloride, sulphate, total alkalinity	47
80/B	Determination of trace metals	Cadmium, chromium, copper, iron, lead, manganese, zinc, arsenic, selenium, mercury	28
80/C	Determination of trace metals in sewage sludge	Aluminium, cadmium, chromium, copper, iron, lead, manganese, nickel, zinc	20
81/A	Nitrogen and phosphorus analysis	Kjeldahl, ammonia, nitrate and nitrite nitrogen, total phosphorus, orthophosphate	45
81/B	Determination of physical properties	pH, electrical conductivity, total residue, colour, turbidity	42
81/C	Determination of chlorinated hydrocarbon pesticides in water	Aldrin, dieldrin, DDD, DDE, DDT, heptachlor, chlordane	7
82/A	Determination of boron, silica, fluoride, MBAS, phenols, cyanide and sulphide	Boron, silica, fluoride, Methylene Blue active substances, phenols, cyanide, sulphide	31
82/B	Analysis of a drinking-water and a mine drainage effluent	pH, electrical conductivity, colour, turbidity, chemical oxygen demand, Kjeldahl, ammonia, nitrate and nitrite nitrogen, total phosphorus, orthophosphate, chloride, sulphate, fluoride, total alkalinity, total filterable residue, silica, calcium, magnesium, potassium, sodium, copper, iron, manganese, zinc, aluminium	40

have a reasonable knowledge of the application of statistics.

(2) The objective of the study should be clearly stated and understood. Clear, concise, unambiguous instructions for performing the study must be issued, along with a suitable form for the recording and return of the required data.

(3) Careful selection, preparation, preservation and packaging of the samples is essential.

(4) Complete co-operation of the participating laboratories in adhering exactly to the instructions supplied must be enlisted.

Samples

More or less similar sample preparation procedures were employed for all the studies involving the analysis of synthetic water samples. These samples were generally prepared by dissolving the calculated amounts of analytical-reagent grade chemicals (or standard metal solutions) in known volumes of demineralized distilled water containing, where applicable, the necessary preservative.[19] In the case of natural water samples, only the required preservative was added. Suitable aliquots of each sample were sent to each participating laboratory.

The samples were contained in either 250-ml or 500-ml polythene bottles, which, prior to addition of the sample solutions, had been treated, along with their plastic caps, as follows.

(1) Soaking for a minimum of 24 hr in a 100-ml/l. Decon cleaning solution, followed by rinsing with demineralized distilled water.

(2) Soaking for a minimum of 24 hr in a 100-ml/l. nitric or hydrochloric acid solution (depending on the constituents in the sample), followed by rinsing with demineralized distilled water.

(3) Rinsing with sample solution.

Instructions

Each laboratory was supplied with a table detailing the constituents to be determined, along with the concentration range of each constituent in the sample. For all studies to date, the participants were allowed complete freedom of choice as to the analytical procedure to be employed. It was also requested that references to or brief details of the method used should be recorded along with the results in the data sheets provided.

A period of one month was generally allowed for analysis of the sample and submission of the results. Complete anonymity was maintained by allocating to each laboratory, at the beginning of each programme of studies, a code number, which was known only to that laboratory and the co-ordinator of the study.

STATISTICAL EVALUATION OF THE RESULTS

On completion of each study, all the results submitted were first examined for the presence of "outliers",

i.e., results which deviate to such a degree from the other results in the same set that they are considered irreconcilable with the other data. Rejection of outliers is often necessary in the evaluation of interlaboratory comparison studies, but considerable care must be exercised, as the treatment of outliers is a somewhat controversial subject. Literature on their detection and rejection is relatively extensive, and includes a wide variety of suggested techniques, for example Dixon's Q-test,[20,21] Cochran's maximum variance test,[20] Grubb's test,[21] Student's t-test,[21] coefficient of variance test,[21] and coefficient of skewness test.[21]

For simplicity and because it is recommended in a standard text on water analysis, the ASTM procedure for outlier rejection[22] was selected for application in these studies. In this method, a suspected outlier is tested by calculating its "T value". If the T value is greater than that recorded in a table of critical values for T, the outlier may be rejected:

$$T_n = \frac{(x_n - \bar{x})}{s}$$

where $T_n = T$ for the observation being tested, $x_n =$ individual value being tested, $\bar{x} =$ arithmetic mean of all values in the level containing x_n, $s =$ estimated standard deviation of the set of results.

After the removal of outliers, the mean value of each set of results was then calculated, followed by the determination of simple measures of accuracy (mean error and relative mean error) and precision (standard deviation and coefficient of variation). For certain studies, the 95% confidence limits were also calculated. At this stage, an interim report, showing details of the results and statistical evaluations, was sent to all participants. An example of such a report, taken from study No. 77/B,[3] is shown in Table 3.

In almost all the studies involving the analysis of synthetic water samples, two sets of similar samples were sent to each participating laboratory, the sets containing the same constituents but in slightly different concentrations. This was to allow for use of Youden's graphical technique of statistical evaluation.[23] In this technique, a graph is prepared of the results for each constituent determined by each laboratory, the results from one sample being plotted on the x-axis and those from the other on the y-axis. The two scales must be subdivided in the same units. Thus for each laboratory's pair of results, one point is produced, and is indicated by the code number of that laboratory. A horizontal line is then drawn through the mean of the values reported for the first sample and a vertical line through the mean of the values reported for the second sample. These two lines divide the graph into four quadrants (Fig. 1).

Graphical representation of the data in this manner allows interpretation to indicate the overall performance of a laboratory, as well as the types of error

*Outlier.

which may account for poor performance by a particular laboratory. For example (Fig. 1), points lying close to the intersection of the horizontal and vertical lines represent a high degree of accuracy (laboratories 1 and 2), whereas distant points represent poor accuracy (laboratories 3 and 4). Points lying close to one line but far from the other demonstrate inconsistent performance (laboratories 5 and 6). Information on a participating laboratory's precision may also be obtained from the graph. If all participants achieved perfect precision (i.e., no determinate error), but each had its own constant absolute bias, then all the paired points would fall in a 45° line passing through the origin (laboratories 1, 4, 7 and 8). Therefore, the distance of each laboratory's point from this 45° line is indicative of the measure of that laboratory's precision. Still further interpretation is possible for points lying far from the intersection of the horizontal and vertical lines. In theory, due to random or chance factors affecting the results, an equal number of points should fall into each of the four quadrants. In practice, however, this rarely occurs; most graphs of this nature show the majority of points falling in the upper right or lower left quadrants, suggesting that systematic errors consistently produce high or low results. Each quadrant identifies different effects which influence a laboratory's results. In general, results in the upper right or lower left quadrants are indicative of the presence of systematic errors, for example poor instrument calibration, inaccurate standards and/or faulty technique. Results in the upper left or lower right quadrants are inconsistently affected, and may be due to human errors such as those caused by mistakes in the calculation, recording, or reporting of results.[24] An actual example of a Youden graph, taken from study No. 77/C,[4] is shown in Fig. 2.

The results were then statistically assessed according to the method of Greenberg et al.,[24] viz. (i) results falling between the mean and ±1 standard deviation are acceptable; (ii) results falling between ±1 and ±2 standard deviations are acceptable but questionable; (iii) results outside the limits of ±2 standard deviations are unacceptable.

An example of such an assessment, taken from study No. 77/B,[3] is shown in Table 4.

Finally, the values obtained from the assessment of the results according to Greenberg's method were processed further by means of Madden's "ranking" technique employed by the Oklahoma Water Resources Board in their laboratory certification programme.[25] Each laboratory was allocated five points for every result within ±1 standard deviation of the mean, two points for every result between ±1 and ±2 standard deviations, and no points for any result falling outside ±2 standard deviations. The total number of points gained was then divided by the total number of analyses done, to give a quotient. The maximum quotient possible is 5.0. The laboratories were then ranked in order of the quotient
Fig. 1. Example of Youden's graphical technique for result evaluation.[23]

obtained. An example of a ranked assessment, again taken from study 77/B,[3] is shown in Table 5.

In the Oklahoma laboratory certification programme, if all the determinands available are analysed for by a particular laboratory, and that laboratory obtains a quotient of greater than 2.5, it is certified "A" for unrestricted analysis. If a laboratory analyses for all the available determinands and obtains a quotient of between 2.0 and 2.5 it is certified "R" for restricted analysis. If not all the determinands available are analysed for, and the laboratory obtains a quotient of greater than 2.0, is

is also certified "R". If a laboratory obtains a quotient of less than 2.0, it is not given certification, and is regarded as being unable to submit to the Board "data relating to the discharge of industrial water and to natural water quality".[25]

Quotients obtained by the 16 laboratories participating in the first programme of studies ranged from 2.9 to 4.7, with a mean of 4.0. In the second programme of studies the quotients obtained by the 46 participants ranged from 2.7 to 4.5 with a mean of 3.8. In both studies, therefore, all the laboratories would have qualified for certification in terms of the

Oklahoma Water Resources Board certification programme.

Other methods exist for ranking interlaboratory comparison-study results, for example, those of Thompson,[26] Youden,[26] and the National Environmental Research Centre,[26] but they are generally rather more complicated than the technique employed in these studies.

Where applicable, precision data obtained in the various studies were compared with those from similar overseas studies (mainly in the U.S.A. and Canada). In general, the comparison was favourable. However, in order to establish arbitrarily whether reasonable precision has been obtained in a particular study, use may be made of an equation derived from a study by Horwitz of the results obtained in over 150 independent interlaboratory comparison studies.[27] The equation relates interlaboratory coefficients of variation with concentration, as follows:

$$CV(\%) = 2^{(1 - 0.5 \log c)}$$

Where CV = coefficient of variation, c = concentration expressed in kg/l.

To be acceptable, the coefficient of variation obtained in the study for a particular concentration should approximate to or be less than the value obtained from the general curve based on this equation (Fig. 3).

In some studies, it was possible to apply "tests of significance" to the results; for example, in cases where two or more methods of analysis were

sufficiently employed to allow comparison of their accuracy by means of the t-test (which determines the significance of differences between the means of two sets of results), and of their precision by means of the F-test (which determines the significance of differences between the standard deviations of two sets of results).[28]

Mention should also be made of one other statistical evaluation technique. In certain studies, particularly those in which the reliability of particular analytical methods is being investigated, an evaluation which combines both the precision and the accuracy in an estimate of a "total error" can be used to judge the acceptability of a method:

$$\text{Total error (\%)} = \frac{(\bar{x} - T) + 2s}{T} \times 100$$

where $\bar{x}$ = arithmetic mean of the results, T = true value, s = estimated standard deviation of the set of results. Methods where the calculated value of the total error is less than 25% are rated as "excellent"; those where the value is greater than 25% but less than 50% are rated "acceptable"; and those where the value exceeds 50% are rated "unacceptable".[29]

SPECIFIC FINDINGS AND RECOMMENDATIONS

The information on analytical methods gained from the various studies has allowed a fairly comprehensive picture to be built up of the state of water analysis in southern Africa. It became evident early in the series that many of the laboratories involved in the studies were employing, for many determinands, a wide variety of both standard[19,22,30] and non-standard methods, as well as outdated standard procedures. The preparation of an updated recognized set of standard methods for the analysis of waters and wastewaters was therefore recommended, and this task has been undertaken by the National Institute for Water Research. In the interim, a list of recommended methods of water analysis, based on those given in the latest editions of *Standard Methods for the Examination of Water and Wastewater*[19] and *Methods for Chemical Analysis of Water and Wastes*[30] was drawn up and issued to the participating laboratories, along with a list of recommended sampling and sample-preservation procedures, also given in the same texts.[18] Also included in the list were the recommended SI units and the form in which the concentrations of the various determinands should be reported. The adoption of approved standard methods of analysis, units of concentration, and sample-collection and preservation procedures can significantly improve the reliability and comparability of the results obtained by water-analysis laboratories in southern Africa.

Specific findings and recommendations made during the studies included the following.

(1) Several laboratories initially submitted results

expressed as "trace", "not detectable", "nil", or "0". Such results are of little value. "Trace" and "not detectable" are practically meaningless unless accompanied by further explanation. Results should not be reported as "nil" or "0", but rather as less than the detection limit of the method used, for example, < 25 $\mu g/l.$, < 0.01 mg/l.[8,17]

(2) A wide variety of digestion procedures was used for total Kjeldahl nitrogen and total phosphate determinations, which could result in varying degrees of effectiveness in the digestion process, particularly where significant quantities of organic nitrogen and organic phosphorus compounds were present.[3,8,13,17]

(3) An examination of total alkalinity results showed that significantly higher values were obtained by laboratories using the indicator titration method than were obtained by laboratories using either the potentiometric titration or automated colorimetric techniques. In the case of laboratories employing the indicator titration method, the most accurate and precise results were obtained by those using the mixed Bromocresol Green/Methyl Red indicator. The high positive bias found could be attributed to the results submitted by laboratories using Methyl Orange as indicator.[10]

(4) A few laboratories determined some of the trace metals, as well as boron and silica, by means of inductively-coupled plasma optical-emission spectroscopy. The excellent results obtained are indicative of the value of this new, but as yet relatively expensive, technique for trace element determination.[12,16,17]

(5) The recommended interference suppressants should be used in the flame atomic-absorption determination of many of the major and trace metals routinely determined in water and wastewater, in particular calcium, magnesium, chromium, iron and manganese.[4,5,10,11,19,30,31]

(6) The use of similar interference suppressants was also recommended for the determination of metals in sewage sludge, as well as the use of background correction for metals such as cadmium, lead and nickel.[12]

(7) For purposes of standardization and comparison, all electrical conductivity determinations should be done at the standard temperature of $25°$,[19,30] or, alternatively, the appropriate correction factor should be applied.[2,8]

(8) Results of turbidity determinations should be reported only in nephelometric turbidity units (NTU) as recommended in the latest standard texts.[6,8,19,30]

(9) It was observed that several laboratories were still employing manoxol OT as the standard reference material in the determination of Methylene Blue active substances (MBAS). The use of linear alkylate sulphonate (LAS) as the only standard reference material was recommended, as specified in *Standard Methods*,[19] since the detergent industry changed over in 1965 from the use of alkylbenzenesulphonate (ABS) to the more biodegradable LAS.[6,16,19]

CONCLUSIONS

It is hoped that these programmes of interlaboratory comparison studies have been of assistance to the participating laboratories in assessing the effectiveness of their analytical procedures and the comparative reliability of the results obtained, and that the foregoing findings and recommendations will make a significant contribution to the achievement of a greater degree of standardization in methodology among water analysis laboratories in southern Africa.

Similar comparison studies, in which any water or wastewater analysis laboratory in southern Africa is welcome to participate, will continue to be conducted at regular intervals. Future studies will also be concerned, *inter alia*, with method comparison and evaluation.

Interlaboratory comparison studies such as those described in this paper can easily be adapted for use by any group of laboratories engaged in the analysis of a given type of material, for example food, pharmaceuticals, toiletries and detergents, soils, minerals, iron and steel, coal, and oil.

EXTRACTION–SPECTROPHOTOMETRIC DETERMINATION OF SMALL AMOUNTS OF BORON IN COPPER METAL AND COPPER-BASE ALLOYS WITH METHYLENE BLUE

Zdeněk Čížek and Vlasta Študlarová

Central Research Institute, Škoda Co., 316 00 Plzeň, Czechoslovakia

Summary—A sensitive and rapid spectrophotometric method for the determination of small amounts of boron in copper metal and some copper alloys is described. The method is based on the extraction of a BF_4^-–Methylene Blue complex into dichloroethane after decomposition of the sample with hydrogen peroxide and sulphuric acid. The optimum reaction conditions and the influence of alloying elements have been investigated. Boron contents in the range 0.00–0.1% can be determined with a relative error ranging from about 9 to 2%.

Boron is not usually determined in pure copper and copper-base alloys, mainly because it is generally present only as an impurity, though in special cases it may be added to improve some property of the metal, *e.g.*, grain refinement. Hence little attention has been paid to development of methods for the determination. Spectrographic methods are most commonly used for the purpose; the fluorimetric determination based on the boron–2,4-dihydroxy-benzophenone complex in sulphuric acid medium[1] and the spectrophotometric method based on the boron–curcumin complex[2] can also be used.

Here we propose use of the well-known tetra-fluoroborate–Methylene Blue method,[3–11] which has been applied to boron determination in various types of inorganic materials, *e.g.*, steels,[4,8,9,10,12–17] aluminium,[18,19] nickel alloys,[20] and sediments and rocks.[21]

For the sample decomposition we use hydrogen peroxide and sulphuric acid.[22,23]

EXPERIMENTAL

Apparatus

Teflon separating funnels (100 ml) were used for extraction.

Reagents

All reagents used were of analytical grade.
Sulphuric acid. Concentrated, and a 2.5M solution.
Hydrogen peroxide, 30%.
Hydrofluoric acid, 5% v/v solution.
Methylene Blue. A 0.002M solution, in water.
1,2-Dichloroethane. Purification by double distillation is recommended.
Standard boron solution, 0.100 mg/ml. Dissolve 0.572 g of boric acid in water and make up to 1000 ml. Before use, dilute to 10 μg/ml.

General procedure

Transfer 0.100 g of sample into a silica (or boron-free glass) tube (about 20 cm long and 1.5 cm internal diameter).

For copper metal samples add 1 ml of 30% hydrogen peroxide and then 0.7 ml of concentrated sulphuric acid. Mix well and let the sample dissolve without application of heat. When the dissolution is complete (*ca.* 1 min) add 10 ml of water. For alloys containing iron (*e.g.*, brass, bronze) use 1 ml of 30% hydrogen peroxide followed by 2 ml of 2.5M sulphuric acid and warm gently in a water-bath; when the sample has dissolved, add 3 ml of 2.5M sulphuric acid and 5 ml of water. For all samples, next mix thoroughly and heat the tube in a water-bath (90–95°) for about 10 min. After cooling, transfer the contents of the tube into a 100-ml Teflon separating funnel, rinsing the tube with 5 ml of water. Add 5 ml of 5% hydrofluoric acid and mix again. Leave to stand at room temperature for 1 hr. Then add 5 ml of 0.002M Methylene Blue and 25 ml of dichloroethane and shake the funnel vigorously for 1 min. Allow several minutes for the layers to separate, then drain the organic layer into a dry 25-ml beaker. Immediately transfer a 5-ml aliquot into a dry 25-ml standard flask and dilute to the mark with dichloroethane. Mix the contents and measure the absorbance at 660 nm in 5-mm or 1-cm cells against a blank prepared in the same way with boron-free high-purity copper.

Calibration graph

Weigh six 0.100 g portions of boron-free high-purity copper into silica tubes and dissolve them as described in the general procedure. Add 0, 1, 2, 3, 4, 5 ml of the standard 10-μg/ml boron solution and dilute each solution to 10 ml with water. Mix well, heat the tubes in a water-bath (90–95°) for about 10 min, and complete by the procedure described above.

RESULTS AND DISCUSSION

Sample decomposition

Nitrate and chloride interfere particularly strongly in the BF_4^-–Methylene Blue method, mainly by increasing the blank. Therefore decomposition with hydrogen peroxide and sulphuric acid was examined. It was found that the sample dissolved very rapidly if the sulphuric acid was added after the hydrogen

peroxide to a sample in the form of fine chips. The use of dilute acid for decomposition of copper alloys containing iron is to prevent the fast catalytic decomposition of the hydrogen peroxide. Both decomposition methods are rapid and quantitative and give the proper acidity for the extraction. So far as we can tell, decomposition of any borides is also complete. For accurate determination, the decomposition should be done in silica, boron-free glass, or plastic ware (polyethylene, polypropylene, Teflon). Any residual hydrogen peroxide after heating in the water-bath does not interfere in the formation of the BF_4^-–Methylene Blue complex.

Optimization of the reaction conditions

The extraction of the BF_4^-–Methylene Blue complex into dichloroethane has been studied in detail by a number of authors, so only certain aspects were investigated, viz. the formation of tetrafluoroborate in the presence of a large amount of copper(II), and optimization of the conditions for the boron determination.

It is known that the rate of formation of BF_4^- is slow, and the conversion of borate into BF_4^- is therefore the slowest part of the analytical procedure. The reaction can be accelerated by adding iron(III), which has a catalytic effect. However, it was found that in the presence of a large amount of copper(II) the conversion takes only 15 min, and if iron(III) is also present, it does not further increase the reaction rate. If the solution containing fluoride is left for more than 20 hr there is slight loss of boron (4% after 24 hr) by volatilization of boron trifluoride.

The reaction medium (type of acid used, acidity and the concentration of fluoride) has a significant influence on the formation of the BF_4^- complex, and on the extraction of the BF_4^-–Methylene Blue complex, and also on the blank value. The influence of the sulphuric and hydrofluoric acid concentrations and

the volume ratio of the aqueous and organic phases (R) was investigated by factorial experiment. The importance of the three factors decreases in the order $R > c_{HF} > c_{H_2SO_4}$. An increase in R or $c_{H_2SO_4}$ ($> 0.5M$) decreases the extraction efficiency; increasing c_{HF} increases the blank value. On the basis of the factorial experimentation, the optimum conditions are those given in the general procedure ($R = 1:1$, $0.5M$ sulphuric acid and 5 ml of 5% hydrofluoric acid used for the conversion). Under these conditions, the sensitivity is twice that for many other methods, the blank value is small and the results have good reproducibility.

Zinc, tin, aluminium, lead, antimony and arsenic do not interfere at concentrations (w/w in the sample) of 30, 15, 10, 4, 1 and 0.1%, respectively. If the tin content is greater than 1%, the metastannic acid precipitate should be filtered off after the sample decomposition; any loss of boron is negligible.

The calibration graph constructed by the method given is not linear and this must be taken into consideration in calculating the boron content if other aliquot volumes of sample solution are chosen.

Accuracy and precision

As standard samples of copper metal with certified boron content are not available, the method was validated by analysing synthetically prepared standard and real samples of copper alloys containing small amounts of boron.

The accuracy and precision established by spiking various types of copper metals and copper-base alloys with known amount of boron after the sample decomposition are summarized in Table 1. Similar precision was found by repeated determination of boron in real samples of copper alloys containing boron (special welding electrodes). The relative standard deviations were 2.3, 4.3 and 9.2% for 0.038,

0.006 and 0.0009% of boron, respectively. The detection limit (defined as three times the standard deviation of the blank) is 0.0002% B.

DETERMINATION OF HEXACELSIAN BY INFRARED SPECTROSCOPY

M. Carmen Guillem Villar* and Claudio Guillem Monzonís

Department of Inorganic Chemistry, Faculty of Chemistry, University of Valencia, Valencia, Spain

Summary—Hexacelsian has been determined by infrared spectroscopy with KBr discs and $K_4Fe(CN)_6$ as internal standard. A KBr particle size of $<40 \mu m$ gave better homogenization of the sample–KBr mixture than a particle size in the 40–70 μm range. For determinations of hexacelsian in synthetic samples containing amorphous phase or celsian, calibration curves were constructed. A least-squares fit yielded correlation coefficients of 0.998 and 0.997.

Hexacelsian, the hexagonal modification of barium feldspar ($BaAl_2Si_2O_8$), is thermodynamically stable between 1590 and 1760°, but persists as a metastable phase up to 1590°.[1] On heating of an equimolar mixture of kaolin and barium carbonate[1,2] the first product of the reaction is an amorphous phase formed between 650 and 950°; from this amorphous phase hexacelsian crystallizes at about 1000° and finally, at $>1200°$, celsian begins to be formed. Celsian is the monoclinic modification of barium feldspar, stable up to 1590°.

Hexacelsian has a sheet-like structure[3] consisting of SiO_4 and AlO_4 tetrahedra which form a double sheet parallel to the (0001) plane, with hexagonal symmetry. Barium atoms occupy positions between such double sheets, with a co-ordination number of 12, holding the sheets together. Hexacelsian has a perfect cleavage parallel to the (0001) plane, where the double sheets with residual negative charges (due to replacement of Si by Al) are matched by Ba^{2+} ions. Accordingly, it shows a high tendency towards a preferred orientation when examined by X-ray diffraction. For this reason, the X-ray diffraction technique cannot be applied to the determination of hexacelsian. In this work, a method for determining hexacelsian by infrared spectroscopy is described.

EXPERIMENTAL

Standards of the phases found in a sample containing hexacelsian obtained by synthesis were prepared, *i.e.*, the pure amorphous, hexacelsian and celsian phases. These pure phases were obtained from a standard equimolar mixture of kaolin and barium carbonate. The following raw materials were used: barium carbonate, analytical-reagent grade; kaolin, particle size $<2 \mu m$ (from Lage, Spain), with the following chemical composition (in %): SiO_2, 45.7; Al_2O_3, 38.3; Fe_2O_3, 0.2; CaO, 0.2; MgO, 0.1; Na_2O, 0.1; K_2O, 0.1; weight loss at 1100°, 14.5.

The pure amorphous phase, hexacelsian and celsian were prepared by heating this mixture for 24 hr at 800, 1020 and 1350°, respectively.

In order to select the key band for determination of hexacelsian, infrared spectra of the three pure phases were obtained (Figs. 1–3). The strong band at about 1220 cm^{-1} produced by hexacelsian suffers minimum interference from other bands and was therefore selected for hexacelsian determination.

The potassium bromide disc method[4–8] was employed. The use of an internal standard eliminates the need for determination of sample thickness and makes preparation of the calibration graph easier. The strong, sharp band of potassium ferrocyanide at about 2100 cm^{-1} was used for this purpose.

Sample treatment

Sample particle size has a marked effect on absorbance in infrared spectrometry.[9,10] To standardize the particle size distribution, the samples were ground by hand for 5 min in a porcelain mortar and then sieved with a 40-μm mesh sieve. Then about 10 mg of the fraction passing the sieve was placed in a small agate mortar, 5 drops of absolute ethanol were added, and the mixture was ground until just dry. This wet grinding was repeated twice more.

Sample and internal standard concentration

To minimize the relative error the absorbance should be in the range 0.2–0.8. Tests were made with different proportions of standard hexacelsian to potassium bromide to find the minimum and maximum proportions corresponding to this absorbance range. The same was done with the potassium ferrocyanide. The amount of KBr used for making a disc was also varied between 50 and 100 mg.

Fig. 1. Infrared spectrum of amorphous phase.
Fig. 2. Infrared spectrum of hexacelsian.
Fig. 3. Infrared spectrum of celsian.

Use of a mixture of 2 mg of sample and 0.6 mg of potassium ferrocyanide per 100 mg of potassium bromide, and of about 50 mg of mixture per disc was found to be the most suitable combination, because it gives an absorbance in the optimum range, and mixing is easy.

Analytical grade potassium bromide and potassium ferrocyanide were used. The latter was ground in the same way as the samples and then dried at 100°.

Previous experiments showed that a difference between particle sizes of matrix and sample affected the absorbance values measured. On the basis of these results, a potassium bromide fraction having particle size $<40~\mu m$ was used, and was heated at 450° for the time required to remove all residual water. This was monitored by means of the infrared spectrum and it was found that heating for 10 hr was sufficient for the water content to become negligible. The mixture was thoroughly homogenized with absolute ethanol in a planetary type ball mill for 1 hr.

Preparation of discs

About 100 mg of sample–matrix mixture was homogenized in a small agate mortar for 30 min. About 50 mg of this mixture was pressed into a disc 13 mm in diameter. The force on the plunger was 9.5 tons, maintained for 2 min. Two discs were prepared and two values of absorbance measured, the difference indicating the degree of homogenization.

Operating conditions

Measurements were made with a Pye Unicam IR-SP 2000 double-beam spectrophotometer in the range 1000–1400 cm^{-1} for hexacelsian and 1800–2400 cm^{-1} for the internal standard. Spectra were recorded with a linear absorbance scale, so a reproducible zero setting was achieved and the absorbance could be measured directly on the spectrum. Normal slit-width, a scanning speed of 95 cm^{-1}/min and a time constant of 10 sec were selected.

The absorbance was measured from the band maximum to a base-line drawn tangentially to the spectrometer tracing, at 1215 cm^{-1} for hexacelsian and 2060 cm^{-1} for the internal standard.

Calibration graphs

Samples containing hexacelsian can also contain either amorphous phase or celsian. Calibration graphs for both types were obtained by use of standard mixtures of the pure phases: amorphous phase–hexacelsian and celsian–hexacelsian. About 100-mg quantities of standards containing 10, 20, 30, 40, 50, 60, 70, 80 and 90% of hexacelsian were prepared. They were mixed by grinding in a small agate mortar, first in the dry form for 30 min and then (three times) to dryness after addition of 0.5 ml of absolute ethanol.

By the procedure described above, two discs of each calibration sample were prepared. On the corresponding infrared spectra, the absorbances at the wavenumber for the hexacelsian maximum, A_H, and that for the ferrocyanide standard, A_S, were measured. The ratio, A_H/A_S, for each disc, and the average ratio for each sample, $\overline{A_H/A_S}$, were calculated. The two calibration curves were constructed by plotting $(\overline{A_H/A_S})$ vs. concentration of hexacelsian (H) expressed as mg of H per 100 mg of KBr. The linearity of both plots shows that the Beer–Lambert law is obeyed. Least-squares analysis yielded correlation coefficients of 0.998 for samples containing amorphous phase and 0.997 for those containing celsian.

Points corresponding to samples containing low percentages of hexacelsian are not used because the broad intense absorption band, either of amorphous phase or of celsian, near the analytical band, interferes by its effect on the base-line on the low wavenumber side. The highest interference is observed in samples containing hexacelsian and amorphous phase, because the band of the amorphous phase overlaps the analytical band to a greater extent than the band of celsian does.

RESULTS AND DISCUSSION

The method of quantitative analysis described in this paper has been applied to samples obtained by heating equimolar mixtures of kaolin and barium carbonate at temperatures from 900 to 1200° for 6 hr,[11] and also to the kinetic study of hexacelsian formation and the hexacelsian → celsian phase transition.[12]

In the analysis of samples, A_H and A_S were measured and the A_H/A_S ratio was calculated for each disc. The least-squares fitting of the $\overline{A_H/A_S}$ values and mg of H per 100 mg of KBr for the calibration standards was made by a computational program that also handled the measured A_H/A_S values for the test samples (obtained in the same measurement session) to output the mg of H per 100 mg of KBr ratios for the samples. The mg of sample per 100 mg of KBr ratio was known from the quantities used in preparing the discs. The ratio of the hexacelsian content of the unknown samples (mg of H/100 mg of KBr) to the weighed amount of these samples (mg of sample/100 mg of KBr) gave the hexacelsian/sample weight ratio. This proportion, compared with the theoretical value calculated from the reaction equation, assuming a maximum yield of 100%, gave the degree of conversion. For each sample, the average of

the values for the two discs was taken. This allowed the rate of formation of hexacelsian from the amorphous phase to be found, and also the extent of conversion of hexacelsian into celsian, when the samples analysed had been heated in the temperature range in which this transition took place.

To study the reproducibility, twelve pellets of an equimolar mixture of kaolin and barium carbonate were heated, all at the same time, at 1000° for 6 hr. From ten of them the corresponding individual sample–matrix mixtures were prepared. From each of the other two, eight sample–matrix mixtures were prepared. The standard deviations obtained in the analyses were 1.6% hexacelsian for the 10 separate samples identically synthesized, 1.3% hexacelsian for the 8 mixtures of one sample, and 1.4% for the 8 mixtures of the other sample. The standard deviations were also calculated for the duplicate discs obtained from each sample–matrix mixture. The average value for these standard deviations was 0.8% hexacelsian.

CONCLUSIONS

A particle size of <40 μm should be used, because it gives better homogenization than the 40–70 μm size range recommended earlier. The results obtained show the importance of using, for the calibration samples, a matrix as similar as possible to that present in the samples to be analysed, because of the partial overlap of the spectral bands of matrix and analyte.

The method has the advantages of small sample size, easy handling and reproducibility of sample preparation. It provides a method of analysis for those cases, such as hexacelsian, where the X-ray diffraction technique cannot be applied. Although the method has been described for the specific case of samples obtained by synthesis and which can therefore contain amorphous phase or celsian, the method can be applied to any sample containing hexacelsian. Furthermore, the lower limits to the determination of hexacelsian in the presence of amorphous phase ($>30\%$) or of celsian ($>15\%$) are reduced where these two phases are not present. In order to apply the method to other samples the effect of the matrix must be taken into account, and if the hexacelsian content is $<10\%$ then the sample size must be increased above the 2 mg per 100 mg of KBr recommended here.

UREA AS THE BASIC COMPONENT IN PYRIDINE-FREE KARL FISCHER REAGENT

M. Bos

Department of Chemical Technology, Technical University Twente, P.O. Box 217, 7500 AE Enschede,
The Netherlands

Summary—A solution of urea, sulphur dioxide and sodium salicylate in methanol is proposed as the solvent in the Karl Fischer titration, with a separate iodine solution as titrant. Comparison of the performance of this solvent with that of some commercial reagents shows that it is has distinct advantages for use with amine samples.

Since the elucidation of the reaction mechanism of the Karl Fischer titration by Verhoef and Barendrecht,[1,2] a number of compounds have been proposed to replace the pyridine in the classical reagent, *viz.* sodium acetate,[3] diethanolamine[4] and imidazole.[5] These components serve, as the pyridine did, to buffer the titration medium at a pH-value that ensures a convenient overall titration rate and a stable end-point. Other criteria that determine the usefulness of the reagents are the long-term stability of the solution and the number of classes of compound for which the water determination can be done without problems.

The goal of the investigation described here was the preparation of a new reagent that—just like the original pyridine-containing reagent—would have its buffering action in a more acidic range than that of the reagents mentioned above.

EXPERIMENTAL

Reagents

The following substances were used as received: urea (puriss. p.a.), triethanolamine (puriss. p.a.) and imidazole (purum) from Fluka, sodium salicylate (zur Analyse) from Merck, triethylamine (puriss.) from Koch-Light, salicyclic acid from ACF, sulphur dioxide from Matheson, and the sodium salt of benzenesulphinic acid from Janssen. The methanol used to prepare the Karl Fischer solvents was reagent grade from Baker, and dried with 3A molecular sieve (Union Carbide) for 24 hr before use. The lithium chloride (Merck, Suprapur) was dried for 24 hr at 150°.

The commercial Karl Fischer solvents used were Karl Fischer Lösung A (Merck, Pyridin Schwefeldioxid Lösung), Karl Fischer Lösungsmittel Pyridinfrei (Merck) and Hydranal solvent (Riedel-de Haën).

Apparatus

The titrations were done with Radiometer Karl Fischer titration equipment consisting of the Karl Fischer titration assembly TT-A1-KF, titrator TTT11b and mV/pH-meter PHM28. The pH of the titration medium was measured with a Knick pH-meter, type PH60, and an Ingold combined glass/reference electrode, type 405, of which the reference electrode compartment was filled with a saturated solution of lithium chloride in methanol. The electrode was calibrated with methanolic solutions of salicylic acid and sodium salicylate as described by Bos and Lengton.[6]

Procedure

The titration procedure is based on the separate titrant/solvent-reagent system and was performed as follows. The titration vessel was filled with 20 ml of the reagent under study (SO₂/base/methanol) and pretitrated with the iodine/methanol titrant to a preset end-point (300 mV) with

Table 1. The amount of water that can be titrated in 20 ml of reagent, and the resulting pH-change

the bipotentiometric detection system, operated with a fixed current in the range 2–3 μA. The value of 300 mV should persist for at least 20 sec. After this pretitration the water-containing sample was introduced into the titration vessel and the titrator was started again.

The short-term stability of the reagent was checked by measuring the iodine titrant consumption after the stop criterion of the titration was met, by continuing the titration in the "no stop mode". The iodine/methanol reagent was standardized against weighed samples of pure water. The long-term stability of the reagent was checked by period-ically measuring the amount of iodine titrant consumed in the pretitrations.

RESULTS

Table 1 shows the amount of water that can be titrated in 20 ml of solvents of various compositions, together with the change in pH that accompanies the process.

A solvent with the composition $1M$ urea/$1M$ SO_2/methanol gave inaccurate results because the reaction proceeded very slowly, and was not studied any further.

As can be seen, the urea/sodium salicylate/SO_2/methanol mixture is the most acidic of the reagents tested and the only one that shows overlap in pH-range on the acidic side with the classical pyridine/SO_2/methanol reagent as manufactured by Merck. The amount of water that can be titrated in 20 ml of this reagent compares favourably with that for the commercial products not containing pyridine.

The urea/sodium salicylate/SO_2/methanol mixture was investigated somewhat further with regard to its stability on storage (Table 2) and with regard to the influence of the concentrations of its constituents on the speed of the titration (Table 3).

Table 2 shows that the stability on storage is rather good. No significant increase in the water content of the reagent was observed during the first 4 weeks of storage at room temperature, and only a minor increase after that period.

From Table 3 it can be seen that an increase in the concentrations of urea and sulphur dioxide consid-erably speeds up the titration of 100 mg of water. At concentrations of urea and sulphur dioxide above $1.5M$ the gain in titration speed levels off. This composition seemed a good compromise between reagent cost and titration speed and was compared with two commercial products in the consecutive titration of a number of actual samples of different chemical classes (Table 4). All titrations were per-formed with 20 ml of reagent as solvent. The sample size varied between 1 and 4 g, depending on the water content. For the entries marked "no problems" in Table 4, the reproducibility was better than $\pm 1\%$.

In general the results obtained with the urea-containing reagent are comparable with those ob-tained with the commercial reagents. However, for the amine samples there is a significant difference; these can only be titrated successfully in the urea-containing reagent. It is likely that this is due to the more acidic nature of this reagent. The effect of varying the sodium salicylate concentration was not examined, since the $0.5M$ concentration initially used seemed suitable enough.

DETERMINATION OF TRACE WATER IN ORGANIC SOLVENTS BY A SPECTROFLUORIMETRIC METHOD

Ci Yunxiang and Jia Xin

Department of Chemistry, Peking University, Beijing, People's Republic of China

Summary—A new method for the spectrofluorimetric determination of water in organic solvents has been developed. It is based on formation of the exciplex of pyridoxal with water. The procedure is sensitive, reproducible and useful for the determination of trace water in cyclohexane, petroleum ether, benzene, carbon tetrachloride, diethyl ether, tetrahydrofuran, dioxan, *etc*. The solubility of water in benzene at various temperatures has been determined.

Many methods have been developed for determination of water in organic solvents. The early methods[1-4] suffered from certain limitations and lack of precision and accuracy. The modern methods, such as the isotope-dilution method,[5-7] the infrared difference-spectroscopy method[8] and chromatography,[9,10] have greatly increased the accuracy, and the results obtained by different methods have become more and more consistent. These methods involve some quite complicated procedures, however, which limits their application. The widely used Karl Fischer method has certain shortcomings in trace analysis. In order to extend the work in this area, a new spectrofluorimetric method has been developed for the determination of trace water in organic solvents, and is presented here. It is based on the formation of an exciplex[11] between pyridoxal and water. The method is characterized by its simplicity, sensitivity and accuracy. Representative solvents examined include cyclohexane, petroleum ether, benzene, carbon tetrachloride, diethyl ether, tetrahydrofuran, dioxan, ethanol and methanol. The solubility of water in benzene at various temperatures has been determined.

EXPERIMENTAL

Reagents

The organic solvents used were preliminarily treated by addition of a molecular sieve, shaking for 3 hr in a vibrator and standing for about 2 weeks. The pyridoxal (PL) solution ($5 \times 10^{-3}M$) was prepared by dissolving pyridoxal hydrochloride in methanol. A standard solution of water was prepared by adding redistilled water to the dried solvent with a miniature injector. All reagents were of analytical grade.

Procedure

To 4.75 ml of organic solvent containing water add 0.25 ml of pyridoxal solution in methanol, and mix thoroughly. Let stand for 30 min at room temperature, then measure in a 1-cm quartz cell with a suitable spectrofluorimeter.

RESULTS AND DISCUSSION

Excitation and emission spectra

Pyridoxal has an excitation maximum at about 305 ± 5 nm and an emission maximum at 330 nm. When trace water is present in the solvent, a new maximum may appear at 385 ± 5 nm in the emission spectrum and show a small bathochromic shift with increase in the solvent polarity, except for dioxan and diethyl ether (Table 1).

Figure 1 shows the excitation and emission spectra for tetrahydrofuran (THF) medium. The new emission band at 385 nm was considerably enhanced by increase in the amount of water, and the fluorescence intensity of pyridoxal at 330 nm was decreased.

In the case of carbon tetrachloride, however, no new emission band appeared when water was introduced and only the decrease in fluorescence intensity at 330 nm was observed.

It appears that the new emission band results from the interaction of pyridoxal and water, presumably to form an exciplex, $[PL \cdot H_2O]^*$.

Table 1. Maximum emission wavelength in PL–H_2O–solvent systems

Fig. 3. Effect of pyridoxal concentration in benzene, C_{PL}: (1) $2.5 \times 10^{-4}M$; (2) $3.5 \times 10^{-4}M$; (3) $4.5 \times 10^{-4}M$.

Equilibration time

It takes only 30 min from the addition of pyridoxal for the fluorescence spectra to become stable, and there is then no change in excitation and emission spectra or fluorescence intensity for at least 24 hr, at room temperature.

Calibration graph

The calibration graphs based on the fluorescence at 385 ± 5 nm are linear, but the sensitivity (slope) depends on the solvent, and decreases in the order:

cyclohexane > petroleum ether > benzene

> diethyl ether > tetrahydrofuran

> dioxan > ethanol > methanol

When the pyridoxal concentration is $2.5 \times 10^{-4}M$, the relative sensitivities are given in Table 2.

It can be seen from Table 2 that the sensitivity in aliphatic hydrocarbons is much higher than that in

Effect of pyridoxal concentration

The pyridoxal concentration affects the fluorescence intensity. Figure 2 shows that for maximum fluorescence intensity a pyridoxal concentration of 2.0–$3.0 \times 10^{-4}M$ is optimal.

Pyridoxal has very low solubility in non-polar organic solvents, and it is necessary to add a small amount of methanol or ethanol to ensure dissolution of the pyridoxal added. Nevertheless, the amount of methanol should not be too large, or it will decrease the sensitivity for the determination of water.

*This value was measured at 43.78°.

benzene, ether and alcohols, which is in keeping with the order of solubility of water in these solvents. In other words, the higher the solubility of water, the lower the fluorescence sensitivity. For instance, the lowest limit of determination of water is 10 ppm (v/v) in cyclohexane, 20 ppm in benzene, 500 ppm in methanol and so on.

The linearity was examined up to water concentrations (% v/v) of 0.06, 0.04, 0.15, 0.20, 1.0, 1.0, 2.0, 2.0 respectively for the eight solvents listed in Table 2. In the case of carbon tetrachloride, the decrease in fluorescence intensity of pyridoxal at 330 nm may be used to determine the water content.

The pyridoxal concentration affects the range of linearity: the larger the concentration of pyridoxal, the wider the linear range for water (Fig. 3).

Determination of solubility of water in benzene

As an application of this method, the solubility of

water in benzene at various temperatures was determined. Table 3 shows the results and the values reported in the literature.[9]

ANALYTICAL DATA

THE pKₐ VALUES OF THE CONJUGATE ACID OF IMIDAZOLE IN WATER–ETHANOL MIXTURES

Janusz Oszczapowicz* and Małgorzata Czuryłowska
Department of Chemistry, University of Warsaw, Poland

Summary—The pK_a values of protonated imidazole in 10 different water–ethanol mixtures were determined at 25° by potentiometric titration in a cell without liquid junction (glass and silver–silver bromide electrodes). The pK_a values can be used in a standardization procedure that allows determination of pK_a values for protonated organic nitrogen bases in aqueous ethanol.

For determination of the pK_a values of the conjugate acids of organic bases in non-aqueous solvents, either appropriate buffers of known pH or standard compounds with known pK_a values in the solvents are necessary. In the second case the pK_a values can be calculated from the expression[1]

$$pK_{a_i} = pH_{x_i} + pK_{a_s} - pH_{x_s}$$

where pK_{a_i} and pK_{a_s} are the pK_a values of the sample (*i*) and standard (*s*) and pH_x is the pH reading at the degree of titration $x = C_{HA}V_{HA}/C_0V_0$ (where C_0 is the initial concentration of the sample, V_0 the initial volume of titrand, and C_{HA} and V_{HA} are the concentration and volume of added titrant) for the sample (pH_{x_i}) and standard (pH_{x_s}) respectively.

For many organic bases the pK_a values of the conjugate acids in various water–ethanol solutions can be found in the literature, but unfortunately there is much inconsistency in the data. To study the influence of various solvents on the sensitivity of the basicity of organic bases to substitution effects, all the data must be related to a single standard. The pK_a values for this standard in the solvents concerned should be determined under the same conditions and, if possible, in one laboratory. Such a procedure should ensure self-consistent results, because systematic errors ought to be the same for all the solutions.

In the course of our study on the influence of substitution on basicity of amidines and related compounds,[2–6] imidazole was chosen as a convenient standard. It is commercially available, can be easily purified by recrystallization and is stable enough to be stored. It is very convenient as a standard for determination of the basicity of such compounds as amidines, guanidines and heterocyclic compounds containing the

$$-N=\overset{\displaystyle |}{C}-N<$$
group, because the protonation of imidazole also occurs on the imino-nitrogen atom of this group, and therefore any unpredictable effects due to change of solvation in different solvents are comparable and the resulting errors minimized.

EXPERIMENTAL

Reagents

Water–ethanol mixtures were prepared by mixing appropriate weights of analytical grade azeotropic rectified spirit, fractionally distilled before use, with water that had been twice distilled in quartz apparatus. The sodium carbonate, sodium bromide, perchloric acid (60%) and imidazole used were of analytical grade.

Procedure

All pH values were measured with a Radiometer PHM 64, with a constant temperature cell without liquid junction, equipped with a glass electrode (GE) and silver–silver bromide electrode:

GE ‖ 0.1*M* (imidazole + HClO₄ + NaBr);

water-ethanol ‖ Ag-AgBr

The 50-ml samples contained about 0.5 mmole of imidazole in 0.1*M* sodium bromide. Silver–silver bromide electrodes were prepared by immersion of a cleaned 0.1-mm diameter silver wire for 30 min in aqueous ferric bromide solution, rinsing, drying in air and then aging for at least two days in aqueous potassium bromide solution.

The titrant was prepared by dilution of 1.1 ml of 60% perchloric acid with 98.9 ml of 0.1*M* sodium bromide in the water–ethanol mixture to be used for the determination; it was standardized by potentiometric titration of sodium carbonate in water.

RESULTS AND DISCUSSION

To obtain reliable results some precautions were taken. To prepare water–ethanol mixtures, redistilled rectified spirit was used, because it does not contain

*Commercial "absolute alcohol."

the impurities which may remain from preparation of so-called "absolute alcohol". Also, its azeotropic composition (95.6% ethanol, w/w) is known and constant.

A newly prepared Ag–AgBr electrode always behaves as a cathode with respect to older ones that have been aged in a bromide solution.[7,8] Its potential changes considerably during the initial 20–30 hr and equilibrium is sometimes reached only after two days. For that reason the Ag–AgBr electrode was kept for at least 48 hr in $0.01M$ aqueous potassium bromide before use.

The pK_a value of the conjugate acid of imidazole was determined by the direct method given by Zikolov et al.[9,10] for aqueous solutions. The shapes of the titration curves indicate that his method can be used for water–ethanol solutions as well.

The pK_a values were calculated from the equation[7]

$$pK_a^c = \frac{E - E^o}{59.16} + \log\left(\frac{x}{1 - x}\right)$$

where E is the e.m.f. of the cell, E^o is E for $[H^+] = 1$; x is the degree of titration and 59.16 is the value of $2.303RT/nF$ at 25°.

For calculations only the E values for x within the range 0.3–0.8 were taken, because only in this range was the titration curve approximately linear. The E^o value was determined by measuring the cell e.m.f. after the equivalence point, according to the equation[7]

$$E = E^o + 59.16 \log [C_2H_5OH_2^+]$$

The constancy of the E^o value determined in each titration indicated that perchloric acid is fully dissociated in the conditions used, and thus this equation is valid.

In the direct method of pK_a determination, the ionic strength must be kept constant, so the titrations

are usually done in the presence of an inert and completely ionizable salt (KCl) at a concentration at least an order of magnitude greater than that of the titrant. Alkali metal chlorides have low solubilities in ethanolic solutions, so are unsuitable. Therefore, sodium bromide had to be used to maintain the ionic strength, and this in turn required use of the Ag–AgBr electrode.

Accuracy

The error in potential measurements should not exceed 0.05 mV, so the corresponding error in the pK_a values should be less than 0.05. Errors caused by the ionic-strength changes occurring during the titration are much smaller than this and can be neglected. The errors in the mean values given in Tables 1 and 2 refer to a confidence level of 95%.

Changes in pK_a values with solvent composition

The value of pK_a depends on the nature, acidity, dielectric constant and solvation ability of the solvent. In water–ethanol mixtures these properties change with composition, thus the difference between pK_a values measured in water and in 95.6% ethanol is 0.98. For imidazole, the pK_a values pass through a minimum.

ANNOTATION

ANALYSIS OF SEDIMENTS FOR HEAVY METALS BY A RAPID ELECTROTHERMAL ATOMIC-ABSORPTION PROCEDURE

M. J. T. Carrondo, F. Reboredo, R. M. B. Ganho and J. F. S. Oliveira

Departamento de Ciências do Ambiente, Faculdade de Ciências e Tecnologia, Universidade Nova de Lisboa, 2825 Monte da Caparica, Portugal

Summary—A rapid electrothermal atomic-absorption spectrophotometric procedure with homogenization as the only pretreatment is compared with two wet pretreatment methods followed by flame atomic-absorption, in a statistically designed experiment. Samples from the top 5 cm of sediments at three different points of the Tejo estuary were used for the tests. The results show that the electrothermal procedure performed as well as whichever was the better of the flame methods for the determination of cadmium and nickel, irrespective of the sand content of the samples; although not statistically significant, there was apparently a decrease in recovery for chromium, copper and lead by the electrothermal method as the sand content of the sample increased. For zinc the electrothermal method gave results statistically different from those of the flame procedures when the sand content was high but not when the organic content of the sample was high. Because of the limited degree of replication (5 variates) the relative differences between the average values obtained by the three methods were significant only if they exceeded 15%. The electrothermal method has the advantage of substantially greater speed.

Before the determination of the total heavy metal content of a sample, it is normally necessary to bring the metals into solution, exceptions being the use of neutron-activation analysis, X-ray fluorescence spectroscopy and, in some situations, electrothermal atomic-absorption spectrophotometry (AAS).[1,2] For environmental samples AAS is the method of choice for the majority of heavy metal determinations.[3]

The procedures available for bringing the heavy metals into solution depend on the matrix and are generally grouped into three classes: fusion with molten salts, dry ashing followed by acid dissolution, and wet digestion with acids (individually or in mixtures).[1,4] These are all potentially applicable to sediment analysis. Fusion methods greatly increase the salt content and contamination, thus making it difficult to use atomic-absorption methods. Dry ashing might cause loss of metals by volatilization, *e.g.*, cadmium and lead, and does not always yield complete recovery of metals.[4,5] Various acids are utilized for wet digestion, namely nitric, sulphuric, perchloric, hydrochloric and hydrofluoric; even though the use of automated digestion techniques and digestion bombs has improved the method, losses due to volatilization, retention or loss of insoluble species in the digestion vessel or poor recovery from the matrix might occur.[1,6,7]

These pretreatments are time-consuming. If the sample is amenable to homogenization, electrothermal atomic-absorption procedures may be utilized without pretreatment.[5,8] Various types of interference arise in electrothermal atomic-absorption[9] but it is generally accepted that this method can be used for matrices that are mainly organic in nature.[9,10] An increase in inorganic salt content makes the method less reliable, especially for the more volatile elements cadmium, lead and zinc.[10,11]

This paper evaluates the applicability of a procedure previously reported for sewage and sewage sludge analysis,[5,8,11] based on ultrasonic homogenization followed by electrothermal atomization for total heavy-metal analysis of sediments. Consequently the statistical design was the same as that of this earlier work; it became apparent later that the limited degree of replication made statistical differentiation rather insensitive, a relative difference of at least 15% being required for statistical significance. The samples used were taken from three different points in the Tejo estuary (Fig. 1), as part of a survey sponsored by U.N.D.P. and U.N.E.S.C.O.

EXPERIMENTAL

Instrumentation

A Perkin-Elmer model 503 atomic-absorption spectrophotometer fitted with a deuterium background-corrector was utilized for all determinations. A single-slot air–acetylene burner and an HGA72 graphite atomizer were used for flame and electrothermal analyses respectively. The operating conditions were slightly modified from those recommended by the manufacturer and have been reported elsewhere.[5,8]
Fig. 1. Location of the sampling points.

Reagents

Pro analysi grade reagents (Merck) were used for the treatment of the samples to minimize blank values. Standards were prepared by serial dilution of commercially available stock solutions (Fisher).

Homogenization

Samples to be analysed by electrothermal analysis were diluted and acidified to contain 1% (v/v) nitric acid and homogenized with an Ultra Turrax T 45 N in a similar way to that previously described.[5,8,11] Results obtained by direct comparison with aqueous standards and by the standard-addition method were found to be in good agreement.

Nitric–sulphuric acid digestion

Digestions were done in a similar way to that described previously[8,11] but 100-ml borosilicate beakers were used instead of 500-ml flasks. For each g of wet sediment 20 ml of concentrated nitric acid and 5 ml of concentrated sulphuric acid were used.

Nitric–perchloric acid digestion

Digestions were done in a similar way to that previously described,[7] again with 100-ml borosilicate beakers. For each g of sediment 20 ml of concentrated nitric acid and 5 ml of 60% perchloric acid were used.

Other analytical parameters

The solids content was determined according to reference 12 and the geological analysis was done by the methods given by Maxwell.[13]

RESULTS AND DISCUSSION

Samples taken from the top 5 cm of the sediment were obtained from three points in the estuary; a rough characterization of the samples is presented in Table 1; sample 1 can be seen to have a rather high organic content but no sand. The sand fraction increased as the samples were taken from nearer the ocean and beaches, the organic and clay silt fractions decreasing correspondingly.

Each sample was divided into three groups of five subsamples. Two of the groups of five samples were used for digestion with the acid mixtures and analysis by flame atomic-absorption. The samples in the other

group were individually homogenized and analysed by electrothermal atomic-absorption, Eppendorf micropipettes being used for injection of 20 or 50 μl aliquots. Two blanks were also run for each pre-treatment. In all cases analysis was by direct comparison with acidic standards.

The results were treated statistically; the mean values, within-group relative standard deviation and the results of an analysis of variance by the F-test[14] are reported in Table 2. Tukey's procedure[14] was used to identify which means were statistically different at the 0.05 significance level. Metal recoveries obtained by the different procedures, calculated on the assumption that the higher flame result corresponded to complete recovery, are also compared in Table 2. It was not possible to make a statistically significant discrimination between means, however, unless the relative difference was at least 15%.

From the comparisons presented in Table 2, no statistically significant difference exists between the best digestion–flame procedure and the homogenization–electrothermal procedure for the determination of chromium, copper and nickel. Nevertheless there is an apparent decrease in recovery by the homogenization method with decrease in organic content and increase in sand present: this effect is more pronounced for copper and, to a lesser extent, chromium in sample 3, recoveries lower than 90% having been obtained. The low recoveries obtained for chromium by the perchloric acid digestion procedure might be due to the volatilization of chromyl chloride.[1,13]

As the more serious matrix interference effects reported in the literature for the electrothermal technique are usually associated with cadmium, lead and zinc,[9,10] the results obtained for chromium, copper and nickel were to be expected. More surprisingly, the results in Table 2 indicate that the homogenization procedure compares well with the better of the flame methods for determination of cadmium and lead. For lead the recovery appears to fall with the increase in inorganic content, but not for cadmium. The apparent absence of interferences may be entirely fortuitous or may result from a match between enhancement and suppression effects. Alternatively, synergic effects may have occurred, similar to those reported for lead and cadmium in fertilizer samples.[15] The most marked matrix influence takes place in the determination of zinc, a recovery of less than 70% having been obtained for the high sand-content sample 3, which is consistent with previous studies.[10,16]

Table 1. Characterization of the samples

	Solids		Solid fraction

§95% confidence interval.
‡Assuming the result of the better flame method corresponds to complete recovery.

Undoubtedly, the use of the deuterium background-corrector is invaluable for this type of analysis, particularly for the volatile elements lead, cadmium and zinc. The low recovery obtained for lead by the sulphuric acid digestion procedure can be accounted for by the low solubility of the sulphate. The incomplete recovery of zinc by the sulphuric acid method and of cadmium by the perchloric acid method is less easy to explain; the latter has been reported previously.[7]

Reported values for the precision of the rapid method applied to sewage sludge samples[5] and sewages and sewage effluents[8] averaged 8 and 6%, respectively, whereas in these sediment samples, admittedly harder to homogenize, the average is closer to 10% for the procedure as a whole.

Comparing the absolute metal concentrations in the Tagus sediments with those reported for other estuaries,[17,18] it is apparent that sample 3 is relatively uncontaminated whereas samples 1 and 2 present concentrations ranging from two (for cadmium) to five (for lead) times those reported for unpolluted rivers.

CONCLUSION

The rapid electrothermal procedure described here can be used advantageously for routine analysis for total heavy metals in sediments associated with contamination by currents and matrices with reasonably high organic content. As the amount of sand in the sample increases, this procedure yields lower results for zinc. Recoveries for copper, chromium and lead might drop to about 90% for samples containing almost only sand. The time saved is considerable, because homogenization takes only 5 min as opposed to the 3–6 hr required for a digestion. This more than compensates for the additional time (2–3 min) required for the electrothermal analysis.

A VERSATILE LOW-COST LABORATORY COMPUTER NETWORK

R. L. A. SING and ERIC D. SALIN*

Department of Chemistry, McGill University, Montreal, Quebec, Canada

Summary—An inexpensive but powerful computer network particularly suited to the research laboratory is discussed. The primary advantages of the system are low cost, flexibility, freedom of choice of manufacturer, and convenience of upgrading. The principal limitations are speed of data transfer and the requirement for a certain level of skill during setting up. The system operates with both the CP/M and MP/M operating systems, but the principles of operation are generally applicable.

Laboratory automation has many advantages for both the research and the production laboratory. In general, laboratory automation can provide higher sample throughput with an attendant reduction in cost per sample. The digitized data can be stored and later retrieved and processed by application programs or data-base management systems, for production of reports.

In the research laboratory, automation not only allows the rapid collection of large amounts of data but encourages use of intensive statistical and graphical evaluation, which might otherwise be too laborious. Research work often makes unusual demands on the acquisition hardware and software. Versatility, flexibility and low cost may be far more important in the research laboratory than in the production laboratory.

We have found that an excellent solution to these requirements is a laboratory computer network. Networks in the laboratory have been discussed in general by Dessy[1] and specifically by Levy and Terpstra.[2] We will present here a discussion of a very effective and inexpensive laboratory computer network which is particularly well suited to the research laboratory and its unpredictable future needs.

NETWORK DESIGN

There are several features of computer networks which are particularly important in a research laboratory involved in the development of instrumentation, though these attributes may be considered to be universal. The "dedicated microcomputer" network has been discussed previously[3] and appears to meet these needs far more efficiently than any other. The most important network attributes are listed below and will be discussed in order to allow readers to evaluate their importance for their own laboratories.

The laboratory computer-network should:

(1) have a powerful, fast "dedicated" computer;
(2) use low-cost hardware and software;
(3) offer flexible expansion;
(4) produce graphics;
(5) have long-term data-storage in real time;
(6) possess multiple high-level language capabilities;
(7) use simple operating procedures;
(8) not be entirely dependent on the products of a particular manufacturer.

In a "local computer" or "dedicated computer" network, microcomputers act as dedicated I/O (input/output) modules and provide local processing of data so that only information requiring storage or sophisticated processing is sent to a central laboratory computer. The dedicated computer's functions are relatively limited: local I/O operations, collection of data as fast as required, primitive processing and transmission of the processed data. The central laboratory computer (hereafter called simply the laboratory computer) provides storage, powerful processing capability and extensive I/O capability (*e.g.*, printers and plotters). Our particular network configuration provides the advantages of (1) remote operation, (2) autonomous local I/O, (3) local control and processing and (4) a certain degree of modularity if several of the dedicated processors are of the same type. Serial communication techniques allow convenient transmission over distances up to several kilometres, and by use of telephone lines communication can be made over almost unlimited distances. Local processing of the data may be desirable for several reasons: (1) local output, particularly hardcopy, can be used for operational monitoring, or back-up in case of network failure, and (2) the transmission of only the vital information will minimize the network traffic (high traffic might slow down the laborabory computer and cause loss of

---

*Author to whom correspondence should be addressed.

information. Conventional serial transmission techniques are not always satisfactory if data-rates are high. With a conventional 9600 baud (bits/sec) transmission rate, the system may be limited to the transfer of approximately 100 data values per second.[3] This will certainly not be satisfactory for some experiments, though adequate for most. There are at least two solutions to this problem. If the distances between the dedicated and the central laboratory computers are short, then parallel transmission techniques may be used. If the data set is not too large, a more convenient solution may simply be expansion of the memory of the dedicated computer to allow the set to be stored until the end of the acquisition period (delayed transmission).

Another limitation to a network of this type can be the limited software capabilities of some of the microcomputers most appropriate for the dedicated function. It might, for example, be much more convenient to use compiler BASIC for acquisition and processing, since it can be two orders of magnitude faster than interpreter BASIC and is far more convenient and efficient in many aspects than assembler-level coding, particularly when used by laboratory personnel. Arguments can be made for other compiler languages, since they have their own particular advantages, but they almost inevitably require a disk-based system, which will increase the cost. Generally then, when using the term "powerful" in connection with a dedicated computer, we are referring to a high-level language capability, usually an interpreter language such as BASIC or a compiler–interpreter language.[5] Other factors, such as ease of physical interfacing, might initially appear to be important, but almost all major processor manufacturers include powerful timer–counter, parallel and serial interface integrated circuits in their equipment, and many of the single-board computers can either be acquired with these or easily expanded.

The cost of a small single-board computer suitable for the dedicated function is usually quite low, but that of a suitable laboratory computer can be quite high and usually represents over 80% of the total network cost when the price of the software is included in the total price. Generally the 8-bit computer systems are significantly cheaper than 16-bit systems, and because of their popularity and high-volume sales, a great variety of powerful low-cost software is available. The apparent advantage of 16-bit systems is their ability to address directly large blocks of memory. This should enable them to run larger programs faster as well as being more efficient for multi-user operating systems.

Graphics may not be important in all laboratories, but humans are excellent pattern recognizers and work far more efficiently with graphical than with tabular data. The power of graphical information has been recognized by many manufacturers, who now have gone beyond simple graphical display to an intelligent use of colour so as to transmit more information to an operator. Some graphics systems use sections of computer memory, while others have their own memory for image storage. Image generation can take up quite a lot of computation time. For example, a 500 × 500 pixel display consists of 2.5×10^5 pixels, each of which must be set, often with additional intensity or colour information. Intelligent independent graphics systems or subsystems can minimize laboratory computer slow-down by doing these computations themselves, often with specialized software.

If the laboratory computer is to be truly useful to the researchers in the laboratory, then it must do more than store the data. It must be able to process and output those data at a time convenient to the researcher. This is one of the distinct advantages of operating the laboratory computer with a multi-user capability. Data can be acquired from an experiment while other researchers are processing their data from other experiments. If the number of simultaneous users is relatively small, then an 8-bit computer can satisfactorily handle the task provided there is sufficient mass-storage. If intensive disk usage is required then a fast disk system may be essential, but most computational work tends to be processor-intensive, and fast storage, though always convenient, may not be essential.

Because scientists may come from a wide variety of backgrounds and possess different programming skills, it is important to be able to offer a selection of software which will allow each user to achieve maximum efficiency with minimum of frustration. BASIC (Beginners All-Purpose Symbolic Instruction Code) is ideal for simple calculations and can easily be learned independently. Certain software manufacturers (e.g., Microsoft) have made available compiler versions which can run significantly faster than the interpreter forms. Pascal has a wide variety of data and programming structures which make it an extremely flexible and powerful language for computation as well as other purposes. It is a highly structured language, which makes it popular as a professional tool because the rigid structuring makes the written code easy to follow, and it is easy for new programmers to take over programming responsibilities. A great deal of powerful software is available for 16- and 8-bit computers. In general, the 8-bit software is less expensive and can often be purchased from a maker other than that of the hardware or the software operating system.

It quickly becomes apparent that the laboratory computer is the system which is most likely to be overloaded and consequently need upgrading. The dedicated computer is normally purchased with a given experiment or apparatus in mind, and as long as this does not change considerably, there is no need to change the dedicated computer. On the other hand, the load on the laboratory computer will increase with time. Additional dedicated computers will be added, and researchers will increase their

demands on the laboratory system as they become increasingly competent in its use. The laboratory staff will often come to use the laboratory computer for a great deal of what might be called "administrative" work, such as data-base management, and report-writing with the use of word processors and computer "spread sheets" like VisiCalc. The word processor will often be extremely popular because it can be used as a text editor for programming as well as in its more traditional role. Some word processors are highly disk-intensive, owing to the use of menus and search requirements. This creates an additional load on the laboratory computer. For these reasons, the laboratory computer is more likely than the dedicated computers to be outgrown. Because of the investment of researchers' time in learning and developing software, it is imperative that the software run by the laboratory computer should be highly portable. It is obviously most satisfactory if the software can be transferred to a more powerful computer and run completely without modification.

Perhaps the most difficult problem to overcome is that of the networking software. The most desirable dedicated computer may not be made by the same firm as the most suitable laboratory computer, or investments may already have been made in one or the other of these. Our solution to this is quite simple. We have installed on our laboratory computer a modern multi-user operating system which we run entirely without modification. Each of our dedicated computers is physically connected to the laboratory computer by a standard RS-232C protocol and appears to it to be a user terminal. The only operating-system modifications that we make are very simple and are limited to the dedicated computer, which is unlikely to be outgrown by the particular experiment for which it was purchased. An arrangement of this type allows us to replace the laboratory computer with a more powerful unit without any modifications to the dedicated computers as long as the laboratory computer operating system remains the same. We have achieved a certain degree of independence from the manufacturer by using an operating system which is used by many manufacturers on a wide variety of computers. From analysis of the trade journals, it appears that the operating system will be utilized into the foreseeable future.

NETWORK SPECIFICS

Hardware

Our laboratory computer is an S-100 bus-based computer (IEEE-696 standard)[5] which at present operates with 256 kbytes of R/W memory and two 8-in. flexible disk drives for mass storage. A more complete configuration listing is provided in Table 1. The graphics are provided by the MicroAngelo, an intelligent 512×480 pixel video subsystem which relieves the main processor of the heavy burden of graphics generation. The MicroAngelo has its own Z-80 processor with 32 kbytes of R/W memory for image storage and an instruction set in ROM on a single S-100 board. We have developed our own software to transfer the screen image directly to an Epson MX-80 printer with Graftrax Plus. Commercial versions of this type

of software are available. The image transfer takes 3 min, but we have found that the printer has the advantage that it can be left unattended while multiple text or graphics print-outs are made, whereas most of the cheaper plotters require manual sheet-feeding.

The dedicated computer selected is the Rockwell AIM-65 single-board computer. Table 2 lists the features of the AIM, the most important for network use being the on-board printer, the use of BASIC, and the very well documented monitor (operating system). The printer is important because it allows the AIM to be used autonomously and to get hardcopy output data if the laboratory computer breaks down. BASIC allows convenient processing of the data before passing them on to the laboratory computer, and the source-code listing for the monitor allows slight modifications to the monitor for convenient operation within the network. All the software can be contained in the Read-Write (also called R/W or RAM) memory, but if the system is RESET the operator has to reinitialize certain pointers. The monitor ROM can readily be modified so that the AIM loads the program and starts the task automatically as soon as it is switched on.

The minimal configuration AIM is equipped with a 20-mA current-loop serial communication line. This interface is implemented primarily through software using a 6522 Versatile Interface Adapter (VIA) rather than with an integrated circuit specifically designed for serial communication, such as a 6551 ACIA (Asynchronous Communication Interface Adapter). Though adequate for operation with a terminal, this system is not adequate for network operation, because of the low speed at which transactions take place. The 20-mA loop system simply does not respond quickly enough, and characters are lost during the simple transmission procedure that we insist upon. For this reason we expanded the AIM with a 6551 ACIA, an integrated circuit specifically designed for serial communications, and some EPROM memory to contain the networking software. By using the 6551 ACIA, we are able to communicate at 9600 baud. We have found it convenient to build our own combined board which includes a 6522 VIA, a 6551 ACIA, and memory sockets which can be used for RAM (6116), ROM (2316) or EPROM (2716). Once again, the excellent documentation of the AIM make this a relatively straightforward task. The increased memory capacity allows more data to be stored before transmission to the laboratory computer and consequently minimizes the load on the latter. The circuit diagram for the interface is available from the authors, but serial communication expansion ports, memory and additional parallel I/O can be purchased commercially from a number of vendors, some of whom are listed in Table 3.

Software

We have adopted for our laboratory computer what appears to be the most common operating system, CP/M, with the expectation that MP/M, the multi-user version, will become equally as popular. CP/M and MP/M are both produced by Digital Research, which seems to nullify our claim to be tied to one manufacturer, but there are over 100 manufacturers of different computers which run CP/M, and many of these can run MP/M. They range from the oldest 8080 CPU-based systems through the popular 8088–8086 Intel family to the very powerful 68000 series. The use of this operating system then frees us from dependence on any particular manufacturer of computers or family of logic devices, or manufacturer of integrated circuits. This will allow us in the future to expand or replace the laboratory computer with a more modern system without having to discard either our own high-level language application programs which run on the laboratory computer, or our dedicated computers and their communication techniques.

The CP/M and MP/M operating systems used on the laboratory computer are run without modification. Instead,

the AIMs are provided with software to make them comply with the requirements of CP/M and MP/M.

Networking software had to be developed only for the AIM. The excellent documentation of the AIM monitor made this task quite straightforward. A program of only 350 bytes was required to allow a number of operating modes for the AIM within the network (listings of the software are available from the authors). The network software provides the AIM with the ability to communicate to the laboratory computer one character at a time or to transfer program and data files to the disks of the laboratory computer. The latter task is accomplished by having the AIM emulate a user and transfer the data as characters to the disk by using the CP/M Peripheral Interchange Program (PIP). Most operating systems have a Peripheral Interchange Program (PIP in CP/M or MP/M, PIP for DEC RT-11, COPY for MS DOS) and these operate in much the same manner. Therefore, our implementation of the laboratory network could easily be adapted to other laboratory computers.

The AIM software allows the RS 232C network interface to be used either as an auxiliary input/output device or as the main input/output device (enabling direct external control of the AIM). There are routines which perform file transfers by using the PIP with either monitor (operator) control or BASIC program control. The latter is used to transfer data files to the laboratory computer. In order to make the software as general-purpose as possible, the handshake strategy adopted was the echo and XON/XOFF protocol; that is, each character transferred on the network interface must be echoed by the receiver and the latter can halt and resume the transmission by using the XON/XOFF (terminal on/off) protocol. This handshake strategy is supported by most of the Peripheral Interchange Programs of the various operating systems when interacting with a console.

NETWORK OPERATING MODES

Figure 1 shows the many system configurations obtainable, with the same hardware in each case. These configurations are completely interchangeable with a minimum of effort, quite often by simply choosing the single- or multi-user version of the operating system. Figures 1c and 1d illustrate the two modes of operation of the network as we have arranged it. The first (Fig. 1c) can be called the "slave" network operating mode while the second (Fig. 1d) can be called the "co-user" mode. With the 256-kbyte memory of our laboratory computer, the operating system allows up to 5 independent users (terminals or AIMs) or tasks on the system at any given time.

In the "co-user" mode of operation (Fig. 1d), the laboratory computer runs MP/M, the multi-user operating system, and each of the dedicated computers acts as a user at the same level as a user at a terminal. The AIMs have the capability of initiating any process on the laboratory computer that a terminal user can. Generally, an operator at the experimental site will load and execute a program on the AIM, which will perform the experiment and then, using the file-transfer routines of the network software, will transfer the data as a file to the laboratory computer disks through use of the PIP. The AIM can execute a continually running program which will perform the experiment on a series of samples and send the sample data files to the laboratory computer without operator intervention. The program on the AIM could, in fact, execute an application program for a data-base management system, interact with it, and thereby ensure transfer of the processed sample data directly into the laboratory data-base. The AIMs printer can be used to obtain hard copy for verification and back-up in case of network malfunction.

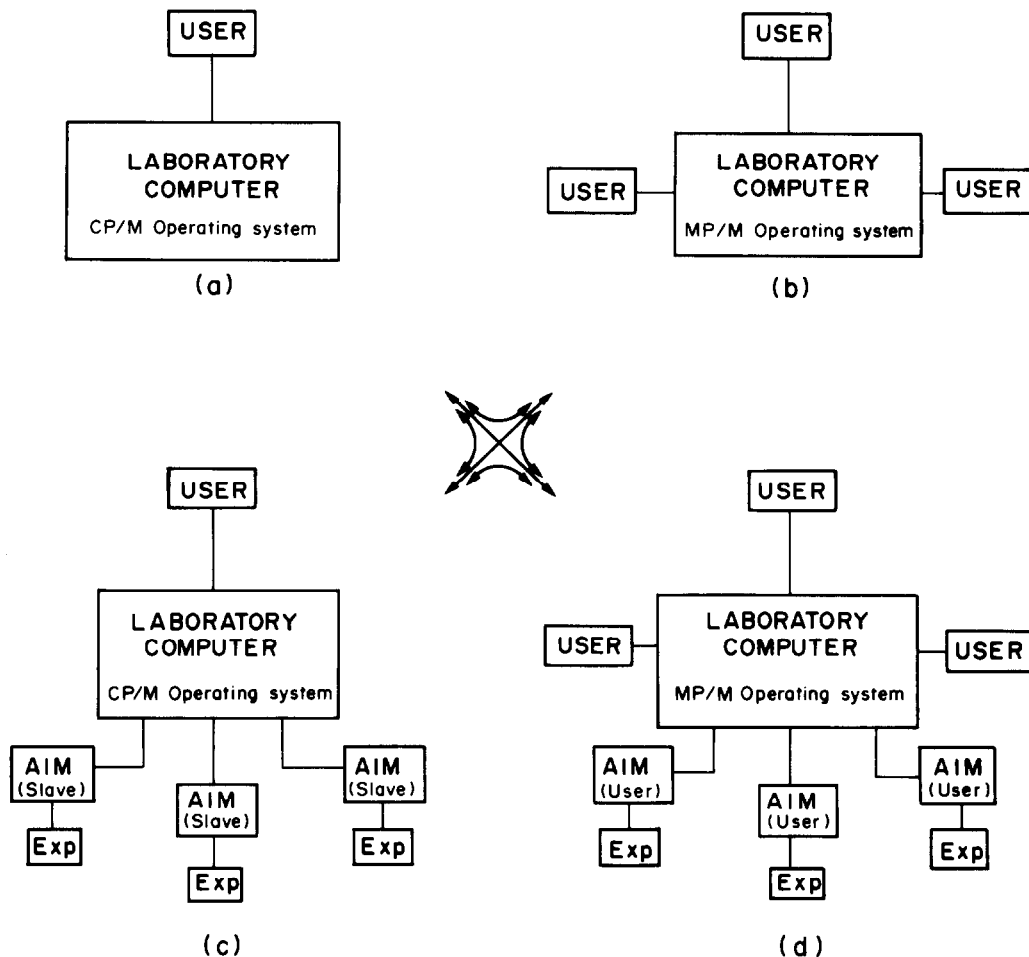
In the "slave" mode of operation (Fig. 1c), the dedicated computers are put under direct control of


Fig. 1.

the laboratory computer and a single user. This is done by entering AIM BASIC and then selecting the RS 232C interface to the laboratory as the main input/output device. Generally, this mode requires that the laboratory computer be running the CP/M operating system (single user), though MP/M could be tolerated under certain circumstances. The single user could be at a terminal or could equally be one of the dedicated computers in its user-emulating role. The program being executed on the laboratory computer is responsible for sending commands and programs to the AIMs and receiving their output. This mode of operation of the network is that which allows the highest possible rate of data acquisition, since the laboratory computer is dedicated to the execution of a single process.

The laboratory computer program can, in this mode, synchronize the activities of a number of dedicated computers. For example, if one AIM were controlling a stepper motor attached to a spectrometer drive and another interfaced to a data-acquisition system, the laboratory computer would send to the drive-controlling AIM the wavelengths needed to locate the line of interest, but would receive information from the data-acquisition AIM in order to position the drive exactly at the position corresponding to the spectral line. An additional feature of the CP/M operation is that it uses only a quarter of the 256 kbytes available on the laboratory computer. The remaining 192 kbytes can be used for disk emulation so that data can be stored at significantly higher rates than on flexible or rigid disks. Memory-disk emulation (RAM disk) products are commercially available for many systems.

The languages and programs that we have found useful for running under CP/M or MP/M are listed in Table 1. We generally avoid writing at the assembler level on the laboratory system, because of the lack of portability. BASIC has proved to be especially valuable, owing to its ease of use. Programs are developed by using the interpreter and then compiled if they are slow and need to be used often. Pascal is used for more complex programs, on account of its highly structured nature. Our particular implementation of Pascal supports the use of a 9511 arithmetic processor to increase the speed of computation and decrease the program size, but we have not yet felt the need to instal it.

CONCLUSIONS

An inexpensive laboratory computer network which is not dependent on any particular hardware supplier has been developed, and requires a relatively low level of expertise. Proper selection of components and operating procedures allows the laboratory computer to be used for unrelated processing during the data-acquisition process. Though the network does not provide the high transfer rates available with the proprietary networks, the simplicity of operation does allow a high degree of flexibility and control, which is very advantageous in a research laboratory, where the nature of the work may frequently change.

The system can be upgraded by acquisition of hardware and software from a wide variety of sources. Software compatibility when upgrading can be ensured by the use of a popular hardware-independent operating system.

CRITICAL STUDY OF THE DETERMINATION OF TIN BY ELECTROTHERMAL ATOMIC-ABSORPTION SPECTROMETRY USING RESONANCE AND NON-RESONANCE LINES

JÁNOS FAZAKAS

Center for Analytical Spectrochemistry, Bd. Mărăsti 61, R-71331 Bucharest 32, Rumania

Summary—The 235.48 nm non-resonance line of tin gives a sensitivity for AAS determination equal to that given by the most sensitive resonance line. Vaporization from a platform improves some twofold the sensitivities of all lines investigated. The atomization temperature has only slight influence on the relative sensitivities given by the non-resonance tin lines studied. Phosphoric acid shows a rather peculiar interference pattern, low concentrations (0.05%) depressing the signal, but high concentrations (1%) enhancing it. Contrary to expectation, the resonance and non-resonance lines are affected to the same extent by phosphoric acid. Platform-vaporization does not change the interference pattern of phosphoric acid. Calibration can be done by injecting various volumes of a single standard solution onto a platform coated with tantalum carbide. This method yields calibration graphs that are just as linear as those obtained with identical volume of standards of various concentrations. Some suggestions are made for further improvement of the analytical potential of non-resonance lines.

The analytical potential of non-resonance lines in electrothermal atomic-absorption spectrometry has formed the subject of several papers[1–7] from this laboratory. The non-resonance lines of palladium,[1–5] lead, indium and thallium,[6] as well as those of gallium[7] all show considerable analytical potential. Besides sensitivity, another factor worth mentioning is the better linearity of some calibration graphs when non-resonance rather than resonance lines are used. The present paper continues our previous studies with another element of low volatility, namely tin.

EXPERIMENTAL

Details of the commercially available electrothermal atomizer (radiational feed-back, 2000°/sec heating rate) and spectrometer (time resolution 20 msec) were given in previous papers.[6,7] Pyrocoated graphite furnaces were used as provided by the manufacturer.

The solid pyrographite platforms used have also been described elsewhere.[2] The normal platforms were coated with tantalum carbide.[8] The solid pyrographite could not be coated efficiently with tantalum carbide since it tended to flake off after a few firings. The normal platforms were coated by a single soaking in coating solution followed by repeated injections of it.[8] The colour of the coated platform was shiny bronze.

Drying and ashing temperatures for wall-vaporization were as recommended by the manufacturer.[9] For platform-vaporization, drying was done at 200° for 60 sec with a ramp of 5°/sec, and ashing was done as for wall-vaporization, *i.e.*, at 800°. Atomization was always done in the "temperature control" mode (radiational feed-back). Argon was used as purge gas at a flow-rate of *ca.* 2 l./min.

Working solutions were prepared by dilutions of a 1000-μg/ml stock solution. According to the manufacturer (Merck) the stock solution contains tin(IV) chloride in 1*M* hydrochloric acid. The calibration was done by injecting various volumes (5, 10, 15 and 20 μl) of a single standard solution.

A Varian hollow-cathode lamp was used as the primary radiation source and was operated at 10 mA. A spectral bandpass of 0.2 nm was used for all wavelengths. Some characteristics of the transitions studied are given in Table 1.

In order to prevent the continuum radiation of the platform from reaching the detector, a 1-mm aperture was placed after the furnace when high atomization temperatures were used (over 2200°).

RESULTS AND DISCUSSION

Influence of set atomization temperature on signal strength

As seen from Table 1, considerable controversy exists in the literature as to the most sensitive line for

Table 1. Spectral characteristics of some tin lines, and literature values for relative sensitivities

λ, nm	Spectral term energy values, cm^{-1}	gf^{10}	Relative sensitivities			
			Ref. 11	Ref. 12	Ref. 13	Ref. 14
224.61	0–44509	0.20	1	—	1	—
235.48	1692–44145	0.93	1.6	1	2.0	1
284.00	3428–38629	2.5	—	—	—	—
288.33	0–34914	0.65	1.6	1.3	1.5	—

A relative sensitivity of 3 would mean that the line gives a sensitivity that is worse by a factor of 3 than that given by the line with which it is compared.
Fig. 1. Variation of the population of energy levels of tin as a function of temperature. The curves drawn are based on the data of Parsons et al.[15] ●—●—● 0 cm^{-1}; △—△—△ 1691.8 cm^{-1}; □—□—□ 3427.7 cm^{-1}

Table 2. Relative sensitivities of some tin lines under various experimental conditions

Wavelength, nm	224.61	235.48	284.00	286.33
Wall 2200°C	2.1	2.2	4.5	2.8
Wall 2800°C	2.0	2.1	4.2	2.8
Platform 2200°C	1.2	1.2	2.2	1.4
Platform 2800°C	1	1	2.3	1.4

The absolute sensitivity for tin (amount giving 0.00436 absorbance or absorbance.sec) at 224.61 and 235.48 nm with platform vaporization at 2800° is ca. 5 pg for peak-height and ca. 8 pg for peak-area measurement. Relative sensitivities are similar for peak height and area. The results from this table represent the average value of several hundred measurements made during ca. 1 year with various graphite tubes and platforms.

the determination of tin. Some of the discrepancies in the literature data are probably due to the use of different flames (air–H_2, air–C_2H_2, N_2O–C_2H_2). As a consequence of the different flame temperatures, the population of the excited states and hence the sensitivity of the non-resonance lines will vary.

The influence of temperature on the sensitivity of resonance and non-resonance lines was recognized by Parsons et al.[15] as long ago as 1973. Rather unfortunately, not much attention was paid to their highly interesting article. Parsons et al.[15] have calculated the population of the excited states for some elements, as well as the relative sensitivities, as a function of temperature. For tin they predicted the 224.61 nm resonance line would be the most sensitive. However, the sensitivity of the 235.48 nm non-resonance line increases with temperature, almost equalling that of the 224.61 nm line at around 2800 K. Parsons et al.[15] also calculated the population of various energy levels of tin at different temperatures. Their results are summarized in Fig. 1. It may be seen from this figure that the depletion of the ground-state population with temperature is mostly due to population of the 3428 cm^{-1} level. It is certainly interesting to note that as shown in Fig. 1, at a temperature of 3200 K the ground state ranks only third in atomic population.

With flames it is only possible to vary the temperature of the analytical zone (and hence the population of excited states) by changing the flame stoichiometry or the observation height. However, in most cases it will mean a departure from the optimum atomization conditions. Thus any gain in the relative population of excited states will be more than offset by the decrease in the total number of free atoms available. However, with graphite furnaces it is possible to vary the temperature, without changing the chemistry of the atomic environment, and thus to keep constant the total number of free atoms available in the system.

Table 2 shows the relative sensitivity of various tin lines with wall- and platform-vaporization. It is in

order to note here that though the manufacturer recommends[9] atomization at 2400°, we have found that a sensitivity plateau is already reached at 2200°, and that the relative sensitivity varies very little with atomization temperature. Also there is very little difference in relative sensitivity between wall- and platform-vaporization. This is contrary to our experiments with another element of low volatility (palladium)[2,3] but in accordance with data for indium,[6] a rather volatile element with non-resonance lines originating from levels close to those of tin. It was recently proposed[16] that the ratio of the absorption at resonance lines to that at non-resonance lines be used to characterize graphite furnaces and draw conclusions on the temperature of the atom cloud. Since in our case there is little difference in the sensitivity ratios with wall- and platform-vaporization, it is tempting to conclude that the temperature of the atom cloud is not influenced by atomization temperature. This is probably not the case, but for the time being we cannot offer any reasonable explanation for the phenomena observed. One possibility would be that the population of an excited state is not purely thermally controlled but rather is governed by collisions with electrons emitted by the furnace. Thus the actual temperature would have little influence on relative sensitivities even though the electron flux should be dependent on the furnace temperature. More work is needed with other elements before definite conclusions are drawn.

It should be mentioned that many of the other tin lines[10] show analytically useful absorption signals, but are not all discussed here since it would be beyond the scope of the present work to investigate the complete atomic-absorption spectrum of tin.

Before proceeding further we have to mention that the detection limits with the non-resonance lines are much better than those with the resonance lines. This is no doubt at least partly due to the fact that non-resonance lines are emitted more intensely by hollow-cathode lamps (and probably also by EDLs), thus allowing the use of much lower photomultiplier voltages than those needed when resonance lines are used.

The sensitivity of low-volatility elements is known to be impaired by the use of platform-vaporization. We have found this to be also the case for palladium.[2] It was concluded[2] that the peak-height sensitivity for palladium is lower with platform- than with wall-vaporization, because of the slower heating rate of the platform. Contrary to our expectations we have found that for tin both peak-height and area are almost doubled by use of platform-vaporization. Since it is known that tin has a strong tendency towards carbide formation we think it likely that the enhancement of both resonance and non-resonance lines may be due to the platform material being more inert than the furnace itself. A similar trend was noted by Manning.[17] Similar sensitivities were obtained by us whether the platform was of solid pyrographite or normal graphite coated with tantalum carbide.

It is certainly interesting to note the rather remarkable sensitivity of the 284.00 nm non-resonance line (Table 2). Though the 284.00 nm line was reportedly used[18] for temperature measurements in the graphite furnace, there is no mention in the literature of any analytical application of it.

The temperature of atomic vapour in electrothermal atomizers

Several attempts[18-21] have been made to determine the temperature of the atomic vapour in graphite furnaces,[18,19] on filaments[20] and in metal tube atomizers.[21] Most workers concluded that the temperature of the furnace fill gas (and hence the temperature of atoms) closely follows the wall temperature.

In a system at thermal equilibrium, the resonance and non-resonance line peaks should appear simultaneously. Previous work with palladium[3] has shown that a considerable difference exists in the peak characterization times of the resonance and non-resonance lines. This should be taken to mean that the furnaces used were far from reaching thermal equilibrium during the evolution of the atom cloud.

In the work of Manning[17] it was found that with wall-vaporization there is indeed a considerable difference in the peak times of the resonance and non-resonance lines. His results are summarized in Table 3, from which it may also be seen that even with platform-vaporization the difference in peak times still persists, even though much less than that for wall-vaporization. The logical conclusion is that

Table 3. Peak times for tin (*msec*) under various vaporization conditions[17]

	224.6 nm	235.3 nm
Wall 2350°C	200	300
Wall 2500°C	190	270
Platform 2350°C	1020	1060
Platform 2500°C	890	970

Atomization in an HGA-500 with pyrocoated furnaces and solid pyroplatforms.

vaporization conditions are far from isothermal even with the use of a platform, and even one second after the onset of atomization. Even though Manning[17] used an experimental system different from ours, we consider that since the time-resolution of the detection systems and the heating rates of the furnaces are very similar, our data are directly comparable. Unfortunately we had no possibility to monitor the peak shapes with the present experimental arrangement. In an independent work, Ohta and Suzuki[21] also found different peak shapes for the 224.61 nm resonance and 235.48 nm non-resonance lines. These authors found that the peak for the non-resonance line appears later and at higher temperature than that for the resonance line. However, they found the non-resonance line to be less sensitive than the resonance line under their experimental conditions. It is indeed remarkable that our data and those of Manning and of Ohta and Suzuki are in such close agreement, in spite of the quite different instrumentation used (graphite furnaces of different design by us and Manning and a molybdenum microtube atomizer by Ohta and Suzuki). This proves yet again, that when optimized experimental systems are used (high atomizer heating rates and high time-resolution of the detection system), reproducible, reliable and accurate results may be obtained from different laboratories.

In view of the above we consider that the rather optimistic view of atomic-vapour temperature taken by previous workers is probably due to the inaccuracy of the *gf* values used in their calculations. Thus we believe it worthwhile to make further refinements in the design of furnace atomizers, with a view to increasing the atomic-vapour temperature. The "contour"[22] and "curtain"[23] tubes as well as the use of capacitive discharge heating[24] with or without platform-vaporization may prove to be at least a temporary panacea for those ardently pursuing isothermality in non-isothermal, pulsed atomizers.

Linearity of calibration curves

In previous papers from this laboratory[2-7] we discussed the reasons for the linearity of the calibration graphs being better for non-resonance than for resonance lines. For tin we have found that the 235.48 nm non-resonance line gives a much more linear calibration than the 224.61 nm resonance line. However, the 286.33 nm resonance line yields just as linear a calibration (up to a peak-height absorbance of *ca*. 1). When speaking of the linearity of calibration curves we consider only the absorbance domain. With the detection system used, there is no instrumental contribution to the non-linearity of calibration curves.

As mentioned earlier, we did the calibration by using various volumes of a single standard. Such a procedure was previously considered as inherently yielding less linear calibration than that from injection of the same volume of solutions of different concentrations, on account of differences in the spreading when different volumes are injected.

Recent work in our laboratory[25] on the reduction of interferences by use of carbide coatings showed that this is due to better spreading of the sample drop on the carbide coat than on pyrocoated or normal graphite surfaces. Aqueous samples will wet the carbide-coated surfaces, thus covering a larger surface area and hence reducing the risk of formation of macrocrystals of the matrix salts. In the case of carbide-coated platforms, even a 5-μl sample will cover the whole recess in the platform. The same is true for a 20 μl sample, so the surface area covered will not be dependent on the sample volume, at least in the range 5–20 μl. As a result of this, the calibration graphs constructed by use of various volumes of a single standard are just as linear as those constructed by using a constant volume and different solution concentrations. In the case of real samples, the magnitude of the tolerable background may set an upper limit for sample volumes, but for most aqueous samples it will be possible to use the varied volume method for calibration when a carbide-coated platform is used. Though only tantalum carbide was tested in the present work, it is quite likely that other carbide coatings will behave similarly. Tantalum carbide was chosen because it is the only refractory-metal carbide that is not black, and the formation or destruction of the protective carbide layer can be monitored visually.

Interference patterns of phosphoric acid

Our previous results[1-7] with non-resonance lines of different elements seemed to indicate that interference patterns may be different for resonance and non-resonance lines, as a result of the different appearance times of the two peaks. The non-resonance line would be expected to be more affected than the resonance line by vapour phase dissociation interferences at low atomizer heating-rates. In such cases, because of the early vaporization atoms will escape from the furnace before the gas temperature is high enough to populate excited states. However, with high heating rates (such as used in the present study) the whole mass of analyte plus matrix is vaporized practically instantaneously and the non-resonance line should be less affected than the resonance line by vapour phase dissociation interferences. The non-resonance peak will occur later in time[3,17,21] (so at a higher atomic-vapour temperature), so the dissociation of molecular compounds should be more complete than at the time of measurement of the resonance line peak.

The influence of phosphoric acid on the AAS of tin has been discussed by at least two groups of workers.[21,26] Though one group used a graphite-furnace atomizer[21] and the other a molybdenum microtube,[26] both noted considerable enhancement of the tin signal by phosphoric acid. Both also noted earlier appearance of the tin peak, i.e., at lower atomic-vapour temperature.

Our results are shown in Fig. 2. It is seen that while 1% phosphoric acid considerably enhances the tin
Fig. 2. Influence of phosphoric acid on tin signals. Atomization temperature 2200°C, with vaporization from the wall. Wavelength 286.33 nm. ●—●—● Peak height; ○—○—○ Peak area.

signal, there is signal depression at the 0.05% acid level. Our results illustrate that extreme care should be exercised when postulating positive or negative interferences since concentration of the interferent may have an important effect. Since we do not consider to have elucidated the effect of phosphoric acid on the tin signal, no line is drawn through the data points in Fig. 2.

Since previous workers noted a shift of the tin peak towards lower temperatures we expected the non-resonance line to be more affected than the resonance line. Contrary to our expectations, the 235.48 nm non-resonance line is affected to the same extent as the resonance line. The interference patterns were the same with both wall- and platform-vaporization. Measurement with background correction showed that there was no molecular absorption, so the explanation should be sought elsewhere. The effect described above might have been expected, however, from the constancy of the relative sensitivity of the non-resonance line at different atomization temperatures (Table 2). More work is needed with other elements and various excited levels in order to elucidate these phenomena.

CONCLUSIONS

The non-resonance lines of tin show a considerable analytical potential in electrothermal atomic-absorption spectrometry.

The 235.48 nm non-resonance line has a sensitivity equal to that of the 224.61 resonance line, but gives better linearity of response and better detection limit. Vaporization from a solid pyrographite platform or a normal graphite platform coated with tantalum carbide gives a sensitivity twice that obtained by wall-vaporization. The atomization temperature seems to have little influence on the relative sensitivity of the non-resonance lines. It seems likely that the non-resonance lines originating at energy levels below ca. 4000 cm^{-1} are little affected by atomization tem-

perature, at least in the range normally used in furnace work (2000–3000°).

The interference patterns of phosphoric acid are rather curious and the interaction mechanism is not yet clear. Low acid concentrations (0.05%) depress the signal, but higher concentrations (1%) enhance it.

The calibration for tin (and other elements) may be done by placing various volumes of a single standard on a tantalum carbide coated platform.

In view of earlier work on palladium[3] and tin[17,21] and the present work with tin, it seems necessary to reconsider some literature data on temperature of the atomic vapour in electrothermal atomizers. It is now quite clear that since the resonance and non-resonance peaks have different appearance times, the ratio of the peak absorbances will not necessarily yield the true atomic-vapour temperature, and thus may be misleading.

It certainly seems worthwhile to investigate further the analytical potential of the non-resonance lines of various elements, but the full potential will only be realized in atomizers isothermal in space and time. Unfortunately such atomizers are not yet available commercially. Optimization of sensitivity at the non-resonance lines is not an aim in itself. It should be borne in mind that the best sensitivity for non-resonance lines is achieved when the atomic-vapour temperature is highest. The very same conditions should mean a reduction of interferences at the resonance line. It is also to be expected that the optimum conditions for non-resonance line AAS will also be optimum for electrothermal atomic-emission spectrometry.

Our work on the non-resonance lines is not intended to relegate the use of resonance lines to a minor importance. Their use is here to stay, but we regard the non-resonance lines as being a welcome addition to the analytical arsenal of practising spectroscopists, since they may considerably enlarge the flexibility of the technique.

The first paper to draw attention to the analytical potential of non-resonance lines was by Siemer and Stone[27] in 1975. Rather unfortunately, however, that paper soon passed into oblivion. We hope that our series of papers[1-7] will not suffer the same fate, but will succeed in drawing the attention of our colleagues to this unjustify neglected aspect of atomic-absorption spectrometry. We believe the time has come to give this step-child of atomic absorption its rightful place.

Summary—Ion-selective electrodes based on silver chloride precipitates have been investigated in the low concentration range, by use of a specially designed cell of small volume. Electrode potential measurements and silver determinations in the corresponding solutions by atomic-absorption spectrometry were made. The results prove that the potential response of these ion-selective electrodes in the low concentration ranges is governed by inequality of the ion concentrations in the boundary zone of the test solution contacting the electrode membrane. This is a result of adsorption–desorption processes, a dissolution process followed by recrystallization of the silver chloride at the electrode membrane surface, and photoreduction of silver ions at the electrode surface.

Our earlier studies[1] on ion-selective electrodes based on silver iodide showed that use of a micro-cell with electrode membranes of relatively large surface area allowed information to be obtained for processes taking place at the electrode/solution interface. Deviations from the ideal Nernstian response at concentrations below $10^{-4} M$ were explained by adsorption–desorption processes, which means that the solubility of the precipitate-based membranes is not the only process to be considered in interpreting the behaviour of the electrode at concentrations near the detection limit. Silver iodide has a relatively low solubility product, and it is a question whether the same considerations hold for membranes based on precipitates with higher solubility products, such as silver chloride (for which[2] K_{sp} is 1.56×10^{-10} at 25°).

Various authors have based theoretical equations on the solubility product, for describing the electrode potential *vs.* activity function of silver chloride based ion-selective electrodes at low concentrations.[3–7] However, the theoretical and practical calibration curves did not match completely (*e.g.*, in the work of Morf[6,7]) but no detailed explanation for this anomalous behaviour was given. In spite of this, chloride has been determined potentiometrically at the ng/ml level, with good reproducibility, by optimization of the analytical conditions (temperature, *etc.*) for the particular analytical problem.[8–11]

The combined potentiometric and atomic-absorption technique described in our previous papers[1,12] seemed to be appropriate for studying the membrane/solution interface processes in the case of the silver chloride based membrane electrodes, and to interpret their anomalous behaviour in the lower concentration ranges.

EXPERIMENTAL

Electrodes

(a) A home-made AgCl-based homogenous pressed-pellet electrode. A mixture of 100 ml of $1M$ potassium chloride, 300 ml of distilled water and 100 ml of $1M$ nitric acid was potentiometrically titrated to the equivalence point, with $1M$ silver nitrate, a Radelkis OP-Ag-711 silver ion-selective electrode and OP 820 P Ag/AgCl, KNO_3 double-junction reference electrode being used. Analytical grade reagents were used throughout the work.

(b) A home-made Ag_2S/AgCl electrode, prepared as described earlier.[13]

(c) An Ag/AgCl electrode of the second kind. A properly pretreated silver disc (12 mm diameter) was covered electrolytically with a silver chloride layer.[14] Pellets (diameter 12 mm) were pressed from the precipitates used for electrodes (a) and (b), at a pressure of 10^6 N/cm^2, and were glued onto glass tubes with "Araldite". The inner electrode was an Ag/AgCl electrode of the second kind, and the inner electrolyte was $10^{-3}M$ potassium chloride.

Cell and measuring device

The same micro-cell and measuring method were used as described in our previous papers.[1,12] The volume of the cell was $300 \mu l$ and the electrode potentials were measured every minute after immersion of the electrodes, but the readings taken at the tenth minute were accepted as the final value. After the potential measurements the actual silver concentrations of the solutions were determined by atomic-absorption spectrometry (Varian AA6 instrument). All potential measurements were done at $25 \pm 0.5°$.

Conditioning of the electrode membranes

Before potentiometric measurements were made the elec-

trodes were conditioned in most cases in stirred distilled water for 30 min, or in special cases in counter-ion solutions, *e.g.*, in 0.1*M* potassium chloride before investigation of silver-ion response and in 0.1*M* silver nitrate before that of chloride-ion response.

Calibration was done over the concentration range 10^{-6}–$10^{-2}M$ silver nitrate or potassium chloride, in both micro- and macro-cells. The activity values were calculated by means of the Debye-Hückel theory.[15]

RESULTS AND DISCUSSION

The calibration graphs for the three kinds of electrode are presented in Fig. 1. The graphs are similar but the E° values differ slightly, which is in agreement with the earlier findings of Marton and Pungor.[16]

To follow membrane/solution interface reactions by measuring the activity changes in the test solution, the potentiometric calibrations were repeated with the Ag$_2$S/AgCl-based electrode in the micro-cell (Fig. 2) after the electrode had been conditioned in distilled water. Similar curves were obtained with the other two types of electrodes.

Figure 2 shows that the calibration graphs for silver and chloride are not mirror images. To compare the experimental and theoretical curves, the latter were calculated on the basis of the existing theories based on the solubility equilibrium ($K_{sp} = 1.5 \times 10^{-10}$ at 25°). With the E° data obtained from extrapolation of the calibration graphs, the theoretical calibration curves supposed to be valid in the region of the lower detection limit were calculated by using the following equation:[3]

$$E = E^\circ \pm \frac{RT}{F} \ln\left(\frac{a_y + [a_y^2 + 4K_p]^{1/2}}{2}\right) \quad (1)$$

where E is the calculated electrode potential, E° is the standard potential, a_y is the activity of the ionic species (Ag$^+$ or Cl$^-$), K_p is the solubility product of

Fig. 2. Calibration graphs for an Ag$_2$S/AgCl electrode in the micro-cell.

the membrane material and R, T and F have the usual electrochemical meaning. Theoretically the two calibration graphs should be mirror images, but Fig. 2 shows that the theoretical curve for silver-ion response is higher than the experimental one.

To interpret this anomalous behaviour, the following processes were considered: dissolution of the membrane material; adsorption and recrystallization of the membrane surface layer; kinetic processes; photoreduction.

Dissolution of the membrane material

Figure 3 shows the rate of dissolution of silver ions from the surface of the Ag$_2$S/AgCl-based membrane in the microlitre cell filled with distilled water (similar curves were recorded for the other two types of electrode). The silver concentration was measured both potentiometrically in a microcell and by AAS. The dissolved silver concentrations measured in the tenth minute after the introduction of the electrode into the micro-cell are compared and summarized in Table 1. The silver concentration was found to be about 2–4 $\times$ $10^{-6}M$, which is much less than expected
Fig. 3. Silver-ion dissolution as a function of time; measured in a 300-μl cell with an Ag$_2$S/AgCl membrane in contact with distilled water.

Fig. 1. Calibration graphs for the three types of silver chloride electrodes (25 ml solution volumes).

Table 1. The silver and chloride ion concentrations in 300 μl of distilled water in contact with different types of AgCl-selective electrodes

Type of electrode	[Ag$^+$] measured by AAS, $10^{-6}M$		[Cl$^-$], $10^{-6}M$	
	Average	RSD, %	Calculated by solubility equilibrium from [Ag$^+$] data measured	Measured by Cl$^-$ electrode
AgCl pressed pellet	3.0	5.0	52	50
Ag$_2$S/AgCl pressed pellet	3.85	2.0	40.5	50
Ag/AgCl of the 2nd kind	2.75	7.0	57	40

for equilibrium solubility. If we assume that the solubility equilibrium still holds at the membrane/solution interface, the chloride concentrations calculated from K_{sp} and the silver concentration measured by AAS are about one order of magnitude higher than the silver concentrations (Table 1, second column). The chloride concentrations (determined as described later) are also summarized in Table 1 and indicate that the concentrations of the silver and chloride ions in a solution in contact with silver chloride are not equal.

Adsorption of ions on the membrane surface; recrystallization of the surface layer

The difference between the silver and chloride ion concentrations in distilled water in contact with a silver chloride membrane may be interpreted as due to the different adsorptivity of the two ions on the AgCl pellets. To prove the existence of adsorption the actual silver ion concentrations were measured during calibration with a series of standard silver nitrate or potassium chloride solutions (Table 2). Evidently at low silver concentrations ($\leq 10^{-6}M$) the effect of dissolved silver ions cannot be neglected, but at higher concentrations the decrease in the bulk concentrations, caused by adsorption, seems to be more important. This phenomenon characterized by the decrease in silver ion concentration is supposed to be followed by formation of silver chloride microcrystals on the membrane surface. For the chloride cali-

bration, on the other hand, the AAS values for the silver concentration are around $10^{-6}M$ or less, which is lower than the values calculated on the basis of the solubility equilibrium.

The phenomenon is even more pronounced if we treat an AgCl-based electrode with the counter-ion before the calibration (*e.g.*, conditioning for 30 min in stirred 0.1M chloride before the silver calibration and *vice versa*). The counter-ion treatment is also characterized by the potentiometric behaviour shown in Fig. 4, where the silver and chloride calibration curves cross each other if counter-ion treatment is used. The values given at the points of the curves are the actual silver concentrations measured by AAS. This anomalous deviation of the calibration curves is rectified by replotting the calibration curve with the silver concentrations actually measured by AAS, instead of the nominal values (Fig. 5). It is evident from Fig. 5 that the Nernstian behaviour for silver holds even down to $10^{-6}M$. From these results, it may be concluded that the detection limit is governed by the actual concentration of the revelant ions in the solution boundary phase, which is affected by adsorption and microcrystal formation with counterions; the latter effect always exists, owing to dissolution of the electrode membrane material.

Figure 6 shows electronmicrographs (magnification $\times$ 540) of the surface of the Ag$_2$S/AgCl electrodes; *A* shows the surface of a polished but non-treated electrode pellet, *B* the surface of a pellet

Table 2. Silver concentrations measured in the 300-μl cell by AAS and by potentiometry (with calibration of the AgCl-based electrode in the same cell with AgNO$_3$ or KCl solutions)

	Nominal sample concentration, M	Measured silver concentration, M	
		AgNO$_3$ solution	KCl solution
Without electrode conditioning	0 (distilled water)	2.9×10^{-6}	3.1×10^{-6}
	10^{-6}	4.3×10^{-6}	3.1×10^{-6}
	10^{-5}	8.1×10^{-6}	2.3×10^{-6}
	10^{-4}	8.4×10^{-5}	1.1×10^{-6}
	10^{-3}	9.4×10^{-4}	5.4×10^{-7}
Electrode conditioned with 0.1M counter-ion before calibration	0 (distilled water)	1.8×10^{-6}	4.6×10^{-5}
	10^{-6}	2.8×10^{-6}	8.6×10^{-6}
	10^{-5}	8.3×10^{-6}	3.7×10^{-6}
	10^{-4}	9.2×10^{-5}	1.4×10^{-6}
	10^{-3}	—	7.0×10^{-7}

treated with $0.1M$ silver nitrate for 30 min, and C shows the electrode surface after treatment in $0.1M$ potassium chloride for 30 min. The pictures clearly show the formation of microcrystals at the surface, indicating that a recrystallization process takes place during use of the electrode.

Kinetic processes

These time-dependent membrane/solution interface processes were studied by recording potential *vs.* time curves. If it is supposed that the anion and cation activities in a solution contacting an AgCl membrane are at the same level as a function of time, then the potential measured in the micro-cell should not change with time. This means that E *vs. t* curves with a positive or negative slope are a proof of
unequal concentration of cation and anion in the boundary zone of the test solution. Typical examples of E *vs. t* curves are shown in Fig. 7. For chloride, the potentials measured in a micro-cell filled with distilled water generally decrease with time (curve c) in contrast to the case for a macro-cell (curve d). In the latter case, the E *vs. t* curve is horizontal, which probably means that the effects of deposition or dissolution of the component ions of the membrane, on the primary ion activities in the boundary zone of the sample solution, are not so pronounced, owing to the steady-state diffusion of the ions dissolved, towards the bulk. E *vs. t* curves with a negative slope suggest that chloride ions are in excess in the solution phase, compared to silver ions. This conclusion is consistent with the results obtained in the work on dissolution of the membrane material. The E *vs. t* curves which exhibited an increase in chloride concentration with time in the microlitre cell were used to determine the chloride ion concentration dissolved from the membrane, as mentioned above.

The measurement of the actual dissolved chloride concentration was attempted in the following way. During 10 min after the immersion of the electrode in distilled water in a micro-cell the ion activities develop according to the solubility equilibrium and the corresponding electrode potential can be measured. The chloride ion concentration at the tenth minute was evaluated by means of a chloride calibration curve recorded in the micro-cell a few seconds ("zero minutes") after immersion of the electrode; it is supposed that at this time the dissolution of the electrode membrane material is insufficient to influence the bulk concentrations. The concentration data obtained by this method are in good correlation with the calculated values (Table 1, third column). This evaluation method was also checked by means of a calibration curve plotted on the basis of macro-cell measurements.

Photoreduction

Ion-adsorption at the membrane surface does not explain satisfactorily the anomaly observed in the low concentration ranges. There must also be another effect, which is more pronounced for the silver response than the chloride response and results in a deviation from the theoretical silver calibration graph in the direction of more negative potential values.

As silver chloride is photosensitive, the photo-effect has also to be considered in interpretation of the anomalous response behaviour. If it is supposed that there is photoreduction of the adsorbed silver on the solid membrane face or of the silver chloride membrane material, to metallic silver, *e.g.*,[17]

$$2Ag^+ + 2H_2O \xrightarrow{h\nu} 2Ag + H_2O_2 + 2H^+$$

$$2AgCl \xrightarrow{h\nu} 2Ag + Cl_2$$

and

$$Cl_2 + H_2O \rightarrow HOCl + HCl$$

Fig. 5. Emf *vs.* log C_{Ag^+} in the dissolution range for the AgCl electrode.
Fig. 6. Electron micrographs of $Ag_2S/AgCl$ membrane surfaces. (a) Polished untreated membrane surface; (b) membrane surface after treatment in $0.1M$ $AgNO_3$ for 30 min; (c) membrane surface after treatment in $0.1M$ KCl for 30 min. Magnification $\times$ 540.
Fig. 7. Emf *vs.* time functions for an AgCl electrode: (A) after treatment in 0.1M AgNO$_3$, measured in 300 μl of distilled water; (B) after treatment in 0.1M KCl, measured in 300 μl of distilled water; (C) without treatment, measured in 300 μl of distilled water; (D) without treatment, measured in 25 ml of distilled water.

then the silver concentration in the solution phase should decrease. Thus the shift of the E *vs. t* curves towards more negative potentials is even more understandable. Some decrease in the silver concentration of the test solutions could also be attributed to the action of light, since the experiments were all done in daylight.

The photoreduction can be made more pronounced by irradiation with ultraviolet light. To prove the effect of photoreduction the following studies were made. A 1-g portion of the Ag$_2$S/AgCl precipitate used for pressing the membrane pellets was suspended in 20 ml of distilled water and stirred for 10 min. The pH and the chloride and silver concentrations of the solution were then measured. The pH was found to be 5.6, [Cl$^-$] 1.1 $\times$ 10^{-5}M and [Ag$^+$] 2.5 $\times$ 10^{-6}M.

The suspension, in a quartz beaker, was then irradiated with ultraviolet light for 10 min. After irradiation the pH had decreased to 4.7, and [Cl$^-$] had increased to 1.5 $\times$ 10^{-4}M. The silver concentration measured by AAS was 3.6 $\times$ 10^{-6}M: that determined potentiometrically was 1 $\times$ 10^{-6}M. The slight difference in silver concentrations observed could be explained by the fact that the AAS data give the total silver concentration, not just the ionic concentration.

Similar experiments done with the micro-cell containing a silver chloride ion-selective membrane elec-

trode in contact with distilled water confirmed these findings.

These experiments explain the data shown in Fig. 7, curve A, and prove that the photoeffect must also be taken into consideration in interpretation of the response of the AgCl-based chloride electrode at low concentrations.

CONCLUSION

From the experimental findings it can be concluded that the potential response of the silver chloride ion-selective electrodes in the low concentration ranges is governed by inequality in the ion concentrations in the boundary zone of the test solution in contact with the electrode membrane. This is a result of adsorption–desorption processes and a dissolution process followed by formation of microcrystals of silver chloride at the electrode membrane surface. The effect of light may also contribute to the anomalous pote.atiometric behaviour observed. These effects were found for the three different types of AgCl-based ion-selective electrodes tested.

Summary—A systematic study has been made of the extraction of potassium p-nitrophenoxide from aqueous medium into a number of organic solvents that are immiscible or partly miscible with water, in the presence of several macrocyclic crown ether and cryptand complexing agents. The efficiency of extraction varies extremely widely with the nature of the ligand and the solvent. For some solvent systems, DC-18-C-6 is more efficient than [2.2.2] cryptand as an extractant. The extraction values, however, provide only limited insight into the fundamental reasons behind the observed results. Hence equilibria involved have been considered and the results analysed in terms of the equilibrium constants. The microscopic and macroscopic properties of these systems are discussed.

Macrocyclic crown ethers and cryptands have found increasing use in various areas of chemistry through their characteristic ability to bind metal cations.[1–5] One important usage results from the solubilization of typical inorganic salts in non-polar and polar aprotic organic solvents, enabling reaction of the salts with a variety of organic compounds in homogeneous solution. Concomitantly, the binding of the metal cation by the macrocyclic ligands often leads to greatly enhanced reactivity of the "naked"[6] anion;† hence such macrocycles can be of special value in studies of nucleophilic reactivity as well as in proton-abstraction processes.[8]

Partition of metal cation complexes of macrocyclic polyethers and cryptands between water and organic solvents has been extensively used as a measure of the complexing capability of the ligands.[9] Indeed, newly synthesized ligands are generally examined in this manner.[10–12] However, despite the importance of extraction studies, for example in membrane model systems,[13,14] analytical applications[15] and phase-transfer catalysis,[16] systematic studies have seldom been made.

In the present paper we report the results of a systematic study of the extraction of potassium

p-nitrophenoxide from aqueous medium into a number of organic solvents, with several common macrocyclic ligands as complexing agents. At the simplest, though nonetheless useful, level, the study provides a systematic body of data on the efficiency of the various ligand/solvent systems for extraction of potassium with p-nitrophenoxide as counter-ion. One advantage of the latter is the ease of its spectrophotometric measurement. At a deeper level, analysis of the equilibrium constants involved in this system provides insight into the fundamental relationships governing extractions, such as solute–solute and solute–solvent interactions, in the context of the special properties of the macrocyclic ether and cryptand ligands and their interactions with metal cations.

RESULTS

The extraction study was performed with dicyclohexano-18-crown-6 ether (DC-18-C-6), dibenzo-18-crown-6 ether (DB-18-C-6), 18-crown-6 ether (18-C-6), and [2.2.2]cryptand (2,2,2) as the complexing agents. The stability constants (K_s) of the potassium complexes with these ligands in water are known (Table 1). The distribution constants (K_{dc}) of the ligands between the aqueous and organic phases were determined by the method of Frensdorff[2] and are also given in Table 1.

The degrees of extraction of potassium p-nitro-

†For tert.-amyl alcohol, the experiments with DB-18-C-6 were done with a different KOH concentration from that used with the other complexing agents (see Table 3), necessitating the measurement of a new K_{ds} value (2.83) under those conditions, for use in the calculation of K'_e, K_e, K_{dcs} and K_a.

phenoxide were determined spectrophotometrically.[2] In the procedure used, both potassium and ligand were usually present in excess. Results obtained in the absence and presence of ligand are given in Table 2. The former yield the distribution coefficient of the salt, K_{ds}, between the aqueous and organic phases. Other equilibrium constant data, as defined in the next section and calculated according to the method given in the Appendix, are presented in Table 2.

To test the procedure, sample calculations were done for various concentrations of potassium hydroxide and complexing agent; the resulting K_e values showed satisfactory agreement, confirming that the scheme accommodates variations in the concentrations of potassium hydroxide and complexing agent as well as of the salt.

DISCUSSION

The results show a wide range in the effectiveness of the macrocyclic ligands in extraction of potassium p-nitrophenoxide from aqueous medium into organic solvents of various polarities. To explain the observed differences in behaviour, an analysis of various factors which determine the microscopic and macroscopic properties of the systems is presented.

Table 3. Initial concentrations of complexing agent (C), *p*-nitrophenol (ArOH) and potassium hydroxide in the extraction experiments

K_{dc} values

An important consideration in these extractions is partition of the ligand itself between the aqueous and organic phases. Earlier studies have shown that ligands such as (2,2,2), 18-C-6 and their analogues strongly prefer the aqueous phase to a purely hydrocarbon solvent such as cyclohexane. The present results, for organic solvents of varying polarity, show that for the cyclohexano- and benzo-ligands there is in all cases a strong preference for the organic phase. With the exception of phenylacetonitrile, where K_{dc} (DC-18-C-6) > K_{dc} (DB-18-C-6), the largest values of K_{dc} are observed for DB-18-C-6, which is clearly in accord with the hydrophobic nature of this ligand. On the other hand, for (2,2,2) and 18-C-6 there is generally a preference for the aqueous phase, which is in accord with the more hydrophilic nature of these ligands.

It should also be noted that in the presence of a complexing salt, the partitioning of the ligand into the aqueous phase will be accentuated. This means that in considering extraction equilibria it is generally not valid to regard the ligand as confined to the organic phase (*vide infra*).

K_{ds} values

The results in Table 2 show that though potassium *p*-nitrophenoxide is not detectably soluble in methylene chloride or the ethereal solvents anisole, phenetole or n-propyl THPE (n-propyl tetrahydropyran ether), it is somewhat soluble in several of the more polar solvents, especially cyclohexanol, tert.-amyl alcohol, phenylacetonitrile and adiponitrile. However, quantitative evaluation of this factor is complicated by the fact that some of these organic solvents are miscible to various degrees with water, which might be expected to influence strongly the partitioning of the salt between the two phases. This partitioning, however, must be allowed for in calculation of the various constituent equilibrium constants in the subsequent treatment.

Extraction efficiencies

The results in Table 2 show that the degree of extraction varies widely, depending on the solvent and ligand used. The ethereal solvents n-propyl THPE, TFTP [2-(tetrahydrofurfuryloxy)tetrahydropyran] and 1,4-dioxaspiro(4,5)decane are quite poor in this respect, while phenetole and anisole are marginally better. Also, somewhat surprisingly, 2-methyl-3-hexanone is considerably poorer than the other ketones. With these exceptions, it is clear that efficient extraction can be achieved with most of these solvents, especially with DC-18-C-6 and (2,2,2) as the ligands. It is noteworthy that in some cases DC-18-C-6 is in fact more efficient than (2,2,2), which could have important practical implications in view of the large difference in cost of these ligands. It is, however, difficult to make strict comparisons of the extraction

efficiencies from the degrees of extraction since a uniform set of conditions could not be maintained, owing to the widely different efficiencies in the respective systems. Such comparisons are more readily made in discussion of the equilibrium data.

K_e and K_e' values

The equilibrium constant for extraction (as ligand-complexed ion-pairs) of a salt MX that is dissociated in the aqueous phase, is defined by

$$K_e = \frac{[MC^+X^-]_{org}}{[M^+]_{aq}[X^-]_{aq}[C]_{org}} \qquad (1)$$

where C is the ligand. However, for many systems discussed in the literature,[2,5,10] the authors appear to use an apparent equilibrium constant (which we will call K_e'), defined by

$$K_e' = \frac{[MC^+X^-]_{org}}{[M^+]_{aq}'[X^-]_{aq}[C]_{org}'} \qquad (2)$$

in which $[M^+]_{aq}'$ and $[C]_{org}'$ are the total concentrations of M^+ and C, exclusive of $[MC^+X^-]_{org}$. Thus:

$$[M^+]_{aq}' = [M^+]_{tot} - [MC^+X^-]_{org} \qquad (3)$$

$$[C]_{org}' = [C]_{tot} - [MC^+X^-]_{org} \qquad (4)$$

In the definition of K_e', it is assumed that there is no ligand in the aqueous phase and no uncomplexed salt in the organic phase, and that no polymeric species are formed. Therefore, for solvent/ligand systems in which partitioning of either free or complexed ligand into the aqueous phase is very small, the K_e' values are a valid measure of the extraction equilibria. K_e' values can be calculated for systems where K_{dc} data are not available, and can be useful in an exploratory study. Values of K_e' calculated according to the expressions above are given in Table 2.

For phenetole and n-propyl THPE, K_e' is quite small, but is somewhat larger for 1,4-dioxaspiro(4,5)-decane and TFTP, being comparable with the value for 2-methyl-3-hexanone. Much larger K_e' values are observed for phenylacetonitrile and adiponitrile, and for tert.-amyl alcohol and benzyl alcohol.

Our previous considerations show that, particularly in the case of (2,2,2) and 18-C-6, considerable partitioning of the ligand into the aqueous phase occurs and therefore a more rigorous analysis of the equilibria is required.

Detailed analysis of equilibria

A pictorial representation of the equilibria involved in this system is given in Scheme 1.

$$M^+ + X^- + C \xrightleftharpoons{K_s} MC^+ + X^-$$

$$- - - K_{ds} \Updownarrow \quad K_{dc} \Updownarrow \quad - - - K_{dcs} \Updownarrow \quad \frac{(aq)}{(org)}$$

$$M^+X^- + C \xrightleftharpoons{K_s} MC^+X^-$$
Scheme 1.

In this scheme, it is assumed that the degrees of dissociation of the uncomplexed ion-pair into free

ions, *i.e.*,

$$(M^+ X^-)_{org} \rightleftharpoons (M^+)_{org} + (X^-)_{org}$$
and of dissociation of the complexed ion-pairs into free charged species, *i.e.*,

$$(MC^+ X^-)_{org} \rightleftharpoons (MC^+)_{org} + (X^-)_{org}$$
in the organic phase are both negligible. The assumption that $(M^+ X^-)_{org}$ does not dissociate into the free ions is probably valid for rather non-polar organic solvents. It is considered that this and the assumption that $(MC^+ X^-)_{org}$ does not dissociate, will not affect the overall conclusions regarding the trends observed (see below).

The equilibrium constants in Scheme 1 are defined as:

K_s: stability constant for complex formation in aqueous phase;

K_{ds}: distribution constant of salt between aqueous and organic phases;

K_{dc}: distribution constant of complexing agent between aqueous and organic phases;

K_{dcs}: distribution constant of complexed salt between aqueous and organic phases;

K_a: equilibrium constant for complexation of salt in organic phase.

The algebraic expressions for the respective equilibrium constants are given in equations (5)–(9). Concentrations are used instead of activities, because of the lack of activity coefficient data. The agreement between the K_e values obtained on variation of the concentrations of the complexing agent, p-nitrophenoxide and potassium ions suggests that the procedure and approximations used are valid.

$$K_s = \frac{[MC^+]_{aq}}{[M^+]_{aq}[C]_{aq}} \quad (5)$$

$$K_{ds} = \frac{[M^+ X^-]_{org}}{[M^+]_{aq}[X^-]_{aq}} \quad (6)$$

$$K_{dc} = \frac{[C]_{org}}{[C]_{aq}} \quad (7)$$

$$K_{dcs} = \frac{[MC^+ X^-]_{org}}{[MC^+]_{aq}[X^-]_{aq}} \quad (8)$$

$$K_a = \frac{[MC^+ X^-]_{org}}{[M^+ X^-]_{org}[C]_{org}} \quad (9)$$

For purposes of calculation, only four of the constants above are independent and the first three can be determined separately from extraction experiments. In the scheme, seven different species exist in equilibrium. Their concentrations can be determined under equilibrium conditions by evaluation of the stoichiometric relationships (10)–(12):

$$[C]_{tot} = [C]_{aq} + [C]_{org} + [MC^+]_{aq} + [MC^+ X^-]_{org} \quad (10)$$

$$[M^+]_{tot} = [M^+]_{aq} + [MC^+]_{aq} + [M^+ X^-]_{org} + [MC^+ X^-]_{org} \quad (11)$$

$$[X^-]_{tot} = [X^-]_{aq} + [M^+ X^-]_{org} + [MC^+ X^-]_{org} \quad (12)$$

together with the equilibrium constants K_s, K_{ds} and K_{dc} [equations (5)–(7)] and the measured concentration of $[X^-]_{aq}$. An iterative procedure described in the Appendix was used for derivation of the various quantities which are further discussed below.

Evaluation of results

Comparison of K_e *and* K_e' *values.* The values of these two equilibrium constants are expected to agree provided that (*i*) the partition of the ligand into the aqueous phase is small (K_{dc} large), and (*ii*) the stability constants (K_s) of the aqueous complexes are small.

The results in Table 2 show that these conditions are mostly met for the DC-18-C-6 and DB-18-C-6 complexes. On the other hand large differences between K_e and K_e' are found for the 18-C-6 complexes and especially for the (2,2,2) complexes (note that the K_e/K_e' ratios vary by up to 10^6). For the latter complexes, this is the result of moderate partitioning of the free ligand into the aqueous solution, in conjunction with very strong complex formation in aqueous solution.

Absolute K_e *values.* In all cases in Table 2, the highest K_e values are observed for the (2,2,2) complexes, while DB-18-C-6 is in general associated with the lowest K_e values. With the exception of the (2,2,2) systems, methylene chloride and the ethereal solvents are associated with K_e values which are orders of magnitude smaller than those obtained with the other solvents. The overall extraction efficiency, as represented by K_e values, is extremely favourable for the (2,2,2) complexes, for all the solvent/ligand systems studied.

Thus examination of the K_e data has revealed a relative order quite different from that for the experimental degrees of extraction, which suggested that (2,2,2) and DC-18-C-6 are often comparable in extraction efficiency. The reason for the relatively diminished degree of extraction with (2,2,2) is that a significant amount of this ligand is held in the aqueous phase, unlike DC-18-C-6.

K_{dcs} *values.* A different picture emerges for the extraction of the complexed salt as represented by the K_{dcs} values. Except for the solvents phenylacetonitrile, and methylene chloride, for which K_{dcs} (DC-18-C-6) > K_{dcs} (2,2,2) > K_{dcs} (DB-18-C-6), and amisole [K_{dcs} (DC-18-C-6) > K_{dcs} (DB-18-C-6)], the K_{dcs} values for DB-18-C-6 are the largest. The smallest K_{dcs} values are observed for 18-C-6.

The observation that DB-18-C-6 is associated with large K_{dcs} values can presumably be accounted for by the hydrophobic nature of this ligand and hence also of the complexed cation. However, the much less

hydrophobic nature of 18-C-6 and the fact that interactions between the cation and solvent molecules can still occur in the plane perpendicular to the ligand in the 18-C-6-complexed cation, together result in making this the least efficiently extracted of the various complexed salts.

The case of (2,2,2) is somewhat intermediate. Although this ligand is not hydrophobic, it forms a 3-dimensional cavity containing the complexed cation, which leads to the overall result observed.

Comparison of K_{ds} and K_{dcs}. It is interesting that there appears to be no correlation between the K_{dcs} and K_{ds} values. For example, in terms of K_{dcs} values, methylene chloride is comparable to the other solvents, whereas it is very poor on the basis of the K_{ds} values. This is a reflection of the fact that once the cation is complexed, specific cation–solvent interactions are essentially removed. As K_{dcs} values are governed by the complexation reaction and the K_{ds} values by the specific interactions, any connection between these quantities can only be fortuitous.

K_a *values.* These give a measure of the complexing ability of the ligand in the organic phase. The experimentally observed order of K_a values in practically all cases is $(2,2,2) \gg (18\text{-}C\text{-}6) > DC\text{-}18\text{-}C\text{-}6 > DB\text{-}18\text{-}C\text{-}6$, which is the order for the K_s values in methanol and water.[21,22] It appears, therefore, that the different microscopic states of the salt, *i.e.*, free ions in water or methanol, and ion-pairs in the organic solvents, do not significantly affect the relative order of the stability constants of the complexes with the different ligands.

EXPERIMENTAL

Materials

The macrocyclic ligands were purchased from BDH, Aldrich, Merck or Parish Chemical Co. and used as received. The organic solvents were purified, dried and distilled. *p*-Nitrophenol was recrystallized from 2% v/v aqueous hydrochloric acid.

Extraction procedure

A standard aqueous solution of potassium *p*-nitrophenoxide was prepared from *p*-nitrophenol and a standard potassium hydroxide solution, the latter being in excess. A standard solution of the ligand in a particular organic solvent was also prepared. Equal volumes (1 ml) of the two solutions were placed in a small glass-stoppered test-tube and after thorough mixing on a Vortex mixer for 1 min, allowed to stand for phase separation to occur; alternatively, separation was effected by centrifugation. The equilibrium concentration of *p*-nitrophenoxide ion in both phases was determined spectrophotometrically after appropriate dilution. The measured value of the *p*-nitrophenoxide concentration in the organic phase agreed satisfactorily with the difference in the concentration in the aqueous solution before and after extraction. A "blank" extraction in the absence of ligand was also performed with each solvent for evaluation of the distribution constant K_{ds}. Only solvents which were partially miscible with water dissolved the potassium salt to a measurable degree. Details of the concentrations of reagents used are given in Table 3. The results are based on duplicate or triplicate determinations, which usually agreed within ±2%.

K_{dc} values were measured spectrophotometrically as described by Frensdorff.[2]

APPENDIX

For the present systems, two cases in which K^+ is in excess relative to the other species involved can be considered for evaluation of the various equilibrium constants.

(1) The solubility of K^+X^- in the organic phase is negligible, *i.e.*, $[K^+X^-]_{org} = 0$.
Then

$$[K^+]'_{aq} = [K^+]_{tot} - [KC^+X^-]_{org} \qquad (A1)$$

$$[X^-]_{aq} = [X^-]_{tot} - [KC^+X^-]_{org} \qquad (A2)$$

From equation (4), $[C]'_{org} = [C]_{tot} - [KC^+X^-]_{org}$, and from equation (10) $[C]_{tot} = [C]_{aq} + [C]_{org} + [KC^+]_{aq} + [KC^+X^-]_{org}$, *i.e.*,

$$[C]'_{org} = [C]_{aq} + [C]_{org} + [KC^+]_{aq} \qquad (A3)$$

From equation (7), $[C]_{aq} = [C]_{org}/K_{dc}$, and from equation (5), $[KC^+]_{aq} = K_s[K^+]_{aq}[C]_{aq}$; hence

$$[KC^+]_{aq} = K_s[K^+]_{aq}[C]_{org}/K_{dc} \qquad (A4)$$

Substitution for $[C]_{aq}$ from equation (7) and $[KC^+]_{aq}$ from equation (A4), converts equation (A3) into

$$[C]_{org} = \frac{[C]'_{org}}{1 + 1/K_{dc} + K_s[K^+]_{aq}/K_{dc}} \qquad (A5)$$

For the first iteration, $[K^+]'_{aq}$ is determined experimentally from equation (A1) and $[C]'_{org}$ from equation (4). Substitution of these values into equation (A5) yields the first value of $[C]_{org}$ which with equation (7) gives $[C]_{aq}$ and with equation (A3) gives $[KC^+]_{aq}$. These first estimates permit the use of the more exact expression for $[K^+]_{tot}$, *viz.* equation (11), to calculate a new $[K^+]_{aq}$ since $[K^+X^-]_{org}$ is assumed to be zero. The cycle is repeated, using equations (4), (A5), (7) and (A3) to yield new values for $[K^+]_{aq}$ until the values converge (usually 2 or 3 cycles), giving all the concentrations required for calculation of K_a and K_{dcs}.

(2) The solubility of K^+X^- in the organic phase is significant. In this case, the total amounts of X^- and K^+ in the organic phase are measured, and

$$[X^-]_{org} = [K^+]_{org} = [K^+X^-]_{org} + [KC^+X^-]_{org} \qquad (A6)$$

For the first iteration, the approximation $[KC^+]_{aq} = 0$ is employed in equation (11), yielding:

$$[K^+]_{aq} = [K^+]_{tot} - [K^+]_{org} \qquad (A7)$$

Substitution of equation (A6) into equation (12) yields a value for $[X^-]_{aq}$:

$$[X^-]_{aq} = [X^-]_{tot} - [X^-]_{org} \qquad (A8)$$

These values of $[K^+]_{aq}$ and $[X^-]_{aq}$, when substituted into equation (6), give a value for $[K^+X^-]_{org}$ which with equation (A6) yields a value for $[KC^+X^-]_{org}$:

$$[KC^+X^-]_{org} = [K^+]_{org} - [K^+X^-]_{org} \qquad (A9)$$

To finish the cycle, equations (4) and (A5) are invoked, with the current values of $[K^+]_{aq}$ and $[KC^+X^-]_{org}$, to yield $[C]_{org}$ which, when substituted back into equations (7) and (A3) gives a value for $[KC^+]_{aq}$.

For the second cycle, the full expression for K^+, equation (11), is used: $[K^+]_{aq} = [K^+]_{tot} - [KC^+]_{aq} - [K^+X^-]_{org} - [KC^+X^-]_{org}$, which on substitution from equation (A6), reduces to

$$[K^+]_{aq} = [K^+]_{tot} - [KC^+]_{aq} - [K^+]_{org} \qquad (A10)$$

The cycle of equations (A10), (A8), (6), (A6), (4), (A5), (7) and (A3) is repeated until there is convergence of the desired values.

DIFFERENTIAL PULSE POLAROGRAPHIC DETERMINATION OF MOLYBDENUM AFTER SEPARATION BY 8-HYDROXYQUINOLINE EXTRACTION INTO DICHLOROMETHANE

Yukio Nagaosa and Katsunori Kobayashi

Faculty of Engineering, Fukui University, 3-9-1 Bunkyo Fukui 910, Japan

Summary—A polarographic investigation of several metal 8-hydroxyquinolinates in dichloromethane medium following solvent extraction has been made. From the data obtained, a selective, specific and sensitive method for the determination of molybdenum at ng/ml levels has been developed involving direct differential pulse polarographic measurement on the dichloromethane extract. In this work, EDTA is used as an effective masking agent to separate molybdenum from other metals. The proposed method has been applied to the determination of molybdenum in a variety of steels and NBS-SRM 1577 bovine liver with good accuracy and precision.

Molybdenum is one of the important elements affecting the physical properties of steels, alloys and high-purity metals, and it is also an essential trace element in biological systems. Therefore, numerous analytical methods have been developed for its determination, *e.g.*, by spectrophotometry,[1] atomic-absorption,[2–4] X-ray fluorescence,[5] neutron-activation analysis[5] and various electrochemical methods.[6–8] Of these, a polarographic method utilizing a catalytic wave of molybdenum enables the metal to be determined with high sensitivity,[9–12] as does anodic-stripping voltammetry at mercury and graphite electrodes.[13]

In general, a preliminary separation by solvent extraction provides good selectivity for instrumental methods of analysis that tend to be subject to matrix effects or interferences from concomitant elements. Several extraction–polarographic methods for the determination of molybdenum have been reported, with ethyl acetate or chloroform as solvent for its 8-quinolinol (oxine)[14,15] or benzohydroxamic acid[16,17] complexes. Polarographic measurements in such cases were made after the extracts had been diluted with a polar solvent such as ethanol or acetic acid in order to enhance the conductivity of the solution. These methods are highly selective but troublesome as routine analytical procedures. Direct polarographic measurement on organic solvent phases after extraction with methyl isobutyl ketone,[18] acetylacetone[19] or acetonitrile[20] improves the simplicity and sensitivity of determination. More recently, we have developed a new extraction–polarographic method using dichloromethane,[21] which gives a simpler and more sensitive procedure for the determination of nickel.

The present paper describes the differential pulse polarographic determination of molybdenum(VI) after its separation by extraction of its oxine complex into dichloromethane from aqueous medium. It is demonstrated that this method is acceptably sensitive and very specific, and it has been successfully applied to the determination of molybdenum in steels and NBS-SRM 1577 bovine liver at the ppm level.

EXPERIMENTAL

Apparatus

Direct current (d.c.) and differential pulse (d.p.) polarographic measurements were made with Yanako Model P-8 and P-1100 polarographic analysers respectively, equipped with a Rika Denki Kogyo Model RW-11 X–Y recorder. A silver–silver chloride electrode served as the reference electrode and a platinum wire electrode as the counter-electrode. The dropping-mercury working electrode had the characteristics: $m = 1.9$ mg/sec and $t = 4.00$ sec in dichloromethane at open circuit. A Toa Dempa Model HM-5A pH meter was used to measure the pH of the aqueous phase after extraction

Reagents

Guaranteed-grade reagents were used unless otherwise stated.

Standard molybdenum solution (10.0 μg/ml). Pure molybdenum trioxide (1.500 g) was dissolved in 50 ml of 2M sodium hydroxide solution, then diluted to 1 litre with water. The standard solution was prepared by diluting 10 ml of the stock solution to 1 litre with water.

Standard metal solutions. Prepared from Wako Pure Chemicals standard solutions (1000 μg/ml) for use in atomic-absorption spectrometry.

Extraction solution. A 0.1M oxine (Wako Pure Chemicals)/0.1M tetrabutylammonium perchlorate (Tokyo Kasei Chemicals) solution in dichloromethane (Wako Pure Chemicals).

All solutions were prepared with water obtained from a Millipore Milli-Q water system.

Sample treatment

A steel sample weighing 0.1–1.0 g was transferred to a 100-ml beaker, and decomposed with 10 ml each of concentrated hydrochloric acid and 50% nitric acid on a hot

water-bath. After addition of 5 drops of concentrated hydrofluoric acid, the solution was evaporated almost to dryness. The residue was taken up with 10 ml of $2M$ hydrochloric acid and diluted to volume in a 100-ml standard flask with water. An aliquot of the sample solution was subjected to the polarographic determination of molybdenum as described below.

A biological sample (NBS-SRM 1577) weighing up to 5 g was transferred to a 1-litre beaker and decomposed with 10 ml each of concentrated nitric acid, concentrated sulphuric acid and concentrated perchloric acid with gentle heating (the final temperature should not exceed 170°). The subsequent procedure was the same as that described for the treatment of steel samples.

Procedure

A known volume of the sample solution was transferred to a 100-ml separatory funnel, the pH was adjusted by addition of $2M$ hydrochloric acid or a buffer solution, and the solution was made up to a total volume of about 50 ml. It was then shaken with 10 ml of a $0.1M$ oxine–$0.1M$ TBAP mixed solution in dichloromethane for 3 min. An aliquot of the extracted organic layer was transferred into a polarographic cell, and dissolved oxygen was removed by passage of nitrogen saturated with dichloromethane. The nitrogen stream was then directed over the solution surface and the d.c. and d.p. polarograms were recorded at 25° under the following conditions: modulation amplitude, 25 mV; drop-time, 1 sec; scan-rate, 5 mV/sec.

RESULTS AND DISCUSSION

Direct current polarographic behaviour of metal oxinates

Polarographic studies were made for all metal oxinates which could be extracted into dichloromethane from aqueous solution, at the optimum pH values. In the available potential range from 0 to -1.2 V vs. Ag/AgCl electrode, most of the metal ions examined gave d.c. polarograms after extraction into the organic phase containing $0.1M$ TBAP as supporting electrolyte. Table 1 lists pH values after extraction, half-wave potentials $(E_{1/2})$, limiting currents, and slopes of the standard potential vs. current log-plot for d.c. polarograms, obtained under the experimental conditions. The data indicate that the Fe(III), Sn(IV), Mn(II) and Mo(VI) complexes all

exhibit well-defined d.c. waves which could be useful for polarographic analysis. However, the polarographic determination of molybdenum(VI) is particularly favourable because the $E_{1/2}$ value differs greatly from those of the other metal complexes and also the limiting current per unit concentration is large compared with the others. From the results shown in Table 1 it can be estimated that the d.c. diffusion current corresponding to a one-electron reduction was ca. 0.4 μA for a $10^{-4}M$ solution (in the dichloromethane extract) for the capillary used. On this basis it is likely that the d.c. waves for Mo(VI) as well as for U(VI) and probably for Bi(III) complexes are catalytic in nature. Therefore, a highly sensitive polarographic determination of molybdenum(VI) is possible.

Linear calibration curves for molybdenum(VI) were obtained over the concentration range from 0.04 to 20 μg/ml with respect to the dichloromethane extract, at modulation amplitudes of 25 and 50 mV. The extraction technique using EDTA as a masking agent rendered the determination of molybdenum(VI) more specific in the presence of other ions (e.g., Fe, Bi and Cu) in sample solutions.

Effect of pH on the d.c. polarogram of the molybdenum complex

In order to determine the optimum pH-value for the determination of Mo(VI) we examined d.c. polarograms of the molybdenum complex after extraction at various pH-values. The pH was adjusted with hydrochloric acid and sodium hydroxide. A maximum and approximately constant limiting current was obtained over the pH range from 1.0 to 1.5, as shown in Fig. 1. The pH range 1.0–1.5 almost coincides with that for quantitative extraction of the molybdenum(VI) oxine complex from acidic solutions, probably as the form of MoO_2 (oxine).[22] For analytical determinations the pH was kept in the range 1.0–1.2. The $E_{1/2}$ value shifted to more negative potentials with increasing pH of the aqueous solution.

Table 1. Polarographic data for various metal oxinates

Metal	pH	$E_{1/2}$, V vs. SSE	I_1, μA*	Slope of the log plot, mV
Cu(II)†	2.70	-0.342	0.97	99
Fe(III)	3.43	-0.425	0.39	50
Pb(II)†	8.51	-0.622	0.81	98
Sn(IV)	2.51	-0.453	0.37	85
		-0.625	0.78	51
Mn(II)	5.82	-0.610	0.66	67
Mo(VI)	3.09	-0.800	7.21	93
Bi(III)†	5.14	-0.431	3.02	61

Fig. 2. Differential pulse polarograms of metal oxinates. (1): Cu(II), (2): Fe(III), (3): Bi(III), (4): U(VI), (5): Mo(VI), (6): Pb(II). pH: 4.6 ± 0.1 (10.5 for Pb and 1.2 for Mo). Each metal ion taken: 10 μg/ml (23.8 μg/ml for U). Conditions were modulation amplitude, 25 mV; scan-rate, 5 mV/sec; drop-time, 1 sec.

Differential pulse polarographic determinations of molybdenum(VI)

In order to improve the sensitivity of the direct d.c. polarographic determination of molybdenum, d.p. polarographic studies were undertaken on dichloro-methane extracts of the oxine complex. Maximum sensitivity was obtained at the same optimum pH-values observed for d.c. polarographic studies. Figure 2 shows the d.p. polarograms obtained for the copper(II), iron(III), bismuth(III), uranium(VI), molybdenum(VI) and lead(II) complexes in a dichloromethane solution containing $0.1M$ TBAP as supporting electrolyte. As stated previously, the d.p. polarographic determination of molybdenum(VI) was investigated in detail because the response is sensitive and the peak well separated from those for other metals. When a large modulation amplitude and a short drop-time were used for the d.p. polarographic measurement, the peak height became maximal. In the present work, a modulation amplitude of 25 mV and drop-time of 1 sec were chosen as being very suitable for analytical purposes.

Calibration curve for determination of molybdenum(VI)

The peak height increased linearly from 0.01 to 2.0 μg/ml molybdenum concentration in a dichloromethane extract at a modulation amplitude of 25 mV. In five replicate determinations of 1.0-μg/ml molybdenum(VI), the average peak height was (17.5 ± 0.4) nA. If a *ca.* 10% relative standard deviation is acceptable, the lower limit of molybdenum(VI) determination is 0.005 μg/ml at a modulation amplitude of 50 mV, corresponding to 1 ng/ml molybdenum(VI) in the original aqueous solution.

Interferences

EDTA could be used as the masking agent for selective extraction of the molybdenum(VI)–oxine complex into dichloromethane, since iron(III), copper(II) and bismuth(III) are not extracted in its presence. For example, the interference from 10 mg of iron(III) is eliminated by addition of 2.0 ml of $0.1M$ EDTA (disodium salt). The data shown in Table 2 indicate that foreign oxo-anions in large amounts may interfere to varying degrees with the d.p. polarographic determination of molybdenum(VI). However, interferences are generally minimal and a rapid reliable method can be developed for most matrices.

Table 2. Effect of diverse anions on the determination of Mo(VI)

Ion	Added, mg	Mo(VI) found, μg	Error, %
None	—	10.00	—
CrO_4^{2-}	0.02	10.12	+1.2
	0.05	9.09	−9.1
VO_3^-	5.0	10.57	+5.7
	10.0	—	—
MnO_4^-	0.01	10.64	+6.4
	0.02	10.91	+9.1

Analytical applications

The present method was applied to the determination of molybdenum in various steels and in bovine liver (SRM-1577). The analytical results are given in Table 3. Extractions were done after addition of 2.0 ml of $0.1M$ EDTA to the sample solution, and the dichloromethane extract was subjected to direct d.p. polarographic measurements. It is evident that the molybdenum contents of such samples are consistent with the certified values. We conclude that this polarographic method is accurate and specific for the determination of molybdenum in such samples.

SIMULTANEOUS SEPARATION OF COPPER, CADMIUM AND COBALT FROM SEA-WATER BY CO-FLOTATION WITH OCTADECYLAMINE AND FERRIC HYDROXIDE AS COLLECTORS

L. M. Cabezon, M. Caballero, R. Cela and J. A. Perez-Bustamante

Department of Analytical Chemistry, Faculty of Sciences, Cadiz, Spain

Summary—A method is proposed for the simultaneous quantitative separation of traces of Cu(II), Cd(II) and Co(II) from sea-water samples by means of the co-flotation (adsorbing colloid flotation) technique with ferric hydroxide as co-precipitant and octadecylamine as collector. The experimental parameters have been studied and optimized. The drawbacks arising from the low solubility of octadecylamine and the corresponding sublates in water have been avoided by use of a 6M hydrochloric acid–MIBK–ethanol (1:2:2 v/v) mixture. The results obtained by means of the proposed method have been compared with those given by the usual ammonium pyrrolidine dithiocarbamate/MIBK extraction method.

Considerable attention has been paid in the past few years to flotation methods,[1] especially co-flotation,[1–8] on account of their promising analytical potential for separation and preconcentration of trace elements, both as anionic or cationic species, in media of low and high salinity. There is special interest in application to the analysis of marine waters.[2,3,6,9–11]

Most of the papers published so far are centred on the selection of experimental conditions for quantitative flotation of individual species,[2–8] considerably less attention being paid to multielement preconcentration and separation methods.[9–13] Also, most of the systems investigated involve use of anionic surfactants as collectors because of their greater solubility in aqueous media, which is advantageous in subsequent dissolution of the sublates for analytical purposes.

Since the flotation yield generally decreases with increasing ionic strength, the use of high molecular-weight amine-type cationic surfactants as well as of chelating surfactants is a convenient alternative in the analysis of sea-water.[9–14]

Results are presented here on a multielement co-flotation investigation on Cu, Cd and Co in sea-water, based on use of octadecylamine as collector and ferric hydroxide as precipitant. The sublates are readily soluble in an acidified mixture of ethanol, water and MIBK, which also increases the sensitivity in the determination of these elements by flame atomic-absorption.

EXPERIMENTAL

Reagents

All reagents used were of analytical grade except the octadecylamine (stearylamine) (Eastman, pract.) and were used without purification. A Cu(II), Cd(II), Co(II) (1000 ppm each) multistandard stock solution was suitably diluted daily for use in standard-additions work and for calibration standards. The calibration standards were matched with the

samples in all respects (solution composition and treatment).

Apparatus

A Pye-Unicam SP9-800 atomic-absorption spectrophotometer was used with an air–acetylene flame under optimized conditions (Table 1) giving a coefficient of variation of 1%.[15]

The co-flotation apparatus was the same as described elsewhere.[16,17]

Procedure for co-flotation

Place 500 ml of the sea-water sample in a 600-ml beaker and add 4 ml of 0.05M iron (III) solution. Adjust to pH 9.5–9.9 with concentrated ammonia solution, with continuous stirring to avoid adding ammonia in excess. Transfer the mixture quantitatively into the flotation column and adjust the air flow to 150 ml/min. Add 15 ml of 0.3% octadecylamine solution in ethanol, and 2 min later add a further 5 ml of this solution and 5 ml of 0.3% sodium lauryl sulphate (NaLS) solution. After 5 min switch off the air stream and suck off the mother liquor, first through the side-drain of the column and finally through the sintered-glass plate at the bottom of the column. Dissolve the precipitate with a few 10-ml portions of 6M hydrochloric acid–MIBK–ethanol mixture (1:2:2 v/v), collecting the solution in a 50-ml standard flask under suction, and making up to the mark with the solvent mixture. Measure the Cu, Cd and Co in this solution by AAS, using calibration graphs or the standard-additions method.

Under the conditions given, the sensitivity is too low to allow reliable determination (especially of cobalt) at levels below 5 ng/ml. It is then necessary to use a larger volume of samples or an analytical technique with lower detection limits (*e.g.*, graphite-furnace AAS). For 2-litre samples the amounts of the reagents must increased to 6 ml of iron(III) solution, 25 ml of octadecylamine solution and 10 ml of NaLS solution, and the air-flow increased to 180 ml/min.

RESULTS AND DISCUSSION

Influence of salinity

According to Matsuzaki and Zeitlin,[9] octadecylamine floats Fe(III) and Th(IV) hydroxides at pH 6–7, Hg (II) sulphide and Mn(IV) oxide at pH 3–9 and Cd(II) sulphide at pH ~9 but will not float

Al(III) hydroxide. These results refer to high-salinity solutions (sea-water) and no information was given for low-salinity solutions.

Our first experiments with iron(III) hydroxide as co-precipitant at pH 5–10 showed a clear trend of the flocs to ascend to the surface, with very little tendency to form a stable foam layer, so the flocs re-entered the mother solution. Even so, the co-flotation yields obtained within 45–60 sec were > 90% for Cu(II), Cd(II) and Co(II) in the pH range 9–9.5. Also, at pH > 10, obtained by addition of sodium hydroxide, the froth layer was thicker and firmer, indicating that the froth formation and, hence overall yield, depends on the salinity. This is illustrated in Fig. 1, showing the variation of cadmium concentration in a solution subjected to co-flotation with iron(III) hydroxide and octadecylamine, as a function of time. Practically all the cadmium is removed from the solution within the first 45 sec, then re-enters it. Addition of 2.5 g of sodium chloride, followed by 5 ml of octadecylamine solution, gives a quick and sharp increase in the removal of cadmium, without rapid reversal of the process. Thus octadecylamine is especially useful for flotation from high-salinity solutions.

Choice of co-precipitant

Iron(III), aluminium, thorium and lanthanum hydroxides were tried as co-precipitants for removal of Cu(II), Cd(II) and Co(II) (present at the 2-μg/ml level) from solutions of salinity similar to that of sea-water. The initial results seemed to indicate good flotation yields (over 90% for all three species at pH 9–10, whichever co-precipitating agent was used), the solutions becoming clear very quickly, though the stability of the froth layers was generally not very satisfactory.

These results were mainly contradictory to those of Matsuzaki and Zeitlin,[9] who reported that octadecylamine does not bring about the flotation of iron(III), thorium and aluminium hydroxides at pH 9–10. We noticed, however, that though flotation took place readily when Cu(II), Cd(II) and Co(II) were present, in their absence there was practically no flotation of lanthanum and thorium hydroxides and only partial flotation of aluminium hydroxide, whereas iron(III) hydroxide was readily floated.

Experiments on the flotation of Cu(II), Cd(II) and Co(II) hydroxides without a co-precipitant present gave yields of over 60%, even when the metals were present at very low concentration levels (about 0.05 μg/ml), which strongly suggests that they are co-precipitated on the surface of the aluminium, lanthanum and thorium hydroxide precipitates, and consequently modify the flotation behaviour of these hydroxides; this could explain the apparent difference between Matsuzaki and Zeitlin's results[9] and ours.

The most suitable of the co-precipitants tested was clearly iron(III) hydroxide, which was therefore investigated further.

Co-flotation with iron(III) hydroxide

Influence of pH. Figure 2 shows the influence of pH on the co-flotation of Cu(II), Cd(II) and Co(II) with iron (III) hydroxide as co-precipitant in 3.5% sodium chloride medium. The pH is particularly critical in the case of Co(II), and the practical pH-range is restricted to 9.5–10. Figure 2 also gives information on the co-flotation yields obtained after 20 min of operation with solutions at pH 10.5 and 11, obtained by addition of sodium hydroxide (filled circles on the graphs). These yields are all higher than those obtained when the pH was adjusted with ammonia (remaining data on the graphs), presumably because formation of the amine complexes will inhibit co-precipitation of the hydroxides. Further, alkalization with sodium hydroxide makes the rate of the flotation separation much slower than that when ammonia is used.
Fig. 1. Influence of salinity on the co-flotation of Cd(II) co-precipitated with iron(III) hydroxide and octadecylamine as collector.
Fig. 2. Influence of the pH on the co-flotation of Cu(II), Cd(II) and Co(II).

Because, in general, the foam layer formed is not very stable, any increase in the time needed for the flotation necessitates periodic additions of surfactant to maintain the consistency of the froth layers. This is a practical inconvenience, so the use of ammonia for alkalization is generally to be preferred. However, as shown below (collector/co-precipitant ratio), though the resulting increase in surfactant concentration increases the process rate, it does not result in better yields, suggesting that the observed differences in flotation kinetics and co-flotation yield are directly related to the type of alkalization reagent and to the surface characteristics of the precipitate, respectively.

It was also observed that octadecylamine does not cause flotation of the magnesium hydroxide precipitated when the sea-water samples are made fairly strongly alkaline. This precipitate does not decrease the co-flotation yields, but in practice diminishes the final recovery of the sublates by plugging the pores of the sintered-glass plate of the column, thereby practically nullifying one of the main advantages of co-flotation over co-precipitation for isolation and preconcentration of trace ions. Addition of 1 ml of concentrated ammonia solution to a 500-ml sea-water sample that has been acidified to pH < 2 for preservation[18,19] will raise the pH to 9.5–9.8, which guarantees that no magnesium hydroxide will be precipitated.

Influence of the flotation-gas flow-rate. Figures 3 and 4 show that the gas flow-rate does not play a significant role in the process, and it has also been
Fig. 3. Influence of the air flow-rate on the co-flotation yield [—●— Co(II); —■— Cu(II); —▲— Cd(II)].

found not to influence appreciably the amount and consistency of the froth layer. A flow-rate of 150 ml/min was systematically established as optimal.

Collector/co-precipitant ratio. The influence of the octadecylamine/iron(III) hydroxide molar concentration ratio (ϕ) on the process yield and kinetics is represented in Figs. 5 and 6, which show that the process yield is practically independent of ϕ but the rate increases with increasing ϕ to become constant at $\phi \geqslant 2.4$. It should be noted that the ϕ values shown refer to the starting conditions, and any octadecylamine periodically added to improve the stability of the foam layer may give rise to much greater ϕ values if the process is very prolonged.
Fig. 4. Influence of the air flow-rate on the Co(II) co-flotation kinetics.
Fig. 5. Influence of the collector/co-precipitant ratio (ϕ) on the co-flotation yield [—●— Co(II); —■— Cu(II); —▲— Cd(II)].
Fig. 7. Influence of the induction time on the co-flotation yield [—●— Co(II); —■— Cu(II); —▲— Cd(II)].

Induction time. Figure 7 shows that the process yield is apparently very little influenced by this parameter despite the fact that the yield tends to decrease with increasing induction time. Figure 8, however, shows a clearly negative effect of the induction time on the kinetics (similar results were obtained for copper and cobalt). Hence zero induction time is optimal, which means that the usual stirring of the precipitate in contact with the surfactant must be omitted, and this is a further advantage of octadecylamine over other surfactants. Further, Fig. 8 clearly shows a decrease in the process yield (down to about 40%) for induction time > 0, which is compensated for by the periodical additions of octadecylamine for foam stabilization. In fact, the data of Fig. 7, which are related to the yields obtained after 15 min of co-flotation, do not properly depict the influence of the induction time, thus showing the importance of simultaneously testing both the yield and the kinetics to achieve optimization of the co-flotation process.

Use of auxiliary agents for foam formation

As mentioned repeatedly above, the foam layer formed by octadecylamine is not very stable, and the foam initially formed coalesces after 4–5 min. The periodical addition of the surfactant to maintain the foam gives satisfactory separation yields but increases the surfactant consumption and requires continuous attention by the operator. An occasional consequence of coalescence of the foam layer is adherence of the sublate flocs to the column walls, resulting in lower recovery for analysis. To reduce such effects the addition of small amounts of non-ionic surfactants (Triton X-100, *etc.*) has been proposed,[20] but anionic and cationic surfactants can also be used. We have tried the addition of sodium lauryl sulphate (NaLS) and hexadecyltrimethylammonium bromide (HTAB), on the basis of our earlier work,[13,16] which indicated that under the salinity and pH conditions considered here they do not cause flotation of the iron(III) hydroxide but simply improve the stability of the foam layer. They can be added during the flotation process or along with the main surfactant at the start (making it unnecessary to make further additions of it). The greater consistency thus imparted to the froth layer gives better support to the sublate, and formation of a clean and compact foam layer, thus avoiding the floc re-entry into the mother solution that can occur on coalescence of the foam formed by the principal surfactant.

Fig. 8. Influence of the induction time on the co-flotation yield [—●— Co(II); —■— Cu(II); —▲— Cd(II)].

Recovery and dissolution of the sublates

Octadecylamine dissolves in most hot solvents which are suitable for AAS work,[21] but is insoluble in hot or cold water. The use of hot organic solvents produces practical problems in the recovery of the sublates adhering to the column wall, however, since the solvent rapidly becomes cold on the column wall.

We therefore sought a mixed solvent which would dissolve the sublates in the cold. From the data in Table 2 it can be seen that ethanol-containing binary mixtures are suitable. In principle the MIBK–ethanol mixture would be selected on the basis of the excellent suitability of MIBK for AAS work, but in any case the solvent mixtures have to contain hydrochloric acid to dissolve the sublates.

However, when a 1:2:2 v/v 12M hydrochloric acid–MIBK–ethanol mixture was used in analysis of sea-water samples or synthetic solutions of 3.5% salinity, a large insoluble residue was obtained. AAS analysis of the solution phases showed, however, that practically all the Fe(III) collector and the co-precipitated metals were totally dissolved, and the insoluble residue was found to be mostly sodium chloride. The proportion of water in the solvent

mixture was therefore increased in order to dissolve the residue completely, but without bringing about phase separation. A similar ternary mixture containing 6M hydrochloric acid was therefore used for all subsequent work, and this concentration of acid is sufficient[21] to prevent phase separation. This mixture dissolves the sublate in the cold, and the solution remains stable for about 1 hr, after which small amounts of precipitate may appear. However, the mixture influences the AAS measurements, making it mandatory to optimize the operating conditions. The recommended parameters are given in Table 1; the set conditions increase the sensitivity of the deter-

minations by a factor of about 3 for the elements investigated.

Analysis of real and synthetic sea-water samples

To compare the performance of the proposed method with that of the common APDC/MIBK preconcentration method, as recommended by Rodier,[22] a synthetic sea-water sample[23] was prepared with high-purity reagents, and a 40-μg/l. concentration of each of the elements investigated. The results are given in Table 3 and show our proposed method is satisfactory.

Table 4 shows results for real sea-water samples, some of which have been spiked with the elements investigated. The recovery and precision are both satisfactory. The results obtained by the APDC/MIBK preconcentration method are also given for comparison. It should be noted that the results obtained for the unspiked samples are not directly comparable, since the samples were taken on different dates, though from the same site.

CHEMILUMINESCENT REACTION OF LUCIGENIN WITH REDUCING SUGARS

Robert L. Veazey,† Howard Nekimken and Timothy A. Nieman*

Department of Chemistry, University of Illinois, 1209 W. California St., Urbana, Illinois 61801, U.S.A.

Summary—The chemiluminescent reaction, in alkaline solution, of lucigenin with the reducing sugars sorbose, fructose, lactose, glucose, xylose, galactose, arabinose and mannose has been studied. There is a linear relationship (correlation coefficient = 0.996) between the emission intensity and the second-order rate constant for the alkaline oxidation of these sugars. The emission intensity is linearly related to the sugar concentration; at high sugar concentrations (>5 mM) it is independent of the lucigenin concentration, but at low concentrations (<0.05 mM) is linearly related to the lucigenin concentration. These facts support the view that the rate-limiting step is the tautomerization of the sugars to the 1,2-enediol form; the enediol then undergoes reaction with lucigenin.

The use of chemiluminescence in solution to determine clinically-important organic species is becoming common. One such reaction is that of lucigenin (N,N'-dimethyl-9,9'-biacridinium dinitrate) in aqueous solution. We have reported on the use of lucigenin chemiluminescence for stopped-flow determination of reductants, such as glucose, uric acid, ascorbic acid, creatinine, glucuronic acid and glutathione,[1] for HPLC detection in ascorbic acid determinations[2] and for determination of the mucopolysaccharide heparin.[3]

Chemiluminescent reactions of lucigenin with hydrogen peroxide and with reducing agents were first reported by Gleu and Petsch.[4] Since that time the reaction has received considerable mechanistic study,[5-7] but lucigenin probably remains the least understood of all classic organic chemiluminescent agents. Maskiewicz *et al.*[8] have recently studied the kinetics of several reactions of lucigenin; for reactions with hydrogen peroxide, they concluded that the rate-determining step is the conversion of lucigenin(OOH) to lucigenin(OO⁻); for reactions with hydroxide ion and other nucleophiles, they concluded that the rate-determining steps involve the production of N-methylacridone from lucigenin(OH) or lucigenin (OH)$_2$. We report results which deal with the reaction of lucigenin and reducing sugars, and from these results, the rate-limiting step in the reaction can be identified.

EXPERIMENTAL

Reagents

The concentrations used are those previously shown to yield good signal-to-noise ratios for chemiluminescence detection.[1] All solutions were prepared with demineralized, glass-distilled water. Lucigenin (Aldrich Chemical Co.) was used without further purification. Potassium hydroxide stock solution was prepared from an "Acculute" solution (Anachemia Chemicals, Ltd.). Sugars were obtained as follows: arabinose and xylose (Sigma), fructose (Pfanstiehl Lab.), galactose (Nutritional Biochemicals), glucose and lactose (Mallinckrodt), mannose (Baker), sorbose (Aldrich).

Apparatus

All measurements were made with a home-made inert stopped-flow instrument, described previously.[1] This consists of three glass-barrelled syringes driven by an air piston. The syringes deliver solution through check valves and a mixer to the observation cell. The solutions come into contact only with surfaces of glass, Teflon, Kel-F and sapphire. The observation cell is a modification of one described previously.[9] The cell cavity and inlet and exit ports are machined in a Teflon block; this piece is pressure-sealed against a glass window. The cell has a volume of 100 μl and exposes a 2.0-cm^2 surface area to the detector. The photomultiplier detector (RCA 1P28) was approximately 4 cm from the cell window; no wavelength discrimination was used. A Pacific Instruments model 126 photometer was used to amplify the photocurrent and give an output signal to a strip-chart recorder.

Procedure

The stopped-flow syringes were filled with the solutions of lucigenin, base and reductant, and delivered three portions of each solution to rinse the mixer and cell twice, and a fourth portion for the experiment itself. Data collection began with completion of the last delivery, and continued for 75 sec. An auxiliary valve to the flow cell was then opened and a peristaltic pump activated to flush the cell and mixer with approximately 4 ml of nitric acid (1 + 1). This acid rinse was necessary to remove reaction products (such as N-methylacridone) which were insoluble in the aqueous alkaline reaction mixture. This measurement routine was then repeated three times, to give a total of four measurements with each sample. Sample solutions were alternated with blank solutions. The analytical signal was the average of four sample measurements minus the average of four blank measurements. All intensities reported are given in arbitrary units and are the maximum intensity observed (relative to the blank) within the 75-sec observation period.

The data-acquisition time was chosen by consideration of the emission intensity *vs.* time curve. The emission intensity reaches approximately 90% of its peak value after 1 min, but continues to increase very slowly, not reaching the peak for 10–15 min. The chosen observation period (75 sec) gives a

reasonable compromise between experiment time and signal intensity. The maximum intensity observed within the 75-sec period is about 93% of the peak intensity.

RESULTS

Table 1 lists the emission intensities observed for the reaction of 0.6mM solutions of each sugar with 1.0mM lucigenin at three different concentrations of potassium hydroxide. The intensities are normalized so that the largest signal (sorbose with 1M alkali) has a value of 100. A wide range of relative emission intensities is observed with these reductants. MacDonald et al. have noted a strong correlation between emission intensity and metal-ion reduction potential for lophine chemiluminescence in the presence of trace metal ions.[10] With the lucigenin–sugar system there is apparently no such relationship; regression analysis of emission intensity as a function of reduction potential[11,12] yields a correlation coefficient of only 0.11.

In order to identify which property of these sugars is important in determining relative intensity, the rates of oxidation for reducing sugars have been studied. Nath and Singh studied the oxidation of sugars by alkaline ferricyanide[13,14] and from the data they present we have calculated values for the second-order rate constants (k_s) for the oxidation of each sugar (Table 2). To facilitate comparison with our

observations of the chemiluminescent emission intensity (at a single constant temperature of 25°), we have normalized the rate data. Conveniently, rate data are available for glucose at several temperatures. The factor k_s/k_g is the ratio of the rate constant for a given sugar to the rate constant for glucose at the same temperature; this removes the temperature dependence of the rate data provided that the different sugars have nearly identical activation energies for alkaline oxidation. The assumption concerning activation energies is reasonable. Singh and Ghosh[15] have determined the activation energies for alkaline oxidation of arabinose, galactose, glucose and xylose as 29.2, 28.7, 27.0 and 25.8 kcal/mole, respectively, at 30°. For xylose, galactose and arabinose the value of the activation energy can be used to compute k_s at 25° instead of 30°, as in Table 2. The k_s/k_g values for these three sugars are then 0.818, 0.568 and 0.397 at 25°; they agree within 10% of the values at 30° of 0.755, 0.568 and 0.402, given in Table 2. No activation energy value is available for mannose. Judging from the mean value and the spread of the four available activation energies, it can be estimated that the k_s/k_g value for mannose is within 20% of the correct value. The rate of sugar oxidation is not dependent on the difference between the standard potentials for the reductant and the oxidant; the correlation coefficient is only 0.14 for the rate of oxidation as a function of potential difference.

It is noteworthy that there is a good correlation between emission intensity and rate of oxidation. Figure 1 shows a plot of emission intensity (from Table 1) vs. k_s/k_g (from Table 2). The emission intensities are for reaction with 1M potassium hydroxide. Similar graphs using the intensities for 0.5M and 0.1M potassium hydroxide show the same trend; the slopes are different because the intensities decrease as the concentration of potassium hydroxide decreases (Table 1). The least-squares correlation coefficients for the 1M, 0.5M and 0.1M potassium hydroxide plots are 0.998, 0.994 and 0.995, respectively. To make sure that this high degree of correlation was not an artifact of our chosen mea-
Fig. 1. Relative chemiluminescent emission intensity vs. relative oxidation rate for sugars. The solid line is the least-squares line.

surement time of 75 sec, we repeated the experiments with a measurement time of 15 sec. All the intensities were lower, but the plots showed the same trend as that in Fig. 1 and had correlation coefficients larger than 0.99.

We have also examined the dependence of the emission intensity on reagent concentration, with glucose as a representative sugar. The concentrations were varied (one at a time) over the following ranges: lucigenin (0.05–1.00mM), potassium hydroxyde (0.05–1.00M) and glucose (0.28–9.71mM). When not varied, the concentrations were held at 1.00mM for lucigenin, 1.00M for potassium hydroxide and generally 6.00mM for glucose. Least-squares analysis of plots of log emission intensity vs. log concentration yielded the following values ($\pm$ the standard deviation) for the slopes: OH^- 0.45 $\pm$ 0.04, glucose 0.91 $\pm$ 0.02. The slope for the lucigenin plot depends upon the glucose concentration. At high glucose concentrations (> 5mM) the slope is essentially zero (0.01 $\pm$ 0.02 at 6mM). The slope increases as the glucose concentration decreases. The slope was 0.92 $\pm$ 0.03 at a glucose concentration of 0.05mM while in the absence of glucose (i.e., for the background reaction between lucigenin and OH^-) the slope was 1.3 $\pm$ 0.2.

It is interesting that the intensity is independent of lucigenin concentration at high glucose concentrations. In reactions of lucigenin with hydrogen peroxide and with OH^- and other nucleophiles, the reaction rate is dependent on the first power of the lucigenin concentration. Our observation that the dependence on lucigenin concentration can vary from zero-order to first-order, depending on experimental conditions, is consistent with other observations. Totter[16] has observed that the emission intensity is independent of the lucigenin concentration for the reaction with fructose and is related to the square root of the lucigenin concentration for the reaction with hydroxylamine. With glucuronic acid, the emission intensity has been reported to be linearly related to the lucigenin concentration.[3]

The half-order dependence on OH^- concentration seemed unusual, so we examined the effect of OH^- concentration on the emission intensity in the reaction between hydrogen peroxide and lucigenin. At OH^- concentrations below 0.05M the emission intensity increases as the OH^- concentration increases. However, at above 0.05M OH^- (the region studied with the sugars) the emission intensity decreases with OH^- concentration. Therefore, the half-order dependence is probably a combination of a higher order dependence on the OH^- concentration in the lucigenin–sugar portion of the reaction and a negative order depencence in some later step of the lucigenin chemiluminescence.

DISCUSSION

For a chemiluminescent reaction, one factor controlling the observed emission intensity is the rate-determining step leading to production of excited states. Therefore observation of changes in emission intensity with changes in experimental conditions can shed light on the nature of that rate-determining step. Totter[16] suggested that the rate-determining step in the reaction between lucigenin and fructose was a slow reaction between fructose and OH^-. This hypothesis was proposed because the emission intensity was independent of the lucigenin concentration and because fructose was oxidized at the same rate (under the same conditions) by lucigenin as by ferricyanide. The results of our study support this hypothesis. In the case of the eight reducing sugars studied, the emitted light intensity is strongly correlated with the rate of alkaline oxidation of the sugar (Fig. 1), independent of the lucigenin concentration (at high sugar concentrations), linearly proportional to the sugar concentration, and proportional to the base concentration to a power of greater than one-half. Studies of the kinetics of the oxidations of reducing sugars by alkaline ferricyanide[13,14] and by alkaline cupric ion[15,17] have shown these reactions to be first-order with respect to the reducing sugar and hydroxyl ion and zero-order with respect to the oxidant. The rate-determining step in the chemiluminescent reaction between lucigenin and reducing sugars is thus probably the same as that in the alkaline oxidation of those sugars by ferricyanide or copper(II).

The alkaline oxidation rates of reducing sugars are thought to be dependent on the rate of formation of their 1,2-enediol tautomeric forms in the Lobry de Bruyn–Alberda van Eckenstein rearrangement:[13,14,18]

Glucose   Mannose

Fructose
The 1,2-enediol is a stronger reducing agent than the parent sugar. Apparently, the sugars (in their aldo or keto forms) are not sufficiently strong reductants to react with lucigenin. Hence the rate-limiting step in the chemiluminescent reaction between lucigenin and reducing sugars is the production of the 1,2-enediol tautomer. This intermediate enediol is oxidized by lucigenin in a subsequent series of faster steps so that the emission intensity (and therefore the overall reaction rate) is independent of the lucigenin concentration.

The results of our study suggest that relative oxidation for other reducing sugars might be conveniently determined by comparison of lucigenin chemiluminescent emission intensities for sugars of known oxidation rate, and the results used in planning the analytical procedures.

STANDARD-ADDITION DETERMINATION OF NITROGEN IN COAL WITH AN AMMONIA-SENSITIVE ELECTRODE*

T. D. Rice, V. Sweeney, R. Semitekolos and G. J. Rhyder
New South Wales Department of Mineral Resources, Chemical Laboratory Branch, P.O. Box 76,
Lidcombe, 2141, Australia

Summary—After semimicro Kjeldahl digestion of the coal sample with a K_2SO_4–V_2O_5–Se catalyst and sulphuric acid, the digest is cooled, diluted with water, neutralized and then made alkaline with NaOH/EDTA solution. The ammonia thus formed is determined by measuring the potential of a properly conditioned ammonia-sensitive electrode containing an appropriate filling solution; a gravimetric standard-addition technique is used. Known additions of 1–2 μg of N per g to blank solutions enables all measurements of potential to be made in the linear region of the electrode-response curve. The electrode measurement procedure gives blank-corrected recoveries of between 99.0 and 101.0% for synthetic sample solutions. Results obtained for nitrogen in reference coal samples by the electrode procedure have been found to agree well with those obtained by other methods.

Doolan and Belcher[1] have shown that the ammonia-sensitive electrode provides a valid alternative to standard ammonia-distillation procedures for determining nitrogen in coal. The following modifications, described in this paper, have streamlined the procedure of Doolan and Belcher.[1]

1. Use of specially designed tubes and a heated aluminium block enables up to 40 Kjeldahl digestions to be performed concurrently.

2. Use of samples ground to pass a 212-μm sieve instead of a 76-μm sieve.

3. Use of 10M NaOH/0.02M EDTA solution instead of 10M NaOH solution minimizes the possibility of the electrode membrane being clogged by precipitate.

4. Exact weighing of the test solution is not necessary–any weight between 230 and 280 g can be used without significant effect on the result.

5. Electrode measurements are done by gravimetric single standard-addition,[2] after appropriate conditioning of the electrode, instead of by direct comparison with standards (which requires that all measurements be done at the same temperature). The electrode-response slope is assumed to have linear temperature-dependence, and is conveniently obtained by replicate double standard-addition measurements previously done on the same day. The electrode used was chosen because it has a fast response time and a long-lasting, easily replaced membrane.

EXPERIMENTAL

Reagents

Catalyst. As described by Doolan and Belcher,[1] this consists of K_2SO_4 (anhydrous), V_2O_5 and Se finely ground and mixed in 93:5:2 w/w ratio. Bradstreet[3] has also recom-

mended this catalyst. *Safety note.* Skin contact with the catalyst must be avoided. The catalyst must be handled with care so that none of it becomes airborne.

Electrode internal filling solution. A 0.01M $(NH_4)_2SO_4$/0.50M $NaNO_3$ solution plus (for easy visibility in the electrode) 0.002 g of Rhodamine B per 200 ml.

Nitrogen standard solution No. 1 (5000 μg of N per g). Weigh, to the nearest 0.01 g, 56.6–56.7 g of analytical grade ammonium sulphate (of guaranteed or known purity, and previously dried for 2 hr at 105°) by difference into a 1000-ml beaker. Dissolve it in 600 ml of water and transfer quantitatively (using less than 200 ml of water) to a dry 2.5-litre polyethylene bottle previously weighed. Dissolve 158 g of low nitrogen-content sodium sulphate in 1200 ml of water. Transfer to the bottle containing the ammonium sulphate solution, and dilute with water to give a weight of solution 42.40 times the weight of ammonium sulphate taken. Seal the bottle and mix the contents well. Transfer about 180 ml of this solution to a 250-ml polyethylene dispensing bottle.[4]

Nitrogen standard solution No. 2 (500.0 μg of N per g). Weigh about 18 g of standard solution No. 1 (to 10 mg) into a 250-ml polyethylene dispensing bottle. Dilute the solution to exactly 10 times its weight with water.

Other reagents. Concentrated sulphuric acid (low nitrogen content); 0.3M sodium sulphate; 10M NaOH/0.02M EDTA solution, conveniently prepared by diluting 2 volumes of technical grade 60% sodium hydroxide solution with 1 volume of 0.06M EDTA; 2M sulphuric acid; sucrose. Use demineralized water throughout.

Apparatus

Digestion tubes. Borosilicate glass, 26 mm outside diameter, 310 mm long, with a constriction towards the top (Tecator, Sweden; No. 1000-0154). They are conveniently held in a 50-position stainless-steel stand.

Digestion apparatus. A Tecator DS-40 digestion block housed in a fume cupboard. This block can hold 40 tubes at a time; its temperature stability at 380° is ±4° and its repeatability of temperature setting is ±3°.

Polypropylene jars for diluted digests. Capacity 360 ml, with snap-on plastic lids and a line at the 250-ml mark.

Measurement lid. A snap-on lid of the type supplied with the polypropylene jars, drilled with a 19-mm diameter hole for electrode insertion and a 4-mm diameter hole for standard addition.

Ammonia electrode. HNU Model ISE-10-10-00 with

---

screw-on cap containing built-in membrane (HNU Systems, Inc., Newton, Massachusetts 02164, U.S.A.)

pH/millivolt meter. Orion Model 811 with Orion Model 91-70-02 temperature-measurement probe and Orion Model 090020 electrode holder.

Electronic top-loading balances. Sartorius 1602 MP6, for weighing subsamples; 1205 MP, for standard additions and preparation of standard solution No. 2, and 3802 MP for preparation of standard solution No. 1. The precision and accuracy should be regularly checked with reference weights.

Stirrer bars. PTFE-coated, length 45 mm.

Sampling

All samples were ground to pass a 212-μm sieve and equilibrated with the laboratory atmosphere before analysis. Moisture determinations, by loss in weight on heating 300-mg samples for 2 hr at 105°, enabled calculation of results on a dry basis.

Procedures

Solution preparation. Weigh a 100-mg sample into a dry digestion tube. In each batch of analyses include 2 control samples and 2 blanks (comprising either 100 mg of sucrose plus catalyst and acid or merely catalyst and acid). Add 2.0 g of catalyst down the inner wall of the tube so that all sample particles are transferred to the bottom of the tube. Add 3 antibumping granules. Swirl to mix, 4.0 ± 0.2 ml of concentrated sulphuric acid, and swirl again. Place the tube (uncovered) in the digester block, already heated to 380 ± 5°. Digest for 60 min. Remove the tube and let it cool for 10 min, then add 25 ml of water and carefully swirl it. Pour the solution down a glass stirring rod into a polypropylene jar, rinsing in with three 20-ml portions of water. Add a further 130 ml of water to the jar. With continuous manual stirring, slowly add ~11 ml of NaOH/EDTA solution until the solution changes from blue to green (indicating a pH of 3–7). At this pH ammonia cannot be lost from the solution. If the solution turns dark blue or brown, indicating that the pH may be above 7, add 2M sulphuric acid dropwise to restore the green colour.

Add water until the solution reaches the 250-ml mark on the jar, and weighs 230–280 g. Seal the jar and let the contents cool to ambient temperature ±0.5° before electrode measurement.

Electrode measurement. The electrode is stored with its cap immersed in a synthetic sample solution consisting of 240 ml of 0.3M sodium sulphate, 1.5 g of nitrogen standard solution No. 2 and 5 ml of NaOH/EDTA solution kept in a polypropylene jar containing a stirrer bar and sealed with a measurement lid.

The standard-addition technique is essentially the same as that recently described for fluoride determination.[2] The electrode-response slope is determined by double standard-addition measurements on the first 6 solutions of a batch. The average of these slopes is then used for evaluating single standard-addition measurements on the remaining solutions in the batch and obtaining single standard-addition results for the first 6 solutions. Figure 1 shows a flow diagram describing the electrode conditioning and measurement procedure. With the electrode used in our laboratory, the potential reached equilibrium within 40–60 sec and then increased by not more than 0.1 mV in the ensuing 30 sec. This slight upward drift was probably due to slight loss of ammonia from the solution and slight migration of water vapour through the electrode membrane from the sample solution. *Note*: if the sample contains less than about 0.2–0.3% nitrogen, add a known weight M (about 0.5–1.0 g), of nitrogen standard solution No. 2 after the initial insertion of the electrode, to bring the electrode signal into the linear region of the response graph; do the same for the blank measurements (blanks are run by applying the whole procedure without sample present).

Calculations. The iterative procedure for calculating electrode slope by double standard-addition has already been described.[2] Table 1 gives the formulae for the calculations, which can conveniently be done with a programmed calculator. Details of a Texas Instruments TI-59 program for these calculations are available on request.

Care of electrode. When the electrode is in regular use, replace the internal filling solution every 14 days and store the electrode with its cap immersed in synthetic sample solution as described above. Add a few drops of nitrogen standard solution No. 1 to this storage solution at ~7-day intervals to prevent excessive lowering of its ammonia concentration with time; prepare fresh storage solution after 3 months. If the electrode will not be used for several months, drain the filling solution, rinse the electrode body and cap with water, and store the disassembled unit dry.

Experience in this laboratory indicates that a single membrane and cap can be used for at least six months before needing replacement.

RESULTS AND DISCUSSION

Importance of proper conditioning of electrode

The aim of the electrode conditioning procedure (Fig. 1) is to eliminate memory effects of the type described by Evans and Partridge,[5] and Umezawa et al.[6] Its reliability has been repeatedly checked by

---

Remove electrode from its stirred conditioning solution and rinse with water

↓

Place stirrer bar in solution to be measured and put measurement lid on jar; stir magnetically so that a vortex just forms, and add 5.0 ± 0.2 ml of NaOH/EDTA

↓

Insert electrode, withdraw it after about 60 sec, rinse it with water and insert it again; record to the nearest 0.1 mV the most negative potential, E_1: for blanks or if the nitrogen content is below 0.2%, add M_1 = 0.5 – 1 g of nitrogen std. soln. 2 after the initial insertion of the electrode (so that E_1 is in the linear region of the electrode response)

↓

Add M_2 = 0.8 – 1.5 g of nitrogen std. soln. 1; record the most negative potential, E_2, which should be at least 30 mV less than E_1

↓

For double standard addition only: add M_3 = 2.5 – 5 g of nitrogen std. soln. 1; record the most negative potential, E_3, which should be at least 30 mV less than E_2

↓

Transfer electrode to stirred conditioning solution; record measurement solution temperature, to nearest 0.2°; switch off stirrer if there are no more solutions to measure

Fig. 1. Flow-sheet for potentiometric measurement of nitrogen content by gravimetric standard addition.

Table 1. Formulae required for calculation with a nominal sample solution mass of 250 g

Quantity	Formula
Solution concentration,	$C_x = \dfrac{5000M_2/(250 + M_1 + M_2)}{\text{antilog}\,\{(E_1 - E_2)298/ST\} - \{(250 + M_1)/(250 + M_1 + M_2)\}}$
Electrode response slope at 25°,	$S = \left(\dfrac{E_2 - E_3}{\log \dfrac{\{C_x(250 + M_1) + 5000(M_2 + M_3)\}(250 + M_1 + M_2)}{\{C_x(250 + M_1) + 5000M_2\}(250 + M_1 + M_2 + M_3)}}\right)\dfrac{298}{T}$
N in sample, %	$(\{(250 + M_1)C_x - 500M_1\}10^{-4}/M_c) - \text{blank}$

Notes. 1. The first formula is the "single standard-addition formula." For the electrode used in this laboratory, S is initially taken to be 57.9 mV per decade at 25°C.

2. The symbols are defined in Fig. 1, with the exception of: (i) T, the absolute temperature of measurement and (ii) M_c, the weight of sample (g).

3. The blank is the mean blank value for the batch, expressed as % N, and calculated from the formula for the nitrogen content, for a nominal 0.1000-g nitrogen-free sample.

analysis of a synthetic sample solution comprising 240–245 ml of 0.3M sodium sulphate and about 3 g of nitrogen standard solution No. 2 (weighed to 2 mg). The blank-corrected nitrogen recovery has always been in the range 99.0–101.0%.

A simpler conditioning procedure consists of placing the electrode in stirred conditioning solution for at least 60 sec and then rinsing it with water, between samples; *i.e.*, the conditioning in the solution to be measured (third step in Fig. 1) is omitted. However, this procedure gives blank-corrected nitrogen recoveries in the range 99.5–104.0% and so is inferior to the full conditioning procedure. This bias towards high results is consistent with the fact that in the full conditioning procedure the E_1 value obtained before removal of the electrode, rinsing with water and re-insertion can be as much as 0.6 mV more negative than the value recorded after the rinsing and re-insertion. The second value is the more reliable.

Variability of the blank

When the simpler conditioning procedure was used, individual blank values for a batch of analyses typically ranged between 0.02 and 0.11% nitrogen in spite of every precaution being taken to avoid contamination of solutions by airborne ammonia. The full conditioning procedure gave lower blanks with much less variation, typically $0.02 \pm 0.01\%$ nitrogen.

Unimportance of exact solution mass

It can readily be shown that replacement of the number 250 (the nominal number of grams of measurement solution) in the formulae in Table 1 by 220 or 280 causes a change of less than 0.1 mV/decade in the calculated response slope (for 25°) and a change in the blank-corrected result not exceeding 0.002% nitrogen.

Single vs. double standard-addition

Many analyses of synthetic sample solutions in our laboratory have shown that single standard-addition, with the response slope taken as the mean of 6 replicate slope values obtained by double standard-

addition on the same day, is at least as reliable as the lengthier double standard-addition. A slope value differing from the mean by 0.5–0.7 mV per decade has occasionally been obtained by double standard-addition measurement of a synthetic sample solution; the single standard-addition recovery in such a case has always been found to be nearer to 100.0% than the double standard-addition recovery was.

Constancy of electrode slope

The means of 12 sets of 6 replicate response slope determinations at 25° during a 6-week period by double standard-addition varied randomly with time between 57.7_1 and 58.0_4 mV per decade. The mean range of the individual sets of 6 slope values was 0.52 mV per decade. The overall mean slope and 99% confidence limit was $57.9_0 \pm 0.1_0$ mV per decade. Rather than assuming from this result that the slope remains constant, it is probably sounder to assume that slight day-to-day variations of slope occur, and that the slope should be determined during each batch of measurements.

For a single standard-addition measurement with $E_1 - E_2 = 20$, 30 and 40 mV, an error of ± 0.10 mV per decade in the response slope can be shown to cause a relative error in the concentration measurement of ± 0.25, 0.29 and 0.34% respectively; an error of ± 0.1 mV in $E_1 - E_2$ will increase these relative errors to ± 0.76, 0.63 and 0.60% respectively.[2]

Results for reference coal samples

Single 100-mg samples of five reference coals were included in batches of nitrogen analyses done on different days by the procedure described. Table 2 shows that the results agree well with those obtained in other laboratories by other methods.

Sample throughput

An analyst using this procedure can readily determine nitrogen in 18 samples plus 2 control samples and 2 blanks in a 7-hr day.

⧣Mean of results from 9 laboratories, 8 of which used standard methods.[10]

¶ISO semimicro Kjeldahl method.[9] Laboratory: Australian Coal Industry Research Laboratories Ltd., North Ryde 2113, Australia.

SARM 18, 19 and 20 are South African coal samples obtained from E. J. Ring, Council for Mineral Technology, Private Bag X3015, Randburg 2125, South Africa.

Conclusion

The procedure described provides a simple and reliable alternative to current standard procedures for determination of nitrogen in coal which involve distillation and titration of ammonia, and should be readily usable for determination of nitrogen in Kjeldahl digests of other materials.

A COMPARISON OF CATIONIC POLYMERIZATION AND ESTERIFICATION FOR END-POINT DETECTION IN THE CATALYTIC THERMOMETRIC TITRATION OF ORGANIC BASES

Edward J. Greenhow and Pilar Viñas*

Department of Chemistry, Chelsea College, University of London, Manresa Road, London, England

Summary—A systematic comparison has been made of two indicator systems for the non-aqueous catalytic thermometric titration of strong and weak organic bases. The indicator reagents, α-methylstyrene and mixtures of acetic anhydride and hydroxy compounds, are shown to give results (for 14 representative bases) which do not differ significantly in coefficient of variation or titration error. Calibration graphs for all the samples, in the range 0.01–0.1 meq, are linear, with correlation coefficients of 0.995 or better. Aniline, benzylamine, n-butylamine, morpholine, pyrrole, L-dopa, α-methyl-L-dopa, DL-α-alanine, DL-leucine and L-cysteine cannot be determined when acetic anhydride is present in the sample solution, but some primary and second amines can. This is explained in terms of rates of acetylation of the amino groups.

Various indicator reagents have been used in the non-aqueous catalytic thermometric titration of organic bases.[1-3] Vajgand *et al.*[1] employed a mixture of acetic anhydride and water, the indicator reaction being the exothermic hydration of the anhydride, catalysed by the first excess of the titrant, perchloric acid, when the organic base had been neutralized. Later, Greenhow[2] showed that very weak bases could be determined if the co-reagent with the acetic anhydride was an alcohol or a phenol instead of water. A completely different type of thermometric indicator is α-methylstyrene, which undergoes exothermic cationic polymerization when the perchloric acid titrant appears in excess in the sample solution.[3]

In the present work the esterification[2] and cationic polymerization[3] systems are compared for the determination of representative strong and weak primary, secondary and tertiary amines and an amide, thiourea, in terms of precision of replicate titrations, titration error and linearity of calibration graphs relating titrant volume to sample size. In addition, the limitations of the two end-point methods for the determination of primary and secondary amines have been assessed.

Titrations were done on sample solutions in which acetic anhydride had been added to the α-methylstyrene indicator, in order to compare the effect of acetic anhydride on the determination of primary and second amines by both end-point procedures, *i.e.*, cationic polymerization and esterification. Acetic anhydride is known to have a beneficial effect on the sharpness of the end-point inflection when α-methylstyrene is the indicator, if

the sample solution contains trace amounts of water, which normally inhibit or retard the cationic polymerization.

EXPERIMENTAL

Reagents

Hydroquinone, quinhydrone, α-methylstyrene, 4-hydroxy-4-methylpentan-2-one, acetic acid, acetic anhydride, 98–100% formic acid and 71–73% perchloric acid were analytical-reagent grade. Acetic acid and formic acid were dried over a molecular sieve, type 4A, before use.

Amines, amino-acids, catecholamines and thiourea were of laboratory-reagent grade. The 0.1M perchloric acid in acetic acid was prepared by the method of Belcher *et al.*[4] Solutions were standardized against solutions of analytical-grade potassium hydrogen phthalate in dry acetic acid.

Apparatus

Details of the automatic titration apparatus, in which the titrant is introduced by means of a motor-driven micrometer syringe and the temperature is measured by means of a thermistor and recorded on a potentiometric chart-recorder, are given elsewhere.[5] The titration vessel was a Dewar beaker (14 ml) and solutions were stirred with a magnetic stirrer.

Procedure

To 0.01–0.1 meq samples of the base dissolved in 3 ml of acetic acid, or in 2.5 ml of acetic acid + 0.5 ml of formic acid in the case of the more difficultly soluble amino-acids and catecholamines, in the Dewar beaker, was added the appropriate amount of indicator solution, either (a), 0.5 ml of α-methylstyrene dissolved in 4 ml of acetic acid or 4 ml of acetic acid, as desired, or (b), 4 ml of acetic anhydride + 0.5 ml of 4-hydroxy-4-methylpentan-2-one or 4 meq of hydroquinone or quinhydrone. The titrant was added at a rate of about 0.2 ml/min, and the chart recorder set for 400 mV full-scale deflection. The end-point was measured on the titration graph at the point where the tangent to the main heat rise left the curve at the lower temperature end (see Fig. 1a), as suggested by Vaughan and Swithenbank to allow for the "overlap" of the determinative and indicator reactions in the thermometric titration of very weak acids, with acetone as indicator,[6] except for titrations

*Present address: Department of Analytical Chemistry, Faculty of Sciences, University of Murcia, Murcia, Spain.

of primary amines in the absence of acetic anhydride (the true titration value then corresponded more closely to the point obtained as shown in Fig. 1f). It appears that when a mixture of acetic anhydride and α-methylstyrene is the indicator reagent, the overlap effect is dominant, but in the absence of acetic anhydride this is not so.

RESULTS AND DISCUSSION

Titration curves obtained for the primary, secondary and tertiary amines with α-methylstyrene, and mixtures of acetic anhydride with 4-hydroxy-4-methylpentan-2-one, hydroquinone and quinhydrone as indicator reagents are shown in Figs. 1–3.

It can be seen in Figs. 1–3 that the end-point inflections are sharp when strong bases, or their hydrochlorides, are titrated, but are more rounded in the titrations of weak bases such as thiourea, pyrrole and caffeine. Figure 3 shows that the sharpness of the end-point inflections is similar, irrespective of the nature of the oxygen grouping(s) of the indicator reagent.

When acetic anhydride was present in the sample solution, some primary amines could not be determined quantitatively; these included n-butylamine, benzylamine, aniline and its hydrochloride, representative α-amino-acids (DL-α-alanine, DL-leucine and L-cysteine) and L-dopa and α-methyl-L-dopa. The secondary amines pyrrole and morpholine also could not be determined quantitatively, but it is interesting that diethylamine, pyrrolidine and adrenaline tartrate

could be determined, in the presence of acetic anhydride. The effect of allowing morpholine and diethylamine to remain in contact with acetic anhydride in the sample solution for various periods of time was examined, and it was found that the rate of acetylation of the sample, as measured by the reduction in the titration value as this delay time was increased, was much faster for morpholine than for diethylamine, so that while the latter could be determined quantitatively under normal titration conditions, i.e., titration times of about 5 min, the former could not. As expected, all the tertiary amines can be determined quantitatively in the presence of acetic anhydride.

As noted previously,[4] the hydrochlorides of several amines and the hydrogen tartrate of adrenaline can be determined by the catalytic thermometric method without addition of mercury(II) acetate to the sample solution, though this is a requirement when visual indicators are used in the non-aqueous titration of amine hydrochlorides with perchloric acid.

Precision and accuracy

In Tables 1 and 2, values for the precision of three replicate determinations of samples that can be titrated quantitatively are shown as the coefficients of variation (CV; relative standard deviation). In addition, the average relative errors (E) are quoted, calculated on the assumption that the samples are 100% pure (which, of course, is not in fact the case).
Fig. 1. Catalytic thermometric titration of primary amines with 0.1M perchloric acid. Amine (mg): a/a′, dopamine·HCl 18.94; b/b′, DL-noradrenaline·HCl 20.91; c/c′, ethylamine·HCl 8.21; d/d′, tris buffer 12.05; e/e′, thiourea 7.87; f, aniline 9.83; g, aniline·HCl 12.98; h, benzylamine 11.14. Table 2. Results for precision and "accuracy" in titrations of amines, with quinhydrone and hydroquinone as co-reagents with acetic anhydride in the thermometric indicator

Compound	Sample weight, mg	Quinhydrone			Hydroquinone		
		Mean titre,* meq	CV,%†	E,§%	Mean titre,* meq	CV,%†	E,§%
Diazepam	29.34	0.1028	0.5	−0.4	0.1022	0.9	−1.0
Caffeine	19.68	0.1006	0.6	−0.7	0.1004	0.9	−0.9
Pyridine	8.56	0.1073	0.6	−0.8	0.1066	0.8	−1.5

* See footnotes to Table 1.

Simple comparison tests (F and t) applied to the results show that there is no significant difference, at the 5% probability level, between the CV and mean titration values for individual compounds determined by the two methods, the averages of the CV values for all the compounds, and the variances of the E values for each indicator system. For the results in Table 2, there is again no statistical evidence to show that the average precisions etc. differ, or that they differ from those in Table 1.

The results obtained show that in terms of precision and applicability to titration of very weak bases, there is nothing to choose between the two indicator systems considered. However, an important difference is that the α-methylstyrene indicator can be used in the absence of acetic anhydride, provided that the solvents are dried efficiently, e.g., with a molecular sieve. This means that primary and secondary amines that are readily acetylated can be determined quantitatively by use of this polymerization indicator,

whereas they cannot be determined by using the acetic anhydride/esterification indicator system.

Graphs of titration volume vs. sample size over the range 0.01–0.1 meq for the bases titrated all showed a good linear correlation (6 points, coefficients better than 0.995).

Résumé—Plusieurs molécules polyphénoliques appartenant à la classe des flavonols et ayant un intérêt thérapeutique incontestable grâce á leurs propriétés vasculaires ont été étudiées. Elles dérivent toutes du quercétol, qui est un *o*-diphénol. L'oxydation électrochimique de ces molécules a été envisagée en utilisant des électrodes solides tournantes. Le choix du solvant et du pH est discuté. Les résultats obtenus en polarographie à courant continu et à impulsions sont présentés. Une relation a été établie entre la structure et le comportement électrochimique. L'application au contrôle des médicaments est envisagée; la technique représente à la fois un moyen d'identification, un critère de pureté et peut être appliquée sur le plan quantitatif. Il y a en effet une bonne linéarité de réponse de 5×10^{-6} à $10^{-4}M$, ce qui représente une sensibilité largement suffisante pour le dosage dans les formes pharmaceutiques.

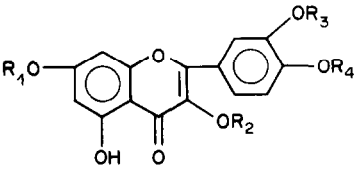
Plusieurs molécules polyphénoliques appartenant à la classe des flavonols ont un intérêt thérapeutique incontestable grâce à leurs propriétés vasculaires. Ces molécules sont prescrites en effet dans tous les états pathologiques se traduisant par une fragilité vasculaire, car elles renforcent la résistance des capillaires et diminuent leur perméabilité. Elles sont classées dans la série des molécules à activitié vitaminique P. Dans cette série figurent la rutine (flavonol naturel) et ses dérivés hémisynthétiques. Leur structure polyphénolique leur confère une facilité d'oxydation, exploitée d'ailleurs pour leur détermination quantitative par voie chimique.

Nous avons essayé de réaliser une oxydation quantitative de ces flavonols par voie électrochimique dans le but d'une part d'étudier la relation entre structure et comportement électrochimique, et d'autre part, d'appliquer la polarographie de ces molécules à leur contrôle dans les formes pharmaceutiques.

Toutes les molécules étudiées sont des flavonols, dont la structure de base est le quercétol, diversement substitué dans le cas des dérivés:
Si l'hydroxyle en 5 est toujours libre, l'hydroxyle en 3 est lié aux sucres dans les hétérosides et les hydroxyles en 7, 3′ et 4′ sont éventuellement sous forme d'étheroxydes. Les dérivés étudiés sont présentés dans le Tableau 1.

Plusieurs des dérivés présentés sont des *o*-diphénols qui ont été traités par différents agents oxydants comme le nitrite de sodium ou le molybdate de sodium, produisant en milieu éthanolique des dérivés d'oxydation colorés en rouge.[1] L'acide périodique peut aussi conduire à un titrage potentiométrique.[2]

Toutes ces molécules présentent également un spectre d'absorption dans l'ultra-violet du fait de leur structure polyinsaturée, de la présence d'un carbonyle et des substitutions phénoliques. L'absorption maximale se situe vers 368 nm pour les génines et vers 342 nm pour les hétérosides.[1]

La spectrofluorimétrie a également été mise à profit. Si le substituant en 5 est un hydroxyle phénolique ou un groupement méthoxylé, la molécule possède une fluorescence importante, mais qui manque de spécificité par rapport aux dérivés flavoniques.[3]


Les méthodes chromatographiques ont été proposées pour l'identification et le dosage de la rutine et de ses dérivés, notamment la chromagraphie en phase gazeuse[4] et la chromatographie en phase liquide sous pression avec détecteur ultra-violet.[5]

Les méthodes électrochimiques ont été peu exploitées dans ce domaine. Une réduction des flavones, chalcones et flavonnes à l'électrode à goutte de mercure a été proposée par Geissman.[6,7] Davideck propose la détermination polarographique du quercétol après sa transformation en chélate de cobalt.[8] Enfin Hamilton[9] étudie la réduction de flavonols préalablement oxydés par voie enzymatique.

La réduction directe du quercétol en milieu acide et en phase hydro-organique a été décrite par Haluk.[10] Le mécanisme réactionnel proposé est le suivant: il y aurait réduction du carbonyle 4, en alcool, accompagnée d'une réduction de l'hydroxyle

---

en 3. Dans une deuxième étape, une déshydratation intramoléculaire se produirait.
C'est l'oxydation du quercétol et de ses dérivés qui a retenu notre attention. En effet, considérant la présence d'un noyau diphénolique-1,2 dans la molécule, nous avons pensé à un rapprochement possible avec d'autres catéchols et en particulier les catécholamines étudiées par Cantin.[11]

Nous avons donc recherché si les facteurs vitaminiques P à étudier étaient oxydables par voie électrochimique grâce à certaines électrodes solides tournantes.

PARTIE EXPERIMENTALE

Solution de fond

Solvant. Son choix a été guidé par les impératifs suivants:

—assurer une bonne solubilité de la totalité des molécules étudiées,

—avoir un domaine d'électroactivité étendu vers les potentiels positifs,

—ne présenter ni un caractère trop acide (hydrolyse des hétérosides), ni un caractère trop basique (oxydation spontanée des molécules),

—présenter une constante diélectrique suffisante (> 30).

C'est le mélange diméthylformamide–eau (1:4 v/v) qui a été retenu. Il répond aux impératifs cités et permet d'obtenir une vague polarographique bien reproductible avec les composés étudiés.

Tampon. Nous avons adopté le tampon phosphate de Sörensen à pH 7 (39,2 ml de KH₂PO₄ 0,07M et 60,8 ml de Na₂HPO₄·12H₂O 0,07M) qui permet d'obtenir un courant de diffusion élevé, sans risque d'auto-oxydation (i_d croît légèrement avec le pH) (Tableau 2). Ce tampon joue également le rôle d'électrolyte support.

Appareillage

Polarographe. Polarographe Tacussel type PRG₅ pouvant fonctionner en polarographie classique à courant continu et en polarographie à impulsions d'amplitude constante.

Electrodes. Il s'agit d'un montage classique à trois électrodes.

—Electrodes de travail: plusieurs électrodes solides tournantes ont été comparées:

platine: les phénomènes d'adsorption entraînent des déformations des vagues;

carbone vitreux: les courants de diffusion sont peu importants et les pics mal définis en polarographie impulsionnelle;

électrode à disque de graphite: c'est celle qui s'est avérée la plus satisfaisante; elle est constituée d'un disque de graphite de 3 mm de diamètre (Tacussel type Ed₁); sa vitesse de rotation a été réglée à 2500 tours/min grâce à un amplificateur de type Controvit; cette vitesse de rotation permet d'obtenir un courant de diffusion à la fois intense et reproductible; la surface du graphite est repolie avant chaque détermination au moyen d'un papier abrasif imprégné de solution de fond, puis elle est rincée soigneusement à l'eau.

—Electrode de référence: c'est une électrode au calomel saturé, munie d'une allonge renfermant la solution tampon de Sörensen à pH 7.

—Electrode auxiliaire: il s'agit d'une électrode de platine plongeant directement dans la solution à polarographier.

Conditions de travail

La vitesse de déroulement des potentiels a été fixée à 2 mV/sec. La sensibilité a été choisie de telle sorte que la mesure de la hauteur de vague puisse se faire avec précision. Les valeurs retenues vont de 2,5 à 25 µA pour 25 cm de papier. En polarographie à impulsions, la valeur de l'amplitude de l'impulsion surimposée (ΔE) a été fixée à 100 mV. Pour chaque molécule, les tracés ont été réalisés après 10 min de dégazage. L'exploration est faite de −0,2 à +1,7 V contre E.C.S. La température est fixée à 25°. Les solutions mères $10^{-4}M$ de flavonols sont obtenues par dissolution dans le diméthylformamide (DMF), en ajoutant ensuite le tampon phosphate à pH 7 pour respecter la composition du

solvant: DMF–tampon pH 7 (1:4 v/v). Les dilutions ultérieures sont réalisées avec le même solvant. Ces solutions sont conservées à 4° et à l'abri de la lumière. Leur conservation ne doit pas excéder 48 hr.

RESULTATS ET DISCUSSION

Pour chaque molécule étudiée les valeurs de $E_{1/2}$, de E_p, de i_d et $W_{1/2}$ sont présentées dans le Tableau 3. Chaque chiffre représente la moyenne de cinq déterminations. Les valeurs de i_d sont celles obtenues avec une solution $5 \times 10^{-5}M$.

Relation structure–comportement électrochimique

Parmi les molécules étudiées, seule la trioxyéthylrutine n'est pas oxydable à un potentiel inférieur à 1 V contre E.C.S., dans les conditions expérimentales adoptées. C'est du reste la molécule la plus substituée puisque seul l'OH en 5 est libre.

Les autres molécules sont oxydables en donnant une vague bien définie en polarographie classique et un pic en polarographie impulsionnelle.

Quercétol, rutine et morpholinoéthylrutine possèdent la structure o-diphénolique. Ils sont très facilement oxydables au même titre que les catécholamines.[11] Ces molécules se distinguent seulement par le nombre d'hydroxyles libres sur le cycle du chromane. La facilité d'oxydation décroit avec ce nombre de fonctions hydroxylées. Le blocage de l'OH-3 par un ose déplace le $E_{1/2}$ de 110 mV et le potentiel de pic de 114 mV vers les potentiels positifs, lorsqu'on passe du quercétol à la rutine. L'influence du blocage de l'OH-7 est moins importante, le déplacement supplémentaire vers les potentiels positifs est alors de 40 mV en D.C. est de 35 mV en polarographie à impulsions (morpholinoéthylrutine).

La valeur du courant de diffusion semble proportionnelle au nombre de fonctions phénoliques libres. Il apparaît donc que la structure catéchol ne soit pas la seule en cause dans le mécanisme réactionnel. Ce
Fig. 1. Polarogrammes de solutions $5 \times 10^{-5}M$ dans le mélange DMF–tampon (1:4 v/v) à pH 7,6 ($\Delta E = 100$ mV). (a) Quercétine: $E_p = +0,125$ V ($S = 2$ $\mu A/cm$). (b) Rutine: $E_p = +0,240$ V ($S = 1$ $\mu A/cm$). (c) Morpholinoéthylrutine: $E_p = +0,275$ V ($S = 0,5$ $\mu A/cm$). (d) Trioxyéthylrutine: $E_p = +1,450$ V ($S = 0,2$ $\mu A/cm$). (S = sensibilité de l'enregistrement).

mécanisme reste donc à démontrer, ce que nous nous proposons de faire dans l'avenir.

Application au contrôle des médicaments

Le comportement électrochimique des molécules étudiées permet d'envisager des applications qualitatives et quantitatives.

Les différences de $E_{1/2}$ permettent dans une certaine mesure d'utiliser ces valeurs comme critère d'identité. Ce sont surtout les E_p qui présentent dans ce cadre un intérêt. Néanmoins, il n'est pas possible de distinguer la rutine de l'éthoxazorutine (Fig. 1).

Les mêmes déterminations peuvent être mises à profit comme critère de pureté. On peut par exemple rechercher la présence de quercétol libre dans la rutine ou les dérivés hémisynthétiques. On peut également envisager d'identifier la rutine (matière première) dans la trioxyéthylrutine.

Sur le plan quantitatif enfin, les courbes d'étalonnage réalisées en D.C. sur toutes les molécules oxydables ont montré la très bonne linéarité de $5 \times 10^{-6}M$ à $10^{-4}M$, ce qui représente une sensibilité très largement suffisante pour le dosage dans les formes pharmaceutiques.

La limite supérieure de $10^{-4}M$ ne peut être dépassée car des phénomènes d'adsorption se produisent alors à l'électrode et déforment les vagues, ce qui semble en relation avec la structure phénolique de ces molécules.

En polarographie à impulsions, si les valeurs de potentiel de pic sont bien reproductibles, par contre les courants de pic sont fluctuants.

C'est la raison pour laquelle dans nos conditions opératoires, la polarographie à impulsions nous semble surtout utile sur le plan qualitatif, d'autant plus que la valeur des courants de pics enrigistrés permet de déceler des traces de produit.

Conclusion

L'oxydation électrochimique des facteurs vitaminiques P étudiés a pu être obtenue grâce à une électrode de graphite. L'intensité du courant de diffusion est importante, ce qui permet d'envisager des applications quantitatives intéressantes dans le cadre du contrôle des médicaments.

Les différences de comportement électrochimique en fonction de la structure peuvent également être mises à profit dans une optique qualitative et pour le contrôle de pureté de ces molécules.

Summary—Several flavonols of therapeutic interest on account of their vascular properties have been studied. They were all derived from the *o*-diphenol quercetol. Their electrochemical oxidation at a rotating solid electrode has been examined, and the choice of solvent and pH is discussed. Results obtained by d.c. and pulse polarography are presented. A relation between their structure and electrochemical behaviour has been established. Application to drug analysis is proposed, giving identification, determination and purity assay simultaneously. There is a linear response over the range 5×10^{-6}–$10^{-4}M$, a sufficient range for analysis of pharmaceuticals.

CHEMICAL IONIZATION MASS SPECTROMETRY OF NITROSAMINES

YIN FANG, DING JIAHUA* and LIU SHILI†

Department of Chemistry, China University of Science and Technology, Hefei, China

Summary—The mass spectra of eight nitrosamines have been recorded, with excitation by chemical ionization (CI) and electron impact (EI). Comparison of the intensities of the base peaks under CI and EI conditions gives intensity ratios in the range 1.4–1.9 for low resolution measurements and up to 10 for high resolution measurements, confirming the enhanced sensitivity available in the CI mode.

As a preliminary test for the presence of volatile nitrosamines, the technique of gas chromatography (GC) is usually used. However, for the identification of a specific nitrosamine, it is most commonly combined with mass spectrometry (MS). A number of publications have reported the analysis of nitrosamines by electron-impact mass spectrometry (EIMS)[1] since Collin first described the mass spectra of five nitrosamines.[2] Later, the technique of chemical-ionization mass spectrometry (CIMS) was developed and the first successful results were reported by Munson and Field in 1966.[3] The fragmentation patterns obtained are much simpler than those obtained with conventional EIMS, and conform more closely to the structures of the molecules to be identified. The CIMS spectra are therefore more useful for both qualitative and quantitative analysis.

Gadbois *et al.*[4] used this technique for the determination of dimethylnitrosamine. They used methane as the reagent gas, and monitored the ion current at $m/z = 75$. Gaffield *et al.*[5] reported the CIMS spectra for ten nitrosamines, and gave preliminary sensitivity measurements for two of them, nitrosodimethylamine and nitrosodiphenylamine. They used a combination of gas chromatography with CIMS. At the present time there is still a need for more reference chemical-ionization mass spectra of nitrosamines. This paper presents such spectra for eight commercially available pure nitrosamines. A comparison of sensitivities is made for the CI and EI modes of operation with the same mass spectrometer.

EXPERIMENTAL

Apparatus

A JMS-D300 CIMS, coupled to a JMA-2000 computer system was used with methane as reagent gas. It was

*Present address: The Sanitation and Antiepidemic Station of Jilin Province, Changchun, China.
†Present address: Beijing Environmental Protection Research Institute, Beijing, China.

operated at a resolution of 500 (10% valley) and a source temperature of 200°, with an ionizing voltage of 200 V and a trap current of 300 μA. Samples were introduced by means of a direct insertion probe or an adjustable leak valve attached to the gas–liquid inlet.

A gas chromatograph was connected by a solvent-venting valve and a glass jet separator to the mass spectrometer; the glass chromatographic column (2 m × 1.8 mm bore) was packed with 15% PEG-20M/1% KOH on Chromosorb W AW-DMCS. Helium was used as carrier gas at a flow-rate of 40 ml/min, the column temperature was 120° for *N*-nitrosodimethylamine and 160° for *N*-nitrosopyrrolidine, and the sample inlet and interface temperatures were both 200°.

Sensitivity measurement

The sensitivities in the CI and EI modes of operation were compared by setting the instrument to a resolution of 7000 and using the peak-matching facility. The mass range in the vicinity of the appropriate parent ion (74.0480 or 100.06366) and the quasimolecular ion (75.05583 or 101.07149) were continuously scanned. The output was displayed on the oscilloscope of the peak-matching unit, thus enabling the nitrosamine and reference ion-currents to be alternately monitored every 2 sec. The peak height on the oscilloscope gave the appropriate sensitivity.

RESULTS AND DISCUSSION

A summary of the mass spectra of the nitrosamines, obtained by low-resolution CIMS, is given in Table 1. The abundances of the ions listed are in agreement with those reported by Gaffield *et al.*[5] Five of the eight nitrosamines have spectra in which the base peak is that for $(M + 1)^+$. The corresponding EI mass spectra include only three in which the base peak is M^+. The fraction of the total ion-current (σ) carried by the ion responsible for the base peak (expressed as %) for both the CI and EI modes is given in Table 2. It can be seen that this fraction is over 50% for the CI mode and less than 30% for the EI mode for all the nitrosamines except nitrosodiphenylamine. Operation in the CI mode therefore offers increased sensitivity.

Although a rigorous comparison of the sensitivities

Table 1. Summary of mass spectra of nitrosamines, obtained by CIMS using methane as reagent gas*

Compound	$(M+41)^+$	$(M+29)^+$	$(M+1)^+$	$(M-29)^+$	$(M-30)^+$
Nitrosodimethylamine	1.1	0	100	0	1.6
Nitrosodiethylamine	2.6	3.8	100	0	0.8

Nitrosodiethanolamine	0.4	2.7	4.7	8.9	12.8

*All values refer to the intensity relative to the ion with the base peak set equal to 100.

Table 2. Comparison of σ values* for the CI and EI modes of operation

Compound	EI		CI	
	m/z	$\sigma, \%$	m/z	$\sigma, \%$
Nitrosodimethylamine	74	29.5	75	87.5
Nitrosodiethylamine	102	23.6	103	82.1
Nitrosodi-n-propylamine	70	20.2	131	65.0
Nitrosopyrrolidine	100	32.5	101	78.8
Nitrosopiperidine	42	17.5	115	75.2
Nitrosodiphenylamine	169	19.8	169	30.8
Nitrosomethylphenylamine	106	28.8	108	58.1
Nitrosodiethanolamine	42	18.9	74	59.2

*σ is the fraction of total ion-current carried by the ion responsible for the base peak, expressed as %.

of CI and EI mass spectrometry cannot be made for any given nitrosamine, it is possible to compare the intensities of the base peaks for the CI and EI modes. The intensity ratio is a measure of the relative sensitivity of the instrument in the two operating modes. The measured intensity ratios are 1.87, 1.44 and 1.90 for nitrosodimethylamine, nitrosodiethylamine and nitrosodiphenylamine, respectively. Thus the sensitivity of CIMS is higher than that of EIMS under low-resolution conditions. The improvement in sensitivity is even more marked under high-resolution conditions (by the peak-matching technique), the intensity ratio rising as high as 10. Therefore high-resolution CIMS with peak-matching is a useful method of detecting specific nitrosamines in complex mixtures.

GRAVIMETRIC DETERMINATION OF THE ABUNDANCE RATIO OF ZIRCONIUM AND HAFNIUM, BASED ON THE *in situ* THERMAL DECOMPOSITION OF $K_4[(Zr, Hf)(C_2O_4)_4]\cdot 5H_2O$

Tomitaro Ishimori*, Masatomi Sakamoto and Tadao Watanabe
Faculty of Engineering, Ehime University, Matsuyama 790, Japan

Summary—Careful heating of $K_4[(Zr, Hf)(C_2O_4)_4]\cdot 5H_2O$ results in a two-step thermal decomposition which can be written as: $K_4[(Zr, Hf)(C_2O_4)_4]\cdot 5H_2O \rightarrow K_4[(Zr, Hf)(C_2O_4)_4] \rightarrow \{2K_2CO_3 + (Zr, Hf)O_2\}$. The weight-ratio of the successive decomposition products depends on the abundance ratio of Zr and Hf, and forms the basis for the present method of gravimetric determination.

It is well known that both zirconium and hafnium form potassium tetrakis(oxalato)zirconohafnate at all Zr/Hf ratios.[1] The thermal decomposition of the mixed metal complex salt gives thermogravimetric (TG) curves with two well-defined plateaus in the temperature ranges 170–240° and 450–650°, corresponding to the formation of $K_4[(Zr, Hf)(C_2O_4)_4]$ and $\{2K_2CO_3 + (Zr, Hf)O_2\}$, respectively.

As can be deduced from theory, the percentage weight losses at these two plateaus depend on the relative abundance of Zr and Hf in the complex salt. Therefore, a new method for determining the abundance ratio can be based on analysis of the TG curve.

EXPERIMENTAL

Materials

Reactor-grade zirconium metal containing only 42 ppm of hafnium was received from the Japan Atomic Energy Research Institute, Tokai. Three commercial materials were also utilized: hafnium oxide, 99 mole% purity (Merck, Darmstadt); hafnium oxide, 87 mole%; zirconium oxychloride, 97 mole%.

Preparation of the complex salt

Metallic zirconium or hafnium oxide was chlorinated[2,3] in order to prepare aqueous solutions of zirconium and hafnium; aqueous solutions of zirconium oxychloride were prepared directly from the reagent.

A series of zirconium–hafnium solutions with the desired abundance ratios was prepared by mixing standard solutions of known composition. Both zirconium and hafnium in these solutions were converted into the complex salt by the conventional procedure.[1] The Zr/Hf ratios in the salts were the same as in the solutions. In the present study, 7 mixtures with different abundance ratios were prepared, and labelled A, B, C ... G.

Thermal decomposition and gravimetric measurements

About 5 mg of the complex salt was decomposed by heating it on an electric balance, Cahn Model 2000, under a normal atmosphere, in order to measure the change in weight. The temperature was raised at a rate of about 0.7°/min.

RESULTS AND DISCUSSION

Figure 1 shows the typical TG curves for samples A and G. In the temperature regions II and IV, both curves give two well-defined plateaus. The TG curves for all 7 samples displayed these plateaus. Experimental checks showed that the plateaus remain in the same position regardless of the rate of temperature change.

Determination of Zr–Hf abundance ratio

The plateaus in the regions II and IV provide more
Fig. 1. TG curves for samples A and G.

*Author for correspondence.
Fig. 2. Plots of b_{II}/b_{IV} vs. the mole fraction of Zr and atomic ratio Zr/Hf. Value of b_{II}/b_{IV}: 1.4870 ± 0.0001 (A); 1.4846 ± 0.0006 (B); 1.4613 ± 0.0005 (C); 1.4380 ± 0.0007 (D); 1.4154 ± 0.0013 (E); 1.4074 ± 0.0009 (F); 1.3987 ± 0.0006 (G).

than 25 data points in each run. Therefore the constants in the following equations can be determined very precisely by least-squares fitting of the data:

$$W_{II} = a_{II}x + b_{II} \quad \text{and} \quad W_{IV} = a_{IV}x + b_{IV}$$

where suffix II or IV stands for the plateau in the temperature region II or IV respectively, W represents $100 \times$ [observed weight/initial weight], a is the slope of the plateau region, and x denotes observed temperature minus 345°. The origin of the temperature axis is moved to 345° in order to minimize geometrical errors; this temperature corresponds to the mid-point between the two plateaus.

Although both b_{II} and b_{IV} are found from many observed values, they are related to the initial weight of the sample at room temperature, which is measured just once for each experimental run. In the present work, the ratio b_{II}/b_{IV} is used instead of b_{II} or b_{IV} as the variable related to the relative abundance of Zr and Hf, so that the effect of the geometrical errors on the relationship shown in Fig. 2 will be minimized. The values of b_{II} and b_{IV} have no stoichiometric significance, but are used because they can be accurately calculated from the data, whereas the values corresponding to the completion of the two thermal decomposition steps are somewhat dependent on experimental variables such as heating rate and weight of sample. The method of calculation is purely empirical.

Experimental values of b_{II}/b_{IV} are plotted against mole fraction of Zr. The experimental points fall on a smooth curve and have satisfactorily small standard deviations, showing that this curve can be used for

the determination of the abundance ratio. This relationship can be seen in Fig. 2, in which the abundance ratio is given both as mole fraction of Zr and atomic ratio Zr/Hf. The standard deviations for b_{II}/b_{IV} were obtained by repetition of the thermal decomposition. Geometric consideration of Fig. 2 leads to the conclusion that the standard deviation for the mole fraction of Zr in an "unknown" sample should lie in the range (0.005–0.02).

Recommended procedure

Add 20 ml of concentrated hydrochloric acid and 50 ml of 16% mandelic acid solution to the starting solution, containing not more than 300 mg of Zr + Hf. Dilute the solution to 100 ml with water and digest it at 85° for 20 min. Filter off precipitate on a suitable paper and wash it with hot 5% mandelic acid solution in hydrochloric acid (1 + 50).[4] This procedure frees the Zr and Hf from practically all kinds of impurities. Ignite the precipitate to (Zr, Hf)O$_2$ in a platinum crucible. Mix the product with 2–3 times its weight of carbon, place the mixture in a porcelain boat and insert this into a silica tube (25 mm internal diameter, 1000 mm long), connected to a product collector. Purge the tube first with nitrogen and then with chlorine. Maintain a slow flow of chlorine through the reaction tube and heat it to 900°. The (Zr, Hf)Cl$_4$ produced deposits in the collector.[3]

To 20 ml of aqueous solution of 400 mg of the mixed tetrachlorides add 20 ml of an aqueous solution containing 1200 mg of K$_2$C$_2$O$_4 \cdot$H$_2$O and 400 mg of H$_2$C$_2$O$_4 \cdot$2H$_2$O, dropwise with stirring. Heat the mixture to boiling, cool it to room temperature, then add 30 ml of ethanol dropwise. Filter off the precipitate, wash it with ethanol and dissolve it with hot water (70°). Cool this solution to room temperature, add ethanol to reprecipitate the mixed oxalate, and wash it first with ethanol, and then with diethyl ether. Mount about 5 mg of the salt on the thermobalance and heat it for TG curve measurement. Calculate b_{II} and b_{IV} by extrapolation of the least-squares best fit for the points on

plateaus II and IV. From b_{II}/b_{IV} and the calibration curve (Fig. 2), read off the mole fraction of Zr or the atomic ratio Zr/Hf.

CONCLUSION

The method is based on the *in situ* thermal decomposition of the mixed complex oxalato salt on the balance, and empirical analysis of the data. Losses of zirconium and hafnium during the decomposition procedure are expected to be negligible. The amounts of sample required are much smaller than those used in other gravimetric methods for Zr/Hf ratio determination.

SPECTROPHOTOMETRIC DETERMINATION OF ZINC WITH 2-(3,5-DIBROMO-2-PYRIDYLAZO)-5-DIETHYLAMINOPHENOL IN THE PRESENCE OF ANIONIC SURFACTANT

Tan Zhe

Analytical and Testing Institute of Hunan Province, Changsha, People's Republic of China

and

Shui-Sheng Wu*

Changsha Institute of Technology, P.O. Box 410003, 506, Changsha, Hunan, People's Republic of China

Summary—A sensitive spectrophotometric method for zinc has been established by reacting zinc with 2-(3,5-dibromo-2-pyridylazo)-5-diethylaminophenol (3,5-diBr-PADAP) in the presence of an anionic surfactant, sodium lauryl sulphate. The molar absorptivity is 1.3×10^5 l.mole^{-1}.cm^{-1} at 570 nm. The molar ratio of zinc to 3,5-diBr-PADAP is 1:2. Beer's law is obeyed up to 0.7 ppm of zinc. With preseparation of zinc by extraction of its thiocyanate complex, the method has been applied to the determination of zinc in waste water.

Silver[1] and uranium[2] have been determined spectrophotometrically with 2-(3,5-dibromo-2-pyridyl-azo)-5-diethylaminophenol (3,5-diBr-PADAP) in the presence of anionic surfactant. We have now investigated this kind of colour reaction for zinc, and worked out a sensitive spectrophotometric method for determination of zinc with 3,5-diBr-PADAP in the presence of sodium lauryl sulphate (SLS). The practical molar absorptivity is 1.3×10^5 l.mole^{-1}.cm^{-1} at pH 7–10 and at 570 nm, making the reaction one of the most sensitive known for zinc. If the zinc is preseparated by extraction of its thiocyanate complex and stripping, the reaction can be used for the determination of trace amounts of zinc in waste water samples, except when cobalt is present.

EXPERIMENTAL

Reagents

Zinc standard solution, 1 *mg/ml*. Dissolve 0.1245 g of pure zinc oxide in 10 ml of hydrochloric acid (1 + 1) in a 100-ml standard flask and dilute to volume with water. Dilute the solution as required.

3,5-DiBr-PADAP, 5×10^{-4} M *ethanolic solution*. Dissolve 0.020 g of 3,5-diBr-PADAP, synthesized by the procedure described previously,[1] in 100 ml of ethanol.

Sodium lauryl sulphate (SLS) solution, 1%.

Ammonium thiocyanate solution, 40%.

Thiourea solution, 10%.

Buffer solution, pH 8.2. Adjust 0.1M sodium borate with hydrochloric acid to pH 8.2, using a pH-meter. Unless otherwise stated, all reagents used were of analytical-reagent grade, and demineralized water was used throughout.

Recommended procedure

Take a known volume (up to 30 ml) of water sample in

---

*Author for correspondence.

a 60-ml separatory funnel. Add 2 ml of hydrochloric acid (1 + 1), 3 ml of thiourea solution and 3 ml of ammonium thiocyanate solution. Dilute to about 40 ml with water, add 10 ml of methyl isobutyl ketone (MIBK), shake the mixture for 6 min, allow the phases to separate, and draw off the aqueous layer. Shake the aqueous phase with another 10 ml of MIBK, combine the extracts and discard the aqueous phase.

Add 10 ml of hydrochloric acid (1 + 1) to the organic phase and shake the mixture for 6 min. Allow the phases to separate, and collect the aqueous layer in a 100-ml standard flask. Repeat with another 10 ml of hydrochloric acid, add the aqueous layer to the standard flask, dilute to volume with water and mix. Pipette a portion containing not more than 7 μg of zinc into a 10-ml standard flask, adjust to about neutrality with ammonia solution (1 + 1), and add, in the following order and with mixing between additions, 2 ml of pH 8.2 buffer, 0.75 ml of 3,5-diBr-PADAP solution and 2 ml of SLS solution. Dilute to volume with water, mix, and let stand at room temperature for 10 min. Measure the absorbance is 570 nm against a reagent blank similarly prepared, with 1-cm cells.

RESULTS AND DISCUSSION

Spectral characteristics

The absorption spectra of 3,5-diBr-PADAP–SLS, 3,5-diBr-PADAP–Zn and 3,5-diBr-PADAP–Zn–SLS mixtures in aqueous solution at various pH-values have been studied. The spectra at pH 8.2 are shown in Fig. 1. Aqueous solutions of 3,5-DiBr-PADAP-SLS at pH from 2 to 11 are all orange-yellow and give an absorption maximum within the range 445–465 nm (curve A). The 3,5-diBr-PADAP–Zn system forms a new product and exhibits an absorption peak at 600 nm (curve B). In the ternary system, 3,5-diBr-PADAP–Zn–SLS, the zinc complex formed exhibits two absorption peaks, at 530 and 570 nm,

and the molar absorptivity is about twice that in the absence of SLS (curve C). The optimal wavelength for measurement of the zinc complex against a reagent blank is 570 nm. The absorbance of the zinc complex in the 3,5-diBr-PADAP–Zn–SLS system is practically constant when the colour is developed in the pH range 7.5–10.

For 7 μg of zinc in 10 ml of solution, the optimum reagent concentrations of the final solution are 3.0–4.0 × 10^{-5}M 3,5-diBr-PADAP and 0.2–0.25% SLS. The reaction of zinc with 3,5-diBr-PADAP in the presence of SLS gives complete colour development at room temperature on standing for 10 min, and the absorbance at 570 nm remains constant for at least 48 hr. The absorbance does not vary with temperature over the range 15–50°.

The calibration graph prepared according to the recommended procedure is linear and passes through the origin, the colour system obeying Beer's law for zinc concentrations up to 0.7 μg/ml in the solution measured. The practical molar absorptivity at 570 nm is 1.3 × 10^5 l.mole^{-1}.cm^{-1}.

Composition of the complex

The nature of the complex was investigated by the continuous-variations and molar-ratio methods at fixed SLS concentration. The molar ratio of zinc to 3,5-diBr-PADAP in the complex was found to be 1:2.

Effect of diverse ions

Because 3,5-diBr-PADAP produces colour reactions with a number of common metal ions, it was necessary to find a suitable method for preseparation of zinc, if the method were to be usable for determination of zinc in some practical water samples. The method described earlier[3] was considered adequate for the purpose. The thiocyanate complex of zinc is extracted from 0.3–2.1M hydrochloric acid into methyl isobutyl ketone, and then zinc is stripped with 6M hydrochloric acid. This separates the zinc from various other metal ions in the sample. The efficiency of the method has been checked by the determination of 1.00 mg of zinc in the presence of a number of other ions, both individually and collectively. The

$(5 \times 10^{-5}M)$–Zn (0.5 ppm)–SLS (0.2%).

Table 2. Comparison of analytical results for zinc

Sample	AAS method, ppm	Proposed method, ppm
1	122.5	120.1
2	3.89	3.87
3	1.90	1.80
4	1.40	1.38
5	0.28	0.27

results are shown in Table 1. The effect of cetyltrimethylammonium bromide (CTMAB) was also examined, in case it affected the action of the SLS in the determination.

Application

The proposed method has been applied to the determination of zinc in industrial waste-water. The analytical results obtained agreed well with those from atomic-absorption spectrophotometry, as shown in Table 2.

Seven replicate portions of a waste-water sample containing zinc were analysed individually by the recommended procedure and gave an average value of 38.8 ppm with a standard deviation of 0.045 ppm.

recovery of zinc was determined by the recommended procedure, and the distribution of the foreign ions between the residual aqueous phase from the extraction and the stripping solution was determined by atomic-absorption spectrophotometry (AAS). The

STUDIES ON EXTRACTION OF THORIUM FROM NITRATE SOLUTIONS WITH QUATERNARY AMMONIUM HALIDES

I. S. El-Yamani and E. I. Shabana

Nuclear Chemistry Department, Nuclear Research Centre, Atomic Energy Authority, Cairo, Egypt

Summary—Thorium can be quantitatively extracted with $0.1M$ Hyamine 1622 in dichloroethane from $0.25M$ nitric acid/$2M$ sodium nitrate and stripped from the organic phase with $0.1M$ sulphuric acid. The equilibration takes 20 min. Thorium can thus be separated from a large number of elements which are usually associated with it in monazite and in fission products of nuclear fuel.

The use of long-chain amines in the solvent extraction of thorium has been summarized and critically reviewed, but this method for its extractive separation is of limited application.[1,2] It has been pointed out that the extraction efficiency of quaternary ammonium halides is higher than that of amines.[3] The efficiency is enhanced when the number of carbon atoms in the quaternary salt is $\geqslant 24$. Moreover, the introduction of a benzyl group in place of an aliphatic group greatly enhances the extracting ability of the quaternary salt.[4] Hyamine 1622, which justifies such a generalization, has been used previously for the extraction and separation of zirconium.[5] The present investigation is part of a programme of systematic studies on liquid–liquid extraction of some nuclear materials; it reports recently obtained data on extraction of thorium from nitrate solutions by Hyamine 1622 in dichloroethane and the separation of the metal from rare-earth elements.

EXPERIMENTAL

Reagents

Hyamine 1622 (Hn), $R_3R'NCl$, (Rohm and Haas), a pure crystalline quaternary ammonium halide of molecular weight 466.1 and bulk density 0.44 g/cm^3, was used as received. Other chemicals were of reagent grade.

Isotope solutions

^{234}Th was milked from uranium through successive extraction from a solution of uranyl nitrate (50 g) in $6M$ hydrochloric acid (100 ml) with 30% tributyl phosphate in xylene;[6] ^{234}Th remained in the aqueous phase. The isotope solution was evaporated nearly to dryness, converted into nitrate form then diluted to a suitable volume. Other tracers were obtained through (n, γ) reactions or by separation of the initial nuclide from the daughter product (^{95}Zr).[7]

Extraction procedure

Equal volumes (5 ml) of aqueous phase containing the tracer [or the tracer-labelled or even the unlabelled species, the latter being aluminium, gallium and uranium(VI)] in nitric acid of appropriate concentration and of the organic phase pre-equilibrated with nitric acid, were shaken mechanically in glass-stoppered tubes for 20 min at room temperature ($20 \pm 3°$). After centrifugation, aliquots of both

phases were placed in glass cups, evaporated to dryness, then counted with an end-window Geiger–Müller counter (for ^{234}Th). The γ-activities were measured with a scintillation counter and NaI(Tl) crystal. Gallium and aluminium were determined complexometrically by back-titration with zinc, (dithizone as indicator, at pH 2.8 and 4.6 for Ga and Al respectively),[8,9] and U(VI) was determined spectrophotometrically by the hydrogen peroxide method.[10] Experiments were conducted in duplicate and the distribution ratio (D) was calculated as the ratio of the activities of the tracer (or the metal concentrations) in the organic and aqueous phases. The separation factor (selectivity, S) was computed from $S = D_{Th}/D_M$, where M is the metal ion concerned.

Analyses of the extracted complexes

The analytical composition of the species extracted was determined experimentally by saturation of an organic phase consisting of 0.01 or $0.1M$ Hn in dichloroethane, by shaking it for 20 min each time with eight successive aqueous feeds of $0.09M$ thorium in $5M$ nitric acid. The concentration of thorium in the saturated organic phase was determined complexometrically (with Xylenol Orange as indicator) after stripping with $0.1M$ sulphuric acid,[11] and the nitrate concentration was determined by reduction in methanolic solution to ammonia, which was then distilled into excess of hydrochloric acid, the surplus of which was determined titrimetrically.[12]

RESULTS AND DISCUSSION

Effect of initial HNO_3 concentration

The extraction of thorium from its aqueous solution, with $0.1M$ Hn in dichloroethane, was examined at different acidities (0.25–$10.0M$); results are shown in Fig. 1. Higher D values are obtained at lower acidities ($\leqslant 5M$), presumably because of formation of anionic complexes, and the lower values given at higher acid concentrations may be attributed to competition between thorium and nitric acid for association with the extractant, and/or formation of less readily extractable complexes. From Fig. 1, it may be inferred that extraction of thorium with Hn is dominated by solvating and ion-exchange reaction mechanisms at lower ($\leqslant 5M$) and higher acidities
Fig. 1. Extraction of thorium from nitric acid and $0.25M$ $HNO_3/NaNO_3$ solutions by $0.1M$ Hn in dichloroethane.

Table 1. Slopes of plots of log D vs. log[Hyamine 1622] for extraction of Th(IV) from HNO_3

$[HNO_3]$, M	$[Hn] \leqslant 0.05M$	$[Hn] > 0.05M$
3.2	1.2	1.9
5.3	1.3	2.0
8.6	1.2	1.6

respectively, a view consistent with the behaviour of the V(IV)–HCl–Aliquat 336 system.[13]

When the nitric acid in the aqueous phase is partly replaced with sodium nitrate (Fig. 1), D for the $HNO_3/NaNO_3$ mixture is found to increase steadily with increase in total nitrate concentration. This indicates that the controlling factor in the extraction behaviour is the total nitrate ion concentration and hence the fall of the D curve for purely nitric acid media at higher acidities may be ascribed to the effect of the hydrogen ion. Quantitative extraction was obtained with a $0.25M$ $HNO_3/2M$ $NaNO_3$ solution.

Dependence on metal and extractant concentration

The variation of thorium concentration in the organic phase was examined, for extraction with $0.1M$ Hn in dichloroethane. Maximum loading values of about 0.045 and $0.042M$ were obtained at 5.3 and $8.6M$ nitric acid respectively, implying that two quaternary extractant molecules are associated with each metal ion extracted. This is in agreement with the number calculated from a plot of log D vs. log [Hn]; the extractant concentration was varied between 0.005 and $0.1M$, the acidities used were 3.2, 5.3 and $8.5M$, and trace level concentrations of thorium ($\sim 10^{-6}M$) were used. D increased linearly with rise of Hn concentration up to about $0.05M$, above which the slopes of the curves considerably increased. The slopes obtained were consistent and approximated to unity at lower Hn concentration ($\leqslant 0.05M$) and 2 at higher molarities, indicating a first or second power dependence of D on Hn concentration, according to the acidity. The slopes are given in Table 1.

If $Th(NO_3)_4$ is considered to be the neutral species, and $Th(NO_3)_5^-$ and $Th(NO_3)_6^{2-}$ the anionic species, $Th(NO_3)_6^{2-}$ existing predominantly,[14] then if the re-

agent species is $R_3R'N^+ \cdot NO_3^-$ at lower acidities and the adduct $R_3R'N^+ \cdot NO_3^- \cdot HNO_3$ at higher acid concentrations, analogous to Aliquat 336, the extraction mechanism may be expressed as follows.

(a) For $[Hn] \leqslant 0.05M$:

(i) at lower acidities ($\leqslant 5M$)
$$Th(NO_3)_{4_{(a)}} + R_3R'N^+ \cdot NO_{3_{(o)}}^-$$
$$\rightleftharpoons (R_3R'N^+)Th(NO_3)_{5_{(o)}}^- \quad (1)$$

(ii) at higher acidities

$$Th(NO_3)_{6_{(a)}}^{2-} + R_3R'N^+ \cdot NO_3^- \cdot HNO_{3_{(o)}}$$
$$\rightleftharpoons (R_3R'N^+)Th(NO_3)_{5_{(o)}}^- + 3NO_{3_{(a)}}^- + H_{(a)}^+ \quad (2)$$

(b) For $[Hn] > 0.05M$:

(i) at lower acidities ($\leqslant 5M$)

$$Th(NO_3)_{4_{(a)}} + 2R_3R'N^+ \cdot NO_{3_{(o)}}^-$$
$$\rightleftharpoons (R_3R'N^+)_2Th(NO_3)_{6_{(o)}}^{2-} \quad (3)$$

(ii) at higher acidities

$$Th(NO_3)_{6_{(a)}}^{2-} + 2R_3R'N^+ \cdot NO_3^- \cdot HNO_{3_{(o)}}$$
$$\rightleftharpoons (R_3R'N^+)_2Th(NO_3)_{6_{(o)}}^{2-} + 4NO_{3_{(a)}}^- + 2H_{(a)}^+ \quad (4)$$
in which (a) and (o) represent the aqueous and organic phases respectively.

The stoichiometries proposed for the extracted species are also supported by analyses of the organic extracts. The organic solutions, saturated with thorium, gave a molar ratio of $Th:NO_3^-$ of about 1:5 and 1:6 at 0.01 and $0.1M$ Hn concentration re-

Table 2. Separation factors for various metal ions with respect to Th(IV) extracted into $0.1M$ Hn in dichloroethane from $0.25M$ $HNO_3/2M$ $NaNO_3$

spectively, thus confirming the maximum loading and slope-analysis data, and also justifying postulation of the penta and hexanitrato-complexes as the species extracted.

Extraction time

With optimum extraction conditions (0.25M HNO$_3$/2M NaNO$_3$, 0.1M Hn in dichloroethane), the equilibrium period was varied between 1 and 30 min. It was found that the optimum duration was 10 min. However, to ensure complete equilibration, 20 min shaking time was used in further work.

Stripping of thorium

Thorium extracted into the organic phase from 0.25M HNO$_3$/2M NaNO$_3$ solution with 0.1M Hn, may be readily stripped with dilute sulphuric or hydrochloric acid. Shaking the extract for 10 min with 0.1M sulphuric acid quantitatively strips the thorium.

Effect of diverse ions

Table 2 shows the separation factors for various metal ions from thorium. The higher extractability of thorium, compared to those of rare earths, Zr(IV), Hf(IV), Be(II) etc., affords a useful approach to separating thorium from rare earths processed from monazite or fission products. U(VI) and Pa(V), however, should be separated or masked before thorium determination. From this study, we suggest the following method for thorium/rare-earth separation and for thorium determination.

An aliquot (0.02M thorium containing not more than 0.5 mg/ml Ce^{3+}, La^{3+}, Eu^{3+} and Y^{3+} in 0.25M nitric acid/2M sodium nitrate) is shaken mechanically for 20 min with an equal volume of pre-equilibrated 0.1M Hn in dichloroethane at room temperature ($\sim 20°$). After centrifugation, the two layers are sep-

arated. The aqueous phase is extracted twice more with fresh organic phase. Thorium is then stripped from the combined organic phases by shaking with two portions of 0.1M sulphuric acid (each equal to the organic phase in volume). Thorium in the back-extract is then determined complexometrically with Xylenol Orange as indicator (recovery is 99.0 ± 1.0%). The separation from tervalent Ce, La, Eu and Y is shown by γ-spectrometry to be practically complete.

STUDIES ON EXTRACTION OF INDIUM BY TRIBUTYL PHOSPHATE FROM THIOCYANATE SOLUTIONS

I. S. El-Yamani and E. I. Shabana

Nuclear Chemistry Department, Nuclear Research Centre. Atomic Energy Authority, Cairo, Egypt

Summary—Indium can be quantitatively separated from a large number of elements which are usually associated with it, by extraction with 15% tributyl phosphate solution in kerosene from hydrochloric acid (pH 1)/0.5*M* potassium thiocyanate medium and stripping with 6*M* nitric acid. The equilibration takes 20 min.

The importance of indium and its alloys in nuclear reactors [as indicators, control rods, fuel (*e.g.*, In–Pu alloy) or cladding (Zr–In alloy), *etc.*][1,2] is increasing with recent progress in nuclear reactor technology. Attention has been focused, in the last few decades, on the use of tributyl phosphate for analytical and hydrometallurgical aspects of refining nuclear materials. Although tributyl phosphate has been used for extraction of indium from chloride solutions, it has only limited applications.[3,4] Since the donor power of thiocyanate ions is stronger than that of chloride, it might be assumed that indium thiocyanate would be more readily extracted than the chloride.[5] The extraction of americium, iron(III) and uranium from thiocyanate solutions with tributyl phosphate has been summarized and critically reviewed.[6] Similarly, De and Sen utilized the thiocyanate system for the extraction of some transition elements such as cobalt(II), copper(II) and iron(III) with tributyl phosphate.[7] Other workers have made similar studies for beryllium,[8] aluminium and gallium.[5] Most of the work done on the In–SCN-tributyl phosphate system was directed only towards stability constant measurements for indium complexes,[9,10] and information on extractive separation of indium from thiocyanate medium is lacking. In the present investigation, indium was quantitatively extracted and separated from associated elements with tributyl phosphate from thiocyanate solutions.

EXPERIMENTAL

Reagents

Tri-n-butyl phosphate (TBP), was purified as reported elsewhere.[11] Odourless kerosene (Misr Petroleum Co.), was used as diluent. [114m]In was obtained through the (n, γ) reaction. Other chemicals were of reagent grade.

A stock solution of indium was prepared by dissolving 1.84 g of reagent-grade indium metal (99.99% pure) in the minimum amount of hydrochloric acid, and making up to 100 ml with distilled water. The solution was standardized complexometrically.[12]

Recommended procedure

An aliquot (5 ml) of solution containing about 10 mg of indium in hydrochloric acid (pH 1)/0.5*M* potassium thio-cyanate medium, is shaken mechanically for 20 min at room temperature (~20°) with an equal volume of 15% TBP solution in kerosene. After centrifugation, the two layers are separated. Indium is stripped from the loaded organic phase by shaking for 10 min with two successive 10-ml portions of 6*M* nitric acid, then determined complexometrically in the aqueous extract at pH 4 with Xylenol Orange as indicator.

RESULTS AND DISCUSSION

Effect of acidity and TBP concentration

The concentration of hydrochloric acid was varied from 0.001 to 1*M* and that of TBP from 1 to 15% (0.04–0.55*M*). All experiments were done with a fixed 0.5*M* concentration of potassium thiocyanate, and the distribution ratio, *D*, was calculated as the ratio of activity in the organic to that in the aqueous phase, measured with a well-type NaI(Tl) γ-scintillation counter. It was observed (Table 1), that the extraction was incomplete with only about 1.5% TBP in any acid range, but quantitative with 10–15% TBP at pH 1–3 (no significant difference occurs over this range), because at this acidity the chloro-complex has no effect on the degree of extraction. At higher acidity, there was a decrease in extraction, presumably due to competitive complexation by the additional chloride. Even with higher TBP concentration, the extraction was not quantitative at acidities higher than 0.5*M*. It was possible to strip the extracted indium into the aqueous phase by equilibrating twice, for 10 min, with equal volumes of 6*M* nitric acid.

Effect of thiocyanate concentration

The concentration of thiocyanate was varied from 0.1 to 4*M* in presence of hydrochloric acid (pH 1); 3% and 5% TBP solutions in kerosene were used. The results showed that when the concentration of potassium thiocyanate was 0.1, 0.5, 1, 2 and 4*M*, the corresponding degree of extraction was 37.5, 74.4, 54.6, 33.3 and 13.0% with 3% TBP and 86.7, 97.2, 95.7, 84.4 and 83.1% with 5% TBP. Optimum results were obtained at about 0.5*M* potassium thiocyanate solution.

Nature of the extracted species

The variation in the concentration of indium in the organic phase as a function of initial aqueous indium concentration was examined with 14.5% TBP in kerosene. Maximum indium loading values of 0.17 and 0.18M were obtained at pH 1 and 2, indicating that the indium thiocyanate is solvated with three TBP molecules. This conclusion is confirmed by the linear dependence of log D vs. log [free TBP] at various hydrochloric acid (10^{-4}–1.5M) and potassium thiocyanate (0.1–4M) concentrations, [free TBP] being calculated as C_{Tot}–3C_{In}, where C_{Tot} is the total TBP concentration and C_{In} the indium concentration in the organic phase. The slopes of plots of the function (Table 2) were observed to be independent of the acidity and hence only one indium species is extracted over the whole acid range. The results also indicate the predominant formation of a trisolvate at lower thiocyanate concentration ($\leqslant 2M$) and tetrasolvate at higher concentrations ($> 2M$).

Since In(SCN)$_3$ is considered to be the major species at lower thiocyanate concentration ($\leqslant 0.5M$), and In(SCN)$_4^-$ or In(SCN)$_5^{2-}$ can exist at higher concentrations,[10] the extraction mechanism may be expressed as follows.

(i) At lower thiocyanate concentration ($\leqslant 0.5M$):

$$In_{(a)}^{3+} + 3SCN_{(a)}^- + 3TBP_{(o)}$$
$$\rightleftharpoons In(SCN)_3 \cdot 3TBP_{(o)} \quad (1)$$
where subscripts (a) and (o) denote the aqueous and organic phases respectively.

(ii) At higher thiocyanate concentration (> 0.5–$2M$):

$$In_{(a)}^{3+} + 4SCN_{(a)}^- + H_{(a)}^+ + 3TBP_{(o)}$$
$$\rightleftharpoons HIn(SCN)_4 \cdot 3TBP_{(o)} \quad (2)$$
(iii) At $> 2M$ thiocyanate solutions:

$$In_{(a)}^{3+} + 5SCN_{(a)}^- + 2H_{(a)}^+ + 4TBP_{(o)}$$
$$\rightleftharpoons H_2 In(SCN)_5 \cdot 4TBP_{(o)} \quad (3)$$
Period of extraction

With optimum extraction conditions, the equilibrium period was varied between 1 and 50 min. It was found that the optimum time is 20 min.

Effect of temperature

The extraction of indium from aqueous solutions containing 0.5M potassium thiocyanate, by 14.5% TBP in kerosene, at various temperatures (17–52°), was examined. The extraction decreases markedly with rise of temperature (at 17, 21, 31, 42 and 52°, the distribution ratios were 1600, 1000, 625, 304 and 175 for 0.01M HCl and 240, 142, 73, 28.2 and 13.2 for 0.5M HCl medium). Since lower temperature favours higher D, the extraction process is assumed to be exothermic. Extraction at room temperature ($\sim 20°$) is therefore advised.

Effect of other ions

Several ions were tested for their effect on the extraction of indium. The tolerance limit was calculated as described earlier.[13] It was observed that alkali and alkaline-earth metal ions, Cd^{2+}, Zn^{2+}, Al^{3+}, Cr^{3+}, La^{3+}, Ce^{3+}, Y^{3+}, Eu^{3+}, Nd^{3+}, NO_3^-, SO_4^{2-}, PO_4^{3-}, tartrate and citrate were tolerated in ratios of at least 100:1 relative to indium. Hg^{2+} and Ga^{3+} were tolerated in 50:1 ratio to indium, and Co^{2+}, Sn^{2+} and Pb^{2+} in 40:1 ratio. UO_2^{2+}, Fe^{3+}, Th^{4+}, VO_3^-, MoO_4^{2-}, F^- and $C_2O_4^{2-}$ should be separated or masked before indium determination. Indium usu-

ally occurs associated with tin, aluminium, gallium, lead, zinc and iron in ores. The present method is simple, fairly rapid and selective, with a relative standard deviation of $\pm 0.8\%$. It also has the advantage of using lower concentrations of TBP and thiocyanate and lower pH values, rendering the process economically attractive and satisfactory for analytical as well as industrial purposes.

DETERMINATION OF POLY(OXYETHYLENE) NON-IONIC SURFACTANTS BY TWO-PHASE TITRATION

Masahiro Tsubouchi and Yoshiko Tanaka

Laboratory of Chemistry, Kochi Medical School, Oko, Nankoku, Kochi 781-51, Japan

Summary—The solvent extraction of non-ionic surfactants with sodium hydroxide and tetraphenylborate has been studied, and a method developed for the determination of non-ionic surfactants by two-phase titration. A hydrophobic indicator system was used. The method is valid only when the concentration of anionic surfactant in the sample solution is lower than $1 \times 10^{-4}M$.

A mixture of anionic and poly(oxyethylene) non-ionic surfactants is widely used is both industrial and domestic detergents. It is known that the non-ionic surfactant can form spirals which can trap metal ions such as potassium[1,2] and barium.[3] The reaction between anions and the complex cation formed by the non-ionic surfactant and the metal ions has been made the basis for gravimetric,[4] spectrophotometric,[1,2,5] and titrimetric[3] methods for determination of the non-ionic surfactant. However, it is generally difficult to determine total non-ionic surfactants in the presence of anionic surfactants because the metal ion complexes of the non-ionic surfactants form ion-pairs with the anionic surfactants present.

Two-phase titration is one of the most frequently used methods for the determination of ionic surfactants. This paper presents an indirect method for the determination of non-ionic surfactant in the presence of anionic surfactant by two-phase titration.

EXPERIMENTAL

Reagents

The non-ionic surfactants used were Triton X-100, Triton X-405 (Rohm & Haas Company), polyethylene glycol mono-*p*-iso-octylphenyl ether (Wako Pure Chemical Ind., and Nakarai Chemicals Ltd.), polyoxyethylene lauryl alcohol ether, and polyoxyethylene sorbitan monopalmitate (Nakarai Chemicals Ltd.). The number-average degree of polymerization of the surfactants used is 8–12, except for Triton X-405 (for which it is 40). The surfactants, Zephiramine (tetradecyldimethylbenzylammonium chloride), and sodium tetraphenylborate were dried at 80° and dissolved in water. Victoria Blue B (Colour Index 44045, $C_{33}H_{32}N_3Cl$) was dissolved in ethanol to make a 0.01% solution; it was used as an indicator. A pH-9.0 buffer solution was prepared by adding 6M sodium hydroxide to 0.3M sodium dihydrogen phosphate/0.05M sodium borate solution.

Procedure

To 10 ml of a mixture of a non-ionic and an anionic surfactant (non-ionics, 2–0.2 mg/10 ml; anionics, less than $1 \times 10^{-4}M$) in a separatory funnel, add 2 ml of 6M sodium hydroxide and 5 ml of $2 \times 10^{-3}M$ sodium tetraphenylborate, and shake the solution vigorously with 10 ml of 1,2-dichloroethane. After separation of the layers, run off the extract into a glass tube through a filter paper to remove

droplets of water. Place a 5-ml portion of the extract in a 200-ml Erlenmeyer flask, and add 5 ml of buffer solution and 2 drops of indicator. Titrate the mixture with $2 \times 10^{-4}M$ Zephiramine with vigorous shaking after each addition, until there is a colour change from blue (λ_{max} 615 nm) to red (λ_{max} 505 nm) in the organic phase. Titrate a reagent blank prepared in the same way (titre *ca.* 0.6 ml). One mg of non-ionic surfactant requires *ca.* 5.1 ml of $2 \times 10^{-4}M$ titrant, irrespective of the anionic surfactant present.

RESULTS AND DISCUSSION

It is reported that a 12-unit ethylene oxide polymer combines with one barium ion regardless of the kind of alkyl or alkylaryl groups in the non-ionic surfactant.[3] The non-ionic surfactant can also trap sodium ions in its spirals and be extracted into dichloroethane from 0.2–2M sodium hydroxide, as an ion-pair with tetraphenylborate, but any anionic surfactant in the mixture is not extracted. A blank titration is necessary because tetraphenylborate is slightly extracted even in the absence of non-ionic surfactant. The extracted non-ionic surfactant–sodium–tetraphenylborate complex is decomposed by the Zephiramine used as titrant and the Zephiramine–tetraphenylborate ion-pair is formed in the organic phase. The blue indicator–tetraphenylborate complex in the extracts reacts with excess of titrant to form the free indicator (red) at the end-point. The aqueous phase remains colourless throughout the titration, because of the insolubility of Victoria Blue B in alkaline water. This is a hydrophobic indicator system,[6] though a dye-transfer method is usually used in two-phase titrations.

The volume of titrant required is proportional to the amount of non-ionic surfactant present in the sample solution, indicating that the non-ionic surfactant is stoichiometrically extracted. The volumes of $2 \times 10^{-4}M$ Zephiramine needed for 1 mg of non-ionic surfactant were found to be: Triton X-100, 5.–5.1 ml (mean of 10 titrations was 5.06 ml, standard deviation 0.04 ml); Triton X-405, 5.1–5.2 ml; poly-

ethylene glycol mono-p-iso-octylphenyl ether, 4.8–4.9 ml; polyoxyethylene lauryl alcohol ether, 5.2–5.3 ml; polyoxyethylene sorbitan monopalmitate, 5.1–5.2 ml. The volumes vary slightly with the products and type of surfactant, but it seems that in general the volume needed for the same weight of non-ionic surfactant is almost constant, about 5.1 ml of $2 \times 10^{-4} M$ Zephiramine per mg of non-ionic surfactant. It is reasonable to consider that the hydrophile–lipophile balance values of the surfactants used are similar, making the method usable for a range of surfactants.

If less than 2 ml of $2 \times 10^{-3} M$ tetraphenylborate is added, the titrant volume needed decreases slightly. Variation of the pH between 8.5 and 9.5 does not affect the results. Chloroform cannot be used as the organic solvent, since it does not give a sharp end-point. If methyl isobutyl ketone is used as the organic solvent, the sodium salts of the anionic surfactants are extracted as well as the non-ionic surfactants.

The following species do not interfere at the $10^{-3} M$ level: K^+, NH_4^+, Ca^{2+}, Cl^-, SO_4^{2-} and triethanolamine. However, high concentrations ($> 10^{-2} M$) of potassium and ammonium ions give tetraphenylborate precipitates, causing negative errors. Anionic surfactants ($1 \times 10^{-4} M$) such as dodecylsulphate, dodecylbenzenesulphonate, and bis(2-ethylhexyl)-sulphosuccinate do not disturb the determination, but separation of the two layers is poor when the concentration of these anionic surfactants is $\geqslant 2 \times 10^{-4} M$. The recommended procedure is based on these results.

Application to commercial detergents

The number-average degree of polymerization of the commercial non-ionic surfactants is mainly 8–13.

A commercial detergent for wool was diluted with water, and the anionic surfactant was first titrated as follows. To 10 ml of the sample solution were added 5 ml of buffer solution (pH 9), 2 drops of Victoria Blue B indicator, and 4 ml of 1,2-dichloroethane. The mixture was titrated with $2 \times 10^{-4} M$ Zephiramine with vigorous shaking after each addition, until a colour change from blue to red took place in the organic phase. A blank titration was not necessary. The titrant volume corresponded to the anionic surfactant present, irrespective of the non-ionic surfactant present, this was verified with sodium dodecylsulphate, dodecylbenzenesulphonate, and bis(2-ethylhexyl)sulphosuccinate.

A second aliquot of sample solution was diluted with water to reduce the concentration of anionic surfactant to $1 \times 10^{-4} M$ or less, and the non-ionic surfactant was then determined by the recommended procedure. The result found was $0.25 M$ anionic surfactant and 0.13 g/ml non-ionic surfactant in the detergent. A recovery test was done by adding 0.52 mg of Triton X-100 to the 2500-fold diluted detergent, and 0.50 mg was found.

USE OF AMMONIUM MOLYBDATE IN THE COLORIMETRIC ASSAY OF CEPHALOSPORINS

M. M. ABDEL-KHALEK and M. S. MAHROUS

Department of Pharmaceutical Chemistry, Faculty of Pharmacy, University of Alexandria, Alexandria, Egypt

Summary—A colorimetric method for the determination of five cephalosporins (cefoxitin sodium, cefotaxime sodium, cephapirin sodium, cephalothin sodium and cephaloridine), based on the blue colour formed by reaction of the cephalosporins with ammonium molybdate, is described. The effects of reagent concentration and reaction conditions are discussed. The proposed method has been applied to the analysis of cephalosporin injections, the results of which are in good agreement with those obtained by the official method of the British Pharmacopoeia.

Cephalosporins have been determined iodometrically after hydrolysis of the β-lactam ring,[1,2] and titrimetrically with *N*-bromosuccinimide[3] or potassium iodate[4]. Cephalosporins have also been determined spectrophotometrically after treatment with hydroxylamine–nickel reagent[5] and after preliminary acid hydrolysis.[6] Cephapirin has been assayed spectrophotometrically after degradation under controlled conditions.[7] An air-segmented continuous-flow spectrophotometric method has been utilized for the determination of cephalosporins.[8] In addition, the use of high-pressure liquid chromatography,[9,10] and fluorimetric[11,12] and polarographic[13,14] methods of analysis have been reported.

The aim of the present work was to develop a simple and accurate quantitative method for determining cephalosporins, with ammonium molybdate

as reagent. This procedure has been applied to a wide variety of cephalosporins (for structures see Table 1) in pure form and in injections. The reaction product is presumably an isopoly molybdenum blue.

EXPERIMENTAL

Apparatus

A Perkin-Elmer Model 550 S spectrophotometer with matched 1.00-cm quartz cells was used for absorbance measurements.

Reagents

Ammonium molybdate solution, 1.5%.
Sulphuric acid, 0.5M.
Cephalosporin solutions, 0.2 *mg/ml*, freshly prepared in water. Laboratory reference standards were used for calibration. A sample of cefoxitin was provided by Merck Sharp and Dohme (UK), of cefotaxime by Hoechst Orient Laboratories (Egypt), of cephapirin by Bristol Laboratories

Fig. 1. Absorption spectra of the coloured products from: A, cefoxitin sodium; B, cefotaxime sodium; C, cephapirin sodium; D, cephalothin sodium; and E, cephaloridine. [Cephalosporin] = 50 μg/ml in each instance.

(U.S.A.) and samples of other cephalosporins by Lilly Research Centre Ltd. (U.S.A.).

All chemicals and reagents used were of analytical-reagent or pharmaceutical grade. Distilled water was used throughout.

General procedure and preparation of calibration graph

Transfer 5 ml of an aqueous solution containing from 0.2 to 1.0 mg of the sample into a test-tube. Add 1 ml of ammonium molybdate solution and 1 ml of 0.5M sulphuric acid. Prepare a corresponding blank solution with 5 ml of water. Mix well and heat the solutions in a boiling water-bath for 30 min. Cool and transfer into a 10-ml standard flask and dilute to volume with water. Measure the absorbance of the blue colour at λ_{max} for the drug (Table 2). Prepare a calibration graph of absorbance *vs.* concentration of the reference cephalosporin.

For injections. Mix the powder from a vial, and accurately weigh a portion equivalent to about 10 mg of the drug and dissolve it in water. Dilute with water to volume in a 100-ml standard flask. Transfer 5 ml of this solution into a test-tube and complete the assay as described above.
Fig. 2. Effect of ammonium molybdate concentration on the absorbance at λ_{max} of the coloured products from: ●—● cefoxitin sodium; ×—× cefotaxime sodium; O—O cephapirin sodium; △—△ cephalothin sodium; and □—□ cephaloridine. [Cephalosporin] = 50 μg/ml in each instance.

RESULTS AND DISCUSSION

Absorption spectra

The absorption spectra of the reaction products in the range 600–800 nm are shown in Fig. 1. Cephalosporins and ammonium molybdate all have negligible absorbance at and near the λ_{max} regions.

Beer's law is obeyed over the concentration range 20–100 μg/ml. The molar absorptivities are given in Table 2. The coefficient of variation was less than 0.4%.

Choice of analytical conditions

A sulphuric acid concentration of about 0.5M is optimal (Table 3). Use of 1 ml of 1.5–2.5% ammo-

‡Critical value 3.2 ($p = 0.05$).
Fig. 3. Effect of heating time on the formation of the coloured product. ●—● cefoxitin sodium; × — × cefotaxime sodium; ○—○ cephapirin sodium; △—△ cephalothin sodium; and □—□ cephaloridine. [Cephalosporin] = 50 μg/ml in each instance.

nium molybdate solution in the total volume of 10 ml gives maximum absorbance (Fig. 2). Figure 3 shows that heating for at least 30 min is essential for full colour development. The absorbance remains constant for about an hour after maximum colour development. The order of addition of reagents is not critical.

Table 4 gives the results obtained by application of the proposed method and the official method 1 to the determination of cephalosporins in pure form and in injections. The results are in good agreement. Statistical comparison by the Student t-test and the variance ratio, F,[15] shows no significant difference be-

tween the two sets of results. However, the molybdenum blue is simpler and faster than the BP method (but is not stability-indicating).

Interferences

The possibility of interference by other constituents in injections cannot be overlooked. In the determination of cephalosporins in capsules, the excipients usually added, such as starch, lactose and glucose, interfere in the analysis by the proposed method.

POLAROGRAPHIC DETERMINATION OF TRACES OF ZIRCONIUM IN ORES BY USE OF COMPLEX-FORMING COMPOUNDS ADSORBABLE AT THE DROPPING MERCURY ELECTRODE

Ye Hua-Li

Research Laboratory of Hunan Bureau of Geology, People's Republic of China

He You-Hua

Group Testing Laboratory of Hubei Bureau of Petrochemical Industry, People's Republic of China

Summary—A polarographic method is proposed for the determination of trace zirconium down to the $5 \times 10^{-9} M$ level, based on the adsorption of the complex of zirconium with oxalic acid + cupferron + diphenylguanidine at the dropping mercury electrode in sodium acetate–acetic acid solution (pH 5.7). Under optimum conditions the wave-height is proportional to the concentration of zirconium in the range from 0 to 0.4 μg/ml. The serious interference from titanium(IV) can be effectively eliminated by solvent extraction with 3% tri-n-octylamine from $1N$ sulphuric acid and stripping with 0.1M perchloric acid–1M hydrochloric acid–2M nitric acid mixture. The mechanism giving rise to the wave for the zirconium complex has been investigated. The method has been applied to the determination of trace zirconium in ores and ceramics.

The polarographic determination of zirconium has been little used, especially for analysis of ores. Budnikov *et al.*[1] have examined the polarographic wave of the zirconium–4-(2-pyridylazo)-resorcinol complex at pH 1.8–2.0 in ammonium chloride supporting electrolyte, but the sensitivity was low (the determination limit was 2 μg/ml) and the polarographic wave was poor.

More recently Yao Xiu-ren *et al.*[2] have suggested that the zirconium–cupferron–diphenylguanidine complex can produce a more sensitive oscillopolarographic wave in ammonium chloride supporting electrolyte, but it is difficult to find an optimum linear range for the determination of zirconium. However, this reaction at the dropping mercury electrode is so sensitive that we have tried to find supporting electrolytes that would improve the determination. We have found that a well-defined high-sensitivity peak for the zirconium–cupferron–diphenylguanidine complex can be obtained at a potential of about -1.02 V (*vs.* SCE) in sodium acetate–acetic acid buffer (pH 5.5–6.0), but the peak rapidly disappears. Therefore a stabilizing agent was sought and oxalic acid was found to give the best effect.

The effect of some potentially interfering ions, temperature, time and the height of the mercury column on the peak current has been investigated. The advantages of the proposed method are its simplicity, high sensitivity, good selectivity and reproducibility.

EXPERIMENTAL

Apparatus

A Cheng Dou JP-1A single-sweep polarograph with a three-electrode system [a dropping mercury electrode (DME) as cathode, an SCE as reference and a platinum electrode as auxiliary] and a Czechoslovak LP-60 d.c. polarograph were used.

Reagents

Unless otherwise mentioned, all reagents used were of analytical reagent grade.

Buffer solution. Sodium acetate (3.5M)–acetic acid (0.35M), pH 5.7.

Oxalic acid dihydrate solution, 1%.

Cupferron solution, 0.07%. If protected from light, this can be used for up to 15 days.

Diphenylguanidine solution, 0.04%. The base was dissolved with a few drops of 6M hydrochloric acid, then diluted with water.

Tri-n-octylamine (TNOA) solution, 3% v/v in benzene.

Standard zirconium solution (74 μg/ml). A stock solution containing 74 μg of zirconium per ml (ZrO$_2$ 100 μg/ml) is prepared by heating 0.1000 g of zirconium oxide in a platinum crucible with 10 drops of concentrated sulphuric acid and 5–7 ml of concentrated hydrofluoric acid until fumes of sulphur trioxide appear, cooling, washing down the crucible wall with a little water, again evaporating to fumes, and repeating this step, then finally dissolving the residue in 2M hydrochloric acid and diluting to 1 litre with the same acid. The solution is finally diluted to give a working solution in 0.6M hydrochloric acid, containing 1.48 μg of Zr per ml (2 μg of ZrO$_2$ per ml).

Recommended procedure

Transfer various amounts of zirconium standard solution into 50-ml beakers. Add 0.2 ml of perchloric acid (1 + 1), evaporate to fumes, and cool. Add 15 ml of buffer solution, 3 ml of oxalic acid solution, 1 ml of cupferron solution and 1 ml of diphenylguanidine solution and mix. Measure the height of the oscillographic peak at a potential of -1.02 V *vs.* SCE (Fig. 1).

Determination of zirconium in ores

A 0.1000 or 0.2000 g sample is fused in an alumina crucible with 2–3 g of sodium peroxide at 650–700°, and the cooled melt is leached with about 100 ml of water. Then 20 mg of magnesium oxide (as carrier) are added, followed by
Fig. 1. Oscillographic peak of Zr complex at the dropping mercury electrode. Peak potential about -1.02 V. Scan-rate 0.25 V/sec. Zr concentration, μg/ml; 1, 0.0; 2, 0.0185; 3, 0.037; 4, 0.074; 5, 0.111; 6, 0.185.

10 ml of 50% triethanolamine solution, and the solution is boiled. After cooling, the precipitate is filtered off and washed twice with 1% sodium hydroxide solution and then with water. The precipitate is dissolved with hot $1N$ sulphuric acid, the solution being collected in a 50-ml standard flask and diluted to volume with $1N$ sulphuric acid. Then a 10-ml aliquot of this solution is transferred into a 60-ml separatory-funnel, and shaken for 1 min with 10 ml of 3% TNOA solution in benzene. The aqueous phase is removed, and the organic phase washed with 3–5 ml of $1N$ sulphuric acid. Then the organic phase is shaken for 1 min with 10 ml of $0.1M$ $HClO_4/1M$ $HCl/2M$ HNO_3 mixture to back-extract the zirconium. After phase separation the aqueous phase is transferred into a 50-ml beaker and evaporated to fumes of perchloric acid. The residue is cooled and the zirconium is determined as described in the recommended procedure.

RESULTS AND DISCUSSION

Choice of supporting electrolyte and reagents

Effect of pH. Figure 2 shows the effect of pH on the peak height. A pH of 5.7 was chosen, since it gives a pH tolerance of about ± 0.2, and good sensitivity. The concentration for the buffer was selected as the middle of the range that gave maximum peak height (Table 1).

Effect of oxalic acid. The peak was stabilized by the addition of oxalic acid to the mixture. A concentration of $1.2 \times 10^{-2}M$ was found to be optimal.

Effect of cupferron. The presence of a certain amount of cupferron is very important for prod-
Fig. 2. Effect of pH on the peak-height.

uction of the peak. A concentration of $2.2 \times 10^{-4}M$ was found to be optimal with regard to sensitivity and stability.

Effect of diphenylguanidine. The presence of the base up to a certain concentration increases the peak height remarkably, but the peak height is essentially constant when the diphenylguanidine concentration is between 8.3×10^{-5} and $2.0 \times 10^{-4}M$. A concentration of $1.0 \times 10^{-4}M$ is selected.

Under the optimum conditions, the calibration graph is linear over the range from 0 to 4 μg of Zr per ml, and the peak heights remain stable for 3 hr.

Interferences and their elimination

The influence of more than 30 ions was investigated. Tolerance limits for some cations in the determination of 4 μg of Zr are given in Table 2. Hydrochloric, sulphuric, perchloric and nitric acids and their anions do not interfere when present in $0.05M$ concentration (or even more), but more than about 3 mg of phosphoric acid increases the peak-height slightly. Ascorbic acid and triethanolamine do not interfere.

Hafnium gives a polarographic peak, but at the same potential the peak-height is only 10% of that of the zirconium peak, for equal weights of Hf and Zr.

The main interferences are from iron, titanium and fluoride ions, but zirconium can be separated from iron and fluoride by co-precipitation in alkaline solution with magnesium oxide in the presence of triethanolamine, and from titanium by extraction with tri-n-octylamine.

Fig. 3. Electrocapillary curves. Mercury column height 53 cm, temperature 11°, Zr $4.66 \times 10^{-8} M$. I, sodium acetate/acetic acid buffer; II, buffer plus cupferron; III, buffer + cupferron + oxalic acid + Zr + diphenylguanidine.

Zirconium has been extracted with tri-n-octylamine from $11M$ hydrochloric acid[3] and separated by paper chromatography with sulphuric acid as eluent, but the separation from titanium by these methods is not satisfactory.

It has been found that zirconium can be quantitatively extracted from $0.5-1.5N$ sulphuric acid by tri-n-octylamine (TNOA) and that titanium is not extracted. The mechanism of the extraction is

$$[R_3NH^+]_2 \cdot SO_{4(org)}^{2-} + [ZrO(SO_4)_2^{2-}]_{(aq)}$$

$$[R_3NH^+]_2 \cdot ZrO(SO_4)_{2(org)}^{2-} + SO_{4(aq)}^{2-}$$
where $R = CH_2(CH_2)_6CH_3$. Obviously, the equilibrium is shifted to the left by increase in sulphuric acid concentration, and $1N$ sulphuric acid is considered optimal for the extraction. Because hydrochloric acid and perchloric acid have a considerable effect on the paper chromatography of zirconium with sulphuric acid as eluent, these acids, separately and in combination, were tested as stripping agents. Nitric acid was also tested, and a combination of $0.1M$ $HClO_4/1M$ $HCl/2M$ HNO_3 was found empirically to give the best back-extraction. By means of this extraction system, 10 mg of Fe(III) and 2 mg of Ti(IV) can be eliminated efficiently. Hafnium accompanies the zirconium quantitatively.

Nature of the zirconium wave

No wave is observed for a solution of oxalic and diphenylguanidine at the peak potential of -1.02 V (vs. SCE) in the absence of zirconium and cupferron. On the basis of the following observations it is considered that the four components form a mixed-ligand complex, which is adsorbed on the mercury drop.

(i) The relationship between the height of the mercury column and the peak-height corresponds to the formula for an adsorption current:[5]

$$I_a = kh$$

(ii) The relative temperature coefficient of the peak-height for zirconium is $+4.7\%$/deg over the range $0-20°$. This value corresponds to an electrode
reaction with adsorption, and is clearly larger than that for a diffusion-controlled process. The peak-heights do not change in the range $25-45°$ and a negative temperature coefficient appears at temperatures above $45°$.

(iii) The electrocapillary curves shown in Fig. 3 indicate strong adsorption of the zirconium complex at a potential of about -1.02 V, corresponding to the oscillographic peak.

(iv) Adsorption was confirmed by the fact that a log-log plot of current vs. time had a slope greater than unity (1.125).

It is concluded that the zirconium peak is due to adsorption of the zirconium complex, with the cupferron component preferentially adsorbed on the surface of the mercury drop.

The composition of the product has been shown to be 1:2:1:1 Zr(IV)-oxalic acid-cupferron-diphenylguanidine, by the isomolar continuous-variations and slope-ratio methods. Ion-exchange tests show that the product is anionic and we conclude that its structure is
Analysis of ores

The results shown in Table 3 are in good agreement with those obtained by the X-ray fluorescence (XRF) method and with the certified values.

A STUDY OF THE REACTION OF N-CHLOROSUCCINIMIDE WITH INDOLES AND ITS ANALYTICAL APPLICATION

IMADUL ISLAM, D. D. MISRA, R. N. P. SINGH and J. P. SHARMA*
Department of Chemistry, University of Allahabad, Allahabad, India

Summary—The reaction of N-chlorosuccinimide with indole and few of its derivatives in acid medium has been studied. The purified products have been identified by TLC, elemental analysis and infrared studies, and a reaction mechanism is proposed on the basis of the results. The reaction proceeds smoothly and consistently, and can be used for microdetermination of indole and its derivatives.

The indole ring is found in many naturally occurring compounds, and recently some synthetic indole derivatives have been reported to possess antiparkinsonian activity.[1-3] Numerous methods have been proposed for titrimetric determination of indole and its derivatives, mainly based on use of brominating agents such as bromine,[4] N-bromoacetamide,[5] N-bromosuccinimide[6] and bromine monochloride.[7] Decomposition of the reagents and loss of bromine during the reaction are the chief disadvantages of these methods.[8] Spectrophotometric,[8,9] polarographic,[10] gas-chromatographic[11] and fluorimetric[12] methods have also been described. We have found that N-chlorosuccinimide, which is much more stable than N-bromosuccinimide or N-bromoacetamide,[13] can conveniently be used for determination of indoles.

EXPERIMENTAL

Reagent

N-Chlorosuccinimide solution, 0.02M. Dissolve 0.2670 g of N-chlorosuccinimide in the minimum amount of warm distilled water. Dilute to 100 ml with cold water and standardize iodometrically.[14]

The reaction product was isolated by dissolving 100 mg of indole in about 25 ml of glacial acetic acid, slowly adding 0.1M N-chlorosuccinimide with constant stirring till a permanent brown colour persisted, letting stand for 4 hr, filtering off the brown product, washing it with water and air-drying it. The dried compound was recrystallized from chloroform to yield shining brown needles (m.p. 197°). Thin-layer chromatography of this compound on silica gel G with chloroform–96% acetic acid (95:5 v/v) showed a single spot. Analysis showed the presence of 2 atoms of chlorine in the product molecule. The infrared spectrum revealed intense absorption bands for C=O (1630 cm^{-1}) and C–Cl (730 cm^{-1}).

The products from indole derivatives gave similar results except for carbazole, for which the product molecule still contained two chlorine atoms but had no C=O absorption band in its infrared spectrum.

General procedure

Take an accurately weighed sample (2–8 mg) in a 100-ml iodine flask (an aliquot of solution containing 2–8 mg of the indole can also be used). Add 2 ml of glacial acetic acid and 15 ml of 0.02M N-chlorosuccinimide, stopper the flask and shake it well. Let stand for 25 min at room temperature, then add 5 ml of 5% potassium iodide solution and titrate the liberated iodine with 0.04M sodium thiosulphate, using 2% starch as indicator. Run a blank with the same volume of N-chlorosuccinimide under identical conditions.

The amount of indole compound (mg) is $MW(B-A)/2n$ where B and A are the volumes (ml) of thiosulphate (molarity M) needed for the blank and sample respectively, and n is the molar reacting ratio of N-chlorosuccinimide to sample compound (of molecular weight W).

RESULTS AND DISCUSSION

N-Chlorosuccinimide is a mild oxidizing and chlorinating reagent. It has been suggested[15] that the reactive species of N-chlorosuccinimide (NCS) is the protonated molecule NCSH$^+$, which gives rise to the electrophilic chloronium ion:

$$NCSH^+ \rightarrow succinimide + Cl^+$$

Investigation of the reaction stoichiometry by application of the method to samples of known purity showed that the reacting ratio was three moles of N-chlorosuccinimide per mole of indole compound, except for carbazole, for which the ratio was only 2:1.

The π-electron densities[16] on the indole nucleus are shown below and indicate that position 3 is the most susceptible to electrophilic attack. If, however, position 3 is already occupied, position 2 is preferentially attacked by electrophiles, and then position 5.
Scheme 1a.

On the basis of the observed stoichiometry, chlorine content of the reaction products, and the infrared spectra, the reaction can be explained as

---

*To whom correspondence should be addressed.
Scheme 1b
Scheme 2
Scheme 3

given in Schemes 1 (for indole) and 2 (for indole 3-derivatives except carbazole).

In the case of indole, electrophilic substitution of chlorine atoms takes place first at position 3, and then at position 2. The chlorine atom at position 2 is the more likely to be hydrolysed, and this is in keeping with the well known activated nucleophilic substitution in aromatic compounds. Intermediate **IV** tautomerizes to **V**, which reacts with another protonated N-chlorosuccinimide molecule to give the final product 3,5-dichloroxindole. Chlorination of position 6 in preference to position 5 is ruled out by the combined electron-withdrawing effect of the –NH and >C=O groups on the benzene ring further lowering the electron density at position 6.

Since position 3 is already occupied in the case of indole 3-derivatives (Scheme 2), the first step is the chlorination of position 2 followed by hydrolysis and tautomerization. Two chlorine atoms are then introduced at positions 3 and 5 by electrophilic attack by the reagent, giving a 3,5-dichloroxindole-3-derivative (**XII**) as the final product.

The electron densities of the carbazole molecule[17] (**XIII**) indicate that electrophilic substitution would occur preferentially at positions 3 and 6. Since the stoichiometry of the reaction with N-chlorosuccinimide is 1:2, the reaction may be formulated as shown in Scheme 3.

The proposed method has been applied to determination of indole and some of its derivatives, and the results are presented in Table 1. The maximum error is $\pm 1.2\%$ and the relative standard deviation 0.8%.

Variation of the acetic acid concentration does not affect the method. The reaction with indole derivatives is not instantaneous, and is only about 50% complete when titrated immediately after addition of the N-chlorosuccinimide. The rate of reaction is independent of the concentration of the reagent. The lower determination limit for all the samples tested is about 1 mg; erroneous results are obtained with smaller amounts.

PURIFICATION OF XYLENOL ORANGE BY PREPARATIVE PAPER CHROMATOGRAPHY, AND EXAMINATION OF ITS ZIRCONIUM COMPLEX

V. Michaylova

Department of Analytical Chemistry, University of Sofia, 1126 Sofia, Bulgaria

L. Šůcha✠, and M. Suchánek

Department of Analytical Chemistry, Institute of Chemical Technology, 16628 Prague 6, Czechoslovakia

Summary—Preparative paper chromatography is proposed as a suitable method for purification of Xylenol Orange (XO). The last three dissociation constants of pure XO have been determined with the aid of the program SPEKTFOT, the values found being $pK_9 = 12.34$; $pK_8 = 10.66$; $pK_7 = 6.69$ ($0.1M$ KNO$_3$, $20 \pm 0.5°$). The complexation of zirconium with the purified reagent has been studied and the co-existence of ML and M$_2$L complexes proved by use of the program DALSFEK. The following conditional stability constants of the complexes and their molar absorptivities were computed: $\log \beta'_{ML}$ 4.58; $\log \beta'_{M_2L}$ 11.59; ϵ_{ML} 2.00×10^4; ϵ_{M_2L} 9.40×10^4 1.mole^{-1}.cm^{-1} at 550 nm.

The modern tendency to use group reagents in spectrophotometry requires knowledge of their properties, equilibria in solution and complex formation with various ions. There is thus a need for high-purity reagents so that reliable values can be obtained for various constants. Because of the excellent properties of Xylenol Orange (XO) as a group reagent[1] it seemed to be worth while to study its purification and equilibria in solution.

The present study deals with the purification of XO by preparative chromatography. The pure XO obtained was used for studying its equilibria in solution and its complex formation with zirconium.

EXPERIMENTAL

Reagents

Lachema Xylenol Orange was used in the purification procedure. The concentration of XO was determined by spectrophotometric microtitration with $3.00 \times 10^{-3}M$ zinc dipyridyl thiocyanate at 580 nm and pH 6.10 (acetate buffer). The zinc dipyridyl thiocyanate was prepared as described by Buděšínský[2] and used as a standard. A weighed amount was dissolved in a small volume of $0.1M$ hydrochloric acid and diluted to standard volume.

ZrOCl$_2$.8H$_2$O (Merck, *p.a.*) was used to prepare $2 \times 10^{-3}M$ zirconium solution in $2M$ perchloric acid, which was stable for a month. It was standardized by addition of excess of EDTA and back-titration with bismuth nitrate (XO as indicator).

Whatman No. 3 chromatographic paper, washed first with alkaline $10^{-3}M$ EDTA to remove metal ions, then many times with demineralized water, was used for the paper chromatography.

All solutions were prepared from reagent-grade substances with demineralized water.

Apparatus

Absorption spectra were obtained with a Zeiss Specord UV–Vis Spectrophotometer. Spectrophotometric mea-surements were performed with a Zeiss VSU-2P spectrophotometer. A Radelkis OP-201/2 pH-meter with an OP-8071-1/A electrode was used for checking the pH of solutions.

Purification of XO

According to some authors[3,4] the earlier column and thin-layer chromatography methods for purification of XO[5-8] are complex and time-consuming procedures which do not lead to good results. Ion-exchange chromatography has been claimed to give better results.[3] Our experiments with gel-chromatography[9] and column chromatography with Whatman CF 11 cellulose powder failed to give satisfactory results, and now we propose preparative paper chromatography as more suitable. The XO was purified in two ways. In one, XO was first separated by extraction from the Semi-Xylenol Orange (SXO) and Cresol Red (CR) present in the commercial sample. In the other, this step was omitted. The system consisting of $0.1M$ hydrochloric acid and n-butanol–benzene (1:7 v/v) saturated with $0.1M$ hydrochloric acid, used in 1:1 v/v ratio, was used for the separation of CR from XO and SXO. XO and SXO were then separated by partition between n-butanol–benzene (3:1 v/v) and $0.1M$ hydrochloric acid in 1:1 volume ratio.[10] The aqueous hydrochloric acid solution of XO was evaporated under reduced pressure and the XO extracted from the solid residue with absolute ethanol to separate it from the sodium chloride present. The alcohol was evaporated and the purity of the XO was checked by means of paper chromatography.[5,6,9]

Paper chromatography

Descending development was used, with a 4:1:2 v/v n-butanol–acetic acid–water mixture as developing solvent. The mixture was prepared just before use because of the adverse influence of the n-butyl acetate formed.[11] The chromatographic paper strips (5 × 55 cm) were kept for 4–5 hr in the 20 × 30 × 65 cm chromatographic tank for saturation with the solvent vapours. Then 5, 10 or 20 μl of solution containing 5 μg of sample per μl were spotted by micropipette on the starting line and the strips were returned to the tank and developed for 14–16 hr. They were then taken out and dried at room temperature.

Preparative paper chromatography

This method permits easy separation of up to 0.8 mg of sample, the amount used depending on the initial purity. There is a sufficiently sharp separation, into a yellow spot of XO, followed by two spots of unknown compounds (UC$_1$ and UC$_2$) and that of SXO. The mean R_f values were 0.23 for XO, 0.28 for UC$_1$, 0.31 for UC$_2$ and 0.35 for SXO.

A chromatographic test of the XO isolated by extraction showed the presence of UC$_1$, UC$_2$ and small amounts of SXO. This XO was purified chromatographically: about 9 mg of it in acidic form were dissolved in 0.4 ml of 0.1M sodium hydroxide and the solution was uniformly spotted onto six 7 × 25 cm paper strips with a 20-μl micropipette, two spots on each strip, and the strips were developed for 15–20 hr as described above. The strips were taken out and dried in air until the solvent smell was completely removed. The spots of XO obtained were used for preparation of a pure XO solution: they were cut out and eluted with water (~15 ml for each pair of spots); the solution was filtered through a Schleicher & Schüll "white label" filter and its concentration was checked by spectrophotometric titration with ZnPy$_2$(SCN)$_2$ at pH 6 and 580 nm, the predominant complex being ZnXO.[3,6,12] The concentration of pure XO solution was also determined by measuring its absorbance at 435 nm and pH 4–5, ϵ_{XO} being taken as 2.85 × 10^4 l.mole^{-1}.cm^{-1}.

The purity of XO was also checked by a chromatographic test. Two spots, those of XO and UC$_1$, were observed. The spot of UC$_1$ always appeared together with the spot of XO even after the latter had been submitted to chromatography 3 or 4 times. It is probable that UC$_1$ is a decomposition product, formed on passing the developing solvent through the spot of pure XO.

The following spectrophotometric data were found for the purified XO: $\epsilon_{XO} = 2.80 \times 10^4$ l.mole^{-1}.cm^{-1} (430 nm, pH 4–5) and $\epsilon_{Zn_2XO} = 6.90 \times 10^4$ l.mole^{-1}.cm^{-1} (570 nm, pH 5.65), these values being similar to those already reported.[3]

The Lachema commercial XO was purified directly by the same procedure without preliminary isolation of the reagent by extraction. In this case up to 0.5 mg of sample was treated and a more intense SXO spot was observed. The results were compared with those obtained by extraction followed by chromatography. A similar degree of purification was achieved, as well as the same spectrophotometric data.

These results confirm the suitability of the preparative paper chromatography for purification purposes. The direct purification of commercial XO can be recommended for practical use.

Determination of zirconium

Place enough 2M perchloric acid to give a final total acidity of 0.1–0.5M in a 25-ml standard flask. Add 5.00 ml of ~2 × 10^{-5}M XO and 0.20–2.00 ml of the test solution (~10^{-4}M Zr, freshly prepared), dilute to volume and mix. After 15 min, read the absorbance in a 3-cm cuvette at 550 nm with water as a reference. In a similar way prepare a calibration graph covering the zirconium concentration range 0.16–0.68 μg/ml.
Fig. 1. Absorption spectra of Xylenol Orange at different acidities. $C_{XO} = 2.72 \times 10^{-6}M$, $\mu = 0.1$, 5-cm cells, $vs.$ water. pH: 1, 1.70; 2, 4.05; 3, 6.03; 4, 6.84; 5, 7.16; 6, 9.05; 7, 9.98; 8, 10.60; 9, 11.0; 10, 12.40; 11, 13.85.

RESULTS AND DISCUSSION

Solution equilibria of Xylenol Orange

The XO solution was prepared by elution of the chromatographic spots with water. Although this had been shown spectrophotometrically to be stable for several days, a freshly prepared solution was used for the investigations. The absorption spectra of the XO solution showed the presence of different ionic forms of the reagent in acidic and basic media, Fig. 1. The last three dissociation constants of XO were determined by applying the program SPEKTFOT[13] to the curves for A $vs.$ pH [$\mu = 0.1M$ (KNO$_3$), temperature 20° ± 0.5°]. The results given in Table 1 are similar to data already published.[3,6]

COMPLEX FORMATION OF ZIRCONIUM WITH XYLENOL ORANGE

The reaction of Zr(IV) with XO was studied twenty years ago[14–16] but more recent investigations with purified reagent have provided more precise data.[17]

Our studies confirm that the Zr–XO reaction proceeds in strongly acid medium. The absorption spectra presented in Fig. 2 show that the equilibria are complicated and depend on the concentration ratio of metal ion and reagent. With a significant excess of metal ions present a violet complex ($\lambda_{max} = 550$ nm) is formed.

Study of the reaction conditions

To prevent hydrolysis and polymerization of the zirconium a strong acid medium and a low concentration of Zr(IV) were used.[18] The optimal acidity was found to be $0.1–0.5M$ perchloric acid, the absorbance then being constant.

The time needed for colour development and the stability of the absorbance were determined for different concentrations of the reagents in $0.5M$ perchloric acid. It was found that the colour developed immediately and was stable for several days in solutions containing excess of metal. With XO in excess the colour developed in 10–15 min after mixing of the reagents and was also stable for several days.

The influence of temperature on the reaction rate and on the polymerization equilibria[17] of zirconium were also studied. For this purpose two solutions, (a) $2.11 \times 10^{-5}M$ Zr(IV)/$1.60 \times 10^{-6}M$ XO and (b) $1.05 \times 10^{-6}M$ Zr(IV)/$2.70 \times 10^{-6}M$ XO, both in $0.5M$ perchloric acid, were investigated.

Aliquots of $2.11 \times 10^{-4}M$ zirconium solution in $2M$ perchloric acid [prepared daily from $2.11 \times 10^{-3}M$ Zr(IV)] and the corresponding quantity of perchloric acid needed were placed in 25-ml standard flasks. The flasks were heated for 20 min in a water-bath (at $\sim 95°$) then taken out and cooled to room temperature. Corresponding aliquots of XO solution $(\sim 10^{-5}M)$ were added and the solutions were diluted somewhat, heated once again for 30 min, cooled and diluted to volume with water. The absorbances at 550 nm were measured with water as reference.

For comparison, the absorbances of solutions prepared at room temperature were also measured. The differences between corresponding absorbance values were within the limits of the photometric error. On the basis of these results it was concluded that no polymerization of Zr(IV) occurs under these conditions, and all later experiments were performed at room temperature.

Stability constants

The formation of Zr(IV) complexes with Xylenol Orange was investigated by the mole-ratio method with $1.96 \times 10^{-6}M$ XO, $0–4.22 \times 10^{-5}M$ Zr(IV) and $0.48M$ perchloric acid. The data were analysed by the program DALSFEK.[12] The results obtained show the co-existence of two complexes, ML and M_2L. The conditional stability constants of these complexes and their molar absorptivities were found to be: log $\beta'_{ML} = 4.58$; log $\beta'_{M_2L} = 11.59$; $\epsilon_{M1} = 2 \times 10^4$ and $\epsilon_{M_2L} = 9.4 \times 10^4$ $1.mole^{-1}.cm^{-1}$ at 550 nm.

SPECTROPHOTOMETRIC DETERMINATION OF ZIRCONIUM

Because of the complicated equilibrium between Zr(IV) and XO, Beer's law is valid only at certain wavelengths, $e.g.$, at 530 nm for the zirconium concentration range $0.16–0.58$ $\mu g/ml$ $(\epsilon = 2.14 \times 10^4$ $1.mole^{-1}.cm^{-1})$. It is also valid at wavelengths close to 530 nm. The linear part of the calibration curve for measurement at 530 nm (Zr $0.16–0.68$ $\mu g/ml$) might be used for the determination of small amounts of zirconium, since the sensitivity is higher $(\epsilon = 4.14 \times 10^4$ $1.mole^{-1}$ $.cm^{-1})$ and the absorbance of XO is negligibly small.

The tolerance limits for other ions in determination of 10 μg of zirconium are: U(VI) 5.0 mg, Mo(VI) 0.5 mg, Th 4.0 mg, Ga 0.7 mg, Fe(II) 3.5 mg, PO_4^{3-} 0.8 mg, Fe(III) 50 μg, Sn(II) 50 μg, Bi 10 μg. Aluminium and indium do not interfere but fluoride and oxalate should be absent.

SPECTROPHOTOMETRIC DETERMINATION OF HALOGENATED 8-HYDROXYQUINOLINE DERIVATIVES

F. BELAL*

Department of Analytical Chemistry, Faculty of Pharmacy, University of Mansoura, Mansoura, Egypt

Summary—A spectrophotometric method is proposed for the determination of 8-hydroxyquinoline and three of its iodinated derivatives: 5-chloro-7-iodo-8-hydroxyquinoline (clioquinol), 5,7-di-iodo-8-hydroxyquinoline (iodoquinol) and 8-hydroxy-7-iodo-quinolone-5-sulphonic acid (chinoform). The suggested method depends on the reaction with 4-aminoantipyrine in the presence of an alkaline oxidizing agent. A red antipyrine dye with an absorption peak at 500 nm is produced in all cases. The reacting ratio has been determined and a reaction mechanism is presented. The proposed method can be applied to the analysis of pharmaceutical preparations containing the compounds studied, and the results obtained compare favourably with those obtained with the standard methods.

The halogenated derivatives of 8-hydroxyquinoline have been widely used as anti-amoebic compounds, both in the treatment of amoebic dysentry and intestinal amoebiasis, and as topical anti-infectives, because of their very low toxicity. Several methods are available in the literature for the determination of the halogenated derivatives of 8-hydroxyquinoline, in the pure state and in pharmaceutical preparations.

The gravimetric and titrimetric methods include precipitation with cadmium iodide in acetone and weighing the cadmium complex formed,[1] or precipitation with mercuric acetate in acetic acid and weighing the mercury complex.[2] The total halogen content can be determined by fusion with sodium carbonate and titration by the Volhard method, and the iodide by iodate titration.[3] Soliman[4] described an alternative method involving refluxing the compounds with 15% sodium hydroxide solution and zinc powder, followed by titration of the halide(s) with standard iodate solution. These compounds have also been determined by precipitation of the copper complex, and iodometric determination of the copper content.[5] Fusion with potassium carbonate and titration with *N*-bromosuccinimide has also been reported.[6] In non-aqueous media, these compounds can be determined by titration with sodium methoxide, in dimethylformamide[7] or pyridine[8] as solvent.

Colorimetric methods include reaction with iron-(III),[9] copper sulphate,[10,11] sodium nitrite[12] and alcoholic potassium hydroxide.[13]

Other techniques used include polarography,[14] X-ray spectrography[15] and gas–liquid chromatography.[16]

In this paper, a simple and more direct analytical method that is applicable to the determination of low concentrations of halogenated 8-hydroxyquinoline derivatives and their formulations is reported; the method has proved successful for determining accurately the compounds either alone or mixed with the ingredients commonly encountered in dosage forms.

EXPERIMENTAL

Reagents

4-Aminoantipyrine, 2% solution in methanol.
Sodium carbonate, 1% solution in water.
Potassium hexacyanoferrate(III), 4% solution in water.

Materials

Pure drug samples were obtained as gifts from various manufacturers, and used without further purification. Pharmaceutical preparations containing the compounds studied were obtained from commercial sources in the Egyptian market.

Sample preparation

Stock 1.0-mg/ml solutions of each of the compounds studied were prepared in appropriate solvents (Table 1).

Calibration graph

Aliquots (1 ml) of standard solutions of the drug, covering the calibration range (Table 1), were transferred to 25-ml standard flasks, Then 1.5 ml of sodium carbonate solution, 0.6 ml of 4-aminoantipyrine solution, and 1 ml of potassium hexacyanoferrate(III) solution were added to each, in that order, and the solutions diluted to volume with water. The absorbances at 500 nm were measured against a reagent blank and plotted against the final solution concentrations.

Assay procedure for dosage forms

Tablets. Twenty tablets were weighed and pulverized, and a quantity of the powder equivalent to 50 mg of the pure drug was accurately weighed and transferred to a 100-ml beaker and dissolved in the appropriate solvent (Table 1) by heating on a water-bath. The solution was filtered into a 100-ml standard flask and diluted to the mark with the same solvent, then analysed by the calibration procedure.

Syrups. A volume of the suspension equivalent to about 150 mg of the active ingredient was accurately measured and centrifuged at 5000 rpm for 30 min. The clear supernatant liquid was discarded and the residue shaken with a 40-ml portion of distilled water until it was completely in suspension. This mixture was centrifuged as before for 30 min

*Present address: 2360 West Broad Street, Apt. #133, Athens, Georgia 30606, U.S.A.

and the clear supernatant liquid discarded. The washing and centrifugation were repeated, with a further 40-ml portion of water. The residue was transferred completely into a 250-ml standard flask with dimethylformamide (DMF) and dissolved by heating on a water-bath. The solution was diluted to volume with DMF, and the determination completed as already described.

Ointments. A composite sample was prepared by mixing the contents of five containers and a sample equivalent to 100 mg of the drug was accurately weighed into a 100-ml beaker, dissolved in 80 ml of a hot mixture of 4:1 DMF–water mixture and heated on a water-bath for 5 min. The solution was cooled in ice for 10 min, allowed to warm to room temperature, diluted to volume in a 100-ml standard flask with the DMF–water mixture, mixed and filtered. The determination was completed as before.

DISCUSSION

8-Hydroxyquinoline and its derivatives are phenolic compounds, and can therefore react with 4-aminoantipyrine in the presence of an alkaline oxidizing agent to form an antipyrine dye;[17] the product has maximum absorption at 500 nm.

It is reported that in this reaction of 4-aminoantipyrine with phenolic compounds, a quinonoid structure of the following type is formed:
This necessitates the position *para* to the phenol group being either free or substituted with a group that can be expelled during the reaction. In the case of the halogenated 8-hydroxyquinoline derivatives, an iodine atom in the *para* position is difficult to expel under the reaction conditions described. An alternative reaction pathway is suggested in the scheme below (X and Y substituents at positions 5 and 7 respectively), and is substantiated by the fact that 8-hydroxyquinoline (with the *para* position unsubstituted) and the other members of the group have nearly identical molar absorptivities (Table 1), indicating that the chromophore formed is the same in all cases.

To study the reaction further, the reacting ratio of 4-aminoantipyrine and 8-hydroxyquinoline or clioquinol (as an example of a *para*-substituted compound) was studied by the continuous-variation method[18] and found to be 1:1 in both cases.

Table 1 summarizes the data for the reaction between 4-aminoantipyrine and the compounds studied. The time listed in the table is critical. After the specified time, precipitation will occur. The molar absorptivities are the average of 10 separate determinations.

Table 2 shows the analytical results obtained by means of the proposed method and the compendial
ones.[19–21] There was no significant difference between the results obtained by the two methods.

In Table 3 the results obtained for clioquinol, iodoquinol and chinoform in pharmaceutical preparations are given. Tablet excipients, such as starch, gelatine, talc, soluble saccharine and silica do not interfere. Substances likely to be encountered in clioquinol or iodoquinol suspensions or ointments, such as sulphaguanidine, bismuth subcarbonate, light kaolin, sodium citrate, sucrose, carboxymethylcellulose, liquid extract of belladonna, hydrocortisone or prednisolone, also do not interfere. The recovery of clioquinol from commercial suspensions was determined by adding a known amount of the pure drug to suspensions already analysed for clioquinol. Representative results are given in Table 4. These control experiments were conducted in order to differentiate between experimental error and errors due to the interaction of other constituents of the system, or errors resulting from the bulk production.

The method developed in this investigation has the advantages of being simple and applicable over a convenient range of concentrations to the determination of halogenated 8-hydroxyquinoline derivatives in the pure state or in pharmaceutical formulations. In addition, it requires no special skill. A spectrophotometer is the only instrumentation required, and this is an advantage in developing and underdeveloped countries, where preparations containing halogenated 8-hydroxyquinoline derivatives are most needed.

Table 1. Collective data for the reaction of 4-aminoantipyrine with halogenated derivatives of 8-hydroxyquinoline

Compound	Solvent	Molar absorptivity, $l.mol^{-1}.cm^{-1}$	Range of conc., $\mu g/ml$	Stability time min
8-Hydroxyquinoline	Methanol	1.20×10^4	2–24	15
Clioquinol	DMF	1.22×10^4	2–20	10
Iodoquinol	Hot DMF	1.29×10^4	4–32	5
Chinoform	Hot water	1.23×10^4	2–20	5

Table 2. Determination of halogenated 8-hydroxyquinoline derivatives by the proposed and official methods

	Recovery, %	
Compound	Proposed method	Official or other method
8-Hydroxyquinoline	100.3	99.7[22]
	(0.4)	(0.5)
Clioquinol	99.8	99.3[19]
	(0.5)	(0.6)
Iodoquinol	98.9	99.1[20]
	(0.3)	(0.4)
Chinoform	99.1	100.4[21]
	(0.5)	(0.5)

The results are the averages of 10 separate determinations. The figures in brackets are the coefficients of variation.

Table 3. Determination of halogenated 8-hydroxyquinoline derivatives in synthetic and commercial preparations

	Recovery, %	
Preparation	Proposed method	Official method
Enterovioform tablets	98.3	99.1
(200 mg of clioquinol per tablet)	(0.5)	(0.5)
Parameb tablets	101.3	101.0
(250 mg of iodoquinol per tablet)	(0.3)	(0.5)
Nimarol suspension	104.5	105.0
(3% clioquinol suspension)	(0.4)	(0.6)
Vioderm ointment	103.2	102.9
(3% clioquinol ointment)	(0.4)	(0.4)
Chinoform tablets	100.6	100.2
(prepared tablets containing 200 mg per tablet)	(0.4)	(0.2)

The results are the averages of 6 separate determinations. The figures in brackets are the coefficients of variation.

Table 4. Recovery of iodoquinol added to 5 ml of commercial suspensions nominally containing 125 mg of the drug

Added amount of drug, mg	Total recovered, mg	Recovery of added drug, %
0.0	131.2	
100.0	231.0	99.8
0.0	130.5	
200	331.0	100.3

LETTER TO THE EDITOR

THE COLOURS OF CO-ORDINATION COMPOUNDS: METHODS OF CLASSIFICATION

Sir,

The colours of compounds and, in particular, metal complexes are an important parameter and should be accurately reported. However, the literature abounds with colour names that are ambiguous, and thus meaningless to other workers. This arises because the names given to the colours of compounds are arbitrarily chosen by individual workers, who assign a name to the colour of an object by comparing it with their colour memory. Most people have a poorly developed colour memory. If an observer has difficulty in recalling colours, it will be even more difficult for him to convey a recalled colour impression to another person.[1]

It is possible to describe the colour of solids and liquids accurately and simply by reference to a colour order system, a number of which have been proposed. The most popular is that of Munsell.[2] An alternative that has the advantages of cheapness and simplicity is the Methuen system.[1] Some interconversions between different systems have been reported.[1,3,4]

Three parameters are required to describe a particular colour completely:

(a) hue - that property of visual perception by which different regions of the spectrum are distinguised and named, e.g., red, yellow;

(b) saturation - the intensity of a hue or its degree of freedom from admixture with white;

(c) lightness - the variation of visual perception along the continuum between white and black.

In the Munsell system these parameters are referred to as hue, chroma and value respectively.

Although colour order systems have been used extensively in fields such as biology, pharmacology and geology, to our knowledge there has been no extension of these methods to co-ordination compounds. We have therefore classified a number of complexes by both the Methuen and Munsell colour systems (see Table). From the Munsell notation a systematic name that unequivocally describes the colour of the complex can be derived by means of the ISCC-NBS* method of designating colour.[3]

Whenever possible the complexes were assessed in the form in which they were prepared. Only in the case of very intense colours was it necessary to grind the crystals to bring about a reduction in saturation. For complexes having colours with a low degree of lightness [e.g., $Cr(pd)_3$] grinding also results in a slight change in hue, which in turn may give rise to a change in the colour name.

---

* Inter Society Colour Council - National Bureau of Standards

Table 1. Colour classification and systematic colour names of some co-ordination compounds

Compound*	Reported colour	Treatment†	Colour notation Methuen[1]	Colour notation Munsell[2]	Colour name Methuen[1]	Colour name ISCC-NBS[3]
$[Co(en)_3]I_3 \cdot H_2O$	deep orange[5]	P	5A 8	7.5YR 7.5/>15	deep orange	vivid orange yellow
$K_2Cr_2O_7$	red,[6] orange red[7]	P	7A8	1.5YR 6/15	reddish orange	vivid reddish orange
$Na_2[Fe(NO)(CN)_5] \cdot 2H_2O$	ruby red[7]	G_2	7D6	1.5YR 5/5.5	light brown	greyish reddish orange
K_2PtCl_4	red brown[6]	P	8D8	10R 4/8	reddish brown	dark reddish orange
		G_2	8C6.5	10R 5/8	brownish red	moderate reddish orange
$Cr(pd)_3$	red violet[8]	G_2	11F7	1R 2/4	violet brown	dark purplish red
		G_3	11E4	5.5RP 4/3	violet brown	greyish purple
trans- $K[Co(ox)_2(py)_2] \cdot 3H_2O$ pink[9]		P	15A4.5	6.5P 7/8	light lilac	light purple
$Co(py)_2Cl_2$ α form	violet[10]	P	16A6	5P 5.5/11	reddish violet	strong purple
β form	deep blue	G_1	20A8	7.5PB 4/17	vivid blue	vivid blue
$Cu(pd)_2$	light blue[6,11]	P	21D5	6PB 4.5/6.5	greyish blue (dull blue)	moderate blue

* en = ethylenediamine; pd = 2,4-pentanedione (acetylacetonate); py = pyridine.

† p = assessed as prepared or obtained; G_1 = coarse grinding; G_2 = medium grinding; G_3 = fine grinding.

This method of colour classification would be of greatest utility for complexes with very dark colours (<u>i.e.</u>, low degree of lightness) and for those of metal ions which form a large number of complexes with similar colours [<u>e.g.</u>, Cu(II), Rh(III)].

Résumé—L'oxydation vanadique de dérivés hétérocycliques oxygénés a montré la réactivité de cette structure à l'égard de l'ion vanadate. L'oxydation de la khelline nous a permis d'obtenir une méthode sensible de dosage de ce produit, puisque la consommation de réactif oxydant est de 16 moles par mole de produit. Dans le milieu réactionnel ont été isolées des quantités importantes d'acide furanne dicarboxylique-2,3. Cette méthode d'oxydation est utilisable à des fins préparatives pour obtenir ce produit.

L'étude de l'oxydation vanadique de dérivés hétérocycliques oxygénés tels que le chromanol-4 et la chromanone-4 montre[1] la réactivité de cette structure, mais aussi la stabilité de la chromone formée au cours de la réaction. Des études précédentes ont d'autre part permis de constater que la présence de groupements éther–oxyde de phénol sur un cycle aromatique entraine une fragilité plus grande de la molécule vis à vis de cet oxydant.[2]

La khelline, furanochromone naturelle[3,4] utilisée pour ses propriétés thérapeutiques, présente de tels groupements. Aussi, avons-nous envisagé son oxydation qui est intéressante tant du point de vue fondamental que pour ses éventuelles applications analytiques.

Khelline
PARTIE EXPERIMENTALE

Réactif

La solution sulfovanadique (0,1*M*)[4] présente une concentration finale en acide sulfurique voisine de 0,72*M* et est étalonnée par titrage avec une solution de sulfate de fer(II) et d'ammonium.

Mode opératoire

Une prise d'essai de 25 mg de khelline soit 96 μmoles, est introduite dans une fiole conique rodée de 100 ml; 30 ml de la solution de pentoxyde de vanadium sont ensuite ajoutés ainsi que 10 ml d'acide sulfurique 2,5*M* et 10 ml d'acide sulfurique 8*M*. La fiole est munie d'un réfrigérant à reflux, l'oxydation est réalisée au bain marie bouillant. Au cours de la réaction, le vanadium(V) en excès est dosé par une solution de sulfate de fer(II) et d'ammonium 0,3*M* avec une indication potentiométrique.

Isolement et dosage de composés au cours de l'oxydation vanadique

Les quantités de dioxyde de carbone libérées au cours de l'oxydation ont été déterminées par la technique de Chaigneau.[5] L'isolement du formaldéhyde est réalisé par entraînement à la vapeur d'eau dans un appareil de Parnas et Wagner. L'identification et le dosage sont obtenus par formation d'une déhydrolutidine selon la méthode de Hantzch.[6]

Les acides formique et acétique sont isolés après distillation du milieu réactionnel. Ils ont été identifiés par chromatographie sur couche mince et dosés par chromatographie en phase liquide après réaction avec une nitrocoumarine.[7,8] Les résultats ont été comparés avec ceux obtenus sur des solutions étalons d'acide formique et d'acide acétique en solution sulfovanadique, réduite préalablement par du sulfate de fer(II) et d'ammonium.

Isolement, identification et dosage de l'acide furanne dicarboxylique-2,3

Par extraction éthérée du milieu réactionnel, est isolée une substance jaunâtre de caractère acide. Le point de fusion de ce produit est de 228°. Les résultats expérimentaux de l'analyse élémentaire sont conformes aux valeurs calculées pour un acide furanne dicarboxylique: calculé C 46,25%, H 2,56%; trouvé C 46,3%, H 2,7%. Le dosage titrimétrique en milieu aqueux de cet acide par la soude 0,1*M* permet de déterminer deux pK_A (2,40 et 7,35) concordant avec des travaux antérieurs.[9]

Le spectre de résonance magnétique nucléaire du proton à 60 MHz d'une solution dans le diméthyl sulfoxyde-*d*6, met en évidence deux protons à 6,9 et 8 ppm (*a* et *b*) sous forme de doublets. Le proton *b* est légèrement plus déblindé que le proton équivalent de l'acide furanne-3 monocarboxylique.[10] Le singulet à 11,1 ppm correspond d'après l'intégration aux deux protons acides (*c* et *d*).

Le spectre de résonance magnétique nucléaire du carbone-13 dans le chloroforme deutérié permet de constater que les carbones 4 et 5 se distinguent des carbones quaternaires, indépendamment des spectres "of resonance", par l'effet Overhauser qui n'est que partiel dans le cas des carbones quaternaires. Les résonances de ces derniers ont des intensités faibles, par rapport à celles des carbonyles. Les attributions proposées sont fondées sur les effets en α et β de la substitution par un oxygène de carbones insaturés.[11]

L'identification des carbonyles doit tenir compte de l'effet mésomère de l'oxygène furannique. Celui-ci entraîne une résonance à champs relativement élevés comme le montre l'exemple de l'ester méthylique de l'acide furanne carboxylique-2 où l'on observe un déplacement chimique de $\delta = 159$ ppm pour le carbonyle.[12]

En outre, la disubstitution *ortho* crée un effet stérique supplémentaire responsable lui aussi d'un déplacement des résonances vers les champs élevés.
Le spectre infra-rouge du produit isolé est voisin de celui de l'acide furanne carboxylique-3. A 3100 et 3050 cm^{-1}, on peut observer deux bandes dues à la vibration de valence de la liaison carbone–hydrogène du noyau furanne. A 1640 cm^{-1}, on observe une bande double qui peut être attribuée à la fonction carboxyle, cette bande est légèrement déplacée par rapport à celle de l'acide furanne carboxylique-3 qui se trouve à 1670 cm^{-1}.[13] Ce déplacement vers des nombres d'ondes plus petits est dû probablement à la présence d'un système conjugué de deux carbonyles. La présence du deuxième carboxyle augmente d'ailleurs comme cela est prévisible l'intensité de la bande à 1610 cm^{-1} (bande de la liaison carbone–carbone du cycle furannique).[14]

Nous avons étudié le spectre de masse de l'ester diméthylique, obtenu après méthylation au diazométhane[15] et séparation par chromatographie en phase gazeuse.

Le spectre obtenu est voisin de celui de l'ester diméthylique de l'acide furanne dicarboxylique-2,5.[16] Les différences obtenues à la fragmentation peuvent être expliquées par la présence du deuxième carboxyle en 3 au lieu de 5. Les principaux pics observés et leur abondance relative sont indiqués dans le tableau 1.

Le mécanisme envisagé est proposé ci-dessous:

Identification du méthyl-2 méthoxy-5 formyl-6 hydroxy-7 chromone

Ce produit a été identifié par spectrométrie de masse couplée à la chromatographie en phase gazeuse par comparaison avec la fragmentation d'un échantillon authentique.[17]

RESULTATS

Cinétique d'oxydation

Pour différentes concentrations de khelline dans le milieu sulfovanadique, après une heure de réaction au bain marie bouillant, la consommation d'oxydant est proportionnelle à la quantité de khelline soumise à l'oxydation. En effet, pour des concentrations de khelline entre 0,16 et 0,80 mg/ml, nous avons remarqué que la quantité d'oxydant consommé est une fonction linéaire ($r = 0,9987$) de la quantité de produit de départ soumise à l'oxydation.

Une étude statistique sur cinq échantillons à 25 mg de khelline, oxydés dans les mêmes conditions opératoires que celles utilisées pour établir la courbe d'étalonnage, a montré que l'erreur expérimentale maximale par rapport à cette même courbe était égale à 0,1%.

Dans ces conditions opératoires et dans l'intervalle de concentrations en produit de départ cités ci-dessus, la consommation d'oxydant rapportée est de 16 moles à une mole de khelline en milieu sulfurique 2,5M.

Nous avons constaté que l'oxydation est terminée au bout d'une heure comme le montre la cinétique de l'oxydation en fonction du temps représentée ci-dessous (Fig. 1).

Produits d'oxydation

Pour expliquer la quantité d'oxydant consommée et la cinétique de l'oxydation, nous avons isolé et dosé un certain nombre de produits d'oxydation. Le dosage du dioxyde de carbone a montré qu'en milieu sulfurique 2,5M, il y a formation de 3,37 moles de

Tableau 1.

95	24,8
Fig. 1. Oxydation sulfovanadique de la khelline en milieu 2,5M en acide sulfurique (concentration 1,92 μmole/ml).

dioxyde de carbone par mole de khelline. Le dosage du formaldéhyde produit en milieu sulfurique 2,5M a montré que la concentration de cet aldéhyde passe par un maximum et diminue en fonction du temps (Fig. 2). En ce que concerne les trois acides isolés, une mole de khelline forme 0,68 mole d'acide formique, 0,63 mole d'acide acétique et 0,67 mole d'acide furanne dicarboxylique-2,3 en milieu sulfurique 2,5M.

Proposition d'un mécanisme réactionnel

La formation en milieu sulfurique 2,5M de quantités voisines d'acide furanne dicarboxylique-2,3, d'acide acétique et d'acide formique laisse prévoir que ces trois produits pourraient se former selon un même mécanisme réactionnel qui intéresse les 2/3 (66%) des molécules présentes. Ce mécanisme induit une attaque initiale soit au niveau du noyau pyrannique, soit au niveau du noyau benzénique substitué, mais laisse intact le cycle furannique.

L'isolement et l'identification du méthyl-2 méthoxy-5 formyl-6 hydroxy-7 chromone montre l'existence d'un second mécanisme réactionnel, sans pour autant qu'actuellement un dosage de cette molécule ait pu être mis en oeuvre. L'oxydation selon le
premier de ces deux mécanismes peut être schématisée selon l'équation:

$$\underset{\text{khelline}}{C_{14}H_{12}O_5} + \tfrac{15}{2}O_2$$

$$\rightarrow \underset{\substack{\text{Acide furanne}\\\text{dicarboxylique-2,3}}}{C_6H_4O_5} + HCOOH + CH_3COOH + 5CO_2$$
Cependant, ceci suppose que les groupements méthoxylés subissent une oxydation totale en dioxyde de carbone. Or, dans les conditions opératoires envisagées lors de cette oxydation, l'hypothèse du passage par un état CH_3^- ou CH_3^+ conduisant par réaction avec le solvant à du méthanol est plausible compte-tenu du caractère radicalaire de la réaction. Aussi, avons-nous soumis le méthanol à l'oxydation dans les mêmes conditions. Nous avons constaté qu'une mole de méthanol en milieu sulfurique 2,5M ne réduit que 1,67 moles d'ion vanadyle.

Ces valeurs nettement inférieures aux 6 moles nécessaires pour une oxydation totale peuvent, peut être, s'expliquer par la volatilité des molécules considérées. En tout état de cause, ce palier de la quantité d'oxydant consommé ne peut être dépassé quelque soit le temps de la réaction.

Ainsi pouvons-nous considérer que ce ne sont pas 30 moles d'ion vanadyle, correspondant aux 7,5 moles O_2, qui sont réduites, mais:

$$30 - 2(6 - 1,7) = 21,4 \text{ moles}$$

Si ce mécanisme intéresse les deux tiers des molécules, la quantité d'oxydant consommée est de:

$$\frac{21,4 \times 2}{3} = 14,3 \text{ moles}$$

Dans le cas où le second mécanisme conduirait essentiellement à la méthoxy-5 formyl-6 hydroxy-7 chromone, l'équation serait:

$$C_{14}H_{12}O_5 + \tfrac{5}{2}O_2 \rightarrow C_{12}H_{10}O_5 + 2CO_2 + H_2O$$
L'oxydation dans ce cas d'un seul groupement méthoxylé nous conduit par le même raisonnement à envisager la consommation, non pas de 10 moles d'ions vanadyle théoriquement prévues dans le cas de l'oxydation complète du groupement méthoxylé, mais seulement de 5,7 moles. En appliquant le même type de calcul, puisque le tiers des molécules initiales peut être justiciable de ce mécanisme, la consommation serait de 5,7/3 = 1,9 moles d'ions vanadyle.

La consommation totale serait donc de 14,3 + 1,9 = 16,2 moles d'oxydant par mole de khelline.

L'hypothèse concernant le second mécanisme est beaucoup plus délicate à émettre et fera l'objet d'un travail ultérieur.

Application au contrôle de médicament

Nous avons dosé la khelline par spectroscopie ultraviolette et par oxydation sulfovanadique dans

Fig. 2. Cinétique de formation du formaldehyde en fonction du temps.

Tableau 2. Comparaison des deux méthodes de dosage: 1, dosage sur une solution
pure; 2, dosage après dépot sur une plaque de C.C.M. et extraction

Etalon, *mg*	Absorbance à 326 nm		Consommation d'oxydant, *µeq*	
	1	2	1	2
2	0,438	0,400	123	116
3	0,656	0,609	186	178
4	0,871	0,811	244	237
5	1,09	0,998	305	296

une forme pharmaceutique contenant de la khelline et de la prométhazine (Khelline-Promethazine sirop, Laboratoires Berthier).

Méthode d'extraction et de préparation des échantillons. Les deux produits sont extraits du sirop par le dichlorométhane. L'extrait organique est évaporé à sec à 40° sous pression réduite. Le résidu est repris par un volume de dichlorométhane exactement mesuré. Une fraction de la solution obtenue est déposée sur une plaque de silice GF 254 (0,2 mm) dont le support est en feuille d'aluminium. Le dépot a été fait grâce au déposeur (Camag 10-74-F), car la résolution des bandes est d'autant meilleure que le dépot est fin.

Après séparation chromatographique (solvant utilisé:acétate d'éthyle 40, toluène 50, acide formique 10) et séchage, la bande correspondant à la khelline est récupérée par un volume précis de dichlorométhane. Pour avoir des résultats comparatifs, une fraction de l'éluat est utilisée pour le dosage spectrophotométrique et une autre est oxydée par le pentoxyde vanadium. D'autre part, une partie de la plaque chromatographique parcourue par la phase mobile est traitée de la même manière. L'éluat obtenu est utilisé comme "blanc" pour les deux méthodes.

La droite de régression obtenue pour quatre analyses effectuées par spectrophotométrie ultra-violette et oxydation sulfovanadique montre une bonne corrélation entre les deux méthodes ($r = 1$) (Tableau 2).

L'exactitude de la méthode et le rendement de l'extraction ont été déterminés en déposant sur la plaque chromatographique des quantités connues de khelline. Les valeurs obtenues, données dans le Tableau 2, montrent un meilleur résultat pour le dosage oxydimétrique que pour le dosage spectrophotométrique.

Les dosages effectués sur la spécialité mentionnée précédemment ont donné respectivement des valeurs de 33 mg/100 g pour la méthode oxydimétrique et de 32,5 mg/100 g pour la méthode spectrophotométrique pour une valeur théorique indiquée sur le conditionnement de 36 mg/100 g de sirop. Il est possible de conclure que les teneurs déterminées par les deux méthodes sont très voisines et qu'elles correspondent à une valeur acceptable si l'on considère des limites de $\pm 10\%$.

CONCLUSION

En conclusion, l'oxydation de la khelline nous a permis d'obtenir une méthode de dosage de ce produit pouvant être appliquée à de faibles quantités puisque la consommation de réactif oxydant est de 16 moles par mole de produit. La sensibilité de la technique est au moins comparable à celle obtenue par la spectrométrie ultra-violette. L'identification et le dosage des produits réactionnels, nous a conduit à isoler notamment l'acide furanne dicarboxylique-2,3, dont nous avons pu déterminer les différents paramètres spectrométriques.

Summary—In studies of the reactivity of oxygen heterocycles, it has been found that khelline gives a molar reacting ratio of 1:16 with vanadate in 2.5*M* sulphuric acid, the products being vanadium(IV), 2,3 furan dicarboxylic acid, formic acid, acetic acid and carbon dioxide. This reaction can be used for determination of khelline and also for preparation of 2,3-furan dicarboxylic acid.

STABLE-ISOTOPE RATIO ANALYSIS BASED ON ATOMIC HYPERFINE STRUCTURE AND OPTOGALVANIC SPECTROSCOPY

WILLIAM G. TONG and EDWARD S. YEUNG*

Department of Chemistry and Ames Laboratory, Iowa State University, Ames, Iowa 50011, U.S.A.

Summary—Atomic hyperfine structures were measured for the Cu I transition at 5782 Å by optogalvanic spectroscopy at high resolution, with a cw dye laser. Samples were electro-deposited on the demountable cathode of a home-made hollow-cathode lamp. By spectral deconvolution, the relative isotopic abundances of ^{63}Cu and ^{65}Cu could be determined with good accuracy and precision. The technique is applicable to copper concentrations as low as 1.6 ppm.

Reliable and safe application of isotopes as tracers is important in many areas, including biomedical, environmental and geochronological sciences. The presence of trace levels of both essential and non-essential elements can significantly affect biological processes. It is important to study how and where metals are absorbed, distributed and accumulated in various parts of the body. Radioactive isotopes have been most frequently utilized for these studies. However, the application of these techniques in humans is severely limited because of the hazardous nature of the radioactive isotopes. An alternative is measurement of the abundance ratio of stable isotopes, which can be done by a variety of mass spectrometric methods, including GC–MS,[1,2] thermal ionization MS,[3] field ionization MS,[4] ICP–MS,[5,6] fast-atom bombardment MS,[7] electron-impact ionization MS,[8] and spark-source MS.[9] The major disadvantage of all mass spectrometric methods is the interference caused by other ions having exactly the same m/e value as the analyte. The resolving power of most commercial mass spectrometers is not sufficient to avoid some of these interferences,[7] and the overall sensitivity decreases if higher resolving powers are used.

In this paper, we report a new approach to stable-isotope ratio analysis, based on atomic hyperfine structure available from the optical absorption profile. This spectroscopic scheme is virtually interference-free because of the highly selective and specific nature of hyperfine structures. Each hyperfine structure has its own unique shape and profile within a narrow range of frequencies (less than 15 GHz or 0.5 cm^{-1}). Thus, a minor constituent in a complex matrix can be studied without extensive sample preparation.

The study of isotope shifts and hyperfine structures of optical transitions in atomic spectra has yielded detailed information about the changes in the radial

moments of the nuclear charge distribution for the isotopes of an element. The high spectral resolution necessary to study hyperfine splittings has been achieved by using a wide variety of spectroscopic tools including etalons,[10–13] interferometers,[14–20] and spectrometers.[21] Atomic-beam sources[22,23] have been used to minimize the Doppler broadening of the line-widths. However, it was not until the development of tunable dye lasers that measurements with high spectral resolution and high precision for a large number of elements were possible, for optical transitions ranging from the infrared to the ultraviolet regions. Important laser spectroscopic techniques include Doppler-free[24] and non-linear[25–27] optical methods.

In this work we use a single-frequency tunable cw dye laser as the optical excitation source and a specially designed and constructed demountable cathode discharge as the atomizer and detector. Hyperfine profiles are collected by monitoring the optogalvanic signal[28] generated between the two electrodes of the discharge when the laser frequency is scanned across the optical transition range. Optogalvanic spectroscopy has become a powerful technique, with applications in many areas of research including analytical chemistry,[29,30] wavelength measurements and calibration,[31,32] and atomic[33] and molecular[34] spectroscopy. Since the electrical signal is directly generated from the optical absorption, no optical detection is required. In the low-pressure environment (2–7 mmHg) of the discharge plasma, the Lorentzian line-width broadening is negligible and the spectral resolution is limited only by Doppler broadening. Some Doppler-free optogalvanic techniques have been used[35,36] to study isotope shifts and hyperfine structures. However, for obtaining isotope ratios, it is not always necessary to use Doppler-free methods to obtain baseline resolution of hyperfine components. All components that are convoluted under the Doppler-limited spectrum can be recovered by matching the experimental and theoretical

---

*Author for correspondence.

hyperfine profiles by a least-squares criterion. This method is demonstrated here for the determination of ^{63}Cu and ^{65}Cu by using the hyperfine structure of the Cu I 5782 Å, $^2D_{3/2}-^2P_{1/2}$ transition.

THEORY

Splitting of an optical transition for a single isotope into two or more hyperfine components is due to the interaction of the nuclear magnetic moment with the electronic magnetic field. The number of hyperfine splittings F depends on the nuclear angular momentum of the isotope I, and the electronic angular momentum J:

$$F = (I + J), (I + J) - 1, (I + J) - 2, \ldots (I - J) \quad (1)$$

For the Cu I 5782 Å ($^2D_{3/2} - ^2P_{1/2}$) transition, $J' = 3/2$ and $J = 1/2$, and both ^{63}Cu and ^{65}Cu have $I = 3/2$. Therefore, for each isotope, there are two hyperfine splittings ($F = 2, 1$) at the upper level and four hyperfine splittings ($F' = 3, 2, 1, 0$) at the lower level. The selection rule, $\Delta F = \pm 1, 0$, allows six hyperfine transitions $K_{F'F}$ as shown in Fig. 1. Consequently, the ^{63}Cu and ^{65}Cu isotopes each have a set of six hyperfine components, resulting in a 12-component hyperfine structure.

The relative hyperfine-component strengths of a set of hyperfine lines are well defined, and can be calculated from their direct relation to the excitation or emission rate. Excitation rate is directly proportional to ξ^2, where ξ can be defined by the expression

$$\xi = \langle \alpha JIFM_F | \hat{\varepsilon} \cdot \bar{r} | \alpha'J'IF'M_{F'} \rangle \quad (2)$$

for weak fields; $\hat{\varepsilon}$ is the polarization vector and $\bar{r}$ is the position vector, J and M_F are the quantum numbers needed for complete specification of the states for the upper level and α', J' and $M_{F'}$ are those for the lower level. It is assumed here that no optical, fine-structure or hyperfine-structure pumping effects exist. For linear polarization along the z axis,[37]

$$\xi_{[F'M_{F'} \to FM_F]}$$

$$= \left\langle \alpha JIFM_F \left| \left(\frac{4\pi}{3} \right)^{\frac{1}{2}} rT_0^{(1)} \right| \alpha'J'IF'M_{F'} \right\rangle \quad (3)$$
Fig. 1. Hyperfine transitions for the Cu I atomic line at 5782 Å.

where $T_0^{(1)}$ is a spherical tensor $T_q^{(k)}$ of rank k in J-space with $k = 1$ and $q = 0$, and r is the distance along the z axis. We then use the Wigner–Eckart theorem[38] to remove the dependence of matrix elements of $T_0^{(1)}$ on the magnetic quantum numbers M_F and $M_{F'}$. The result is

$$\xi = (-1)^{F-M_F} \begin{pmatrix} F & 1 & F' \\ -M_F & 0 & M_{F'} \end{pmatrix}$$

$$\times \left\langle \alpha JIF \left\| \left(\frac{4\pi}{3} \right)^{\frac{1}{2}} rT^{(1)} \right\| \alpha'J'IF' \right\rangle \quad (4)$$

where

$$\begin{pmatrix} F & 1 & F' \\ -M_F & 0 & M_{F'} \end{pmatrix}$$

is a 3-J symbol[38] and

$$\left\langle \alpha JIF \left\| \left(\frac{4\pi}{3} \right)^{\frac{1}{2}} rT^{(1)} \right\| \alpha'J'IF' \right\rangle$$

is a reduced matrix element,

$$\langle \alpha JIF \| rT^{(1)} \| \alpha'J'IF' \rangle$$

$$= (-1)^{J+I+F'+1} [(2F + 1)(2F' + 1)]^{1/2}$$

$$\times \begin{Bmatrix} F & 1 & F' \\ J' & I & J \end{Bmatrix} \langle \alpha J \| rT^{(1)} \| \alpha'J' \rangle \quad (5)$$

where

$$\begin{Bmatrix} F & 1 & F' \\ J' & I & J \end{Bmatrix}$$

is a 6-J symbol.[38] By combining equations (5), (4) and (2), and summing over M_F and $M_{F'}$, it is apparent that the excitation rate ξ^2 is directly proportional to the transition strength K and

$$K_{[F' \to F]} = \sum_{\substack{M_F \\ M_{F'}}} K_{[F'M_{F'} \to FM_F]}$$

$$= (2F + 1)(2F' + 1) \begin{Bmatrix} F & 1 & F' \\ J' & I & J \end{Bmatrix}^2$$

$$\times \sum_{\substack{M_F \\ M_{F'}}} \begin{pmatrix} F & 1 & F' \\ -M_F & 0 & M_{F'} \end{pmatrix}^2 \quad (6)$$

Since the last term in equation (6) becomes unity, the final expression for the relative hyperfine-component strength is

$$K_{F'F} = (2F + 1)(2F' + 1) \begin{Bmatrix} F & 1 & F' \\ J' & I & J \end{Bmatrix}^2 \quad (7)$$

By means of equation (7), the six hyperfine-component strengths K_{32}, K_{21}, K_{22}, K_{11}, K_{12} and K_{01} of the Cu I 5782 Å line, as shown in Fig. 1, are calculated and the results agree with the experimentally observed data.

To simulate the actual absorption profiles, the magnitudes of the hyperfine shifts must next be found. For the Cu I 5782 Å transition, there are 12 hyperfine-component frequencies $\nu_{0,n=1-12}$, and the hyperfine shift values Δ_n (i.e., $\nu_{0,n+1}-\nu_{0,1}$) have been reported by other workers.[39-41] However, these values vary slightly, depending on the measurement method, the electric field and the geometry and dimension of the electrodes used. Since it is essential to obtain these values with high accuracy (within ±0.0005 cm^{-1}), they must be determined for the specific type of discharge plasma used. This is accomplished by least-squares fitting of experimental profiles from a sample with known isotope abundances, by varying each $\nu_{0,n}$ value by 0.001 cm^{-1} at a time until the best matching set of $\nu_{0,n}$ is obtained.

Once all $K_{0,n=1-12}$ and $\nu_{0,n=1-12}$ values have been determined, we can simulate theoretical profiles for various combinations of isotope ratio R, and plasma temperature T, by summing over the individual Doppler-broadened contributions. Ratio R is used to adjust the relative absorption strengths of the two isotopes, $K_{0,n}$ (^{63}Cu) and $K_{0,n}$ (^{65}Cu). Figure 2 shows the two 6-component sets of hyperfine structure simulated for ^{63}Cu and ^{65}Cu, with the natural ^{63}Cu/^{65}Cu abundance ratio of 2.235 and plasma temperature of 20 K for the lower traces and 1400 K for the upper trace. The isotope ratio of the analyte is calculated by matching the experimental hyperfine structure to these theoretical profiles and picking the set which yields the least squared deviation.

EXPERIMENTAL

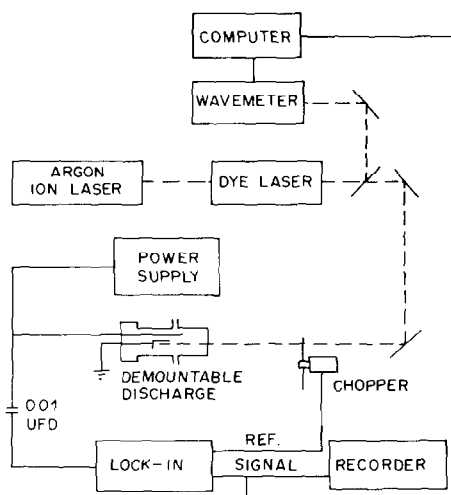
A schematic diagram of the experimental arrangement is shown in Fig. 3. An argon ion laser (Control Laser, Orlando, FL, Model 554 A) is used to pump a high-resolution (40 MHz jitter) cw ring dye laser (Spectra Phys-


Fig. 3. Experimental arrangement for optogalvanic measurements. Optical paths are shown as broken lines and electrical connections are shown as solid lines.

ics, Mountain View, CA, Model 380 A) which provides tunable single-frequency radiation which can be electronically scanned over 30 GHz. A wavemeter (Burleigh Instruments, Fishers, NY, Model WA-20) accurate to 0.01 cm^{-1}, is used to monitor the laser frequency, and the I/O port of the wavemeter is interfaced to a minicomputer (Digital Equipment Corp., Maynard, MA, PDP 11/10) to collect and store the frequency values. A mechanical chopper (Rofin, Newton Upper Falls, MA, Model 7510) is used to modulate the laser beam at 1 kHz modulation frequency. The dye laser beam is directed into the cathode cavity of the demountable hollow-cathode discharge tube (constructed in our workshops) operated by a constant-current power supply, and the resulting optogalvanic signal is sent to a lock-in amplifier (Princeton Applied Research, Princeton, NJ, Model HR-8) where a 1-sec time constant is used. The output of the lock-in amplifier is connected to a digital voltmeter (Keithley, Cleveland, OH, Model 160 B), and the analogue output of the voltmeter is digitized by the laboratory peripheral system (LPS-11) of the minicomputer. The computer takes simultaneous readings of both the optogalvanic signal and the laser frequency every 0.5 sec, and the real-time spectrum is displayed on a graphics terminal (Visual Technology Inc., Tewksbury, MA, Model 550). The real-time spectrum monitoring is useful for detecting any experimental defects, such as laser mode-hopping, while the experiment is in progress.

A simple demountable cathode discharge tube can be constructed from a 1.5-in. outside diameter (o.d.) 6-in. long Pyrex-to-Kovar joint with a quartz window attached on the glass end and a 3-in. diameter stainless-steel vacuum flange welded on the Kovar end. A 3-in. diameter $\frac{3}{4}$-in. thick nylon flange is attached to the stainless-steel flange to allow dismounting. Vacuum seal is provided by an O-ring between the flanges. The cathode and anode are mounted on the nylon flange through the central axis of two nylon bolts screwed onto the flange through O-ring seals. A $\frac{1}{16}$-in. diameter 7-in. long tungsten welding rod (Welders Engineering Research Co., Charlotte, NC, Cleaned Finish) is used as the anode. A screw-mount cathode rod and cathode housing assembly is shown in Fig. 4. A $\frac{1}{8}$-in. diameter nickel (or copper) rod serving as the cathode is screw-mounted in a 4-mm inner diameter, 8-mm long nickel housing through a 5-40 thread (the high-purity nickel used, containing less than 0.9 ppm copper, was obtained locally from the Ames Laboratory). Pyrex tubing is sealed on the cathode housing for insulation and to confine cathode sputtering inside the cathode cavity. The gap between the cathode and anode is

Fig. 2. Doppler-broadened hyperfine structure. Top, 1400 K; bottom 20 K, broken lines for ^{63}Cu and solid lines for ^{65}Cu.
Fig. 4. Demountable hollow cathode.

9 mm. The anode rod is approximately 1 in. longer than the cathode assembly so that the sharp edge of the tip of the anode rod is facing away from the cathode cavity. This reduces the chance of electrical arcing between the electrodes, especially at higher gas pressures and lamp currents. Analyte, at trace level, is deposited onto the $\frac{1}{8}$-in. diameter end-surface of the cathode tip. Research grade (99.9999%) neon gas (Matheson, East Rutherford, NJ) is used for the discharge gas, and the gas pressure is monitored by a capacitance manometer (0–10 mmHg full scale; MKS Instruments, Burlington, MA, Model 221A). No brass is used in the vacuum line and only a mechanical vacuum pump is used for the vacuum system. The discharge tube can be disassembled and assembled, and the electrodes replaced, within a few seconds. After the vacuum has been broken and the electrodes exposed to the atmosphere, a baking period of 10 min is sufficient to restore a noise-free discharge base-line. Baking is done by simply firing the lamp at normal operating current (30 mA) and then flushing with the discharge gas. A reasonably stable galvanic base-line can be obtained even without any baking, each time the lamp is reassembled after exposure to the atmosphere. The lamp intensity and optogalvanic signal generated are comparable to or better than those for a commercial hollow-cathode lamp (Perkin-Elmer Corp., Norwalk, CT).

All enriched isotopes, ^{63}Cu (99.89%) and ^{65}Cu (99.69%), were purchased from Oak Ridge National Laboratory. Stock solutions were prepared by dissolving the isotopes in 10% nitric acid (containing less than 0.05 ppm Cu). Natural-abundance copper stock solutions were prepared by dissolving electrolytic copper metal powder (Electrolytic Purified, Fisher Scientific Co., Fairlawn, NJ) in 2% nitric acid. Copper is deposited on the cathode tip by controlled-potential electro-deposition with the cathode rod as the working electrode, a platinum wire as the counter-electrode and a saturated calomel electrode as the reference electrode. A controlled potential of −0.35 V vs. SCE is applied to the cathode rod. All the cathode rod surface that is submerged in the solution, except the flat tip, is insulated by Teflon tape so that the electro-deposition is concentrated on the small area of the cathode tip. All electro-depositions are done at pH 2 with potassium nitrate as supporting electrolyte. After deposition, the cathode rod is rinsed with triply distilled demineralized water and air-dried before installation in the demountable lamp.

Human whole blood samples (3-ml portions) obtained from the Ames Laboratory medical department were digested with 20 ml of a 1:1 v/v mixture of 70% perchloric and 70% nitric acids in a miniaturized Bethge apparatus. A reflux time of 30 min was sufficient to obtain a clear solution. For larger amounts of blood, water condensate was removed from the side-arm of the Bethge apparatus in order to raise the perchloric acid concentration and increase the oxidizing power.

The ring dye laser has a fairly good electronic wavelength-scanning mechanism with minimum scan-rate deviation. However, even slight deviation was unacceptable for our scheme for fitting the hyperfine-component frequencies with ±0.0005 cm^{-1} accuracy. Hence the wavemeter was interfaced to the minicomputer so that signal data could be collected simultaneously with the corresponding frequency values. The I/O port of the wavemeter was connected to the digital I/O port of the LPS-11, and the laser frequency (in BCD code) from the wavemeter converted to base-10 number, as displayed on the wavemeter LEDs. However, the wavemeter frequency-updating rate (every 1.6 sec) was too slow for our data-collection rate (every 0.5 sec). The result was inadequate resolution along the frequency co-ordinate. This problem was solved by using a 5-point data-smoothing routine to smooth the frequency co-ordinate. This was justified because the dye laser itself was stable to 40 MHz, whereas the wavemeter had a resolution of only 300 MHz.

All calculations, including generation of theoretical profiles and least-squares fitting of experimental profiles, were done by using a minicomputer (Digital Equipment Corp., Maynard, MA, PDP 11/45) with a floating-point processor. The computer determined the base-line of the experimental profile. Then an adjusted base-line was determined. Finally, the whole profile was normalized with respect to area. For experimental profiles with noisy background, 5–21 point third-degree polynomial smoothing routines were available to reduce the noise level without substantially degrading the spectral resolution. For fitting at the lowest concentration of 1.6 ppm, only the region from 17289.6 to 17289.8 cm^{-1} (Fig. 2) was used, to avoid excessive contributions from base-line instability.

RESULTS AND DISCUSSION

Abundance analysis

By use of equation (7), the six relative hyperfine-component strengths K_{FF} for both the ^{63}Cu and ^{65}Cu isotopes are calculated to be $K_{32} = 1.0000$, $K_{21} = 0.3571$, $K_{22} = 0.3571$, $K_{11} = 0.3571$, $K_{12} = 0.0715$ and $K_{01} = 0.1429$. Both isotopes yield the same K_{FF} values since they have the same nuclear angular momentum of $I = 3/2$. From these K_{FF} values, the central frequencies, $v_{0,n=1-12}$, are calculated from the signals obtained by using a solid copper cathode in our home-made lamp, operated at 30 mA. The $_{1}^{63}$Cu–^{65}Cu isotope shift is found to be 0.067 ± 0.0005 cm^{-1}, which compares well with results reported by other workers.[24,39–41] The reliability of this isotope-ratio measurement scheme depends largely on how accurately the central frequencies of the hyperfine lines can be determined. To double check our calculated $v_{0,n}$ values, we used pure ^{63}Cu and ^{65}Cu isotopes respectively for calculations of $v_{0,n=1-6}$ (^{63}Cu) and $v_{0,n=1-6}$ (^{65}Cu) separately. These $v_{0,n=1-12}$ values agree very well with those determined from a natural-abundance Cu sample. Theoretical profiles generated by using these K_{FF} and $v_{0,n}$ values are stored in reference tables in the computer for various values of R and T. A base-line-subtracted, area-normalized and frequency-aligned experimental profile is tested for fit with each theoretical profile in the reference tables. Figure 5 illustrates the goodness of spectral fit of our experimental profile with theoretical profile that yields the least sum of squares of the deviations (SSD). The reliability and accuracy of
Fig. 5. Fitting of the atomic hyperfine profile. Circles, experimental profile; solid line, theoretical profile.

the ratio calculation depend on the ability of the computer to decide which theoretical profile yields the least SSD. To ensure this, the calculated surface of SSD in the entire range of R and T values should have only a single minimum point, forming a smooth "hole". Figure 6 displays a typical calculated surface of SSD, showing that such a condition is satisfied.

The abundances of ^{63}Cu and ^{65}Cu isotopes are determined by using the demountable cathode lamp with natural-abundance copper and enriched copper isotopes deposited on it. The results are shown in Table 1. The reliability and accuracy of these calculations are tested for some extreme cases, such as calculation for a minor isotope (5% abundance) in the presence of a major isotope (95% abundance). Ratio analysis can be performed successfully in this way for

a copper concentration as low as 1.6 ppm. Table 1 shows that both the accuracy and the precision of the method are in the $\pm 1\%$ range for concentrations at the 50-ppm level or higher. At the 9-ppm concentration level, the precision is about $\pm 2\%$. Below this concentration, the precision is probably not sufficient for practical applications. Although absolute total copper detection is possible at much lower concentration, the accuracy of ratio analysis decreases because of distortion of the hyperfine structure at very weak signal levels. Human blood serum contains 20–50 $\mu g/ml$ copper and human urine excretion of copper is 200–500 μg in a 4-hr period. These biological samples provide sufficient amounts of copper for ratio analysis by our scheme. A 3-ml human whole blood sample was analysed, and as expected, the isotopic ratio determined was equal to the natural abundance ratio, since only normal copper is available in diet. This shows that matrix effects are not important in these measurements.

Since most elements have at least one isotope possessing non-zero nuclear angular momentum, unique hyperfine structures for these elements are available for many optical transitions. Thus, the

94	95.3	4.7	96.0 ± 1.0	4.0 ± 1.0

*Concentrations refer to sample solution from which copper is deposited onto the nickel cathode.

isotopic-ratio analysis scheme can be applied to all these elements, by using appropriate optical excitation sources. All information necessary to generate theoretical profiles for any element can be readily calculated once the optical transition is known. In fact, copper is probably one of the most difficult cases because of the complexity of the hyperfine structure. For elements with well-resolved isotopic lines, deconvolution is not necessary, and even higher precision can be expected. Application of this scheme is useful not only in biological studies, but also in environmental analysis such as the identification of pollution sources, by use of tracer isotopes. It should also be useful in geochronological studies, including the determination of the source and age of oceanic rock samples, and for isotope dating (e.g., lead-210). It is even applicable for detection of art forgeries by characterization and authentication of paintings, based on the isotopic ratios of an artist's lead pigment.[42,43]

Stark effect

The hyperfine-component frequencies $\nu_{0,n=1-12}$ for the commercial cathode discharge and the demountable cathode discharge were found to be slightly different, as shown in Table 2. The major contributing factor is the electric field shift, caused by the difference in electric field strengths available for the two discharges. The electric field effect on hyperfine shift was further tested by applying two different electric fields (volts/electrode distance) in the demountable cathode discharge, by modifying the positions of the electrodes. As expected, the higher electric field (348 V/mm) shifted the hyperfine lines toward higher frequencies.

Pressure effects

The pressure effect on hyperfine-component frequencies was also tested for the useful range of gas pressures in the discharge. The discharge can be operated from about 2.5 to 7 mmHg neon pressure without sacrificing the stability or intensity of the optogalvanic signal. Hyperfine structures measured

at different neon pressures (2.6 and 7.1 mmHg) were compared, and no significant difference was observed. Therefore, the discharge can be operated over a reasonably wide range of useful gas pressures, without affecting the hyperfine frequencies.

Conclusions

We have demonstrated a novel method for determining isotopic ratios in complex samples. It benefits from many advantages of optogalvanic spectroscopy. The advantages of using a discharge as the atomizer include narrower Doppler width and negligible Lorentzian broadening, because of the lower temperature and pressure of the plasma, compared to, for example, those of an analytical flame. Because of the high electron-sputtering energy, the discharge provides higher collisional excitation. Although analytical flames provide a more convenient way of analyte introduction, the simple electro-deposition step used for preparing the discharge tube is an effective procedure for concentration of the analyte from very dilute solution. This scheme yields the ratios of all isotopes present, with a single sweep of the laser frequency and within a few seconds of calculation time. This is more efficient than some mass-spectrometric methods where the peak-match unit has to be switched between the exact masses of the isotopes of interest. Also, the instrumentation is less expensive than mass spectrometers with a comparable resolving power. Finally, this scheme is extremely selective and interference-free, because each hyperfine structure has its own unique shape, within a narrow range of frequency. Since both resonance and non-resonance optogalvanic effects can be readily observed, plenty of transition lines are available, from which to choose an excitation wavelength where spectral interference is minimal. If needed, sensitivity and selectivity can be further enhanced by utilizing multiphoton optogalvanic methods.

UNTERSUCHUNGEN ZUR ANWENDUNG TERNÄRER KOMPLEXE IN DER PHOTOMETRIE—III

DIE BESTIMMUNG DES TITANIUM(IV) MIT BROMPYROGALLOLROT IN GEGENWART VON NITRILOTRIESSIGSÄURE bzw. ETHYLENEDIAMINTETRAESSIGSÄURE

S. Koch, G. Ackermann und H. Mosler

Bergakademie Freiberg, Sektion Chemie, Lehrstuhl für Analytische Chemie, 9200 Freiberg,
Deutsche Demokratische Republik

Zusammenfassung—Zur Bewertung ternärer Komplexe in der Photometrie wurden die Modellsysteme (BPR = Brompyrogallolrot) Ti(IV)/BPR (I), Ti(IV)/BPR/EDTE (II) und Ti(IV)/BPR/NTE (III) analytisch charakterisiert. Neben der Ermittlung der Kennzahlen Arbeitsbereich, Extinktionskoeffizient, Standardabweichung, Variationskoeffizient, Eichfunktion, Nachweisgrenze und Erfassungsgrenze erfolgte auch eine Untersuchung der Störung durch 47 Ionen. Es zeigte sich, daß die ternären Systeme—besonders System II—gegenüber dem binären System I eine höhere Selektivität aufweisen.

Zur Bewertung ternärer Komplexe für die photometrische Analyse wurden die Systeme Titanium(IV)/Tiron und Titanium(IV)/Tiron/Aminopolycarbonsäure (APC) umfassend charakterisiert.[1,2] Die Untersuchungen ergaben, daß für eine Reihe von Störionen das Verfahren selektiver wird, wenn das Titanium als ternärer (Ti/Tiron/APC) und nicht als binärer Komplex (Ti/Tiron) bestimmt wird. Genannte Selektivitätssteigerung ist besonders deutlich bei den Zweitliganden Ethylendiamintetraessigsäure (EDTE) und Nitrilotriessigsäure (NTE), die Empfindlichkeit dieser Reaktionen ist aber gegenüber dem einfachen Tironverfahren geringer. Eine Erhöhung der Empfindlichkeit der Reaktionen dieser ternären Komplextypen mit Tiron ist aus komplexchemischen Gesichtspunkten prinzipiell nicht möglich, so daß man auf einen stark chromophoren Liganden mit Resonanzsystem (Farbstoff) angewiesen ist. Auf Grund der analytisch funktionellen Gruppierung für Titanium(IV)[3] ist als chromophorer Ligand Brompyrogallolrot (Dibrompyrogallolsulphophthalein, BPR) geeignet, zumal dieses Reagens mit Titanium(IV)[4,5] und einer Reihe weiterer Kationen[6] empfindliche Farbreaktionen gibt. Weiterhin ist die Bildung ternärer Titaniumkomplexe mit BPR in Gegenwart von H_2O_2[7] sowie NTE[8] bekannt, so daß folgende Systeme charakterisiert wurden:

System I Ti(IV)/BPR
System II Ti(IV)/BPR/EDTE
System III Ti(IV)/BPR/NTE

System I wurde dabei mit untersucht, um exakte Vergleiche zu den ternären Systemen ziehen zu können.

KOMPLEXBILDUNG IM SYSTEM TITANIUM(IV)/BPR bzw. TITANIUM(IV)/BPR/APC

Titanium(IV) reagiert mit BPR bei pH > 1 zu intensiv violetten Lösungen, welche durch Reaktion mit der *o*-OH-Gruppierung des Farbstoffs entstehen. Die Färbungen bleiben je nach pH auch in Gegenwart von Zweitliganden wie Diethylentriaminpentaessigsäure, Ethylendiamintetraessigsäure, Nitrilotriessigsäure, Iminodiessigsäure, Tartrat, Citrat und Oxalat erhalten. Nach Untersuchungen von Suk *et al.*[4] wird die Reaktion des Titanium(IV) mit BPR analytisch wertvoller, wenn in Gegenwart von Gelatine gearbeitet wird. Die beschriebene Wirkung der Gelatine findet man auch bei anderen Reaktionen von Metallkationen mit Triphenylmethan-Farbstoffen, wobei folgende Vorteile bestehen: zeitliche Stabilität der Systeme, bathochrome Verschiebung von $\lambda_{max}(MeR_n)$, so daß ein großer Farbkontrast $\Delta\lambda = \lambda_{max}(MeR_n) - \lambda_{max}(R)$ resultiert, hohe Empfindlichkeit der Reaktionen.

Den Gelatineeffekt konnten wir im System Titanium(IV)/BPR auch in Gegenwart von EDTE sowie NTE nachweisen, wobei nur Lösungen mit pH ≤ 3,5 mehrere Stunden stabil sind. Bei allen hier untersuchten Lösungen wurde deshalb zur Stabilisierung Gelatine benutzt. In den Systemen Ti(IV)/BPR/(APC) liegen—wie die Wirkung der Gelatine zeigt—äußerst komplizierte Gleichgewichte in der Lösung vor, so daß ihre komplexchemische Untersuchung deshalb problematisch ist.

Die Charakterisierung der Systeme Titanium(IV)/BPR/APC erfolgte mit Hilfe spektralphotometrischer Methoden. Zum Nachweis ternärer

Komplexe in der Lösung diente die Methode des isosbestischen Punktes,[9] wonach bei

$$E_{iso}(Ti/BPR/APC) \neq E_{iso}(Ti/BPR\ BPR)$$

ternäre Komplexe anzunehmen sind. Die Ermittlung der Molarkoeffizienten n für BPR erfolgte nach der Methode der photometrischen Titration mit $(C_{Ti}, pH, C_{APC}) =$ konst. Desweiteren wurde der Koeffizient n nach der Job-Methode für ternäre Komplexe[10] bestimmt. Aus der allgemeinen Job-Gleichung erhält man für $\epsilon_2 = \epsilon_L = 0$:

$$Y = E - \frac{M\epsilon_{L'} V_{L'} d}{V_2}$$

und mögliche Substitutionseffekte können wegen $C_{APC} \gg C_{Ti}$ vernachlässigt werden ($\epsilon_2 =$ Extinktionskoeffizient von ML_m; $\epsilon_L =$ Extinktionskoeffizient von L; $Y =$ von E abgeleitete Hilfsfunktion; $E =$ Extinktion; $M =$ Konzentration der Metall-Stammlösung in mole/l.; $\epsilon_{L'} =$ Extinktionskoeffizient von L'; $V_{L'} =$ zugesetztes Volumen der Stammlösung L'; $d =$ Schichtdicke in cm; $V_2 =$ Arbeitsvolumen).

Zur Beschreibung der einzelnen Gleichgewichte sollen folgende Symbole dienen: H_4R (BPR); H_4Y (EDTE); H_3X (NTE); Ligandenüberschuß p ($p = C_R/C_{Ti}$); Ligandenüberschuß s ($s = C_{Y(X)}/C_{Ti}$).

System Ti(IV)/BPR

Nach Untersuchungen von Suk *et al.*[4] liegen bei kleinen Ligandüberschüssen ($p = 4$) in Gegenwart von Gelatine im pH-Bereich 2,2 bis 2,9 Komplexe mit dem Komponentenverhältnis 1:2 bzw. 1:3 vor. Schon die Wellenlängenabhängigkeit des Molarkoeffizienten bei pH 2,2 nach der Methode von Job $[x_{max} = f(\lambda)]$ weist darauf hin, daß kein einheitlicher Reaktionsmechanismus vorliegt. Wie eigene Ergebnisse bei pH 3,5 (photometrische Titration) zeigen, existiert auch unter diesen Bedingungen kein einheitlicher Komplex. Der ermittelte Molarkoeffizient $n(R) = 2,2$ deutet auch Komplexe der Zusammensetzung 1:2 bzw. 1:3 an. Die Funktion $E = f(pH)$ ($C_{Ti} = 2 \times 10^{-5}M$, $p = 10$) ist im pH-Bereich 2,7 bis 3,5 konstant, so daß bei pH 3,5 eine photometrische Titaniumbestimmung (Verfahren I) möglich ist.

System Ti(IV)/BPR/EDTE

Die pH-Kurve ($C_{Ti} = 2 \times 10^{-5}M$, $p = 10$, $s = 1000$) zeigt im pH-Bereich 3,0 bis 3,8 einen Verlauf $E = f(pH) =$ konst. Bei pH 3,5 ($p = 10$, $s = 1000$, $C_{Ti} = 10^{-5}M$) muß wegen

$$E_{iso}(T) > E_{iso}(B)(R)$$

wo (T) = System (Ti/BPR/APC); (B) = (Ti/BPR); (R) = (BPR) ternäre Komplexbildung angenommen werden. Mit Hilfe der photometrischen Titration ($C_{Ti} = 2 \times 10^{-5}M$, $s = 1000$, $p = 0-4$) wurde bei pH 3,5 der Molarkoeffizient $n(R) = 2,2$ gefunden. Dieser Wert konnte mit der Job'schen Methode ($C_0 = 10^{-4}M$) bestätigt werden.

Nach den durchgeführten Untersuchungen existiert im System Titanium(IV)/BPR/EDTE in schwach saurer Lösung ein ternärer Komplex in Gegenwart binärer Titanium–BPR-Komplexe. Im pH-Bereich 3,0 bis 3,8 sind die optischen Eigenschaften des Systems nahezu pH-unabhängig, so daß es deshalb zur photometrischen Titaniumbestimmung (Verfahren II) geeignet ist.

System Ti(IV)/BPR/NTE

Für die pH-Kurve ($C_{Ti} = 2 \times 10^{-5}M$, $p = 10$, $s = 1000$) gilt im pH-Bereich 3,1 bis 3,6 $E = f(pH) =$ konst. Bei pH 3,5 ($p = 10$, $s = 1000$, $C_{Ti} = 10^{-5}M$) liegt wegen

$$E_{iso}(T) > E_{iso}(B)(R)$$

ternäre Komplexbildung vor. Die photometrische Titration ($C_{Ti} = 2 \times 10^{-5}M$, $s = 1000$, $p = 0-4$) ergab bei pH 3,5 einen Molarkoeffizient von $n(R) = 2,5$, welcher auch nach der Methode von Job ($C_0 = 10^{-4}M$) bestätigt wurde.

Auch im System Titanium(IV)/BPR/NTE liegt ein ternärer Komplex im Gleichgewicht mit binären Titanium–BPR-Komplexen vor. Auf Grund der optischen Eigenschaften ist das ternäre System bei pH 3,5 ebenfalls zur photometrischen Titaniumbestimmung (Verfahren III) geeignet.

EXPERIMENTELLER TEIL

Für die photometrischen Messungen dienten die Geräte VSU 2 und Specord UV-VIS des VEB Carl Zeiss Jena. Zur Kontrolle der pH-Werte kamen die Geräte MV 85 (VEB Präcitronik Dresden) sowie TM 5 (Forschungsinstitut Meinsberg) zum Einsatz.

Reagenzien

EDTE, NTE (VEB Berlin-Chemie). BPR (Ferak, 24 Stunden bei 100° getrocknet). Gelatine (DAB 7, VEB Laborchemie Apolda).

Komplexchemische Untersuchungen

Bei der Herstellung der Lösungen wurde nach folgender Variante gearbeitet: Ti, APC, BPR, pH $\approx$ 2, Gelatine (2 ml 1%ig). Die Messungen erfolgten bei 620 nm nach 1 Stunde gegen Wasser bzw. eine Vergleichsprobe (BPR). Zur Herstellung der verwendeten Ti-Stammlösung gingen wir von einer bereits beschriebenen Vorschrift[11] aus.

Analytische Untersuchungen

Ti-Stammlösung. Es wurde 1,6681 g TiO$_2$ mit der 8-fachen Menge K$_2$S$_2$O$_7$ aufgeschlossen, die erkaltete Schmelze in $2M$ Schwefelsäure gelöst und damit auf 1 Liter aufgefüllt (Ti Gehalt: 1 mg/ml). Aus der Stammlösung wird eine Lösung hergestellt, welche $0,1M$ an Schwefelsäure ist (Ti Gehalt: 5 μg/ml).

Alkalische EDTE(NTE)-Lösung. Zu einer $0,2M$ EDTE (NTE)-Lösung gibt man soviel Natriumhydroxid, daß sich beim Hinzufügen von 5 ml dieser Lösung zu 15 ml $0,1M$ Schwefelsäure ein pH-Wert von etwa 2,5 einstellt.

Formiatpuffer. Es wurde 45 ml 85%ige Ameisensäure sowie 15 g Natriumhydroxid auf 1 Liter aufgefüllt und der pH-Wert auf 3,5 eingestellt. Die so erhaltene Pufferlösung ist etwa $1M$.

Stammlösungen der Störelemente. Die verwendeten Störlösungen (5 mg/100 ml) wurden weitgehend nach Koch und Koch-Dedic[12] hergestellt, wobei als Säure $0,2M$ Schwefelsäure bevorzugt wurde.

Arbeitsvorschriften

Verfahren I. Zur schwefelsauren Probelösung (etwa $0,1M$ an Schwefelsäure) gibt man soviel $0,1M$ Schwefelsäure hinzu, daß insgesamt 15 ml Lösung vorliegen. Die Lösung wird mit 10 ml $10^{-3}M$ BPR-Lösung und danach mit 2 ml 1% ige Gelatinelösung versetzt. Mit $1M$ Natriumhydroxid stellt man den pH-Wert von 3,5 ein, fügt 5 ml Formiatpuffer dazu und füllt mit Wasser auf 50 ml auf. Die Proben werden nach 20 Minuten bei 615 nm in 1-cm Küvetten gegen eine Blindprobe gemessen.

Verfahren II. Zur schwefelsauren Probelösung (etwa $0,1M$ an Schwefelsäure) gibt man soviel $0,1M$ Schwefelsäure hinzu, daß insgesamt 15 ml Lösung vorliegen. Die Lösung wird mit 5 ml alkalischer $0,2M$ EDTE-Lösung, 10 ml $10^{-3}M$ BPR-Lösung und danach mit 2 ml 1%ige Gelatinelösung versetzt. Mit $1M$ Natriumhydroxid stellt man den pH-Wert von 3,5 ein, fügt 5 ml Formiatpuffer zu und füllt mit Wasser auf 50 ml auf. Die Proben werden nach 30 Minuten bei 610 nm in 1-cm Küvetten gegen eine Blindprobe gemessen.

Verfahren III. Die Proben werden wie bei Verfahren II hergestellt, nur daß an Stelle von EDTE eine alkalische $0,2M$ NTE-Lösung Verwendung findet. Nach 20 Minuten werden die Proben bei 610 nm ebenfalls gegen eine entsprechende Blindprobe gemessen.

DISKUSSION

Vergleichende Charakterisierung der Verfahren

Zur vergleichenden Charakterisierung der einzelnen Verfahren machte sich eine statistische Kennzeichnung der Systeme **I**, **II** und **III** notwendig, wobei nach den schon beschriebenen Prinzipien[1] vorgegangen wurde. Die Berechnung der scheinbaren Extinktionskoeffizienten sowie der Standardabweichungen (mit $f = 20$ Freiheitsgraden) erfolgte für 25 μg Titanium. Bei der Berechnung der Eichfunktionen mit Hilfe der Regressionsrechnung (mit $f = 8$ Freiheitsgraden und $P = 0,99$) wurde von $y = bx + a$ ausgegangen. In Tabelle 1 sind die erhaltenen Daten zusammengestellt.

Die zur Kennzeichnung der Selektivität ermittelten Grenzverhältnisse g (bis maximal $g = 1000$) für 25 μg Titanium sind in Tabelle 2 enthalten. Das Grenzverhältnis ist nach

$$g = \frac{C_{\text{Störion}}}{C_{\text{Ti}}}$$

definiert und stellt ein Verhältnis dar, bis zu welchem keine Störung vorliegt. Die Ermittlung von g erfolgte wie bereits beschrieben durch lineare Extrapolation[1] unter Berücksichtigung von $3s$-Schranken für den Grundwert. Durch Untersuchung der Einflüsse von Natriumchlorid, Natriumnitrat sowie Natriumsulfat konnten eventuelle Störungen dieser Salze (Metall-Stammlösungen) ausgeschlossen werden.

Ein Vergleich der ermittelten Kennzahlen von Verfahren I (Ti/BPR), II (Ti/BPR/EDTE) und III (Ti/BPR/NTE) in Tabelle 1 zeigt, daß die Aminopolycarbonsäuren die analytischen Eigenschaften der Systeme beeinflussen. Die Extinktionskoeffizienten bzw. Eichfunktionen weisen auf empfindliche Verfahren hin, wobei die Empfindlichkeit von Verfahren II und III gegenüber Verfahren I etwas größer ist. Der genannte Effekt läßt sich mit der Unterdrückung

Erfassungsgrenze, μg	3,0	1,8	1,7

von Hydrolysereaktionen des Titanium(IV) durch die APC erklären, und wegen der höheren Zähnigkeit der EDTE gegenüber NTE ist die Empfindlichkeitssteigerung bei Verfahren II besonders deutlich. Auf Grund der wenig unterschiedlichen Empfindlichkeiten aller drei Verfahren ergeben sich auch nur unwesentliche Abweichungen in Arbeitsbereich, Nachweisgrenze sowie Erfassungsgrenze.

Wie aus der Analyse der Variationskoeffizienten (F-Test, $\bar{P} = 0,99$, $f = 20$ Freiheitsgrade) folgt, besteht ein signifikanter Unterschied zwischen den Zufallsfehlern der Verfahren I/II bzw. II/III. Besonders auffällig ist der niedrige Variationskoeffizient (0,6%) für Verfahren II, d.h. unkontrollierbare Nebenreaktionen des Titanium(IV) werden besonders wirksam durch EDTE unterdrückt.

Wenn die Anwesenheit eines Störions zur Erniedrigung der Extinktion führte, wurde dies mit ↓ gekennzeichnet.

Zur Betrachtung der Selektivität können die ermittelten Grenzverhältnisse in Tabelle 2 herangezogen werden. Die angegebenen g-Werte zeigen, daß durch den Einsatz ternärer Systeme für 33 von 47 Ionen die Störungen herabgesetzt sind. Der nach

$$S = \frac{\sum\limits_{i=1}^{n} g_i}{n} \quad (n \text{ Anzahl der Störionen})$$

definierte Selektivitätskoeffizient S hat wegen seiner eingeschränkten Aussagekraft zwar nur formale Bedeutung, macht aber die Selektivitätserhöhung bei den Verfahren II und III besonders deutlich. Die Störelemente Cs, K, Li, Mg, Na, Rb, Se, Tl gehen dabei nicht mit ein, da in allen drei Systemen praktisch keine Störungen ($g = 1000$) vorliegen.

$$S_I = 72$$

$$S_{II} = 329 \quad (n = 39)$$

$$S_{III} = 204$$

Wie man sieht, existieren deutliche Vorteile bei der Anwendung von EDTE (Verfahren II) gegenüber NTE (Verfahren III). Die Ursache dafür liegt ganz allgemein in der hohen Stabilität von EDTE–Störion-Chelaten sowie der weitgehenden Absättigung von Koordinationsstellen dieser Ionen durch den sechszähnigen Liganden, so daß die Bildung von binären bzw. ternären BPR-Chelaten

$$MeY + n_1 BPR \rightleftharpoons Me(BPR)_{n_1} + Y$$

$$MeY + n_2 BPR \rightleftharpoons MeY(BPR)_{n_2}$$
erschwert ist.

Eine Ausnahme dazu bilden die Ionen der Elemente Au, Cu, Ir, Nb, Ta, Th, Zr, wo die Störungen mit NTE (Verfahren III) geringer sind. Während bei Nb, Ta, Th, Zr auf Grund ihrer hohen Koordinationszahlen ($Z = 8$) die entsprechenden EDTE-Komplexe (1:1) den zweizähnigen Liganden BPR unter Bildung ternärer Species noch anlagern können, ist die Koordinationssphäre dieser Kationen bei den NTE-Komplexen (1:2) wegen der Vierzähnigkeit von NTE abgesättigt, und es resultiert eine geringere Störung mit NTE gegenüber EDTE. Im Falle von Au und Ir handelt es sich offensichtlich um eine oxydative Zerstörung von BPR, welche möglicherweise durch Stabilisierung von (Au, Ir)-Zwischenstufen in Gegenwart von EDTE begünstigt wird. Bei Cu schließlich besteht ein Vorteil für NTE, weil die Eigenfärbung des Chelates CuX^- weniger intensiv ist als die von CuY^{2-}.

Es konnte bereits mit Hilfe der Selektivitätskoeffizienten gezeigt werden, daß das Verfahren II selektiver als Verfahren III ist. Im weiteren soll deshalb einiges zur Selektivität des Verfahrens II gegenüber Verfahren I (binäres System) herausgestellt werden.

Für folgende Ionen tritt durch EDTE eine starke Verbesserung der Selektivität ($g_{II}/g_I \geqslant 10$) auf: Al(50), Bi(520), Ca(40), Ce(290), Co(40), Cu(90), Fe(260), Ga(420), Hg(10), In(3300), La(140), Mn(70), Pb(60), Pd(1400), Sr(10), Th(30), V(40). In Klammern sind dabei die gerundeten Quotienten g_{II}/g_I angegeben. Eine schwache Verbesserung der Selektivität ($10 > g_{II}/g_I > 1$) ist bei den Elementen Ag(2), As(2), Be(9), Cd(2), Cr(4), Ge(2), Nb(2), Pt(7), Rh(2), Sb(4), Sn(2), U(6), Zn(2), Zr(2) zu finden.

Bei folgenden Ionen ist keine Verbesserung ($g_{II}/g_I = 1$) zu beobachten: Cs, K, Li, Mg, Mo, Na, Rb, Se, Te, Tl.

Dagegen konnte eine Verschlechterung der Selektivität ($g_{II}/g_I < 1$) bei den Elementen Au(0,1), Ba(0,2), Ir(0,2), Ni(0,5), Ta(0,3), W(0,6) nachgewiesen werden.

Die in dem System Titanium(IV)/BPR/EDTE gefundene Erhöhung der Selektivität gegenüber dem System Titanium(IV)/BPR für eine große Zahl von Störionen wird naturgemäß von den Stabilitätsverhältnissen Me–EDTE und Me–BPR unter vorliegenden Reaktionsbedingungen bestimmt. In Abhängigkeit dieser Stabilitätsverhältnisse ist die Lage der entsprechenden Gleichgewichte schematisch

$$Me(BPR)_n + Y \rightleftharpoons MeY + n BP$$
$$[\epsilon(Me(BPR)_n \geqslant \epsilon(MeY)]$$

im Zusammenhang mit dem Extinktionskoeffizienten entscheidend für den Grad der Selektivitätserhöhung. Bei den Ionen mit $g_{II}/g_I = 1$ existieren in Lösung keine bzw. nur wenig stabile EDTE-Chelate, eine Verbesserung der Selektivität tritt hier deshalb nicht ein. Die Unterdrückung der Störungen bei Ca^{2+}, Pb^{2+} und Sr^{2+} mit EDTE beruht darauf, daß die im System Ti/BPR auftretenden schwer löslichen Sulfate durch die Aminopolycarbonsäure vollständig bzw. teilweise aufgelöst werden. Wie die Werte $g_{II}/g_I < 1$ zeigen, existieren auch einige wenige Fälle, wo die Anwesenheit von EDTE eine Verschlechterung der Selektivität mit sich bringt. Als Ursachen dafür kommen Redox-Reaktionen (Au, Ir/BPR), Fällungsreaktionen (Ba/SO$_4$), Eigenabsorption (Ni/Y) sowie Hilfskomplexbildnerwirkung (Ta, W/Y) in Frage.

Spurenanalyse, Teil 2, S. 1511. Springer Verlag, Berlin, 1974.

Summary—As part of a continued investigation of the analytical applications of ternary complexes, the systems Ti(IV)/BPR, (I), Ti(IV)/BPR/EDTA (II), and Ti(IV)/BPR/NTA (III), where BPR = Bromopyrogallol Red, have been investigated and compared in terms of working concentration range, molar absorptivity, standard deviation, coefficient of variation, calibration sensitivity, limit of detection and of determination. A novel way of summarizing the effects of interferences of a large group of ions (some 47 in all) is presented. The results show that the ternary systems, in particular system **II**, have a better selectivity than the simple binary system **I** of titanium with Bromopyrogallol Red.

SPECTROPHOTOMETRIC DETERMINATION OF CYANIDE BY UNSEGMENTED FLOW METHODS

A. Rios, M. D. Luque de Castro and M. Valcarcel

Department of Analytical Chemistry, Faculty of Sciences, University of Córdoba, Córdoba, Spain

Summary—Photometric methods for cyanide determination by normal and reversed FIA techniques and by completely continuous monitoring are proposed. The sampling rates for the first two techniques are 20 and 28/hr, respectively, the r.s.d. being less than 0.8% in both cases. A simulation of cyanide control in industrial waste waters shows the usefulness of the continuous monitoring method.

The toxicity of cyanide has long made necessary its determination in a great variety of samples, and fast methods for continuous or non-continuous monitoring are still needed. The unsegmented flow techniques offer a wide range of possible methodologies. Thus flow-injection analysis in its conventional form (nFIA;[1] injection of sample into a continuous flow of the reagent) allows analysis for cyanide with minimum consumption of the sample solution. In cases such as waste-water analysis, where the reagents constitute the major cost of the determination, reversed FIA (rFIA)[2] is more suitable. In this the reagents are injected into a continuous flow of the sample to be analysed. When possible variations in sample composition necessitate continuous monitoring, an analysis utilizing completely continuous flow[3] (continuous recording of the signal produced after the confluence of very small sample and reagent streams) is ideal.

Of these unsegmented flow techniques, only nFIA has previously been used for determination of cyanide. Pihlar *et al.*[4] have proposed voltammetric determination of cyanide over a wide range of concentrations (from 0.5 μg/l. to 1 g/l.), but there were many interfering species. In a later paper,[5] many of the interferences were eliminated by prior distillation of the sample and decomposition of possible cyanide complexes by irradiation with ultraviolet light. The only potentiometric determination of cyanide, by Müller,[6] used a selective Ag_2S electrode, but interferences were not studied. The determination range was 10^{-6}–10^{-3} *M*. The only method involving optical detection is the fluorimetric determination by catalysis of the aerial oxidation of pyridoxal or pyridoxal-5-phosphate. The range of determination is similar with the two reagents (0.1–20.0 μg/ml). Interferences were eliminated or their tolerance levels increased by use of a stopped-flow technique.[7]

Since the most common detector in a control laboratory is likely to be a colorimeter or spectrophotometer, we considered that a simple, well-tested classical reaction would be the most convenient to use. We chose a reaction in which a dye is formed by use of chloramine-T, pyridine and barbituric acid.[8] Three variants are proposed, for analysis of (*a*) scarce or valuable samples (use of normal FIA), (*b*) waste waters (use of reversed FIA), (*c*) a continuous stream (completely continuous method).

EXPERIMENTAL

Reagents

All reagents were of analytical-reagent grade and solutions were prepared with distilled water.

Pyridine–barbituric acid reagent. Place 15 g of barbituric acid in a 250-ml standard flask and add just enough water to wash the sides of the flask and wet the barbituric acid. Add 75 ml of pyridine and mix. Add 15 ml of concentrated hydrochloric acid, mix and cool to room temperature. Dilute to volume with water and mix.

Chloramine-T solution. Dissolve 1.0 g in 100 ml of water.

Sodium dihydrogen phosphate–sodium hydroxide buffer solution. Dissolve 138 g of $NaH_2PO_4.H_2O$ and 2 g of sodium hydroxide in 1 litre of distilled water (total phosphate concentration = 1.0*M* and pH = 6.3).

Cyanide solution. Aqueous potassium cyanide solution containing 1.000 g of cyanide per litre.

Apparatus

A Pye Unicam SP 6-500 spectrophotometer was used as a detector, connected to a Radiometer REC 80 recorder. The accessory instruments were a Beckman pH-meter and a thermostat. A Gilson Minipuls-2 peristaltic pump, a Hellma 178.10 flow-cell (inner volume 18 μl), a Tecator L 100-l injection valve and a Tecator TM II "chemifold" were used.

Manifolds

Figure 1 shows the various manifolds used and the optimum values of the variables for each method.

NORMAL FIA

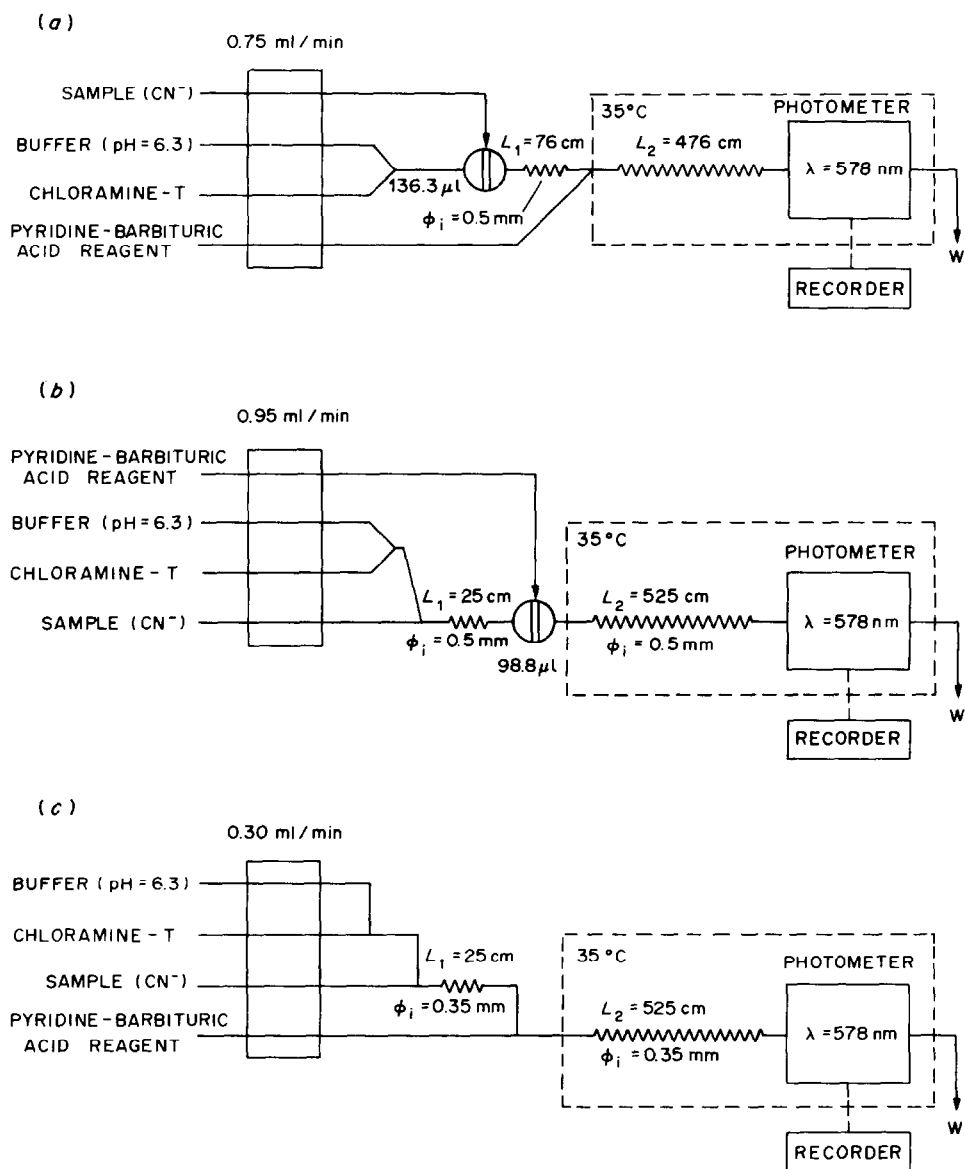
In this method (Fig. 1*a*) the carrier consists of a mixture of chloramine-T solution and buffer into which the sample is injected. In reactor L_1, CNCl is formed from chloramine-T; the subsequent confluence of the CNCl bolus with a stream of


Fig. 1. Manifolds and optimum working conditions for the determination of cyanide by: (a) normal FIA; (b) reversed FIA; (c) completely continuous technique.

pyridine–barbituric acid solution causes the formation in L_2 of the detectable product, which is violet with an absorption maximum at 578 nm.

The FIA variables (flow-rate, length of the reactor sections L_1 and L_2 and volume of the injected sample) were optimized by a modified simplex method.[9] Later, the influence of the bore of the reactor sections (0.35, 0.50 and 0.70 mm) was studied. There were five initial experiments, then 19 more points in 10 different cycles with 9 reflections, 3 expansions and 3 positive contractions. For each point (in duplicate) the corresponding blank (distilled water) was recorded, because the change in the refractive index[10] between the carrier and the sample caused a small peak which must be subtracted from the sample

signal. The addition of pyridine to the sample solution to equalize the refractive index of the sample and carrier was unsatisfactory. The maximum response (height of the FIA peak) was obtained for the following values of the variables: $q = 0.48$ ml/min; $V_i = 136.3 \mu$l; $L_1 = 76$ cm; $L_2 = 476$ cm. Some variables had to be limited for operational reasons. Thus, the simplex treatment shows the optimum flow-rate should be about zero, but it must be set at 0.45 ml/min for a reasonably high sampling rate to be obtained (though at the expense of a 10% decrease in the absorbance). The length of reactor L_1 should also be zero, and its minimum value was initially set at 10 cm. Subsequent operations established the practical optimum value as 76 cm.
Fig. 2. Effect of temperature in the normal (1 ppm CN⁻) and reversed (4 ppm CN⁻) techniques.

kept between 6 and 8. More acidic pH values cause loss of cyanide as hydrogen cyanide gas. Values above 8 are not desirable because the reaction between chloramine-T and cyanide is then followed by a fast hydrolysis.

Concentrations of chloramine-T more or less than 1% make the response function decrease slightly. An increase in concentration of the pyridine–barbituric acid mixture improves the response of the system, but at higher concentrations than the one used the barbituric acid does not dissolve completely.

The influence of temperature was studied for the range 20–55° and the results are given in Fig. 2. A sharp rise in the signal is observed between 20 and 40°. A temperature of 35° was chosen as an optimum working temperature; although the signal obtained at 40° is slightly higher, small bubbles are then formed in the reactor.[11]

The optimum values for the FIA variables are logical from the chemical point of view. The flow-rate has to be small because the reaction between CNCl and the pyridine–barbituric acid mixture is slow. For this reason the value of L_2 is also high, although the dispersion requirements limit its value. On the other hand, the length of L_1 is small because CNCl can be hydrolysed to form CNO⁻, which does not react to give the coloured compound.

The height of the FIA peak increases with the volume of sample injected, but samples bigger than 136.3 μl cause a double peak to appear, because the reaction is incomplete in the central zone of the bolus.

Study of physical and chemical variables

The pH of the carrier and sample solutions was

Determination of trace levels of cyanide

The absorbance *vs.* concentration calibration graph consists of two distinct segments (Fig. 3*a*). The equations for these segments are:

$$A = 0.44[CN^-] - 0.015$$
$$\text{for} \quad [CN^-] = 0.1\text{–}0.4 \ \mu g/ml \quad (r = 0.992)$$

and

$$A = 0.67[CN^-] - 0.108$$
$$\text{for} \quad [CN^-] = 0.4\text{–}1.0 \ \mu g/ml \quad (r = 0.998).$$

The relative standard deviations calculated from the results for 11 samples of cyanide were 0.8% and 0.5%, respectively. The lower detection limit corresponds to the first segment, although its sensitivity (slope of the straight line) is less than that for the
Fig. 3. Calibration runs for determination of cyanide by (*a*) nFIA and (*b*) rFIA.

second. The precision in both cases is good. The sampling frequency is about 20/hr.

Here (Fig. 1*b*) the main carrier is the sample solution, mixed before the injection valve with a secondary carrier consisting of a mixture of buffer and chloramine-T. The formation of CNCl occurs in reactor L_1. Later, this product reacts in L_2 with the pyridine–barbituric acid mixture injected to produce the violet colour.

Study of FIA variables

The flow-rate, lengths of the reactors and injected volume were optimized as before. In this case it is again necessary to subtract from each signal the corresponding blank, and in rFIA the signal produced by the blank is six times the one obtained by normal FIA. This significant increase in the blank signal causes a higher detection limit for cyanide. Addition of pyridine to equalize the refractive indices again does not help. The simplex involved five initial experiments and a total of 18 points in 11 cycles, with 9 reflections, 2 expansions and 2 contractions (one positive and the other negative). The maximum response corresponds to the values: $q = 0.95$ ml/min; $V_i = 98.9$ μl; $L_1 = 25$ cm; $L_2 = 525$ cm. Some variables again had to be limited, and the values again can be related to the chemistry. The higher flow-rate used here necessitated a greater length of L_2 to provide the same reaction time. The volume injected (reagent in this case) now has to be smaller to decrease the blank signal. The bore of the reactors has very little influence on the signal, although for a tubing diameter of 0.50 mm the peak is slightly higher.

Study of physical and chemical variables

The influence of the concentration of the reagents is similar to that in nFIA. However the temperature affects the system in different ways, as can be seen in Fig. 2. Between 40 and 50° the signal increases, but this is not analytically useful, because bubbles form along the manifold. The working temperature chosen was therefore again 35°.

Determination of traces of cyanide

The calibration graph is linear for the cyanide range 0.3–5.0 μg/ml, the equation being

$$A = 0.146[CN^-] + 0.031 \quad (r = 0.999).$$

Eleven injections of a 2.0 μg/ml cyanide solution gave a 95% confidence interval of $\pm 0.7\%$. The sampling-rate was 28 samples/hr.

The manifold for this (Fig. 1*c*) is similar to that for reversed FIA (Fig. 1*b*), but without an injection

valve. The analyte and reagents flow continuously through the measurement cell and the cyanide concentration is determined without interruption. Thus it is very useful for the control of cyanide in industrial waste waters.

Influence of the variables

Since the manifold is the same as that for rFIA (omitting the injection valve), the same conditions are used, with the advantage now that the blank does not give a signal and only the variation of cyanide concentration with time is recorded.

To reduce consumption of sample and reagent, the flow-rate is restricted to 0.30 ml/min, and the bore of the reactors is 0.35 mm.

Simulation of continuous control of cyanide in waste water

Figure 4*a* shows a calibration run for cyanide in waters. The calibration range is 0.7–4.0 μg/ml, and the graph is a straight line with the equation:

$$A = 0.30[CN^-] - 0.19 \quad (r = 0.989).$$

Figure 4*b* shows the results of a simulation of analysis for cyanide in waste waters throughout a working day. The cyanide came from a 2-litre container which initially contained 500 ml of distilled water. Another vessel containing cyanide solution was fixed to this tank. Periodically different volumes of cyanide or distilled water were added to the container in such a way that the cyanide concentration was changed.

Two sorts of comparison of the results obtained in this work can be made:

(*a*) the traditional technique can be compared with the unsegmented-flow techniques;
(*b*) the three unsegmented-flow techniques used in this paper can be compared with one another.

The first (*a*) is summarized in Table 1. The flow techniques have clear advantages over the traditional photometric one (except that the sensitivity and the detection limit are more favourable in the traditional technique).

The second (*b*) is made in Table 2. The highest sensitivity and lowest detection limit are obtained by nFIA. This finding is at variance with previous observations. Previously the main advantage claimed for rFIA has been higher sensitivity.[2,12] The relative loss of sensitivity observed in this work may be due to the large increase of the blank signal in the rFIA, which can mask sample peaks at concentrations below 0.3 μg/ml. An alternative cause is the inability to ensure presence of the excess of reagent necessary for the optimum reaction in rFIA. The detection limit is lower in the FIA methods than in the completely continuous one. nFIA permits determination of cy-
Fig. 4. Completely continuous technique. (a) Calibration run; (b) simulation of continuous monitoring of [CN⁻] in waste waters during a working day.

anide levels as low as 0.1 μg/ml (linear range 0.1–1.0 μg/ml); on the other hand, rFIA permits determination over a wider range (0.3–5.0 μg/ml)

Table 1. Comparison between the unsegmented flow methods for determination of cyanide and the conventional method

Conventional photometric method	Unsegmented flow methods
Lower detection limit	Higher analysis rate
Higher sensitivity	Easier handling
	Greater versatility for the required type of analysis
	Good precision
	Automated continuous methods are possible
	Minimum exposure of the analyst to the highly toxic CNCl
	Diminution of interferences

with a straight line calibration graph. The sampling frequency is a little higher in rFIA. Table 2 suggests applications for the three modifications.

Interferences

As shown in Table 3, the most significant interferences come from species with cyanide groups (thiocyanate, ferrocyanide and ferricyanide are positive interferences) and cations that form complexes with cyanide (silver, copper, cobalt, nickel, etc., which cause negative interference). Bromide and iodide diminish the analytical signal, perhaps because of formation of CNBr and CNI, which do not react with the pyridine–barbituric acid. Fluoride does not interfere. Sulphide and nitrite, which interfere seriously in the conventional method,[8,13] are tolerated in these flow methods when present in up to tenfold ratio to cyanide.

The interferences are practically the same in the three unsegmented flow methods, although in rFIA they appear to be slightly less severe.

Table 2. Comparison of the unsegmented flow methods

Method	Typical application	Samples/hr	[CN⁻], μg/ml	Slope of calibration line
Normal FIA	Scanty samples	20	0.1–0.4	0.44
			0.4–1.0	0.67
Reversed FIA	Waste water analysis	28	0.3–5.0	0.15
Completely continuous	Automated continuous analysis	Continuous	0.7–4.0	0.30

AEROSOL COLLECTION AND RF PLASMA VOLATILIZATION ON A TUNGSTEN WIRE ELECTRODE

KEIJO HAAPAKKA* and ROGER STEPHENS†
Trace Analysis Research Centre, Department of Chemistry, Dalhousie University, Halifax, Nova Scotia,
Canada

Summary—Electrostatic trapping of desolvated aerosols on a wire electrode is described. A capacitively-coupled radiofrequency discharge is used to vaporize and excite collected material. The apparatus shows a clear and controllable transition between different modes of electrostatic collection. Boron shows unexplained anomalous behaviour.

Electrostatic trapping has been applied to the collection of atmospheric particulates[1,2] and to the preconcentration of aqueous solutions.[3,4] In the latter case the solution is converted into an aerosol, desolvated, and deposited on either a wire or a liquid-filled trough electrode. However neither of these types of electrode is ideal. The former is unsatisfactory because of the difficulty of removing trapped material without also destroying the wire. A liquid collector avoids this problem, but is tedious to set up and must be renewed each time it is used.

The present work examines an alternative method of performing an electrostatic collection and retrieval cycle, which works for a wide range of elements and requires no manipulation of the electrode system between samples. The method uses a wire point as the collector. The high field-gradient associated with the small radius of curvature at the tip of the wire ensures that material is collected with high efficiency and is deposited over a small surface area. Given this geometry, the subsequent removal of deposited material is easily achieved by volatilization with a low-power capacitively-coupled radiofrequency (RF) plasma, which can be made to vaporize the surface coating of the wire while leaving the substrate intact. In the present work the plasma was used both to evaporate the sample and excite it so that the vaporized material could be detected by means of its atomic emission.

EXPERIMENTAL

The device used in the present work is shown in Fig. 1. Dry aerosol entering from B flows around a wire electrode E (the working electrode) which is connected to a suitable high voltage (either positive or negative). Some of the aerosol particles are attracted to the electrode surface and retained. The process is continued until sufficient material has built up on the working electrode to allow its subsequent

detection by atomic emission from a plasma generated directly at the electrode surface. A ground electrode was also used during the collection cycle to collect aerosol particles which might become charged and repelled from the working electrode. The trapping efficiency of a wire collector and the stability of the atomizing plasma both depend on the cell geometry used because of build-up of static charge on insulating surfaces. The cell shown in Fig. 1 was found to be suitable. The body was made of Pyrex glass. The working (E) and ground (F) electrodes were made of 0.5 mm diameter tungsten wire, with lengths of 6 and 2 mm, respectively. A ground plane was provided by wrapping a few turns of copper wire (D) around the body of the cell.

The RF plasma used to volatilize the collected material was generated in argon by a laboratory-built supply which delivered 30 W at 2 MHz. The output was connected to the working electrode and ground plane through an impedance-matching transformer which developed a zero-load secondary voltage of 3 kV. This was sufficient for spontaneous initiation of the plasma, which appeared as a stable, arc-like streamer between the working electrode and the glass of the

cell body. The electrode became red-hot during this process, but its temperature was insufficient to cause thermal volatilization of the majority of compounds examined. It was concluded that sputtering by the plasma was the primary cause of vaporization.

Detection of vaporized material was by atomic emission, measured with a Varian AA5 spectrometer. The optical alignment which gave the best signal-to-noise ratio was that in which the image of the electrode was slightly offset (in either direction), when the monochromator was viewing a section of the plasma immediately adjacent to the electrode surface.

Procedure

The d.c. collection voltage was connected to the working electrode. Sample solutions were aspirated with a pneumatic nebulizer and desolvated as described in earlier work. Air was used as the carrier. After collection was complete the gas supply was switched to argon to purge the cell. The argon flow was reduced, normally to 0.04 l./min with the present cell, and the working electrode switched over to the RF supply to initiate the plasma. A transient atomic-emission signal was observed, with a duration of a few msec. A burn time of 5 or 10 sec normally cleared the electrode even of heavy salt deposits; this is a sufficiently short interval to avoid serious etching of the tungsten surface (even if traces of oxidizing gases are present in the argon supply).

RESULTS

The elements Ag, B and Cd were selected to test the behaviour of the system. The effects of trapping voltage and of argon flow-rate are shown in Figs. 2 and 3.

The results in Fig. 2 show that collection efficiency for all three elements increased to a maximum at about 9 kV. The maximum efficiency was found, by methods described previously,[3] to be around 30%. This is a lower efficiency than was achieved with earlier designs because, although a high field-gradient exists around the electrode, its influence extends over only a small volume.

For trapping voltages below 9 kV, transferring the plasma to the ground electrode (F in Fig. 1) gave only a weak emission signal. Washing the inside of the cell also failed to reveal any material deposited on the glass walls. It was concluded that the bulk of the trapped aerosol was retained on the working elec-

trode. These results altered as the collection voltage was increased above 9 kV. Increasing amounts of material were transferred to the walls and to the ground electrode. At the same time a faint corona became visible. Therefore the occurrence of the maximum in Fig. 2 was attributed to a change in the mechanism of collection, from one involving attraction of polarized aerosol particles to the working electrode at low collection voltages, to one in which the aerosol particles became charged in the corona and repelled away from the working electrode.

Boron alone showed erratic behaviour for collection voltages below 9 kV. Borax gave apparently normal emission signals for initial boron concentrations above 0.4 μg/ml, but for lower concentrations the response fell abruptly to zero. Addition of 2 μg/ml of sodium chloride corrected this behaviour and all results for boron were obtained in this way. However, boron as boric acid failed to give any response at all, even in the presence of sodium chloride. This sensitivity to the physical and chemical nature of the aerosol is similar to the behaviour of the liquid collector.[4] It is apparently related to the different properties of the two collection modes and presumably reflects the complex behaviour of boron oxyanions. However, the unusual magnitude of the variations caused by minor changes in the initial solution remains an unexplained curiosity.

The effects of varying the argon flow-rate during the atomization cycle are shown in Fig. 3. The results indicate that the volatilization process is not particularly sensitive to the argon flow, but that the excitation temperature falls as the argon flow increases. However, the argon flow could not be completely stopped or the plasma column itself became unstable.

Results were repeated for ground and working electrodes varying in length from 1 to 10 mm, but no major variations were observed. Other plasma gases were examined but none gave as satisfactory results as argon, possibly because of the low RF power used. Following these preliminary results, the collection voltage and argon flow-rate during plasma generation were fixed at 8 kV and 0.04 l./min,
Fig. 3. Effect of argon flow on the emission intensity of Ag (O), Cd ($\triangle$), B ($\square$). Conditions as in Fig. 2.

*For a signal corresponding to 3 times the relative standard deviation of 6 successive blank readings, 50-ml sample volume.

respectively. The analytical behaviour of the three test elements was examined and the detection limits for others were determined. Results are summarized in Tables 1 and 2.

In order to assess the sensitivity of the apparatus to matrix effects, or to the action of added buffering agents, the responses of the three test elements in the presence of sodium chloride were observed. The results are shown in Fig. 4. Sodium chloride was found to influence the response by increasing the intensity of the (wide-band) background emission. This was particularly marked at short wavelengths as shown by the Cd response in Fig. 4 (total emission at the Cd wavelength). In addition, sodium chloride causes a reduction in collection efficiency, shown by the fall of the curves for Ag and B in Fig. 4 (corrected for wide-band emission by dual-wavelength measurements). The spectroscopic interference appears to be the more serious; the collection process itself tolerates small amounts of sodium chloride reasonably well.

CONCLUSIONS

The behaviour of the present apparatus shows that an aerosol can be collected onto a single pointed wire electrode with useful efficiency. It also shows the ability of a low-power RF plasma to volatilize refractory materials, such as oxygen-containing or hydrated salts of B, Si and Zr, from the surface of the wire.
Fig. 4. Effect of NaCl on the emission intensity of Ag ($\bigcirc$), Cd ($\triangle$), B ($\square$). Conditions as in Fig. 2.

Considerable sensitivity is lost in the present apparatus through the inefficient delivery of vaporized material to the region of highest temperature in the plasma, and through spreading of the sample over a larger volume than can be observed by the optical system. In principle, the technique is capable of good sensitivity, since the material collected from a large volume of solution can be retained on a surface of small area, and reintroduced into the vapour phase over a time interval of a few msec.

The technique is of use in its present form because it provides a simple method of loading wire probes to any desired level. It also affords a convenient way of examining the transition between different modes of collection (*i.e.*, attraction of particles to the working electrode or coronal charging and repulsion). This transition is observed with any type of electrostatic trap, but its onset is sensitive to design and operation of the trap as well as to the nature of the aerosol. The present behaviour is unusual in that the transition occurs abruptly, leading to a sudden switch from efficient collection to zero, or *vice versa*, as a result of small changes in operating conditions. Its investigation is of interest partly because of this sensitivity *per se*, and partly because of the necessity to control the transition point for a given type of aerosol.

GEL SPECIATION STUDIES–II

AN EXTENSION OF EARLIER STUDIES OF THE PROTONATION EQUILIBRIA OF CROSS-LINKED CARBOXYMETHYLDEXTRAN

Summary—The potentiometric properties of the rigidly cross-linked Sephadex gel CM-25 have been studied. The gel was equilibrated in sodium perchlorate at fixed concentration levels (0.010 and 0.0010M) and with variable concentration levels of NaClO$_4$ (from 0.0010 to 0.10M). The volume of the gel was measured for every equilibrated sample simultaneously with the solution pH and pNa. The pK computed after correction for a Donnan potential term was found to be independent of α, the degree of neutralization, and ionic strength; its value of 3.35 ± 0.15 was in excellent agreement with the intrinsic pK measured earlier for the flexible CM-50 Sephadex gel and reported for its linear polyelectrolyte analogue, carboxymethyldextran. An interesting observation from these studies is the efficient screening of the charged surface by the counter-ions in the presence of a three-dimensional charged network.

It has been shown that in the investigation of gel-phase equilibria, such as the dissociation of a weakly acidic group repeated in a regular way throughout the gel structure, and/or the complexation of metal by this acidic group, a Donnan potential term must be calculated[1,2] to permit an estimate of non-ideality at the site of the reaction. For this purpose it is necessary to know the gel-phase concentration of the potential-determining counter-ion (e.g. Na$^+$) as well as the solution pH and pNa at every experimental point, since

$$pC_H^g = pH_{(s)} - pNa_{(s)} + pC_{Na}^g \qquad (1)$$

where

$$pC_H^g - \log \frac{\alpha}{(1-\alpha)} = pK_{(HA)}^{app} \qquad (2)$$

and

$$pK_{(HA)}^{app} - pK_{(HA)}^{int} = -0.434 \frac{e\psi_{(a)}}{kT} + \log y_{H^+}^g \qquad (3)$$

In equation (1) the subscript s and the superscript g refer to the solution and gel phases, with C_H^g and C_{Na}^g representing the molar concentration of H$^+$ and Na$^+$ in the gel. In equation (2) α refers to the fraction of gel acidic groups that is dissociated and p$K_{(HA)}^{app}$ corresponds to the apparent pK of the acid unit (HA) which is repeated in the polymer. Finally, in equation (3) the superscript int designates the intrinsic pK of the repeating HA unit, $\psi_{(a)}$ refers to the potential at the surface of the charged gel matrix, and $y_{H^+}^g$ is the molar activity-coefficient correction for long-range

Debye-type ion-interaction forces acting on the H$^+$ ion in the gel phase.

Since electroneutrality must be preserved in the gel phase, the Na$^+$ content of the gel can be equated directly with the quantity (meq) of acid dissociated, (A$^-$)$_v$ or αv, on controlled addition of standard base, by means of equation (4):

$$(A^-)_v = \alpha v = bV_b + hV_s = Na_{(g)}^+ \qquad (4)$$

where b and h are the molarities of the base and acid, respectively, and V_b the volume of base added and V_s the volume of the aqueous phase after the addition of base. Measurement of the gel volume, V_g, then permits evaluation of C_{Na}^g with equation (5):

$$C_{Na}^g = \frac{v\alpha}{V_g} \qquad (5)$$

The neutralization by sodium hydroxide of the cation-exchange gel in equilibrium with a sodium salt of a strongly acidic polyelectrolyte such as sodium polystyrene sulphonate, NaPSS, can be expressed by the equation

$$pH_{(s)} - pNa_{(s)} + \log V_g^*$$
$$= pK_{(HA)}^{app} + \log y_{Na}^g + \log \frac{\alpha^2}{(1-\alpha)} = S \qquad (6)$$

where V_g^* is now defined as the specific volume (ml per 1 meq of the gel).

By inclusion of y_{Na}^g and other terms such as y_{A^-}, the activity coefficient of the acidic unit of gel, and y_{Na}^h and y_H^h, the solvation contributions of both the H$^+$

and Na^+ ions in the pK^{app} term, as done by Slota and Marinsky,[1] the pK^{app} value can be obtained by the relationship:

$$pK^{app}_{(HA)_v} = pH_{(s)} - pNa_{(s)} + \log V^*_g - \log\frac{\alpha^2}{(1-\alpha)} \quad (7)$$

If a simple neutral electrolyte, e.g., sodium perchlorate, is used to control the ionic strength of the aqueous medium, an accurate estimate of the extent of gel invasion by the salt [which is reduced sufficiently by the use of a high molecular-weight polyelectrolyte (NaPSS) to be neglected in equations (5)–(7)], must now be made for correct assessment of pC^g_H with equation (1). At equilibrium the activity of sodium perchlorate is the same in both phases:

$$a^g_{NaClO_4} = a^s_{NaClO_4} \quad (8)$$

so

$$(\gamma^{\pm}_g)^2(C^g_{Na})(C^g_{ClO_4}) = (\gamma^{\pm}_s)(C^s_{Na})(C^s_{ClO_4}) \quad (9)$$

where $\gamma^{\pm}$ represents the mean molar activity coefficient of sodium perchlorate in the separate solution (s) and gel (g) phases. Now

$$C^g_{Na} = \frac{v\alpha}{V_g} + C^g_{NaClO_4} \quad (5a)$$

and

$$(\gamma^{\pm}_g)^2\left(\frac{v\alpha}{V_g} + C^g_{NaClO_4}\right)(C^g_{NaClO_4}) = (C^s_{NaClO_4})^2 (\gamma^{\pm}_s)^2 \quad (9a)$$

Little error is introduced by equating $(\gamma^{\pm})_g$ with $(\gamma^{\pm})_s$ in equation (9a) to facilitate evaluation of $C^g_{NaClO_4}$ from the resultant quadratic equation. The value of C^g_{Na} [equation (5a)] so corrected can then be transferred to equations (5)–(7) for a more accurate analysis of the potentiometric data with equation (7a):

$$pK^{app}_{(HA)_v} = pH_{(s)} - pNa_{(s)} - \log\frac{\alpha}{(1-\alpha)}$$
$$- \log\left(\frac{\alpha}{V^*_g} + C^g_{NaClO_4}\right) \quad (7a)$$

The research described below was intended to extend an earlier study of the potentiometric behaviour of Sephadex, a weakly cross-linked carboxymethyldextran. A Sephadex gel (CM-25) more rigid than that used in the earlier studies[1,2] was employed to increase the effective concentration range of counter-ions in the gel beyond that examined before, so that the effect of counter-ion screening of the charged macromolecular surface, confined to a gel-network geometry, could be observed over an extended counter-ion concentration range.

EXPERIMENTAL

Preparation of the resin

Sephadex CM-25, commercially available from Pharmacia fine chemicals (Sweden), was obtained in the sodium form with a nominal capacity of 4.5 meq/g for the material. It was first placed in water to swell before transfer to a chromatographic column for conversion into the acid form,

by slow passage of large excess of $0.2M$ perchloric acid through the resin column. Use of more concentrated acid was avoided, to prevent hydrolysis of the glycosidic bonds of the carboxymethyl dextran. After the conversion was complete doubly distilled water was passed through the column until the pH of effluent and influent were the same. The wet resin was then stored in sealed polyethylene containers.

Batch equilibration procedure

Approximately 1-g samples of wet resin were accurately weighed out and transferred quantitatively to 20-ml screw-capped glass tubes. Controlled volumes of standard sodium hydroxide solution were then added to each sample, under a nitrogen atmosphere, to cover the neutralization range from approximately 5 to 85%. The final volume of the solution varied from 10.0 to 20.0 ml. In one type of experiment the ionic strength was maintained constant in each sample at 0.010 or 0.001 by addition of a volume of $0.020M$ or $0.002M$ sodium perchlorate (as appropriate), just equal to the volume of base added in adjusting the degree of neutralization of a particular sample. At the lower α values, $0.010M$ or $0.001M$ sodium perchlorate was added to the sample to bring the final volume up to 10.0 ml. In the other type of experiment the ionic strength was allowed to vary.

Each of the samples was equilibrated at ambient temperature ($20 \pm 2°$) for at least 15 hr with continuous agitation provided by a rotating platform. The samples were sealed with parafilm to avoid the absorption of CO_2 during equilibration. At the end of the equilibration period essentially all of the supernatant solution was collected, under a nitrogen atmosphere, for potentiometric pH and pNa measurement.

Gel volume determinations

The surface of the residual solution, defined by a 1–2 mm depth beyond the gel boundary, was first marked by a line drawn on the exterior wall of the tube, tangentially to the solution meniscus (the tube was ~10 mm in diameter). Exactly 1.00 ml of a 0.010% aqueous solution of Blue Dextran 2000, a macromolecular dye with an average molecular weight of 2×10^6 (from Pharmacia Fine Chemicals of Sweden) was then added to the resin and the residual solution. After vigorous shaking to ensure complete mixing of the dye with the solution as rapidly as possible, a small aliquot of the solution was withdrawn for spectrophotometric measurement at 620 nm, with a Perkin-Elmer model 554 spectrophotometer. The brief interval ($<1/2$ min) of agitation before sampling was believed to keep the absorption and/or diffusion of the dye sufficiently low to avoid any disturbance of the volume measurement. To obtain the volume of resin, the volume of solution, accurately accessible from this measurement, was then subtracted from the total volume of resin and solution, determined by weighing the quantity of water needed to fill the tube to the added mark, after the resin and solution had been quantitatively added to the supernatant solution withdrawn earlier for the electrochemical measurement of pH and pNa.

Total resin capacity measurement

The total capacity of each resin sample was determined by back-titration with standard acid of the excess of standard sodium hydroxide solution added to each gel–solution mixture.

Potentiometric measurements

All electrochemical measurements were made (to ±0.1 mV) with a Crison (Barcelona) digital pH-meter equipped with an Ingold combination (405–M5) electrode (a glass electrode and an Ag/AgCl internal reference electrode) for the pH determinations and a Radiometer sodium ion-selective electrode (G502 Na) joined with a reference calomel electrode (Radiometer K401) for the pNa determinations. During each measurement nitrogen gas was used

to blanket the solution to prevent interference by CO_2. Before and after each series of measurements the electrodes were calibrated, the glass electrode with standard buffer solutions and the sodium electrode with standard sodium perchlorate solutions. The pH and pNa ranges encountered in the experimental programme were covered in the calibration programme. Since there is interference by H^+ in the electrochemical measurement of the Na^+, its extent was quantitatively estimated when necessary, by the "separate solution" method.[4] With this approach a mean potentiometric interference parameter, $K^{pot}_{Na(H)}$, equal to 5.0, was found applicable in the modified Nernst equation used to compute pNa:

$$E = E_0 + g \log (a_{Na} + K^{pot}_{Na(H)} a_{H^+}) \qquad (10)$$

where $g = 59.16$ mV/decade at 25°.

Reagents and solutions

All chemicals used were Merck analytical grade products. Solutions were prepared with doubly distilled demineralized water. The sodium perchlorate solution was made by neutralizing pure perchloric acid with pure sodium carbonate.[5] The $0.100M$ sodium hydroxide was prepared from 50% sodium hydroxide stock solution and standardized against potassium hydrogen phthalate; the $0.100M$ perchloric acid was standardized with tris(hydroxymethyl)aminomethane. The stock sodium perchlorate solution used to prepare the standard solutions for calibration of the sodium ion-selective electrode was standardized gravimetrically by precipitation of sodium zinc uranyl acetate.[6]

RESULTS AND DISCUSSION

The potentiometric data obtained in the first type of experiment (fixed ionic strength) have been used directly in the standard Henderson–Hasselbalch equation

$$pH_{(s)} - \log \frac{\alpha}{(1 - \alpha)} = pK^{app}_{(HA)_r} \qquad (11)$$

to obtain the two separate plots of $pK^{app}_{(HA)_r}$ vs. α presented in Fig. 1. The points of the upper curve correspond to such an analysis of the pH data for the $0.0010M$ sodium perchlorate system, and the middle
Fig. 1. Plots of apparent pK vs α: in the two upper curves the $\Diamond$ and $\blacklozenge$ ($I = 0.0010M$) and $\triangle$ and $\blacktriangle$ ($I = 0.010M$) points were computed by means of equation (11); the lower curve was obtained by using equation (7a) to incorporate a Donnan potential term for the resolution of pK.

curve is based on data obtained with the $0.010M$ sodium perchlorate system. When these potentiometric data are analysed by using equation (7a), where correction is made for the Donnan-potential term, $pNa_{(g)} - pNa_{(s)}$, all of the computed $pK^{app}_{(HA)_r}$ values fall on a single straight line of zero slope. The pK value of 3.35 ± 0.15, defined by the best straight line that can be drawn through these points, is in excellent agreement with the intrinsic pK determined for the linear, uncross-linked carboxymethyldextran analogue[7] of the Sephadex gel employed in this study. This result once again provides support for the model proposed and used for analysis of the protonation equilibria in gels.[1,2]

Potentiometric data obtained from the second type of experiment (variable ionic strength) have also been analysed by means of equation (7a). The data from this phase of the research are listed in Table 1. The

Fig. 2. A representation of gel volume measurements at different degrees of neutralization in $0.0010M$ NaClO$_4$ ($\lozenge$) and $0.010M$ NaClO$_4$ ($\triangle$) media.

pK values obtained in these experiments corroborate the earlier results; the pK value of 3.35 ± 0.15 is (1) independent of ionic strength and degree of neutralization, and (2) identical with the intrinsic pK already found for the repeating functional unit of the Sephadex. The scatter of ± 0.15 in the pK value is, we believe, attributable to the experimental uncertainty in the value of the gel volume determined in each individual experiment. The V_g^* values measured in the constant ionic-strength experiments are plotted *vs.* α in Fig. 2 to demonstrate this point.

The observation that V_g^* is, within experimental error, independent of the ionic strength of the system, is to be expected; only with this result can the pK *vs.* α curve obtained by using equation (7a) be completely independent of ionic strength. It has already been demonstrated[2] that with the flexible Sephadex gel (CM-50-125) the p$K_{(HA)_v}^{app}$ found with equation (7a) is a sensitive function of the solution ionic strength, like the behaviour of a typical polyelectrolyte. In this instance, deviation from ideality arising from the charged surface of the gel matrix is enhanced at each α value by a decrease in the shielding efficiency of the counter-ions in the increasingly expanded gel as the

Fig. 4. A plot of α *vs.* pH for a Sephadex gel in $0.0010M$ ($\lozenge$, $\blacklozenge$), and $0.010M$ ($\triangle$, $\blacktriangle$) NaClO$_4$ media.

water activity is increased by reducing the ionic strength of the system. This result is pictured in Fig. 3 where p$K_{(HA)_v}^{app}$ values computed with equation (7a) for the flexible Sephadex CM-50, NaPSS, system studied at three different NaPSS concentrations (0.0010, 0.010, and $0.10M$) is plotted *vs.* α. These curves, when compared with the Sephadex CM-25 pK data obtained in this study, show how easily a three-dimensional arrangement of charge is screened by increasing the concentration of the counter-ions.

The rigidity of the Sephadex CM-25 may not seem fully demonstrated, because of the experimental uncertainty of the gel-volume measurements. However,

Fig. 3. The potentiometric properties of a flexible Sephadex gel at different water activities.
Fig. 5. A plot of α *vs.* MH$_s$ $-$ pNa$_s$ for a Sephadex gel in $0.0010M$ ($\lozenge$, $\blacklozenge$) and $0.010M$ ($\triangle$, $\blacktriangle$) NaClO$_4$ media.
Fig. 6. A plot of pK vs. α for salt-free polymethacrylic acid.

the following argument demonstrates unambiguously that the gel matrix of the Sephadex C-25 is indeed so rigid that a unique gel volume, independent of the water-activity in the external solution phase, is obtained at each α value. With such rigidity of the gel matrix, the concentration of Na^+ in the gel (pNa_g^+) is essentially fixed at each particular α value (neglecting electrolyte invasion). Since $pH_g - pNa_g = pH_s - pNa_s$, equation (1), a plot of pH_s vs. α should be dependent on the ionic strength of the system, whereas a plot of $pH_s - pNa_{(s)}$ vs. α should not. That this is indeed the case with our system can be seen from comparing Figs. 4 and 5.

An important initial objective of this programme was examination of the shielding efficiency of counter-ions in a three-dimensionally charged network. A qualitative estimate of this aspect has been provided by comparing the screening efficiency of counter-ions in a linear, hydrophobic polyelectrolyte (two-dimensional surface) with screening observations obtained from the CM-50[1,2] and the CM-25 gel (three-dimensional network). We present in Fig. 6 plots of $pK_{(HA)}^{app}$, vs. α for four salt-free polymethacrylic acid samples, initially 0.335, 0.467, 0.621 and $1.006m$, respectively, using equation (11) for the computation.[8] It is quite apparent from a comparison of these plots with those obtained for Sephadex (Fig. 3) that the drop in efficiency of counter-ion screening of surface potential with concentration is a great deal smaller in the polyelectrolyte system. By the time the counter-ion concentrations reach 0.3–$0.4M$ the charged matrix of the Sephadex gel is completely screened. For the polyelectrolyte system the magnitude of the $exp[-\varepsilon\psi_{(a)}/kT]$ term is still a factor of about 20.

and

Roger Stephens

Trace Analysis Research Centre, Department of Chemistry, Dalhousie University, Halifax, Nova Scotia, Canada

Summary—The methods of Jones's calculus are used to derive expressions for the signal-to-noise ratio in polarimetric measurements. The formulae show that in shot-noise limited systems there is an optimum angle between the polarization planes of the polarizer and analyser and that, once this angle is employed, the signal-to-noise ratio of the system cannot be appreciably improved by improving the quality (*i.e.*, lowering the extinction ratio) of the polarizers used. The main way to improve the signal-to-noise ratio is to use an intense light source, large optical aperture and a long integration time.

There is an increasing need for developing more sensitive methods to measure optical rotation. For example, a large number of naturally occurring compounds, carbohydrates, and a number of amino-acids do not show high absorbance in the ultraviolet region, but do possess optical activity. One advantageous way of employing the latter property might be for detection in HPLC. However, the polarimeters available commercially do not meet the sensitivity requirements for trace analysis. Yeung *et al.*[1] managed to construct a highly sensitive polarimeter, using rather impressive equipment: a 0.5-W argon ion laser as the light-source, a selected pair of prism polarizers, and two Faraday rotators as polarization modulators. According to these authors, the performance of such an instrument depends on the extent to which it can reject light of improper polarization, *i.e.*, on the quality of the polarizers which are used. In this paper we shall consider how this requirement could be eased in certain cases. It is also intended to produce working equations for the relative signal-to-noise ratio of a standard photoelectric polarimeter with a non-ideal polarizer and analyser, and to devise a way to optimize the performance of the device.

THEORY

The mathematical treatment of the theory of optical equipment working with polarized light is most conveniently done by using the Jones matrix formalism (see *e.g.*, reference 2 and references cited therein). According to this, an ideal polarizer with the polarizing plane aligned with the x-axis can be represented by a matrix

$$P_x = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} \tag{1}$$

and the corresponding "crossed" analyser

$$P_y = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} \tag{2}$$

In practice, however, no polarizer is ideal, and a better representation of a polarizer is

$$\bar{P}_x = \gamma_x \begin{pmatrix} 1 & 0 \\ 0 & k \end{pmatrix} \tag{3}$$

where γ_x is a scalar attenuating factor and k is a parameter representing the non-ideal polarizing properties of the device. The off-diagonal elements of the matrix $\bar{P}_x$ are still assumed to be zero. In fact, any symmetric or Hermitian matrix can be brought into the form (3) by an orthogonal transformation. In the optical train an orthogonal transformation means nothing else but the rotation of the optical element around the optical axis. In the general case the transformation leads to complex values of γ and k.

In practice, the quality of a pair of polarizers is characterized by their extinction ratio ϵ, which is defined as the ratio of the intensity observed when the two polarizers are crossed, to that observed when their transmission axes are parallel.

When the incoming light is unpolarized, the intensity of light (I) transmitted by an optical element A is[2]

$$I = \tfrac{1}{2} I_0 \operatorname{Tr}(A^\dagger A) \tag{4}$$

where A is the Jones matrix of A, and I_0 is the intensity of the incident non-polarized light. By applying this first to the crossed polarizers, we obtain

$$I_\perp = \tfrac{1}{2} I_0 \operatorname{Tr}(\bar{P}_y^\dagger \bar{P}_x \bar{P}_x^\dagger \bar{P}_y)$$

$$= \tfrac{1}{2} I_0 |\gamma_x|^2 |\gamma_y|^2 (|k_x|^2 + |k_y|^2) \tag{5}$$

*Author for correspondence.
Fig. 1. Schematic diagram of a simple polarimeter.

For the axes parallel, this becomes

$$I_{\parallel} = \frac{1}{2}I_0 \, \mathrm{Tr} \, [(\boldsymbol{P}_x^{\dagger})^2 \boldsymbol{P}_x^2]$$

$$= \frac{1}{2}I_0 |\gamma_x|^2 |\gamma_y|^2 (1 + |k_x|^2 |k_y|^2) \quad (6)$$

Consequently

$$\epsilon = \frac{I_{\perp}}{I_{\parallel}} = \frac{|k_x|^2 + |k_y|^2}{1 + |k_x|^2 |k_y|^2} \quad (7)$$

With nearly ideal polarizers, k is very small and equation (7) becomes

$$\epsilon \simeq |k_x|^2 + |k_y|^2 \quad (8)$$

The polarimeter to be analysed by the Jones calculus is shown schematically in Fig. 1. It is assumed that the co-ordinate axes are defined according to the transmission and extinction axes of $\boldsymbol{P}_y$. The transmission axis of $\boldsymbol{P}_x$ is now assumed to make an "offset angle" θ with the extinction axis (x-axis) of $\boldsymbol{P}_y$. The introduction of this offset angle has important consequences for the behaviour of the system. The total matrix $\boldsymbol{S}$ of the system is now

$$S = \boldsymbol{P}_y D \boldsymbol{R}_\theta \boldsymbol{P}_x \boldsymbol{R}_\theta^T \quad (9)$$

The sample, denoted by matrix D, is assumed to be circularly dichroic and optically active:[2]

$$D = \exp\left[j\frac{\omega b}{c}(\hat{n}_+ + \hat{n}_- - 2)\right]\begin{pmatrix} \cos \chi & -\sin \chi \\ \sin \chi & \cos \chi \end{pmatrix} \quad (10)$$

where ω is the circular frequency of the wave, b is the path-length, c the velocity of light, j is $\sqrt{-1}$, and

$$\hat{n}_+ = n_+ + j\frac{\alpha_+ c}{2\omega}; \quad \hat{n}_- = n_- + j\frac{\alpha_- c}{2\omega} \quad (11)$$

n_+ and n_- being the indices of refraction for right and left circularly polarized light and α_+ and α_- the corresponding Napierian absorption coefficients. The angle χ is the complex angle of rotation

$$\chi = \chi' + j\chi'' = \frac{\omega b}{2c}(\hat{n}_- - \hat{n}_+) \quad (12)$$

The offset angle θ of the polarizer is taken into account by means of the orthogonal transformation matrix $\boldsymbol{R}_\theta$:

$$\boldsymbol{R}_\theta = \begin{pmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{pmatrix} \quad (13)$$

It is seen that the sample matrix D also has the form of the orthogonal rotation matrix and therefore may be denoted by

$$D = \exp\left[j\frac{\omega b}{c}(\hat{n}_+ + \hat{n}_- - 2)\right]\boldsymbol{R}\chi \quad (14)$$

Thus $\boldsymbol{R}_\theta$ and $\boldsymbol{R}_\chi$ can be combined as

$$\boldsymbol{R}_\theta \boldsymbol{R}_\chi = \boldsymbol{R}_\chi \boldsymbol{R}_\theta = \boldsymbol{R}_{\theta+\chi} \quad (15)$$

The intensity of light transmitted by the system of Fig. 1 is

$$I = \frac{1}{2}\mathrm{Tr}(S^{\dagger}S)I_0 = \frac{1}{2}\exp[-\frac{1}{2}b(\alpha_+ + \alpha_-)]$$

$$\times \mathrm{Tr}(\boldsymbol{R}_\theta \boldsymbol{P}_x^{\dagger} \boldsymbol{R}_{\theta+\chi}^{\dagger} \boldsymbol{P}_y^{\dagger} \boldsymbol{P}_y \boldsymbol{R}_{\theta+\chi} \boldsymbol{P}_x \boldsymbol{R}_\theta^T)I_0$$

$$= \frac{1}{2}\exp[-\frac{1}{2}b(\alpha_+ + \alpha)]$$

$$\times \mathrm{Tr}(\boldsymbol{P}_x \boldsymbol{P}_x^{\dagger} \boldsymbol{R}_{\theta+\chi}^{\dagger} \boldsymbol{P}_y^{\dagger} \boldsymbol{P}_y \boldsymbol{R}_{\theta+\chi})I_0 \quad (16)$$

Here the orthogonality of $\boldsymbol{R}_\theta$, commutativity under the trace operation, and equation (15) have been used. After some algebraic manipulation equation (16) can be cast into the form:

$$I = \frac{1}{2}I_0 \exp[-\frac{1}{2}b(\alpha_+ + \alpha_-)]|\gamma_x|^2|\gamma_y|^2$$

$$\times [(|k_x|^2 + |k_y|^2)|\cos(\theta + \chi)|^2$$

$$+ (1 + |k_x|^2|k_y|^2)|\sin(\theta + \chi)|^2]$$

$$= \frac{1}{2}I_0 \exp[-\frac{1}{2}b(\alpha_+ + \alpha_-)]|\gamma_x|^2|\gamma_y|^2$$

$$\times [(|k_x|^2 + |k_y|^2)\cos^2(\theta + \chi')$$

$$+ (1 + |k_x|^2|k_y|^2)\sin^2(\theta + \chi')$$

$$+ (1 + |k_x|^2)(1 + |k_y|^2)\sinh^2\chi''] \quad (17)$$

This equation allows the intensity transmitted by the system to be determined. The resultant electronic signal observed at the detector will now be defined as the difference between the results of two measurements, the first taken with the optically active sample in the cuvette and the second with pure solvent, i.e., $\chi = 0$. Assuming that the system noise is dominated by photon noise, the noise σ_1 is proportional to the square root of the light intensity at the detector and inversely proportional to the square root of the integration time:[3]

$$\sigma_1 = g\left(\frac{I}{t}\right)^{1/2} \quad (18)$$

In the present case the intensity can be presented generally as:

$$I = f(\theta, \chi)I_0 \quad (19)$$

and hence the signal-to-noise ratio becomes:

$$S/N = \frac{(tI_0)^{1/2}}{g} \frac{[f(\theta, \chi) - f(\theta, 0)]}{[f(\theta, \chi) + f(\theta, 0)]^{1/2}} \quad (20)$$

In order to optimize the detector in terms of the influence of θ on S/N, the constant coefficient in equation (20) is unimportant. Further, we are concerned, in particular, with the signal-to-noise ratio at very small values of χ. Hence it is useful to define a new parameter, the relative signal-to-noise ratio, r:

$$r = \lim_{\chi \to 0} \frac{1}{\chi} \frac{[f(\theta, \chi) - f(\theta, 0)]}{[f(\theta, \chi) + f(\theta, 0)]^{1/2}} \quad (21)$$

Substitution of equation (17) into (21) gives

$$r = \frac{1}{2}|\gamma_x|\,|\gamma_y|(1 - |k_x|^2)^{1/2}(1 - |k_y|^2)^{1/2}$$

$$\times \frac{\sin 2\theta}{(\beta + \sin^2 \theta)^{1/2}} \quad (22)$$

where $\beta = \epsilon/(1 - \epsilon)$. The relative signal-to-noise ratio is now differentiated with respect to θ:

$$\frac{dr}{d\theta} = |\gamma_x|\,|\gamma_y|(1 - |k_x|^2)^{1/2}(1 - |k_y|^2)^{1/2}$$

$$\times \frac{2(2\beta + 1)\cos 2\theta - \cos^2 2\theta - 1}{(\beta + \sin^2 \theta)^{3/2}} = 0 \quad (23)$$

which gives

$$\theta_{opt} = \frac{1}{2}\arccos[2\beta + 1 - 2\sqrt{\beta(\beta + 1)}]$$

$$= \arctan \epsilon^{1/4} \quad (24)$$

The maximum value of r is obtained by substituting (24) into (22):

$$r_{max} = |\gamma_x|\,|\gamma_y|(1 - |k_x|^2)^{1/2}(1 - |k_y|^2)^{1/2}\sqrt{\cos 2\theta_{opt}}$$

$$= |\gamma_x|\,|\gamma_y|(1 - |k_x|^2)^{1/2}(1 - |k_y|^2)^{1/2}\sqrt{\frac{1 - \sqrt{\epsilon}}{1 + \sqrt{\epsilon}}}$$

$$\quad (25)$$

EXPERIMENTAL

Apparatus

The measurements were made by using the apparatus shown schematically in Fig. 2. The light-source was a sodium hollow-cathode lamp (Varian-Techtron) run at ca. 5 mA. The polarizer and analyser were two identical 2-in. plastic square dichroics (Edmund Scientific Co., N.J.). The length of the sample cuvette was 8.3 cm and the sample was a 2% solution of sucrose, which gave a calculated optical rotation angle of 1.1°. The photomultiplier was a 1P28 with a calibrated gain curve.

Procedure

With the sample cuvette removed, the extinction ratio of the polarizer–analyser pair was measured, giving $\epsilon = 6.5 \times 10^{-4}$. The measurements were started by first crossing the polarizer and analyser, and recording the "blank" signal on a recorder. Then the sample cuvette was inserted into the light-path and the signal recorded again. This procedure was repeated with intermittent rotation of the polarizer. The offset angles θ were calculated from the equation derivable from equation (17):

$$\theta = \arcsin \sqrt{\left(\frac{I_0 - I_\perp}{I_\parallel}\right)\left(\frac{1}{1 - \epsilon}\right)} \quad (26)$$
Fig. 2. Block diagram of the polarimeter used in the present work.
Fig. 3. Relative signal-to-noise ratio as a function of the offset angle of the polarizer. ●: experimental points; ———: calculated from equation (22) and scaled to fit the experimental points.

where I_0 is the intensity measured with the offset angle θ, $I_\perp$ with the polarizer and analyser crossed and $I_\parallel$ with the parallel polarization axes. The noise was measured as the average peak-to-peak noise from the recorder tracing during a 10-sec interval.

RESULTS AND DISCUSSION

The values of experimental signal-to-noise ratios plotted against log θ are shown in Fig. 3, along with the theoretical relative signal-to-noise ratios calculated from equation (22). The theoretical curve is scaled to optimize the fit with the experimental points. The optimum offset angle θ_{opt} calculated from equation (24) is 9.07° and is marked in Fig. 3. The position of the optimum is very well matched by the experimental points, although the shapes of the observed and calculated curves differ somewhat.

Equation (25) for the maximum value of r shows one of the results of present interest. The upper limit of r which is attainable by any real polarizer and analyser is unity. The inexpensive polarizer sheet used in this work had an extinction ratio of 6.5×10^{-4} which gives $r = 0.975$, assuming that $\gamma_x = \gamma_y = 1$. Naturally there are losses represented by γ_x and γ_y, but equally there are reflection and aperture losses in the case of the much more expensive prism polarizers. Hence the unavoidable conclusion is that there is little point in investing in high-performance polarizers when practically the same signal-to-noise ratio is obtained by using cheap plastic dichroic filters (or even reflection polarizers for work in the ultraviolet). It should be noted that this conclusion is strictly valid for shot-noise limited systems. For instance, in our system the change in the transmitted intensity is recorded as the sample is changed from optically active to inactive. The offset angle of the polarizer is maintained constant. With very small optical activities the changes in the intensity may be buried in the

flicker noise of the source. The signal-to-noise ratio can then be improved by modulating the offset angle, as done by Yeung et al.[1] With a high-grade polarizer the optimum modulation amplitude is small, and a non-mechanical and highly stable Faraday rotator can be used for modulation. With polarizers of low quality the optimum modulation amplitude is large, Faraday rotation cannot be used, and corresponding demands are made on the mechanical or optical stability of the system. Thus high stability is the price to be paid for using cheap polarizers.

According to equation (20), the principal way to improve the signal-to-noise ratio is to increase the integration time or the source intensity, either directly or by increasing the optical aperture. The latter option is more easily achieved if prism polarizers are avoided, since dichroics have a larger area and less need for collimation. If measurement at a single wavelength is sufficient, a laser is an ideal light-source.

VOLTAMMETRIC STUDY OF THE REDOX BEHAVIOUR OF THE Hg(II)/Hg(I)/Hg SYSTEM AT A ROTATING METAL-RING/GLASSY-CARBON DISC ELECTRODE

P. Kiekens, E. Temmerman and F. Verbeek
Laboratorium voor Analytische Scheikunde, Rijksuniversiteit Gent, Krijgslaan 281, S12, B-9000 Gent, Belgium

Summary—The reduction of Hg(II) at a glassy-carbon electrode in various electrolytes has been studied by rotating ring–disc voltammetry. Reduction proceeds directly to metallic mercury in a single 2-electron step. However, at the foot of the wave, and only during the first reduction sweep after pretreatment of the electrode surface, a small amount of Hg(I) species is detected at the ring. The appearance of an Hg(I) intermediate is most pronounced in sulphuric acid solution. The reduction of Hg(II) is found to proceed irreversibly and to be of first order. At sufficiently negative potentials the reduction is convective-diffusion controlled. Stripping voltammetric experiments indicate that the dissolution of mercury gives Hg(II) in complexing electrolytes. In non-complexing electrolytes the initially formed Hg(II) reacts with mercury atoms on the electrode surface to give Hg(I). During electrodissolution, two stripping peaks may be observed as a result of underpotential adsorption of mercury on glassy carbon. The difference in peak potential between the adsorption (mono) layer peak and the bulk mercury peak has been related to the difference in work functions of the deposit (mercury) and substrate (carbon). A rotating glassy-carbon electrode has been used for the anodic stripping determination of mercury. When an appropriate amount of a cation such as cadmium(II) or copper(II) is added to the test solution, mercury down to $2 \times 10^{-9}M$ (0.4 ng/ml) can be determined in acidified thiocyanate electrolyte with a relative standard deviation of about 22%.

Several papers have dealt with the reduction of Hg(II) at graphite electrodes.[1-6] With a freshly polished electrode only a single reduction wave is obtained. From the standard potentials of the reactions[7]

$$2Hg^{2+} + 2e^- \rightarrow Hg_2^{2+} \qquad (1)$$

$$Hg_2^{2+} + 2e^- \rightarrow 2Hg \qquad (2)$$
which are 0.920 and 0.789 V respectively, two individual waves would be expected, and for the disproportionation equilibrium[8]

$$Hg_2^{2+} \rightleftharpoons Hg + Hg^{2+} \qquad (3)$$
we have $K = 6.0 \times 10^{-3}$.

As the stepwise reduction of Hg(II) may result in production of the dimeric Hg(I), it seemed to us of interest to use a rotating ring–disc electrode system, which has been proved to be very efficient in detecting electroactive intermediates,[6,9,10] to find whether this occurs.

Mercury has widespread use in electroanalytical chemistry. In stripping voltammetry, a mercury film on solid electrodes offers great advantages and has been used in a large number of researches. However, the kinetics of electrodissolution of mercury itself from a solid electrode have received little attention and no unambiguous answer can be found to the problem of the oxidation state of the mercury ions formed in the process. The oxidation may produce only one of the two states, or both. The present study was undertaken to try to elucidate this problem and to obtain an insight into the kinetics of electrodissolution of mercury.

Anodic stripping (oxidation) of thin metal films from solid electrodes often shows two or even three dissolution peaks.[10,12-15] The extra peaks at potentials which are more positive than the normal dissolution peak potential of the bulk metal, are generally due to dissolution of the deposited metal atoms in direct contact with the solid substrate electrode.

If more than one extra dissolution peak is observed in addition to the bulk stripping peak, interaction of the atoms of the first monolayer with different sites on the electrode substrate is thought to occur.[12]

Underpotential adsorption of mercury on glassy carbon has scarcely been studied. According to Dunsch,[16] underpotential monolayer adsorption of mercury on glassy carbon can be observed, provided that the electrode surface is freed from "oxides", which are characteristic for glassy carbon.[16-18]

As part of an extended study of the redox reactions of the Hg(II)/Hg(I)/Hg system on glassy carbon, the mercury monolayer adsorption behaviour was also investigated by the rotating ring–disc technique.

Anodic stripping voltammetry (ASV) is a very suitable technique for determining metal ions at extremely low concentrations. The introduction of solid electrodes enables ASV to be used for the

determination of noble metals such as gold, platinum, iridium and mercury. The present work also deals with the determination of microamounts of mercury by ASV after deposition of this element on a rotating glassy-carbon disc electrode. To enhance the sensitivity and reproducibility of the analytical method, a second ion, *e.g.* Cd(II), was added to the test solution.

EXPERIMENTAL

Experiments were performed in $1M$ sulphuric acid, $0.1M$ solutions of perchloric acid and nitric acid and $0.1M$ solutions of sodium sulphate, potassium nitrate, sodium perchlorate and sodium thiocyanate at various pH values. Solutions were prepared from analytical grade reagents (Merck) and water freshly generated by a Milli-Q system (Millipore Inc.). A $0.1M$ standard Hg(II) solution was prepared from the nitrate. This solution was stabilized by addition of enough concentrated nitric acid to give a final acid concentration of $0.1M$.

Home-made ring-disc electrodes with a glassy carbon (GC) (Tokai Electrode Mfg. Co., Tokyo) disc and a gold or platinum ring were used. The dimensions were 0.249 and 0.225 cm for the disc radii, 0.270 and 0.246 cm for the inner ring radii and 0.301 and 0.268 cm for the outer ring radii, the first value referring to the gold system and the second to platinum. This gives a theoretical collection efficiency,[19] N_0, of 0.25 for the gold–GC electrode and 0.21 for the platinum–GC electrode.

The cell consisted of a Teflon vessel of about 150 ml capacity in which the rotating ring-disc electrode was centrally placed. A platinum auxiliary electrode was placed in a compartment separated from the cell by a fritted glass disc. A saturated calomel electrode (SCE) was connected to the cell by means of a U-tube and a salt bridge, filled with saturated potassium chloride solution and the cell solution respectively. All potentials are referred to the SCE. Experiments were performed at $25.0 \pm 0.1°$.

Electrode rotation was achieved by a Brion-Leroux motor (Birotax, Type I) and the speed controlled by means of a proximity probe (Philips PR 9373) and frequency meter (Philips PM 6601).

Potential control was maintained by means of a GSATP Tacussel sweep generator and a BI-PAD potentiostat. Curves were recorded on a Hewlett-Packard X-YY′ recorder, Model HP 7046 A.

Standard metallographic procedures were used for polishing the electrode. Final polishing was done with 0.05-μm alumina on Buehler microcloth to a mirror-like finish. Ultrasonic cleaning served to remove any alumina or other impurities that might adhere to the electrode surface.

The electrochemical pretreatment of the glassy-carbon disc consisted of continuous cycling of the potential between fixed values (in the range from -1.5 to 1 V) in the working electrolyte at a sweep-rate of 0.1 V/sec until a reproducible and very low background current was obtained. The ring was pretreated in the same way. During this pretreatment nitrogen containing <1 ppm of oxygen was passed through the cell solution. After the electrode activation period, a nitrogen atmosphere was maintained above the cell solution.

Experiments at the disc were started from an initial potential positive enough to avoid Hg(II) reduction, the potential being made more negative. The ring potential, E_R, was held at a value sufficiently positive to ensure a convective-diffusion controlled oxidation of any Hg(I) ions leaving the disc electrode.

Stripping experiments at the disc were performed by switching the potential of the disc to the desired deposition potential, E_{dep}. After the deposition, the disc potential was scanned linearly in the anodic direction and the mercury dissolution curve (disc) and collection curve (ring) were recorded.

RESULTS AND DISCUSSION

Reduction of Hg(II)

Figure 1 shows the voltammetric curves for the reduction of 0.99mM Hg(II) in $1M$ sulphuric acid at a glassy-carbon disc, and the corresponding ring current at $E_R = 1.4$ V, where the only possible reaction is the oxidation of Hg(I). A substantial oxidation current at the gold ring was observed during the first voltammetric curve recorded with a newly polished and activated electrode. This ring current first increases with decreasing disc potential and then drops to zero. This means that Hg(I) is produced at the disc surface or in the adjacent solution layer in a restricted potential range, at the foot of the reduction wave of Hg(II) at the disc. Subsequent scans obtained without reactivating the electrode surface produced much lower amounts of Hg(I) (Fig. 1).

At potentials more positive than that giving the current maximum for the oxidation of Hg(I) at the ring, $I_{R,M}$, I_R increases proportionally with the disc current I_D and obeys the equation

$$I_R = N_0 I_D \qquad (4)$$

This means that the production of Hg(I) probably occurs according to equation (1). Once the current maximum at the ring is reached, the disc current starts rising more steeply and I_R/I_D becomes smaller than N_0. Finally the ring oxidation current drops to zero.
Fig. 1. Current–potential curves for the reduction of 0.99mM Hg(II) in $1M$ H_2SO_4 at a glassy-carbon disc (a), and corresponding curves for the oxidation of the intermediate Hg_2^{2+} at the gold ring (b), as a function of the disc electrode potential. $E_R = 1.4$ V *vs.* SCE; $\omega = 157$ rad/sec; $v = 0.01$ V/sec. (1) Obtained during first scan with freshly pretreated electrode; (2) second and subsequent scans.
Fig. 2. Plot of the maximum current for the oxidation of Hg_2^{2+} at the ring. $I_{R,M}$ plotted against $\sqrt{\omega}$, for $1M$ H_2SO_4 medium; $c_{Hg(II)} = 0.50mM$; $E_R = 1.4$ V vs. SCE.

The variation of the current maximum for the oxidation of Hg(I) at the ring, $I_{R,M}$, with the speed of rotation of the electrode, is represented in Fig. 2. The result is typical of a disc-electrode reaction controlled partially by mass transfer and charge transfer at the potential of the ring-current maximum. The subsequent beginning of the direct reduction of Hg(II) to metallic mercury prevents the full development of the first wave into a diffusion-controlled region at still more negative potentials.

From an equation derived by Levich[20] for reactions that are controlled by mixed charge-transfer and diffusion kinetics, the standard heterogeneous rate constant for the Hg(II)/Hg(I) couple was calculated to be about 10^{-7} cm/sec. Consequently the reduction of Hg(II) to Hg(I) is highly irreversible. Plots of log $[I/(I_L - I)]$ vs. potential are linear at potentials more positive than 0.4 V. Assuming a one-electron transfer, the transfer coefficient obtained from the slopes of these plots varies between 0.54 and 0.60. Here I_L was taken as half of the limiting current for the subsequent reduction of Hg(II) to metallic mercury at more negative potentials. This result is indicative of a first-order reaction in which soluble species are involved, according to the equation

$$Hg(II) + e^- \rightarrow Hg(I) \qquad (5)$$
Production of Hg(I) during the reduction of Hg(II) at glassy-carbon has also been observed in $0.1M$ sulphuric acid, $1M$ perchloric acid, $0.1M$ nitric acid and $0.1M$ sodium sulphate (pH = 2) media, but to an extent that is only a tenth or less of that in $1M$ sulphuric acid. The more pronounced wave of Hg(II)/Hg(I) reduction in $1.0M$ sulphuric acid may result from the superior complexing properties of sulphate for mercury.[21]

In sulphuric acid medium, specific adsorption of sulphate ions[22] may increase the rate of the Hg(II) reduction so that the Hg(II)/Hg(I) reaction is favoured by anion interaction with the transition state.

Generally, the production of Hg(I) becomes less when the acidity of the solution decreases and it is possible that the activity of the glassy-carbon towards the Hg(II)/Hg(I) reduction decreases with increasing pH because of a change in the surface state of the glassy-carbon. This material has a redox potential which is pH-dependent[23,24] owing to the electrode reaction of oxygen adsorbed on the surface or present in solution.

In the case of $0.1M$ sodium sulphate (pH = 2.0), the solubility of the Hg(I) generated is lower than that in $1M$ sulphuric acid.[25] This could result in the formation of a precipitate on the electrode surface, and hindrance to detection of Hg(I) at the ring. At potentials more negative than that giving the current maximum at the ring, the direct reduction of Hg(II) to metallic mercury gradually replaces the one-electron transfer and the ring current drops to zero.

Kinetic parameters for the reduction of Hg(II) at disc potentials more negative than the potential at which $I_{R,M}$ occurs at the ring, have been evaluated by the method of Frumkin and Tedoradze.[26] Reciprocal currents, $1/I$, recorded at constant potentials in the region preceding the limiting-current plateau, gave linear plots against the reciprocals of the square roots of the rotation rates, $1/\sqrt{\omega}$. These plots were used to derive the kinetic currents, I_k, by extrapolation to $1/\sqrt{\omega} = 0$. These currents were used to calculate the apparent standard heterogeneous rate constant, k_{sh}^a, at $E°$ of the Hg(II)/Hg couple. In $0.1M$ sodium sulphate solution (pH = 2.0) the value of k_{sh}^a obtained in this way was ca. 10^{-5} cm/sec with αn (α = cathodic transfer coefficient) equal to 0.55. Thus the reduction of Hg(II) proceeds irreversibly. The observed dependence of the half-wave potentials on the rate of stirring was also indicative of an irreversible process.

The linear dependence of $1/I$ on $1/\sqrt{\omega}$ points to a first-order reduction. The order of the reaction was also evaluated by the method of Frumkin and Tedoradze.[26]

Their procedure is demonstrated in Fig. 3 which shows in addition to the limiting currents, I_L, the currents at different potentials along the rising portion of the wave, as a function of ω. The nature of the plot indicates that before the limiting plateau is reached, the electrode reaction is under mixed control.

The order, μ, can be found by using the equation

$$\mu = \frac{\log (AC/BC)}{\log (AC/AB)} \qquad (6)$$

The reaction was found to be first-order, since μ varied between 0.80 and 0.92 ($0.1M$ Na_2SO_4, pH = 2). This confirms the ring–disc results and shows that the reduction to metallic mercury involves only one mercury atom:

$$Hg(II) + 2e^- \rightarrow Hg$$
It was found that at sufficiently negative potentials the limiting reduction current, I_L, at the disc was proportional to $\sqrt{\omega}$ (with zero intercept) for all
Fig. 3. I vs. $\sqrt{\omega}$ plot for the reduction of 0.50mM Hg(II) at a glassy-carbon disc in 0.1M Na$_2$SO$_4$ (pH 2.0). Numbers indicate applied potential, V vs. SCE; I_L is the limiting current; I_k the cathodic kinetic current at 0.31 V obtained after extrapolation of $1/I$ to $\omega = \infty$.

concentrations of Hg(II). Thus the Levich equation[27] for a convective diffusion-limited process was obeyed.

For 0.1M sodium perchlorate and 1M potassium nitrate solutions we examined the influence of a change in pH on the reduction wave of Hg(II). Both solutions responded in almost the same way. An increase in pH resulted in the appearance of two well-separated waves (Fig. 4); from about pH 3, the
Fig. 4. Current–potential curves obtained with a newly activated electrode for the reduction of 0.50mM Hg(II) at a glassy-carbon disc and corresponding curves for the oxidation of the intermediate, Hg(I), at the ring in 0.1M NaClO$_4$ at pH values of 2.0 (— × —), 3.9 (—●—) and 8.9 (—○—) as a function of the disc electrode potential. E_R = 1.4 V; ω = 188 rad/sec; v = 0.01 V/sec.

original wave started to decrease and a second wave appeared, shifting to more negative potentials with increasing pH. At pH ~ 6 the first wave had almost vanished, while at pH 8–9 only the second wave remained ($E_{1/2} \sim 0.07$ V vs. SCE). When the pH was increased still further, this wave also disappeared.

The ring current indicated that it was only during the second wave that Hg(I) ions left the disc, no Hg(I) being detected during the first wave. With increasing pH, the production of Hg(I) passed through a maximum (at pH = 4–5).

We believe that during the first reduction wave Hg^{2+} ions are reduced, but during the second wave HgOH$^+$ and/or Hg(OH)$_2$ are also reduced. The occurrence of these complexes is predicted by a Pourbaix diagram.[28] With increasing pH, more Hg(OH)$_2$ is formed and more Hg(I) ions are produced at the disc and detected at the ring. For example, at pH 2, the ratio of the amounts of free Hg^{2+} ions and Hg(OH)$_2$ is about 100, while at pH 4, it is about 0.01.[28]

The decline of the ring current with increasing pH after reaching a maximum can have several causes. The Hg(I) ions formed at the disc may be transformed into polynuclear complexes[29] which become more stable with increasing pH. On the other hand solubility limitations are also important, not only for Hg(OH)$_2$ but also for the Hg(I) complexes.

Oxidation of metallic mercury

A survey of the literature data[11,30–37] for electrodissolution of mercury indicates that Hg(II) ions are mainly formed as a reaction product in complexing electrolytes, whereas Hg(I) ions are found in noncomplexing electrolytes. Some of these data are summarized in Table 1. There is one exception, however; according to Combet and Dozol,[36] electrodissolution of mercury in perchloric acid and nitric acid media at a glassy-carbon electrode produces only Hg(II) ions.[33]

According to Brainina,[35] a linear relation is expected between the anodic peak potential, E_p, of the metal-stripping curve and the logarithm of the potential scan-rate, v. Such a relationship was found for mercury in various electrolytes. From the slope,[38] the

Table 1. Electrodissolution products of mercury at various electrodes in diverse electrolytes

Electrode	Electrolyte	Mercury species formed	Reference
Platinum	KNO$_3$, HClO$_4$	Hg(I)	30
Glassy-carbon	H$_2$SO$_4$	Hg(I)	11

Mercury	NaCN	Hg(II)	37

*$E_d < 0.6$ V.
†$E_d < 0.85$ V.

value of βn (β = anodic transfer coefficient) was found to be 1.44 for $0.1M$ sodium thiocyanate + $0.01M$ perchloric acid and 1.74 for $0.1M$ perchloric acid media. Other values obtained are 1.31 for $1M$ sulphuric acid and 1.69 for $0.1M$ acetate buffer (pH 4.66).

These results suggest that ions formed during the electro-oxidation must be Hg^{2+} (irrespective of the electrolyte used) if a reasonable value for β is to be obtained.[39]

However, ring–disc experiments in perchloric acid and sulphuric acid media have proved the existence of Hg_2^{2+} ions during electrodissolution. This finding is also in accordance with the experiments by Allen and Johnson.[11] The Hg(I) ions produced at the disc may react at a sufficiently positive potential at the ring to give Hg(II), or they may also react at a negative ring potential to give metallic mercury. This is shown in Fig. 5. The ring collection peaks at 1.4 V (oxidation) and -0.2 V (reduction) are almost equal, indicating that the mercury deposited is stripped mainly as Hg(I). This is in contradiction to the results obtained from simple semilogarithmic analysis of the mercury ionization peak at the disc, as mentioned before.

These conflicting experimental results can be explained by assuming the occurrence of a special type of chemical reaction following the mercury electrodissolution, which we will call "reproportionation". The Hg(II) ions first formed are supposed to react with unoxidized mercury atoms still present on the electrode surface, leading to the formation of Hg(I)

Fig. 5. Current–potential curves for electrodissolution of mercury at a glassy-carbon disc and simultaneous collection of stripped mercury ions at the platinum ring of a rotating ring–disc electrode in $0.1M$ $HClO_4$. $c_{Hg(II)} = 5$ μM; deposition time = 1 min; $\omega = 188$ rad/sec; $E_{dep} = -1.0$ V; $v = 0.1$ V/sec; E_R = ring potential; E_D = disc potential.

ions. This explanation is acceptable, as the value of the equilibrium constant, K, for the reaction

$$Hg(II) + Hg \rightleftharpoons 2Hg(I) \qquad (8)$$

is 166,[8] indicating that mercury(I) is the dominant species. These Hg(I) ions reach the surrounding ring electrode where they can be oxidized or reduced.

This proposed reaction mechanism for mercury dissolution also explains why the stripping peak obtained with thiocyanate solutions (or generally with complexing electrolytes) is double the size of the dissolution peaks obtained in perchloric acid medium (or generally with non-complexing electrolytes). In non-complexing electrolytes, half of the mercury deposit may be stripped from the electrode surface in a non-electrochemical way, because of the reproportionation reaction. For a complexing electrolyte, however, our experiments indicate that the Hg(II) ions newly formed at the electrode surface are involved in subsequent chemical reactions, stabilizing the Hg(II) ions as complex ions. Investigations with an electrolyte solution of constant ionic strength containing xM sodium thiocyanate + $(2 - x)M$ sodium perchlorate + $0.01M$ perchloric acid suggest that $Hg(SCN)_3^-$ is the primary product of mercury electrodissolution ($0.1 \leqslant x \leqslant 2$). The co-ordination number of 3 is derived from the dependence of the anodic peak potential on the thiocyanate concentration.[35] The co-ordination number is reported to be 4 for the species present in the bulk of the solution.[34–40] The ability of complexed Hg(II) species to oxidize mercury atoms is less than that of uncomplexed or weakly complexed Hg(II) ions. In complexing electrolytes, the absence of Hg(I) ions is also confirmed by ring–disc experiments. At the ring, only the reduction signal for stripped Hg(II) ions can be obtained at sufficiently negative potentials. It is concluded that the complexing properties and concentration of the electrolyte are important in electrodissolution of mercury. For example, at low hydrochloric acid concentrations, e.g., $0.01M$, an oxidation as well as a reduction peak for Hg(I) ions produced at the disc can be observed at the ring. With increasing chloride concentration, both the dissolution peak at the disc and the reduction peak at the ring grow, while the oxidation peak at the ring diminishes. This means that more Hg(II) ions are produced instead of Hg(I) ions and that reproportionation becomes less important because of the increased formation of Hg(II) chloride complexes. At a hydrochloric acid concentation exceeding $2M$, the mercury dissolution peak reaches its maximum value and no oxidation peak at the ring can be observed. This indicates exclusive formation of Hg(II) ions at the disc.

Figure 6 shows the voltammetric curves for the electrodissolution of mercury at the glassy-carbon disc and simultaneous collection (oxidation) of stripped mercury ions at the platinum ring of the rotating ring–disc electrode in $0.1M$ potassium

Fig. 6. Current–potential curves for the electrodissolution of mercury at a glassy-carbon disc and simultaneous collection (oxidation) of stripped mercury ions at the platinum ring of a rotating ring–disc electrode in $0.1M$ KNO$_3$ + $0.01M$ HNO$_3$. $c_{Hg(II)}$ = 5 μM; deposition time = 6 min; E_{dep} = -0.5 V; E_r = 1.4 V; v = 0.05 V/sec; ω = 188 rad/sec; E_D = disc potential.

theoretical charge for a monolayer. Simultaneously with the increase of the charge associated with the adsorption peak, there is a decrease in the difference of peak potential, ΔE_p, between the bulk and adsorption layer peaks (Fig. 7).

For a theoretically complete monolayer, i.e., complete coverage of the electrode surface, θ = 1, a value of 73 ± 6 mV for ΔE_p is found experimentally (Fig. 7). The half-width[13] δ of the monolayer stripping-peak is 41 ± 4 mV. According to Kolb et al., [13] the underpotential shift (ΔE_p) is related to the difference in work function ($\Delta \Phi$) for the substrate atom (carbon) and monolayer atom (mercury):

$$\Delta E_p = \alpha \, \Delta \, \Phi$$

where α = 0.5 V/eV. Reasonable values for Φ (C) and Φ (Hg) are 4.6 and 4.5 eV respectively,[42,43] from which ΔE_p is calculated to be 50 mV. This differs from the experimental value but the discrepancy may be ascribed to the uncertainty of the value to be used for Φ (C). The literature values refer to a well-outgassed polycrystalline material that is not subject to oxygen adsorption.[44] As glassy-carbon is supposed to be covered with oxide in the experiments performed, a somewhat higher value for Φ(C) should not be excluded,[45] resulting in larger ΔE_p values. Deviations of ΔE_p might also be due to specific interactions between monolayer and substrate,[13] a roughening of the electrode surface (pretreatment), a difference in the value of the electrosorption oxidation state γ and charge of the mercury ions,[46] co-adsorption of anions, or surface imperfections.[14] As mentioned previously,

nitrate + $0.01M$ perchloric acid. At the disc, a small stripping current peak is obtained at more positive potentials, in addition to the large peak due to the electro-oxidation of the bulk deposit. The smaller peak is assumed to result from the oxidation of a monolayer of mercury atoms which are more tightly bound to the electrode surface. The stripping curve at the disc in Fig. 6 is obtained after 11 min of electrolysis at a deposition potential of -0.5 V. More negative deposition potentials, e.g., -1.0 V, appear to inhibit the formation of a mercury adsorption layer in which the mercury atoms are more firmly bound to the carbon surface. In all cases, it is necessary to keep the electrolysis potential for a sufficient time at a negative value to overcome the poor adhesion of the mercury atoms to the glassy-carbon surface (in agreement with the finding of Morcos).[15]

For a close packed monolayer of mercury atoms, a total of 205 μC per cm^2 of electrode surface is needed for the area under the stripping peak, assuming a mercury atom radius of 0.15 nm,[41] and the exclusive production of Hg(I) ions during stripping. In $0.01M$ potassium nitrate + $0.01M$ nitric acid solution the total charge associated with the adsorption peak (peak II in Fig. 6) may even exceed the

Fig. 7. Charge (Q_{ads}) under the adsorption layer peak vs. underpotential shift ΔE_p (see text) at a glassy-carbon disc electrode in $0.1M$ KNO$_3$ + $0.01M$ HNO$_3$. $c_{Hg(II)}$ = 10μM; deposition time variable; other conditions as for Fig. 2; θ = assumed coverage of the glassy-carbon surface with mercury.

the area of the adsorption layer peak (Fig. 6) can correspond to a charge greater than that for a monolayer. Consequently more mercury atoms than can be accommodated in a monolayer may be interacting with the glassy-carbon surface. At the same time ΔE_p decreases to a constant value of about 60 mV (Fig. 7). With increasing deposition time and mercury(II) concentration, ΔE_p remains practically constant at 60 mV. Finally, the bulk stripping peak grows so that it interferes severely with (or even masks) the adsorption peak, and hence no further measurements of that peak are possible. The appearance of the monolayer adsorption peak depends on the deposition potential at which electrolysis takes place and is favoured by a negative deposition potential (which, however, does not produce any significant reduction of hydrogen ions), e.g., -0.5 V for $0.01M$ potassium nitrate $+0.01M$ nitric acid medium.

Simultaneous reduction of hydrogen ions would inhibit the formation of a mercury atom layer with stronger binding between the metal and the electrode material. According to Combet and Dozol,[36] the reduction of hydrogen ions might replace the reduction of Hg(II) ions at more active sites on the electrode. These sites act as places at which the tendency of the mercury atoms to form an adsorption layer is more pronounced. This might explain the limited appearance of a mercury adsorption layer as found for $0.1M$ perchloric acid medium, and the absence of any adsorption peak at any deposition potential, for $1M$ perchloric acid medium.

Any other ion deposited at the plating potential of the mercury ions acts in the same way as the hydrogen ions, the adsorption peak completely disappearing with the addition of a sufficient concentration of the interfering ion, e.g., $1\mu M$ Cu(II). In this case, the reduction of Hg(II) may take place on the reduced copper atoms, which may explain the "support effect"[3,47,48] of ions such as copper and cadmium. Obviously this "support effect" enhances the analytical possibilities of the carbon electrode.[3,11,47,48]

Determination of mercury

Glassy-carbon is a useful electrode material for mercury determination by stripping analysis. Amalgamation of the electrode substrate by the deposited mercury, which occurs when gold or platinum electrodes are used, is avoided.

Stripping experiments for mercury determination were performed with $0.1M$ perchloric acid and $0.1M$ sodium thiocyanate $+0.01M$ perchloric acid media. These two solutions can be taken as typical of non-complexing and complexing electrolytes respectively. With $0.1M$ perchloric acid it was found that the lowest detectable concentration of mercury was $7 \times 10^{-7}M$. Because of the weak adhesion forces between mercury and glassy-carbon,[15] the reduction and deposition of mercury from dilute solutions is a serious problem.[16] This may be overcome by the addition of a known concentration of other metal
Fig. 8. Dependence of the electrodissolution peak current, I_p, on Hg(II) concentration in $0.1M$ HClO$_4$ (—●—) and in $1M$ NaSCN $+0.01M$ HClO$_4$ (— × —). $v = 0.1$ V/sec; $\omega = 188$ rad/sec; (—●—) $E_{dep} = -1.0$ V; $t_{dep} = 24$ min; (— × —) $E_{dep} = -1.5$ V; $t_{dep} = 16$ min.

ions to the sample solution. These metals are electrodeposited together with the mercury to be determined. Various authors[49-51] have found that the introduction of these auxiliary elements in sufficient amounts decreases the detection limit of the determination, provided that they are oxidized (stripped) from the electrode surface at potentials more negative than the dissolution potential of the metal to be determined. Therefore metals such as copper, cadmium and lead (electronegative elements) should be used for determination of mercury (an electropositive element).

To detect very small quantities of mercury in $0.1M$ perchloric acid medium, cadmium(II) was added to the cell solution. The effect on the mercury dissolution peak is clearly perceptible with about $10^{-6}M$ Cd(II). Optimal results are obtained in the $1-20\mu M$ cadmium(II) concentration range. The effect of the co-deposition of cadmium allows mercury to be determined at concentrations of $10^{-8}M$ Fig. 8).

The acidified thiocyanate medium was chosen for stripping experiments because of the excellent results obtained with it previously.[48,52-54] Anodic stripping voltamperograms for mercury in $0.1M$ sodium thiocyanate $+0.01M$ perchloric acid solution containing Hg(II) $(5-70nM)$ and Cd(II) $(1\mu M)$ are presented in Fig. 9. A second ion [here Cd(II)] must be added to the cell solution to make the detection of microamounts of Hg(II) possible. Our results also indicate that a very negative deposition potential, e.g., -1.5 V, is necessary to obtain a well-defined oxidation signal. This very negative electrolysis potential inhibits the deposition of copper. It is possible that the formation of a copper hydride is responsible for the difficulties encountered in Hg(II) determination in the presence of Cu(II) ions at such negative deposition potentials. Cadmium(II) is therefore preferred as support ion for mercury deposition on glassy-carbon. Cd(II) is also preferred to Cu(II) for the detection of Hg(II) because the copper electro-
Fig. 9. Current–potential curves for the anodic stripping of mercury at a glassy-carbon disc electrode in $0.1M$ NaSCN $+ 0.01M$ HClO$_4$. $E_{dep} = -1.5$ V; $t_{dep} = 30$ min; $v = 0.1$ V/sec; $\omega = 188$ rad/sec; $c_{Hg(II)} = (1)$ 5 mM, (2) 10 mM, (3) 20 mM, (4) 40 mM, (5) 70 mM.

dissolution peak at -0.2 V may interfere with the mercury stripping peak at about 0.0 V. This is particularly true for very small Hg(II) concentrations, since the Cu(II) stripping peak resulting from a hundredfold or higher ratio of copper to mercury may partially mask the mercury stripping peak.

The sensitivity for Hg(II) achieved with the stripping voltammetric technique at glassy-carbon by using the support effect is $2 \times 10^{-9}M$ (0.4 ng/ml). A calibration curve is shown in Fig. 8, for a deposition potential of -1.5 V, deposition time of 20 min, rotation of the electrode at 188 rad/sec and anodic sweep rate of 0.1 V/sec, with 1 μM Cd(II) also present in the cell solution. At the detection limit the reproducibility of the determination was about 22%.

According to Ulrich and Rüegsegger,[48] the detection limit for mercury at a carbon-paste electrode in $0.1M$ potassium thiocyanate $+ 0.025M$ hydrochloric acid containing 25 ng/ml copper(II) is about $1.25 \times 10^{-8}M$. The better results obtained in the present work may be due to the use of cadmium as support element for mercury deposition and to the rotation of the electrode during the whole experiment (deposition and stripping).

According to Kendall[55] 0.5 ppm $(2.5 \times 10^{-9}M)$ mercury(II) can be determined in $0.1M$ perchloric acid medium with a glassy-carbon electrode; Allen and Johnson[11] found the mercury detection limit to be $5 \times 10^{-10}M$ in $1.0M$ sulphuric acid. They used a glassy-carbon rotating ring–disc electrode with a thin film of gold (two monolayer equivalents) electroplated on the disc electrode.

EFFECT OF SURFACE-ACTIVE COMPOUNDS ON VOLTAMMETRIC STRIPPING ANALYSIS AT THE MERCURY FILM ELECTRODE

Joseph Wang* and Den-bai Luo†
Department of Chemistry, New Mexico State University, Las Cruces, NM 88003, U.S.A.

Summary—The effects of various organic compounds on the differential-pulse anodic-stripping voltammetric response at the *in-situ* plated mercury film electrode are explored. These effects vary from metal to metal and from one organic compound to another. The most pronounced effects are observed in measurements of copper. The main effect of the organic compound is to depress the peak current rather than change the peak shape or potential. The differences between the organic interferences observed at the mercury film electrode and those reported at the hanging mercury drop electrode are explained by the different morphology and geometry of the two electrodes. The implications of these interferences for the reliability and feasibility of stripping measurements in natural waters are discussed. Gelatin, camphor, humic acid, starch, agar, sodium dodecyl sulphate and albumin were used as representative organic compounds, and cadmium, lead, and copper as test metal ions.

Stripping analysis and, in particular, differential-pulse anodic-stripping voltammetry (DPASV) have recently received much attention because of their great sensitivity for determination of several metals of environmental and biological significance.[1–4] As a result of its inherent sensitivity, DPASV is widely used for direct measurements on various environmental samples. Such measurements are subject to interference from organic substances present in the sample, particularly surface-active compounds. The adsorption of organic compounds on the mercury working electrode may affect both the deposition and stripping steps, leading to a decrease or increase in the peak current and a shift in peak potential.[5] Two comprehensive studies of the possible effects of organic compounds on the response of stripping voltammetry were made by Brezonik *et al.*[5] and Sagberg and Lund.[6] Both studies employed the hanging mercury drop electrode and various representative organic compounds.

The aim of the present study was to characterize the effect of model organic compounds on the DPASV response of the mercury film electrode (MFE). The inherent sensitivity, improved resolution, and better mechanical stability of the MFE make it preferable in many practical situations.[4] Of the various MFEs, the glassy-carbon electrode mercury-plated *in situ* seems to be the electrode of choice.[7,8] It has been pointed out that organic compounds exhibit different effects on the stripping response obtained at the MFE and hanging mercury drop electrode.[9] Such differences are to be expected, from consideration of the morphology and geometry of both electrodes. Microscopic examination[10] shows that the MFE consists of tiny mercury droplets, the dimensions and distribution of which depend on the deposition potential. Thus, not all the exposed car-

bon substrate is coated with mercury, and the electroactive surface is a composite of mercury and carbon sites.[11] The additional carbon sites of the MFE may result in adsorption characteristics different from those of the homogeneous surface of the hanging mercury drop. The geometry of the two electrodes can also affect their filming by organic compounds. The hanging mercury drop, being deformable, can flex and continuously break and renew the surface.[9] In addition, the continuously renewed surface of the *in-situ* plated MFE may alter the adsorption process. With the increasing use of the MFE, a detailed knowledge of the changes in its stripping response in the presence of organic compounds occurring in natural waters is required for understanding and minimizing the organic interferences. Thus systematic investigations in this field seem justified.

EXPERIMENTAL

Apparatus and reagents

The electrochemical cell and the reagents have been described previously,[12] except as noted. The working electrode was a thin mercury film deposited on a 0.20-cm diameter glassy-carbon disk. Measurements were made with a Sargent-Welch Model 4001 and EG&G PAR Model 174 polarographic analysers. Solutions (200 ppm) of the organic compounds were prepared daily by dissolving the reagent grade materials at room or elevated temperature. Most samples were prepared in 0.1*M* acetate buffer (pH 4.6). Various "real" samples, such as Las Cruces tap water and Rio Grande river water, were used. The river water sample was acidified to pH 1.3 with nitric acid, and 10 ml of the acetate buffer were added to 90 ml of the tap water.

Procedure

A 95-ml portion of the supporting electrolyte solution and 5 ml of $1 \times 10^{-3}M$ mercury solution were introduced into the cell. The mixture was deaerated by passage of nitrogen for 5 min, while the working electrode was kept at 0.0 V. The nitrogen delivery tube was then raised above the solution, and a potential of −1.0 V was applied while the

solution was stirred at 550 rpm. After 8 min, the potential was switched to 0.0 V and held there for 2 min. Following this, the electrode was ready for use in an analytical run. Background and sample measurements were made successively, by applying a deposition potential of -1.1 V for 2 min, stopping the stirring, and after 15 sec stripping the metals from the mercury by applying a differential-pulse anodic potential ramp, the scan being stopped at 0.0 V; after 1 min the system was ready for the next cycle. The mercury film was removed at the end of the experiment by wiping with a soft tissue wetted with $1M$ nitric acid.

RESULTS AND DISCUSSION

The differential-pulse stripping mode was employed throughout most of this study, as it is widely used for ultratrace measurements on sea-water and known to be more susceptible to organic interferences.[13] Similarly, acetate medium (pH 4.6), commonly used in environmental studies, was employed. Figures 1–4 show the effects of gelatin, humic acid, camphor and starch, respectively, on the stripping response for cadmium, lead and copper. It is obvious that the effect of the organic compounds varied from metal to metal and from one organic compound to another. In all cases, the copper peak was most severely affected. The copper peak-current continued to decrease with increasing concentration of the four organic compounds; at the 15-ppm level of the organic material, the copper peak was depressed by 15–70%.

The addition of gelatin (Fig. 1), a known maximum suppressor in polarography and a representative colloidal protein, only slightly affects the lead peak. Six ppm of gelatin will depress the cadmium peak-current by 40% but further addition (up to 18 ppm) causes no further decrease. A 55% depreciation of the cadmium peak was observed when the hanging mercury drop electrode was used following the addition of 20 ppm gelatin (at pH 3).[5] A 70% reduction of the copper peak-current is observed at the 18-ppm gelatin level. Humic acid (Fig. 2) depresses the peak-current for all three metals: a slight (20% at the 15-ppm humic acid level) and gradual decrease is observed for the cadmium peak; the lead peak-current decreases sharply (35%) on addition of 3 ppm humic acid, and then

Fig. 4. Effect of starch on the determination of Cd, Pb, and Cu by DPASV at the MFE. Conditions as in Fig. 1, except that the Cu concentration was $1.3 \times 10^{-7}M$.

Fig. 1. Effect of gelatin on the determination of Cd, Pb, and Cu by DPASV at the MFE. Conditions: 3 min deposition at -1.1 V with stirring at 550 rpm. Pulse amplitude, 50 mV; scan-rate, 1.0 V/min. $1.1 \times 10^{-7}M$ Cd, $1.0 \times 10^{-7}M$ Pb, $1.5 \times 10^{-7}M$ Cu.

only slightly with further humic acid; the copper peak progressively decreases (by 85% with 15 ppm humic acid). As humic acid is a natural chelating agent, as well as a surface-active compound, part of the peak depression may be due to complexation of the metal ions. Thus, it is very difficult to distinguish between the effect of complexation and of adsorption, unless

strongly acidic conditions—so that no complexation occurs—are employed (or when the peak current in the presence of surfactants is independent of pH[6]). The situation may be further complicated when the adsorbed organic species participates in the complexation reaction.[14] Because of these combined effects, it is important to re-emphasize the danger inherent in the use of stripping analysis for characterizing metal binding by organic chelating agents. Additional information on the effects of humic acid may be obtained from the shape of the stripping peaks and standard-addition data, as will be described later.

Camphor (Fig. 3) has only a slight effect on the cadmium and lead peak-currents and a pronounced effect (45% depression for 15 ppm camphor) on the copper peak. The addition of starch (Fig. 4), a representative polysaccharide, causes approximately 40% increases in the cadmium and lead peaks, and a 15% decrease in the copper peak. With the hanging mercury drop and pH 3, no change in the cadmium and lead response is observed.[5]

The effect of varying the organic compound concentration in the 0–15 ppm range was also evaluated for agar, sodium dodecyl sulphate and albumin (not shown; conditions as in Fig 1). Addition of 8 ppm of the polysaccharide agar caused 40–60% increases in the three metal peaks, but further addition up to 15 ppm caused no further change. With the hanging mercury drop electrode and pH 3, agar causes no change in the cadmium and copper response.[5] The addition of 6 ppm of the anionic surfactant sodium dodecyl sulphate did not alter the lead and cadmium peaks, but addition of 10 ppm caused a 75% depression of these peaks. In contrast, the copper peak gradually decreased (up to 40% depression at the 10 ppm sodium dodecyl sulphate level) with successive additions of the surfactant. Significant peak-current depressions ($\sim 80\%$ of the copper peak, $\sim 65\%$ of the cadmium and lead peaks) were observed on adding 1 ppm of albumin—another model high molecular-weight organic compound. Further additions of albumin, up to 10 ppm, caused only slight ($\sim 5\%$) further depression in the responses. As in the case of humic acid, part of this depression is attributed to complexation by the albumin binding sites.

For most of the organic compounds discussed (except albumin and sodium dodecyl sulphate) the adsorption phenomenon did not vary with time. Four successive runs at each concentration of the organic compound yielded relatively reproducible stripping-peak currents. This is in contrast to the effect frequently observed for surfactants, that successive voltamperograms, i.e., increased contact time with the solution, show progressive decrease in the peak height, owing to gradual blocking of the electrode surface.[15] The relatively stable response observed in this study may be a feature of the in-situ plated MFE, at which a continuously renewed surface is maintained.

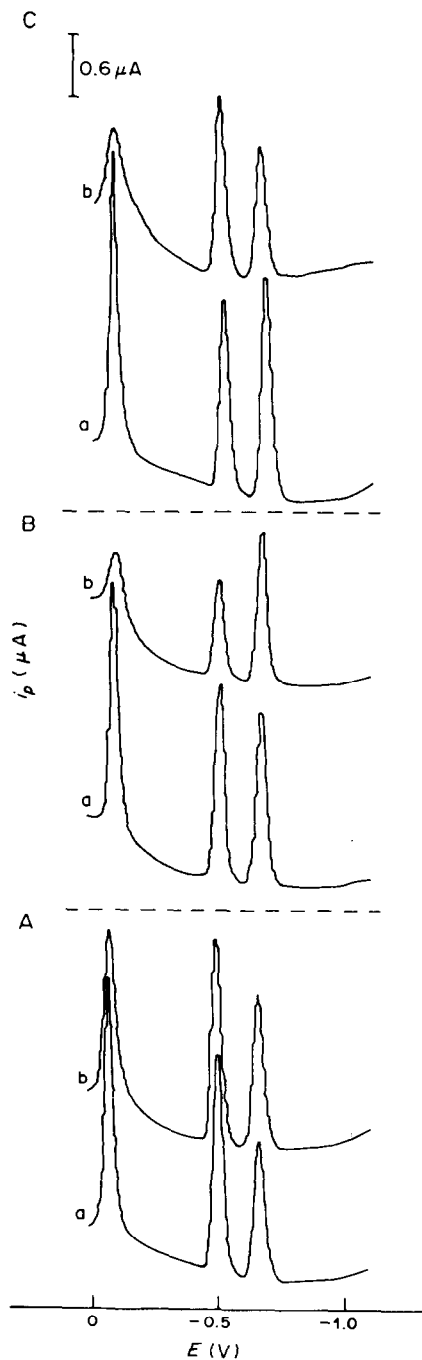
Another interesting response characteristic observed in this study was that only minor changes in the stripping-peak shape or potential accompanied the changes in magnitude of the peak current (caused by the organic compounds). Figure 5 shows stripping voltamperograms for cadmium, lead, and copper obtained in the absence (a) and presence (b) of different organic compounds: camphor (A), humic acid (B), and gelatin (C). These compounds do not affect the shape and potential of the lead and


Fig. 5. Stripping voltamperograms for $1 \times 10^{-7} M$ Pb and Cd, and $1.3 \times 10^{-7} M$ Cu, obtained in the absence (a) and presence (b) of 9 ppm camphor (A), humic acid (B), and gelatin (C). Conditions as in Fig. 1.

cadmium peaks. In contrast, significant broadening of the copper peak (width at half-height doubled from 35 to 70 mV) is observed in the case of gelatin and humic acid. In the humic acid experiment, the copper-peak broadening is accompanied by a slight (30 mV) cathodic shift in the potential. Such a shift may be attributed to complexation rather than to sorption. The addition of starch, agar and sodium dodecyl sulphate to $1 \times 10^{-7}M$ cadmium, lead and copper solutions did not change the shape and location of the stripping peaks (not shown; conditions as for Fig. 5). The relatively minor changes in the peak shape and potential indicate that the main effect of surface-active organic compounds at the *in-situ* plated MFE is to hinder the transport of the metals to the surface during the deposition step (and thus to change the magnitude of the peak current). Except for the copper peak, no effect on the reversibility of the stripping reaction was observed. This is especially important, as the differential-pulse stripping response is known to be more sensitive to small changes in the rate of the electrode reaction. The differential-pulse mode is known also to yield organic

adsorption/desorption peaks; such peaks were not observed for the compounds tested in this study. Some of these observations may be features of the *in-situ* plated MFE.

From the analytical point of view, certain organic interferences can be corrected by using the standard-addition procedure. This correction is valid when the interferent changes the slope of the calibration graph (which must be linear), and in effect a calibration specific for the interferent concentration present can be obtained by spiking the sample with aliquots of standard metal solution. For example, Fig. 6A shows that the standard-addition method can compensate for the decrease in the stripping-peak currents caused by the addition of gelatin to a tap water sample: the response after the addition of known amounts of a metal is proportional to the added metal concentration. However, when the fraction of the electrode area covered by the organic compounds progressively increases with time or a slow metal–organic compound combination occurs, the standard-addition method would not correct for the peak depression. For example, non-linear responses were obtained
Fig. 6. Differential pulse voltamperograms for (A) tap water and (B) river water samples. (a) Samples spiked with Cd ($1 \times 10^{-7}M$) and Pb (7×10^{-8}M (A), and $1 \times 10^{-7}M$ Cd and Pb (B)); (b) same as (a), but after addition of 10 ppm of gelatin (A) or humic acid (B); (c) and (d), same as (b) but after addition of (c) $1 \times 10^{-7}M$ and (d) $2 \times 10^{-7}M$ Pb and Cd. Conditions, 1 (A) or 2 (B) min deposition at -1.1 V, with stirring at 550 rpm. Pulse amplitude, 25 mV; scan-rate, 5 mV/sec. Also shown are the resulting calibration plots based on the data for (b)–(d).

following successive additions of aliquots of standard metal solution to samples containing 10 ppm sodium dodecyl sulphate and humic acid (not shown). When metal–organic compound combination is responsible for the non-linearity, lower pH values may be used to prevent the complexation (however, because of the suppressive effect of chloride on copper stripping peaks,[16] hydrochloric acid should not be used for acidifying acetate media). Figure 6B illustrates this approach for a river water sample that had been acidified to pH 1.3 (as in the usual preservation procedures) and then spiked with humic acid, cadmium and lead. The stripping peaks for the solutions containing standard additions of cadmium and lead are proportional in height to the added metal concentrations and though the slope for the lead response is lower than that in the absence of humic acid (cf. curves a and b), that for cadmium is not affected by the humic acid. However, for convenience and to avoid erroneous conclusions, especially when analysing organic-rich water samples, e.g., inshore or near-shore waters, waste-water or sewage, it is best to destroy the organic matter beforehand by ultraviolet radiation.[4]

INFLUENCE OF VOLATILE HYDRIDE-FORMING ELEMENTS ON ANTIMONY DETERMINATION BY ATOMIC-ABSORPTION SPECTROMETRY WITH HYDRIDE-GENERATION

Lauri H. J. Lajunen*, Timo Merkkiniemi and Hannu Häyrynen
Department of Chemistry, University of Oulu, SF-90570 Oulu 57, Finland

Summary—A study was undertaken to determine the interfering effects of arsenic, bismuth, germanium, lead, selenium, tin and tellurium on trace determination of antimony by atomic-absorption spectrometry with hydride-generation. A 1% $NaBH_4$ solution was used as reductant and a small amount of oxygen was added to the hydrogen produced, to support the combustion and atomization of SbH_3. The interference from selenium in the determination of antimony is removed if potassium iodide–ascorbic acid solution or copper sulphate is added to the sample solution. The interference of tin and tellurium can also be avoided by adding potassium iodide–ascorbic acid solution. A possible interference mechanism is discussed.

Interferences caused by a number of metal ions are a serious problem in the practical use of the hydride-generation method in the atomic-absorption determination of volatile hydride-forming elements (the most studied are As and Se).[1-8] The interference studies in the literature fall into two groups: (*a*) those on elements predominantly in the periodic groups VIII and Ib (especially Cu, Ni, Pd and Pt) and (*b*) those on the mutual interactions of the elements forming volatile hydrides. Most papers deal with the first type of interference, but relatively little information is available on the second, especially in the determination of antimony.

The aim of the present work was to study this second aspect in the determination of antimony by the hydride-generation atomic-absorption method originally developed by Siemer and Hageman[9] for selenium determination, and in particular to find methods for removing the interferences. In addition, possible interference mechanisms were considered.

EXPERIMENTAL

Reagents

Distilled and demineralized water was used throughout.

Sodium borohydride solution, 1%. Prepared weekly, and stabilized by addition of one pellet of potassium hydroxide per 100 ml.[10]

Standard antimony(III) stock solution (1000 μg/ml). Prepared by diluting a "Titrisol" solution (Merck) containing 1.000 g of antimony (as $SbCl_3$) to 1 litre with 5% w/v hydrochloric acid.

Standard arsenic(III) stock solution (1000 μg/ml). Prepared by dissolving 1.320 g of As_2O_3 (Merck, analytical grade) in 50 ml of concentrated hydrochloric acid and diluting to 1 litre with water.

Standard selenium(IV) stock solution (1000 μg/ml). Prepared by diluting a "Titrisol" solution (Merck) containing 1.000 g of selenium (as SeO_2) to 1 litre with water.

Standard tin(II) stock solution (1000 μg/ml). Prepared by dissolving 1.000 g of metallic tin in 200 ml of concentrated hydrochloric acid and diluting to 1 litre with water.

Standard lead(II) stock solution (1000 μg/ml). Prepared by dissolving 1.598 g of $Pb(NO_3)_2$ (Merck, analytical grade) and diluting to 1 litre with water.

Standard bismuth(III) stock solution (1000 μg/ml). Prepared by dissolving 1.115 g of Bi_2O_3 (Merck, analytical grade) in 50 ml of concentrated hydrochloric acid and diluting to 1 litre with water.

Standard tellurium(IV) stock solution (1000 μg/ml). Prepared by dissolving 1.000 g of tellurium in a mixture of 15 ml of concentrated hydrochloric acid and 5 ml of concentrated nitric acid and dilution to 1 litre with water.

Standard germanium(IV) stock solution (1000 μg/ml). Prepared by dissolving 1.441 g of GeO_2 (Merck, analytical grade) in a mixture of 15 ml of concentrated hydrochloric acid and 5 ml of concentrated nitric acid and diluting to 1 litre with water.

Standard potassium iodide stock solution (1M). Prepared by dissolving 16.6 g of potassium iodide (Merck, analytical grade) and 2.0 g of ascorbic acid in 100 ml of water.

Standard copper(II) stock solution (5000 μg/ml). Prepared by dissolving 3.140 g of $CuSO_4$ (Merck, analytical grade) in 250 ml of water.

Apparatus and method

A Pye Unicam SP 9-800 atomic-absorption spectrometer equipped with an SP 9 computer, hollow-cathode lamps, a conventional deuterium-lamp for background correction, and a hydride generator and atomization unit were used in the determinations.[9,11] The hydride generator and atomization unit was attached in place of the burner of the spectrometer. Table 1 shows the instrumental parameters of the spectrometer. Deuterium-lamp background correction was used for each measurement.

*To whom correspondence and requests for reprints should be addressed.

Hydrogen was used as the carrier gas at a flow-rate of 1.1–1.2 l./min to flush the generated hydrides into the atomization tube. A small hydrogen–oxygen flame was ignited inside the quartz tube to support the combustion and atomization of the hydrides. A safe oxygen flow-rate was 50–60 ml/min. The excess of hydrogen was burned at the ends of the quartz tube.

The specimen (volume 4 ml) was added to the hydride-generation cell with an injection syringe, and reductant with a Socorex sampler (volume 5 ml). A load of about 0.5 kg was attached to the piston of the sampler to keep the addition rate constant. The hydride-generation cell was washed with about 10 ml of distilled and demineralized water between successive injections.

The absorbance measurements were begun after the flame had burned for at least 10 min. The peak area was used for measurement, and each sample was analysed 3–5 times. When the excess of hydrogen was burned at the ends of the quartz tube, it caused a small signal. The area of this signal for a blank run with 5M hydrochloric acid was measured and always deducted from the measured antimony signals. The reading cycle was induced manually. The background absorption of the antimony signals was low and symmetrically distributed around the peak, which permitted automatic induction of the reading cycle.

Procedures

Effect of HCl on antimony determination. The effect of the concentration of hydrochloric acid on the antimony atomic-absorption signal was investigated with 20-μg/l. antimony solutions over the hydrochloric acid concentration range 1–12M.

Interference studies. The solutions to be measured (and working standards) were prepared from the standard solutions by dilution with 5M hydrochloric acid. Two series of test solutions were always prepared, with antimony concentrations of (*a*) 20 and (*b*) 50 μg/l., and the interfering
Fig. 1. The effect of HCl on the determination of antimony.

element at 0, 100, 250, 500, 1000, 2000 and 4000 μg/l. concentration.

Masking studies. To the solution containing Sb(III) and the interfering ion, 1 ml of 1M potassium iodide or 5% copper solution was added in the hydride-generation cell just before the addition of the sodium borohydride.

RESULTS AND DISCUSSION

We have recently reported on the performance of the apparatus and procedure.[11] The optimum range extended from 1 to 50 μg/l., the calibration curve then being linear. The detection limit was found to be about 0.5 μg/l. (taken as the mean value of the blank signal plus three times its standard deviation) and the slope of the calibration curves (absorbance *vs.* weight of Sb) 4.4 μg^{-1}. The peak-area was found to give greater sensitivity than the peak-height. With peak-area detection the relative standard deviation varied

between 2 and 7%, depending on the antimony content and the nature of the matrix.

Figure 1 shows that the hydrochloric acid concentration has only a small effect on the determination; the optimum is in the range 4–8M and 5M acid medium was therefore selected.

Table 2 shows the influence of the different elements forming volatile hydrides, on the determination of antimony(III). All those studied, except bismuth and lead, strongly interfere by decreasing the absorption signal for Sb, the interference increasing in the order Pb < Bi < As < Te < Ge < Se < Sn. Lead has practically no effect at all, and for the others (except Bi) the interfering effect becomes noticeable only when the concentration of the interfering cation is above 100 µg/l. The same effect is obtained at two different Sb concentrations (20 and 50 µg/l.), and the interference seems to be independent of the analyte/interferent ratio and to depend only on the concentration of the interfering element. On the other hand, in consideration of the mechanism, the number of atoms of analyte and interferent must be compared, so the concentrations of analyte and interferent must be translated into molarities. Figure 2 shows, for example, the interference of Sn and Ge at two different Sb concentrations. The shapes of the

curves are similar in both cases but the degree of interference is greater for the greater Sb concentration.

Antimony also influences the determination of the other elements forming volatile hydrides, as illustrated in Fig. 3. Its effect on the determination of Se is considerably less pronounced than that of Se on Sb determination, whereas it has a greater effect on determination of As than As has on determination of Sb.

A possible explanation for the mutual interference is a competitive reaction between the reducing species. NaBH$_4$ decomposes in acidic solutions to give H$_3$BO$_3$ and H$_2$, and if most of the reductant is consumed in this way, only a limited amount will be available for the production of hydrides. If there is more than one hydride-forming element in the test solution, the reductant should be consumed predominantly by the element which reacts fastest with it. If this explanation is correct, the most severe signal suppressions can be expected for slowly reacting analyte elements in the presence of interfering elements that react more quickly. Figure 4 superimposes the absorption signals obtained for Sb(III), As(III) and Se(IV) as a function of time elapsed after addition of the reductant. Sb(III) and Se(IV) seem to react
Fig. 3. The effect of Sb on the determination of Se ($\bigcirc$), As on the determination of Sb ($\square$), Sb on the determination of As ($\triangle$), Se on the determination of Sb ($\bullet$), As on the determination of Se ($\blacksquare$), and Se on the determination of As ($\blacktriangle$). The concentration of the analyte was 50 ng/ml in each case.
Fig. 4. Superimposed recorder tracings for 5 ng/ml As(III), 5 ng/ml Sb(III), and 10 ng/ml Se(IV) in 5M HCl. Chart-speed 300 mm/min.

at practically the same rate, and As(III) a little more slowly. If the competitive reaction theory is correct, the mutual interferences between Sb and Se should be about the same, and the depressive influence of these faster reacting elements on determination of the slower reacting As should be more pronounced than that of arsenic on their determination. From the results shown in Fig. 3 it seems likely that competition is not the reason for the effect, since the effect of Se on Sb is much greater than that of Sb on Se. Further, a simple calculation shows that the reductant is present in very large excess, so hydride generation should be complete anyway.

Dedina and Rubeska[12] have shown that the atomization of selenium hydride is not caused by thermal decomposition but by free radicals generated in the reaction zone of the diffusion flame. They also used a system with atomization of gaseous hydrides in an extremely fuel-rich hydrogen–oxygen flame burning inside an unheated quartz tube. The probability of formation of free atoms from the hydrides is proportional to the number of collisions with free H atoms and OH radicals. Welz and Melcher[8] have investigated the decomposition mechanism of selenium and arsenic hydrides in a heated quartz-tube atomizer and concluded that the atomization under these conditions is also due to collisions with free radicals.

If this free-radical mechanism occurs, there might often be conditions in which there is a lack of radicals. Then if the decomposition rate of the various hydrides were the same, the ease of volatilization of the hydrides would be the decisive factor, since the hydrides volatilized first would decrease the number of radicals, so that there would be insufficient radicals to cause the quantitative atomization of hydrides volatilized later. If this explanation is correct, the effect of Se and Sb on the As signal should be stronger than that of As on their signals, and that of Sb on Se similar to that of Se on Sb. Again the Sb/Se system gives anomalous results (Fig. 3). Thus, according to our findings there might also be differences in decomposition rates of the different volatile hydrides and/or interactions between the hydrides in the gas phase. On the other hand, it can be expected that the mutual interference described above will depend on both the molar concentration of the interfering

hydride which consumes radicals, and its molar concentration ratio to the analyte hydride, since the degree of interference caused by a given number of interferent atoms is the greater, the smaller the number of analyte atoms (Fig. 2). However, the degree of interference, as well as the acidity required, also depends on the structure of the apparatus.

When the mutual interference of the volatile hydrides occurs in the gas phase in the atomizer, it is possible to decrease or eliminate this interference by preventing the formation or evaporation of the interfering hydride. As shown in Table 2, the interference caused by selenium, tellurium and tin can be avoided completely by using potassium iodide–ascorbic acid solution as a masking agent and the interference of bismuth as well as selenium can be eliminated by addition of copper(II) sulphate (but not nitrate, since nitrate itself interferes[13]). The masking reagents react with the interfering ions and prevent their evaporation as covalent hydrides. Iodide–ascorbic acid solution reduces Se(IV) to Se, and iodide forms complexes with Sn(II) and Te(IV), but does not prevent the formation and evaporation of SbH_3. According to the theory proposed by Meyer et al.,[6] SeH_4 reacts with Cu(II) by forming an insoluble copper selenide, $CuSe$, in acid medium, whereas Cu(II) does not prevent the evaporation of SbH_3. Because selenium and tellurium are chemically very similar, it is reasonable to think that the mechanism in the case of Cu(II) and Te(IV) is similar to that for Cu(II) and Se(IV). Arsenic and antimony are also chemically very similar, and it is therefore very difficult to find a masking agent which would prevent the production of AsH_3, but not of SbH_3.

CONCLUSIONS

In the determination of antimony the degree of interference of the elements forming volatile hydrides is significant when the concentrations of the interferent is more than about 100 µg/l. The interference is dependent on the concentration ratio of the analyte and interferent. The interference seems to occur in the gas phase in the atomizer tube, and to be due to collisions with free radicals, as postulated first by Dedina and Rubeska[12] for arsenic and selenium. All the interfering elements studied have a depressive influence on the Sb signal, increasing in the order: Pb < Bi < As < Te < Ge < Se < Sn. The influence of Se, Te and Sn can be avoided by the addition of KI–ascorbic acid solution, and that of Te and Se by the addition of Cu(II) sulphate.

SHORT COMMUNICATIONS

REACTION OF IRON(III) WITH TIRON IN THE PRESENCE OF FERROZINE, AND DETERMINATION OF TIRON

Ninus Simonzadeh and Bruno Jaselskis

Department of Chemistry, Loyola University of Chicago, Chicago, IL 60626, U.S.A.

Summary—Tiron is oxidized by iron(III) in the presence of Ferrozine with an apparent four-electron transfer and aromatic ring opening. The apparent molar absorptivity referred to the Tiron in the reaction corresponds to approximately 1.12×10^5 l.mole^{-1}.cm^{-1}.

Tiron (1,2-dihydroxybenzene-3,5-disulphonate), forms coloured iron (III) complexes which differ in stoichiometry according to the pH. The colour of these complexes has been used for the determination of small amounts of iron(III).[1] However, in the presence of ligands capable of stabilizing iron(II), iron(III) oxidizes Tiron as well as other catechols. Rapid oxidation of catechols by iron(III) in the presence of 1,10-phenanthroline, with a two-electron transfer, has been reported,[2] and D-α-tocopherol (vitamin E) has been determined by use of iron(III) in the presence of Ferrozine.[3] In the determination of vitamin E it was observed that after a rapid transfer of two electrons, the vitamin E was further oxidized. This has led us to investigate the reaction of Tiron with iron(III) in the presence of Ferrozine, and we have developed a suitable colorimetric method for the determination of small amounts of Tiron.

EXPERIMENTAL

Reagents

All reagents were of analytical grade. Demineralized water was used to make all solutions.

Iron(III) solution. Prepared by dissolving approximately 193 mg of ferric ammonium sulphate, $Fe(NH_4)(SO_4)_2.12H_2O$ (Baker Analyzed) in 1.0 ml of concentrated sulphuric acid and a sufficient amount of water. The solution was transferred to a 250-ml standard flask and diluted to volume.

Buffer solution, 0.3M, pH 3.4. Prepared by adding sodium hydroxide pellets to $0.3M$ monochloroacetic acid.

Tiron standard solution. A stock solution was prepared by dissolving exactly 440 mg of disodium-1,2-dihydroxy-benzene-3,5-disulphonate monohydrate (G. Frederick Smith Chemical Co.) in 1000 ml of demineralized water. Other catechols tested were recrystallized from n-hexane and used for comparative studies.

Ferrozine solution. Prepared by dissolving 171 mg of 3-(2-pyridyl)-5,6-bis(4-phenylsulphonic acid)-1,2,4-triazine disodium salt trihydrate (Aldrich Chemical Co.) in 100 ml of demineralized water and stored in a tinted glass bottle.

Procedure

In all experiments the reagents were added to 50-ml standard flasks in the following order: 20 ml of $0.3M$ chloroacetate buffer followed by 6.0 ml of $0.003M$ Ferrozine, a varied amount (50–200 μl) of Tiron standard solution and water to give a volume of about 45 ml. The flasks were then placed in a constant-temperature bath (40°) for approximately 10 min; 3.0 ml of $0.002M$ iron(III) were added to each flask, the solutions diluted to volume, and timing was started. Tinted glass flasks or flasks covered with aluminium foil were used in order to protect the solutions from sunlight. For kinetic studies, a 3.0-ml sample was withdrawn every 5 min and the absorbance measured at 562 nm against water. Similarly, a blank containing all of the reagents except Tiron was prepared, and its absorbance measured as a function of time. The net absorbance was used for kinetic and analytical purposes. The reaction was studied at different temperatures. At temperatures below 40° the absorbance measurements were made at 10 or 15 min intervals. The data were used to evaluate the pseudo first-order rate constants and the Arrhenius activation energy.

The amount of Tiron in a given sample was determined by measuring the net absorbance of a solution heated for 40 min at 40° or left for 3 hr at room temperature. Other catechols were determined in a similar manner, except that longer reaction times were needed.

RESULTS AND DISCUSSION

The oxidation of Tiron and of other substituted catechols by iron(III) in the presence of Ferrozine at pH 3.4 proceeds in two steps. In the first, Tiron is rapidly oxidized by a two-electron transfer and in the second, which is slower, an additional two electrons are transferred, resulting in the opening of the aromatic ring.

Cleavage of the carbon–carbon bond in catechols by copper(II) in pyridine solutions and in the presence of oxygen has been reported.[4] This cleavage of catechols proceeds with a four-electron transfer and the formation of *cis,cis*-muconic acids. A similar cleavage of catechols in the presence of iron(III), nitrilotriacetic acid and pyrocatechase as a catalyst

Table 1. Absorbance of Iron(II) Ferrozine produced, as a function of Tiron concentration*

Concentration of Tiron, $10^{-6}M$	Absorbance†	Molar absorptivity, $10^5 \, l.mole^{-1}.cm^{-1}$
1.42	0.159 ± 0.004	1.12
2.12	0.236 ± 0.005	1.11
2.83	0.317 ± 0.007	1.12
5.65	0.598 ± 0.010	1.06

*Reaction at 40° with $1.2 \times 10^{-4}M$ iron(III) and $3.6 \times 10^{-4}M$ Ferrozine.

†Measured after 40 min reaction time and corrected for the blank. The average and range of four determinations are reported.

has been observed.[5] In the determination of vitamin E the second step was prevented by the addition of bifluoride or orthophosphate.[3]

At pH values $\geqslant 5$ Tiron forms different coloured complexes with iron(III) and has been used for the determination of small amounts of iron(III).[1] However, in the presence of an excess of iron(III) and ligands which stabilize iron(II), Tiron is oxidized with opening of the aromatic ring. A pH of 3.4 was chosen for the method described here, because at this pH the iron(II)–Ferrozine complex is stable, iron(III) does not form a precipitate of hydrous oxide, and the oxidation of Tiron proceeds quite readily.

Examination of the reaction of Tiron with iron(III) in the presence of Ferrozine, as a function of time and temperature shows that the change in absorbance levels off after about 35 min when the reaction is done at 40°, but after about 2.5 hr when the reaction is done at room temperature. Absorbance values for different concentrations of Tiron are summarized in Table 1. The apparent molar absorptivity, referred to Tiron, is about $1.12 \times 10^5 \, l.mole^{-1}.cm^{-1}$, whereas referred to iron(II)–Ferrozine it is 2.80×10^4 $l.mole^{-1}.cm^{-1}$. The ratio of these molar absorptivities is 4, which is in agreement with the number of electrons transferred in the oxidation process.

The reactivity of catechols with iron(III) is affected not only by substituent groups but also by their positions, and decreases in the order Tiron > catechol > 4-chlorocatechol > tetrabromocatechol.

The pseudo first-order reaction activation energy calculated from the rate constants for various catechols at different temperatures is in the range of 30–60 kJ/mole, indicating that the opening of the aromatic ring most likely proceeds through a free-radical intermediate. In fact, the reaction is somewhat faster in an atmosphere of nitrogen than in the presence of oxygen. Also, the reaction is affected by sunlight. Hence the blank and sample solutions are protected from direct sunlight by covering the flasks with aluminium foil or using tinted glass flasks. In this manner Tiron can be determined at ppm levels with a relative precision of better than 3%. Substances which can be oxidized by iron(III) must be eliminated before the determination.

TITRIMETRIC DETERMINATION OF VANADIUM(IV) WITH DCTA

RAM PARKASH*, KULDIP SINGH, JITENDRA PAL KAUR
and R. L. SINGHAL
Department of Chemistry, Panjab University, Chandigarh, India

Summary—Vanadium(IV) has been determined by DCTA titration conductometrically, spectrophotometrically and visually (with Alizarin Red S, Gallein and Catechol Violet as indicators at pH 4.0, 4.2 and 4.5–4.6 respectively). The interference of nickel, copper, lead, aluminium and thorium can be removed, and the method utilized for the analysis of binary mixtures of vanadium(IV) with nickel, copper or thorium.

Except for an attempt by Mendez and Diez[1] to determine it spectrophotometrically, no work has been reported on the estimation of vanadium(IV) with 1,2-diaminocyclohexanetetra-acetic acid (DCTA). In the investigation described here, vanadium(IV) alone or in the presence of various ions has been determined by direct titration with DCTA, conductometrically, spectrophotometrically and visually, Alizarin Red S, Catechol Violet and Gallein being used as indicators.

EXPERIMENTAL

Procedures

Vanadium(IV) sulphate solution ($5 \times 10^{-3}M$, 0.5–10 ml) was titrated with DCTA solution after addition of 10 drops of 0.5% aqueous Alizarin Red S solution or 2 drops of 0.2% ethanolic Gallein solution or 1 drop of 0.1% aqueous Catechol Violet solution as indicator, at pH 4.0, 4.2 and 4.5–4.6 respectively, to the corresponding sharp colour changes (from orange red to greenish yellow, from light violet through weakly pink to yellow, and from blue to lemon yellow). The pH was adjusted with $0.1M$ sodium acetate–acetic acid buffer[2] (5–10 ml) or by addition of water and/or glacial acetic acid, as required.

Copper(II) (10 μmoles) was masked by adding ascorbic acid (~ 5 ml of 0.1% solution) and potassium cyanide (~ 10 ml of 1% solution), and Gallein or Catechol Violet was used as indicator. The interference of 10 μmoles of lead was dealt with by adding ~ 1 ml of $0.5M$ sulphuric acid; the excess of acid was partly neutralized with ammonia before addition of the buffer for the titration. Potassium fluoride (~ 1 ml of 0.5% solution) was added to mask 10 μmoles of aluminium or thorium. Potassium cyanide (~ 2 ml of 1% solution) was added to remove the interference due to 10 μmoles of nickel in titrations employing Gallein or Catechol Violet as indicator (Table 1).

Conductometric titration was done in the usual way, the specific conductance being measured 2–3 min after each addition of DCTA, with at least 5 or 6 readings taken each side of the equivalence point. No buffer was used.

*To whom correspondence should be addressed (present address: Pro-Vice-Chancellor, Kurukshetra University, Kurukshetra, India).

For the spectrophotometric titrations, Catechol Violet solution (2 drops) or Alizarin Red S solution (10 drops) was added to 1–5 ml of vanadium(IV) solution which was then buffered to pH 4.5 or 4.0, respectively, with ~ 10 ml of $0.1M$ sodium acetate–acetic acid buffer, and titrated with DCTA solution with measurement of absorbance at 607 nm (Catechol Violet) and 520 nm (Alizarin Red S) (Figs. 1 and 2). The absorbance was corrected for dilution and plotted as a function of the volume of DCTA added (Fig. 3).

The titrations were repeated at least five times at each concentration level.

RESULTS AND DISCUSSION

The study confirms that vanadium(IV) reacts with DCTA stoichiometrically in 1:1 molar ratio as expected. The titrations are quantitative and satisfactory when done at room temperature (25–30°). If DCTA is titrated conductometrically with vanadium(IV), the equivalence point found is not reliable, whereas the reverse titration is satisfactory.

Vanadium(IV) and Alizarin Red S form a stable orange red complex at pH 4.0 (λ_{max} 485 nm); the corresponding Catechol Violet complex is blue (λ_{max} 620 nm at pH 4.5) (Figs. 1 and 2). The yellow vanadium(IV)–DCTA complex shows no significant absorbance in these wavelength regions, which can therefore be used in the spectrophotometric titration (Fig. 3). The error in the spectrophotometric titration is less than that in the visual titration, particularly at low concentrations of vanadium(IV). The slight curvature near the equivalence point is customary in spectrophotometric titrations based on use of indicators.

Interferences

The determination is not affected by 100-fold molar ratio of lithium, sodium, potassium, magnesium, strontium, chloride, nitrate, sulphate or acetate to vanadium. The visual titration is not affected by silver, though a precipitate of silver chloride is formed if chloride is present (and this causes inter-

ference in the spectrophotometric titration). With Alizarin Red S, Gallein and Catechol Violet as indicators, the corresponding tolerance limits (molar ratio to vanadium) are 10, 100 and 10 for calcium, 10, 20 and 60 for barium, 10, 10 and 1 for mercury(II), 25, 100, and 25 for fluoride, and 5, 10 and 10 for sulphide. Higher levels of calcium and barium result in formation of precipitates, presumably of sulphate, which interfere in detection of the end-point (surprisingly, there is better tolerance for strontium). Chromium(III) does not interfere if its concentration is less than 0.17 mg/ml. Cobalt, zinc and thorium are

quantitatively co-titrated. Manganese(II), nickel, copper(II) and cadmium are also quantitatively co-titrated when Gallein or Catechol Violet is used as indicator. Lead and aluminium also interfere.

Lead can be masked by precipitation as sulphate, and aluminium and thorium can be masked with potassium fluoride. Copper(II) is masked by adding ascorbic acid and potassium cyanide solution, and the interference due to nickel is dealt with by adding potassium cyanide solution (but the end-point is not clear if Alizarin Red S is used as the indicator).

Attempts to mask cobalt, manganese(II), zinc and cadmium with common masking agents have not been successful. The application of the titration is therefore rather restricted.

THE POLISHED PRECIPITATE ELECTRODE: A NEW VOLTAMMETRIC METHOD WITH THE SOLID ELECTRODE

Taitiro Fujinaga

Nara University of Education, Takabatake, Nara 630, Japan

Takashi Kimoto*

Kimoto Electric Co., Ltd., 3-1, Funahashi-Cho, Tennoji-Ku, Osaka 543 Japan

Summary—A new surface-renewal technique at the solid electrode has been developed, based on continuous polishing. Well-defined and reproducible current–voltage curves similar to those obtained in polarography are given by the "polished precipitate electrode" (PPE). The method can be used for the continuous determination of electroactive substances and for the study of electrode reaction mechanisms at the solid–liquid interface.

Voltammetry with solid electrodes should give information about charge-transfer across solid–liquid interfaces, but most conventional solid electrodes are not satisfactory because of surface contamination.

Polarography has no such contamination problems because the electrode surface is continuously renewed. Recently, for the investigation of charge-transfer between two immiscible electrolyte solutions, the electrolyte dropping electrode (EDE), similar to the dropping mercury electrode (DME) in polarography, has been developed.[1-5]

In this paper we describe a new "polished precipitate electrode" (PPE), the surface of which is continuously renewed by polishing with a magnetic stirrer bar coated with silicon carbide. This idea was first used by Hirata *et al.*[6] in application of a ceramic-type ion-selective electrode for a process-monitoring detector system.

EXPERIMENTAL

Apparatus

Polished precipitate electrode. The assembly of this electrode is shown in Fig. 1 and a more detailed diagram is given in Fig. 2. The polished precipitate electrode is in a flow-cell, the sample flowing in at the base and out from the upper part, at approximately 1 ml/min. The working electrode (silver–silver halide) is at the centre of the electrode body and is 3 mm in diameter and 10 mm long. It is lowered into the ring-type counter-electrode (4 mm inner diameter and 6 mm outer diameter), the gap between the working electrode and counter-electrode being filled with epoxy resin to provide electrical insulation. The outside of the counter-electrode is also coated with epoxy resin. A cylindrical polishing magnetic stirrer bar (6 mm in diameter, 7 mm long) is mounted on top of the combined working and counter-electrode. The surface of the bar is coated with a paste consisting of a 7:3 w/w mixture of 600-mesh silicon carbide powder and epoxy resin. The bar is rotated at 600

rpm by the motor-driven magnet under the electrode, thus continuously polishing the electrode surface.

The sample flows from the working electrode to the counter-electrode because of the action of the stirrer. The electrode surface is thus kept clean and free from any contamination. An Ag/AgCl electrode in $1M$ potassium chloride solution is used as reference electrode (normal silver electrode: NSE) installed above the stirrer bar.

Preparation of working electrode. Silver sulphide–silver iodide powder (Ag_3SI) was precipitated from solution at room temperature, and used after drying at 60° for several hr: 130 mg of this powder were mixed thoroughly with 50 mg of silver bromide powder and pressed into a cylindrical

Fig. 2. Detailed diagram of working electrode and counter-electrode.

Fig. 3. Current–voltage curves obtained with the polished silver electrode at a scan-rate of 1 mV/sec. Curve 1, polished, base electrolyte $0.1M$ KNO_3. Curve 2, unpolished, $2 \times 10^{-4}M$ Cl^-, $2 \times 10^{-4}M$ Br^- and $2 \times 10^{-4}M$ I^- in $0.1M$ KNO_3. Curve 3, polished, test solution as for curve 2.

pellet (3 mm in diameter and 5 mm long). Once the pellet had been formed, 100 mg of silver metal and 100 mg of the Ag_3SI powder (Ag/Ag_3SI) were added and the whole compressed again to make a single pellet 3 mm in diameter and 10 mm long. A wire was attached to the surface of the Ag/Ag_3SI pellet with silver paint. When silver metal was used as the working electrode, a silver cylinder 3 mm in diameter and 10 mm long was used instead of the silver halide precipitate pellet.

RESULTS AND DISCUSSION

The result of experiments on continuous renewal of the solid electrode is shown in Fig. 3, the current–voltage curves at room temperature being recorded at a rate of 1 mV/sec.

The curves were obtained with the polished silver-metal electrode (PSE) in the base electrolyte ($0.1M$ potassium nitrate) in the absence (curve 1) and presence (curve 3) of a mixture of chloride, bromide and iodide, each $2 \times 10^{-4}M$. The polished electrode gives well-defined current–voltage curves similar to those obtained in polarography.

Curve 2 was obtained with the unpolished electrode, the surface being engraved in order to prevent polishing by the stirrer. The solution used for curve

2 was the same as that for curve 3. Comparison of the curves shows that the polished electrode can overcome the contamination problems associated with solid electrodes, making possible quantitative analysis by voltammetry with such electrodes.

At the surface of the polished silver-metal electrode, ionization of the metallic silver and formation of the silver halide take place at the same solid–liquid interface. Therefore, the half-wave potential of each halide ion is shifted to more negative values according to the solubility product of its silver salt.

Figure 4 shows the reproducibility of the diffusion current for various concentrations of iodide in $0.1M$ potassium nitrate. The potential during this measurement was set at 0.05 V vs. NSE. As the figure shows, the diffusion current is proportional to the concentration of iodide ion. The gradual increases and decreases in diffusion current on changing the test solution are not due to slow response of the electrode but to delay in mixing.

As the recorder was undamped during this measurement, current oscillations due to stirring can be seen. When the stirrer was turned off, the diffusion current fell almost to zero (a in Fig. 4). When stirring was restarted, the current returned immediately to the original level. As can be seen from Fig. 4, the diffusion current is proportional to the concentration of halide in the test solution.
Fig. 4. Reproducibility of the diffusion current measured by the polished silver electrode. Sample flow-rate 1 ml/min; setting potential 0.05 V vs. NSE; test solution $5 \times 10^{-5}M$, $10^{-4}M$ and $2 \times 10^{-4}M$ I^- in $0.1M$ KNO_3. (a) indicates the period during which the polishing stirrer is switched off.
Fig. 5. Current–voltage curves obtained with the silver halide precipitate polished electrode (AgBr/Ag$_3$SI, SH-PPE) at a scan-rate of 1 mV/sec, base electrolyte 0.1M KNO$_3$. [Br$^-$]: 1, nil; 2, 10^{-5}M; 3, 2.5 × 10^{-5}M; 4, 5 × 10^{-5}M; 5, 10^{-4}M.

Figure 5 shows the current–voltage curves obtained with the silver halide polished precipitate electrode (SH-PPE) having an AgBr/Ag$_3$SI pellet as the working electrode. The cell can be written as:
The curves in Fig. 5 were recorded for the base electrolyte (0.1M potassium nitrate) in the absence and presence of bromide ion.

In the curves in Fig. 3, no cathodic current is observed from +0.4 to −0.3 V vs. NSE. However, in the curves in Fig. 5, cathodic waves do appear and the zero-current potential for each wave is shifted to more negative values, according to the concentration of bromide ion in the aqueous phase.

CONCLUSION

The polished precipitate electrode has been developed in order to avoid contamination problems on solid electrode surfaces. Voltammetry with this electrode may be used for quantitative analysis and in the investigation of charge-transfer processes at the solid–liquid interface.

POLAROGRAPHIC DETERMINATION OF MALONONITRILE

D. Ph. Zollinger, M. Bos, A. M. W. van Veen-Blaauw and W. E. van der Linden
Department of Chemical Technology, Twente University of Technology, P.O. Box 217, 7500 AE
Enschede, The Netherlands

Summary—A procedure is proposed for the determination of malononitrile by differential pulse polarography in methanolic $0.1M$ tetraethylammonium iodide/$0.001M$ tetramethylammonium hydroxide as the supporting electrolyte. In this medium malononitrile is chemically converted into an electroactive species. With close control of timing of the steps in the procedure the error of the method is $\pm 1.5\%$ in the concentration range $0.0001–0.001M$. Acrylonitrile, benzonitrile and succinic acid dinitrile do not interfere.

Malononitrile is an important compound in the technical synthesis of vitamin B1, various herbicides and insecticides, and a number of dyes. The methods described for its determination include gas chromatography,[1] thin-layer chromatography,[2] titration in non-aqueous solvents[3] and a luminescence procedure.[4] Some of these methods also apply to the assay of the riot-control agent o-chlorobenzal malononitrile (CS) by hydrolysis of this compound to chlorobenzaldehyde and malononitrile.[4,5]

For CS, Tarantino[6] has described a polarographic method based on the electroreduction of the compound itself or the o-chlorobenzaldehyde formed from it by hydrolysis. The other hydrolysis product (malononitrile) was found to be electro-inactive in his study.

We have observed that malononitrile gives rise to a polarographic reduction wave in alkaline methanolic medium. This paper describes a procedure for the polarographic determination of malononitrile based on this.

EXPERIMENTAL

Reagents

Methanol (p.a.), tetraethylammonium iodide (TEAI) (für die Polarographie), tetramethylammonium hydroxide (TMAOH) ($0.1M$ in propan-2-ol/methanol), tetraethylammonium chloride (TEACl) (zur Synthese), lithium chloride (Suprapur), dimethylsulphoxide (zur Synthese) and ethanol (p.a.) were used as received from Merck. The malononitrile (Merck–Schuchardt, zur Synthese was recrystallized from ethanol until a colourless product was obtained. Succinic acid dinitrile (Fluka, puriss.) and benzonitrile (Riedel de Haen) were used as received. Acrylonitrile, malonic acid and cyanoacetic acid were from Fluka and used as received. The dimer of malononitrile, 2-amino-1,1,3-tricyanopropene, was synthesized according to the procedure given by Carboni et al.[7]

Apparatus

A Metrohm E536 polarograph was used. The polarographic cell was kept at $25 \pm 0.1°$ with a Tamson thermostat. Two mercury electrodes were used; their characteristics (open circuit in $0.1M$ TEAI/MeOH) were $m = 0.795$ mg/sec,

$t = 4.73$ sec for DME #8 and $m = 0.77$ mg/sec, $t = 4.92$ sec for DME #5 and a mercury height of 66 cm. The reference electrode was a silver/silver chloride electrode in methanol saturated with TEACl. A platinum wire was used as the auxiliary electrode.

The nitrogen used for deaeration was saturated with methanol to prevent loss of solvent from the sample during removal of dissolved oxygen.

Procedure

The polarographic measurements on calibration standards and samples of malononitrile were performed as follows. A 35-ml portion of the supporting electrolyte ($0.1M$ TEAI/$0.001M$ TMAOH in methanol) was deaerated by passage of nitrogen for 5 min. Then the malononitrile sample or standard was added and nitrogen was passed for 15 min. Then either the sampled d.c. or differential pulse polarogram was recorded over the range from -1.0 to -2.0 V applied potential vs. silver/silver chloride (in saturated TEACl/MeOH). The drop-time used was 0.4 sec. In the DPP technique a pulse amplitude of 20 mV was used.

The sampled d.c. polarograms were evaluated by the use of a three-parameter curve-fitting procedure, for the parameters limiting current, half-wave potential and slope of the log plot of current vs. potential.[8]

RESULTS AND DISCUSSION

When malononitrile is polarographed in $0.1M$ TEAI/$0.001M$ TMAOH/MeOH, a reduction wave can be observed if a polarogram is run after the usual deaeration period (see Fig. 1). Its half-wave potential lies at -1.50 V vs. silver/silver chloride (in saturated TEACl/MeOH). Drop-time variation shows that this reduction wave is diffusion-controlled (Table 1). The slopes of the log plots indicate irreversibility and most likely a one-electron transfer.

The diffusion current for this reduction decreases if the alkaline solution of the malononitrile is kept for longer than 1 hr (Table 2), presumably because of chemical conversion of the electroactive species. However, in the period 30–60 min after mixing of the malononitrile and the supporting electrolyte, the limiting current remains fairly constant.

The formation and decomposition of the electro-

Table 1. Sampled d.c. polarography of $0.00111M$ malononitrile in $0.1M$ TEAI/$0.001M$ TMAOH/MeOH (DME No. 5)

Drop-time, sec	Limiting current, i_d, μA	Half-wave potential, V	Slope of log plot, V/decade	$i_d/t^{1/6}$, $\mu A/sec^{1/6}$
0.6	1.493	−1.519	0.1035	1.63
0.8	1.627	−1.506	0.0893	1.69
1.0	1.655	−1.503	0.0888	1.66

3.0	2.098	−1.494	0.0907	1.75

active species is strongly influenced by the concentration of TMAOH in the supporting electrolyte, as can be seen from Table 3. If the polarograms are run about 15 min after mixing of the malononitrile and the supporting electrolyte, the optimum concentration of TMAOH is about $0.001M$.

Malononitrile is known to form a dimer, 2-amino-1,1,3-tricyanopropene, in alkaline solutions.[9] Polarography of this product, synthesized according to the procedure given by Carboni *et al.*[7] showed a reduction wave at −1.76 V, but not at −1.50 V, so this dimer cannot be the electroactive species.

Malononitrile itself is reported to be electroinactive in $0.1M$ lithium nitrate/MeOH.[6] In the media $0.1M$ NaOH/water, phosphate buffer (pH 7)/water, $0.1M$ LiCl/$0.001M$ TMAOH/DMSO and $0.1M$ LiCl/MeOH, malononitrile is also polarographically inactive. The reduction wave at around −1.50 V, however, is present in polarograms of malononitrile in $0.1M$ LiCl/$0.001M$ TMAOH/MeOH and with a much smaller limiting current in $0.1M$ LiCl/$0.001M$ TMAOH/EtOH.

These findings indicate that the base TMAOH and the alcoholic solvent take part in the conversion of the malononitrile into the electroactive species. This was confirmed by ultraviolet spectrometry measurements. Malononitrile shows no ultraviolet absorption in methanol. Addition of $4 \times 10^{-4}M$ TMAOH to $4.5 \times 10^{-4}M$ malononitrile produces an absorption peak with a maximum shifting from 230 nm to 250 nm, with substantial broadening over a period of 30 min. Again this behaviour is different from the behaviour of the dimer, which shows a rather stable absorption peak at 300 nm under these conditions.

Attempts to isolate and identify this electroactive species by UV, MS and NMR spectrometry were

unsuccessful, most likely because of the instability of the electroactive compound.

Nevertheless, on the basis of the findings mentioned above, it was possible to develop a procedure for the polarographic determination of malononitrile in which the parameters that influence the formation of the electroactive species are closely controlled. This was accomplished by accurate temperature control of the polarographic cell, standardization of the concentration of TMAOH in the supporting electrolyte, and a strict time schedule in the procedure.

The results for measurement of a number of standard and test solutions, prepared by directly weighing purified malononitrile and dissolving it in methanol, are given in Table 4. The calibration graph is not linear, but the calibration data can be fitted to a cubic spline function with 3 knots equally spaced over the concentration interval measured, and this function used to retrieve the concentration of the test sample. This approach allows automation of the system. The deviation between the amount taken and found was 1.3%, and the standard deviation for 6 replicate samples was 0.5%

The procedure was tested for interference by the compounds cyanoacetic acid, malonic acid, acrylonitrile, benzonitrile and succinic acid dinitrile. These compounds did not change the reduction wave of the malononitrile at -1.50 V when present at concentrations not exceeding that of the malononitrile.

ANALYTICAL DATA

THE STABILITY OF METAL COMPLEXES WITH 8-MERCAPTOQUINOLINE AND ALKYL-SUBSTITUTED 8-MERCAPTOQUINOLINES IN DIMETHYLFORMAMIDE

N. A. Ulakhovich, H. C. Budnikov, T. S. Gorbunova and A. P. Sturis
Faculty of Chemistry, V.I. Ul'yanov-Lenin State University, Lenina 18, Kazan, 420008, USSR

Summary—The stoichiometry and stability constants of 8-mercaptoquinoline and alkyl-8-mercaptoquinoline complexes of Zn(II), Cd(II), Pb(II), Ni(II), Bi(III) and Ag(I) were determined potentiometrically in dimethylformamide. The stability of the 8-mercaptoquinolinates decreases in the order Ag(I) > Bi(III) > Ni(II) > Pb(II) > Cd(II) > Zn(II). Metal 7-methyl-8-mercaptoquinolinates are the most stable. The presence of the alkyl group in the 2-position (which has a steric effect) lowers the strength of metal–ligand bonding.

8-Mercaptoquinoline and alkyl-8-mercaptoquinolines are well known as complexing reagents for heavy metals.[1] These reagents are especially promising when used for combining concentration and separation with a sensitive method of determination. Hence the stability constants of these complexes in non-aqueous solutions should prove of interest. As a rule the extracted species is a non-electrolyte. Therefore, in order to study the stability of the 8-mercaptoquinolinates by potentiometry it is necessary to add some polar solvent to the extract or to use only a polar solution.

This article deals with measurement of the redox potentials of systems containing the ligand (8-mercaptoquinolinate anion), an oxidized form of the ligand (the disulphide of 8-mercaptoquinoline), and metal ion, at a constant concentration of the disulphide.[2,3] The conditions for application of the method are that the electrode process is reversible and the metal complexes only with the reduced form of the ligand.

The stability constants of Zn(II), Cd(II), Pb(II), Ni(II), Bi(III) and Ag(I) alkyl-8-mercaptoquinolinates in dimethylformamide have been determined, the alkyl positions in the ligand being 2,4, 6,7 and 2,7.

EXPERIMENTAL

Reagents

The sodium salts of the alkyl-8-mercaptoquinolines and corresponding disulphides were prepared as described in the literature.[4] The analytical (total) concentrations of the ligand and disulphide were constant in all experiments, and $5 \times 10^{-4} M$ and $2.5 \times 10^{-4} M$ respectively. The metal ion concentrations were varied in the range 1×10^{-4}– $1 \times 10^{-3} M$. Stock solutions of the anhydrous metal perchlorates (twice recrystallized) were prepared from the solids and standardized by EDTA titration.[5] Lithium perchlorate solution ($0.1 M$) was used as the background

electrolyte. Dimethylformamide (DMF) was used as solvent. The purity of the electrolyte was checked by recording polarograms with a platinum electrode. The base-line for DMF was run as a check on electrochemical purity.

Apparatus and potentiometric measurements

Potentiometric measurements were made with an R363 potentiometer (USSR) at $25 \pm 0.2°$. The indicator electrode was a platinum plate, the reference electrode a saturated calomel electrode. The solutions were deoxygenated, and a slow stream of argon was passed over the solution throughout the experiment. The logarithmic values obtained from a series of measurements differed by not more than ± 0.1, even in the most unfavourable conditions.

The stability constants were obtained from the experimental data by the method of Schulman *et al.*[3] with some slight alterations. Instead of the simultaneous titration of a ligand with a metal and a background electrolyte, the redox electrode potentials in the presence and absence of metal ions were measured to save time. The values of the stability constants were calculated according to Bjerrum, with the formulae

$$-\log[L] = \frac{\Delta E}{0.059} - \log C_L$$

$$\bar{n} = \frac{C_L(1 - 10^{-\Delta E/0.059})}{C_M},$$

where C_L and C_M are the total concentrations of the ligand and metal respectively, ΔE is the difference in the equilibrium potential of the ligand redox-system in the presence and absence of metal ions. In a number of cases, where the values of the stepwise stability constants were rather close, another method of calculating was used to correct the data.[6]

RESULTS AND DISCUSSION

The relations between the average ligand number, $\bar{n}$, and the corresponding concentration of the free, uncomplexed, ligand are shown in Fig. 1 for some metal–ligand systems. Logarithmic values of the stability constants are given in Table 1, and show that the metal alkylmercaptoquinolinates have high

stability. The chelating power of an alkyl-mercaptoquinoline is accounted for by the donor heterocyclic nitrogen atom, the sulphur atom conjugated with the quinoline ring, the dative π-bonding of the central atom and finally by the formation of five-membered rings. In the case of Ag(I), Zn(II), Cd(II), Pb(II) and Bi(III) stepwise complex formation takes place. Simultaneous addition of two molecules of the ligand to nickel occurs in accordance with the values of the stepwise constants. When a metal with occupied d-orbitals forms a cationic complex with an alkylmercaptoquinoline, bonding characteristics do not vary apart from a slight decrease in the conjugation of the chelating ring, which makes the metal–sulphur bonding more ionic.

The situation is more complicated for the complexes formed by a metal with empty d-orbitals. It is well known that the stability of complexes depends on the possibility for charge levelling by σ-bonding and π-back-bonding. Like many polyatomic ligands the alkylquinolinate ligands can have the special features of σ-donation and π-back-donation, the canonical structures b, c, d providing the greatest contribution (Scheme 1).[1]

The donor–acceptor interaction M←S which more or less increases the stability of the dative M→S π-bonding, and the existence of the dative π-bonding formed by the d-electrons of the central atom and the delocalized p-orbitals of the quinoline nucleus, are a characteristic feature of the meso-ionic structures of the complexes. This strengthening of bonding leads to greater stability of the transition metal chelates, e.g., in the case of nickel.

The introduction of an alkyl group into the
Scheme 1.

8-mercaptoquinoline molecule generally increases the complex stability (Table 1). This is connected with strengthening of the basic properties of the donor nitrogen atom and weakening of the acid properties of the mercapto group. An alkyl group in the 7-position causes further weakening of the acidity of the mercapto group. The reduced acidity strengthens the covalent bonding $M \rightarrow S$, distorts the π-d-conjugation of the sulphur atom with the quinoline ring and finally increases the basicity of the nitrogen atom. The possibility of coplanarity being destroyed in the case of the 7-alkyl ligand, together with the factors mentioned above, brings about the greater stability of the metal 7-alkyl-8-mercaptoquinolinates. A greater influence of the 7-alkyl group appears for the nickel chelates. The increase in basicity of the nitrogen atom results in a greater stabilization of the meso-ionic structure. The greatest stability of the meso-ionic structure and a thus higher stability constant is characteristic of the nickel 4-methyl-8-mercaptoquinolinate complex. This is likely to be a result of the hyperconjugation of the methyl group with the quinoline ring and increase in the basicity of the nitrogen atom.

The lower stability of the nickel complex with the 2-alkylmercaptoquinolines is notable in the range of metal complexes studied. This is likely to be a result of the steric effects of an alkyl group in the 2-position, which cause the nickel complex to take the configuration of a distorted tetrahedron, whereas all the other nickel complexes have a square-planar configuration.[7] The deviation from the square-planar configuration is assumed to decrease the strength of the dative d_π-p_π bonding formed by the d-electrons of the central atom and the delocalized p-orbitals of the quinoline nucleus. The alkyl group in the 2-position influences the stability of other metal 8-mercaptoquinolinates in a similar manner, although to a lesser extent (because these metal 8-mercaptoquinolinates do not have a square-planar configuration). Therefore the chelates with 2,7-dimethyl-8-mercaptoquinoline are the most stable. In spite of the steric hindrance the methyl group in the 2-position strengthens the basicity of the nitrogen atom. Furthermore the methyl group in the 7-position helps to strengthen the metal–ligand bonding. Attention should be drawn to the determination of the stability constants of silver alkyl-8-mercaptoquinolinates in DMF containing 2.5% water. The character of the relation between the stability constant and the water content has been clarified for the silver 6-methyl-8-mercaptoquinolinate complex. The stability of this complex was found to increase with increase in the DMF content. A plot of log k vs. the reciprocal of the dielectric constant of the medium is linear (Fig. 2) and extrapolation to 100% DMF (points A_1 and A_2 in Fig. 2) makes it possible to compare the stability constant for the silver complex with those for other
Fig. 2. The relation between stepwise stability constants of silver 6-methyl-8-mercaptoquinolinates and the composition of the medium.

8-mercaptoquinolinates. The values obtained are log $k_1 = 15.4$; log $k_2 = 5.7$. To extrapolate the values for the other silver complexes is difficult, because of the low solubilities in DMF. The complexes are also adsorbed on the platinum electrode when there are traces of water in the DMF, and this causes unsatisfactory results.

According to the data obtained, the number of ligands in the complex is usually the same as the oxidation state of the central atom, over a large range of concentrations. The reason for this is considered to be the large size of the 8-mercaptoquinoline molecule and the ease of polarization of sulphur, which transfers charge to the central atom and therefore prevents the appearance of a high co-ordination number. However, in silver 8-mercaptoquinolinate two ligands are bonded to the metal, forming the species $[AgL_2]^-$. The possibility of existence of analogous complexes has been reported by Suprunovich and Shevchenko.[8] The central atom is likely to use the electron-acceptor $5s$-, $5p$- and $5d$-orbitals for bonding the second molecule of 8-mercaptoquinoline. The stability of the complexes decreases in general in the order $Bi(III) > Ag(I) > Ni(II) > Pb(II) \sim Cd(II) \sim Zn(II)$.

DETERMINATION OF THERMODYNAMIC IONIZATION CONSTANTS FOR EIGHT MEDICINAL BENZYLIMIDAZOLINES

J. E. KOUNTOURELLIS*, N. PAPADOPOULOS and A. RAPTOULI

School of Pharmacy, Aristotelian University of Thessaloniki, Greece

Summary—The thermodynamic dissociation constants at 25° for eight medicinal benzylimidazolines have been determined by potentiometric titration.

The common feature of the compounds investigated is that they include in their molecular structure the 2-imidazoline ring. Apart from this, they possess different pharmacological actions:[1,2] tolazoline and phentolamine are alpha-adrenergic blocking agents. Naphazoline, xylomethazoline, oxymetazoline, cirazoline and tymazoline have marked alpha-adrenergic activity, and antazoline is an antihistamine.

The compounds are the active ingredients of many liquid pharmaceutical preparations such as decongestants, injectable solutions and ointments. Because they undergo rapid base-catalysed hydrolysis[3] in aqueous solutions, the development of a stability-indicating assay was initiated.

High-pressure liquid chromatography (HPLC) has been studied as a means of identification and determination of 2-imidazolines and their degradation products.[4] The proposed method employs a cation- or anion-exchange resin, and a mobile phase buffered at about pH 12. Since the chromatographic conditions have to be varied from compound to compound, we have determined pK_b for the compounds because we believe that accurate values will help in the development of better chromatographic systems.

EXPERIMENTAL

Reagents

The samples supplied by the manufacturers included phentolamine mesylate and the hydrochlorides of tolazoline, naphazoline, xylometazoline, oxymetazoline, cirazoline, tymazoline, and antazoline. The melting points of the compounds agreed with those quoted in the literature. The PMR and ^{13}CMR spectra were in agreement with the molecular structures. Water was purified with a Millipore ion-exchange apparatus.

Apparatus

A Radiometer PHM 63 digital pH-meter and a Radiometer GK 2401 B combined glass electrode were used. The electrode was calibrated with a series of buffer solutions.[5]

Determination

In each case, a sample of the salt of the base was dissolved in 50 g of freshly demineralized water to give a solution with a concentration of about $1 \times 10^{-3}M$. The titrations were done under a nitrogen atmosphere in a water-jacketed vessel kept at $25 \pm 0.1°$. The amounts of sodium hydroxide added were determined by weighing. The thermodynamic dis-

Table 1. The pK_b values for the eight 2-imidazolines

Compound	pK_b	Compound	pK_b
Xylometazoline	3.15 ± 0.04	Antazoline	3.77 ± 0.03
Tolazoline	3.41 ± 0.01	Tymazoline	4.42 ± 0.02
Oxymetazoline	3.46 ± 0.02	Cirazoline	4.44 ± 0.02
Naphazoline	3.52 ± 0.02	Phentolamine	4.71 ± 0.01

sociation constants pK_b were calculated from the equations:[6,7]

$$pK_b = -\log[OH^-] + \log\frac{[BOH]}{[B^+]} - 2\log\gamma_\pm$$

$$pK_w = 14.00$$

$$[B^+] = C_{tot} + [OH^-] - [Na^+]$$

$$[BOH] = C_{tot} - [B^+]$$

$$-\log\gamma_\pm = 0.512\sqrt{I}/(1 + 1.6\sqrt{I}).$$

The symbols have their usual meanings.

RESULTS AND DISCUSSION

Table 1 shows the data obtained for the eight benzylimidazolines. The decrease in basicity from xylometazoline to phentolamine follows the increase of electron-withdrawing ability of the aromatic substituent in the 2-position of the imidazoline (heterocyclic) ring. Different substituents in the aromatic ring do not cause great differences in the pK_b values, since the aromatic and the heterocyclic moieties of the molecule are separated by a bridging methylene group. The basicity of the compounds decreases when a heteroatom is attached to the linking methylene group.

HYDROXIDE COMPLEXES OF LANTHANIDES—VII*
NEODYMIUM(III) IN PERCHLORATE MEDIUM

J. KRAGTEN and L. G. DECNOP-WEEVER

Laboratorium voor Analytische Chemie der Universiteit van Amsterdam, Nieuwe Achtergracht 166,
1018 WV, Amsterdam, The Netherlands

Summary—From the precipitation borderline in the pNd'–pC_H diagram the stability constants for the mononuclear and polynuclear species of neodymium hydroxide have been established. The values found were $\log^*\beta_1 = -8.1$, $\log^*\beta_2 = -16.2$, $\log^*\beta_3 = -24.3$, $\log^*\beta_{2,2} = -11.6$ and $\log^*K_{s0} = 19.4$. The data refer to precipitates prepared under CO_2-free conditions at room temperature ($21.5 \pm 0.5°$) in sodium perchlorate medium with an ionic strength of 1.

The hydrolysis constants of neodymium(III) reported in the literature[1-5] (Table 1), like those of the other rare earths studied before, show a fair diversity. Moreover the set of constants is not completely known, hence description of the hydrolytic behaviour at pH > 7 is impossible. The diversity can be attributed mainly to the fact that most investigations were done with concentrated solutions over small pH ranges, usually 4.5–7. Under these conditions the average hydroxide co-ordination number remains below 0.01, so determination of all the constants is impossible. Moreover, the affinity of Nd^{3+} ions for carbonate ions has been neglected in all cases.

Burkov *et al.*[6] postulated the presence of $Nd_2(OH)_2^{4+}$ and $Nd(OH)^{2+}$ from the concentration dependence of the hydrolysis curves. If their results, $\log^*\beta_{2,2} = -13.93$ and $\log^*\beta_1 = -9.4$ (perchlorate medium, $I = 3$, $25°$), are corrected for the presence of soluble carbonate–neodymium complexes and a lower ionic strength ($I = 1$), $\log^*\beta_{2,2} = -12$ and $\log^*\beta_1 = -8$ can be estimated, but these data are too unreliable to be of any practical value.

Azhipa *et al.*[5] determined $\log^*K_{s0} = 20.4$ from the precipitation line, but obviously also did not consider the interference of insoluble carbonate. However, the

conclusion that the region of polycomplexation is rather small, with its 1% borderline intersecting the pH-axis near pH = 5, does seem reliable.

Our experiments were designed to cover a wide range of concentration and pH (Fig. 1) and were done in sodium perchlorate medium ($I = 1.0$ at $21.5 \pm 0.5°$) in a nitrogen atmosphere in a glove-box. All manipulations were standardized for reasons discussed before.[8-11] The precipitate was formed by a procedure similar to that for ytterbium.[11] At $pC_H < 12$ the pC_H value was determined with a pH-meter calibrated in pC_H units;[10] for $pC_H > 12$ the pC_H value was established by potentiometric titrations.[11,12]

RESULTS AND CONCLUSIONS

The borderline of the precipitation region for Nd (Fig. 1) consists of two straight lines connected by a curve from pC_H 8 to pC_H 9. From regression analysis a slope of 3.5 ± 0.3 can be deduced for the steep part up to $pNd' = 4.5$. This suggests that a polynuclear hydroxide complex with charge 4+ is present in solution. Of the series of possible species $Nd_2(OH)_2^{4+}$, $Nd_3(OH)_5^{4+}$, *etc.*, only the first is likely.[13]

Fig. 1. The solid curve [the borderline of precipitation of $Nd(OH)_3$] was constructed with the values given in Table 3. The dashed line is the borderline for 1% polycomplexation. The numbers 0, 1, 2, 3 and 4 near the straight lines correspond to the slopes of the straight-line segments [equations (1a)–(1e)] approximating the exact envelope curve. The circles denote the experimental results.

According to the theory[8-10] in which straight-line segments determine the borderline of precipitation, we can assign equation (1a) (see Table 2) to the steep part, giving as the best fit

$$pNd' = 4pC_H - (27.4 \pm 0.05) \qquad (2)$$

Hence

$$2 \log^* K_{s0} + \log^* \beta_{2,2} = (27.1 \pm 0.05) \qquad (3)$$

Equation (1e) can be assigned to the horizontal part of the borderline. The best fit corresponds to

$$pNd' = 4.93 \pm 0.03 \qquad (4)$$

from which follows, with equation (1e)

$$\log^* K_{s0} + \log^* \beta_3 = -4.93 \pm 0.03 \qquad (5)$$

Because it is found that with the equation

$$[Nd']_{max} = 10^{-(4pC_H - 27.4)} + 10^{-4.93} \qquad (6)$$

a good fit is obtained for the rather sharp bend connecting the straight-line parts, it can be concluded that the major species in equilibrium with the precipitate are $Nd_2(OH)_2^{4+}$ and $Nd(OH)_3$. If one of the ions Nd^{3+}, $Nd(OH)^{2+}$ or $Nd(OH)_2^+$ were present, the corresponding equation from the set (1b)–(1d) would contribute to the shape of the envelope curve. The

Table 3.

$\log^* \beta_1 = -8.1$	$\log^* \beta_{2,2} = -11.6$
$\log^* \beta_2 = -16.2$	
$\log^* \beta_3 = -24.3$	$\log^* K_{s0} = 19.4$

alteration in the shape would involve first the bend in the curve, as can be seen by moving the corresponding lines (in Fig. 1) from left to right. It follows that there must be limiting positions for the straight-line segments. As a consequence, $p^* K_i$ ($= \log^* \beta_i - \log^* \beta_{i-1}$) cannot exceed certain values (the line segments intersect at $pC_H = p^* K_i$).

A series of plots was made with $p^* K_i$ values approaching 8.1, the value that corresponds to the pC_H value of the intersection point of the line-segments corresponding to equations (2) and (4). It was found that $\log^* K_1 = \log^* K_2 = \log^* K_3 = -8.1$ are upper limits and hence $p^* \beta_1 = 8.1$, $p^* \beta_2 = 16.2$ and $p^* \beta_3 = 24.3$. If we combine these values with equations (5) and (3) we can deduce $\log^* K_{s0} = 19.4$ and $\log^* \beta_{2,2} = -11.6$.

Substitution in equation (1f), which represents the 1%-borderline of the polycomplex region, gives

$$pNd'_{1\%} = 2pC_H - 9.3 \qquad (7)$$

On this borderline, by definition, 1% of the total Nd is present as polycomplex [here $Nd_2(OH)_2$], which corresponds in this case to an average hydroxide co-ordination number of 0.01. Lower $p^* K_i$ values cause a shift of this line to lower pC_H. Thus, equation (7) represents the 1%-borderline that is furthest to the right.

In earlier work with other rare earths, an additional criterion has been adopted, namely that the region of polycomplexation should be as small as possible. In some cases, we could find support for this assumption from investigations of others. In the case of neodymium we again have support for this assumption from the experimental results of Burkov et al.[6] These authors found 1% co-ordination in a region just inside our polycomplex region, but the experiments were done at higher ionic strength ($I = 3$). Thus, we may conclude that the set of hydrolysis constants reported in Table 3 can be regarded as useful for analytical practice. Neodymium shows no amphoteric character at high pC_H values.

It is difficult to discuss the accuracy of the individual constants. If the envelope curve is constructed,

Table 2.

Equation	p	q	Slope $(np - q)$	Equation for the borderline segment
1a	2	2	4	$pNd' = 4pC_H - (2 \log^* K_{s0} + \log^* \beta_{2,2} + 0.3)$
1b	1	0	3	$pNd' = 3pC_H - \log^* K_{s0}$
1c	1	1	2	$pNd' = 2pC_H - \log^* K_{s0} + \log^* \beta_1)$
1d	1	2	1	$pNd' = pC_H - (\log^* K_{s0} + \log^* \beta_2)$
1e	1	3	0	$pNd' = -(\log^* K_{s0} + \log^* \beta_3)$
1f				$pNd'_{1\%} = 2pC_H + \log^* \beta_{2,2} + 2.3$

$$^* \beta_{q,p} = \frac{[Nd_p(OH)_q][H^+]^q}{[Nd^{3+}]^p} \quad \text{and} \quad ^* \beta_{q,1} = ^* \beta_q$$

the position of the actual Nd'_{max} value is uncertain within 0.1 log units, and this offers an estimate for the spread around the line. It holds for both the steep part and the horizontal part, assuming a "fresh precipitate" and CO_2-free conditions.

DISSOCIATION CONSTANTS OF SOME ORGANIC ACIDS

Zs. Wittman

Hungarian Oil and Gas Research Institute, Veszprém

Summary—Dissociation constants of di(nonylphenyl)dithiophosphoric acid, di(nonylphenyl)phosphoric acid and 9-phenyltetracosansulphuric acid, determined by two methods, are reported.

There are two methods for determination of dissociation constants of organic acids that are poorly soluble or insoluble in water: potentiometric titration in 40 or 50% w/w ethanol in water,[1,2] and distribution between two phases.[3–5] The constants for some organic phosphoric acids are listed in Table 1.

Higher members of homologous acid series, and alkylphenyldithiophosphoric acids, are insoluble in water, and benzenesulphuric acid derivatives with long alkyl chains only poorly soluble. In this paper, the determination of the dissociation constants of two organic phosphoric acids and a sulphuric acid are described. These acids were synthesized and examined as part of a systematic investigation of industrial acids of this kind.

EXPERIMENTAL

Samples

Di(nonylphenyl)dithiophosphoric acid; found: acid number 1.87 mmole/g, P = 5.8%, S = 12.0%: theory requires P = 5.80%, S = 11.98%. Di(nonylphenyl)phosphoric acid; found: acid number = 1.99 mmole/g, P = 6.2%; theory requires 6.18%. 9-Phenyltetracosansulphuric acid; found: acid number = 2.02 mmole/g, S = 6.5%; theory requires S = 6.47%. All the reagents used were of analytical grade.

Apparatus

The pH measurements were made with a Radelkis pH-meter type OP-204/1, glass electrode OP-07181 and calomel electrode OP-08301.

Procedure

The method was adopted from Handley *et al.*[3] The dissociation constants of di(nonylphenyldithiophosphoric acid and di(nonylphenyl)phosphoric acid (Table 2) were

Table 2. Dissociation constants (± standard deviations) for di(nonylphenyl)dithiophosphoric acid (A) and di(nonylphenyl)phosphoric acid (B) (ionic strength = 1.0M at 25.0°)

Acid	Solvent system	pK
A	CCl_4–water	5.40 ± 0.05
	n-hexane–water	5.38 ± 0.05
B	CCl_4–water	6.30 ± 0.06
	n-hexane–water	6.26 ± 0.06

calculated from data obtained from distribution between aqueous sodium chloride solution and carbon tetrachloride or n-hexane.

No evidence was found for the dimerization of the acids in the organic phase, since log c_{org} *vs* log $[H^+][R^-]$ was a straight line with slope equal to one.

The dissociation constant of 9-phenyltetracosansulphuric acid was determined by the method of White.[2] This potentiometric titration was done in 50% w/w ethanol in water at 25.0° by using the non-thermodynamic cell and buffer solution proposed by White.[2] A value was calculated for the constant in water, pK = 3.31 − 1.66 = 1.65, by applying a correction of Δ pK = 5.87 − 4.21 = 1.66 by analogy with the pK values for benzoic acid measured in water and in 50% w/w ethanol in water. The standard deviation was 0.02.

POTENTIOMETRIC INVESTIGATION OF THE STABILITY OF SILVER(I) COMPLEXES OF SOME *N*-METHYL SUBSTITUTED 4-H-DIETHYLENETRIAMINES IN AQUEOUS SOLUTION

J. Yperman, J. Mullens, J.-P. François and L. C. Van Poucke

Limburgs Universitair Centrum, Departement SBM, Universitaire Campus, B-3610 Diepenbeek, Belgium

Summary—By means of potentiometric pH and pAg measurements, the stability constants and the stoichiometric composition of the silver(I) complexes of some *N*-methyl-substituted 4-H-diethylenetriamines, in aqueous medium of ionic strength 1.3 and at a temperature of 25.00°, have been determined. In addition to mononuclear and polynuclear complexes, together with their protonated forms, some hydroxo complexes are formed. The values of the stability constants are discussed in terms of possible structures.

The formation of complexes between silver(I) and some *N*-methyl-substituted 4-methyldiethylene-triamines has already been studied.[1] This paper describes the investigations of the *N*-methyl-substituted 4-H-diethylenetriamines, namely, diethyl-enetriamine (PSP); 1-methyldiethylenetriamine (SSP); 1,1-dimethyldiethylenetriamine (TSP) and 1,1,7,7-tetramethyldiethylenetriamine (TST):
where R stands for CH$_3$ or H. The shorthand notation given in parentheses indicates whether the amino groups, in the sequence end, central, end, are primary (P), secondary (S) or tertiary (T). Complex formation between PSP and silver(I) has been investigated by various workers;[2-5] the species reported include AgL,[2,4,5] AgLH,[2,4] Ag$_2$L,[2,4] and AgLH$_2$,[4] where L is PSP and charges are omitted for simplicity. For imino-bis(methylene-2-pyridine) and silver(I), Rometsch *et al.*[6] found only the mononuclear species corresponding to AgL and AgL$_2$.

In contrast to these results, for the analogous ligands, the 4-methyl derivatives,[1] in addition to these complexes, we have found dinuclear and trinuclear complexes, together with protonated and hydroxo complexes. Diethylenetriamine is of analytical interest; for example it has been shown to be the most satisfactory of a number of aliphatic amines for impregnating the silica gel layer in TLC separation of metal ions.[7]

EXPERIMENTAL

Apparatus and reagents

The pH values were obtained by means of a calibration procedure using Gran plots.[8] The Ag$_2$S-electrode used gave Nernstian response. More details are given in previous papers.[1,9]

Measurements

Because a great diversity of complexes is expected, a large concentration range is needed. On the other hand it is desirable that the concentration of free ligand should be calculable without any assumptions about the stoichiometric composition of the complexes formed, *i.e.*, by using the Österberg method[10] (method 1) or the dilution method (method 2).[11]

Titration curves for PSP and Ag$^+$ were measured and treated by using the Österberg method.[10] It was found that a very small change in the pK_A-values causes a very great change in the calculated free ligand concentration. On the other hand, the so-called "dilution method", which was described[11] and applied[1] earlier, gives very good results in the calculation of free ligand concentrations, and the experimental data can be treated without any transformation. As the experimental data were finally to be handled by the computer program Miniquad,[12] and knowledge of the free ligand concentration was therefore not needed, a third set of data was added, in which C_L/C_{Ag} and C_{Ag} were changed for each titration curve (method 3).

For the so-called "dilution method", titration curves were recorded for $C_L/C_{Ag} = 3$, by the procedure used earlier.[1] In the third set of experimental data, the C_L/C_{Ag} ratios studied were 10, 5, 2, 1, 0.5 and 0.25. More details were given earlier.[1,9]

RESULTS AND DISCUSSION

The general formation reaction of the complex Ag$_p$L$_q$H$_r$ is given by equation (1):

$$qL + pAg^+ + rH^+ \rightleftharpoons Ag_pL_qH_r^{(p+r)+} \tag{1}$$
The overall concentration stability constant is given by:

$$\beta_{pqr} = \frac{(Ag_pL_qH_r^{(p+r)+})}{(Ag^+)^p(L)^q(H^+)^r} \tag{2}$$

Negative values for *r* imply formation of hydroxo complexes.

From the titration curves, obtained by method 2,
Fig. 1. $\bar{p}$, $\bar{q}$ and $\bar{r}$ for TST $vs.$ the pH for three different but constant C_L and C_{Ag} values. The "dilution method" is used. C_L, $10^{-3}M$: ● 17.1; × 8.52; ■ 4.26. C_{Ag}, $10^{-3}M$: ● 5.71; × 2.86; ■ 1.43.
Fig. 2. $\bar{p}$, $\bar{q}$ and $\bar{r}$ for PSP $vs.$ the pH for two different but constant C_L and C_{Ag} values. The "dilution method" is used. × C_L 0.0120M; C_{Ag} 0.00400M; ● C_L 0.00460M; C_{Ag} 0.00154M.

it is found that there is some weak complex formation before the first equivalence point. In calculating the free ligand concentration, as a first approximation we neglected this complex formation and later found that corrections for it, calculated from the stability constants obtained, were insignificant.

The results obtained by means of this method for TST are shown in Fig. 1, where $\bar{p}$, $\bar{q}$ and $\bar{r}$ are the mean values found for p, q and r. This figure shows

that mononuclear species are dominant. Because $\bar{p}$ is slightly greater than 1, the polynuclear TST complexes are not negligible. By comparison, the results for PSP (Fig. 2) indicate that polynuclear complex formation is much more pronounced. TSP and SSP give figures similar to that for PSP. The values of $\bar{q}$ are always higher than the corresponding $\bar{p}$ values, and $\bar{r}$ varies between 1.0 and -0.1.

From these results it can be concluded that for TST
Fig. 3. pH $vs.$ amount of KOH added for PSP with and without Ag^+. Curve 1: C_L = 0.1571 mmole and C_{Ag} = 0.0 mmole. Curve 2: $C_L/C_{Ag} \approx 10/1$. Curve 3: $C_L/C_{Ag} \approx 5/1$. Curve 4: $C_L/C_{Ag} \approx 2/1$. Curve 5: $C_L/C_{Ag} \approx 1/1$. Curve 6: $C_L/C_{Ag} \approx 1/2$. Curve 7: $C_L/C_{Ag} \approx 1/4$.

the most probable species formed are AgL, AgLH, AgL$_2$ and AgL$_2$H. As there is some indication of the presence of polynuclear complexes, Ag$_2$L$_2$ must be taken into account, and hydroxo complexes are also possible.

For TSP, SSP and PSP, the most likely species are Ag$_2$L$_2$, and AgL$_2$, and their corresponding protonated species. The presence of AgL and perhaps AgLH is less probable than in the case of TST, but cannot be excluded.

For PSP even the complex Ag$_2$L$_3$ can be considered. There are also some indications of the presence of a hydroxo complex.

In Fig. 3, as an example, the experimental data obtained by method 3 for PSP, with and without Ag$^+$, are presented, $i.e.$, the measured pH $vs.$ the amount of potassium hydroxide added. From this

elimination of complexes in the minimization process are given in our previous article.[1] The final results of these calculations are summarized in Table 1.

For all four ligands the following complexes were found to be formed: AgLH$_2$, AgLH, AgL$_2$H$_2$, AgL$_2$, Ag$_2$L$_2$, Ag$_3$L$_2$ and AgL(OH). In the dilution method $\bar{p}$ never exceeds 2 but it must be remembered that C_L/C_{Ag} is fixed at 3. A number of protonated Ag$_2$L$_2$ complexes were detected for PSP, SSP and TSP, but not for TST. AgL$_2$H was not found for TSP. AgL was found only for TST. Several attempts were made to prove or disprove the existence of AgL for SSP, PSP and TSP, but no positive evidence was found. We must conclude that this species is not present for these triamines. The complex Ag$_2$L$_3$ was found only for PSP, but only in small amounts.

The further discussion requires definition of the following equilibria and their equilibrium constants.

$$AgL^+ + L \rightleftharpoons AgL_2^+$$

$$Ag^+ + LH^+ \rightleftharpoons AgLH^{2+}$$

$$AgL^+ + H^+ \rightleftharpoons AgLH^{2+}$$

$$Ag^+ + LH^+ + L \rightleftharpoons AgL_2H^{2+}$$

$$AgL_2^+ + H^+ \rightleftharpoons AgL_2H^{2+}$$

$$Ag^+ + 2LH^+ \rightleftharpoons AgL_2H_2^{3+}$$

$$AgL_2H^{2+} + H^+ \rightleftharpoons AgL_2H_2^{3+}$$

$$Ag^+ + LH_2^{2+} \rightleftharpoons AgLH_2^{3+}$$

$$AgLH^{2+} + H^+ \rightleftharpoons AgLH_2^{3+}$$

$$AgL_2^+ + Ag^+ \rightleftharpoons Ag_2L_2^{2+}$$

$$2AgL^+ \rightleftharpoons Ag_2L_2^{2+}$$

$$2Ag^+ + HL^+ + L \rightleftharpoons Ag_2L_2H^{3+}$$

$$Ag_2L_2^{2+} + H^+ \rightleftharpoons Ag_2L_2H^{3+}$$

$$2Ag^+ + 2HL^+ \rightleftharpoons Ag_2L_2H_2^{4+}$$

$$Ag_2L_2H^{3+} + H^+ \rightleftharpoons Ag_2L_2H_2^{4+}$$

$$2AgLH^{2+} \rightleftharpoons Ag_2L_2H_2^{4+}$$

$$Ag_2L_2^{2+} + Ag^+ \rightleftharpoons Ag_3L_2^{3+}$$

$$Ag^+ + L + H_2O \rightleftharpoons AgL(OH) + H^+$$

$$K_{12} = \beta_{120}/\beta_{110} \tag{3}$$

$$K_{111} = \beta_{111}/\beta_{011} \tag{4}$$

$$K'_{111} = \beta_{111}/\beta_{110} \tag{5}$$

$$K_{121} = \beta_{121}/\beta_{011} \tag{6}$$

$$K'_{121} = \beta_{121}/\beta_{120} \tag{7}$$

$$K_{122} = \beta_{122}/\beta_{011}^2 \tag{8}$$

$$K'_{122} = \beta_{122}/\beta_{121} \tag{9}$$

$$K_{112} = \beta_{112}/\beta_{012} \tag{10}$$

$$K'_{112} = \beta_{112}/\beta_{111} \tag{11}$$

$$K_{22} = \beta_{220}/\beta_{120} \tag{12}$$

$$K_d = \beta_{220}/\beta_{110}^2 \tag{13}$$

$$K_{222} = \beta_{222}/\beta_{011}^2 \tag{16}$$

$$K'_{222} = \beta_{222}/\beta_{221} \tag{17}$$

$$K'_d = \beta_{222}/\beta_{111}^2 \tag{18}$$

$$K_{32} = \beta_{320}/\beta_{220} \tag{19}$$

$$\beta_{11(-1)} \tag{20}$$

figure, it can be seen that weak complexation occurs before the first equivalence point. For TST, TSP and SSP the picture is very similar, but the less the degree of N-methyl substitution, the greater the difference in pH between the titration curves, $i.e.$, the stronger and probably the more diverse the complexation is before and after the first equivalence point.

Only the experimental data from methods 2 and 3 were treated by the computer program Miniquad, in order to handle all the triamines in the same way, and seek the best model for the stoichiometric compositions and corresponding stability constants. For each system, more than 1000 titration points over a wide concentration range were used. Criteria for

The log K and the log K' values can thus be calculated from the log β_{pqr} values in Table 1 and the values of log β_{01r}, the formation constants[9] of the three protonated forms of L. The log β_{01r} values are given in Table 2. The absence of the species AgL in the case of PSP, SSP and TSP is very striking. It was found earlier,[13] in a study of complexes of Ag$^+$ with ethylenediamine, that the complex AgL was not present at all. A possible reason for this might be the increasingly high stability of the polynuclear complexes formed, especially Ag$_2$L$_2$ and even Ag$_3$L$_2$, with decrease in the degree of N-substitution of the ligand.

In the case of PSP, SSP and TSP, equilibrium (13) is shifted strongly towards the right, because of the

Table 1. The log β_{pqr} values for the complexes formed according to reaction (1) for the four ligands; for AgL(OH), reaction (20) must be considered

Complex	β_{pqr}	PSP	SSP	TSP	TST
$AgLH_2$	β_{112}	20.32(1)	20.56(1)	19.56(1)	18.81(1)

$AgL(OH)$	$\beta_{11(-1)}$	−5.54(2)	−6.10(4)	−5.96(2)	−6.62(1)
Ag_2L_3	β_{230}	16.39(4)	—	—	—

The numbers in brackets are the standard deviations and refer to the last significant figure, i.e., (1) means 0.01.

great stability of the Ag_2L_2 complexes, their log β_{202} values being 3 units greater than log β_{202} for the TST complex (Table 1).

The great stability of the Ag_2L_2 complex can only be explained by suggesting that this species has a ring structure. It is found that the smaller the ring size for rings with more than six members, the greater the stability. Therefore a ten-membered ring is proposed for the species Ag_2L_2, besides a ring with sixteen members, especially in the case of PSP. Examination of the magnitudes of the log K_{22} values (Table 2), shows that the formation constants for the PSP, SSP and TSP complexes are twice that of the TST complex. This demonstrates again the great dependence of the stability of the Ag_2L_2 complex on the nature of the ligand.

For PSP, SSP and TSP, the magnitude of these formation constants (log K_{22}) is of the same order as the log β_{120} values. We conclude, therefore, that reaction (12) involves formation of two further Ag–N bonds: in other words, ring closure. The log K_{22} value for TST refers to the formation of only one extra

Ag–N bond. Probably a terminal tertiary N–Ag bridge is formed: because of extra charge repulsions a displacement of the central N–Ag bridge is possible.

As already mentioned, AgL but not Ag_2L_2 was previously reported in the case of PSP as ligand.[2,4,5] Prue and Schwarzenbach[2] also reported the complex Ag_2L, but Machtinger et al.[4] mentioned only the possible existence of this species. We made several attempts to demonstrate the presence of this complex, but our computer-preferred model always gave the species Ag_2L_2 and Ag_3L_2 rather than Ag_2L.

It is also striking that the complex $AgLH_2$ is found for these 4-H-derivatives but not for the 4-methyl derivatives.[1] The log K_{112} values and, to a lesser extent, the log K'_{112} values, show that this complex is not very stable. The nature of the central amino group plays an important role in the structure and possibility of existence of this complex.

The log β_{120} values indicate[1,14] that AgL_2 must have a linear structure, and the log K_{121} and log K_{122} values show that binding of another proton does not change the proposed linearity. The formation constants are of the same magnitude as the log β_{120} values, though somewhat lower because of the extra positive charge. For TST the log K_{122} value is much smaller, possibly because of competition between Ag^+ and H^+, concerning the most likely N–Ag or N–H- bond. The log K'_{122} and log K'_{121} values support this.

For PSP, SSP and TSP, the addition of one or two H^+-ions to Ag_2L_2 results in partial ring opening, as is demonstrated by the smaller log K_{221} and log K_{222} values, in comparison with the log β_{220} values.

The log $\beta_{11(-1)}$ values show a very peculiar sequence, according to the nature of the ligand. This was also found in the study of the 4-methyl derivatives.[1] An explanation for this is a change in the co-ordination number of Ag^+, as reported by Ohtaki et al.[15,16]

Table 2. The log K and log K' values for the complexes formed according to reactions (3)–(19) for the four triamines

Constant	PSP	SSP	TSP	TST	Complex
log K_{111}	3.63	3.53	3.27	3.00	AgLH (4)

ANNOTATIONS

COMMENT ON LASER-EXCITED FLUORESCENCE LINE-NARROWING: AN ANALYTICAL STUDY

J. M. HAYES and G. J. SMALL

Ames Laboratory—USDOE, Iowa State University, Ames, Iowa 50011, U.S.A.

Summary—A recent paper (D. Bolton and J. D. Winefordner, *Talanta*, 1983, **30**, 9) on the analytical utility of laser-excited fluorescence line-narrowing is critically assessed.

In a recent paper[1] Bolton and Winefordner (BW) reported on the limit of detection (LOD) for fluorescence line-narrowing spectroscopy (FLNS) of polycyclic aromatic hydrocarbons (PAHs) in a glycerol:ethanol:water glass at 4.2 K. The PAHs studied were anthracene, 2- and 9-methylanthracene, 9,10-dimethylanthracene, perylene and pyrene. The LOD values were compared with those determined for the same compounds by room-temperature fluorescence and low-temperature fluorescence spectrometry. In our opinion the BW paper presents a very misleading assessment of the analytical utility of FLNS. Because of our experience in exploring this question[2-9] we feel compelled to make the following comments.

1. The procedure and apparatus used by BW for FLNS are similar to those employed by us. The liquid-helium bath, sample preparation, sample cooldown procedures and monochromator bandpass (1 Å) are identical. Comparison of the N_2-pumped dye lasers, monochromator apertures and slit-widths utilized by BW and by us indicates there should be approximate parity in sensitivity. Nevertheless, for the compounds listed, BW report LOD values between 100 and 1000 ng/ml. For the same compounds and several others our *standard* FLN spectra were generally obtained with *very high* signal-to-noise ratio (S/N) at 200 ng/ml.[3,5] Indeed, for perylene (BW LOD = 100 ng/ml), pyrene (BW LOD = 300 ng/ml), and 1-methylpyrene we obtained a detection limit (S/N > 5) of ~0.02 ng/ml.[5] In the *direct* analysis of a solvent-refined coal II sample, 1-methylpyrene, benzo[e]pyrene, benzo[a]pyrene, anthracene, perylene and benzo[k]fluoranthene were characterized and determined at concentrations between ~2 and 30 ng/ml (in the glass).[3] Thus, the rather bleak sensitivity picture for FLNS painted by BW is hardly warranted. As discussed elsewhere,[3,5] with improvements in the FLNS apparatus used in reference 3, detection limits of 1 pg/ml are readily

achievable for strongly fluorescent PAHs in *pure* solvents.

2. The failure of BW to achieve with FLNS the respectable LOD for PAHs that is routinely obtained in our laboratory may be due, in part, to the different gated-detection electronics and data-handling procedure they utilize. They mention a problem with high background signals but are not specific about it. We have never experienced background interference except at very low concentrations ($\ll 1$ ng/ml).[5] Nor has small bubble formation from boiling He posed an insurmountable problem as it did in their work.[5] However, another problem in the BW studies appears to be their choice of excitation wavelength (λ_{ex}) and emission wavelength (λ_{em}). For example, in the case of anthracene, $\lambda_{ex} = 364.0$ nm (as used by BW) excites vibronic bands at an energy level some 1200 cm^{-1} above the S_1 origin. At this energy there is considerable overlapping of vibronic bands, so FLN is observed from several isochromats. Although a similar λ_{ex} (363.8 nm) was used in reference 2, that work was done with a non-tunable Ar$^+$ laser. A better choice of λ_{ex} is given in references 3 and 5. In that work $\lambda_{ex} = 373.8$ nm was used. This corresponds to excitation into the centre of the first vibronic band, so that only a single isochromat will fluoresce. Consider also the case of 9-methylanthracene. The $\lambda_{ex} = 382.5$ nm chosen by BW is midway between the centres of two overlapping vibronic absorption bands. Thus two bands, separated by the vibronic energy difference, will emit. This emission will be weak because the excitation is into the tail of each band. Furthermore, the most intense zero-phonon line associated with the emissions will be at ~388 nm and ~393 nm, respectively. The λ_{em} value chosen by BW, however, is 390.6 nm, in a "valley" nearly midway between the two zero-phonon lines! Finally, it has been observed in our laboratory that 2-methylanthracene is not amenable to FLN analysis in glycerol, water, ethanol glasses at concentrations greater than 100 ng/ml (BW's LOD

for this species). At these concentrations the emission is broad, owing to aggregation.[5]

3. BW assert that the loss of FLN behaviour when λ_{ex} pumps vibronic levels of the fluorescent state possessing $\geqslant 1500$ cm^{-1} excess vibrational energy is due to "rapid local site-melting". This explanation is erroneous. The correct explanation[2,3,10] has to do with the fact that at such high excess vibrational energy several isochromats belonging to different overlapping vibronic absorption bands are pumped.

In conclusion, BW report LOD values for FLNS which are *anomalously* high, do not discuss their results in the light of those from earlier work,[3,5] and ignore several other attributes of the technique. For example, FLNS possesses high selectivity,[3–9] which was initially the reason why our laboratory pursued and developed it as an analytical technique. Another example is that water-based glasses impart to it a versatility which other solid-state fluorescence methods do not possess. For example, by acidification of the glass the amino-derivatives of PAHs can be studied.[7–9] As another example we cite recent work where we have successfully applied FLNS to aromatic carcinogen–DNA adducts and shown that two adducts formed by different metabolic paths for benzo[a]pyrene can be distinguished in a mixture.[9,11]

TESTING THE ADEQUACY OF EQUILIBRIUM MODELS FOR COMPLEX FORMATION

COMPLEXATION BETWEEN MOLYBDATE AND OXALATE REVISITED

Erik Sylvest Johansen and Ole Jøns*
Royal Danish School of Pharmacy, Department of Pharmaceutical Chemistry AD, 2 Universitetsparken,
DK-2100 Copenhagen, Denmark

Summary—In potentiometric studies of metal–ligand equilibria a given model is tested by adjustment of the corresponding stability constants with the purpose of obtaining as good a fit as possible to the experimental data. When judging the goodness-of-fit it is of great importance to be in control of any possible systematic error in concentrations or electrode parameters. The molybdate–oxalate system is used to demonstrate how one crucial parameter influences the evaluations of goodness-of-fit. The system is simple, having only one complex species, MoO_3oxal^{2-}, with logarithmic stability constant 13.816 in the pH-range 4–7.

For several decades potentiometric methods have been applied to the study of complex-formation in solution. Above all, the glass electrode has proved valuable in the determination of accurate formation constants. Admittedly, experimental conditions must be carefully controlled and even then there remain uncertainties concerning the electrode parameters.

These uncertainties will be transmitted to the next phase of the study: the calculation of formation constants of the equilibrium model under trial, and the evaluation of some measure of goodness-of-fit, often the sum of the square of the differences between observed and calculated values. If the number of complex species formed is unknown the experimental uncertainties will contribute to the problem of when to stop adding species to the model.

May *et al.*[1] have described these problems at length and proposed some computational methods for the simultaneous determination of protonation constants and glass-electrode parameters. The purpose of this paper is to direct attention to one source of error which in our investigations appeared to be crucial when judging the adequacy of a model.

The complex formation between molybdate(VI) and oxalate will be used to demonstrate how a modified electrode calibration procedure led to significant improvement in the description of the equilibrium system. The molybdenum(VI)–oxalic acid system has been the subject of several investigations. Recently Beltran *et al.*[2] applied spectroscopy and saline cryoscopy to the problem and concluded that species with Mo/oxalate stoichiometric ratios 1:2 and 2:2 were present. According to

Mikešová and Bartušek,[3] using potentiometric titration techniques, a monomeric 1:1 species is present. This was also found by Starý.[4] Chalmers and Sinclair,[5] who used spectroscopy and pH measurements, also reported a 1:1 complex, but considered that a dimeric structure was also possible; their work was done with much higher concentrations of molybdate and acid than those used by us, however. It seems that potentiometric titrations combined with comprehensive computerized methods have not yet been applied to the system.

THEORY

The electrochemical cell used in this work is very conventional:

glass electrode | test solution | reference electrode
The boundaries, g and l, respectively, indicate the glass membrane and the liquid junction between the test solution and the salt bridge. The measured emf of the cell is given by the equation:

$$E_{cell} = E^0 + \frac{RT}{F} \ln\{H^+\} \tag{1}$$

where E^0 is a "constant" including the standard electrode potentials and the liquid-junction potential.

The experimental conditions relevant to this work seem to ensure constancy of the liquid-junction potential. In accordance with others we find the glass electrode to exhibit a Nernstian response over a wide range of concentration. Since we are not interested in the hydrogen-ion activity, the ionic strength of the solution is kept constant, and consequently equation

---

*Author for correspondence.

(1) can be simplified:

$$E_{cell} = E_{const} + s \, \log[H^+] \qquad (2)$$

where s has the theoretical Nernstian value and $[H^+]$ represents the concentration of free hydrogen ions. Hence, all constants (including the hydrogen-ion activity coefficient) are collected as E_{const}. Because of small variations in the asymmetry potential, E_{const} has to be determined for each titration. An internal calibration performed in the test solution itself is highly desirable but not always possible. In the present investigation of molybdate–oxalate mixtures, internal calibration is not feasible. The electrode calibration for a titration taking place with pH-values below 7 will be based on measurements on solutions with known concentrations of hydrogen ions in the pH range of about 2.3–2.9. The test solution is completely characterized by the total concentrations of the individual reactants and by the corresponding formation constants. A number of mass-balance equations will correlate these concentrations to the model; for example

$$T_H = [H^+] + \sum_p \sum_r r \, \beta_{pr} \, [L]^p \, [H^+]^r \qquad (3)$$

$$T_L = [L] + \sum_p \sum_r p \beta_{pr} \, [L]^p \, [H^+]^r \qquad (4)$$

The data-processing in the present work sets no theoretical limits to the number of equations necessary to define the model, i.e., the number of complex species. All parameters needed, viz. E_{const}, analytical concentrations, and titration volumes, are subject to errors which impose uncertainties on the model testing, by influencing the measure of goodness-of-fit.

In this work T_H is singled out as the dependent variable, i.e., it is calculated as a function of all the other parameters and compared with the expected value by a non-linear least-squares method.

EXPERIMENTAL

Reagents

Sodium oxalate and sodium molybdate (both Merck p.a.) were titrated with a standardized permanganate solution according to methods described by Vogel.[6] Standardized nitric acid diluted from Merck Suprapur nitric acid was used as the acidic titrant. The ionic strength was kept constant at 0.150 by means of potassium nitrate (Merck p.a.). In a few titrations potassium nitrate (Merck, Suprapur) was used for comparison.

Apparatus

The emf values were measured as described earlier[7] but a few changes were made in the equipment. The motor-driven burette used was a Radiometer ABU80, and a Radiometer PHM84 pH-meter was used as an electrometer. The free hydrogen-ion concentration was monitored by means of a glass electrode (Metrohm EA 109), and a calomel electrode (Metrohm EA 494) was used as reference electrode. The cell temperature was kept constant at $25.00 \pm 0.05°$ by means of a water thermostat. The electronic timers[7] were replaced by a computer, HP9825 B/T, used as a process controller. The motor-driven burette was controlled by a relay actuator, HP59306A. BCD outputs from the pH-meter and the
Fig. 1. Concentration diagram showing the concentrations used.

burette were input to the computer by means of a BCD-interface, HP98033A. The process controller ensured that equilibrium was attained before read-out and before the next addition of titrant.

The absolute concentration ranges used are displayed in Fig. 1 for the separately titrated solutions of molybdate and oxalate and for the mixtures. The metal-to-ligand ratio was varied between 1:2 and 2:1 in the mixtures, which were titrated in the pH-range from ca. 7 to ca. 4. For titration of oxalate and for the calibrating titrations of potassium nitrate the pH-range was extended down to ca. 1.8.

Calculations

All calculations were performed on the RC8000/15 at this Institution. The software program TITRER is essentially the same as that outlined earlier.[7] The non-linear least-squares minimization algorithm has been improved so that even very poor initial guesses can now be effectively handled. The weighting has been slightly adjusted along the lines described by Avdeef;[8] the weighting factor is calculated from

$$\sigma(ml)^2 = weight^{-1} = \sigma_b^2 + [\sigma_e d(ml)/de(mV)]^2$$

In the present work the values $\sigma_b = 0.003$ ml and $\sigma_e = 0.1$ mV, respectively, are used, and the necessary slopes are calculated by means of a cubic spline technique. The weighting has proved reasonable, since simple test systems with known models give variance values close to those expected for a normalized distribution, namely unity.

NUMERICAL EXPERIMENTS

The two protonation constants of oxalic acid were determined, with E_{const} from equation (2), and the results are displayed in Table 1. Simulations of the titrations were then run with synthetic errors added

Table 1. Protonation constants of oxalic acid using different calibration systems; 5 titrations with a total of 52 points

Calibration method	$\log \beta_{11}$	$\log \beta_{12}$	Variance
E_{const} equation (2)	3.825	4.831	3.17
E_{const} equation (6) (individual calibrations)	3.744	4.768	0.51
E_{const} equation (6) (combined calibrations)	3.748	4.742	0.57

to one primary parameter at a time. These numerical experiments clearly proved the initial concentration of hydrogen ions to be the most sensitive parameter. Indeed, this observation has been made on other systems by other authors and some methods have been proposed for the analysis of titration curves.[1] We have adopted the practice of introducing an additive correction to the initial concentration of hydrogen ions and letting the data-fitting program optimize the corrections as parameters specific to the individual titrations, in the hope that the corrections to the initial hydrogen-ion concentration will be so small compared with the analytical uncertainty that they can be accepted, and the adequacy of the model can be evaluated without bias. When the corrections are too great to be accepted it has been the practice to revise the model or discard the titration. The new procedure described below is of value in making an objective evaluation of the goodness-of-fit.

CALIBRATION OF ELECTRODE

Calibration of the glass electrode is in principle the calculation of E_{const} from measurements of E_{cell} in solutions with known hydrogen-ion concentration

$$E_{const} = E_{cell} - s \log[H^+] \qquad (5)$$

Because of experimental uncertainties it is necessary to take the mean value of E_{const} over a pH-range. For some time we have been haunted by too large an error in the initial hydrogen-ion concentration predicted by analysis of titration curves. At the same time it was clear to us that the calibration procedure for the glass electrode was not quite satisfactory, since stable values for E_{const} emerged only from a rather narrow range of low pH-values and, more seriously, the values obtained from higher pH-values were systematically low. The procedures of May et al.[1] remedy this adverse situation by simultaneously refining E_{const} and the titrant acid concentration. Following such a procedure, however, we arrived at greater changes in titrand concentration than were acceptable. An obvious cause for this could be the presence of a hydrolytic system in the ionic-strength buffer ($0.150M$ KNO_3) so that the calibration was being performed with a constant bias to the hydrogen-ion concentration

$$E_{const} = E_{cell} - s \log([H^+] + \Delta) \qquad (6)$$

where s is assumed to have the theoretical Nernstian value. By performing a non-linear regression analysis on the experimental data (E_{cell} and the analytical $[H^+]$) we arrived at very well determined values for E_{const} and Δ, and a very satisfying fit to the calibration curve. It turned out, as expected, that Δ had a negative sign corresponding to an alkaline impurity. To find out whether this impurity was real or an artefact, we tested several batches of potassium nitrate, including Merck *Suprapur* quality, and it turned out that Δ was clearly related to batches and

was virtually nil for the *Suprapur* salt. Potassium nitrate of analytical grade showed a hydrogen-ion concentration of -0.07 ± 0.005 mole% whereas the *Suprapur* quality showed -0.005 ± 0.002 mole%. This conclusion is supported by the observation that calibrating with use of varied volumes of salt solutions leads to different (but all in the same direction) deviations from the extrapolated values of E_{const} and that introduction of Δ yields the same correction to the total hydrogen-ion concentration (Fig. 2).

Calibrations performed in this way are in fact quantitative determinations of very small amounts of acid or base in the potassium nitrate. The value of Δ is consequently used to correct the initial concentrations of hydrogen-ion for all titrations of protolytic systems. Thereafter equation (2) is applied for the calculation of $[H^+]$.

The discrepancy between the extrapolated and computed values of E_{const} should be noted. The final proof of the reality of the alkaline impurity comes from the fact that when titrations of oxalic acid (and some hydroxy acids to be reported) were re-examined, introduction of Δ from the calibrations led unconditionally to better fits. The oxalic acid system especially benefited from the adjustment, since without it the curve fitting would have an unacceptably large variance (far from the ideal value of unity). The calibration procedure now adopted at this laboratory is to make frequent calibrating titrations of potassium nitrate and then to make a combined curve-fitting with all the calibrating titrations in a short series, so as to produce an $[H^+]$-correction common to all the titrations, but with individual values for E_{const}. There seems to be no need for recrystallizations of the potassium nitrate. The presence of a slight amount of alkali will not lead to an initially alkaline solution, since the unavoidable presence of carbon dioxide will turn it into a buffer system. The pH of such a solution (without additional strong acid) is ill-defined, but definitely in the acidic part of the pH-scale.
Fig. 2. Calculated values of E_{const} obtained by using equations (2) (■) and (6) (□). Horizontal line indicates the best value of E_{const} with equation (6).

Table 2. Stability constants (log β_{pqr}) of complex species $M_pA_qH_r$ (M = molybdate, A = oxalate, H = proton) in 0.15M KNO$_3$ at 25°C

	Species			Number of titration points/ number of titrations	log β_{pqr} $\pm 3\sigma$	Variance
	p	q	r			
Oxalate	0	1	1		3.748 ± 0.002	
	0	1	2	52/5	4.742 ± 0.012	0.57
Molybdate	1	0	1		3.809 ± 0.038	
	7	0	8	122/15	52.976 ± 0.040	2.42
	7	0	9		58.083 ± 0.013	
	7	0	10		61.792 ± 0.031	
Molybdate–oxalate with fixed primary parameters	1	1	2	51/6	13.816 ± 0.003	2.83
Molybdate and molybdate–oxalate with only oxalate as fixed parameter	1	1	2		13.816 ± 0.003	
	1	0	1		3.805 ± 0.033	
	7	0	8	173/21	52.978 ± 0.038	2.54
	7	0	9		58.082 ± 0.013	
	7	0	10		61.793 ± 0.032	

A special computer program called ENUL has been written in ALGOL8 for non-linear curve-fitting for a series of calibration titrations.

Table 1 shows how the formation constants depend on the calibrating procedure. The variances are satisfactorily small with the new procedure, as they ought to be for a simple system with a known model.

RESULTS AND DISCUSSION

There are a number of papers concerning the problem of deciding whether a species is really present in solution or is only an artefact caused by excessive interpretation of the titration data. Kayali and Berthon[9] summarize seven investigations on the copper(II)–histidine system. There is consensus agreement on the major species predicted, but for minor species there is little agreement. The selection of species and the calculation of stability constants are the subject of a paper by Vacca et al.[10] Their R_{lim} factor has the same significance as our variance. More recently Avdeef[8] has discussed the proper weighting of potentiometric data with the purpose (amongst others) of obtaining relevant values of the goodness-of-fit for comparison of models. In his experience refinements of pK-values converge at goodness-of-fit values in the range 0.5–1.2.

Our results for the molybdate(VI)–oxalate system are presented in Table 2.

For the molybdate system the set of species previously reported by us was used. The corresponding stability constants are slightly changed because of the new calibration procedure. The variance for this system is a little high compared to that for the simpler oxalate system. It is possible to get a lower variance (1.49) by replacing the H$_2$Mo$_7$O$_{24}^{4-}$ species ($p, q, r = 7, 0, 10$) with the H$_2$MoO$_4$ species (1, 0, 2), but that model does not work well in connection with oxalate, and furthermore neither species is of much concern in mixtures with oxalate.

As is clearly demonstrated by the data in Table 2, just one complex species ($p, q, r = 1, 1, 2$) will fit the

titrations in a very satisfactory way.

$$MoO_4^{2-} + oxal^{2-} + 2H^+ \rightleftharpoons$$

$$MoO_3oxal^{2-} + H_2O \quad (7)$$
We found no other single species with the same property. The fit is so close that inclusion of more species is not warranted, and testing of the species claimed by Beltran et al.[2] did not lower the variance, the new species simply being rejected by the least-squares program.

The concentration ranges used in this work proved to be amply wide to distinguish between ML and M$_2$L$_2$ type complexes. The "best" M$_2$L$_2$ complex tested gave a variance which exceeded that for the best ML complex by a factor of 50.

Previously we tested a final model for internal consistency by letting the optimizing program adjust the values for both the ternary complex and the entire molybdate system. If only small changes in formation constants and variance resulted, the model was accepted. As is seen from Table 2, the changes are comfortably small. The stability constant found (log $\beta_{112} = 13.816$) is in agreement with the value 13.98 found by Mikešová and Bartušek,[3] using poten-
Fig. 3. Titration curves for mixtures of molybdate and oxalate in the ratio 2:1 and 1:2, respectively.

tiometric titrations in potassium nitrate medium, $I = 0.22$.

When performing the test just mentioned it was necessary to include the titrations made on molybdate only, because the molybdate–oxalate complex is so strong that most titrations on mixtures contained so little information on molybdate alone, that the "global" fitting was somewhat uncertain.

An alternative method for confirming the existence of only one molybdate–oxalate complex is to compare titration curves of mixtures of molybdate and oxalate in exactly the ratios 2:1 and 1:2, respectively.

The two curves in Fig. 3 are identical in the first part of the titrations until two equivalents of H^+ have been added. This confirms the equilibrium (7). In the more acidic regions of the titration curves, the excess of molybdate and oxalate, respectively, is titrated.

PRELIMINARY COMMUNICATION

A SENSITIVE METHOD FOR THE FLUOROMETRIC DETERMINATION OF LITHIUM
WITH A "CROWNED" BENZOTHIAZOLYLPHENOL

Kenichiro Nakashima, Shin'ichi Nakatsuji and Shuzo Akiyama*

Faculty of Pharmaceutical Sciences, Nagasaki University, Bunkyo-machi,
Nagasaki 852, Japan

Isamu Tanigawa, Takahiro Kaneda and Soichi Misumi*

The Institute of Scientific and Industrial Research, Osaka University, Mihogaoka,
Ibaraki 567, Japan

Recently, a new method has been proposed,[1] for the spectrophotometric determination of lithium in the concentration range 25 - 250 ng/ml with a "crowned" dinitrophenylazophenol CDPA, I).   It was the first example of the determination of lithium with a crown ether. The incorporation of a fluorescent moiety in the place of the dinitroazo group of CDPA should much improve the sensitivity in the determination of lithium.[2]

A new fluorescent "crowned" benzothiazolylphenol (CBTP, II, pale yellow crystals, m.p. 155 - 156°) has now been synthesized and shows characteristic fluorescence with the alkali and alkaline-earth metal ions.[3]
This communication reports a highly sensitive fluorometric determination of lithium based on complex formation with CBTP, followed by the measurement of the fluorescence of the phenolate of the complex, obtained by treatment with triethylamine (TEA).

The procedure is as follows.   To a 50-μl portion of LiCl solution in methanol (Li 7.8 μg/ml) in a 10-ml standard flask, 5.0 ml of 10^{-4}M CBTP in benzene are added and mixed in.

---

* To whom requests for reprints should be addressed.

After addition of 50 µl of TEA the mixture is diluted to the mark with benzene and mixed well, then the relative fluorescence intensity (RFI) is measured at 410 nm, with excitation at 375 nm.

Figure 1 shows the excitation spectra for the complex (a) and a reagent blank (c) and the emission spectra of the complex (b) and the reagent blank (d) excited at 375 nm. The excitation maximum for the reagent blank is at 330 nm, and the emission intensity of the reagent blank is negligible compared with that of the complex when an excitation wavelength of 375 nm is used. The emission maximum of the blank is at 382 nm if λ_{ex} is 330 nm.

Before establishment of this procedure the effects of the CBTP, TEA and MeOH concentrations were examined. Figure 2 shows that at least a 10-fold molar excess of reagent is necessary in the final concentration. Maximal RFI of the complex was obtained with final concentrations of 0.5 - 1.1% v/v TEA and 0.3 - 0.5% v/v MeOH. The fluorescence developed immediately and its RFI was constant during 120 min or more when the solution was kept in the dark, but decreased by about 84% within 120 min if kept in room lighting.[5] The cause of this quenching is not known, but is being investigated.

Fig. 1. Fluorescence spectra
Fig. 2. Effect of CBTP concentration

The calibration graph obtained by the standard method passed through the origin and was linear from 0.39 to 39 ng/ml. The coefficient of variation for five replicates at the 24-ng/ml level was 2.2%.

The principal advantages of the method are that it is simple, rapid, and sensitive. The sensitivity is superior to that of the CDPA method[1] and of the method based on the 1,8-dihydroxyanthraquinone complex (50 - 450 ng/ml).[4]

The RFI of each of the CBTP-M^{n+} complexes (M^{n+} = alkali or alkaline-earth metal ion) obtained by the procedure was measured. The order of decreasing RFI is

<p style="text-align:center">Li > Ba > (Na, Sr) >> (K, Rb, Cs, Be, Mg, Ca)</p>
In this series the intensity ratios of the Li to Ba, Na, and K complexes were about 2, 4 and 10 respectively. It is interesting to note that the RFI of the Na, Be, Ba, and Sr complexes,

which would interfere in the determination of Li(I), decrease remarkably within 30 min, even in the dark.   This behaviour (also not yet explained but under investigation) should be useful for improving the selectivity, and work along this line is in progress.

The authors wish to express their gratitude to the Japan Ministry of Education, Science, and Culture for a Grant-in-Aid for Scientific Research.

LETTER TO THE EDITOR

Comment on "LASER-EXCITED FLUORESCENCE LINE-NARROWING: AN ANALYTICAL STUDY"

Sir,

The paper by Bolton and Winefordner (Talanta, 1983, 30, 9) has been commented upon by Hayes and Small (HS).* We agree that J.C. Brown, M.C. Edelson, and G.J. Small (Anal. Chem., 1978, 50, 1394) were among the first to explore the analytical use of fluorescence line narrowing spectroscopy (FLNS), and in fact our study resulted because of that paper. We did not intend to imply that our study was the first analytical one. We wish, however, to respond to the first three points of the HS comment.

1. As far as the poor limits of detection (LODs) are concerned, these are the values we obtained for the experimental conditions listed. We realize the LODs are considerably poorer than the ones obtained by Small et al. (references 3 and 5 in HS's comment).

2. We made numerous attempts over a period of more than a year to improve our detection power but no matter what excitation/emission wavelengths and boxcar detector conditions were used, the LODs remained in the concentration range of approximately 1–1000 ng/ml. It is possible that our high LODs are correlated to an abnormally high background, but this is difficult to rationalize since our studies were done over a long period of time, with several batches of reagents and a variety of experimental arrangements and conditions.

3. The hypothesis of rapid local site-melting causing a loss of FLNS behaviour when λ_{ex} pumps vibronic levels of the fluorescent state possessing $\geqslant 1500$ cm^{-1} excess vibrational energy was not ours but rather that of the authors of the two papers cited in our manuscript

Despite our analytically limited results for FLNS, we still feel the method has considerable analytical use, primarily because of the fine work by Small, Hayes, and their colleagues at Iowa State University.

SOLVENT EXTRACTION OF NOBLE METALS BY FORMAZANS—I

COMPARATIVE STUDY ON THE EXTRACTABILITY OF Pt(IV), Pd(II) AND Ag(I) BY FORMAZANS COMBINED WITH A LIQUID ANION-EXCHANGER

M. Grote, U. Hüppe and A. Kettrup*

Fachbereich Chemie und Chemietechnik, "Angewandte Chemie", Universität-GH Paderborn, Warburger
Straße 100, D-4790 Paderborn, Bundesrepublik Deutschland

Summary—The extraction properties of ion-pairs composed of quaternary ammonium cations and a sulphonated formazan were compared with those of an unsulphonated formazan, for various solvent media. In dichloromethane the combined system behaves as a "coloured anion-exchanger", with displacement of the sulphonated formazan, whereas in toluene Pd(II) and Ag(I) are extracted as the metal formazan chelates from aqueous medium. The rates of extraction are remarkably higher than with the simple extractants. Because of the higher stability only the simple chelating extraction systems afford satisfactory separation of Pd(II) from excess of Pt(IV) and of Ag(I) from Cu(II). The extracted metals can be stripped and the extractant regenerated.

The removal and recovery of valuable metals from aqueous solutions by use of ion-exchangers and liquid extracts is a growing need in, for example, the electroplating industry and hydrometallurgy.[1-6] The extractants used should be highly selective and easy to regenerate. Liquid–liquid extraction systems usually offer a wider range of stripping methods and better preconcentration factors than solid ion-exchangers do. Anionic complexes of the noble metals have been extracted with solid[7-10] as well as "liquid" ion-exchangers.[6,11-17] The behaviour of analogous functional groups in the two systems is similar, but the liquid–liquid extraction behaviour can differ markedly from the sorption behaviour. Our investigations on chelating ion-exchangers with high affinity for noble metals have resulted in use of formazan-modified strongly basic polystyrene and silica gel.[18,19] These sorbents separate silver(I) from an excess of Cu(II) and allow complete removal of the noble metals. This work has now been extended by use of solvent extraction with mixtures of liquid anion-exchangers and sulphonated formazans.

The ion-pairs formed by quaternary ammonium salts with anionic chelate complexes have been extensively used in extraction–spectrophotometric determinations and offer advantages in selectivity and sensitivity over conventional spectrophotometric methods based on metal complexes in aqueous solutions.[20-25] The chelates can be formed in the aqueous phase and extracted with an organic solution of the ammonium salt, or the metal can be extracted with an organic solution of both the chelating agent and the ammonium salt.

Thus Przeszlakowski and Habrat[25] efficiently extracted Fe(III) by means of the ion-association compound formed by its ferron complex and Aliquat 336 in chloroform. This reaction is analogous to the one we have produced by use of the sulphonated formazan F32 (Fig. 1) and a quaternary ammonium salt in various solvents (Table 1).

The properties of the Q_LF32–T and Q_LF32–D systems can be compared with those of the corresponding simple chelating extraction systems with the unsulphonated *o*-chloro-substituted ligand F43 (Fig. 1, Table 1).

EXPERIMENTAL

Reagents

The preparation of the formazans F32 and F43 has already been described.[18,26] The solvents used were toluene (T) and dichloromethane (D) (the symbol T/D will be used to indicate that either solvent can be used but both are being investigated). A $0.01M$ $Q_L^+Cl^-$ solution in T or D was prepared with methyltrioctylammonium chloride ($Q_L^+Cl^-$)
Fig. 1. Structure of formazans used for liquid–liquid extraction (R = H: F43; R = SO$_3$H: F32).

*Author for correspondence.

Table 1. Composition of the extraction systems

Symbol	Solvent	Chelating agent	Liquid anion-exchanger

$Q_L F32$–D	Dichloromethane		
F43–T	Toluene	F43 (unsulphonated)	
F43–D	Dichloromethane		—

(Merck) and 500 ml of it were shaken with five successive 100-ml portions of $0.1M$ hydrochloric acid and then with five successive 500-ml portions of water. The tendency to form emulsions could be reduced by adding a small amount (0.2% v/v) of 1-octanol. The same procedure was applied, with $0.1M$ nitric acid, to obtain the nitrate form $Q_L^+NO_3^-$ of the liquid anion-exchanger.

$Q_L F32$-T/D

F32 was extracted by shaking 500 ml of $Q_L^+Cl^-$–T/D with 100 ml of 0.2% aqueous formazan solution for 2 min and rejecting the aqueous phase. The process was repeated about ten times with fresh formazan solution until the absorbance of the organic phase at 436 nm became constant. The organic phase was then washed several times with 500-ml portions of water to remove excess of F32, and stored in a brown glass bottle to prevent decomposition by light. The binary systems $Q_L F32$-T/D in the nitrate form were analogously prepared and were preferred for extraction of silver, to prevent interference by chloride.

Determination of the concentration of F32 in $Q_L F32$-T/D

Irving's method[27] was used. The stock solution of $Q_L F32$-T/D was diluted 100-fold with toluene or dichloromethane, and 5 ml of the diluted solution were shaken for 1 min with 5 ml of $0.1M$ sodium perchlorate. The formazan stripped was determined photometrically by dilution of an aliquot of the centrifuged aqueous phase with water and measurement of its absorbance at 436 nm against water. The acid dissociation constants of the formazans were evaluated spectrophotometrically by the method of Pelizzetti.[28] Solutions of F43 in dioxan and of F32 in water were diluted with aqueous buffer to give final solutions with concentrations in the range $0.4–1 \times 10^{-4}M$. Isosbestic points were observed at 470 nm (F43) and 505 nm (F32).

Determination of distribution ratios

All experiments were performed at ambient temperature ($22 \pm 2°$), by mechanically shaking 5 ml of $0.001M$ aqueous solutions of the appropriate metal salt (Na_2PtCl_6, Na_2PdCl_4, $AgNO_3$) containing dilute mineral acid (hydrochloric or nitric) or a buffer ($10^{-2}M$ citric acid, $10^{-3}M$ sodium tetraborate) with an equal volume of the extractant solution ($\sim 0.004M$) in a 50-ml separatory funnel. For work with silver the funnels were covered with aluminium foil, to prevent photodecomposition. After phase separation the aqueous solution was centrifuged and analysed by d.c. plasma atomic-emission spectrometry (see below). The distribution ratio D was calculated in the usual way.

A Beckman Spectraspan III d.c. argon-plasma emission spectrometer with a three-electrode plasma jet was used, as described elsewhere.[29,30] The wavelengths used were based on the manufacturer's recommendations: Pt 265.945 nm (85th order); Pd 340.458 nm (66th order); Ag 338.289 nm (66th order); Cu 324.754 (69th order). The spectral background was compensated for by matrix-matching of samples and standards.

The standard solutions were prepared from commercially available stock solutions (1000 and 500 mg/l., SPEX Industries Inc.). Noble metal salts were donated by Degussa, Hanau. A Perkin-Elmer 554 spectrophotometer and a Bruker WP 250 Fourier-transform spectrometer were used.

Separation of Pd(II) from Pt(IV)

Stock solutions ($10^{-2}M$) of Pd(II) and Pt(IV) were prepared by dissolving Na_2PdCl_4 or Na_2PtCl_6 in $10^{-2}M$ hydrochloric acid. The metal content of each solution was determined by d.c. plasma emission spectrometry before use. Solutions containing various amounts of Pd and Pt were obtained by mixing appropriate aliquots of the stock solutions and diluting with $10^{-2}M$ hydrochloric acid.

Extraction. Twenty ml of a mixture containing ~ 10 mg/l. Pd and between 10 and 2000 mg/l. Pt were placed in a 100-ml separatory funnel and 20 ml of $4 \times 10^{-3}M$ extractant were added. The mixture was shaken for 24 hr, then the phases were separated. The palladium concentration in the aqueous phase was then determined.

Stripping. Ten ml of the organic layer from the extraction system were transferred to a 50-ml separatory funnel and shaken with 10 ml of 5% thiourea solution in $0.1M$ hydrochloric acid for 48 hr. The amounts of Pd and Pt stripped were measured simultaneously in the separated aqueous phase.

A 5-ml aliquot of the organic phase regenerated by stripping was transferred to a glass beaker and the solvent was carefully evaporated. Then 5 ml of concentrated nitric acid were added and boiled down to 2 ml, then 0.5 ml of 70% perchloric acid was added and the solution evaporated to dryness. The residue was dissolved with 3 ml of aqua regia and the solution evaporated to dryness. The residue was taken up in 5 ml of $6M$ hydrochloric acid and the solution diluted to 10 ml with water, before measurement by emission spectrometry.

Separation of Ag(I) from Cu(II)

Appropriate aliquots of standard $0.01M$ silver nitrate and standardized $0.1M$ copper nitrate were mixed in a 100-ml glass beaker. After dilution of 5 ml of $1M$ sodium citrate and 5 ml of $0.1M$ sodium tetraborate the mixture was

Table 2. Dissociation constants and spectrophotometric data of formazans

Formazan	pK_a	pH 1		pH 13		Solvent
		λ_{max}, nm	ε_{max}, 10^4 $l.mole^{-1}.cm^{-1}$	λ_{max}, nm	ε_{max}, 10^4 $l.mole^{-1}.cm^{-1}$	
F43	12.19	435	2.64	521	2.47	water/dioxan (6:4 v/v)
F32	11.48	441	1.40	513	1.87	water

diluted with water to ~40 ml and the pH adjusted to 9.4 by dropwise addition of 1M sodium hydroxide or nitric acid. The solution was diluted to volume in a 50-ml standard flask with water, giving a final concentration of 0.1M citrate and 0.01M borate. The final concentration of Ag(I) was ~10 mg/l., and that of Cu(II) varied from 62 to 6240 mg/l.

The separation procedures and analytical measurements were similar to those described above. A shaking time of 15 min was sufficient for the extraction of silver with F43-D, and it was stripped by 10 ml of 0.01M nitric acid within 2 min.

Some dichloromethane was present in the nitric acid after the stripping and interfered in the simultaneous determination of Ag and Cu by atomic-emission spectroscopy. It was therefore necessary to evaporate the solution to dryness (on a steam-bath); to prevent losses of silver; 5 ml of concentrated nitric acid were added before the evaporation. The residue was taken up in 5 ml of concentrated nitric acid, 5 ml of water were added, and the final solution was analysed.

The extractant remaining from the stripping was analysed for copper and silver as already described, the final residue being taken up in 2 ml of concentrated nitric acid and 2 ml of water.

RESULTS AND DISCUSSION

F32 may be extracted by quaternary ammonium cations (Q_L^+) in accordance with the equilibrium:

$$2(Q_L^+ Cl^-)_o + [F](SO_3^-)_2$$

$$\rightleftharpoons \{(Q_L^+)_2[F](SO_3^-)_2\}_o + 2Cl^- \quad (1)$$
where [F] represents formazan, and subscript o the organic phase. Determination of F32 in the binary system Q_LF32-T showed that in toluene medium the molar ratio of Q_L^+ to F32 is reproducibly about 2:1 as predicted by equation (1), but in dichloromethane, a solvent of higher polarity, excess of F32 is extracted and the ratio varies from 2:1 to nearly 1:1. Q_LF32-T and Q_LF32-D solutions are fairly stable for a period of weeks in the dark and in daylight (Table 3), whereas aqueous solutions of F32 decompose more rapidly after storage for 100 days in the dark. Some anions (A^-) may interfere in the extraction by displacement of the chelating anion:

$$\{(Q_L^+)_2[F](SO_3^-)_2\}_o + 2A^-$$

$$\rightleftharpoons 2(Q_L^+ A^-)_o + [F](SO_3^-)_2 \quad (2)$$
To study this displacement (Table 4), equal volumes of Q_LF32-T or Q_LF32-D and aqueous phases con-

taining various acids or salts were shaken for 1 min. The dichloromethane system (Q_LF32-D) was very unstable in contact with mineral acids and alkalis. Thus the Q_LF32-D system has the typical properties of the "coloured liquid anion-exchangers" utilized by Itoh et al.[31] and Irving and co-workers[27,32] for the spectrophotometric determination of perchlorate. In the toluene system displacement of the chelating agent is more difficult, so the reagent is fairly stable in the presence of dilute hydrochloric acid and alkaline buffers.

Extractability of Pd(II) and Pt(IV)

Palladium and platinum form similar chloro-complexes, which are difficult to separate by normal anion-exchange. Their distribution in the presence of formazans was investigated by shaking together equal volumes of the aqueous metal salt solution and the extractant for at least 1 min. The properties of the Q_LF32-D system differ considerably from those of the Q_LF32-T system.

Q_LF32-D system. This is characterized by displacement reactions, and a shaking time of 1 min is sufficient to replace some of the F32 by PtCl$_6^{2-}$. This exchange reaction is rather inhibited in the presence of citric acid. Analysis showed that F32 and platinum are exchanged in about 1:1 ratio, in accordance with the reaction:

$$\{(Q_L^+)_2[F](SO_3^-)_2\}_o + PtCl_6^{2-}$$

$$\rightleftharpoons \{(Q_L^+)_2(PtCl_6^{2-})\}_o + [F](SO_3^-)_2 \quad (3)$$
in contrast, PdCl$_4^{2-}$ is virtually unable to displace the formazan in this period of shaking (Table 5). This difference in extractability conforms with the hypothesis that the extraction of anions is favoured by increase in size (the "hole theory").[33] In principle, separation of Pt(IV) from Pd(II) by anion-exchange extraction seems to be possible with the Q_LF32-D system, but the distribution ratios for Pt(IV) are too low for the system to find practical application.

pH 4	0.020	0.006

Q_LF32-T *system.* There was much less exchange between this system and platinum and palladium, even after shaking time of 24 hr, than between these metals and Q_L^+Cl$^-$ in toluene. This behaviour (Fig. 2) is analogous to that of solid anion-exchange resins with and without formazan-loading.[18]

Sorption of Pd(II) by the F32-loaded solid resin is fast, and complete up to a metal:ligand ratio of 1:1, but solvent extraction of Pd(II) with the Q_LF32 system proceeds very slowly, a reaction time of 24 hr not being sufficient for equilibrium at pH 2 to be reached (Fig. 3), though 96% of the noble metal is extracted.
Fig. 2. Extractability of Pt(IV) by the liquid anion-exchanger Q_L^+Cl$^-$ in comparison with the combined system Q_LF32 in toluene (shaking time 1 min).
Fig. 3. Extraction of Pd(II) by Q_LF32–T, as a function of time.

In this process the colour of the organic phase changes from red to green, indicating the formation of a formazan–Pd(II) chelate. Stripping of this chelate by means of perchlorate enables it to be isolated and characterized. Thin-layer chromatography and infrared and ultraviolet spectroscopy show it to be the 1:2 metal chelate described earlier, called "Pd–F32".[34]

The low rate of complexation of palladium in solvent extraction with formazans was also observed by Panzel.[35] In general a low rate of complex formation by platinum metals affects their solvent behaviour.[24] In view of the difference in the distribution ratios, separation of platinum and palladium by means of the Q_LF32-T system seems possible, the separation factor being ~50 for a shaking time of 24 hr and 0.01M hydrochloric acid medium, but the extraction of Pd is incomplete (96%, see above). In citric acid medium buffered at pH 3 the extractability of Pd is reduced by its complexation side-reaction with citric acid. To test this separation, three synthetic solutions, containing 105 μg of Pd and various amounts of Pt, were treated individually with the extractant Q_LF32-T. The results, shown in Table 6, reveal that platinum inhibits the complete extraction of palladium. With higher concentrations of Pt ($5 \times 10^{-3}M$) some of the green formazan–Pd(II) chelate was stripped by PtCl$_6^{2-}$. Thus the application of the combined system is impossible for the quantitative separation of Pd from Pt.

Comparison with the simple F43 chelate extraction system

The extraction behaviour of the hydrophobic o-chloroformazan F43, dissolved in toluene (F43–T), differs markedly from that of the mixture of liquid anion-exchanger and water-soluble F32 (Q_LF32–T). As expected, the distribution ratios of Pt(IV) between F43–T and hydrochloric acid (0.01–1M) or citric acid buffer are very low ($D \sim 0.07$). The extraction of Pd(II) with the simple extractant at room temperature is also less effective ($D = 0.64$, shaking time 24 hr) than that with the combined system (Fig. 4), and is also very slow.

A higher distribution ratio ($D \sim 170$) was found for Pd when the dichloromethane system (F43–D) was used.

Table 6. The effect of varying amounts of Pt(IV) on the extraction of Pd(II) with Q_LF32-T (shaking time 24 hr; [HCl] 0.01M; [F32] = $4 \times 10^{-3}M$, 10 ml of extractant; phase volume ratio 1:1)

Separation of Pd(II) from Pt(IV)

In contrast to the Q_LF32-T system, F43-D will give complete separation of small amounts of Pd from excess of Pt provided the w/w ratio of Pt to Pd is not much more than about 20 (see Table 7), but up to almost 200-fold ratio can be tolerated if citric acid is added to give a final concentration of $0.01M$ (pH 2) in the aqueous phase.

The palladium extracted can be stripped and the extractant regenerated with an acidified solution of thiourea, but the rate of ligand substitution in the stripping step is slower than the rate of extraction. Small amounts of Pt are co-extracted and are also stripped from the organic phase. To investigate the efficiency of the stripping procedure, the regenerated extractants were first evaporated to dryness. The residues were then mineralized with nitric and perchloric acids, taken up in hydrochloric acid solutions and analysed. Not even traces of Pt could be detected and only small amounts of Pd (0.2–0.4 μg per 10 ml of extractant).

Extractability of Ag(I)

We have already reported that spectroscopic data indicate that the model compound Ag-F43 is an N,O-co-ordinated complex. Silver is sorbed from slight alkaline sodium acetate or citrate buffers onto solid supports modified with the chelating formazan,

but its liquid–liquid extraction from the same media with the combined (Q_LF32-T/D) and simple (F43-T/D) systems is poor ($D = 0.4$). However, the extraction is much more effective from sodium tetraborate medium.

F43-T/D. The effect of tetraborate concentration on the distribution ratio of silver between the aqueous phase and the extractant F43-D at a fixed concentration of F43 is summarized in Table 8.

The enhanced extraction with increase in tetraborate concentration may be due to the increasing alkalinity of the aqueous phase, and this is confirmed by the data in Table 9 for the effect of pH at a fixed concentration of silver and tetraborate.

Depending on the concentration, pH and temperature, various complexes may be formed in the system $Ag_2O-B_2O_3-H_2O$.[36] However, a plot of log D vs. log [F43] has a slope of unity, indicating a 1:1 metal-F43 chelate is extracted. This result agrees with the structure assumed for the Ag-F43 compound, prepared by liquid–liquid extraction under similar conditions.[34] No evidence was found for additional co-ordination of an inorganic ligand. The extraction

Table 7. *$0.01M$ citric acid medium.
Fig. 5. Extraction of Ag(I) with various extractants, as a function of time.

of silver is much faster than that of palladium, distribution equilibrium with F43–D being established within 30 min (Fig. 5). In toluene medium the rate of co-ordination is slower and the extraction yield lower (Fig. 5).

Q_LF32–T/D. Vigorous shaking of either of these systems with an aqueous solution of silver and sodium tetraborate (each $10^{-3}M$) immediately produces a deep violet colour in the organic phase, indicating very rapid extraction. The distribution is much faster than with the simple extractants (Fig. 5), equilibrium being established within 1 min.

The extractant $Q_LF32–D$, which is subject to displacement reactions in contact with Pt and Pd solutions, is as stable as $Q_LF32–T$ in the presence of aqueous mixtures of tetraborate and silver. Though the rates of extraction with the two combined systems are the same, the degree of extraction is lower with $Q_LF32–D$ (69%) than with $Q_LF32–T$ (90%) under identical conditions.

Stripping of silver. Except for the $Q_LF32–D$ system, stripping is nearly complete with $0.01M$ nitric acid in a single extraction in 1 min shaking time (Table 10). Stripping with $10^{-3}M$ nitric acid is less effective.

Separation of Ag(I) from Cu(II)

Silver was extracted from mixtures of silver and copper under conditions similar to those for silver alone. The alkaline aqueous solutions (pH 9.4) contained sodium tetraborate, and sodium citrate to prevent precipitation of copper salts. When the $Q_LF32–T$ system is used, higher concentrations of $Cu(\geq 10^{-2}M)$ displace the Ag–F32 chelate, and the extraction yields of Ag are lower than 96%. However, about 100 μg of silver can be successfully separated (99.7%) from large amounts of copper by extraction with F43–D (see Table 11). A shaking time of 15 min is sufficient for quantitative extraction. Silver and traces of co-extracted copper are easily stripped with

$0.01M$ nitric acid (2 min shaking time). Mineralization of the stripped extractants and analysis of the residue for metals show that only 0.1–0.25 μg of Ag and ~ 0–0.6 μg of Cu remain in 10 ml of the organic phase after the single stripping. The regenerated F43–D system may be used again for extraction, which is promising for the development of cyclic separation processes.

Conclusion

The rate of extraction of Pd(II) and Ag(I) is much higher with the combined extractants ($Q_LF32–T/D$) than with the simple chelating systems (F43–T/D) but combination of the lipophilic ligand F43 with the

Fig. 6. Structure of isomers of formazans.

quaternary ammonium compound gives no improvement of the extractant rates. The differences found in the extraction behaviour are not yet fully understood. The cationic surfactant makes the extraction mechanism more complicated, and the influence of micelles should be taken into consideration.[23] However, the higher N–H acidity and hydrophilicity of F32 [pK_a (F32) = 11.4; pK_a (F43) = 12.2] may increase the rate of extraction. Furthermore, there may be activation of the sulphonated agent by the surfactant. Similar activating effects are reported in the literature on the formation of mixed-ligand complexes. Savvin et al.[37] interpreted the enhanced reactivity of triphenylmethane reagents with metal ions and N-cetylpyridinium chloride in aqueous solution as a deprotonation process. Improved extractability of lanthanides by use of ion-association complex formation in conjunction with chelation by 8-hydroxyquinoline derivatives was observed by Tochiyama and Freiser.[38] It must also be taken into account that in the presence of surfactants and sulphonated chelating agents metal ions could be favourably co-ordinated at the interface of the two phases and not in the aqueous phase.[25]

The rate of extraction in metal chelate extraction systems can be limited by the rate of reaction between the metal ion and the ligand, as well as by diffusion and transport factors. In the case of the 3-phenylcarbamoylformazans, Pd(II) and Ag(I) are bound by different isomers (Fig. 6).[34] Thus the co-ordination of the noble metal ions is accompanied by ligand conversion. An investigation of the Q_LF32 ion-pair by proton n.m.r. spectroscopy (C_6D_6 medium) gave evidence for only the N–H..N and N–H..O bichelated isomer D, which is favoured for the co-ordination of Ag(I). In contrast to the extractant F43–T (10% of isomer A) and the solid polystyrene loaded with QF32 (30% of A)[34] no monochelated isomer A could be detected.

We assume that the different isomer ratios affect the efficiency of the reaction of both the liquid extractants and solid sorbents with palladium and silver. The binary solvent-extraction system Q_LF32–T

extracts silver faster and more completely than the similar formazan-modified polystyrene QF32 and silica gel Si-QF32,[18,19] but is less effective for extraction of Pd(II).

Unfortunately, the extractant Q_LF32–T is unstable in contact with metal salt solutions of higher concentrations and will find no practical use in separation processes. Only application of the simple chelating system F43–D to synthetic mixtures of Pd/Pt and Ag/Cu gives acceptable results.

Additional studies on the extractability of noble metals and base metals by other substituted formazans are in progress and will be applied to various samples containing noble metals.

THE DETERMINATION OF TRACES OF FORMALDEHYDE

A. D. Pickard*†

IHD, University of Aston in Birmingham, Birmingham, England

E. R. Clark

Department of Chemistry, University of Aston in Birmingham, Gosta Green, Birmingham, England

Summary—An extensive critical review of the methods utilized to determine trace formaldehyde concentrations is presented. The methods are grouped under the physical techniques employed and are discussed with reference to interfering agents, sensitivity, reagent stability and analysis time. The applicability of the procedures is considered for routine monitoring of occupational and environmental exposure to gaseous formaldehyde.

Formaldehyde has been identified as a combustion product from many sources, including automobile exhausts[1] and cigarette smoke.[2] It was estimated in a 1972-4 survey in the United States that 1.6 million workers in some 40 industrial categories were exposed to formaldehyde.[3] Formaldehyde is an odorous, lachrymatory and physiologically active compound. The present threshold limit value (TLV) is 3 mg/m^3 for a 10-min time-weighted average limit (which has now replaced the old "ceiling" limit) for occupational exposure.[4] The health risks associated with the compound are to be assessed by the Advisory Committee on Toxic Substances with a possible view to establishing a control limit. In the United States the ceiling limit for formaldehyde has been reduced to 1.2 mg/m^3 and it has been designated as a suspected carcinogen, class A2.[5] The toxicity of formaldehyde to man and animals has been the subject of a number of reviews,[3,6,7] and studies are still in progress. It has been established as a primary irritant and as a mutagen. Animal studies indicate that it is carcinogenic but epidemiological data have not proved this connection in man.

The proposed changes in exposure limits and the need for data for epidemiological studies have led to increased interest in determining exposure patterns. Workers in clinical laboratories, foundries and the building trade are particularly likely to be exposed, and the use of formaldehyde-based resins in foams and other insulating materials now means that a large proportion of the population may come into contact with the compound.

Concern over environmental pollution from and occupational exposure to formaldehyde, has led to the need to develop methods for the determination of formaldehyde in air. Some of these techniques measure the concentration in air directly, but most require the air to be sampled through an absorbing medium designed to trap formaldehyde selectively prior to analysis. The analytical method used often determines the method of sampling, which can be by solid sorbent, diffusion badge or liquefaction. A discussion of sampling strategies, including the efficiency of collection and the effects of humidity, temperature and interfering agents, could constitute a review in itself. As this review is devoted to the analytical techniques available for determination of formaldehyde only a summary of trapping methods is included here.

Impingers have proved popular and a variety of solutions have been used. The most efficient absorbents are those which give a chemical reaction with formaldehyde. The chemistry of these reactions has been reported[8] and a summary of the solutions and collection efficiencies is given in Table 1. Solid sorbents have been used as sampling media,[9] and some have been treated with chemicals to promote a chemical reaction. Chemical treatment, however, limits flow-rates and collection efficiency. A comparison has been made of a reaction in solution and on a solid support.[10] Some reagents and solid supports used are listed in Table 2.

Units

The diversity of units used in the literature results in unnecessary difficulties in comparison of analytical methods. The concentration units used throughout this review refer to the weight of formaldehyde per unit volume.[11] Of necessity, however, this has led to assumptions and approximations being made in converting from the units given in some of the original papers. For solvent systems the unit of volume is taken as 1 ml of solvent. For direct analysis of gaseous samples, the unit of volume quoted is taken as 1 m^3 of air. Detection limits are quoted in terms of the weight of formaldehyde actually introduced into the instrument.

Table 1. Solutions used in impingers and their collection efficiencies for formaldehyde
(one impinger)

Solution	Collection efficiency, %	Reference
Water	80	12
5mM hydrochloric acid	72	35
5mM hydrochloric acid	85	41
0.05% MBTH aqueous	84	28
5% ammonium acetate	80–95	18
7% ammonium acetate, with a saturated oxalyldihydrazine solution	95–96	30
2,4-DNPH in 2M hydrochloric acid	80–99	10
1.6mM 2,4-DNPH in acetonitrile with a trace of perchloric acid	97.5	66
1% sodium bisulphite	98	19
0.1% chromotropic acid in* conc. sulphuric acid	100	17

*See Ref. 19 regarding the importance of the order of reagent addition.

Table 2. Solid sorbents and reagent coatings for collection of formaldehyde

Reagent	Solid support	Reference	Comments
—	Alumina	9	Sampling period limited to 30 min due to instability of formaldehyde on the sorbent. Immediate desorption required. Desorption efficiency 85%.
—	Molecular sieve 13X	48 79	Quantitative desorption. The sampling period is limited. Water vapour competes for adsorption sites.
2-Benzylaminoethanol	Chromosorb 102	56	Desorption efficiencies vary with batch. Sampling rates are restricted to 50 ml/min.
2,4-DNPH	Glass beads	10	The collection and desorption efficiencies vary widely and are poor under dry conditions.
2,4-DNPH	Amberlite XAD-2	67	Collection efficiency reported comparable to that of a bisulphite impinger
Oxidizing agent	Charcoal	68 69	Instability of the oxidized product on the charcoal has been shown.
J-acid	Silica	—	Results obtained are comparable with collection by a bisulphite impinger and analysis with chromotropic acid.

TITRIMETRIC METHODS

These methods are not specific. The methods using sodium sulphite, ammonium chloride, potassium cyanide, and hydroxylamine hydrochloride are all dependent on the characteristic carbonyl-group reactions of aldehydes and ketones. Oxidation procedures based on alkaline hydrogen peroxide, and iodometric and mercurimetric methods, suffer interference from any other chemicals which can be oxidized under the test conditions.

The procedures are well described[8] but have the limited sensitivity associated with most titrimetric methods. Although largely superseded, the bisulphite–iodine procedure remains the recommended National Institute for Occupational Safety and Health (NIOSH) procedure for evaluation of primary aqueous standards.[12]

SPECTROPHOTOMETRIC METHODS

A number of spectrophotometric methods have been developed for the determination of formaldehyde, many of them by Sawicki et al. Procedures involving spectrophotometric methods are summarized in Table 3.

Xanthylium dyes

In concentrated sulphuric acid, polynuclear xanthylium dyes are formed with chromotropic acid (1,8-dihydroxynaphthalene-3,6-disulphonic acid), J-acid (6-amino-1-naphthol-3-sulphonic acid) and phenyl J-acid (6-anilino-1-naphthol-3-sulphonic acid). The resulting chromogens are illustrated in Fig. 1.

The chromotropic acid method[13] has been used for the determination of formaldehyde in air,[14,15] and for environmental[16] and occupational[17] analyses. The use of concentrated sulphuric acid in the analysis is potentially hazardous, but it has the practical advantage that the heat of mixing with aqueous media facilitates the completion of colour formation.

A recently recommended method in the U.K.[18] uses chromotropic acid but with 50% v/v sulphuric acid, thus reducing the potential hazard. We have noted, however, that the more dilute acid does not liberate formaldehyde quantitatively from the bisulphite complex. Aqueous ammonium acetate must be used as the collection medium, but this has a lower collection efficiency than sodium bisulphite solution. A large volume of the acid is required, which reduces the sensitivity of the method, and we have found the

Table 3. Spectrophotometric techniques

Reagent	Reference	λ_{max}, nm	$10^3\ l.mole^{-1}.cm^{-1}$ ε,	Beer's law range, $\mu g/ml$	Colour stability	Interferences

Oxalyldihydrazide + Cu(II)	28	628	50.0	0.03–1.72	12 min	Sulphur dioxide, hydrogen sulphide, carbon disulphide, aliphatic aldehydes
	30	620	7.7	0.6–3.6	180 min	
1-Ethylquinaldinium iodide	32	608	73	0.04–0.82	30 min	Aliphatic aldehydes
Acetylacetone	33	412	8.0	0.37–8.7	>24 hr	Aldehydes
Schiff's	34	550	3.5	—	30 min	Sulphur dioxide

heating step required to complete colour formation rather time-consuming.

Although the older method has been widely used it has only recently been reported that the order of addition of reagents affects the extent of colour development.[19] If a composite chromotropic acid/sulphuric acid reagent is added to an aqueous sample the calibration graph is markedly non-linear. We therefore recommend that the chromotropic acid is added first, followed by sulphuric acid.

Optimization of the chromotropic acid reaction[20] and the effect of interfering agents[21] have been investigated in detail. Saturated aldehydes, ketones, ethanol and methanol do not interfere. Higher molecular weight alcohols, phenols, aromatic hydrocarbons and alkenes cause a negative error when present in excess. Of the unsaturated aldehydes, acrolein gives the greatest positive error, and oxides of nitrogen also interfere positively. We believe that the order of reagent addition affects the degree of interference.

In concentrated sulphuric acid medium, J-acid forms a stable, triply-charged yellow cation with formaldehyde.[22] The reagent may be used with aqueous samples in an analogous way to chromotropic acid,[23] with slightly improved sensitivity. For personal sampling we prefer to use J-acid coated onto silica as a solid adsorbent for formaldehyde. For analysis, concentrated sulphuric acid is then added and the samples are left at room temperature. (We find that heating at this stage increases the colour intensity but not in relation to the formaldehyde concentration.) The absorbance is measured after filtering or centrifuging. This simplified collection and analytical procedure gives reproducible results comparable with those obtained by the chromotropic acid–impinger method. Dilution of the yellow sulphuric acid solution with water leads to the formation of an unstable, singly-charged blue cation. If aqueous ammonium acetate solution is used as the diluent the stability is improved sufficiently to allow absorbance measurement,[23] and acrolein does not interfere.

In concentrated sulphuric acid a mixture of singly and triply-charged cations is formed with phenyl J-acid, which on dilution gives only the singly-charged species ($\lambda_{max} = 660$ nm). The sensitivity is 2.5
Reagent : chromotropic acid   J-acid   phenyl J-acid

Fig. 1. Structures of the xanthylium dyes.

times that of the chromotropic acid method, but
when the reagents are mixed and the colour devel-
oped the temperature must be carefully controlled.[23]

Formazan dyes

Formazan dyes are formed by the reaction of
formaldehyde with aromatic hydrazines and hy-
drazones in the presence of an oxidizing agent. The
reaction is not specific and is essentially an aldehyde
group method. Reaction of aldehydes with phenyl-
hydrazine in the presence of potassium hexa-
cyanoferrate(III) gives an unstable red dye[24] and this
reaction has been applied to the determination of
formaldehyde in air.[25]

2-Hydrazinobenzothiazole (HBT) has been shown
to be a suitable reagent for formaldehyde.[26] The
reaction is thought to give a chromogen with the
structure represented in Fig. 2. The procedure is more
sensitive than the chromotropic acid method but the
oxidation time is critical and the colour is stable for
only 20 min after the final dilution step. We have
found this restrictive when several samples have to be
analysed.

3-Methyl-2-benzothiazole   hydrazone   hydro-
chloride (MBTH) undergoes an analogous reaction in
the presence of iron(III) chloride–sulphamic acid
mixture as oxidant. The resulting chromogen has two
absorption maxima, and two procedures have been
developed. One involves measurement at 670 nm
where the molar absorptivity is high, but acetone
must be added to overcome turbidity.[27] The second
method does not require acetone as there is no
problem of turbidity, but measures the lower absorp-
tion maximum at 627 nm.[28] The reagent is one of the
most sensitive spectrophotometric reagents available
as a group reagent for aldehydes. It suffers inter-
ferences from aromatic amines and imino hetero-
cyclic compounds. In the presence of concentrated
sulphuric acid the MBTH complex breaks down, and
a technique has been proposed in which the MBTH
and chromotropic acid methods are both applied to
the same sample to determine total aldehydes and
formaldehyde simultaneously.[29]

Metal complexes

The formation of a hydrazone is suggested as the
first step in a procedure using oxalyldihydrazide.[30]
The hydrazone then forms a blue complex with
copper(II) in aqueous solution, $\lambda_{max} = 620$ nm. The
formaldehyde:oxalyldihydrazide:Cu(II) reacting ra-
tio is 2:2:1. The procedure is very simple but the pH
must be carefully controlled, with ammonium acetate
as buffer. Sulphur compounds, including hydrogen

sulphide, carbon disulphide, and sulphur dioxide,
interfere. Other aliphatic aldehydes react but the
wavelength of maximum absorption differs from that
for the formaldehyde product.

A second spectrophotometric procedure involving
formation of a metal complex is the reaction of
formaldehyde with tryptophan in the presence of
sulphuric acid and iron(III).[31] A violet chromogen,
$\lambda_{max} = 575$ nm, is formed, which obeys Beer's law up
to 3 μg/ml. The technique is more applicable to
biological assays than air samples, and methanol,
acetaldehyde, amino-acids, sugars and related com-
pounds do not interfere. Other metal ions, notably
Fe^{2+}, Ni^{2+} and Co^{2+}, may replace Fe^{3+} in the
reaction and other 3-substituted indoles also give a
colour. The disadvantages are the use of concentrated
sulphuric acid and the time-consuming incubation
period (heating at 70° for 90 min is optimal).

Trimethine dye

A trimethine dye is formed by 1-ethylquinaldinium
iodide with formaldehyde on heating in basic solu-
tion.[32] The molar absorptivity at 608 nm is high, but
the reproducibility is poor and other aliphatic al-
dehydes interfere.

Hantzsch reaction

The Hantzsch reaction between acetylacetone, am-
monia and formaldehyde to form 3,5-diacetyl-1,4-
dihydrolutidine ($\lambda_{max} = 412$ nm) forms the basis of a
spectrophotometric procedure.[33] The procedure re-
quires pH adjustment with ammonium acetate and
gentle warming to complete the reaction. The reac-
tion is selective for aldehydes and although not as
sensitive as some others it is useful on account of the
mild conditions employed. It may be used in the
presence of trioxan and other compounds which
degrade to formaldehyde under strongly acidic condi-
tions. The sensitivity may be increased by measuring
the fluorescence spectrum.

Schiff's reagent

Finally, one of the earliest and most sensitive
analytical   reagents   is   the   Schiff   reagent.
Modifications to this method have been published
but the reaction employed is that of fuchsin or
pararosaniline which, in the presence of sulphite and
formaldehyde, yields a rose chromogen.[34] It has been
applied to the determination of formaldehyde in
urban air.[35] A modification of the reaction, involving
scrubbing   the   air   sample   with   sodium   tetra-
chloromercurate(II) solution, has been established
as a reference method for sulphur dioxide deter-
mination.[36] Simply varying the order of reagent addi-
tion allows this method to be used to determine
formaldehyde.[37] A modification has eliminated the
need for the toxic mercury complex[38] and has been
compared with the chromotropic acid method. De-
spite these modifications the procedure is generally
the most lengthy and complex of all those reviewed.
Fig. 2. Structure of the formazan dye formed with
2-hydrazinobenzothiazole ($\lambda_{max} = 582$ nm).

The final absorbance is dependent on temperature and pH[39] and the reagent has poor stability.[40] The analogous reaction with p-aminoazobenzene[41] has higher sensitivity but gives high blank values.

FLUORIMETRIC METHODS

Some of the spectrophotometric reagents can also be used for fluorimetric determination of formaldehyde. These methods are more difficult to use and tend to show poor reproducibility and fluorescence stability. They are, however, more sensitive and are summarized in Table 4.

GAS CHROMOGRAPHY (GC)

Direct methods

No completely satisfactory GC method has been demonstrated, largely because most detectors, especially the widely used flame ionization detector (FID), have a poor response to formaldehyde. Several procedures have been developed to overcome this difficulty. In general they are methods for aldehydes, the individual components being separated on the column. For details of operational conditions the individual papers should be consulted but a summary is given in Table 5. A second difficulty is that formaldehyde is eluted from GC columns as a distorted peak, owing to interactions and polymerization on the column. Nevertheless GC has been used for analysis for free formaldehyde, and for formaldehyde solutions,[42] vapour,[43,44] pollution sources[45-47] and ambient air[48] have been analysed. Typically, porous polymers have been used as the stationary phase, with various detectors.

When a thermal conductivity detector (TCD) is used, a detection limit of approximately 1 μg of formaldehyde in the volume injected can be obtained.[42] Temperatures above 100° and glass columns are recommended to reduce the tailing of peaks. Porous polymer column packings have been found to give satisfactory performance lasting over a year[43] and with reproducible retention times.[43,46]

It is well established that the FID is insensitive to formaldehyde, but one report[44] quotes a detection limit of 70 mg/m^3 in air by use of the FID without prior concentration. However, the methods used for calibration and standard atmosphere generation were unreliable.

To improve the sensitivity of detection a microreductor may be fitted between the column and the FID.[46,47] The formaldehyde is reduced to methane, to which the FID is more sensitive. The detection limit is then 5 mg/m^3 of air, with approximately 3 ng injected into the chromatograph. Carbon dioxide, carbon monoxide and methanol are similarly reduced, but since they are separated from formaldehyde on the column the technique can be applied to exhaust gases.[47]

Mass spectrometric analysis has been coupled with GC for determination of the components of ambient air, including formaldehyde.[48] Measurement of the peak heights for $m/z = 29$ and 30 enabled formaldehyde to be detected in nanogram quantities. The formaldehyde was first trapped on a solid adsorbent and then desorbed into the chromatograph, by which means a few μg/m^3 could be detected. The technique is sensitive and selective but the equipment required militates against its widespread use.

The problems with analysis of formaldehyde vapour have led to most of the proposed GC methods being based on derivatives. Initial attack on the carbonyl group by a nucleophilic nitrogen centre leads to several possible derivatives.

Nitrogen derivatives

The 2,4-dinitrophenylhydrazine (2,4-DNPH) derivative has proved popular because of the selectivity of the reaction for carbonyl compounds and the efficiency of the reaction at room temperature. Early methods gave poor reproducibility, variable response factors and spurious peaks, but modifications have improved the method and made possible the determination of aldehydes in exhaust fumes.[49] Symmetrical carbonyl compounds give single peaks but other aldehydes form isomers which when eluted give rise to multiple peaks.[50] Use of an excess of 2,4-DNPH and a packed column was reported to cause deterioration of the column and necessitate frequent recalibration.[49] Nevertheless the method allowed detection down to the equivalent of 70 ng of formaldehyde injected, and good separation of the components from a combustion source.

Table 4. Fluorimetric techniques

Reagent	Reference	Excitation wavelength, nm	Emission wavelength, nm	Stability, min	Comments
J-acid	32	470	522	120	The detection limit is 1 ng/ml but the reproducibility is poor and acrolein interferences
Acetylacetone	80 81	410	510	90	The detection limit is 5 ng/ml; the excitation spectrum varies with concentration
Cyclohexane-1,3-dione	82	395 460	460 505	60 3	The reproducibility of both procedures is poor
Dimedone	82	395 465	460 520	30 5	The fluorescence spectra of the products are stable for a very limited period

Table 5. Gas chromatographic techniques

Derivative	Column conditions				Retention time, min	Detector
	Reference	Length, m	Stationary phase	Temperature, °C		
None	42	1.96	Porapak N	120	~3.5	TCD
None	45	2.0	Porapak Q	83	11.4	TCD
None	45	2.0	Chromosorb 102	83	7.6	TCD
None	48	1.96	Porapak T	30–150 at 16°/min	~8.5	MS
2,4-DNPH	49	1.2	4% OV-17	150–300 at 7.5°/min	~11	FID
2,4-DNPH	50	2.4	2% SE-30	200–270 at 4°/min	0.52	FID
2,4-DNPH	50	1.5	12% F-60	225	0.38	ECD
2,4-DNPH	53	20 (capillary)	SF-96	200–240	—	FID
O-(2,3,4,5,6-pentafluorobenzyl)hydroxylamine	55	2	3% XE-60	90	~2.5	FID
2-Benzylaminoethanol	56	25 (capillary)	Carbowax 20M	70–200 at 10°/min	~11	FID
Dimedone	60	25 (capillary)	SE-30	270	—	FID/MS
Thioethanol	61	2	3% OV-17	200	7.6	FID

The method has been modified[50] to improve the sensitivity of the FID for the analysis of solutions containing 1.5 μg/ml of formaldehyde. The 2,4-DNPH derivatives were extracted from aqueous solution into carbon disulphide, and this solution was then injected; this saves a great deal of time since no purifying and drying of the derivatives is required, and the extraction is satisfactory. The relative merits of the FID and the electron-capture detector (ECD) have been evaluated.[51] The ECD is very sensitive but has a limited response range (20–500 pg) whereas the FID is less sensitive but has a broad linear response range (10–10^4 ng) to the 2,4-DNPH derivative.

The use of capillary glass columns and temperature programming facilitates the separation of carbonyl compounds as their 2,4-DNPH derivatives.[52,53] The procedure has been applied to food samples,[52] exhaust gases[53] and cigarette smoke.[53] We consider the collection procedure employed in the latter case[53] to be restrictive and the purification of derivatives needlessly slow. Extraction from aqueous solution into carbon disulphide is generally adequate, in view of the resolving power of a capillary column.

Pentafluorophenylhydrazine (PFPH) has been used as a reagent for preparing aldehyde derivatives for GC analysis,[54,55] but separation of the carbonyl derivatives on packed columns was incomplete. The use of a capillary column or temperature programming might overcome this.

Oximes have been investigated as an alternative to the hydrazones. In particular, benzyloxyamine has been used to form the O-benzyloximes of carbonyl compounds in cigarette smoke for subsequent GC analysis.[2] Pairs of isomers are formed from unsymmetrical carbonyl compounds, leading to additional peaks. Temperature programming on a capillary column was used to resolve these peaks, but the reproducibility was poor and the method is described as only semi-quantitative.

The pentafluoro compound O-(2,3,4,5,6-penta-fluorobenzyl)hydroxylamine has also been used and compared with the analogous hydrazine derivative (PFPH),[55] over which it was found to have some advantages, but the reagent has poor stability in aqueous solution and a long reaction time is required for some carbonyl compounds.

Another proposed reagent containing a nucleophilic nitrogen centre is 2-benzylaminoethanol: with formaldehyde this forms 3-benzyloxazolidine, which is detectable by the FID. The reaction is fast enough for the reagent to have been proposed as a trapping agent on a solid sorbent,[56] but the desorption is time-consuming and difficult. The reaction is again not specific for formaldehyde, and although the higher aldehydes do not isomerize, the separation of the derivatives of carbonyl compounds is incomplete on packed columns. Analysis by split and splitless injections of solutions of the derivative into a temperature-programmed capillary column gives a linear and reproducible response over the range

6.6–56.5 μg of formaldehyde. This is a very limited range, especially in view of the need to vary the injection technique, and the detection limit is poor for industrial-hygiene analyses requiring short-term sampling. The limited sampling rate restricts the method largely to time-weighted average sampling. Furthermore there is some difficulty in preparing calibration standards, as pure 3-benzyloxazolidine is not commercially available. However, there are no time-consuming purification and drying stages in the derivative preparation, and the method has been evaluated by NIOSH.[57]

Carbon derivatives

Attack at the carbonyl group by a nucleophilic carbon centre can lead to formation of suitable derivatives. Dimedone (5,5-dimethylcyclohexane-1,3-dione) contains a nucleophilic carbon centre at C-2 and forms crystalline aldehyde derivatives, which can be used for infrared[58] or GC[59,60] determination of aldehydes. The FID may be used but higher aldehydes may interfere; MS is therefore used in preference.[60] The method is restricted to use with capillary columns operated at above 220°C.

Sulphur derivatives

Thiols have been proposed as agents leading to formation of dithioacetal derivatives through reaction at the sulphur atom. Use of thioethanol has been proposed, on account of its odour being less offensive than that of simple thiols, and the trimethylsilyl derivatives of the complexes may be determined by GC.[61] The method is a general one for aldehydes, but separation is possible on short packed columns, and the derivatives are eluted as single peaks. An FID was used[61] but a flame photometric detector might give better sensitivity. No quantitative formaldehyde determination was reported and the derivative preparation is complex and lengthy, involving two reactions of 30-min duration. One of the reactions requires heating, so compounds which are thermally degraded to formaldehyde will interfere.

HIGH-PRESSURE LIQUID CHROMATOGRAPHY (HPLC)

Determination of carbonyl compounds by HPLC has been based exclusively on the 2,4-DNPH derivatives.[62–67] The earliest technique[62] used normal-phase liquid chromatography, which is suitable for formaldehyde determination, but some of the higher aldehydes are not fully resolved. The separation is improved by the use of reversed-phase liquid chromatography[64] and the two approaches have been compared.[65] Solvent programming also facilitates separation.[65,66] The use of acetonitrile as solvent has eliminated the time-consuming filtration, extraction and drying steps from the work-up procedure, but involves either heating[65] for 30 min at 70° or the use of a catalyst.[66] The formaldehyde can be trapped from air on a solid support coated with 2,4-DNPH,

and this allows phenol to be co-sampled and determined by GC, the aldehydes being determined by HPLC.[67] The detection limit of the HPLC method is 1.8 ng of formaldehyde, by use of an ultraviolet detector operating at 254 nm or near 360 nm. The method is therefore comparable with gas chromatography in sensitivity, and the limiting factors for detection of atmospheric formaldehyde are the collection and work-up procedures.

ION CHROMATOGRAPHY

The formaldehyde is oxidized to formate on a treated charcoal sampling tube. After desorption with a solvent the formate is passed through ion-exchange columns, and detected as formic acid.[68] A detection range of 0.3–40 μg/ml is claimed if a 10-ml desorption volume is used. The technique has a number of drawbacks. Formic acid and formate in the sample obviously interfere, as do acetate, acetaldehyde and acetic acid. The sample desorption requires ultrasonic treatment, and recent studies have shown significant loss of formaldehyde from the solid sorbent. Hence the NIOSH recommendation for this method has been withdrawn.[69]

ELECTROCHEMICAL METHODS

Polarography has been used to determine formaldehyde, although the method has not proved popular. The Girard T derivative is used: its half-wave potential at a dropping mercury electrode is −0.99 V vs. a saturated calomel electrode.[70] The method lacks sensitivity, having a detection limit of 2 μg/ml, and other aldehydes interfere. The sensitivity can be improved to 1 μg/ml by use of indirect differential pulse polarography,[71] but the procedure is complicated.

An instrument for direct measurement of formaldehyde in air has been based on an electrochemical fuel cell.[72] Clean air diffuses to the cathode of the cell, and the sample is passed to the anode, at which formaldehyde is oxidized. The resulting potential change is related to the formaldehyde concentration. The device is portable and simple to operate. It has a detection limit of 0.4 mg/m³ but suffers severe interference from alcohols and phenols.

MISCELLANEOUS SPECTROSCOPIC METHODS

Chemiluminescence

A chemiluminescent method is based on the vigorous reaction between formaldehyde, alkaline hydrogen peroxide and 3,4,5-trihydroxybenzoic acid.[73] The resulting strong orange luminescence may be monitored by a photomultiplier; the detection limit is 3 ng/ml of formaldehyde, which is comparable to the sensitivity of the HPLC method. The luminescence lasts several minutes, and the analysis is rapid, but there are several interferences. Chemical interferences

include carbonyl compounds, particularly acetaldehyde, humic acids and some inorganic ions. The intensity of luminescence is also dependent on temperature and pressure.

The methods discussed below all involve direct analysis of gaseous samples and do not require a trapping medium.

Laser-induced fluorescence

Formaldehyde in clean air has been determined by using a pulsed frequency-doubled tunable dye-laser covering the region 320–345 nm.[74] The laser beam is passed through a cell containing the gaseous sample at reduced pressure; the detection limit is around 1 μg/ml. Nitrogen dioxide and sulphur dioxide do not interfere. It may be possible to improve on the sensitivity but the test of the method would be its application to ambient and polluted air.

Microwave spectroscopy

The microwave rotational spectral lines of small molecules at low pressures are very sharp and characteristic, and the absorbance is proportional to the concentration. The method has been used for determining formaldehyde by examining the microwave absorption spectra of polluted atmospheres.[75] The experimental detection limit was estimated to be 0.3 mg/m^3 but theoretically this could be improved. Although the analysis time is short the instrument requires a recovery time of 20 min or ultrasonic treatment to eliminate carry-over between samples. The apparatus is expensive, requiring sophisticated electronic equipment to ensure high resolution, stability and sensitivity. It requires high power and use of a vacuum pump and is unsuitable as a field instrument, and the low operating pressure makes accurate gas sampling difficult.

Infrared spectroscopy

An infrared spectrometer tuned to the carbonyl absorption band can be used to detect atmospheric formaldehyde. Thus a portable Miran infrared monitor may be used, and a detection limit of 0.3 mg/m^3 is claimed. However, the infrared spectrum of formaldehyde is not particularly characteristic and many compounds interfere.

Infrared spectroscopy has been used to monitor atmospheric pollutants over an extended period of time in California.[76] To determine concentrations of specific atmospheric pollutants a long path-length and a Fourier transform technique were used.[77] The method is a highly sensitive and selective technique for measuring most of the pollutants present in the atmosphere. The analysis is fast and the lower detection limit is approximately 1.2 μg/m^3, but the equipment is highly specialized.

CONCLUSIONS

Increasing concern over the effects of prolonged

exposure to formaldehyde, coupled with the widespread use of the substance, makes it likely that the trend towards lower threshold limit values will continue. Epidemiological studies will require more information from monitoring surveys on exposure patterns.[78] Accurate and increasingly sensitive analytical techniques are therefore required, which should be simple and suitable for on-site testing.

Of the techniques reviewed, the chromotropic acid method is widely tested and will therefore remain popular. However, it can be used only for air samples collected by an impinger, and has limited sensitivity, and the use of concentrated sulphuric acid restricts its use in the laboratory; J-acid offers some advantages as an alternative.

High-pressure liquid chromatography is rapidly becoming a standard laboratory technique, and the sensitivity and short analysis time for the determination of formaldehyde suggest it will become more widely used for this purpose. No gas chromatographic method has proved to be without some drawback, though selected methods may be very suitable for particular applications. It is also the technique most likely to be applied on-site, if the difficulties of derivative preparation and solvent handling can be overcome. The methods utilizing direct analysis of gaseous samples require expensive and complex instrumentation which currently prevents their widespread use.

Summary—A method has been developed for the determination of Dy, Eu, Gd, Sm and Th in uranium (after chemical separation) by use of an inductively-coupled argon plasma in conjunction with a direct-reading spectrometer. The method can be used for the determination of Dy and Eu down to 0.02 μg/ml, Gd to 0.05 μg/ml, Sm to 0.1 μg/ml and Th to 0.20 μg/ml.

The inductively-coupled argon plasma (ICAP) is finding increasing application as an excitation source for simultaneous multielement analysis by atomic-emission spectrometry (AES).[1–4] This system has high sensitivity, large dynamic range and exceptional stability and relative freedom from matrix effects, but use has not yet been made of it for trace metal determinations in matrices, such as uranium and plutonium, which have rich emission spectra. It is potentially of great use for analysis of such matrices for elements such as the rare earths, which themselves give a large number of emission lines. Brockaert *et al.*[5] have reported the determination of rare earths in mineralogical samples by use of a low-power ICAP, and Brenner *et al.*[6] have described a procedure for determination of rare earths in a large variety of geological materials, with a medium-power argon-nitrogen ICP coupled with a 3.4-m Ebert spectrograph.

Owing to their large neutron-absorption cross-sections, determination of Gd, Sm, Eu and Dy at sub-ppm levels is important in the quality-control of nuclear materials such as uranium. The well established d.c. arc carrier-distillation technique,[7,8] though useful in the direct determination of volatile impurities in uranium, cannot be used for estimation of the rare earths at such low concentrations because of their refractory nature. When the ICAP source is used for this analysis, though matrix effects are not expected to be significant, the problem of spectral interference still exists and it is necessary to separate the rare earths from uranium before the determination.

This paper describes the use of an ICAP, coupled with a direct-reading spectrometer, for the determination of Dy, Eu, Gd, Sm and Th after their separation from uranium by solvent extraction[9,10] from hydrochloric acid medium with 20% tri-n-octylamine solution in xylene.

EXPERIMENTAL

Equipment

A Jarrell-Ash Mark III Atomcomp direct-reading spectrometer and associated ICAP source were used. The main features of the equipment are summarized in Table 1. A pneumatic nebulizer with adjustable cross-flow was used for injection of the sample into the plasma.

Procedure

The separation procedure and the preparation of standards and samples were essentially similar to those described earlier[9] except that 1*M* hydrochloric acid was used for the final dilution of the samples. For calibration, aqueous standards and also uranium standards that had been subjected to chemical separation were used.

RESULTS AND DISCUSSION

Optimization of plasma operating conditions

The parameters for each element were optimized for a 10-μg/ml solution of the element in 1*M* hydrochloric acid, the signal-to-noise ratio being studied as a function of (*i*) the observation height above the work coil, (*ii*) the lateral position of the plasma observation zone, (*iii*) the radiofrequency (RF) power and (*iv*) the coolant-gas flow-rate.

The analytical signal was taken as the count in the analytical channel, corrected for the background count. The background was measured on either side of the analytical line, at a wavelength 0.26 Å away from the peak, by use of a spectrum shifter which can give the line profile over a 2-Å range by means of a quartz refractor plate. The optimum position of the spectrum shifter for background measurement was selected after the profiles of the relevant analytical lines had been obtained. The analytical signals for the 10-μg/ml solution of the element and the reagent blank were taken as representing the signal and the noise respectively.

It was found from univariate studies that the

variation of coolant flow-rate from 15 to 25 l./min had no significant effect on the analytical signal. Hence the coolant flow-rate was kept constant at 18 l./min in subsequent studies. The signal-to-noise ratio for the element studied was found to be maximum at an observation height of 8 mm above the work coil. The effect of lateral position was measured by taking the centre of the sample flow channel as the reference line. The maximum intensity was obtained at the centre of the flow channel. The optimum observation height was found to be dependent on the torch dimensions and configuration. For two torches of different dimensions the optimum height was found to be 8 and 12 mm above the coil, but the optimum lateral position was the same in both cases. The optimum RF power was between 1.1 and 1.2 kW.

Because the effects of some of the plasma parame-

*Based on a 5-g uranium sample. For samples A and B, the final volume after separation of impurities from uranium was 20 ml of $1M$ HCl, while for samples C and D, the final volume after separation was 10 ml of $1M$ HCl.
†Based on 12 replicate measurements.

ters may be interdependent, the observation height, lateral position and RF power were optimized simultaneously by the simplex method.[11,12] The values obtained were found to be very similar to those from the univariate study, within the ranges of power and gas flow available with the instrument. The optimum operating conditions are listed in Table 2.

Analysis of synthetic samples

Four synthetic samples were prepared by adding known amounts of the rare earths and thorium to pure uranium to give concentrations ranging from 0.1 to 2 ppm. These elements were then separated from 5 g of sample by the solvent extraction technique. The aqueous phase containing the rare earths and thorium was made up to 20 ml in $1M$ hydrochloric acid medium and analysed. Aqueous standards were used, covering the range 0–10 $\mu g/ml$ for the element in $1M$ hydrochloric acid medium. Additionally, standards prepared from uranium and the test element, and subjected to the same chemical separation procedure as the sample, were also used. The results obtained for both types of standards agreed well within experimental error, so it was concluded that aqueous standards could be used for all the analytes investigated. The results of analysis of synthetic samples are shown in Table 3. There is good agreement between the amounts added and the amounts estimated. The precisions (relative standard deviations) obtained at various concentration levels are also given in Table 3.

Effect of uranium

Because the aqueous phase from the separation will contain traces of residual uranium, it was important to examine the effect of uranium on the determination. This was done by aspirating a 1-mg/ml solution of uranium and measuring the emission signals at the wavelengths used for the analyte determinations. Uranium was found to affect the different analyte channels to varying degrees. The interference was found to be least for Eu and Dy, which appeared to tolerate a 1000-$\mu g/ml$ uranium level. The interference, however, was significant in the Gd and Sm channels, particularly before the background correction. The correction reduced the interference effects by about an order of magnitude, but the 1000-$\mu g/ml$ uranium level still gave signals in the Gd and Sm channels that were about 20 and 7 times those corresponding to the respective limits of detection. Therefore, the tolerance limit for uranium, if significant interference effects are to be avoided, is 10 $\mu g/ml$, and it was found that 25 extractions were necessary to bring the uranium concentration down

Table 4. Detection limits and estimation ranges

Element	Analytical line, $\mathring{A}$	Detection limit, $(X_L = \bar{X}_{bl} + 3\sigma_{bl})$ $\mu g/ml$	Sensitivity, counts/ng	Estimation range, $\mu g/ml$
Dy	3531	0.006	0.58	0.02–10
Eu	4205	0.006	2.39	0.02–10
Gd	3796	0.015	1.79	0.05–10
Sm	4424	0.035	0.68	0.10–10
Th	4019	0.063	3.92	0.20–10

to this level. The reasons for the interference are not clear, but spectral interference cannot be ruled out, since the uranium 3796.2 Å and 4423.7 Å lines are very close to the Gd 3796.4 Å and Sm 4424.3 Å lines used for measurement. In the previous work,[9] the spectrographic buffer used suppressed the effect of uranium, so a much higher level of this element (0.5 mg/ml) could be tolerated and only five extractions were needed (a smaller sample was used).

Detection limits

The detection limits, calculated[13] as the concentration corresponding to a signal equal to the blank signal plus three times its standard deviation, are given in Table 4. The practical limit for quantitative determination was taken to be the concentration corresponding to about three times the detection limit.[2] On this basis the lower limit of estimation is 0.02 μg/ml for Dy and Eu, 0.05 μg/ml for Gd, 0.1 μg/ml for Sm and 0.2 μg/ml for Th. The sensitivities are also given in Table 4.

CONCLUSION

The method described permits the determination by Dy and Eu at 0.02 μg/ml, Gd at 0.05 μg/ml, Sm at 0.1 μg/ml and Th at 0.2 μg/ml concentration levels. With 5 g of sample and a final volume of the sample, after extraction, of 10 ml, the corresponding concentrations in the sample are 0.04, 0.1, 0.2 and 0.4 ppm

respectively. The use of the ICAP source and direct-reading spectrometer provides faster analysis with better precision.

USE OF ACTIVE NITROGEN IN ANALYTICAL CHEMILUMINESCENCE SPECTROMETRY

HEATHER JURGENSEN* and J. D. WINEFORDNER†
Department of Chemistry, University of Florida, Gainesville, FL 32611, U.S.A.

Summary—Methods of obtaining active nitrogen plasmas at both reduced and atmospheric pressures are described. The mechanism of energy transfer from the excited states of nitrogen to metal atoms and to organic molecules and the subsequent emission of characteristic radiation is outlined. The application of these processes to the detection and determination of traces of metals and organic compounds is discussed and recent work on gas chromatographic detectors, based on these systems, is reviewed.

Chemiluminescence arises when a chemical reaction produces an electronically excited state which emits radiation upon return to the ground state. Previous reviews[1-9] on chemiluminescence give extensive discussions of analytical uses of chemiluminescence in the liquid phase, the gas phase and flames. The purpose of this review is to discuss the use of active nitrogen for analytical chemiluminescence spectrometry.

In order for chemiluminescence to occur, three conditions must be fulfilled: (*i*) sufficient energy must be produced in the reaction to populate an excited state; (*ii*) the reaction mechanism must favour the production of the excited state; (*iii*) the excited state formed must be able to emit a photon or transfer its energy to another species that can emit a photon. Chemi-excitation is unusual since most chemical reactions involve ground-state species.[10] Any excess of energy is released as vibrational excitation of ground-state products and is detected as heat.

Direct chemiluminescence is defined as follows.[11]

$$A + B \xrightarrow{(M)} C^* + D$$

$$C^* \rightarrow C + h\nu$$
where M represents a third body and * indicates an excited state. Indirect chemiluminescence consists of:[11]

$$A + B + C \xrightarrow{(M)} AB + C^*$$

$$C^* \rightarrow C + h\nu$$
as well as metastable-energy transfer:[12]

$$A \xrightarrow[\text{process}]{\text{excitation}} A^*$$

$$A^* + B \rightarrow B^* + A$$

$$B^* \rightarrow B + h\nu$$
The production of chemiluminescence by active nitrogen (N_2^*) is an example of metastable-energy transfer.

Most studies of the analytical applications of active nitrogen have involved the detection of metals. Recent work on induction of chemiluminescence of metals by active nitrogen is discussed below and listed in Table 1. Lewis[34-36] was the first to observe spectral lines corresponding to metallic electrode materials in an active-nitrogen afterglow. He also observed mercury lines due to the diffusion of mercury vapour from the pumping system into a nitrogen afterglow. Kenty[14,21,22] conducted a series of experiments in which he examined the metal atomic emissions in an atmosphere of argon and nitrogen (at 300 and 10 mmHg pressure, respectively). He passed a condensed discharge through a gap between electrodes made from the metal of interest and detected the metal arc spectra. Later, Brennen and Kistiakowsky[23] studied the active nitrogen-induced chemiluminescence of metal carbonyls. Active nitrogen was produced by a microwave discharge at low pressure (1–5 mmHg) in a steady-flow apparatus. They discovered that $Ni(CO)_4$, $Fe(CO)_5$, $Cr(CO)_6$, $W(CO)_6$, $Mo_2(CO)_{10}$ and $Co(NO)(CO)_3$ reacted very rapidly to form metal atoms and produced intense flames due to neutral metal atomic emission spectra. The reaction mechanism was concluded to be a stepwise degradation: $Me(CO)_n + N \rightarrow Me(CO)_{n-1} + NCO$. The metal atoms were probably excited by collision with $N_2(A^3\Sigma_u^+)$ molecules.

The analytical potential of chemiluminescence induced by active nitrogen was clearly indicated in the study by Meyer *et al.*,[26] who observed the mercury emission line at 253.7 nm at concentrations of 10^9 atoms/cm^3. They produced the active nitrogen with a microwave discharge and observed the Lewis–Rayleigh afterglow with a photomultiplier tube.

Capelle and Sutton[37] introduced bismuth vapour (produced in a resistively heated crucible) into a Lewis–Rayleigh afterglow. Argon was used to sweep the bismuth vapour into a viewing region in a quartz

*LOD = limit of detection; LDR = linear dynamic range, E_{max} excitation maximum, *i.e.*, maximal emission.

tube. The active nitrogen was generated by a microwave discharge. Bismuth concentrations as low as 1.5×10^4 atoms/cm^3 were measured.

In 1978, Capelle and Sutton[38] named this technique metastable transfer emission spectroscopy (MTES) and presented further uses for this low-pressure system for microwave discharge generation of active nitrogen. They introduced gas phase samples through a stainless-steel capillary into a flow tube where the sample was mixed with an active nitrogen–argon mixture at 1–5 mmHg. Germane (GeH$_4$) concentrations as low as 7×10^7 molecules/cm^3 (corresponding to parts-in-10^{12} levels in the gas) were detected.

The application of MTES for the determination of lead in water was demonstrated by Melzer et al.[30] The apparatus was an improvement on the one employed for the detection of bismuth[37] and the crucible was replaced by a small tantalum boat. A limit of detection of 0.2 ng of Pb was achieved.

The first analytical study of inorganic species with a nitrogen afterglow produced at atmospheric pressure was published by D'Silva et al.[16,17] The active nitrogen was generated in an electrodeless discharge ozonizer operated at 20 kV and 1800 Hz. The hydrides of As, Bi, Ge, Pb, Sb, Se, Sn and Te were produced and mixed with the afterglow in the observation regions. Limits of detection for these elements (Table 1) were compared with those obtained by other spectrometric techniques employing hydride generation. The results were of the same order of magnitude as those obtained by atomic-absorption spectroscopy.

Another approach to the measurement of metals at low pressure was introduced by Dodge and Allen.[27,40] This technique was called metastable energy transfer for atomic luminescence (METAL) and differed from that of Sutton and co-workers[20,30,38] in respect of the method of active-nitrogen generation and the nitrogen emission system. The apparatus of Sutton and co-workers[20,30,38] utilized a microwave discharge for the production of active nitrogen and the emission was the straw yellow Lewis–Rayleigh afterglow.[20] A microwave produces nitrogen plasmas with high concentrations of nitrogen atoms and a concentration[39] of $N_2(A^3\Sigma_u^+)$ of the order of 5×10^9 molecules/cm^3. The concentrations of $N_2(A^3\Sigma_u^+)$ and vibrationally-excited ground-state $N_2(X^1\Sigma_g^+)$ are crucial, since they are the principal energy carriers.[14,17] Many different mechanisms for metal excitation in active nitrogen have been suggested,[14,27,52] but it is generally accepted that the $N_2(A^3\Sigma_u^+)$ state is responsible for excitation of energy levels requiring >4.5 eV while the $N_2(X'\Sigma_g^+)$ state is responsible for excitation of lower levels. Dodge and Allen[27,40] generated active nitrogen by means of a dielectric discharge and the nitrogen emission they observed was the second positive system of nitrogen. The concentration of $N_2(A^3\Sigma_u^+)$ was reported to be in the order of 10^{17} molecules/cm^3. Detection limits of 10^8 and 10^7 atoms/cm^3 were obtained for mercury and zinc, respectively. The

linear dynamic range for zinc was reported to be 7 orders of magnitude.

More recently, Na and Niemczyk[14] measured a series of metals by MTES. Aqueous solutions of trace metals were dried and atomized in a tantalum boat. The metal vapour was mixed in a flow cell with active nitrogen generated by microwave discharge. Limits of detection for Ag, Bi, Cd, Cu, Mg, Pb and Tl ranged from 2 to 300 pg. The measurements were performed at 1–2.4 mmHg. The effect of various interferences in electrothermal-atomization metastable-emission spectrometry has also been examined.[41] The anion effect on the analyte signal is an important parameter since in furnace atomic-absorption spectroscopy (FAAS), the magnitude of the analyte signal intensity depends strongly on sample composition.[41] For example, cadmium and lead nitrates gave higher sensitivities than their chloride counterparts,[42,43] and copper nitrate was found to give a sensitivity the same as or lower than that of copper chloride. Na and Niemczyk have shown that the anion effects of sulphate, nitrate and chloride on the signal intensities of Cu, Cd and Pb (detected by MTES) are minimal.[41] Na and Niemczyk have also investigated the matrix effects of NH$_4$Cl, NH$_4$NO$_3$, NaCl, NaNO$_3$, MgCl$_2$ and Mg(NO$_3$)$_2$ on the analyte signals of Cd, Cu and Pb chlorides and nitrates. In general, there were no matrix effects detected except for negative interferences at high concentrations of matrix materials.

Active nitrogen-induced chemiluminescence of molecules, especially hydrocarbons, is a relatively new research topic. Recent work in this area is discussed below and Table 2 tabulates the results.

Two research groups, Sutton and co-workers[46,49] and D'Silva and co-workers[17,47,48] have examined the application of an active nitrogen-induced chemiluminescence gas-chromatographic detector. The system of Sutton et al.[46] involved a microwave-induced nitrogen plasma operated at 8–30 mmHg. A 0.05 mm bore stainless-steel capillary tube was used to couple the gas chromatograph (operated at 1 atmosphere) to the active-nitrogen detector. When small hydrocarbon molecules (7 carbon atoms or less) were mixed with active nitrogen, CN was produced and emission from the CN($B^2\Sigma^+ \rightarrow X^2\Sigma^+$) transition was detected. By monitoring the CN chemiluminescence at one wavelength, as the eluent from the gas chromatograph became mixed with the active nitrogen, a chromatogram could be obtained. To reduce the limits of detection, a 1% mixture of HCl in nitrogen was added to the nitrogen afterglow. The addition of HCl is known to catalyse the reaction of Group II hydrocarbons (simple saturated compounds) in active nitrogen and hence increase the production of CN; this is due to the catalytic effect of HCl on the residual polymerized CN present.[51] Limits of detection of 10 pg for vinyl fluoride and 4 ng for CH$_4$ were obtained.[46] To make the detector specific for oxygen-containing compounds (as well as air leaks), either the NO($A^2\Sigma^+ \rightarrow X^2\Pi$) bands or the

*MTES = metastable-transfer emission spectroscopy. The active nitrogen is microwave-induced at low pressure. APAN = atmospheric-pressure active nitrogen. The active nitrogen is microwave-induced at 1 atm. AFOM = analytical figures of merit.

OH(A^{2}Σ$^+$→X^{2}Π) transition could be monitored. Selectivity was demonstrated[49] but no limits of detection other than those for methanol were obtained. Mach et al.[51] have used high-resolution capillary gas-chromatography with MTES detection to separate and detect the carbon-, oxygen- and phosphorus-containing compounds in 0.5 μl of jet engine A fuel.

Rice et al.[48] have applied an atmospheric-pressure active-nitrogen afterglow (APAN) as a detector for gas chromatography. A glass-capillary transfer line was used to couple the gas chromatographic column to the APAN system previously described.[17] Selective trace level detection of organo-mercury, -lead, and -tin compounds was achieved by monitoring the metal line emissions. Hexadecane and naphthalene were detected by observing the CN emission at

388.3 nm. Methods for determining methylmercury compounds in fish, water, urine and sediments, and dialkylmercury compounds in water with the GC–APAN system have been reported[47].

Jurgensen et al.[52,53] have used the dielectric discharge[27,40] to excite organic molecules. The excitation is sufficiently gentle to produce no apparent fragmentation. The resulting fluorescence spectra are similar to those obtained in both the liquid and gaseous state. They found that the electronic (iron 2-line method) temperature of the direct discharge was 3280 ± 132 K and that of the afterglow discharge was 3090 ± 70 K. The concentration of the metastable N$_2$ species (N$_2$A^{3}Σ$_u^+$) in the afterglow was found to be 10^{16} molecules/cm^3 (2% of the N$_2$ molecules are in the A^{3}Σ$_u^+$ state). On the basis of these and

other diagnostic measurements, Jurgensen[52,53] found that the afterglow background (and the direct discharge background) was due primarily to the transition $C^3\Pi_u \rightarrow B^3\Pi_g$ and the species responsible for excitation of the organic molecules was $A^3\Sigma_u^+$ (~ 6.3 eV energy). Detection limits were obtained in the subnanogram range for polycyclic aromatic hydrocarbons (Table 2) by using a large-aperture monochromator and either an RI66 or a 1P28A photomultiplier tube. All species (except benzene and naphthalene) were introduced into the afterglow by injecting 0.5 μl of 1–100 ppm solutions in hexane into a heated injection port. Benzene, toluene and naphthalene vapours were introduced continuously into the afterglow through an external heated chamber by a flow of nitrogen. Jurgensen et al.[52,53] also interfaced a gas chromatograph to the dielectric discharge and used a silicon intensified target-vidicon (SIT) for spectral detection. The limits of detection were degraded by a factor of 10–100, and owing to the need to reduce the nitrogen carrier-flow, the separation characteristics were seriously impaired. This system needs further work to be of analytical use.

In conclusion, the dielectric discharge used by Dodge and Allen[27,40] and the atmospheric-pressure active-nitrogen afterglow used by D'Silva et al.[17,47,48] seem to be the most versatile low- and high-pressure means of producing active nitrogen. Both discharges are robust in terms of solvent and matrix introduction, simple to construct and operate and intense for both atomic and molecular species. In addition, the dielectric discharge has future application to identification and determination of molecular species in gas chromatography.[52,53] Microwave-induced metastable-transfer emission spectroscopy (MTES) has been the most fully evaluated means of using active nitrogen for excitation of both atomic and small molecular species, and may ultimately be the method of choice, particularly as a gas-chromatographic detector.

KINETIC FLUORIMETRIC DETERMINATION OF CYANIDE BY MEANS OF ITS CATALYTIC EFFECT ON THE AERIAL OXIDATION OF PYRIDOXAL-5-PHOSPHATE OXALYLDIHYDRAZONE

S. Rubio, A. Gomez-Hens and M. Valcarcel

Department of Analytical Chemistry, Faculty of Sciences, University of Córdoba, Córdoba, Spain

Summary—A highly specific determination of traces of cyanide is described, based on the catalytic effect of cyanide on the oxidation of pyridoxal-5-phosphate oxalyldihydrazone by dissolved oxygen. The reaction is monitored by measuring the fluorescence of the oxidation product (λ_{ex} 350, λ_{em} 420 nm), and allows determination of 3–180 ng/ml cyanide concentrations with relative standard deviations of 0.4–0.8%. The effect of 56 foreign ions has been investigated: 45 of them do not interfere, and only one, Hg(II), interferes when present at the same level as the cyanide. Its application to the determination of total cyanide in industrial and synthetic samples, without preliminary distillation, is reported.

It is well known that cyanide catalyses the oxidation of some aromatic aldehydes to acids, through formation of cyanohydrins,[1] and this has been utilized for spectrophotometric and fluorimetric determination of cyanide.[2-5] The reaction between the cyanohydrin of *p*-nitrobenzaldehyde and *o*-dinitrobenzene to give a highly-coloured blue compound, the doubly-charged anion of *o*-nitrophenylhydroxylamine, has been used by Guilbault and Kramer.[2] The rate of reduction of the *o*-dinitrobenzene was followed spectrophotometrically at 560 nm. Cyanide could be determined in the range 45–450 ng/ml, and the method was highly specific.

The fluorimetric methods for determination of cyanide have been reviewed and critically studied.[6] The reaction of pyridoxal with oxygen to give 4-pyridoxolactone, a highly fluorescent compound, is catalysed by cyanide.[3-5] Factors affecting the reaction rate have been studied by Takanashi and Tamura.[7] The reagents are mixed in phosphate medium at pH 7.4 and heated at 50° for 60 min. The fluorescence is measured at pH 10 (achieved by adding sodium carbonate). The calibration graph is linear from 4 to 180 ng/ml. This reaction is regarded as the most sensitive fluorimetric method for cyanide.[8]

Here, the analytical properties of a new compound, pyridoxal-5-phosphate oxalyldihydrazone (PPOH), are described for the first time, and its aerial oxidation is used for the kinetic fluorimetric determination of traces of cyanide by means of their catalytic effect on the oxidation reaction. Under the conditions proposed, the reaction is rapid, measurements being taken less than 7 min after the start. The method is very selective, no preliminary distillation is needed and cyanide concentrations as low as 3 ng/ml can be determined.

EXPERIMENTAL

Synthesis of the reagent

Pyridoxal-5-phosphate (0.6 g) dissolved in the minimum of hot water–ethanol (3:2 v/v) solution was mixed with 0.13 g of oxalylhydrazide dissolved in hot water–ethanol mixture (1:1 v/v). The mixture was refluxed for 30 min, then let cool to room temperature. The yellow product was filtered off and washed with ethanol. Calculated for $C_{18}H_{22}O_{12}N_6P_2$, C 37.50%, H 3.82%; found C 37.5%, H 4.1%.

Reagents

Pyridoxal-5-phosphate oxalyldihydrazone (PPOH) solution $7 \times 10^{-4}M$, *in methanol.* Several drops of 0.01*M* sodium hydroxide (enough to give an apparent pH of ~7) were added to dissolve the reagent. This solution is stable for at least one month.

Standard cyanide solution. Potassium cyanide (2.5 g, equivalent to 1 g of cyanide) was dissolved in 1 litre of 0.05*M* sodium hydroxide and standardized argentometrically.[9]

Ammonia–ammonium chloride 6M *buffer solution, pH 9.8.*

Chloramine-T solution and pyridine–barbituric acid reagent.[10]

Reagent-grade chemicals and pure solvents were used. All anions tested were added in the form of their sodium or potassium salts.

Apparatus

Spectrofluorimeter. A Perkin-Elmer fluorescence spectrophotometer, model MPF-43A, fitted with a device for kinetic measurement and with 1-cm quartz cells was used. The cell compartment of the spectrofluorimeter was kept at constant temperature by circulating water. The sensitivity was set at 3, and the excitation and emission slits were set to give 6-nm spectral band-pass. A set of fluorescent polymer samples was used daily to adjust the spectrofluorimeter to compensate for changes in source intensity.

Cyanide distillation apparatus.[10]

Air-sampling equipment. A constant-flow pump, Dupont model S2500; impingers, volume 30 ml; cellulose ester filters, 37 mm in diameter and 0.8 μm thick.

Procedure

To 10-ml standard flasks add 0.5 ml of $7 \times 10^{-4}M$ PPOH solution, 5 ml of $6M$ ammonia–ammonium chloride buffer (pH 9.8), 2.5 ml of $4M$ sodium chloride and appropriate volumes of cyanide sample to give a final concentration of cyanide between 3 and 180 ng/ml. Make up to volume with distilled water, mix and after 1 min transfer a portion to a 1-cm quartz cell kept at $62 \pm 0.1°$. Wait 2 min before starting to record the fluorescence intensity (λ_{ex} 350, λ_{em} 420 nm) as a function of time. Run a blank with no cyanide present. Calculate the reaction rate from the difference in the slopes of the fluorescence–time plots for the sample and the blank.

RESULTS AND DISCUSSION

Analytical properties of the reagent

At room temperature, PPOH is highly soluble in water or in sodium hydroxide solution, moderately soluble in dimethylformamide or methanol and slightly soluble in ethanol. Aqueous solutions are unstable whatever their pH. A $3.5 \times 10^{-5}M$ solution in methanol–water (1:24 v/v) has an absorption maximum at 305 nm and a very small absorption band at 360 nm in acidic and neutral media. In alkaline medium it shows a broad band with an absorption maximum at 305 nm. PPOH solutions are fluorescent (λ_{ex} 365 nm, λ_{em} 510 nm in acid medium and λ_{ex} 400 nm, λ_{em} 510 nm in alkaline medium).

The stability of the PPOH solutions is critically dependent on the medium. The reagent is stable in organic solvents such as methanol. Aqueous PPOH solutions are unstable owing to the autoxidation of the reagent by dissolved oxygen. This difference in behaviour occurs because there is a hydrolysis step prior to the oxidation, and this is favoured in an aqueous medium. For this reason, neutral aqueous solutions are more stable than acid or basic ones, because H^+ and OH^- ions catalyse the hydrolysis. This autoxidation reaction occurs at pH values very close to that used for the determination of cyanide, which is why blanks are run.

The pK values for the dissociation in methanol–water (1:24 v/v) were found[11,12] to be 3.9, 8.2 and 10.4.

The colour reactions of the reagent with 62 ions at various pH values were investigated; it reacts with Mg(II), Co(II), Ni(II), Mn(II), Fe(II) and Fe(III). Only the red Mg(II)–PPOH complex formed at pH 4.2 and 50° (acetic acid–sodium acetate buffer) is of any photometric analytical interest. The fluorescence reactions are not important. Only V(V) and Al(III) show fluorescence which is different from that of the reagent, but the sensitivity is low.

Oxidation of PPOH and catalytic action of cyanide

The excitation and emission spectra of PPOH show a hypsochromic change in basic (λ_{ex} 350 nm, λ_{em} 420 nm) and acid (λ_{ex} 320 nm, λ_{em} 395 nm) media in presence of such oxidizing agents as KIO_3, H_2O_2, $K_2S_2O_8$ and $NaIO_4$. Solutions of PPOH in ammonia–ammonium chloride buffer show identical
Fig. 1. Catalytic effect of cyanide on the oxidation of PPOH by dissolved oxygen. Excitation and emission spectra. 1,1': PPOH; 2,2': PPOH + CN^-. [PPOH] = $8 \times 10^{-5}M$; [CN^-] = 0.4 μg/ml; [NH_4Cl–NH_3] = 0.4M. Graphs were recorded after a reaction time of 1 hr. Temperature 50°C.

fluorescence maxima (λ_{ex} 350 nm, λ_{em} 420 nm) to those obtained in the presence of oxidants but the formation of the fluorescent product is so slow that it takes several days for a detectable amount to be produced. In the presence of traces of cyanide, the oxidation rate of PPOH by dissolved oxygen is accelerated. This effect is shown in Fig. 1. The catalytic nature of the cyanide reaction is revealed by the fact that it does not take place in an inert atmosphere. When oxidants are utilized, the reagent is oxidized immediately, and cyanide then does not have a catalytic effect.

Several tests have been made to characterize the oxidation product of PPOH and establish the mechanism of the reaction, with the following results

(a) The characteristic absorption peak at 305 nm of the Schiff's base formed between pyridoxal-5-phosphate and oxalylhydrazide disappears in the course of the reaction. This seems to be due to hydrolytic breaking of the azomethine group.

(b) The fluorescence maxima corresponding to the reagent (λ_{ex} 400 nm, λ_{em} 510 nm) disappear like the absorption maximum, but an intermediate product (λ_{ex} 320 nm, λ_{em} 370 nm) can be observed before the formation of the final product (λ_{ex} 350 nm, λ_{em} 420 nm). This intermediate is in equilibrium with PPOH and subsequently with the final product, and its fluorescence characteristics are the same as those of the pyridoxal-5-phosphate.[13] This seems to corroborate the supposition of hydrolytic breaking.

(c) The fluorescence maxima of the oxidation product of PPOH are similar to those reported for a solution of pyridoxal-5-phosphate treated with hydrogen peroxide, which forms 4-pyridoxic acid.

From these observations it can be inferred that the likely oxidation mechanism consists of hydrolytic
Fig. 2. Effect of the temperature (A), pH (B) and PPOH concentration (C) on the reaction rate of the PPOH–O$_2$–CN$^-$ system.

breaking of the azomethine group and oxidation of the resulting compounds.

Several attempts have been made to isolate the highly water-soluble fluorescent species from mixtures of the parent reagent and cyanide, but without success. Evaporation yielded a reddish brown liquid which would not crystallize. Addition of ethanol produced a yellow solid, the excitation and emission spectra of which were identical to those obtained in the analytical test, but this solid was water-soluble and non-extractable by water-immiscible organic solvents, and was contaminated by the reagent, so meaningful ultraviolet and infrared spectra could not be obtained. Attempts to obtain a pure product by thin-layer chromatography were unsuccessful.

Influence of reaction variables on the oxidation

The temperature of the cell-holder was varied over the range 35–70° (Fig. 2A). The reaction rate increased linearly withtemperature increase between 35 and 60° but less steeply at higher temperatures. A temperature of 62° was selected for use. From Arrhenius plots of ln k vs. reciprocal of the absolute temperature, the activation energy for the catalysed reaction was calculated to be 5.1 ± 0.1 kcal/mole.

The effect of pH on the reaction rate is given in Fig. 2B. The optimum pH is 9.7–10.0. The effect of the type of buffer (phosphate, carbonate, ammonia) was examined. The reaction develops only in the presence of ammonia–ammonium chloride buffer, and is linearly related to the buffer concentration up to at least $4M$. A $3M$ concentration was chosen.

The influence of the PPOH concentration was tested in the range 5×10^{-6}–$10^{-4}M$ and is shown in Fig. 2C. A purely aqueous solution could not be used because of its instability, so a methanol solution was used. However, increasing the methanol content of the final aqueous methanol medium decreased the reaction rate, so its concentration in the solution measured was minimized.

The rate of reaction rises with increasing ionic strength up to $1M$ and then remains constant.

The fluorescence intensity vs. time curves for different cyanide concentrations were recorded. The initial slopes indicate a first-order reaction with respect to cyanide.

The various kinetic dependences on pH (Fig. 2B), reagent concentration (Fig. 2C) and buffer concen-

tration are summarized in Table 1, and the following equation is suggested for the oxidation of PPOH ($3.5 \times 10^{-5}M$) by dissolved oxygen at pH 9.85 in the presence of $3M$ ammonia buffer and cyanide as catalyst:

$$d[\text{PPOH}]_{\text{ox}}/dt = k[\text{NH}_4\text{Cl–NH}_3]^{3/2}[\text{CN}^-]$$

in which $[\text{PPOH}]_{\text{ox}}$ is the concentration of oxidized reagent and k is the conditional rate constant. This equation does not include the effect of the uncatalysed reaction.

Calibration graphs

Three kinetic methods have been tested for the determination of cyanide: tangent ([CN$^-$] 10–180 ng/ml), fixed-time ([CN$^-$] 3–180 ng/ml) and variable-time ([CN$^-$] 3–60 ng/ml).[14] For the fixed-time method, measurements were made after 7 min. For the variable-time method, the inverse of the time necessary to obtain a relative fluorescence intensity of 30% was plotted against the cyanide concentration.

The relative standard deviation for 50 ng/ml cyanide ($P = 0.05$, $n = 11$) is smaller for the initial-rate method ($\pm 0.4\%$) than the fixed-time ($\pm 0.8\%$) and the variable-time ($\pm 0.7\%$) methods.

The initial-rate method is recommended when precision is the prime consideration and the fixed-time method when a low detection limit is the important factor.

Interferences

The effect of 35 anions and 21 cations on the determination of cyanide was tested. The tangent method was used because a change in slope could be more clearly detected than a change in a single data point. The tolerance limits for interfering ions are

Table 1. Summary of kinetic data

Dependence of V_0 on	Concentration range, M
[H$^+$]	4.5×10^{-11}–7.9×10^{-11}

less than 1	Hg^{2+}

summarized in Table 2; 45 of the ions tested did not affect the determination of cyanide when present in 100-fold ratio to it. Silver interferes when present at the same level as cyanide, but mercury(II) interferes at even lower concentrations. Hence, the method is highly specific.

Applications

The determination of microamounts of cyanide in industrial effluents is of interest owing to its toxicity. The pyridine–barbituric acid colorimetric method recommended[10] has a detection limit of 4 ng/ml for cyanide. To determine cyanide in water samples by this method, it is necessary first to separate it from interfering substances by distillation of hydrocyanic acid from the acidified sample. It is well known,[8] and has been verified by us, that when the equipment and conditions described[10] for the distillation are used, the cyanide is not quantitatively recovered at levels below 1 μg/ml in the original sample. The reasons for this

have been investigated[15] and it was found that the hydrocyanic acid is completely distilled but not totally absorbed in the collection solution. The distillation also takes about 90 min.

Because of its high selectivity, we have used the new method for determination of cyanide in several samples without preliminary distillation. Three types of sample were investigated.

Water and air from an electroplating factory. Several samples of water and air were analysed by both the fluorimetric and the standard colorimetric method, with and without distillation. As the true cyanide concentration in the samples was unknown, the distillation was included, on the assumption that the determination could be taken as free of interferences if the results obtained with and without distillation agreed. The air sample (90 litres) was aspirated at 1.5 l./min through three impingers connected in series, each containing 10 ml of 0.1M sodium hydroxide; the solutions were mixed for

5. Copper-plating bath: CuCN (2.6%), NaCN (3.4%), Na$_2$CO$_3$ (1.5%), NaKC$_4$H$_4$O$_6$.4H$_2$O (3.6%).
6. Cadmium-plating bath: CdO (2.6%), NaCN (9%), Na$_2$CO$_3$ (1.5%).
7. Silver-plating bath: AgCN (0.4%), NaCN (6%), Na$_2$CO$_3$ (0.8%).

analysis. A cellulose ester filter was inserted in the sampling line to retain particulate matter.

The results obtained are shown in Table 3. No cyanide was detectable in the water entering the plating bath (sample 1). The value found by the standard method without distillation was probably due to positive interferences, which were also found in samples 2 and 3. The agreement of the values obtained for these samples by the fluorimetric method with and without distillation shows that this preliminary step is not necessary. Owing to the low

concentration of cyanide in sample 4, no results were obtained when distillation was used. The sample of air (sample 5) also contained a low amount of cyanide and gave the same results by the two methods.

Water from synthetic plating solutions. The results obtained with the fluorimetric method for the real samples described above agree with those obtained by the standard method with prior distillation, but, owing to the low concentration of cyanide in some of these samples, it was not possible to obtain reliable results for all of them by use of distillation. For this reason, several synthetic plating solutions were prepared.[16] To obtain a final cyanide concentration similar to that in the waste-water from washing of plated pieces, these solutions were diluted 10000-fold with water. Table 4 shows the values obtained by the fluorimetric method without distillation, and the initial compositions of the solutions. The accuracy of the results proves that preliminary distillation is not necessary, at least for this type of sample.

Other synthetic samples. A series of synthetic samples containing several mixtures of ions which usually interfere in other methods for cyanide determination were prepared, in order to explore the application of the fluorimetric method. Cyanide was determined in several binary, ternary and quaternary mixtures, and the results are summarized in Table 5 and compared with those obtained by the colorimetric method. The standard colorimetric method gave higher errors than the fluorimetric method for all the samples.

Comparison with other methods

Comparison of the fluorimetric determination reported here with the fluorimetric procedures described in the literature leads to the following considerations. Only three other methods have determination limits similar to those in our method. They are based on (a) the catalytic action of cyanide on the

oxidation of pyridoxal to 4-pyridoxolactone,[6] (*b*) the ligand-exchange reaction between cyanide and the non-fluorescent complex Cu(II)–leucofluorescein,[17] and (*c*) quenching of the fluorescence of 2-(*o*-hydroxyphenol)benzoxazole by copper.[18] The first of these involves two steps in the sample preparation and a period of 50 min for the final fluorescence development, whereas only 3–7 min reaction monitoring is needed in our method reported here. Furthermore, the oxidation of pyridoxal is not specific for cyanide, there being numerous interferences.[7] The second method has a relative standard deviation of 10% for 5 ng/ml cyanide, and sulphide and strongly oxidizing and reducing anions must be absent. At this cyanide level our method has a relative standard deviation of only 4.4%. No data have been reported on the selectivity and precision of the third method. This method has also been proposed for the determination of sulphide, and therefore this ion must be absent. The pyridine–barbituric acid method is also not specific, and a preliminary distillation is necessary to avoid interference.

VOLTAMMETRIC INTERPRETATION OF THE POTENTIAL AT AN ION-SELECTIVE ELECTRODE, BASED ON CURRENT-SCAN POLAROGRAMS OBSERVED AT THE AQUEOUS/ORGANIC SOLUTION INTERFACE*

SORIN KIHARA

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611, Japan

ZENKO YOSHIDA

Analytical Chemistry Laboratory, Japan Atomic Energy Research Institute, Tokai, Ibaraki 319-11, Japan

Summary—The potential-generating process at ion-selective electrodes (ISE) of liquid-membrane types has been interpreted by comparing the ISE potential with the current-scan polarogram which indicates the transfer of a particular ion i^{z+} at the aqueous/organic solution (w/o) interface. The potential at zero current, $\Delta V_{I=0}$, in the composite polarogram observed with i^{z+} in both w and o, corresponds to the ISE potential. A stable potential giving Nernstian response to the concentration of i^{z+} in w is obtained at the ISE only when the w/o interface is depolarized by i^{z+}. The detection limits are controlled by the final rise and final descent of the residual current in the polarogram. The interference of a second ion, j^{z+}, in the ISE measurement of i^{z+}, and the role of an ionophore in the membrane of the ISE can be explained by considering the shift of $\Delta V_{I=0}$ in the composite polarogram of i^{z+} in the presence of j^{z+} in w or the ionophore in o. Equations which express the ISE potential, the interference at the ISE, and the effect of an ionophore on the ISE potential have been derived, connected with the polarographic equations for ion-transfer at the w/o interface.

In potentiometry the potential is measured at negligible current-flow, as is well known. This condition, however, does not necessarily mean that electron-transfer at the solution/electrode interface is negligibly small. The equilibrium potential in potentiometry is attained when the rate of the anodic reaction is equivalent to that of the cathodic reaction.[1] The potential at an ion-selective electrode (ISE) should also be interpreted in terms of the above-mentioned concept, although most of the electrode reaction at the solution/membrane interface of an ISE is attributed not to electron transfer but to ion-transfer as represented in equation (1):

$$i_w^{z+} \rightleftharpoons i_m^{z+} \qquad (1)$$

where subscripts w and m indicate the ion i^{z+} in water and in the membrane, respectively.

Koryta[2,3] and Fujinaga[4] advocated that the potential at the ISE, and such important factors in the ISE measurement as Nernstian response, detection limit, and interference, must be explained on the basis of the voltammetry of the ion-transfer at the solution/membrane interface. To realize this idea Koryta presented various voltamperograms for the water/organic solution interface, which were obtained by simulation from extraction data, with certain assumptions.

In a previous communication,[5] we presented several polarograms obtained by polarography at the dropping aqueous-electrolyte electrode (DAEE) combined with the current-scan method[6] and explained briefly the potential-generating process at the ISE on the basis of the polarographic results.

In the present paper, a quantitative interpretation of the potential-generation process is deduced from more detailed experimental results, and the role of the ionophore in the membrane of the ISE is also discussed.

EXPERIMENTAL

Polarographic measurement

The current-scan polarograms were recorded with use of a polarographic cell identical with that described previously.[6] The aqueous electrolyte solution (w), containing $1M$ magnesium sulphate as supporting electrolyte, was forced upward dropwise into nitrobenzene solution (nb) containing $0.05M$ tetrabutylammonium tetraphenylborate (TBA$^+$TPhB$^-$) or $0.02M$ tetraphenylarsonium dipicrylaminate (TPhAs$^+$DPA$^-$) as supporting electrolyte, through a Teflon capillary (1.4 mm bore and 3 mm long) at a mean flow-rate of $m = 0.028$ ml/sec, the time per drop being about 2.1 sec. For the polarographic study, the current, I, applied at the w/nb interface was scanned at a rate v of 0.5 μA/sec. In order to detect the potential difference, ΔV, at the w/nb interface, a silver–silver chloride electrode (SSE) and a tetramethylammonium electrode (TMAE) were set in the aqueous and the nb solutions, respectively, close to the

---

interface. To compensate the ohmic-potential IR drop caused by the resistance, R, between the SSE and TMAE, a resistance R_c equivalent to R was put in series into the current-supplying circuit and the voltage, IR_c, generated by R_c was subtracted automatically from ΔV.[6]

The composition of the TMAE and the cell configuration for the potential measurement are as follows:

SSE (Ag–AgCl, 1M LiCl) (aqueous)	1M LiCl + 10^{-3}M TMA$^+$Br$^-$ (aqueous)	10^{-3}M TMA$^+$TPhB$^-$ or 10^{-3}M TMA$^+$DPA$^-$ (nitrobenzene)

Tetramethylammonium electrode (TMAE)

where TMA$^+$ and i^{z+} are the tetramethylammonium ion and the cation of charge $z+$ under investigation.

The potential of the TMAE is controlled by the Galvani potential difference, $\Delta_{nb}^{w}\phi$, at the w/nb interface, which can be expressed as

$$\Delta_{nb}^{w}\phi = \Delta_{nb}^{w}\phi^{\circ}_{\text{TMA}^+} + (RT/F)\ln(a_{\text{TMA}^+,w}/a_{\text{TMA}^+,nb}) \quad (3)$$

where $\Delta_{nb}^{w}\phi^{\circ}_{\text{TMA}^+}$ is the standard Galvani potential for the transfer of TMA$^+$ from w to nb, and a_{TMA^+} indicates the activity of TMA$^+$. The value of $\Delta_{nb}^{w}\phi^{\circ}_{\text{TMA}^+}$ was found to be 0.035 V by Koryta *et al.*,[7] by using the standard Gibbs energy for the transfer of TMA$^+$, calculated from distribution data with the extrathermodynamic assumption of Parker[8] and Popovych[9] that the transfer energies of TPhAs$^+$ and of TPhB$^-$ across the w/nb interface are equal.

ISE measurement

The cell configuration for the measurement of the ISE potential is summarized in equation (4):

SSE (satd. KCl) (aqueous)	i^{z+}Br$_z^-$ or i^{z+}Cl$_z^-$ (aqueous, inner solution)	i^{z+}(TPhB$^-$)$_z$ or i^{z+}(DPA$^-$)$_z$ (nitrobenzene, liquid membrane)	i^{z+}Br$_z^-$ or i^{z+}Cl$_z^-$ (aqueous, test solution)	SSE (satd. KCl) (aqueous)

(4)

For comparison of the results obtained by polarography with those by ISE measurement, the supporting electrolytes used in the polarographic study were also used in the aqueous inner and test solutions and the nb membrane solution in the ISE cell.

In order to prepare i^{z+}(TPhB$^-$)$_z$ or i^{z+}(DPA$^-$)$_z$ in nb, i^{z+}Br$_z^-$ or i^{z+}Cl$_z^-$ was mixed with Na$^+$TPhB$^-$ or Na$^+$DPA$^-$ in water and the precipitate produced was extracted into nb.

Sigma Chemical Co. valinomycin was used. All other reagents were of reagent grade and all measurements were made at $25 \pm 1°$.

RESULTS

Current-scan polarograms of various ions at the w/nb interface

In the following, we define the transfer of a cation from w to nb or an anion from nb to w as the anodic reaction and that of an anion from w to nb or a cation from nb to w as the cathodic reaction.

The polarogram realized in curve 1 of Fig. 1 was obtained at the DAEE (containing $5 \times 10^{-4}M$ TMA$^+$) transferring drops into an nb solution which did not contain TMA$^+$. (For raw polarograms see references 5 and 6). The polarogram indicates the reversible transfer of TMA$^+$ from w to nb [reaction (5)] and the limiting current is proportional to the concentration of TMA$^+$ in the DAEE, over the range

2×10^{-5}–$10^{-3}M$.

$$\text{TMA}^+_w \rightarrow \text{TMA}^+_{nb} \quad (5)$$
Curve 2 shows the reversible transfer of TMA$^+$ from nb to w [reaction (6)] and the limiting current is

i^{z+}(TPhB$^-$)$_z$ + 0.05M TBA$^+$TPhB$^-$ or i^{z+}(DPA$^-$)$_z$ + 0.02M TPhAs$^+$DPA$^-$ (nitrobenzene)	i^{z+}Br$_z^-$ or i^{z+}Cl$_z^-$ + 1M MgSO$_4$ (aqueous, DAEE)	SSE (Ag–AgCl, 1M LiCl) (aqueous)

(2)
proportional to the concentration of TMA$^+$ in the nb solution, over the range from 5×10^{-5} to $10^{-3}M$.

$$\text{TMA}^+_{nb} \rightarrow \text{TMA}^+_w \quad (6)$$

Curve 3 is the composite polarogram obtained under the same conditions as curve 1 or 2, but with $5 \times 10^{-4}M$ TMA$^+$ in both the DAEE and nb. The composite polarogram sharply intersects the potential axis where the current, I, is zero, suggesting that the w/nb interface is depolarized. The zero-current potential, $\Delta V_{I=0}$, of the composite polarogram becomes about 60 mV more negative when the concentration of TMA$^+$ in the DAEE is increased by one order in the range between 5×10^{-5} and $5 \times 10^{-1}M$

(curves 3–7), and more positive when the concentration of TMA$^+$ in the nb solution is increased by one order in the range between 5×10^{-5} and $5 \times 10^{-3}M$, (*e.g.*, curves 9 and 10). With more than $0.5M$ or less than $10^{-5}M$ TMA$^+$ in the DAEE the composite polarograms overlap the final descent or the final rise, respectively, of the residual current (curve 11).

By varying the concentration of TBA$^+$TPhB$^-$ and changing the supporting electrolyte from TBA$^+$TPhB$^-$ to TPhAs$^+$DPA$^-$, it was confirmed that the anodic final rise and the cathodic final descent in polarogram 11 in Fig. 1 were attributable to the transfer of TPhB$^-$ and TBA$^+$, respectively, from nb to w.

Polarogram 3 in Fig. 1 is reproduced as curve 1 in Fig. 2. Polarograms 2 and 3 in Fig. 2, which show the transfer of Cs$^+$ and tetraethylammonium ion (TEA$^+$) from w to nb solution were recorded under the same conditions as those for curve 1 in Fig. 1, but with $5 \times 10^{-4}M$ concentration of these ions instead of TMA$^+$ in the DAEE. Curves 4 and 5 show composite polarograms recorded with the DAEE containing $5 \times 10^{-4}M$ Cs$^+$ and TEA$^+$, respectively, in addition to $5 \times 10^{-4}M$ TMA$^+$, and nb solution containing $5 \times 10^{-4}M$ TMA$^+$. The $\Delta V_{I=0}$ of the composite polarogram of TMA$^+$ is hardly affected by the Cs$^+$
Fig. 1. Polarograms for the transfer of TMA$^+$ at the w/nb interface. Concentration of TMA$^+$Br$^-$ in w (M): (1), (3), (9), (10), 5×10^{-4}; (4), 5×10^{-5}; (5), 5×10^{-3}; (6), 5×10^{-2}; (7) 5×10^{-1}; (8), 5; (2), (11), 0. Concentration of TMA$^+$TPhB$^-$ in nb (M): (2)–(8), 5×10^{-4}; (9), 1×10^{-3}; (10), 5×10^{-3}; (1), (11), 0. Supporting electrolyte in w: $1M$ MgSO$_4$; in nb: $0.05M$ TBA$^+$TPhB$^-$.

in the DAEE, whereas it is strongly influenced by TEA$^+$.

The effect of supporting electrolyte on the residual current

The final rise or final descent of the residual-current polarogram appears at a different potential when the kind of supporting electrolytes and their concentration in the DAEE or the nb solution are changed, as shown in Fig. 3. The anodic final rise shifts to more negative potentials as the cations in w or the anions in nb are more easily transferred across the w/nb interface, and the cathodic final descent shifts to more positive potentials as the anions in w or the cations in nb are transferred more easily across the interface.[7] The results in Fig. 3 indicate that the widest potential window is achieved in polarography with magnesium sulphate or sodium carbonate and TPhAs$^+$TPhB$^-$ or TPhAs$^+$DPA$^-$ as the supporting electrolytes in the DAEE and nb solution, respectively. The use of TPhAs$^+$TPhB$^-$ is, however, restricted because of its low solubility in nb.

Polarograms of K^+ and Na^+ in the absence and presence of valinomycin in the nb solution

The polarograms illustrated in Figs. 4 and 5 are obtained with the DAEE containing various concentrations of potassium chloride (Fig. 4) or sodium chloride (Fig. 5) and nb solution containing $2 \times 10^{-3}M$ K$^+$TPhB$^-$ with or without valinomycin

Fig. 2. Polarograms for the transfer of TMA$^+$, Cs$^+$, and TEA$^+$ at the w/nb interface. Depolarizer(s) ($5 \times 10^{-4}M$) in w: (1) TMA$^+$Br$^-$; (2), (6), Cs$^+$Br$^-$; (3), (7), TEA$^+$Br$^-$; (4), TMA$^+$Br$^-$ + Cs$^+$Br$^-$; (5) TMA$^+$Br$^-$ + TEA$^+$Br$^-$. Depolarizer ($5 \times 10^{-4}M$) in nb: (1), (4), (5), TMA$^+$TPhB$^-$; (6) Cs$^+$TPhB$^-$; (7) TEA$^+$TPhB$^-$; (2), (3) none. Supporting electrolyte in w: $1M$ MgSO$_4$; in nb: $0.05M$ TBA$^+$TPhB$^-$.
Fig. 3. Residual current in polarograms with various supporting electrolytes. Supporting electrolytes ($1M$) in w: (1), LiCl; (2), HCl; (3), NaCl; (4), KCl; (5), Na$_2$SO$_4$; (6), Na$_2$CO$_3$; (7), NaNO$_3$; (8), NaSCN; (9), NaClO$_4$; (10), (11), MgSO$_4$. Supporting electrolytes in nb: (1)–(10), $0.02M$ TPhAs$^+$DPA$^-$; (11), $0.05M$ TBA$^+$TPhB$^-$.
Fig. 4. Composite polarograms observed with K^+ in w and K^+ in nb in the absence (a) and presence (b) of $3.75 \times 10^{-3}M$ valinomycin in nb. Concentration of K^+Cl^- in w (M): (1), (2), 0; (3), 2×10^{-4}; (4), 5×10^{-4}; (5), 2×10^{-3}; (6), 5×10^{-3}; (7), 5×10^{-2}; (8), 5×10^{-1}. Concentration of K^+TPhB^- in nb (M): (1), 0; (2)–(8) 2×10^{-3}. Supporting electrolyte in w: $1M$ $MgSO_4$; in nb: $0.02M$ $TPhAs^+DPA^-$.

the DAEE was $>10^{-2}M$. This shift is attributed to the transfer of Cl^- from w to nb.

The anodic final rise in the residual polarogram obtained with nb solution containing $3.75 \times 10^{-3}M$ valinomycin and aqueous solution containing no potassium or sodium chloride (curve 1 in Fig. 4b or 5b) shifted by about -130 mV from that obtained in the absence of valinomycin in the nb solution (curve 1 in Fig. 4a or 5a). This potential shift might be attributed to complex formation of valinomycin with magnesium.[10]

$(3.75 \times 10^{-3}M)$. The presence of valinomycin in the nb solution facilitates the transfer of K^+ and Na^+ from w to nb. When the concentration of K^+ or Na^+ in the DAEE was larger than that of uncombined valinomycin in nb, the anodic limiting current controlled by the concentration of uncombined valinomycin was observed. The cathodic final descent shifted to more positive potential when the concentration of potassium chloride or sodium chloride in

Fig. 5. Composite polarograms observed with Na^+ in w and K^+ in nb in the absence (a) and presence (b) of $3.75 \times 10^{-3}M$ valinomycin in nb. Concentration of Na^+Cl^- in w (M): (1), (2), 0; (3), 5×10^{-4}; (4), 2×10^{-3}; (5), 5×10^{-3}; (6), 5×10^{-2}; (7), 5×10^{-1}. Concentration of K^+TPhB^- in nb (M): (1), 0; (2)–(7) 2×10^{-3}. Supporting electrolyte in w: $1M$ $MgSO_4$; in nb: $0.02M$ $TPhAs^+DPA^-$.
Fig. 6. Potential measured at the *nb* membrane ISE for TMA$^+$. Concentration of TMA$^+$TPhB$^-$ in the membrane (M): (1), 5×10^{-5}; (2), (5)–(9), 5×10^{-4}; (3), 5×10^{-3}; (4), 0. Concentration of TMA$^+$Br$^-$ in the inner solution: $5 \times 10^{-4}M$. Supporting electrolyte in inner and test solutions: (1)–(4), none; (5), (8), (9), $1M$ MgSO$_4$; (6), $1M$ HCl; (7), $1M$ NaNO$_3$; in the membrane: (1)–(7), none; (8), $0.05M$ TBA$^+$TPhB$^-$; (9), $0.02M$ TPhAs$^+$DPA$^-$.

The concentration ranges where $\Delta V_{I=0}$ shifts by -60 mV for increase of one order of magnitude in the concentration of K$^+$ or Na$^+$ in the DAEE are $>5 \times 10^{-4}M$ K$^+$ and $>5 \times 10^{-2}M$ Na$^+$ in the absence of valinomycin, but from 2×10^{-4} to $2 \times 10^{-2}M$ for K$^+$ and from 5×10^{-3} to $5 \times 10^{-1}M$ for Na$^+$ in the presence of $3.75 \times 10^{-3}M$ valinomycin in the *nb* solution.

Potentials measured at the liquid-membrane ISE

The relation between the concentration of TMA$^+$ in the test solution and the ISE potential measured at the ISE of equation (4) is shown in Fig. 6. Curves 1–3 were obtained with the ISE cell, in which the *nb* membrane and the inner solution contained various concentrations of TMA$^+$TPhB$^-$ and $5 \times 10^{-4}M$ TMA$^+$Br$^-$, respectively, without any other electrolytes. When the concentration of TMA$^+$ in the membrane was $5 \times 10^{-5}M$, $5 \times 10^{-4}M$ or $5 \times 10^{-3}M$, the ISE potential was proportional to the logarithm of the concentration of TMA$^+$ in the test solution in the range from 10^{-7} to $10^{-2}M$, from 10^{-6} to $10^{-1}M$ or from 10^{-5} to $1M$, respectively. When the ISE was used without TMA$^+$ in the membrane, Nernstian response could not be obtained, as shown in curve 4. Adding such electrolytes as $1M$ magnesium sulphate, hydrochloric acid or sodium nitrate to the inner and to the test solutions or $0.05M$ TBA$^+$TPhB$^-$ or $0.02M$ TPhAs$^+$DPA$^-$ to the membrane, changed the upper or lower detection limits as shown in curves 5–9 in Fig. 6.

The ISE measurement of TMA$^+$ at a concentration $<5 \times 10^{-3}$ or $5 \times 10^{-5}M$ is interfered with by $5 \times 10^{-4}M$ TEA$^+$ or $5 \times 10^{-4}M$ Cs$^+$, respectively, in the test solution.

The relation between the concentration of potassium chloride in the test solution and the ISE potential was investigated by use of the ISE cell with a membrane containing $5 \times 10^{-4}M$ K$^+$DPA$^-$ (curve 1 in Fig. 7). The lower detection limit for K$^+$ with this ISE cell is $10^{-3}M$. The presence of $0.5M$ sodium chloride in the test solution interferes in the ISE measurement of less than $0.02M$ K$^+$. When $3.75 \times 10^{-3}M$ valinomycin is added to the membrane, the lower as well as the upper detection limits for K$^+$ are lowered, and it becomes possible to determine $5 \times 10^{-4}M$–$5 \times 10^{-2}M$ K$^+$ even in the presence of $0.5M$ sodium chloride.

DISCUSSION

Koryta *et al.*[7] discussed the transfer of ions under Faradaic current-flow at the interface of two immiscible electrolyte solutions, by analogy with the transfer of metal ions at the solution/metal amalgam interface, as deduced by Delahay,[11] and derived an equation which expresses the polarographic wave observed at the DAEE for the reversible transfer of an ion i^{z+} from phase α to phase β. With α and β the aqueous and organic phases, respectively, and taking our definition of anodic and cathodic reactions into account, we obtain equations (7) and (8) for the Galvani potential difference at the α/β interface, $\Delta_\beta^\alpha \phi$, and the average current, I, due to the transport of i^{z+} to the interface under the polarographic condition.

$$\Delta_\beta^\alpha \phi = \Delta_\beta^\alpha \phi_{i^+}^0 - (RT/zF) \ln (a_{i^+,\alpha}^{x=0}/a_{i^+,\beta}^{x=0}) \tag{7}$$

$$I = \kappa_{i^+,\alpha}(a_{i^+,\alpha} - a_{i^+,\alpha}^{x=0})$$

$$= \kappa_{i^+,\beta}(a_{i^+,\beta}^{x=0} - a_{i^+,\beta}) \tag{8}$$
Fig. 7. Potential measured at *nb* membrane ISE for K$^+$ with and without valinomycin in the membrane. Concentration of K$^+$DPA$^-$ in the membrane: $5 \times 10^{-4}M$. Concentration of valinomycin in the membrane: (1), (2), 0; (3), (4), $3.75 \times 10^{-3}M$. Concentration of Na$^+$Cl$^-$ co-existing in the test solution: (1), (3), 0; (2), (4), $5 \times 10^{-1}M$.

where $\Delta_\beta^\alpha\phi_{\hat{\imath}^{z+}}^0$ is the standard Galvani potential difference for the ion transfer of i^{z+} between α and β, $\kappa_{\hat{\imath}^{z+},\alpha}$ and $\kappa_{\hat{\imath}^{z+},\beta}$ are the coefficients of the Ilkovič equation, given by equations (9) and (10), and $a_{\hat{\imath}^{z+}}^{x=0}$ and $a_{\hat{\imath}^{z+}}$ are the surface activity and the bulk activity of i^{z+} in each phase, respectively.

$$\kappa_{\hat{\imath}^{z+},\alpha} = KzFD_{\hat{\imath}^{z+},\alpha}^{1/2}m^{2/3}t^{1/6} \quad (9)$$

$$\kappa_{\hat{\imath}^{z+},\beta} = KzFD_{\hat{\imath}^{z+},\beta}^{1/2}m^{2/3}t^{1/6} \quad (10)$$

Here, $D_{\hat{\imath}^{z+},\alpha}$ and $D_{\hat{\imath}^{z+},\beta}$ are the diffusion coefficients of i^{z+} in the α and β phases, K is the Ilkovič constant, m is the volume flow-rate of the dropping electrolyte, and t is the electrolyte drop-time. The Ilkovič constant K had been determined by Samec et al.[12] to be 3.57, taking I, a, D, m and t in ampere, mole/ml, cm²/sec, ml/sec, and sec respectively. If i^{z+} was originally present only in α or β, the polarogram can be described by equation (11) or (12), respectively. These equations are derived by using equations (7)–(10).

obtained at the ISE only when the test solution/membrane interface is depolarized by the analyte ions, as pointed out by Koryta[2,3] and Fujinaga.[4]

Here, it should be stressed that zero current in the composite polarogram does not mean that there is no charge or mass transfer at the interface, but that the rate of transfer by the anodic reaction is equal to that by the cathodic reaction. That is to say,

$$I_{a,\hat{\imath}^{z+}} + I_{c,\hat{\imath}^{z+}} = 0 \quad (16)$$

By using equations (11)–(16), we obtain equation (17), which is similar to equation (7) but contains the bulk activities instead of surface activities of i_α^{z+} and i_β^{z+}.

$$\Delta V_{I=0} + \text{const} = (\Delta_\beta^\alpha\phi)_{I=0}$$

$$= \Delta_\beta^\alpha\phi_{\hat{\imath}^{z+}}^0 - (RT/zF)$$

$$\times \ln(a_{\hat{\imath}^{z+},\alpha}/a_{\hat{\imath}^{z+},\beta}) \quad (17)$$

$$I_{a,\hat{\imath}^{z+}} = I_{ad,\hat{\imath}^{z+}}/[1 + (D_{\hat{\imath}^{z+},\alpha}/D_{\hat{\imath}^{z+},\beta})^{1/2}\exp\{-zF(\Delta_\beta^\alpha\phi - \Delta_\beta^\alpha\phi_{\hat{\imath}^{z+}}^0)/RT\}] \quad (11)$$

$$I_{c,\hat{\imath}^{z+}} = \frac{I_{cd,\hat{\imath}^{z+}} + (D_{\hat{\imath}^{z+},\alpha}/D_{\hat{\imath}^{z+},\beta})^{1/2}\exp\{-zF(\Delta_\beta^\alpha\phi - \Delta_\beta^\alpha\phi_{\hat{\imath}^{z+}}^0)/RT\}}{[1 + (D_{\hat{\imath}^{z+},\alpha}/D_{\hat{\imath}^{z+},\beta})^{1/2}\exp\{-zF(\Delta_\beta^\alpha\phi - \Delta_\beta^\alpha\phi_{\hat{\imath}^{z+}}^0)/RT\}]} \quad (12)$$

where $I_{a,\hat{\imath}^{z+}}$ and $I_{c,\hat{\imath}^{z+}}$ are the average anodic and cathodic currents and $I_{ad,\hat{\imath}^{z+}}$ and $I_{cd,\hat{\imath}^{z+}}$ are the average anodic and cathodic limiting currents, which are given by equations (13) and (14):

$$I_{ad,\hat{\imath}^{z+}} = \kappa_{\hat{\imath}^{z+},\alpha}a_{\hat{\imath}^{z+},\alpha} \quad (13)$$

$$I_{cd,\hat{\imath}^{z+}} = -\kappa_{\hat{\imath}^{z+},\beta}a_{\hat{\imath}^{z+},\beta} \quad (14)$$

The electrical potential difference, ΔV, is given by

$$\Delta V + \text{const} = \Delta_\beta^\alpha\phi \quad (15)$$

The constant in equation (15) depends only on the composition of the solutions of the base electrolyte, on liquid-junction potentials, and on the reference electrodes, and is independent of the nature of the ion i^{z+}.

Nernstian response at the ISE

The results gathered in Fig. 6 clearly indicate that the ISE displays a stable potential and gives Nernstian response to the concentration of TMA⁺ in the test solution, when the membrane contains TMA⁺.

From the polarograms presented in Fig. 1, it is also clear that when both the DAEE and the organic solution contain the analyte ion and the transfer of the ion at the aqueous/organic solution interface is very fast, the polarograms sharply intersect the potential axis at $\Delta V_{I=0}$, which is uniquely determined by the concentration of the ion in the DAEE or in the organic solution. From the ISE and polarographic results, we conclude that Nernstian response is

This equation suggests that $\Delta V_{I=0}$ in the polarogram or the ISE potential is controlled not only by the activity of i^{z+} in the DAEE, $a_{\hat{\imath}^{z+},DAEE}$, or in the test solution, $a_{\hat{\imath}^{z+},test}$, but also by that in the organic solution, $a_{\hat{\imath}^{z+},org}$, or in the membrane, $a_{\hat{\imath}^{z+},m}$. In fact, $\Delta V_{I=0}$ given in Fig. 1 shifts by about +60 mV when the concentration of TMA⁺ in the nb solution is increased by a factor of 10, so the concentration in the DAEE remains constant. In the potential measured in the ISE cell of equation (4), the effect of $a_{\hat{\imath}^{z+},m}$ is not noticeable because the potential is measured as the difference between the potential at the inner solution/membrane interface and that at the test solution/membrane interface, and the effect cancels out. As mentioned later, however, the shift of the detection limit clearly indicates that the absolute potential at the individual interface changes, as a function of $a_{\hat{\imath}^{z+},m}$.

Detection limit in the ISE measurement

The composite polarogram and $\Delta V_{I=0}$ are affected by the anodic final rise or cathodic final descent of the residual current, when $a_{\hat{\imath}^{z+},DAEE}$ is sufficiently high or sufficiently low. Consequently, the shift of $\Delta V_{I=0}$ with $a_{\hat{\imath}^{z+},DAEE}$ is small in these concentration ranges. From comparison of the shift of $\Delta V_{I=0}$ in Fig. 1 with curve 8 in Fig. 6, it is clear that the dynamic concentration range detectable at the ISE is restricted by the same process as that which controls the shift of $\Delta V_{I=0}$.

The kind of supporting electrolytes and their concentration in the DAEE or in the organic solution

influence the final rise or the final descent in the polarogram. Hence, the detection limit at the ISE is affected by other salts present, as shown in Fig. 6.

The detection limit at the ISE is also controlled by $a_{i^z+,m}$ as indicated in Fig. 6, curves (1)–(3), because $\Delta V_{I=0}$ shifts towards more (or less) positive values and comes near to the anodic final rise (or the cathodic final descent) in the residual current with increase in the concentration of the analyte cation (or anion) in the organic solution (Fig. 1).

Interference in the ISE measurement

The polarogram for the transfer of j^{z+} from the α to the β phase is expressed by equation (18), similarly to equation (11) for i^{z+}

$$I_{a,j^z+} = I_{ad,j^z+}/[1 + (D_{j^z+,\alpha}/D_{j^z+,\beta})]^{1/2}$$

$$\times \exp\{- zF(\Delta_\beta^\alpha\phi - \Delta_\beta^\alpha\phi_{j^z+}^0)/RT\}] \quad (18)$$

The interference from j^{z+} in the ISE measurement of i^{z+} can be explained by considering the effect of j^{z+} in the DAEE on $\Delta V_{I=0}$ in the composite polarogram for i^{z+}. The zero-current potential of the composite polarogram recorded in the presence of both i^{z+} and j^{z+} in the DAEE and i^{z+} in the organic solution is obtained when

$$I_{a,i^z+} + I_{a,j^z+} + I_{c,i^z+} = 0 \quad (19)$$

From equations (11), (12), (18) and (19), we obtain

$$\Delta V_{I=0} + \text{const} = \Delta_\beta^\alpha\phi_{i^z+}^0 - (RT/zF)$$

$$\times \ln[\{-B + (B^2 - 4AC)^{1/2}\}/2A] \quad (20)$$

where

$$A = (D_{i^z+,\alpha}/D_{i^z+,\beta})^{1/2}(D_{j^z+,\alpha}/D_{j^z+,\beta})^{1/2}D_{i^z+,\beta}^{1/2}a_{i^z+,\beta} \quad (21)$$

$$B = (D_{i^z+,\alpha}/D_{i^z+,\beta})^{1/2}(D_{i^z+,\beta}^{1/2}a_{i^z+,\beta} - D_{j^z+,\alpha}^{1/2}a_{j^z+,\alpha})$$

$$\times exp\{- zF(\Delta_\beta^\alpha\phi_{j^z+}^0 - \Delta_\beta^\alpha\phi_{i^z+}^0)/RT\} \quad (22)$$

$$- (D_{j^z+,\alpha}/D_{j^z+,\beta})^{1/2}D_{i^z+,\alpha}^{1/2}a_{i^z+,\alpha}$$

$$C = - (D_{i^z+,\alpha}^{1/2}a_{i^z+,\alpha} + D_{j^z+,\alpha}^{1/2}a_{j^z+,\alpha})$$

$$\times \exp\{- zF(\Delta_\beta^\alpha\phi_{j^z+}^0 - \Delta_\beta^\alpha\phi_{i^z+}^0)/RT\} \quad (23)$$

The difference, $\Delta(\Delta V_{I=0})$, between equations (17) and (20) corresponds to the interference of j^{z+} in the ISE measurement of i^{z+}, and is given by

$$\Delta(\Delta V_{I=0}) = (RT/zF)\ln[(a_{i^z+,\beta}/a_{i^z+,\alpha})$$

$$\times \{-B + (B^2 - 4AC)^{1/2}\}/2A] \quad (24)$$

The effect of Cs^+ and TEA^+ in the test solution on the ISE potential of $5 \times 10^{-4}M$ TMA^+ at the ISE
Fig. 8. Effect of Cs^+ or TEA^+ on the ISE potential of $5 \times 10^{-4}M$ TMA^+. ——, – –, – – –; calculated, $\bigcirc$, $\bullet$; experimental. Foreign ion in the test solution: (1), Cs^+; (2)–(4), TEA^+. Concentration of TMA^+ in the membrane (M): (1), (3), 5×10^{-4}; (2), 5×10^{-3}; (4), 5×10^{-5}. Constants used for the calculation: diffusion coefficients $(10^{-6}$ cm²/sec): $D_{TMA+,w}$ 6.4; $D_{TMA+,nb}$ 3.3; $D_{Cs+,w}$ 7.7; $D_{Cs+,nb}$ 2.4; $D_{TEA+,w}$ 5.1; $D_{TEA+,nb}$ 2.8. Standard Galvani potential difference (V vs. TMAE); $\Delta_{nb}^w\phi_{TMA+}^0$ 0; $\Delta_{nb}^w\phi_{Cs+}^0$ + 0.107; $\Delta_{nb}^w\phi_{TEA+}^0$ - 0.105.

(the nb membrane of which contains $5 \times 10^{-4}M$ TMA^+) are calculated according to equation (24) and illustrated as curves 1–4 in Fig. 8. In this calculation the diffusion coefficients of the ions in w and nb were estimated from the average limiting currents in the polarograms illustrated in Fig. 2, by use of equations (9), (10), (13) and (14), and the $\Delta_\beta^\alpha\phi^0$ values were determined from $\Delta V_{I=0}$ in the same polarograms and equation (17), assuming that the constant is negligible and the activity coefficient is unity. These values are given in Fig. 8. The experimental results obtained with the ISE cell of equation (4) are also plotted in Fig. 8. The accordance of the experimental with the calculated results in Fig. 8, especially in the lower concentration ranges, suggests that the interference should be estimated on the basis of equation (24). The deviation between the experimental and calculated values at higher concentrations of TEA^+ is attributable to the final descent in the residual current restricting the shift of $\Delta V_{I=0}$ in the composite polarogram for $TMA_w^+ \rightleftarrows TMA_{nb}^+$ with $TEA_w^+ \rightarrow TEA_{nb}^+$.

From equation (24) it is obvious that the concentration of i^{z+} in the membrane is an important factor governing the magnitude of the interference.

With the aid of the conceptual polarograms in Fig. 9, the influence of the foreign ion, j^{z+}, on the ISE potential of i^{z+}, expressed by equation (24), can be intuitively understood. Curves 1–4 in Figs. 9a and 9b show polarograms for the transfer of j^{z+} in various concentrations from the aqueous (α) to the organic solution (β), $j_\alpha^{z+} \rightarrow j_\beta^{z+}$. Curve 5 is the composite polarogram of i^{z+}, $i_\alpha^{z+} \rightleftarrows i_\beta^{z+}$, and curves 1'–4' are those in the presence of j^{z+} in the aqueous phase, $i_\alpha^{z+} \rightleftarrows i_\beta^{z+}$ with $j_\alpha^{z+} \rightarrow j_\beta^{z+}$. Roughly speaking, the degree of interference of j^{z+} with the ISE potential of i^{z+} can be classified into two categories

(i) $\Delta_\beta^\alpha\phi_{j^z+}^0 < \Delta_\beta^\alpha\phi_{i^z+}^0$, Fig. 9a.

When $a_{j^{z}+,\alpha}$ is small enough to give a smaller limiting current, $I_{ad,j^{z}+}$, than that of i^{z+} in β, $I_{cd,i^{z}+}$, the deviation between $\Delta V_{I=0}$ in the presence of j^{z+}, $\Delta V_{I=0(i_{\alpha}+i_{\beta}+j_{\alpha})}$, and that in the absence of j^{z+}, $\Delta V_{I=0(i_{\alpha}+i_{\beta})}$, is small. At an $a_{j^{z}+,\alpha}$ at which $I_{ad,j^{z}+}$ is equal to $I_{cd,i^{z}+}$, $\Delta V_{I=0}$ jumps from around $\Delta V_{I=0(i_{\alpha}+i_{\beta})}$ to around $\Delta V_{I=0(i_{\beta}+j_{\alpha})}$ (Fig. 9a). Here $\Delta V_{I=0(i_{\beta}+j_{\alpha})}$ is $\Delta V_{I=0}$ in the composite polarogram formed from the cathodic polarogram for $i_{\beta}^{z+} \rightarrow i_{\alpha}^{z+}$ and the anodic polarogram for $j_{\alpha}^{z+} \rightarrow j_{\beta}^{z+}$ when $I_{ad,j^{z}+}$ is slightly larger than $I_{cd,i^{z}+}$. At higher $a_{j^{z}+,\alpha}$, $\Delta V_{I=0}$ shifts from $\Delta V_{I=0(i_{\beta}+j_{\alpha})}$ in almost Nernstian response to change in $a_{j^{z}+,\alpha}$.

(ii) $\Delta_{\beta}^{\alpha}\phi_{j^{z}+}^{0} > \Delta_{\beta}^{\alpha}\phi_{i^{z}+}^{0}$, Fig. 9b.

The interference of j^{z+} is small and $\Delta V_{I=0}$ shifts monotonically with $a_{j^{z}+,\alpha}$. When $a_{j^{z}+,\alpha}$ is large enough, $\Delta V_{I=0}$ shifts in almost Nernstian response to change in $a_{j^{z}+,\alpha}$.

The role of the ionophore in the ISE membrane

In the presence of the ionophore Y in β, i^{z+} complexes with Y:

$$i_{\beta}^{z+} + p Y_{\beta} \rightleftharpoons iY_{p}^{z+},\beta \qquad (25)$$
The stability constant, $K_{st,i^{z}+-Y}$, is

$$K_{st,i^{z}+-Y} = a_{iY_{p}^{z}+,\beta}/a_{i^{z}+,\beta} a_{Y,\beta}^{p} \qquad (26)$$

When $K_{st,i^{z}+-Y}$ is sufficiently large, $a_{i^{z}+,\beta}$ is expressed as equation (27), using total activity of i^{z+} and iY_{p}^{z+}, $a_{i^{z}+,total,\beta}$,

$$a_{i^{z}+,\beta} = a_{i^{z}+,total,\beta}/(K_{st,i^{z}+-Y} a_{Y,\beta}^{p}) \qquad (27)$$

Taking equations (7) and (27) into account, we obtain equations (28) and (29) for polarograms which show the transfer of i^{z+} from α to β and from β to α, respectively, in the presence of Y in β.

$$I_{a,i^{z}+} = I_{ad,i^{z}+}/[1 + (D_{i^{z}+,\alpha}/D_{iY_{p}^{z}+,\beta})^{1/2} (K_{st,i^{z}+-Y} a_{Y,\beta}^{p})^{-1} \exp\{-zF(\Delta_{\beta}^{\alpha}\phi - \Delta_{\beta}^{\alpha}\phi_{i^{z}+}^{0})/RT\}] \qquad (28)$$

$$I_{c,i^{z}+} = \frac{I_{cd,i^{z}+} (D_{i^{z}+,\alpha}/D_{iY_{p}^{z}+,\beta})^{1/2} (K_{st,i^{z}+-Y} a_{Y,\beta}^{p})^{-1} \exp\{-zF(\Delta_{\beta}^{\alpha}\phi - \Delta_{\beta}^{\alpha}\phi_{i^{z}+}^{0})/RT\}}{[1 + (D_{i^{z}+,\alpha}/D_{iY_{p}^{z}+,\beta})^{1/2} (K_{st,i^{z}+-Y} a_{Y,\beta}^{p})^{-1} \exp\{-zF(\Delta_{\beta}^{\alpha}\phi - \Delta_{\beta}^{\alpha}\phi_{i^{z}+}^{0})/RT\}]} \qquad (29)$$

In these equations we assume that i^{z+} diffuses from the bulk of the β phase to the interface as iY_{p}^{z+}, with diffusion coefficient $D_{iY_{p}^{z}+,\beta}$, when $K_{st,i^{z}+-Y}$ is sufficiently large, and that formation of complexes of i^{z+} in the α phase is negligible. $\Delta V_{I=0}$ in the composite polarogram recorded in the presence of i^{z+} in both α and β, and of Y in β, occurs when $I_{a,i^{z}+} + I_{c,i^{z}+} = 0$:

$$\Delta V_{I=0} + \text{const} = \Delta_{\beta}^{\alpha}\phi_{i^{z}+}^{0} - (RT/zF)$$

$$\times \ln(a_{i^{z}+,\alpha}/a_{i^{z}+,total,\beta})$$

$$- (RT/zF)\ln(K_{st,i^{z}+-Y} a_{Y,\beta}^{p}) \qquad (30)$$

$\Delta V_{I=0}$ in the composite polarogram for the ion transfer,

$$(i_{\beta}^{z+} \rightarrow i_{\alpha}^{z+}) + (j_{\alpha}^{z+} \rightarrow j_{\beta}^{z+}),$$

in the presence of Y in β, can be expressed by equations (31)–(34), employing

$$I_{c,i^{z}+} + I_{a,j^{z}+} = 0.$$

Here, $I_{a,j^{z}+}$ is given by equation (28) modified by substituting j^{z+} for i^{z+}.

$$\Delta V_{I=0} + \text{const} = \Delta_{\beta}^{\alpha}\phi_{i^{z}+}^{0} - (RT/zF)$$

$$\times \ln[\{-L + (L^{2} - 4MN)^{1/2}\}/2M] \qquad (31)$$

where

$$L = a_{i^{z}+,total,\beta} (K_{st,i^{z}+-Y} a_{Y,\beta}^{p})^{-1} D_{iY_{p}^{z}+,\beta}^{1/2}$$

$$\times (D_{i^{z}+,\alpha}/D_{iY_{p}^{z}+,\beta})^{1/2} (D_{j^{z}+,\alpha}/D_{jY_{p}^{z}+,\beta})^{1/2}$$

$$\times (K_{st,j^{z}+-Y} a_{Y,\beta}^{p})^{-1} \qquad (32)$$

$$M = \{D_{iY_{p}^{z}+,\beta}^{1/2} a_{i^{z}+,total,\beta} - D_{j^{z}+,\alpha}^{1/2} a_{j^{z}+,\alpha}\}$$

$$\times (D_{i^{z}+,\alpha}/D_{iY_{p}^{z}+,\beta})^{1/2}$$

$$\times (K_{st,i^{z}+-Y} a_{Y,\beta}^{p})^{-1}$$

$K_{st,j^{z}+-Y}$) but also that the lower and upper detection limits are changed, depending on $K_{st,i^{z}+-Y}$. Consider

$$N = - D_{j^{z}+,\alpha}^{1/2} a_{j^{z}+,\alpha} \exp\{-zF(\Delta_{\beta}^{\alpha}\phi_{j^{z}+}^{0}$$

$$- \Delta_{\beta}^{\alpha}\phi_{i^{z}+}^{0})/RT\} \qquad (34)$$

From $\Delta V_{I=0}$ in the polarogram shown in Fig. 4a and equation (17), $\Delta_{nb}^{w}\phi_{K+}^{0}$ is found to be $+0.162$ V vs. TMAE, and from equation (30) and $\Delta V_{I=0}$ in Fig. 4b, $K_{st,K+-val}$ is calculated to be 2.8×10^{9}. Substituting $\Delta_{nb}^{w}\phi_{K+}^{0}$, $K_{st,K+-val}$, and $\Delta V_{I=0}$ in the composite wave given as curve (7) in Fig. 5a, into equation (20) and taking $a_{i^{z}+,\alpha}$ as zero, $\Delta_{nb}^{w}\phi_{Na+}^{0}$ is found to be $+0.290$ V vs. TAME. From equations (31)–(34), $K_{st,Na+-val}$ is calculated to be 3.4×10^{6}. Here, we assumed the diffusion coefficients of Na^{+} and Na^{+}–val to be identical to those of K^{+} and K^{+}–val, respectively, as the solubility of Na^{+} in nb is so low that it is difficult to get these values from the polarograms of Na^{+}. Reported values[10,13] for log $K_{st,K+-val}$ are 6.82 in acetonitrile medium, 3.7–6.3 in ethanol, and 3.9–4.9 in methanol. Because a larger value for $K_{st,K+-val}$ in nb
Fig. 9. The influence of j^{z+} in w on $\Delta V_{I=0}$ of the composite polarogram of $i_w^{z+} \rightleftarrows i_{org}^{z+}$. (1)–(4), $j_w^{z+} \rightarrow j_{org}^{z+}$; (1′)–(4′), $i_w^{z+} \rightleftarrows i_{org}^{z+}$ with $j_w^{z+} \rightarrow j_{org}^{z+}$; (5), $i_w^{z+} \rightleftarrows i_{org}^{z+}$.

that $\Delta V_{I=0}$ in the composite polarogram for K^+ shifts by about -0.42 V in the presence of $3.75 \times 10^{-3}M$ valinomycin in nb, the detection limits are expected to be lowered by about seven orders of magnitude. In the presence of valinomycin, however, the lower detection limit is improved by only two orders of magnitude in the ISE measurement under the conditions of Fig. 7. This may be due to the negative shift of the anodic final rise in the residual current in the presence of valinomycin in nb.

As discussed above, it is possible to find a logical explanation for various essential points which have been empirically recognized in potentiometric ISE measurement, if we take the voltammetric current–potential relations into account.

In conclusion, although no experimental results are presented, we consider that the following may also be explained from the voltammetric viewpoint. (i) The diffusion current in the polarogram grows when the solution is stirred, resulting in a shift of $\Delta V_{I=0}$ in the composite polarogram and hence in the potential at the ISE. (ii) The super-Nernstian response in the ISE measurement may be attributed to irreversible ion transfer at the solution/membrane interface.

was obtained in the present work, we consider that, taking the donor numbers[14] (calculated value) of acetonitrile, ethanol and methanol to be 14.6, 30.4 and 33.8, respectively, solvation of K^+ in nb (which has a donor number of 8.4) may be considerably smaller than that in the other solvents, and consequently K^+ may easily complex with valinomycin in nb.

With regard to the role of the ionophore Y in the ISE measurements of i^{z+} it should be stressed not only that the interference from j^{z+} is reduced by the ionophore (depending on the values of $K_{st,i^{z+}+-Y}$ and $K_{st,j^{z+}+-Y}$), but also that the lower and upper detection limits are changed, depending on $K_{st,i^{z+}+-Y}$. Considering that the lower and upper detection limits are determined by the anodic final rise and the cathodic final descent, respectively, of the residual current and

THE USE OF EMULSIONS IN THE PREPARATION OF SAMPLES AND STANDARDS FOR ANALYSIS BY ATOMIC-ABSORPTION SPECTROSCOPY DETERMINATION OF Cu AND Fe IN MIBK EXTRACTS OF THEIR APDC COMPLEXES

M. DE LA GUARDIA and M. T. VIDAL

Departamento de Química Analítica, Facultad de Ciencias Químicas, Universidad de Valencia, España

Summary—The use of aqueous/organic emulsions is shown to give advantages in the AAS determination of Cu and Fe extracted as their pyrrolidinedithiocarbamate complexes into methyl isobutyl ketone. The emulsions are more stable than the extracts, and the standards can be prepared from aqueous solutions by emulsification, but without extraction.

In the last few years we have studied the application of the emulsion-formation technique to analysis for various metals in lipo-soluble matrices by atomic-absorption spectrometry, and by flame,[2] inductively coupled plasma[3] and d.c. plasma[4] emission photometry, with use of conventional aqueous solutions as standards. We have concluded that for emulsions to be employed successfully, the following requirements must be met.

(1) The emulsions must be stable during the period of analysis.

(2) The emulsions must be physically suitable for introduction into the atomization system.

(3) Atomization of the samples and standards must match for identical concentrations of the analyte.

The first two conditions affect the method of preparing the emulsions, and for a particular matrix require selection of the surfactant, the proportions of the phases and the preparation procedure. The third condition depends essentially on the nature of the analyte compounds present in the matrix.

For example, in the determination of lead and manganese in gasolines[1,5] the tetra-alkyl lead compounds and the tricarbonylmethylcyclopentadienyl-manganese must be previously mineralized with iodine or bromine to enable an emulsified aqueous solution to be used in the preparation of the standards, whereas in the determination of metallic additives in lubricating oils[6] aqueous standards can be used directly for the analysis of oil samples emulsified with water.

However, owing to the complexity of the samples, clear conclusions about the behaviour of the emulsions cannot be deduced, so simple systems such as organic solutions of metallic complexes have been used for fundamental studies. Thus Berenguer *et al.*[7] used oil-in-water (o/w) emulsions in the flame AAS

determination of copper and iron oxinates extracted into benzene and ethyl acetate. Later, we studied the use of o/w emulsions in the determination of aluminium by flame emission spectrometry of aluminium oxinate extracted into methyl isobutyl ketone (MIBK),[2] and also the use of different types of emulsified standards for the determination of magnesium oxinate in MIBK.[8]

In the present work, we examined the use of o/w and w/o (water in oil) emulsions for determination of Cu and Fe, extracted as their APDC complexes into MIBK, and compared the results with those obtained by use of direct aspiration of the organic extracts and of aqueous solutions, with respect to sensitivity and stability.

EXPERIMENTAL

Apparatus

Atomic-absorption measurements were made with a double-beam Perkin-Elmer Model 460 atomic-absorption spectrophotometer equipped with a single-slot burner for use with air/acetylene flame. The following operating parameters were employed:

	Cu	Fe
Wavelength, *nm*	324.8	248.3
Band-pass, *nm*	0.7	0.2
Lamp current, *mA*	15	30

Reagents

Standard 1000-*ppm solutions of Cu and Fe.*

Ammonium pyrrolidinedithiocarbamate (*APDC*). A freshly prepared 1% aqueous solution was purified by extraction with MIBK.

Nemol K 38. Nonyl phenol polyethylene glycol ether with 8 ethylene oxide units (Masso y Carol).

Tergitol XD. (*Union Carbide*), 1% *aqueous solution.*

Emulsogen LBH (*Hoechst*).

Procedure

APDC solution (1%, 1 ml) was added to 50 ml of an aqueous solution of a metal ion and the pH was adjusted to

Table 1. Extraction conditions

Element	Shaking time, min	pH for quantitative extraction	pH for optimum absorbance	Maximum concentration, ppm
Cu	2	0–10	2–10*	20
Fe	3	1–8	5–6	>50

*Except at pH = 8.

a suitable value. The solution was transferred to a separatory funnel and shaken for a suitable time with 20 ml of MIBK (accurately measured). The two phases were then allowed to separate.

For preparation of the o/w emulsions, 10 ml of the organic extract were emulsified with 0.25 g of Nemol K 38 and 25 ml of a 1% aqueous solution of Tergitol XD, and enough distilled water to bring the total volume to 100 ml.

The w/o emulsions were prepared with 10 ml of the organic phase, 2.5 ml of distilled water and 3 ml of Emulsogen LBH, and enough MIBK to make the volume 25 ml.

Samples prepared in this manner were introduced into an air/acetylene flame and analysed under the optimum instrumental conditions. MIBK-in-water and water-in-MIBK emulsions were employed as standards. They were prepared in the same way, but the metal ion was introduced in the aqueous phase.

RESULTS AND DISCUSSION

Extraction conditions

Solvent extraction with APDC in MIBK is the most frequently employed system for determination of Cu and Fe by liquid–liquid extraction and atomic-absorption spectrometry.[9-14] The optimum extraction conditions were described in a previous paper,[15] and are summarized in Table 1.

Instrumental conditions

For each of the four different types of standard used, the flame profiles and instrumental conditions which give the best sensitivity were determined. From the data in Table 2 it can be seen that the presence

of the organic phase changes the flame profiles, and the optimum gas flows and heights of observation in the flame are modified accordingly.

However, there are some differences between the behaviour of the two elements. For iron, the optimum flow ratio (air to acetylene) is 4.1 for aqueous solutions and o/w emulsions, 8.3 for organic extracts and 5.3 for w/o emulsions; that is, the gas mixture is made richer in air as more organic solvent is introduced.

For copper, a different behaviour can be observed, the optimum gas ratio being the same for the aqueous standards and w/o emulsions, but lower for the o/w emulsions and again highest for the organic extracts.

For both elements the aspiration rate of the organic extracts was lower than that for the aqueous standards and greater than that for the o/w and w/o emulsions, so the apparently irregular behaviour of copper (with respect to flame composition) is not due to the rheological features of the emulsions (which were the same as those used for iron) but to the temperature and atomization conditions.

There are also very marked differences in the optimum positions of observation in the flame (i.e., height above burner top) though the pattern is the same for the two elements.

Comparison between emulsified standards and emulsified extracts

One of the principal advantages of the use of emulsions in the AAS determination of metallic

Table 2. Optimum AAS instrumental parameters for maximum sensitivity

Element	Flame parameter	Samples			
		aqueous	extracts	emulsions o/w	emulsions w/o
Cu	air flow, l./min	17.5	29.5	13.4	17.5
	acetylene flow l./min	3.3	3.3	3.3	3.3
	height above burner top, mm	20	17.5	20	10
	aspiration rate, ml/min	6.8	6.5	5	3.8
Fe	air flow, l./min	13.4	27.5	13.4	17.5
	acetylene flow, l./min	3.3	3.3	3.3	3.3
	height above burner top, mm	17.5	12.5	17.5	7.5
	aspiration rate*, ml/min	6.8	6.5	5	3.8

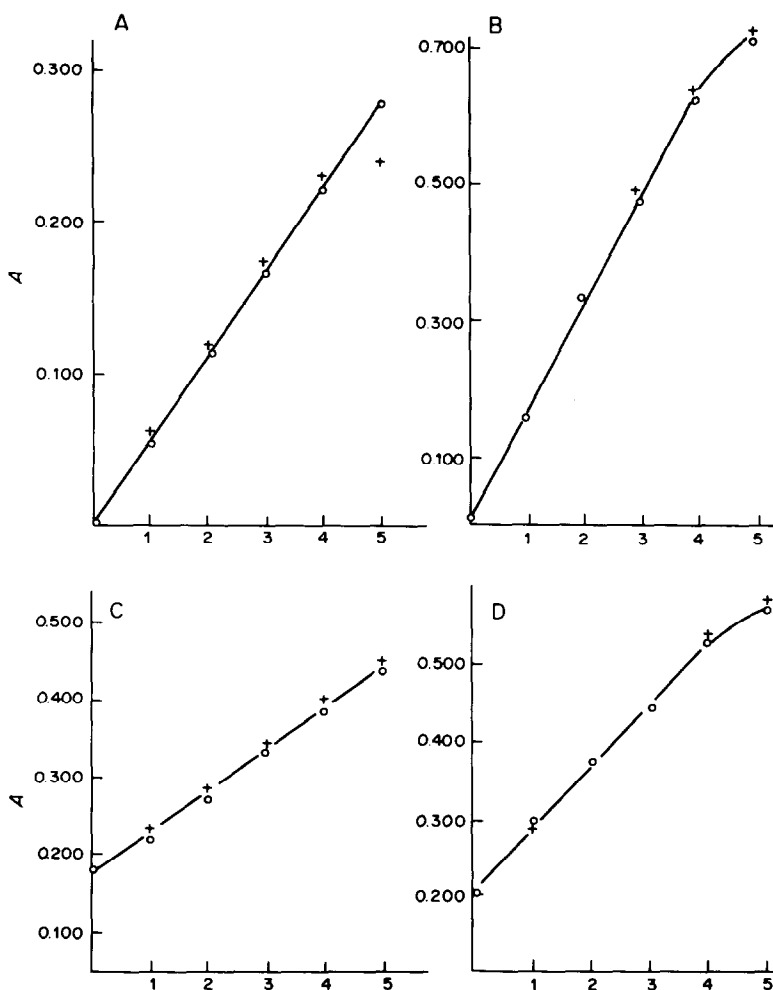
*The aspiration rates have not been optimized, but were measured for identical nebulizer positions and are used in a comparative manner.


Fig. 1. Absorbance values for aqueous emulsified standards (○) and emulsified extracts (+) plotted vs. metal concentration: A, o/w emulsions Cu, $\psi = 0.08$; B, w/o emulsions Cu, $\psi = 0.08$; C, o/w emulsions Fe, $\psi = 0.17$; D, w/o emulsions Fe, $\psi = 0.05$.

elements in organic matrices is that aqueous solutions can be used for preparation of the standards.

To test whether aqueous copper and iron solutions emulsified with MIBK can be used as standards for the determination of these elements in extracts of their complexes with APDC in MIBK, calibration graphs were prepared from emulsified aqueous solutions and from aliquots of emulsified extracts. The results are shown in Fig. 1.

The agreement between the two sets of results was evaluated by means of Exner's parameter[16] and found to be good to very good for all cases, except the iron o/w emulsions for which it was only fairly good.

The slightly greater absorbance obtained for the emulsified organic extracts may be due to the solubility of MIBK in water, although both phases were pre-equilibrated.[15]

Comparison of the different types of standards

Figures 2 and 3 show the calibration graphs obtained with each of the four types of standards

under optimum instrumental conditions. It can be noted that the introduction of an organic phase, alone or emulsified, produces a strong increase in the sensitivity. Although the use of organic extracts and emulsions decreases the feed-rate into the flame, this effect is largely offset by the contribution of the MIBK combustion to the flame temperature.

We have found that in some cases the use of an aspiration rate different from that usually used for aqueous solutions can make the sensitivity for emulsified samples and standards higher than that for direct introduction of organic extracts, but difficulty in reproducing the nebulizer position makes these results less easily reproducible. For that reason the results given here were all obtained at the aspiration rate usually used for aqueous solutions.

The important features of the calibration graphs are summarized and compared in Tables 3 and 4. An important aspect to be considered is the stability of the extracts, since this is one of the disadvantages that can appear in analysis by liquid-liquid extraction and
Fig. 2. Calibration curves for the different Cu standards: ○ extracts; ● w/o emulsions; △ o/w emulsions; + aqueous.
Fig. 3. Calibration curves for the different Fe standards: ● w/o emulsions; ○ extracts; △ o/w emulsions; + aqueous.

AAS. For iron, whereas the extracts are only stable for 2 hr, the o/w and w/o emulsions are stable for 1 day and 3 weeks respectively.

For copper, however, there is less advantage, since the extracts are stable for 5 days, and o/w and w/o emulsions for 1 day and 8 days respectively.

Conclusions

Conversion of MIBK extracts of the APDC com-plexes of iron and copper into aqueous/organic emul-sions allows direct preparation of standards from aqueous solutions of the elements, but the solubility of MIBK in the aqueous phase may lead to system-atic error unless the entire organic extract is con-verted into an emulsion. For iron, the emulsified extracts are appreciably more stable than the more commonly used simple organic extracts. The flame conditions should be optimized for the particular emulsion used.

SPECTROPHOTOMETRIC STUDY OF URANIUM(VI) CHELATE FORMATION WITH β-DIKETONES AND TRIBUTYL PHOSPHATE IN AQUEOUS, NONA(OXYETHYLENE) DODECYL ETHER SOLUTION

Tomitsugu Taketatsu

College of General Education, Kyushu University, Ropponmatsu, Chuo-ku, Fukuoka, Japan 810

Summary—The distribution ratio of uranium(VI) with 2-thenoyltrifluoroacetone, 2-furoyltrifluoroacetone and benzoyltrifluoroacetone in the presence and absence of tributyl phosphate between micellar and bulk phases in nona(oxyethylene) dodecyl ether solution was measured spectrophotometrically as a function of hydrogen-ion concentration. The thermodynamic constants for these reactions were evaluated from the variation of the equilibrium constants as a function of temperature. The entropy change contributes to the synergistic reaction.

It has been shown that uranium(VI)[1] and europium,[2,3] terbium[3] and samarium[2,3] can be determined spectrophotometrically and spectrophotofluorimetrically, respectively, with 2-thenoyltrifluoroacetone (TTA) and trioctylphosphine oxide in micellar solutions of a non-ionic surfactant. The synergistic partition of metal ions with β-diketones and a neutral donor between organic and aqueous phases has been widely studied. Several investigators have estimated the thermodynamic constants for the purpose of explaining the mechanism of synergistic solvent extraction of uranium[4] and europium[5] with TTA and a neutral donor. However, the corresponding partition equilibria between micellar and bulk phases have been scarcely studied, because the estimation of the species in these phases is not always easy. In the present paper, the distribution ratios (D) for uranium(VI) with TTA, 2-furoyltrifluoroacetone (FTA) and benzoyltrifluoroacetone (BFA) in the presence and absence of TBP, between micellar and bulk phases in nona(oxyethylene) dodecyl ether (BL-9EX) solution have been determined as a function of hydrogen-ion concentration, assuming that the absorbance of the metal chelate corresponds to the concentration of metal ion in the micellar phase. The equilibrium constants for those chelates are evaluated from the slopes of plots of log D vs. log [H$^+$]. Thermodynamic constants are calculated from the relationship between the equilibrium constants and temperature.

EXPERIMENTAL

Materials

TTA, FTA and BFA were obtained from Dojin Chemical Co., TBP and uranium acetate from Wako Chemical Co. and BL-9EX from Nikko Chemical Co. The solution of uranium acetate was standardized by titration with EDTA (Xylenol Orange as indicator). All chemicals used were of analytical-reagent grade.

Stock solutions

The concentrations in the mixed stock solution (pH 5.5–6.0) used were $4 \times 10^{-3}M$ TTA, FTA or BFA, $4 \times 10^{-5}M$ uranyl acetate, $0.01M$ acetic acid, $0.2M$ sodium chloride and 1% w/v BL-9EX. The concentration of TBP was $4 \times 10^{-3}M$.

Procedure

Ten ml of the mixed stock solution were placed in a beaker, adjusted to approximately the desired pH value with dilute hydrochloric acid, transferred to a 20-ml standard flask and made up to volume with water. The solution was poured into a 25-ml stoppered flask and the flask was shaken mechanically in a thermostat for at least 3 hr. The absorbance was measured at 385, 375 and 377 nm for TTA, FTA and BFA, respectively, both in the absence and presence of TBP. A reagent blank was used as reference solution.

RESULTS AND DISCUSSION

Figure 1 shows the absorption spectra of the UO_2^{2+}–TTA and UO_2^{2+}–TTA–TBP systems in the BL-9EX micellar solution. The absorption maxima are at 385 nm. A similar pattern was found at 375 nm for the FTA and FTA–TBP systems and at 377 nm for the BFA and BFA–TBP systems.

Figures 2 and 3 show the relationship between the absorbance at 385 nm and pH in the UO_2^{2+}–TTA and UO_2^{2+}–TTA–TBP systems, at different temperatures. It is seen that the absorbances are constant and maximal at pH > 4.0 for the TTA system and > 3.0 for the TTA–TBP system at all the temperatures tested. For the other systems, which behaved similarly, the critical pH values were 4.2 (FTA), 3.3 (FTA–TBP), 3.5 (BFA) and 2.8 (BFA–TBP).

In a previous paper,[6] it was shown by a spectrophotometric method that most of the TTA exists outside the micelles, *i.e.*, in the bulk phase. On the other hand, most of the β-diketone chelates and TBP
Fig. 1. Absorption spectra of $UO_2(TTA)_2$ and $UO_2(TTA)_2TBP$ chelates in micellar solution. UO_2^{2+} $2 \times 10^{-5}M$, TTA $2 \times 10^{-3}M$, TBP $2 \times 10^{-3}M$ and BL-9EX 0.5%. (i) $UO_2(TTA)_2$ chelate, pH 4.16 and (ii) reagent blank; (iii) $UO_2(TTA)_2TBP$ chelate, pH 4.06 and (iv) reagent blank.

seem to exist in the micellar phase, because the species are scarcely dissolved in an aqueous solution if the surfactant is not added. Also, the uranium chelates with β-diketones (HA) are known to be $UO_2(A)_2(H_2O)_x$,[4,7] and $UO_2(A)_2TBP$.[4,7,8] For simplicity, the question of hydration of the chelate will be ignored for the moment, but discussed later. Then the chelate $UO_2(A)_2$ is presumed to be formed by the reaction

$$UO_{2(b)}^{2+} + 2HA_{(b)} \rightleftharpoons UO_2(A)_{2(m)} + 2H_{(b)}^+ \qquad (1)$$
the subscripts (b) and (m) referring to the mutually equilibrated bulk and micellar phases, respectively, and the equilibrium constant is defined by

$$k_1 = \frac{[UO_2(A)_2]_{(m)} [H^+]_{(b)}^2}{[UO_2^{2+}]_{(b)} [HA]_{(b)}^2} \qquad (2)$$

Equation (2) can be expressed as

$$\log D_1 + 2\log [H^+]_{(b)} - 2\log [HA]_{(b)} - \log k_1 = 0 \qquad (3)$$
Fig. 2. Relationship between absorbance and pH for the UO_2^{2+}–TTA system at various temperatures. Concentrations as for Fig. 1, UO_2^{2+} $2 \times 10^{-5}M$, TTA $2 \times 10^{-3}M$ and BL-9EX 0.5%.
Fig. 3. Relationship between absorbance and pH for the UO_2^{2+}–TTA–TBP system at various temperatures. Concentrations as for Fig. 1.

where

$$D_1 = \frac{[UO_2(A)_2]_{(m)}}{[UO_2^{2+}]_{(b)}} \qquad (4)$$

When equation (3) is differentiated with respect to $\log [H^+]_{(b)}$ at constant HA concentration,

$$\frac{d \log D_1}{d \log [H^+]_{(b)}} = -2 \qquad (5)$$

is obtained; here, the concentration of HA can be assumed to be constant if there is a large excess of reagent relative to metal ion. The ionic strength is held constant at about 0.1. Similarly, the equilibrium for the adduct reaction is

$$UO_{2(b)}^{2+} + 2HA_{(b)} + TBP_{(m)} \rightleftharpoons UO_2(A)_2TBP_{(m)} + 2H_{(b)}^+ \qquad (6)$$
for which

$$k_2 = \frac{[UO_2(A)_2TBP]_{(m)} [H^+]_{(b)}^2}{[UO_2^{2+}]_{(b)} [HA]_{(b)}^2 [TBP]_{(m)}} \qquad (7)$$

and

$$\frac{d \log D_2}{d \log [H^+]_{(b)}} = -2 \qquad (8)$$

where

$$D_2 = \frac{[UO_2(A)_2TBP]_{(m)}}{[UO_2^{2+}]_{(b)}} \qquad (9)$$

Equation (11) for the reaction in equation (10) is derived from equations (2) and (7):

$$UO_2(A)_{2(m)} + TBP_{(m)} \rightleftharpoons UO_2(A)_2TBP_{(m)} \qquad (10)$$
$$\beta = \frac{[UO_2(A)_2TBP]_{(m)}}{[UO_2(A)_2]_{(m)}[TBP]_{(m)}} = \frac{k_2}{k_1} \qquad (11)$$

The following assumptions can be introduced from the results shown in Figs. 2 and 3: (i) the concentration of uranium(VI) in the micellar phase is linearly proportional to the absorbance, and (ii) almost all the uranium species exist in the micellar phase, in the pH range for which the absorbance is constant and maximal. Thus, the values of D_1 and D_2 were
Fig. 4. Variation of distribution ratio in the UO_2^{2+}–TTA and UO_2^{2+}–TTA–TBP systems as a function of hydrogen-ion concentration at various temperatures. Concentrations as for Fig. 1.

calculated by using the spectrophotometric data described above.

Figure 4 shows that the slopes of the graphs of $\log D_1$ vs. $\log [H^+]_{(b)}$ and $\log D_2$ vs. $\log [H^+]_{(b)}$ for the UO_2^{2+}–TTA and UO_2^{2+}–TTA–TBP systems, respectively, are almost linear (about -2), irrespective of the temperatures used. Similar results are obtained in the other systems. The values of $\log k_1$ and $\log k_2$ can be estimated by using equations (2) and (7), respectively, and the values of $\log \beta$ by using equation (11). The values at $25°$ are given in Table 1. It is seen that $\log k_1$ and $\log k_2$ decrease in the orders $UO_2(BFA)_2 > UO_2(TTA)_2 > UO_2(FTA)_2$ and $UO_2(BFA)_2TBP > UO_2(TTA)_2TBP > UO_2(FTA)_2$ TBP, respectively. The synergistic effect of TBP adduct formation is obvious for all the systems.

Akiba et al.[9] measured the values of $\log \beta$ in various organic solvents for the UO_2^{2+}–TTA–TBP system by the solvent-extraction method. The values ranged from 4.42 for methylene chloride to 6.81 for

Table 1. Thermodynamic values for $UO_2(A)_2$ and $UO_2(A)_2TBP$ chelate formation

	$\log k_1$	ΔG, kJ/mole	ΔH, kJ/mole	ΔS, J.mole^{-1}.K^{-1}
TTA	0.29	-1.66	53.9	186
FTA	-0.46	2.63	51.3	165
BFA	1.08	-6.16	67.5	247
	$\log k_2$			
TTA	6.83	-39.0	64.7	348
FTA	5.86	-33.6	78.7	376
BFA	7.77	-44.4	68.8	379
	$\log \beta$			
TTA	6.54	-37.3	10.8	161
FTA	6.32	-36.1	27.4	211
BFA	6.69	-38.2	1.3	133
Fig. 5. Variation of $\log k_1$ with temperature. Concentrations as for Fig. 1 and [BFA] = [FTA] = [TTA].

cyclohexane, corresponding to the solubility of water in the solvents. The value of 6.54 for the micellar system is about the same as that of 6.47 for the n-heptane system. This perhaps gives a clue to the state of the micellar microenvironment in which the adduct chelates exist.

Figure 5 shows the variation of $\log k_1$ with reciprocal of the absolute temperature for the simple systems, and the enthalpy changes ΔH were calculated from them by using the van't Hoff equation. The corresponding entropy changes were also evaluated. The values of ΔH for the UO_2^{2+}–TTA, UO_2^{2+}–FTA and UO_2^{2+}–BFA systems are 53.9, 51.3 and 67.5 kJ/mole, respectively. Endothermic reactions are common for chelate formation in which the hydration sheath of the metal ion is replaced by the chelating reagent. The values of ΔS are positive and large. It is thought that the reason for this is release of the water molecules from the $HTTA \cdot H_2O$ and $UO_2 \cdot y H_2O$ species when the reagent reacts with uranyl ion according to equation (1) since the HTTA species that is dominant in the micellar system exists as the keto-hydrate in the bulk phase.

ΔH and ΔS for all the synergistic reactions are both positive, and ΔS is especially large. The large ΔS could be explained as due to release of water molecules from both the hydrated chelate $UO_2(A)_2(H_2O)_x$ and the $TBP \cdot H_2O$ dominant species that is in the micellar system, when the TBP adduct is formed. However, Subramanian et al.[4] reported that the values of ΔH and ΔS were -21.8 kJ/mole and

-34 J.mole^{-1}.K^{-1}, respectively, for the UO_2^{2+}–TTA–TBP system with benzene as solvent. Choppin[10] has stated that these negative values would imply no replacement of water molecules and no expansion of the co-ordination sphere of uranium(VI) in the adduct formation. This contrast in the values for the micellar and solvent-extraction systems could be explained by the degree of affinity of TBP for water. In the micellar system, the alkyl groups and oxygen atom of TBP perhaps orient to the oligophile and hydrophile parts of the micelle, respectively. Therefore, the environment of the TBP-water adduct is more hydrophilic than that in benzene and the adduct perhaps exists as $TBP \cdot H_2O$.

RADIOCHEMICAL DETERMINATION OF TECHNETIUM-99

Norton Y. Chu and Jerry Feldstein*
Environmental Measurements Laboratory, U.S. Department of Energy, New York, NY 10014, U.S.A.

Summary—A procedure has been developed for the determination of ^{99}Tc in vegetation, by use of ^{95m}Tc as an internal tracer. The samples are wet-ashed, without significant loss of Tc. The Tc is separated from most other radionuclides by precipitation with calcium carbonate, and is purified by anion-exchange chromatography and electro-deposition. The radiochemical yield of Tc is determined by Ge(Li) gamma-ray spectrometry of the 204-keV photon peak of the ^{95m}Tc internal tracer, and the ^{99}Tc activity is determined by counting its 0.292-MeV beta-particles with a scintillation counter. The detection limit for ^{99}Tc in a sample weighing about 10 g is 0.1 pCi for a 3000-min count.

There has recently been considerable interest in measuring the environmental concentrations and distributions of ^{99}Tc,[1–7] a potential toxic pollutant hazard originating from nuclear power plants and nuclear fuel reprocessing operations.[4–13] This interest has led to the development of a number of methods for measuring this long-lived beta emitter. ^{99}Tc and the other major isotopes of Tc are listed in Table 1.

Isotope-dilution mass-spectroscopy (IDMS), with a ^{97}Tc tracer, is the most sensitive analytical method for determining ^{99}Tc.[1,8] Measurements of ^{99}Tc activities as small as 0.02 pCi have been achieved by this method. However, IDMS requires expensive sophisticated instrumentation and very thorough decontamination from ^{97}Mo, which causes interference. This interference problem can be eliminated by substituting resonance (laser-induced ionization) IDMS for the usual thermal-ionization IDMS, but at the cost of additional special apparatus.

^{99}Tc has also been determined by beta-counting with ^{97m}Tc as an internal tracer.[9] The ^{97m}Tc yield is measured by counting its conversion electrons in a beta-counter. However, the beta radioassay of the ^{99}Tc requires that the conversion electrons from the ^{97m}Tc be screened out. This is accomplished with 14-mg/cm^2 aluminium absorbers,[9] but the absorbers cause a severe reduction in the sensitivity of the method,[9,14] and a decrease in precision. Because the ^{99}Tc and the ^{97m}Tc are both counted by the same detector, an unexpectedly high ^{99}Tc activity can interfere with the ^{97m}Tc count-rate measurement.[9] (The ^{97m}Tc count rate is typically 30–40 cpm in a Geiger–Müller detector.[9])

^{95m}Tc has been used as an external tracer for the determination of ^{99}Tc by adding it to one of a pair of duplicate samples and attempting to analyse both in an identical manner. The unspiked duplicate was beta-counted, and it was assumed that its Tc chemical yield was the same as that of the spiked duplicate.

The reproducibility of the chemical recovery of Tc was found to depend primarily on the care taken by the analyst.[14,15]

In the method presented here, ^{95m}Tc is used as an internal tracer for the measurement of ^{99}Tc. The yield of ^{95m}Tc is determined by measuring the tracer's 204-keV photon peak by Ge(Li) gamma-ray spectrometry. The activity of ^{95m}Tc tracer added is sufficient for a reasonably precise determination of the radiochemical yield by gamma-ray spectrometry. The interference by this very small amount of ^{95m}Tc tracer activity in the ^{99}Tc beta-counting is less than the beta-counter background and is corrected for in the calculations. Not only are absorbers unnecessary, but their use would be detrimental, because ^{99}Tc beta particles are attenuated more by absorbers than the ^{95m}Tc gamma-rays are. In addition, high levels of ^{99}Tc activity in a sample have no effect on the ^{95m}Tc yield determination by gamma-ray spectrometry.

The volatility of Tc is a unique aspect of its chemistry. Excessive temperatures should be avoided during sample dissolution, wet ashing, and evaporation.[10,14,16,17] Some reports of the volatility of Tc from hot nitric acid solutions conflict with others.[10] One report recommends that to avoid loss of Tc during evaporation of a solution of Tc in nitric acid, the temperature should not exceed 90°.[17] At its melting point (119.5°) Tc$_2$O$_7$ exhibits a vapour pressure of about 1.0 mmHg.[19] We have found that wet-ashing of vegetation samples with nitric acid at moderate hotplate temperature settings results in Tc losses of < 5%.

Tc can be separated from many other elements by treatment with carbonate. Tc remains in solution while actinides, radium, strontium, calcium, lead and transition metals precipitate.[11,15,20]

The anion-exchange behavior of Tc has been extensively studied.[9,17–19,21–25] Dowex 1 × 4 resin has been used successfully to separate Tc from most other elements. It sorbs Tc from alkaline or weakly acidic solutions, and the Tc is eluted with more strongly acidic solutions.

*Author for correspondence.

Table 1. Half-lives and decay modes of the major Tc isotopes[32,33]

Nuclide	Half-life	Mode of decay	Energy of beta and photon emissions, keV
^{95m}Tc	61 days	95+% electron capture	204, 582, 835
		4% internal transition	
^{95}Tc	20 hours	electron capture	17, 20, 766
^{97m}Tc	91 days	internal transition	conversion electrons
^{97}Tc	2.6×10^6 years	electron capture	conversion electrons
^{99}Tc	2.1×10^5 years	beta	292

Electro-deposition of Tc[9,14,17,19] provides additional decontamination from other elements and provides a convenient form for beta-counting and for tracer yield determination by gamma-ray spectrometry.

EXPERIMENTAL

Reagents

The ^{95m}Tc tracer was obtained from Argonne National Laboratory, where it was prepared by cyclotron bombardment of niobium with ^{3}He or ^{4}He nuclei:[14,26]

$$^{93}Nb(^3He, n)\ ^{95m}Tc$$

$$^{93}Nb(^4He, 2n)\ ^{95m}Tc$$
When prepared in this manner the ^{95m}Tc is free from ^{97m}Tc.

^{99}Tc standard solutions were obtained from Amersham Radiochemicals, Arlington Heights, IL 60005. ^{99}Tc can also be obtained from Oak Ridge National Laboratory.[14]

The Dowex 1 × 4 (100–200 mesh) (Bio-Rad type AG) was prepared for use by washing 500 g of it successively with 1 litre of 3M sodium hydroxide, 1 litre of water, 2 litres of 6M hydrochloric acid, and finally with four 2-litre portions of water.

To prepare the anion-exchange column a plug of glass wool was positioned at the base of a 17-mm outside diameter glass tube (280 mm long), then a 10-ml volume of settled resin was transferred into the tube and 200 ml of 0.1M nitric acid were passed through it.

All other chemicals used were of analytical reagent grade.

Apparatus

The electro-deposition equipment comprised platinum discs (17.6 mm in diameter, 0.127 mm thick, one side mirror-finished), an electrolytic cell, a constant-current power supply and a voltage recorder. This system has been described elsewhere.[27,28]

After the electro-deposition, the platinum discs are covered with a plastic scintillating phosphor and a 0.0254-mm thick film of mylar,[28] and mounted on a nylon ring–disc assembly[28] for beta-counting. The plastic scintillating phosphors[28] used were 2.4 cm in diameter (Nuclear Enterprises Ltd., Edinburgh, Scotland).

In the mercury-shielded low-level beta counters[28,29] the phototube and sample were fitted into the well of a Phillips (or Amperex) hollow-anode Geiger tube operated in anti-coincidence. Tennelec scalers, clock and interface fed the data to a teletype paper punch and typewriter.

Chemical procedure

A measured amount of ^{95m}Tc tracer, sufficient to produce a 204-keV peak of about 1 cpm in a Ge(Li) gamma-ray spectrometer, was added to 10 g of vegetation in a 3-litre beaker, and 300 ml of concentrated nitric acid were added and the mixture was stirred. The mixture was wet-ashed until the decomposition of organic compounds was complete. The solution was evaporated to the smallest volume attainable without separation of salts, then allowed to cool; 800 ml of water were added and the mixture was stirred. The solution was then filtered through a 15-cm glass fibre filter and the silica and other insoluble material were discarded.

The filtrate was evaporated to a volume of about 200 ml. Then 200 mg of Ca^{2+}, 100 mg of Ba^{2+}, and 50 mg of Fe^{3+} (as nitrate solutions) were added, followed by 6M sodium hydroxide (with continuous stirring) until a pH of 10 was obtained. Then 60 ml of 2M sodium carbonate were added, with continuous mixing. The precipitate formed was allowed to settle, then filtered off on a glass fibre filter and discarded.

To prepare the filtrate for anion-exchange, 7.5M nitric acid was gradually added until the pH was 4–5, then 12 ml more of the acid were added and the solution was diluted with water to 870 ml. This final solution was 0.1M in nitric acid, and was heated gently to remove the carbon dioxide produced by acidification of the carbonate.

Anion-exchange was performed by passing the solution through a prepared Dowex 1 × 4 anion-exchange column, then washing the column with 500 ml of 0.1M nitric acid. The Tc was then eluted with 100 ml of 5M nitric acid. The eluate was evaporated to about 1 ml on a warm hot-plate and then left overnight at room temperature to evaporate to dryness.

Electro-deposition

An electrochemical cell containing a flamed platinum disc cathode was assembled. The Tc was dissolved in 1 ml of concentrated hydrochloric acid and transferred to the cell with three 1-ml water rinses. A drop of Methyl Red indicator (0.1% solution in alcohol) was added, followed by ammonia until the solution turned yellow. Then 2M hydrochloric acid was added until the solution turned red, and two drops in excess. The electrolysis cell was kept immersed in an ice-water bath during the electroplating, which was performed (with stirring) at a constant current of 1.2 A. After about an hour, the electro-deposition voltage increased abruptly, indicating completion of the electrolysis. The solution in the cell was quenched with 1 ml of concentrated ammonia solution, the current was turned off, and the cell was dismantled. The platinum cathode carrying the electro-deposited Tc was rinsed with water, then with ethanol, and dried on a hot-plate with gentle heat. The electroplated area on the platinum discs was 1.33 cm^2.

Radioassay

The electroplated platinum discs were beta-counted for at least 1000 min. To calibrate the beta-counters for ^{99}Tc radioassay, a known weight of standard ^{99}Tc solution was placed on a platinum disc; the solution was evaporated to dryness and the activity counted. To estimate the response of the beta-counters to the ^{95m}Tc emissions, aliquots of the ^{95m}Tc tracer were electrolysed with platinum discs. These electroplated ^{95m}Tc tracer disc standards were counted on a beta-counter and in a Ge(Li) gamma-ray spectrometer. The solutions remaining after the electro-deposition were gamma-counted with a sodium iodide crystal to correct for any unplated ^{95m}Tc.

To determine the radiochemical yield of a Tc determination, the electroplated platinum disc was counted for 1000 min in a Ge(Li) gamma-ray spectrometer. The area of the 204-keV photon peak of the ^{95m}Tc internal tracer was compared with the corresponding areas from the ^{95m}Tc

Table 2. ^{99}Tc analysis of a reference vegetation sample

| Aliquot | Tc radiochemical recovery | | ^{99}Tc (s.d.) for each beta-counter, pCi/g | | |

tracer electroplated disc standards, to obtain the radio-chemical Tc yield. The gamma-spectrometry measurement of the ^{95m}Tc electroplated disc standards also provided the data needed to calculate the ratio of the beta and 204-keV gamma count-rates for ^{95m}Tc.

Calculations

The ^{99}Tc activity in the sample is equal to the total beta activity, corrected for background and for the beta contribution from the ^{95m}Tc tracer, and adjusted for counting efficiency and chemical yield:

$$^{99}\text{Tc dpm} = (A - C)/(YE)$$

where A = net beta cpm of sample [corrected for background of counter (0.3 cpm)], C = beta cpm from ^{95m}Tc, Y = chemical yield, and E = counting efficiency (about 40% on Environmental Measurements Laboratory, EML, beta-counters) and $C = GR$ where G = net 204-keV gamma cpm of sample [from the Ge(Li) spectrometer] decay-corrected to the time of the sample beta-count, and R = mean ratio of the net beta and 204-keV gamma count-rates of the ^{95m}Tc tracer standard discs, both activities being decay-corrected to the same time, (for the EML systems, this ratio is about 0.5).

DISCUSSION

One important requirement for preparing a plated source of a low-energy beta-emitter such as ^{99}Tc is that a very small mass is electro-deposited on the platinum surface. Therefore, our chemical separation procedure has been designed to separate, by means of an alkaline carbonate precipitation and anion-exchange, Tc from all elements that would also be electro-deposited, with the exception of chromium in chromate form. If barium is added before the solution is made alkaline for the carbonate precipitation, any chromate is precipitated as barium chromate. The removal of chromate is important because it interferes with the electro-deposition of Tc. When applied to pure ^{95m}Tc solutions our electro-deposition procedure plated 95% of the Tc onto platinum.

A blended, homogeneous stable sample of dried grass has been prepared by EML for use as an environmental-type reference material within the scientific community.[30] This material has been analysed by several expert international laboratories to certify its ^{99}Tc content.[30] To demonstrate the quality of our procedure, six aliquots of this vegetation sample were analysed. Each of the Tc electroplated

discs was counted in three different beta-counters. Three samples of distilled water were processed simultaneously to investigate ^{99}Tc contamination in the laboratory reagents. No detectable net activity was observed in any of these blanks. These results are presented in Table 2.

The chemical yield of the procedure, as evidenced by the recoveries of the six samples in Table 2, is good, averaging 68%. The beta activity in these samples was sufficiently high and the counting period long enough, for the relative standard deviation of the beta radioassay to be only ±0.5%. For these samples the main uncertainty was due to the gamma-spectral analysis of the 204-keV photon peak of ^{95m}Tc in the determination of chemical recovery.

The results in Table 2 indicate the precision of the analysis. For any one aliquot, the results among counters agree within 1 standard deviation of the individual counting uncertainties. For any one beta counter, the results among the six aliquots agree within 2 standard deviations of the individual counting uncertainties, with the single exception of sample PG17 on counter Beta 19, which agrees within 3 standard deviations. This indicates that the main imprecision in the procedure is due to the stochastic nature of radioactivity.

The accuracy of the analysis is dependent upon the quality of the calibration of the beta counters, the completeness of equilibration of the ^{95m}Tc internal tracer with the ^{99}Tc of the sample during and subsequent to sample dissolution, and the radiochemical purity of the Tc electroplated onto the disc. The ^{99}Tc standard is certified within ±1.2%. In addition, there is about 4% uncertainty in the actual calibration process, and this outweighs the smaller uncertainty in the certification value.

The radiochemical purity of the separated element is a quality-assurance requirement in every radiochemical procedure. This is difficult to demonstrate by decay-rate in the case of the long-lived ^{99}Tc. The most practical method is to show that the energy of the beta-particle emitted from the sample is equivalent to that of the ^{99}Tc beta-particles ($E_{max} = 292$ keV, $E_{mean} = 97$ keV).[31] One way to accomplish this is to prepare a Harley–Hallden plot[28] in which the log of the reduction in activity of a sample by selected
Fig. 1. Harley–Hallden plot[28] of beta-counting with selected aluminium absorbers. The ranges around each data point represent one standard deviation for the count. The solid line is the theoretical line, slope = 1, for pure ^{99}Tc.

aluminium absorbers is plotted against the log of the reduction in activity of a ^{99}Tc standard by the same absorbers. If the reduction in the sample activity parallels the reduction in activity of a ^{99}Tc standard, the Harley–Hallden plot will have a slope of unity. Such a logarithmic plot, with slope of unity, is shown in Fig. 1 for one of the ^{99}Tc electroplated discs from the reference vegetation analyses.

The good analytical precision obtained strongly suggests that complete equilibration of the ^{95m}Tc internal tracer and ^{99}Tc of the sample was accomplished. The correct analysis of an environmental reference material is an effective way to demonstrate this equilibration, along with other factors that determine analytical accuracy. Although the certified value for the reference vegetation has not yet been published, the mean of the 18 individual results in Table 2 (6.02 pCi/g, standard deviation 0.31) is within one standard deviation of the tentative value.[30] Consequently, there appears to be no demonstrable bias in the procedure.

The lower limit of detection for ^{99}Tc determination by this method is 0.1 pCi for a beta-counting time of 3000 min.[28] This limit is defined as the smallest amount of sample activity that will yield a net count rate for which there is 95% confidence that activity is present.

This study has demonstrated the utility of ^{95m}Tc as an internal tracer for the measurement of ^{99}Tc by beta-counting. A combination of alkaline carbonate precipitation, anion-exchange and electro-deposition provides good radiochemical isolation of ^{99}Tc and satisfactory recovery.

Summary—The effects of knowledge of the solution chemistry of the platinum metals on their separation by solvent extraction and ion-exchange methods are reviewed, for the period 1950-1983. The review concentrates on the chloro-complexes of these metals and indicates those areas which need more investigation or interpretation to provide adequate separational methods.

The complex nature of the solution chemistry of the platinum metals has contributed to the difficulty of developing methods for their separation. With more knowledge of the complexes possible in solution, and of their stability and kinetic properties, the solvent extraction and ion-exchange methods should be better understood. The relationship between the solution chemistry of the platinum metals and the ion-exchange and solvent extraction methods used for their separation is therefore reviewed here, for the period 1950–1983. Because of the common use of the chloro-complexes of these metals in such investigations, the review is mainly restricted to these. In some publications, the solution chemistry has been extensively discussed, whereas in others it has been almost completely ignored. We have divided the methods into appropriate sections with illustrative examples and have tabulated similar procedures. An indication is given in each section of the areas which require additional investigation or interpretation. It is important that the chemistry be elucidated if progress is to be made in this difficult area of analytical chemistry.

ION-EXCHANGE

Ion-exchange methods have been developed for most of the platinum metals, based either on differences in the affinity of similar complexes for a resin or on larger differences caused by varying the solution constituents. The capacity of the resins used is usually large (up to 1 meq/g), which allows concentration of the metals, and the method is rapid and offers separation from a variety of other ions.

Electrostatic effects

Several studies[1–7] of the chloro-complexes of the platinum metals clearly indicate that the strength of interaction with anion-exchangers is highly dependent on the charge of the complex. Doubly-

charged complexes ($PdCl_4^{2-}$, $PtCl_4^{2-}$, $PtCl_6^{2-}$, $IrCl_6^{2-}$, $RuCl_6^{2-}$, $OsCl_6^{2-}$) were found to be strongly sorbed by the resins, whereas the triply-charged ($IrCl_6^{3-}$, $RhCl_6^{3-}$, $RuCl_6^{3-}$) were only weakly bound in static systems used for preconcentrating these metals. The sorption of the chloro-complexes of rhodium and ruthenium also depends on the age of the solution, mainly because of the labile character of these metals towards aquation;[4,8–10] complexes of the type $[MCl_{6-x}(H_2O)_x]^{x-3}$ ($x = 1$–6) are formed.[11–26] This property might be useful in some separations but has mainly been considered a problem in dealing with solutions of rhodium and ruthenium. Several platinum metals have been separated with anion-exchange resins, on the basis of the relative strengths of electrostatic interaction (Table 1).

Palladium and platinum. Palladium and platinum in dilute acid are both sorbed strongly by anion-exchangers but it is possible to use the slight difference in interaction at high acid concentrations for sequential elution of palladium with concentrated hydrochloric acid and then platinum with perchloric acid.[2] Alternatively[27] palladium can be recovered with sodium hydroxide solution and platinum with dilute nitric acid.

Rhodium and iridium. By use of only the differences in the strength of electrostatic interaction with the anion-exchange resin, rhodium is typically eluted from the column first with a dilute acid or salt solution, and can be separated from palladium[2] and platinum.[7] The separation of rhodium and iridium by anion-exchange often requires a suitable oxidizing agent to maintain iridium in the quadrivalent state, which is strongly sorbed by the resin.[8,9] Selective reducing agents can reduce Ir(IV) to the non-extractable Ir(III) ($E° = 1.02$ V),[28] which permits a separation from palladium[2] and platinum.[5,27,29] Furthermore, by controlling the oxidation–reduction conditions it is possible to separate a multicomponent system. Table 1 outlines separations of rhodium and iridium from each other and from palladium and platinum.[2,30]

Table 1. Ion-exchange separation based on electrostatic effects

Metals separated*	Medium	Exchanger	Eluent	Other information	Reference
Pd(II)–Pt(IV)	NaCl	Amberlite IRA-400(Cl⁻)	Pd: 9–12M HCl Pt: 2.4M HClO₄	Pd and Pt quantitatively sorbed	2
Pd(II)–Pt(IV)		Permutite ES(OH⁻)	Pd: 1M NaOH Pt: 2.5M HNO₃	Milligram amounts	27
Rh(III)–Pd(II)	2M HCl	Amberlite IRA-400(Cl⁻)	Rh: 2M HCl Pd: 12M HCl	Quantitative separation; microgram amounts	2
Rh(III)–Pt(IV)	pH 2.1, 0.1M NaCl	Cellulose DEAE	Rh: 0.1M NaCl Pt: 1M HCl	Error 1% for 4.7 mg Pt, 3% for 2.5 mg Rh	7
Rh(III)–Ir(IV)	0.1M HCl, 2% NaCl	Amberlite IRA-400(Cl⁻)	Rh: 2% NaCl in 0.1M HCl and 5% bromine water Ir: 5M NH₄OH followed by 6M HCl	Bromine water maintains iridium as Ir(IV)	8
Rh(III)–Ir(IV)	0.8M HCl, NaCl	Amberlite IRA-400(Cl⁻)	Rh: Cerium(IV) solution Ir: Soxhlet extraction with 6M HCl	Cerium(IV) as oxidizing agent	9
Ir(III)–Pd(II) Ir(III)–Pt(IV)	10M HCl	Dowex-1(Cl⁻)	Ir: 10M HCl	99% Ir eluted: no attempt to recover Pd or Pt	1
Ir(IV)–Pd(II)	2M HCl	Amberlite IRA-400(Cl⁻)	Ir: 2M HCl Pd: 12M HCl	NH₂OH to reduce Ir(IV)	2
Ir(IV)–Pt(IV)		Permutite ES(OH⁻)	Ir: 1M NaOH Pt: 2.5M HNO₃	Sodium oxalate to reduce Ir(IV) selectively	27

Separation*		Resin	Conditions	Remarks	Ref.
Ir(IV)–Pt(IV)	0.1M HCl	Cellulose DEAE(OH⁻)	Ir: 0.1–0.4M NaCl in 0.01–0.1M HCl, 0.035M ascorbic acid; Pt: 1M HCl	Ascorbic acid to reduce Ir(IV) selectively	29
Ir(IV)–Pt(IV)	3M HCl	Dowex A-1(Cl⁻)	Ir: 9M HCl; Pt: 50% HClO₄	NH₂OH·HCl to reduce Ir(IV) selectively	5
Rh(III)–Ir(IV)–Pd(II)	2M HCl, NaCl	Amberlite IRA-400(Cl⁻)	Pd: 9M HCl; Rh: 2M HCl; Ir: Reduced with NH₂OH·HCl and eluted with 2M HCl	Ir(IV) in mixture reduced with NH₂OH·HCl; Ir(III) in effluent oxidized with cerium(IV) before recycling through column	2
Rh(III)–Ir(IV)–Pt(IV)	2M HCl, NaCl	Amberlite IRA-400(Cl⁻)	Pt: 2.4M HClO₄	Ir(IV) in mixture reduced with NH₂OH·HCl; Rh and Ir separation as above	2
Rh(III)–Ir(IV)–Pd(II)–Pt(IV)	2M HCl, NaCl	Amberlite IRA-400(Cl⁻)	Rh: 2M HCl; Ir: 2M HCl; Pd: 9M HCl; Pt: 2.4M HClO₄	Combination of the above two procedures used for separation	2
Ir(IV)–Pt(IV) Rh(III)–Pt(IV) Pd(II)–Pt(IV) Rh(III)–Ir(IV) Ir(IV)–Pd(II)–Pt(IV)	HBr	Dowex-1(Br⁻)	Pt: 8% thiourea	Bromo-complexes separated; Br₂ as oxidant, N₂H₄·HCl as reductant	30
Rh(III)–Ru(IV)		Amberlite IRA-400(Cl⁻)	Rh: 2M HCl; Ru: Not possible even with 1% NH₂OH·HCl	Cerium(IV) to prevent Ru reduction by resin	2

*(–) means "separated from".

Table 2. Ion-exchange separation based on kinetic effects

Metals separated*	Medium	Exchanger	Eluent	Other information	Reference
Ir(IV)–Pd(II)	NH_4OH	Amberlite IR-100(NH_4^+)	Ir: 0.025M NH_4OH–0.025M NH_4Cl; Pd: 1M HCl	Pd retained as $Pd(NH_3)_4^{2+}$; Ir as anionic chloride not sorbed	41
Pt(IV)–Pd(II), Ir(IV), Pt(IV)–Pd(II)	NH_4OH	Amberlite IR-100(NH_4^+)		Similar procedure as above	40
Pd(II)–Rh(III)–Pt(IV)–Ir(IV) [Rh(III)–Pt(IV)–Ir(IV)]	NH_4OH	Amberlite IR-100(NH_4^+); Dowex-2(Cl⁻)	Pd: 1M HCl; Rh,Pt: removed one after another with 0.025M NH_4OH–0.025M NH_4Cl	Effluent from cation-exchanger made acidic before passing through anion-exchanger; Ir not recovered	40
Pd(II)–Pt(IV)	NH_4OH	Silica gel	Pd: 0.5M HCl; Pt: 0.25M NH_4Ac	Static system	42
Pt(IV)–Pd(II)	0.25 M NH_4Ac	AG50W-X4(NH_4^+)	Pd:0.1M HCl in 90% acetone	Heated for 10 min to ensure complete formation of $Pd(NH_3)_4^{2-}$	43
Pd(II)–Pt(IV)	0.25M NH_4Ac	AG1-X8(Cl⁻)	Pd: 0.25M NH_4Ac; Pt: 0.01M HCl–0.1M thiourea mixture at 80°	Anion-exchanger sorbed $PtCl_6^{2-}$ but not $Pd(NH_3)_4^{2+}$	43
Pt(IV)–Rh(III)	pH 2	Varion KS(H⁺)	Pt: water; Rh: 1M HCl	Made alkaline (pH 13) first with NaOH, then acidified with HNO_3	44
Rh(III)–Pt(IV)	pH 3.5	Strongly basic anion-exchanger (Cl⁻)	Rh: 0.2M HCl; Pt: dilute NH_4OH	Made alkaline first with NaOH then acidified with HCl; 3.5% Rh left on column	45
Pd(II)–Rh(III), Pt(IV)–Rh(III)	pH 3.5, NaCl	Dowex 50(H⁺)	Pd or Pt: water; Rh: 6M HCl with heating at 60°	First made basic with NaOH and after 10 min made acidic with HCl	46

Ir(IV)–Rh(III)	pH 2.8	Dowex 50(H$^+$)	Ir: 10% chlorine water / Rh: 6M HCl	Ir(IV) reduced with 1% hydroquinone before Rh precipitated and redissolved as cationic complex, then Ir(III) oxidized with chlorine gas	46
Rh(III)–Pt(IV), Pd(II) / Rh(III)–Pd(II), Ir(IV) / Rh(III)–Pt(IV), Ir(IV)				Combination of the two procedures above used for separation of Rh from the mixtures	46
Rh(III)–Pt(IV), Pd(II), Ir(IV) / Ir(IV)–Rh(III)	Pyridine	KU-2(H$^+$)		Rh reacts 6.5 times faster than Ir to form $(Mpy_4Cl_2)^+$	47
Ir(IV)–Rh(III)	Pyridine	KU-2(H$^+$)		With excess Cl$^-$, Ir(IV) forms $(Irpy_2Cl_4)$ which is reduced with ascorbic acid to $(Irpy_2Cl_4)^-$	53
Rh(III)/Ir(IV)–Pd(II)/Pt(IV)	0.5M HCl, 0.1M thiourea	AG50W-X4(H$^+$)	Rh or Ir: 0.5M HCl–0.1M thiourea / Pd or Pt: 4.5M HBr	Rh and Ir do not react with thiourea under these conditions	48
Ir(IV)–Rh(III)	0.3M HCl, thiourea	Dowex 50W-X8(H$^+$)	Ir: 3M HCl / Rh: 6M HCl at 74°	Heating for 1 hr on steam-bath permits complete formation of the cationic Rh–thiourea complex	49
Pt(IV)–Pd(II)	0.02M NH$_4$SCN, 2M HCl	Cellulose DEAE (SCN$^-$)	Pt: 0.02M NH$_4$SCN–2M HCl / Pd: 0.05M thiourea	Separation done at below 5°, Pd forms $Pd(SCN)_4^{2-}$ and Pt remains as $PtCl_6^{2-}$	50
Pt(II)–Pd(II)	pH 2	Sulphonylguanidine	Pt: water / Pd: 3–4M HCl	Sulphonylguanidine, which forms a neutral complex with Pd, was incorporated into a styrene–divinylbenzene copolymer	51
Rh(III)/Ir(III)–Pd(II), Pt(IV)	3M HCl	Styrene-8-aminoquino-line-based copolymer	Rh or Ir: 3M HCl	Sorbent exhibits both ion-exchange and complex-forming properties	52

*(−) means "separated from"; (,) means "and"; (/) means "or"; [ ] indicates "a subsequent separation of these metals after the preliminary step shown above it".

Ruthenium and osmium. The only description found of an anion-exchange separation of Ru(IV) is for its separation from Rh(III), both being present as chloro-complexes.[2] The ease of reduction of Ru(IV) to Ru(III) by the resin made it essential to add cerium(IV) to maintain the higher oxidation state. However, because of the strong sorption of ruthenium on the resin, its complete recovery was impossible even with reducing agents such as hydroxylamine hydrochloride. If the ruthenium is reduced to Ru(III) in solution, no separation is possible from Rh(III) because of the similar low affinity of both tervalent metals for the exchanger.

No work has been reported on the sorption of the chloro-complexes of osmium by anion-exchange resins, although quantitative liquid ion-exchange extraction of the quadrivalent metal has been achieved.[31-37] No successful ion-exchange separation of osmium and ruthenium has been reported. The ease of reduction of Os(IV) and the reduction or partial hydrolysis of Ru(IV) prevent their quantitative separation.[38] However, liquid anion-exchangers have been used for the separation of the chloro-complexes of Ru(III) and Os(IV),[34,39] as discussed later. Because the ion-exchange resins are usually less reducing than the liquid ion-exchangers, it would be expected that the resin separation of ruthenium and osmium should indeed be possible.

Kinetic effects

The differences in the labile character of the platinum metals in the formation of cationic, anionic, and neutral species has been used for their separation (Table 2). For example, the rate of formation of the cationic ammine complex of Pd(II) from its chloro-complex is sufficiently different from that for other metals[40-43] to permit isolation of the complex. The rapid formation of $Rh(H_2O)_6^{3+}$ through precipitation of the hydroxide and redissolution in dilute acid has been used in several ion-exchange procedures.[44-46] Incomplete conversion and instability in more acid conditions [resulting in formation of other complexes, $RhCl_{6-x}(H_2O)_x^{x-3}$] cause major problems with these methods.

Other studies on the separation of platinum metals have been reported where the differences in their labile character toward pyridine,[47] thiourea,[48,49] thiocyanate,[50] sulphonylguanidine incorporated into a styrene–divinylbenzene copolymer,[51] and styrene–8-aminoquinoline-based copolymer[52] have played an important role.

Though several studies have indicated reasonable success in separation of several of the platinum metals, the advantage of the differences in their labile character could be further utilized.

SOLVENT EXTRACTION

Solvent extraction has been widely used for separation of the platinum metals.[54-55] The difficulty in developing extraction procedures for the individual metals is due to the slow reaction of the chloro-complexes. The solvent extraction methods for the separation of binary or multicomponent systems of these metals use the differences in their kinetic behaviour for the formation of extractable species, as well as the strength of electrostatic interaction of their chloro-complexes with liquid ion-exchangers or with oxygen-containing solvents.

Common binary mixtures

Electrostatic effects. The contribution of the charge of the complex and its labile character towards hydration has been useful in the separation of platinum metal mixtures. The inertness of the chloro-complexes of palladium and platinum toward aquation plays an important role in their extraction from acidic solution by an anion-exchange mechanism with organic bases such as amines, quaternary ammonium salts, antipyrines and other nitrogen-containing exchangers.[34,36,56-63] However, because both metals are highly extractable as chloro-complexes their separation is difficult and has not been reported in the literature reviewed.

The chloride complex of Ir(IV) is highly extractable into organic solvents,[34,36,57,59,62-69] whereas the Ir(III) form is much less extractable[59,62,65,68] owing to the increase in the charge on the complex. On the other hand, the Rh(III) chloro-complex is also poorly extracted,[34,36,57,59,63-66,69] which is due to the charge of the complex as well as its labile character toward aquation, *i.e.,* formation of $[RhCl_{6-x}(H_2O)_x]^{x-3}$ $(x = 1–6)$.

Ruthenium and osmium can also be separated as chloro-complexes because of their different affinities towards the extractant through either the anion-exchange or hydration–solvation mechanism. Ru(IV) is highly extractable but Ru(III) is not.[34,36,59,76-79] The poor extraction of Ru(III), like that of Rh(III), is attributed to both the charge on the complex and to the ease of aquation to form $[RuCl_{6-x}(H_2O)_x]^{x-3}$ $(x = 1–6)$. Os(IV) behaves similarly to Ir(IV) and is inert toward aquation and is quantitatively extracted by anion-exchangers[31-37] or by oxygen-containing extractants.[80-83]

Several procedures (Table 3) have utilized these differences in behaviour of the chloro-complexes of these common binary mixtures of platinum metals for their separation by different types of organic solvents.

Although the separation of rhodium and iridium as their chloro-complexes has been widely investigated with the iridium kept in the quadrivalent state, the problem of recovery of the last traces of rhodium has not yet been solved. In addition, the nature of the extracted rhodium complex needs to be elucidated to provide the necessary information for developing efficient methods for its recovery.

Kinetic effects. The differences in the formation rate of the extractable anionic, neutral, or cationic species of the binary mixtures of Pd–Pt, Rh–Ir, and

Table 3. Solvent extraction based on electrostatic effects

Metals separated*	Aqueous phase	Organic phase	Other information	Reference
Rh(III)–Ir(IV)	6–7M HCl	Tri-n-butyl phosphate	Aqueous phase treated with H_2O_2 to oxidize Ir, heated at 90° to destroy excess peroxide	70
Rh(III)–Ir(IV)	6M HCl saturated with NaCl	Tri-n-butyl phosphate	For quantitative separation, the oxidation of Ir by H_2O_2 is necessary in each of the nine extraction stages required	71
Rh(III)–Ir(IV)	6M HCl	Tri-n-octylamine in benzene	Continuous treatment with chlorine gas to prevent Ir reduction by amine	72
Rh(III)–Ir(IV)	6M HCl	Tri-n-octylamine-loaded silicone rubber foam	In presence of free chlorine, 98% Ir extracted while 99% Rh remained	73
Rh(III)–Ir(IV)	HCl	Diantipyrylpropylmethane in dichloroethane	Acidic solutions containing NaCl and H_2O_2 evaporated to a moist salt before dissolving for extraction	34
Ru(IV)–Os(IV)	3–6M HCl	Diantipyrylpropylmethane in dichloroethane	Solutions containing $N_2H_4 \cdot HCl$ or $N_2H_4 \cdot H_2SO_4$ heated to reduce Ru selectively to Ru(III)	34
Ru(III)–Os(IV)	0.1–0.3M HCl Ph_4AsCl	Chloroform	Os extracted as $2Ph_4As^+ \cdot OsCl_6^{2-}$	74
Ru(III)–Os(IV)	0.058M HCl	Amberlite LA-1 in chloroform	Os extracted then Ru oxidized to RuO_4^- and extracted with Ph_4AsCl in chloroform	39
Ru(III)–Os(IV)	6M HBr	Methyl isobutyl ketone	As bromo-complexes, Os extracted quantitatively whereas only 2% Ru was extracted	75
Ru(III)–Os(IV)	~5M HCl	Triphenylphosphine in 1,2-dichloroethane	A quantitative separation is possible	64

(–) means "separated from".

Ru–Os with several complexing or chelating agents have been utilized for their separation from aqueous solution.

Palladium and platinum. These will be discussed in terms of charge type.

(*i*) *Anionic complexes.* The kinetically labile character of the chloro-complexes of palladium towards a number of hydrophobic anions allows the immediate formation of highly extractable anionic complexes at room temperature.[84–86] Platinum, which reacts slowly under the same conditions,[87] may thus be separated from palladium. For example, milligram amounts of these metals in ammonium thiocyanate–hydrochloric acid solutions can be separated by the weakly basic diethylaminoethyl cellulose ion-exchanger.[50] The efficiency of separation increases with decreasing temperature, and below 5°, about 98% of the platinum (as $PtCl_6^{2-}$) can be separated from palladium, which is quantitatively sorbed as $Pd(SCN)_4^{2-}$. Because the palladium complex is highly extractable by oxygen-containing solvents whereas the $PtCl_6^{2-}$ is not, it should also be possible to separate them by using extractants such as phosphates, alcohols, ketones, esters, ethers, *etc.*

(*ii*) *Neutral complexes.* Neutral complexes of the type MX_nL_2 ($n = 2$ for Pd and 2 or 4 for Pt) are formed by the reaction of palladium[88–97] and platinum[56,88,93,98,99] with suitable singly-charged anions (X) and organic bases (L) such as those containing N, S, P, As, Sb, *etc.* These complexes with ions such as halide or thiocyanate are soluble in carbon tetrachloride, chloroform, 1,2-dichloroethane, cyclohexane, benzene, *etc.* The extractable species of

Pd(II)[64,92,99–102] are produced rapidly even at room temperature, whereas Pt(II) complexes form more slowly and Pt(IV) complexes often require heating[93,100,102,103] or the use of a catalyst such as stannous chloride.[64,93,99–101] Stannous chloride also acts by reducing Pt(IV) to the more reactive Pt(II) species. The rate of formation of the neutral complexes is in the order $Cl^- < Br^- < I^-$ in the presence of excess of the halo-acid; this corresponds to the order of decreasing bond strength and increasing reduction potential. For example, there is no reaction with 2-mercaptobenzothiazole[112] or diphenylthiourea[113] added to a hydrochloric acid solution of platinum, but a yellow precipitate is formed if potassium iodide is added to the solution either before or after the ligand. This can be attributed to reduction to Pt(II) and the subsequent formation of the more labile PtI_4^{2-} from the original $PtCl_6^{2-}$. Also, palladium can be extracted as $PdX_2(DOS)_2$ [DOS = di-n-octyl sulphide] from acidic chloride, bromide or iodide solution with cyclohexane,[106] but platinum can only be extracted from iodide solution [probably as $PtI_2(DOS)_2$ rather than the reported $PtI_4(DOS)_2$].

The separation of platinum and palladium is best accomplished by extracting the palladium complex before formation of the extractable platinum complex becomes significant. This can be done by starting with the chloro-complexes of the metal in neutral solution at room temperature or below. A low salt concentration reduces the formation of $PtCl_nL_2$ and a weakly acidic solution restricts the extraction of $PtCl_6^{2-}$ through the hydration–solvation or anion-extraction mechanism. To minimize the extraction of

platinum, it is best to start with Pt(IV) in the absence of any reducing agent, since this form is less labile, and the separation should be done quickly since the formation of PtX_nL_2 is kinetically slow.

On the basis of these differences in the behaviour of palladium and platinum toward different neutral ligands, several methods for their separation have been considered, some of which are indicated in Table 4.

Several sulphur-containing ligands,[114-116] including dialkylsulphides and dialkylsulphoxides,[107,117-119] have been used to extract palladium and may be efficient for its separation from platinum. Though several derivatives of dithiocarbamic acid have been used in chloroform to extract palladium and platinum individually, it would appear[120] that diphenyl-dithiocarbamic acid can be used for quantitative separation of palladium from platinum. This should be possible in solutions containing sodium sulphide as a reducing agent, even in up to $2M$ hydrochloric acid, though at such high acid concentrations it is customary to use a nitrogen-containing ligand as counter-anion in an ion-association extraction.

Some of the most promising ligands for the separation of palladium and platinum are dialkylsulphoxides, which can be used in oxidizing media, and dialkylsulphides, which can be used in basic or highly acidic solutions ($>6M$ hydrochloric acid), whereas ligands containing sulphur and nitrogen and/or oxygen as donor atoms can be used only in dilute acid solutions. More detail is needed on the effect of branched substituents on the behaviour of the ligand and on whether the different extractable species formed with the sulphoxides in highly acidic solutions are neutral $PdX_2(R_2SO)_2$ or hydrated–solvated $2[H(R_2SO)(H_2O)_n^+]\cdot[PdCl_4^{2-}]$ complexes. Also there may be sufficient differences in the kinetic behaviour of platinum and palladium with different amines to allow separation of these metals, since the tendency of the amines to form the neutral complexes decreases in the order $RNH_2 > R_2NH > R_3N$.

(iii) Cationic complexes. The significant difference in the rate of formation in ammoniacal medium of the ammine complexes $[M(NH_3)_n^{m+}]$ of palladium and platinum has been used for the separation of these metals.[111] High molecular-weight amines such as tri-n-hexylamine, tri-n-octylamine and primene, dissolved in chloroform or benzene, have been used as liquid anion-exchangers for the extraction separation of platinum from palladium, but careful timing was necessary to avoid significant formation of the platinum ammine complex. Other methods could be developed, based on the slower formation of the platinum-ammine, perhaps by enhancing the difference in the formation rates by using ammonium acetate rather than ammoniacal medium, or by use of different liquid anion- and cation-exchangers.

Rhodium and iridium. The chloride complexes of both rhodium[61,64,65,70,87,93,121-125] and iridium[64,65,93,100,101,103,115,124,126,127] react very slowly at room temperature

to form extractable anionic $(M_nCl_mX_p)^{k-}$ [$X = Br^-$, I^-, $SnCl_3^-$, $SnBr_3^-$, SCN^-, etc.] or neutral MCl_mL_n [L = a neutral organic compound containing N, S, P, As, Sb] complexes. Heating the aqueous phase or introduction of a catalyst before extraction accelerates the formation of the extractable species. The relatively labile character of rhodium compared to iridium [Rh(III) > Ir(III) > Ir(IV)] in the formation of the extractable anionic[128-130] or neutral[64,98,99,131,132] complexes plays an important role in their separation; this commonly involves converting rhodium into the extractable form while maintaining iridium in the unextractable chloride form. In addition, the presence of excess of salt or stannous chloride affects the formation of the anionic and neutral complexes, respectively. Table 5 lists the separation of several rhodium and iridium complexes.

(i) Anionic complexes. Rhodium has been extracted in the form $Rh_nCl_mX_p^{k-}$ from solutions containing iridium, by oxygen-containing solvents. The addition of stannous bromide produces the rhodium complex much more rapidly than that of iridium in hydrochloric acid solution.[133] Isopentyl alcohol can be used to remove the rhodium–tin(II) bromide even in the presence of large amounts of sodium chloride, and from perchloric acid solution. The difference in the reaction rates means that the rhodium complex takes 2 hr to form at room temperature (although obviously the time could be shortened by warming the solution) whereas the iridium complex is formed only by heating the solution at 90° for at least 3 min (and even then gives inconsistent results).

Rhodium can also be extracted from iodide solution with tri-n-butyl phosphate in toluene.[134] The formation of the iodo-complex requires heating at 70° for 1 hr at pH 2. The complex is extracted from $1M$ sulphuric acid, probably through the hydration–solvation mechanism, and can be stripped with ammonia solution. The iridium complex is unlikely to be appreciably formed under these conditions and a separation of rhodium and iridium should be possible.

One of the difficulties in the extraction of rhodium and its separation from iridium is the labile character of the starting hexachloro-complex of rhodium towards aquation. With aging, species of the type $[RhCl_{6-x}(H_2O)_x]^{x-3}$ ($x = 1$–6) are formed, which react at different rates with a ligand and thus produce different complexes with varying extractability. To avoid this problem, rhodium can be converted into the hexachloro form by evaporating the solution to dryness in the presence of a chloride salt shortly before use.[133] An example of the effect of aging[135] is the extraction of rhodium as a thiocyanate complex by polyurethane foam; in this case a one-day old solution, containing mainly $[RhCl_5(H_2O)]^{2-}$, was 92% extracted, whereas a seven-month old solution containing mainly $RhCl_3(H_2O)_3$ was only 78% extracted.

The use of a chloride salt for stabilizing rhodium

Table 4. Solvent extraction of palladium and platinum, based on kinetic effects

Aqueous phase	Organic phase	Other information	Reference
Neutral complexes			
pH 2–5, alcoholic solution of p-nitrosodimethylaniline	Chloroform	Five min at room temperature for Pd–p-nitrosodimethylaniline complex formation; no Pt reaction for several hr	104
pH 4	Dimethylglyoxime-treated silicone fubber foam	Quantitative separation; Pd extracted was completely recovered with 8M HNO$_3$	105
HCl or HBr	Di-n-octyl sulphide in cyclohexane	Selectivity of the ligand for Pd permits its separation from Pt	106
HCl or HNO$_3$	R$_2$S in benzene; R = Bu–C$_8$H$_{17}$, Ph	High efficiency of Pd extraction as PdX$_2$·2R$_2$S (X = NO$_3^-$ or Cl$^-$) from HCl or HNO$_3$, may isolate it from Pt	107
Up to 2M HCl 6M HCl	Di-n-octyl sulphoxide in benzene Di-n-heptyl sulphoxide in 1,1,2-trichloroethane	A separation factor of 10^3 permits selective removal of Pd Simultaneous extraction of Pd and Pt and subsequent back-extraction of Pt with water and Pd with 10% dimethylamine can separate Pd and Pt in solution containing Rh and Ir	108 109
pH 3	2-Mercaptobenzothiazole in chloroform	Pd was quantitatively extracted and since 1.8% Pt was extracted, a separation was suggested	93
pH 6, 2-thenoyltrifluoroacetone	n-Butanol	After Pd was extracted as PdCl$_2$L$_2$, solution was made 6M in HCl and Pt extracted with butanol–acetophenone mainly through the hydration–solvation mechanism	110
Cationic complexes			
NH$_4$OH, conc. HCl, SnCl$_2$	Tri-n-hexylamine, tri-n-octylamine, or primene in benzene or chloroform	Delay of 0.5–1 min between addition of ammonia and HCl permits complete formation of Pd(NH$_3$)$_4^{2+}$ while maintaining Pt in its chloro-form	111

Table 5. Solvent extraction of rhodium and iridium, based on kinetic effects

Aqueous phase	Organic phase	Other information	Reference
Anionic complexes			
$SnBr_2$, HBr–$HClO_4$, $NaCl$	Isopentyl alcohol	Extractable Rh-stannous bromide complex formed at room temperature; heating required for Ir	133
NaI, $1M$ H_2SO_4 or $HClO_4$	Tri-n-butyl phosphate in toluene	Under optimum conditions for Rh–iodide complex formation (pH 2, heating at 70° for 1 hr), a distribution coefficient ratio of Rh/Ir of 650 suggests an efficient separation possible	134
$2 \times 10^{-3}M$ $KSCN$, $2M$ HCl	Polyurethane foam	Acid added after heating the solution at 90° for 4 hr; an average of 88% Rh extracted while 91% of Ir remained in aqueous phase	135
$2 \times 10^{-3}M$ $KSCN$, $2M$ HCl, $3M$ $LiCl$	Polyurethane foam	Acid added after heating the solution at 90° for 30 min; an average of 93% Rh extracted; 95% Ir remained in aqueous phase	125
Neutral complexes			
4–$6M$ HCl	2-Mercaptobenzothiazole in chloroform	Solution boiled for 7 min; quantitative for Rh, 6–10% Ir extracted	93
0.25–$2M$ HCl, $SnCl_2$	2-Mercaptobenzothiazole in chloroform	Heating not required; quantitative for Rh; negligible Ir extraction	93
1–$2M$ HCl, 4,5-dimethyl-2-mercaptothiazole	Chloroform	Vigorous boiling for 1 hr required for reduction and maximum formation of complex; both Rh and Ir extractable	136, 137
3–$9M$ HCl, $SnCl_2$, 4,5-dimethyl-2-mercaptothiazole	Chloroform	Reduction and formation of complex at room temperature; no interference by Ir	137
1–$6M$ HCl, $SnCl_2$, diphenylthiourea	3:2 v/v Chloroform–acetone mixture	Standing for 20 min at room temperature for complete Rh–diphenylthiourea complex formation; quantitative separation of Rh and Ir.	113
Cationic complexes			
$<0.05M$ HCl	Dinonylnaphthalene-sulphonic acid in n-heptane	$Rh(OH)_3$ precipitated by $6M$ NaOH and redissolved with $0.1M$ HCl; 90% Rh extracted and recovered with $6M$ HCl; 99% Ir in aqueous phase	138

as the hexachloro-complex in solutions is of considerable importance. Because rhodium solutions usually require heating to form the extractable species, the aquation of the rhodium complex is facilitated. The different aquation complexes react at various rates with a ligand, because the water molecule is less labile than the chloride ion, although eventually the same complex may be produced. When a chloride salt is present in a freshly-prepared rhodium solution, it ensures the rhodium is present as the hexachloro-complex, which is the most labile form.

The use[125] of $2M$ lithium chloride medium reduces the heating time for formation of $Rh(SCN)_6^{3-}$ at 90° to 30 min from the 4 hr required in absence of the chloride. However, with iridium solutions even $4M$ lithium chloride does not decrease the required heating time of 4 hr and in fact decreases the extraction of the thiocyanate complex by polyurethane foam;[125,135] this is due to the inertness of the hexachloroiridate towards aquation, resulting in a competition between the chloride and thiocyanate ions for iridium.

The tin(II) bromide complexes of rhodium and iridium, which are extracted by several nitrogen-containing solvents in chloroform,[129] are also affected by chloride ion. The presence of $4M$ chloride almost completely inhibits the formation of the extractable iridium–tin(II) bromide complex while not affecting the formation of the rhodium complex, for which these are the ideal formation conditions. In this case the competition between $SnBr_3^-$ and Cl^- for iridium is the most likely reason for the decrease in formation of the bromostannate(II) complex.

The role of chloride in the reaction of iridium and in labilizing the formation of anionic complexes of rhodium with different hydrophobic anions, e.g. Br^-, I^-, $SnCl_3^-$, $SnBr_3^-$, etc. needs to be further studied and should be extended to neutral ligands containing N, S, P, As, Sb, etc.

(ii) *Neutral complexes*. Neutral sulphur-containing complexes of rhodium can be formed, and extracted by an organic solvent, while iridium is maintained as the unextractable chloro-complex. Heating is required to accelerate the formation of the rhodium complex and reduction to the more labile Rh(II) form, but this also results in the partial formation of an extractable iridium complex. Though quantitative extraction of rhodium has been obtained[93] by boiling a solution of rhodium and iridium with 2-mercaptobenzothiazole, cooling, and extracting with chloroform, 6–10% of the iridium was co-extracted.

To avoid co-extraction of the iridium with rhodium, acidic solutions of stannous chloride have been used to labilize formation of the rhodium complex. The catalytic behaviour of stannous chloride arises mainly because of its ability to reduce rhodium to Rh(II) and form relatively labile complexes of the type $MCl_m(SnCl_3)_n^{-(n+m)}$. The formation of the extractable neutral sulphur-containing complex ($MCl_m L_n$)

is facilitated by substitution of a sulphur-containing ligand (L) for the more labile $SnCl_3^-$ rather than for Cl^-. In the presence of stannous chloride the rhodium complex forms rapidly and does not require heating, which would result in the simultaneous formation of a similar iridium complex. From acid solutions containing 2-mercaptobenzothiazole and stannous chloride, more than 99% of the rhodium can be extracted into chloroform, but no iridium.[93] It is possible that stannous bromide may be even more effective in accelerating the formation of an extractable rhodium complex, since it is a stronger reducing agent and is more labile than stannous chloride.

The use of sulphur-containing ligands has not been studied extensively and the effectiveness of several alkyl and aryl derivatives of thiourea which are now available should be considered. Dialkyl sulphides and other sulphur-containing reagents with a relatively high electron density should be examined, for example, since dibenzyldithiocarbamate has been noted as introducing an extreme interference from rhodium in the extraction of palladium and platinum[120] because of an analogous rapid reaction. Other neutral-acceptor ligands which are weakly protonated in acidic media, e.g., derivatives of phosphine, arsine and stibine, may also be useful for separations.

(iii) *Cationic complexes*. Liquid cation-exchangers have been used for the separation of the chloro-complexes of rhodium and iridium, utilizing the ease of formation of the cationic $Rh(H_2O)_6^{3+}$ complex. This complex has usually been produced by precipitation of $Rh(OH)_3$ and formation of $Rh(H_2O)_6^{3+}$ by redissolution in dilute acid. The latter complex can be extracted with dinonylnaphthalenesulphonic acid in heptane.[138] These methods are limited because of incomplete $Rh(OH)_3$ precipitation and instability of $Rh(H_2O)_6^{3+}$ in hydrochloric acid, where neutral or anionic chloro-complexes can also be formed.

Ruthenium and osmium. The chloro-complexes of Ru(III or IV)[98,99,116,139-141] and Os(IV)[98,99,142] react with hydrophobic anions or neutral ligands to form extractable species. Several hours are required for the reaction of Ru(III or IV) chloride complex with hydrophobic[141] and neutral complexing agents[143] at room temperature but only a few minutes with heating; the rate of reaction with Os(IV) chloride is much slower.[144-146]

Excess of chloride also plays an important role in the separation, since the chloride complexes of Ru(III or IV), like those of Rh(III)[147] are labile toward aquation, whereas osmium is inert like iridium. Therefore the addition of chloride ions increases the rate of ruthenium reaction with hydrophobic or neutral complexing agents and decreases that of osmium.

(i) *Anionic complexes*. The maximum formation of $Ru(SCN)_6^{3-}$ requires only 5 min heating at 90° while that of $Os(SCN)_6^{3-}$ requires 3 hr. In addition, the presence of $3M$ lithium chloride increases the formation of the ruthenium complex and decreases

that of the osmium complex, so a 95% complete separation is possible.[142] It would be useful to see the effect of other complexing agents in this type of separation.

(ii) *Neutral complexes.* The chloro-complexes of Ru(III or IV) and Os(IV) react with neutral organic compounds (L) such as those containing N, S, P, As, Sb, etc. to form neutral complexes of the type[64,98,99,140] MCl_nL_m which are highly extractable into organic solvents (Table 6). The difference in formation of the complexes of ruthenium and osmium is mainly due to ·the reducing nature of the solution and has played an important role in their separation.

Osmium can be quantitatively extracted from $6M$ hydrochloric acid with triphenylphosphine in 1,2-dichloroethane.[64] Ruthenium is not extracted in the absence of stannous chloride, because of its low lability at room temperature. If stannous chloride is present, the extraction of osmium is reduced to less than 20%, while ruthenium becomes up to 95% extractable from $4M$ hydrochloric acid. Mojski suggested that in the presence of stannous chloride osmium is reduced to an oxidation state lower than the tervalent, and that this forms neither a stable chloride complex with phosphine nor stable negatively charged chloride complexes.

The presence of excess of chloride has a considerable effect on the separation of osmium and ruthenium, as noted[149] in the extraction from 2-mercaptobenzothiazole medium into chloroform. Osmium can be quantitatively extracted from solution at pH 3.5–5.0 after 15 min standing at room temperature. If the solutions are 3–$6M$ in hydrochloric acid and boiled for even as little as 5 min, the extraction is reduced to only 0.4%;[93] this may be due to some reduction and/or the competition between the ligand and chloride for osmium. On the other hand, the chloride accelerates the formation of the extractable ruthenium complex in comparison to the aquated species.

Methods for the separation of osmium and ruthe-

nium and their spectrophotometric determination need to be developed on the basis of the effect of excess of halide and the reaction with organic compounds containing weak donor atoms. At present, the nature of the extractable species formed under reducing conditions is unclear and should be elucidated.

(iii) *Cationic complexes.* The reactions between thiourea and hexabromo-osmate[150] and hexachloro-osmate[146] are extemely slow at room temperature. However, though the osmium complex is not formed in $6.7M$ hydrobromic acid for at least 4 hr, the maximum formation of the cationic ruthenium–thiourea complex occurs in only 15 min.[151] Solvent extraction and ion-exchange separation of osmium and ruthenium should thus be possible, although neither has been reported.

The labile nature of the chloride complex of ruthenium toward aquation to give $[RuCl_{6-x}(H_2O)_x]^{x-3}$ ($x = 1–6$), which is like that of rhodium, results in ruthenium interference in the extraction of rhodium by the liquid cation-exchanger dinonylnapthalene-sulphonic acid,[138] and explains the sorption of some ruthenium on Dowex-50 cation-exchanger.[10] Since, like that of iridium, the chloro-complex of osmium is kinetically inert toward aquation, the difference in the tendency for formation of cationic complexes may be used for separation by converting ruthenium into a cationic form while keeping osmium as an anion, in the manner used for the separation of rhodium and iridium.[138]

Other effects used for separation of binary mixtures

Palladium and platinum. The photosensitive nature of platinum has been used[152] to enhance the formation of the thiocyanate complex and the separation of palladium and platinum by extraction of the triphenylisopropylphosphonium salt into ethyl acetate. It would appear that in the absence of light that the palladium complex should still be formed, while the platinum remains as a chloro-complex, thus

Table 6. Solvent extraction of osmium and ruthenium, based on kinetic effects

Aqueous phase	Organic phase	Other information	Reference
Anionic complexes			
$0.6M$ KSCN, $3M$ NH$_4$Cl pH ~ 3	Polyurethane foam	Heating the solution at 90° for 5 min was enough for maximum formation of $Ru(SCN)_6^{3-}$ while leaving Os as its unextractable chloro-complex	142
Neutral complexes			
~$3M$ HCl	Triphenylphosphine in 1,2-dichloroethane	Presence of SnCl$_2$ accelerates formation of extractable Ru–triphenyl-phosphine complex and reduces Os(IV) to lower states which form no stable complex with the ligand	64
$6M$ HCl, 1,4-diphenyl-thiosemicarbazide	Chloroform	Heated at 100° for 10–15 min in presence of SnCl$_2$, Ru forms an extractable red-violet complex, but Os does not react with the organic reagent	148
$6M$ HCl, 2-mercaptoben-zothiazole	Chloroform	Aqueous phase boiled for 5 min; Ru extracted quantitatively; less than 0.4% Os extracted	93

permitting an extraction of $Pd(SCN)_4^{2-}$ by several organic solvents.[52]

The thiocyanate concentration has a considerable effect on the formation of $Pt(SCN)_6^{2-}$: the rate of formation of the complex decreases up to $0.1M$ thiocyanate concentration and then increases. The rate is also inversely proportional to pH and the reaction is completely inhibited at pH 7.0. Because $Pd(SCN)_4^{2-}$ is easily formed, at a rate relatively independent of thiocyanate concentration, a separation of these metals is possible, and extraction with polyurethane foam, which may be considered as an oxygen-containing solvent, has been reported.[153]

The importance of solution acidity can be seen in the separation of Pd(II) and Pt(IV) from thiocyanate solution adjusted to pH 6.0 with pyridine, $Pdpy_2(SCN)_2$ being extracted with methyl isobutyl ketone.[87] Platinum could only be extracted when the solution was adjusted to pH 2.0 with hydrochloric acid and heated at 90°.

The separation of palladium and platinum by simultaneously controlling more than one of the effects of light, pH, thiocyanate concentration and use of different oxygen-containing solvents, needs more investigation than has been reported in the papers listed in Table 7. In addition, hydrophobic complexing anions other than thiocyanate, such as bromide and iodide, with which replacement reactions with hexachloroplatinate are reported to be strongly photosensitive,[160,161] also warrant study.

Ruthenium and osmium. One of the characteristic features of ruthenium and osmium is their ability to form the volatile non-polar tetroxides, which are extractable with several organic solvents such as carbon tetrachloride,[154,162–165] chloroform[154,166,167] and mepasine[168] (Table 7). Osmium can be selectively oxidized to the tetroxide and separated from ruthenium[154] by extraction into carbon tetrachloride.

Ruthenium and osmium can also be simultaneously oxidized and subsequently distilled as their tetroxides. A separation is possible because of the difference in the kinetics of reduction of the tetroxides. The reduction of OsO_4 to $[OsO_2Cl_4]^{2-}$ and then to $OsCl_6^{2-}$ is slow and highly dependent on the hydrochloric acid concentration, temperature and reduction time, whereas that of RuO_4 to the corresponding anionic chloro-complexes is fast and takes place under much milder conditions.[147] For example,[155] ruthenium can be trapped by reduction in $10M$, $4M$ or $3M$ hydrochloric acid while osmium is not, and instead is subsequently absorbed by 1:1 sulphuric acid–phenyldimethylamine mixture.

Several extraction–spectrophotometric determinations of osmium that start with the tetroxide are reported to suffer no interference from Ru(III) chloride, *e.g.*, the anionic osmium–thiocyanate complex[158,169] and the neutral 2-mercaptobenzothiazole[149] and 2-mercaptobenzimidazole[170] complexes. Alternatively,[75,171] ruthenium may be extracted quantitatively as the cationic thiourea complex,

because in concentrated hydrobromic acid medium, the formation of an osmium–thiourea complex is inhibited.

The tetroxides of ruthenium[157,172] and osmium[144,158,169,170,173–175] have been used for their preconcentration, and the difference in their tendency to form extractable species can play a major role in their separation by organic solvents (Table 7).

The thiocyanate concentration also appears important in the formation of the extractable complexes.[157] After distillation of the tetroxides and collection in $0.2M$ ammonium thiocyanate in $0.4M$ hydrochloric acid, osmium can be extracted quantitatively with diethyl ether containing hydrogen peroxide. If the conditions are then changed to $0.3M$ thiocyanate in $1M$ hydrochloric acid, ruthenium can then be quantitatively transferred into methyl isobutyl ketone. In the presence of $0.04M$ thiocyanate, the extraction of osmium does not require addition of hydrogen peroxide,[169] and although this was not reported, may in fact give a good separation from ruthenium.

The presence of chelating agent and excess of chloride ion increases the difference in the rate of formation of the extractable neutral species of osmium and ruthenium. For example, ruthenium can be separated from osmium by extraction into chloroform after the formation of a ruthenium–diphenylthiourea[74] or 2,4-thiosemicarbazide complex[159] at high hydrochloric acid concentration.

The effect of neutral organic ligands and hydrophobic anions such as Br^-, $SnCl_3^-$, $SnBr_3^-$, *etc.* on the labile nature of the complexes and its contribution to the extraction of ruthenium and osmium with oxygen-containing solvents and liquid anion-exchangers still needs investigation. The tendency of osmium tetroxide to form more than one extractable species with thiocyanate,[157,158,169,176–179] whereas ruthenium forms only one, may also be potentially useful.

Other binary and multicomponent systems

Although Pd–Pt, Rh–Ir, and Ru–Os are the common pairs of platinum metals which often exhibit some difficulty in their separation, there are several other combinations which have been investigated, including those with multiple components. These separations use the electrostatic effects, kinetic effects, and selective oxidation, often in conjunction with one another for complex systems.

Tetroxides. Ruthenium and osmium are commonly separated first from any of the other platinum metals because of their easy removal from the system as their tetroxides. The selective oxidation of ruthenium and osmium to the tetroxides and subsequent extraction by chloroform or carbon tetrachloride has been utilized for the separation of these metals from the rest of the platinum metals. Furthermore, the differences in the kinetic behaviour of these tetroxides toward reduction in acidic solutions has been used for the separation of ruthenium and osmium as discussed

Table 7. Solvent extraction based on other effects

Aqueous phase	Organic phase	Other information	Reference
Palladium and platinum			
NaSCN	Ethyl acetate and methyl isobutyl ketone	Solution irradiated for 15 min with 500-W incandescent bulb; Pt extracted as ion-association complex $[(C_6H_5)_3C_3H_7P^+]_2 \cdot [Pt(SCN)_6^{2-}]$ with ethyl acetate then Pd as $[(C_6H_5)_3C_3H_7P^+]_2 \cdot [Pd(SCN)_4^{2-}]$ with methyl isobutyl ketone	152
0.15*M* KSCN, 0.5*M* HCl, H_2O_2	Polyurethane foam	Under these conditions Pd is present as $Pd(SCN)_4^{2-}$ and Pt as $PtCl_6^{2-}$; 95% Pd extracted, but less than 2% Pt	153
KSCN	Methyl isobutyl ketone	Pd extracted as $Pdpy_2(SCN)_2$ at pH 6 fixed by pyridine; Pt extracted by adjusting the pH to 2 with HCl and heating the solution at 90° for 4 min	87
Ruthenium and osmium			
HNO_3	Chloroform	Tetroxides of Ru and Os reduced with $(NH_4)_2Fe(SO_4)_2$; Os selectively oxidized with 5*M* HNO_3 and extracted	154
$HClO_4$		Ru and Os oxidized with $HClO_4$ and distilled; RuO_4 reduced in 10*M*, 4*M*, 3*M* HCl; OsO_4 reduced with 1:1 sulphanilic acid–phenyldimethylamine mixture	155
$HClO_4$		The tetroxide complexes passed into five flasks; RuO_4 reduced with 1:1, 1:2, 1:3 HCl; OsO_4 reduced with 10% NaOH and alcohol	156
0.2*M* NH_4SCN, 0.4*M* HCl	Peroxide-containing diethyl ether	5 min in a boiling water-bath then Os extracted; Ru was extracted with methyl isobutyl ketone from solution made 0.3*M* in NH_4SCN, 1*M* in HCl	157
0.03–0.06*M* NH_4SCN, 1.25–1.75*M* HCl	Hexamethylphosphoramide in chloroform	No interference in determination of the blue Os–SCN complex suggests a method for its separation from Ru	158
$HClO_4$, 1,5-diphenylcarbo-hydrazide in ethanol	Chloroform	With excess of chloride OsO_4 is reduced to $OsCl_6^{2-}$ which prevents its reaction with the ligand; Ru(III) is highly extractable and can be separated from Os	144
5–7*M* HCl, diphenylthiourea	Chloroform	Extraction of 30 $\mu g/ml$ Ru as diphenylthiourea complex was not affected by 10 mg of Os	74
6*M* HCl, 2,4-thiosemi-carbazide	Chloroform	Heating at 100° for 10–15 min produced extractable Ru complex; extraction not interfered with by Os	159

above. Some of these procedures are summarized in Table 8.

Electrostatic effects. The differences in the strength of interaction of the doubly and triply-charged chloride complexes of platinum metals towards extractants, either through the anion-exchange or hydration–solvation mechanism, have played an important role in the separation of binary and multiple mixtures of these metals. Examples in which liquid anion-exchangers, including amines, quaternary ammonium salts and other nitrogen-containing as well as oxygen-containing extractants, are used, are summarized in Table 9.

Kinetic effects. The differences in the kinetic behaviour of platinum metals in forming extractable species with hydrophobic anions and neutral ligands have also been very important in the separation of these metals. The labile character of the platinum metals decreases in the order Pd > Pt > Ru > Rh > Ir, with osmium between ruthenium and iridium, depending on the solution conditions. Several of the studies listed in Table 10 used these differences in the rate of formation of anionic and neutral species, and the tendency of rhodium for $Rh(H_2O)_6^{3+}$ formation.

Combination effects. The separation of multicomponent sytems of platinum metals often uses a combination of more than one point of difference in the behaviour of their chloride complexes, such as the tendency to volatile oxides, the strength of interaction with anion-exchangers as well as oxygen-containing solvents, and lability in the formation of extractable anionic or neutral species. If osmium and ruthenium are present, they are commonly removed first by oxidation to their tetroxides. Several examples are tabulated in Table 11.

More extensive investigations of the separation of anionic chloride complexes of uncommon binary and multicomponent systems of platinum metals are needed, utilizing the differences in their strength of interaction with quarternary ammonium salts and taking into account the effect of acidity, the oxidation–reduction nature of the aqueous phase, and the tendency to form cationic ammonium complexes. In addition, combinations of these effects in the back-extraction of platinum metals may provide more efficient methods. Several hydrophobic anions such as Br^-, I^-, SCN^-, $SnCl_3^-$, $SnBr_3^-$, *etc.* and neutral organic compounds containing N, P, S, As, Sb, *etc.* may alter the lability of the platinum metals in formation of extractable species. A combination of such studies should generate more efficient methods for the separation of platinum metals in any combination.

In the years since the review by Beamish,[200] many investigators have provided new methods for isolating and separating the platinum metals. As he predicted, knowledge of the solution chemistry of these metals has allowed a somewhat more systematic approach to development in this area. However, there are still many reports which do not treat the platinum metal solution chemistry involved in the separations, or include methods where it is not clear. As suggested throughout this review, there still remain several areas of separation which need considerable investigation and many where the chemistry of the method requires clarification. We expect that the use of newer instrumental techniques in conjunction with the standard methods will facilitate these studies and that the growing knowledge of the solution chemistry of these metals will continue to offer new and exciting answers for their separation and isolation. This expectation seems justified by the recent report of the use of systematic solvent-extraction separation for production of high-purity platinum metals.[201]

Table 8. Solvent extraction of other platinum metal-mixtures, based on tetroxide extraction

Metals separated*	Oxidizing agent	Organic phase	Other information	Reference
Ru–Rh	Cl_2	Carbon tetrachloride	After RuO_4 extraction, Rh co-precipitated with $Fe(OH)_3$, redissolved in $6M$ HCl and separated by the anion-exchanger Deacidite FF (Cl^-)	180
[103]Ru–[103m]Rh	$Ce(SO_4)_2$	Carbon tetrachloride	From H_2SO_4 solution, 96.2% Ru and 6% Rh were extracted	181
[103]Ru–[103m]Rh	NaOCl	Carbon tetrachloride	After [103]RuO_4 extraction, the solution was boiled to eliminate the contamination resulting from droplets of CCl_4 containing [103]RuO_4 and possibly some non-extractable tetroxide	182
Ru–Os in a mixture of Pt-metals	$NaClO_3 + NaBrO_3$	—	After simultaneous distillation of Ru and Os tetroxides, RuO_4 reduced selectively in HCl medium and OsO_4 redistilled and absorbed in ethanolic NaOH	183
Ru–Os in a mixture of Pt-metals	Na_2O_2, NaOCl	Carbon tetrachloride	After simultaneous extraction of tetroxides at pH 5–7, Ru recovered with $6M$ HCl saturated with SO_2 and Os recovered with $6M$ NaOH	184

*Notation used: (–)means "separated from".

Table 9. Solvent extraction of other platinum metal mixtures, based on electrostatic effects

Metals separated*	Aqueous phase	Organic phase	Other information	Reference
Pt(IV)–Rh(III)	2M HCl	Tri-n-octylamine in toluene	Extraction twice to remove Pt quantitatively and Rh partially; Pt and Rh recovered with conc. HCl and extracted twice again; 99.8% Rh in aqueous phase; 99.8% Pt extracted	185
Pt(IV)–Rh(III)	0.1M HCl	Primene, tribenzylamine, tri-n-hexylamine or tri-n-octylamine in chloroform or benzene	Pt determined in the organic phase as an orange Pt(II)–Sn(II) complex; amount of Rh should not exceed that of Pt	111
Pt(IV)–Ru(III)		Tetraoctylammonium chloride in dichloroethane	Pt removed quantitatively; <0.05% Ru extracted	186
Pt(IV)–Rh(III)		$(CH_3)_2(PhCH_2)RNCl$ ($R = C_{12}$–C_{14}) in 5% iso-amyl alcohol in dichloroethane	Displacement of $[Rh(H_2O)Cl_5]^{2-}$ from organic phase takes place easily with aqueous solution of $PtCl_6^{2-}$	187
Pd(II)–Ir(III) Pt(IV)–Ir(III)	2M HCl, tetra-octylammonium bromide	Caprylic acid (5–10%) in dichloroethane	Poor extraction of Rh(III) and Ru(III); their separation from Pt(IV) or Pd(II) may also be possible	188
Pd(II)–Rh(III) Pt(IV)–Rh(III)	1M HCl	Diantipyrylpropylmethane in dichloroethane	Six extraction stages required for milligram amounts; Pd and Pt recovered with HNO_3	34
Pt(IV)–Rh(III)	3M HCl saturated with NaCl	Tri-n-butyl phosphate	Countercurrent extraction; Rh and Ir separation not feasible, owing to reduction of Ir(IV) by the extractant	189
Pd(II),Pt(IV)–Rh(III)	3.5–6.5M HCl	Tri-n-octylamine in benzene	After Pd and Pt extraction, Rh extracted in presence of $SnCl_2$ as Rh–$SnCl_2$ complex by same extractant	61
Pt(IV)–Pd(II)–Rh(III)	4.38M HBr	Methyl isobutyl ketone	Countercurrent extraction and recovery with 25% HNO_3 saturated with $NaNO_3$; 45 stages required for 95% separation	190

*Notation used:(–) means "separated from"; (,) means "and"; (/) means "or".

Table 10. Solvent extraction of other platinum metal mixtures, based on kinetic effects

Metals separated*	Aqueous phase	Organic phase	Other information	Reference
Anionic complexes				
Pd–Rh Pd–Ir Pt–Rh Pt–Ir	pH 1, KSCN	Tri-n-butyl phosphate	Solutions heated for 10 min before extraction; effective separation of 95% of each metal with less than 10 equilibration stages	191
Pd–Rh Pt–Rh	4.38M HBr	Tri-n-butylphosphate (90%) in benzene	Metals extracted as bromo-complexes recovered with 2.5M HNO$_3$ saturated with NaNO$_3$; 10 equilibration stages separated 98.5% Pt–99.5% Rh, 98.5% Pd–98.2% Rh	190
Ru–Rh	pH 2.5, 0.6M KSCN, 3M NH$_4$Cl	Polyurethane foam	Aqueous phase heated at 90° for 5 min; extracted for 1 hr	141
Pd–Ru	KSCN, pyridine	Methyl isobutyl ketone	Pd extracted as Pdpy$_2$(SCN)$_2$ at pH 11 adjusted with NaOH; Ru then extracted as thiocyanate complex from 2M HCl after heating to 90°	192
Pt–Ir	0.05–0.1M KI	Diantipyrylpropylmethane in chloroform	Forms extractable PtI$_4^{2-}$ whereas IrCl$_6^{2-}$ is reduced to unextractable IrCl$_6^{3-}$; subsequent extraction of Ir by the same reagent in dichloroethane achieved after removing iodide and oxidizing to Ir(IV)	68
Pd/Pt/Rh–Ir	1M HBr–1.5M HClO$_4$, 0.15M SnBr$_2$	Isoamyl alcohol	Pd, Pt react immediately at room temperature with SnBr$_2$; Rh requires 1–2 hr; Ir does not react	128
Pd–Pt/Rh	α-Nitroso-β-naphthol, 2–3M HCl	Isoamyl alcohol	Pd forms complex with the ligand preferentially to Pt and Rh	128
Neutral complexes				
Pd/Ru/Os–Rh, Ir	NaSCN, H$_2$SO$_4$	Diantipyrylmethane in isobutyl alcohol–benzene	Over 95% Pd, Ru, Os extracted; Rh and Ir did not form extractable thiocyanate complexes	193
Pd–Ru	pH 3.15, 3-phenyl-5-(2-furyl)pyrazoline dithiocarbamate	Chloroform	Pd extracted quantitatively; <1% Ru extracted	194
Pd–Ir	2M HCl, di-n-octylsulphoxide	Benzene	Extraction difference of 10^5; separation should be possible	108

continued overleaf

Table 10. Solvent extraction of other platinum metal mixtures, based on kinetic effects

Metals separated*	Aqueous phase	Organic phase	Other information	Reference
Pd-Pt-Ir	Organic petroleum sulphide	Dichloroethane	Pd forms extractable species with sulphide at room temperature, Pt requires SnCl$_2$, and Ir must be heated for 1.5 hr	101
Pd from the rest of Pt-metals	Di-n-octyl sulphide, decylmethyl sulphide or dihexyl sulphide		Selective extraction of Pd	195
Pd, Pt-Rh, Ir	Diethyldithiocarbamate, KI, HCL	Chloroform	Conversion of chloro-complexes of Pd, Pd into PdI$_4^{2-}$, PtI$_4^{-}$; PtI$_4^{2-}$ accelerates the reaction with the ligand	104
[Pd-Pt]	pH 2-5, p-nitroso dimethylaniline	Chloroform	Pd extraction after evaporation of extractant to dryness and mineralization of residue by HNO$_3$ and H$_2$O$_2$	
Pd-Pt, Rh, Ir	pH 5,6, 2-mercapto-benzothiazole	Carbon tetrachloride	Pd completely extracted; less than 1% Pt, Rh, Ir extracted; used for Pd in Pt-wire	196
Pd-Pt-Rh	2-Mercaptobenzothiazole	Weakly polar solvents	Differences in distribution at different temperatures and rate of attaining equilibrium can be utilized for separation	197
Pd-Pt-Rh-Ir	HCl, KI, 2-mercapto-benzothiazole	Chloroform	Separates Pd and Pt from Rh and Ir	112
[Pd-Pt] [Rh-Ir]	Dimethylglyoxime HCl, SnCl$_2$, 2-mercapto-benzothiazole	Chloroform Chloroform	Pd separated from Pt SnCl$_2$ accelerates formation of extractable Rh complex	
Pd-Pt-Rh-Ir [Rh-Ir]	HCl, KI, diphenylthiourea HCl, SnCl$_2$, diphenyl-thiourea	Chloroform Chloroform	Separates Pd and Pt from Rh and Ir SnCl$_2$ accelerates formation of extractable Rh-diphenylthiourea complex	113
Cationic complexes Rh-Pd Rh-Pt Rh-Ir Rh-Ru	0.05M HCl	Dinonylnaphthalene-sulphonic acid in heptane	Solution made basic with NaOH to precipitate Rh, then acidic with HCl to dissolve the precipitate; poor separation from Ru	138

*Notation used: (−) means "separated from"; (,) means "and"; (/) means "or"; [ ] indicates "a subsequent separation of these metals after the preliminary step shown above it".

Table 11. Separation of multicomponent systems

Metals separated*	Aqueous phase	Organic phase	Other information	Reference
Pd–Pt–Rh–Ir	4.7M HCl, NaI	Tri-n-butyl phosphate in hexane	Pd and Pt simultaneously extracted as MI_4^{2-}; Rh and Ir do not form extractable species at room temperature and Ir(IV) reduced to unextractable Ir(III) by the iodide medium	65
[Pd–Pt]	p-Nitrosodimethylaniline	Chloroform	Pd complex extracted	
[Rh–Ir]	HCl	Tri-n-butyl phosphate in hexane	After iodide destroyed with HNO_3, Ir(III) oxidized to extractable Ir(IV) by H_2O_2	
Pd–Ir–Pt	1M HCl, H_2O_2	Dianipyrylpropylmethane in chloroform	Simultaneous extraction of chloride complexes of Pd(II), Pt(IV), Ir(IV); back-extraction of Ir with NH_2OH and Pd with $N_2H_4 \cdot HCl$	62
Os–Ru–Pd–Pt–Rh–Ir	70% $HClO_4$		Simultaneous distillation of Ru, and Os and collection in 3% H_2O_2	198, 199
[Os–Ru]	H_2SO_4–H_2O_2 mixture		Selective distillation of Os	
[Pd, Pt–Rh, Ir]	Diethyldithiocarbamate	Chloroform	After evaporation of $HClO_4$ and conversion of metals into chloro-complexes, reagent added and Pd, Pt simultaneously extracted	
[Pd–Pt]	p-Nitrosodimethylanine	Chloroform	Pd complex extracted	
[Rh–Ir]	1M HCl, Cu powder	Chloroform	Reduction and precipitation of Rh	
Os–Ru–Pd–Pt–Rh–Ir		Carbon tetrachloride	Simultaneous extraction of tetroxides of Os, Ru	109
[Ru–Os]			Ru recovered from CCl_4 with 6M HCl containing SO_2; Os recovered with 3M NaOH	
[Pd–Pt–Ir–Rh]	6M HCl, di-n-heptyl-sulphoxide (R_2SO)	1,1,2-Trichloroethane	Extraction of $PdCl_2 \cdot 2R_2SO$ and $(R_2SOH^+)_2 \, MCl_6^{2-}$; [M = Pt(IV) or Ir(IV)]; Rh partially extracted	
[Pt–Ir]	1M HCl, di-n-heptyl-sulphoxide	1,1,2-Trichloroethane	After recovery of Pt and Ir with water, Ir(IV) reduced to Ir(III) with hydrazine or hydroquinone; 10 equilibration stages extract Pt	
[Pd, Rh]			Back-extraction of Pd with 10% dimethylamine and Rh with aqueous $NaNO_2$ at 70° and pH 7	

*Notation used: (−) means "separated from"; (.) means "and"; [ ] indicates "a subsequent separation of these metals after the preliminary step shown above it".

SHORT COMMUNICATIONS

DETERMINATION OF THE STABILITY CONSTANT OF THE TERNARY COMPLEX FORMED IN THE COPPER–BIPYRIDYL–ERIOCHROME CYANINE R SYSTEM, BY AN ISOSBESTIC POINT–SPECTROPHOTOMETRIC METHOD

SHI-FU ZOU and WEI-AN LIANG

Department of Chemistry, Shandong University, Jinan, Shandong, People's Republic of China

Summary—This paper reports a new method for determining the stability constants of ternary complexes, based on analysis of isosbestic points. First, it is necessary to determine the absolute molar absorptivities of the various species concerned, then their concentrations and the stability constant. In this method, the approximate treatment of classical photometric methods is not required. The conditional constant can be calculated directly from the measured data.

Most spectrophotometric methods[1–3] for the determination of the stability constants of complexes are based on measurements made at an absorption peak. The parameters estimated by these methods are not always sufficiently accurate and are unsuitable for application to complicated systems,[2,4–8] so it seems desirable to find new methods based on other characteristics.

The system[9] copper–bipyridyl–Eriochrome Cyanine R (Cu–Bpy–ECR) was chosen as the subject of investigation, because there are two different complexes (1:1:1 and 1:1:2) formed and it is not possible to obtain the stability constants by classical methods.

The method suggested is based on analysis of the isosbestic points of the absorption spectra, from which the absolute molar absorptivities and the concentrations of the species concerned can be obtained.

EXPERIMENTAL

Apparatus

A Hitachi recording spectrophotometer, model 340, and a model pHs-2 pH-meter were used.

Reagents

The Eriochrome Cyanine R (ECR) was purified according to Dixon's procedure,[10] by dextran column chromatography, slightly modified,[11,12] and was used to prepare a $2 \times 10^{-3}M$ standard solution with a final hydrochloric acid concentration of 0.008*M*. The other chemicals used were either of guaranteed grade or analytically pure.

Precipitates are readily formed in the Cu–Bpy–ECR system. In order to prevent this precipitation, Ishida *et al.*[9] added the non-ionic surfactant Triton X-100 as solubilizer. In our experience, this is ineffective when the [Cu–Bpy]:[ECR] ratio is greater than 3:4, or when the pH

is lower than 9.6. We used an anionic surfactant (sodium dodecyl sulphate) instead. This gives a stable solution, even at pH somewhat lower than 9.

Procedure

To each of ten 50-ml standard flasks add a small amount of water, 5 ml of 0.1% surfactant solution, 4 ml of $5 \times 10^{-4}M$ ECR, followed by various amounts of Cu–Bpy mixture (1:1 v/v, each $5 \times 10^{-4}M$) and 20 ml of buffer solution. Dilute the solutions to volume with water, mix well, and allow to stand for 10 min. Record the absorption spectra (with water as reference; 1-cm cells) over the wavelength region 400–620 nm. The ionic strength of the solution is controlled at 0.08*M* by the buffer solution. The pH is redetermined as a check after the measurement of absorbance.

In this way the pH and concentrations of ECR (C_0^R) and surfactant (C_0^s) are kept constant, and the concentration of CuBpy (C_1^{II}) is increased gradually so as to obtain a set of absorption spectra (Fig. 1). Table 1 compares the data with literature values.

CALCULATIONS AND DISCUSSION

The composition of the complexes was studied in detail by earlier workers,[9] and we did not repeat their work.

Analysis of absorption spectra

According to references 13 and 14, the isosbestic point E in Fig. 1 results from incorporation of ECR (with CuBpy) into a 1:1:2 complex. The chemical reaction should be:

$$\text{CuBpy} + 2\text{ECR} \rightarrow \text{CuBpy(ECR)}_2 \quad \text{(I)}$$

$$(C_1^{II} - y) \quad (C_0^R - 2y) \quad (y)$$
Fig. 1. Absorption spectra for the Cu–Bpy–ECR system. pH = 10.41; $\mu = 0.08M$; $T = 24 \pm 1°$; $C_0^R = 4.00 \times 10^{-5}M$; $C_0^s = 0.01\%$; C_1^{II} ($\times 10^{-5}M$) for the curves: 1—0, 2—0.500, 3—1.00, 4—1.50, 5—2.00, 6—3.00, 7—3.50, 8—4.00, 9—4.50, 10—5.00.

Charges on the ions are omitted and y represents the concentration of the 1:1:2 complex at equilibrium. Then the absorbance is

$$A_1 = (\epsilon^y - 2\epsilon^R)y + \epsilon^R C_0^R \qquad (1)$$

where ϵ^y and ϵ^R are the molar absorptivities of the 1:1:2 complex and ECR respectively. The absorbance of CuBpy is practically zero in this region of the spectrum.

At the wavelength of the isosbestic point (λ_E), $\epsilon^y = 2\epsilon^R$. Therefore A_1 is constant and independent of y. Hence an isosbestic point appears (E).

Correspondingly, the isosbestic point P is formed by the transformation of the 1:1:2 complex into the 1:1:1. The reaction is

CuBpy(ECR)$_2$ +   CuBpy   →   2CuBpyECR (II)

$$(\tfrac{1}{2}C_0^R - \tfrac{1}{2}x) \qquad (C_1^{II} - \tfrac{1}{2}C_0^R - \tfrac{1}{2}x) \qquad (x)$$
where $\tfrac{1}{2}C_0^R$ represents the concentration of CuBpy-(ECR)$_2$ when CuBpy and ECR have been mixed in exactly 1:2 ratios and x is the concentration of the 1:1:1 complex at equilibrium for reaction (II). The absorbance is

$$A_2 = (\epsilon^x - \tfrac{1}{2}\epsilon^y)x + \tfrac{1}{2}\epsilon^y C_0^R \qquad (2)$$

where ϵ^x represents the molar absorptivity of the 1:1:1 complex. At λ_p A_2 is constant and independent of x, because $\epsilon^x = \tfrac{1}{2}\epsilon^y$.

Deduction and calculation of the absolute molar absorptivity of the 1:1:2 complex

Two isosbestic points appear consecutively in Fig. 1 (E comes before P), which shows that reaction (I) takes place before (II). If these two reactions take place strictly in this order, then the equivalence point of reaction (I) must also be the starting point of reaction (II). Thus equations (1) and (2) both apply at the equivalence point. This is an over-simplification, of course, because it assumes that there is no overlap of the two equilibria (or that any overlap makes a negligible contribution to the data). In this case, $y = \tfrac{1}{2}C_0^R$ (i.e., $x = 0$). Substituting into equations (1) and (2) respectively, we obtain

$$A_1 = A_2 = \tfrac{1}{2}\epsilon^y C_0^R \qquad (3)$$

A_1 and A_2 have the same form and can be used for any wavelength. That is to say, in principle the absorption spectrum of a solution of composition corresponding to the equivalence point will pass through both of the isosbestic points. It is very important to prove this relationship, since the absorbance at an isosbestic point can be determined accurately. The value of C_0^R is known, so ϵ^y and ϵ^x can be calculated from equation (3). For example, at point P, in Fig. 1, $A = 0.435$ and $\epsilon^y = A/\tfrac{1}{2}C_0^R = 2.18 \times 10^4$ l.mole^{-1}.cm^{-1}. It should be pointed out that such an absorption spectrum cannot be obtained in practice, for some dissociation of the complex will always occur. Thus, the absolute values of ϵ^y and ϵ^x at other wavelengths are difficult to obtain.

Table 2. Values of β_2 from the various curves ($C_0^R = 4 \times 10^{-5}M$; $\epsilon^y = 3.18 \times 10^4 \, \mathrm{l.mole^{-1}.cm^{-1}}$; $\epsilon^R = 3 \times 10^3 \, \mathrm{l.mole^{-1}.cm^{-1}}$)

Curve	A	C_i^{II}, M	y, M	β_2
2	0.193	3.00×10^{-6}	4.62×10^{-6}	1.3×10^{10}
3	0.263	1.00×10^{-5}	9.05×10^{-6}	2.0×10^{10}
4	0.322	1.50×10^{-5}	1.28×10^{-5}	2.8×10^{10}

Calculation of the overall stability constant β_2 of the 1:1:2 complex

As discussed previously, all curves passing through point E correspond to reaction (I), and therefore obey equation (1). If equation (1) is rearranged to give

$$y = (A - \epsilon^R C_0^R)/(\epsilon^y - 2\epsilon^R) \qquad (4)$$

then ϵ^y is known, ϵ^R can be calculated from curve 1, and A is a measured value of each curve at λ_p. Then y can be found. Since

$$\beta_2 = \frac{[\mathrm{CuBpy(ECR)_2}]}{[\mathrm{CuBpy}][\mathrm{ECR}]^2} = \frac{y}{(C_i^{II} - y)(C_0^R - 2y)^2} \qquad (5)$$

substitution of y and the corresponding C_i^{II} from each curve leads to a set of values of β_2. These are listed in Table 2. The mean value of β_2 is taken to be 2×10^{10}.

Calculation of the stepwise stability constants K_1 and K_2

Since β_2 is known, and $\beta_2 = K_1 K_2$, then if either K value is known, the other can be found.

At the equivalence point there must be some degree of dissociation. Therefore curve 5 does not pass through the two isosbestic points but below them. In that case we can write the reaction as

$$\mathrm{CuBpy(ECR)_2} \rightleftharpoons \mathrm{CuBpyECR} + \mathrm{ECR} \qquad (III)$$
$$\tfrac{1}{2}C_0^R - x \qquad x \qquad x$$

The absorbance is

$$A' = \epsilon^y(\tfrac{1}{2}C_0^R - x) + x\epsilon^x + x\epsilon^R$$

$$= x(\epsilon^x + \epsilon^R - \epsilon^y) + \tfrac{1}{2}\epsilon^y C_0^R$$

At λ_p, $\epsilon^x = \tfrac{1}{2}\epsilon^y$, so

$$A' = \tfrac{1}{2}\epsilon^y C_0^R + x(\epsilon^R - \tfrac{1}{2}\epsilon^y) \qquad (6)$$

or

$$A_{\mathrm{isos}} - A' = x(\tfrac{1}{2}\epsilon^y - \epsilon^R) \qquad (7)$$

This gives $x = 1.08 \times 10^{-5}M$. Then, since

$$K_2 = \frac{[\mathrm{CuBpy(ECR)_2}]}{[\mathrm{CuBpyECR}][\mathrm{ECR}]}$$

$$K_2 = 8.0 \times 10^4 \text{ and } K_1 = 2.5 \times 10^5$$

Thus, all the stability constants of the two complexes in this system have been obtained.

Finally, it is worth noting that the values of β_2 given in Table 2 increase with the ratio [CuBpy]:[ECR]. When the same method is applied to a similar system—the binary complexing system of stepwise complexes[14]—the same result is obtained.* Although conditional constants may vary somewhat with variation in the conditions, such a regularity merits further study.

SPECTROPHOTOMETRIC DETERMINATION OF ZINC WITH PHENYLFLUORONE IN THE PRESENCE OF HEXADECYLPYRIDINIUM BROMIDE AND PYRIDINE

Satoru Sakuraba

Industrial Research Institute of Aomori Prefecture, Fukuro-machi, Hirosaki-shi, 036 Japan

Summary—Phenylfluorone reacts with zinc in the presence of hexadecylpyridinium bromide and pyridine to form a water-soluble red chelate. The absorption maximum of the chelate is at 585 nm and its absorbance is constant in the pH range 7.7–8.2. At this wavelength, Beer's law is obeyed up to $1.53 \times 10^{-5} M$ zinc. The sensitivity is very high and the molar absorptivity is 8.0×10^4 l.mole^{-1}.cm^{-1}. The chelate has been utilized in the determination of zinc at the microgram level. The ratio of zinc to phenylfluorone in the complex is 1:1.

Various 2,3,7-trihydroxyfluorone dyes substituted at the C_9 carbon atom have been reported as colour reagents for spectrophotometric determination of metal ions; they include 2,3,7-trihydroxy-9-phenyl-6-fluorone (phenylfluorone).[1-3] The reactions of the dye molecule with vanadium(IV) at different pH values have been reported.[4] Phenylfluorone and its metal chelates are soluble in ethanol, but the solutions are not stable, as a turbidity develops. When a cationic surfactant and a unidentate ligand such as pyridine or nitrite is added the turbidity does not appear. We have applied this reaction to the determination of cobalt,[5] nickel[6] and copper.[7] Zinc reacts with phenylfluorone in the presence of hexa-decylpyridinium bromide and pyridine or nitrite to form a water-soluble red chelate. Pyridine is the more favourable because it gives a molar absorptivity that is nearly twice that obtained with nitrite. The spectrophotometric determination of zinc by means of this colour reaction is described in this communication. The molar absorptivity is 8.0×10^4 l.mole^{-1}.cm^{-1} at the wavelength of maximum absorption (585 nm), about 2.5 times that of the dithizone or zincon complex. Moreover, this method is much simpler than the dithizone method since no extraction is required.

EXPERIMENTAL

Reagents

A standard stock zinc solution was prepared by dissolving 4.40 g of analytical-reagent grade zinc sulphate in water and diluting to 1 litre, and diluted as required to give working solutions. A standard solution of phenylfluorone (PF) was prepared by dissolving a known amount of the reagent (Merck) in ethanol containing a few drops of concentrated hydrochloric acid. Aqueous $2.0 \times 10^{-2} M$ hexadecyl-pyridinium bromide (HPB) and 2.48M pyridine (Py) solutions were prepared. A borate buffer was used. All the other reagents were of analytical-reagent grade. Demineralized water was used.
Fig. 1. Absorption spectra of zinc complex and reagent. Concentrations of Zn(II), HPB, Py and PF $1.22 \times 10^{-5} M$, $2 \times 10^{-3} M$, $0.149 M$ and $3 \times 10^{-5} M$, respectively; pH 7.9; 1, reagent blank *vs.* water; 2, Zn–HPB–Py–PF; 3, Zn–Py–PF; 4, Zn–PF; 5, Zn–HPB–PF. Reference, 2–5 reagent blank.

Procedure

Two ml of buffer solution, 2.5 ml of HPB solution, 1.5 ml of Py solution and 0.75 ml of PF solution were added to the sample solution, in that order. The absorbance was measured at 585 nm against reagent blank after the solution had stood for 30 min at 25°.

RESULTS AND DISCUSSION

Absorption spectra

The absorption spectra of the reagent blank and the zinc complex in the four-component system at pH 7.9 are shown in Fig. 1. For comparison, the spectra for other combinations of zinc with the reagents at the same pH are also given. Zinc reacts with PF to form a red complex (λ_{max} 585 nm) in the presence of HPB and Py. A solution containing the Zn–PF complex is turbid, but addition of HPB and Py clarifies it. The red complex is formed only if both HPB and Py are added to the Zn–PF complex
Fig. 2. Relationship between $a/(A - A')$ and $1/b^n$. Concentrations of Zn(II), HPB, Py and PF $6.12 \times 10^{-6}M$, $2 \times 10^{-3}M$, $0.149M$ and $7 \times 10^{-6}–4 \times 10^{-5}M$, respectively. ◯——◯ $n = 1$; ●——● $n = 2$; measured at 585 nm.

solution, and in the absence of either, the absorbance was only about a tenth of that of the red complex (Fig. 1, curves 3–5). The absorbance is maximal and nearly constant over the pH range 7.7–8.2.

The calibration graph made under optimum conditions is linear up to $1.53 \times 10^{-5}M$ zinc concentration. The molar absorptivity at 585 nm is 8.0×10^4 $1.\text{mole}^{-1}.\text{cm}^{-1}$.

The Benesi and Hildebrand method[8] was used for finding the composition of the complex. For a ZnL_n complex (L = ligand) the following relationship may be derived:

$$a/(A - A') = \{1/(\epsilon_1 - n\epsilon_2)\} + \{K'/(\epsilon_1 - n\epsilon_2)b^n\}$$

where A is the absorbance of the solution measured against the reagent blank, a and b are the initial concentrations of zinc and reagent respectively. The values of ϵ_1 and ϵ_2 ($\epsilon_2 b = A'$), are the molar absorptivities of the complex and reagent blank respectively at a constant pH value. Then if $\log a/(A - A')$ is plotted against $\log 1/b$, the slope will be n. In Fig. 2, $a/(A - A')$ is plotted against $1/b^n$ for 585 nm. A straight line is obtained for $n = 1$. When a similar plot is made for varied concentration of Py ($0.05–0.3M$), a straight line is obtained for $n = 2$.

Therefore it is concluded that a $1:1:2$ complex is formed between zinc, PF and Py.

Interferences

Table 1 shows that alkali-metal, alkaline-earth metal, halide, sulphate and nitrate ions do not interfere. Vanadium(V), iron(III), cobalt, nickel, copper(II), aluminium and tin(IV) ions give some errors.

Table 1. Influence of foreign ions on determination of $10.0 \mu g$ of zinc

DETERMINATION OF ISOCYANO GROUPS ON POLYMER SUPPORTS BY BROMINATION

Reza Arshady and Ivar Ugi
Organisch-Chemisches Institut, der Technischen Universität München, 8046 Garching, Lichtenbergstr. 4, BRD

Summary—The isocyano content of several cross-linked polymer samples, carrying *ca.* 0.5–3.0 mmole of isocyanide groups per gram, was determined by reacting the resins with excess of bromine in chloroform, then treating the unreacted bromine with potassium iodide and titrating the liberated iodine with thiosulphate. The method is not suitable for titration of soluble isocyanides, but for the determination of insoluble macromolecular isocyanides is more satisfactory than the thiocyanic acid method.

Recently we have reported the synthesis of several types of isocyano polymer supports.[1] These resins are currently employed for synthesis of peptides by four-component condensation[2] and immobilization of transition-metal complexes,[3] and are potentially useful for enzyme-immobilization and general organic synthesis. Quantitative determination of functional groups on a polymer support[4] is generally complicated, because of problems such as polymer swelling and partial inaccessibility of the reactive sites, as well as the technical difficulties in the monitoring of a reaction on a cross-linked polymer. However, the isocyano group can undergo many reactions,[5] so there are many potential methods for its determination[6] on a polymer support. This report gives the details of the determination of polymer-bound isocyanides by bromination, and suggests alternative methods based on transition metal co-ordination.

EXPERIMENTAL

Preparation of thiocyanic acid in chloroform

A solution of 1.25 g (20 mmoles) of ammonium thiocyanate in 20 ml of water is stirred with 15 ml of chloroform in an ice-bath, then 10 ml of 2*M* sulphuric acid are added dropwise. The chloroform solution is separated, and the aqueous solution is extracted with three 10-ml portions of chloroform. The combined chloroform solution is dried over anhydrous magnesium sulphate, and stored in a dark bottle. Titration of the chloroform solution with 0.1*M* triethylamine in ethyl acetate shows a thiocyanic acid concentration of 0.35*M*. This decreases to 0.255*M* within 24 hr and to 0.228*M* in 48 hr, but then remains practically unchanged.

Determination of isocyano polymers with thiocyanic acid

The polymer (100 mg) is added to the thiocyanic acid solution in chloroform (5 ml were used for samples 1–3 and 1 ml was used for 4 and 5) and is allowed to react for 2 hr. The mixture is then diluted with ethyl acetate and dimethylformamide (5 ml of each were used for samples 1–3, and 1 ml of each for samples 4 and 5). An indicator (four drops of 0.2% Neutral Red/0.2% Methylene Blue in methanol) is

added, and the mixture is titrated with 0.1*M* triethylamine to a green colour.

Determination of isocyano polymers by bromination

The polymer (100 mg) is swollen in 5 ml of chloroform for about 10 min, then bromine (up to 3.5 ml of 0.1*M* solution in chloroform) is added, and the mixture is stirred for 30 min. Potassium iodide solution (5%, 5–7 ml) is added, and the mixture is stirred vigorously for 30 min, and then titrated with 0.1*M* sodium thiosulphate to a pale yellow colour. The indicator (two drops of 0.5% starch solution) is added and the titration continued (usually over a period of about 30–40 min) with vigorous stirring until the starch–iodine colour persists for about 5 min. The formamide precursor of the isocyano resin is treated similarly.

RESULTS AND DISCUSSION

The reaction of isocyanides with bromine was described by Nef[7] in 1882 and shown to proceed according to equation (1) without any side-reactions. In principle this reaction is ideal for determination of polymer-bound isocyano groups, since the polymer can be treated with excess of bromine, followed by titrimetric determination of unreacted bromine [see equations (2) and (3)].[8]

$$R-NC + Br_2 \rightarrow R-N=CBr_2 \qquad (1)$$

$$Br_2 + 2I^- \rightarrow 2Br^- + I_2 \qquad (2)$$

$$I_2 + 2S_2O_3^{2-} \rightarrow 2I^- + S_4O_6^{2-} \qquad (3)$$
The method is not suitable for determination of soluble isocyanides because the starch–iodine end-point is obscured by the colour of the brominated product, but is particularly useful for determination of polymer-bound isocyanides, because the reaction can be done in chlorinated solvents such as chloroform, which are good solvents for practically all types of isocyano polymer supports. The brominated polymer is insoluble and does not interfere with the end-point. The method is not altogether satisfactory, however, because both bromine and iodine are sorbed by the cross-linked resin. A further complication

is the reaction of bromine with residual double bonds of the polymer backbone; this can cause consumption of up to about 0.5 mmole of bromine per gram of polymer. The first problem is overcome by vigorous mixing and allowing longer times for the oxidations and reductions and the second problem is solved by titration of the formamide precursor of the isocyano resin.

A procedure reported previously,[6] based on the simpler reaction of isocyanides with thiocyanic acid in ethyl acetate, was found to be less suitable, because most isocyano polymers[1] do not swell adequately in ethyl acetate. Modification of this procedure by using chloroform as the solvent also appears to be less satisfactory, primarily because of the low solubility of thiocyanic acid in chloroform (see below).

The results of estimation of the isocyano content of five polymer samples by the two methods are given in Table 1. The bromine method is somewhat laborious, but according to the results presented in Table 1, it provides a highly reliable method for determination of polymer-bound isocyano groups. In the case of the thiocyanic acid method, more satisfactory data are obtained for polymers with low degrees of substitution. It should also be noted that the infrared spectra of the resin samples reacted with thiocyanic acid were not always consistent with the single reaction pathway observed in the case of soluble isocyanides.[6]

Polymer-bound isocyano groups are readily coordinated by various transition metals.[3] For example, when resin sample 1 is reacted with excess of K_2PdCl_4 or $Pd(PhCN)_2Cl_2$, the corresponding bis-co-ordinated palladium derivative is obtained.[3] This complexation by palladium(II) (and probably by other metals) may provide a more convenient route for the deter-

mination of polymer-bound isocyanide through either determination of the excess of metal in solution, or of the metal complexed by the polymer. This method has been examined for samples 1 and 2, and has been found to give fairly good agreement with the theoretical values and those of the bromine method.

MICRODETERMINATION OF IRON IN WATER BY ION-EXCHANGER COLORIMETRY WITH FERROZINE

Li Shi-yu and Gao Wei-ping

Department of Chemistry, Beijing University, Beijing, China

Summary—The use of ion-exchanger colorimetry for determination of microamounts of iron in water with 3-(2-pyridyl)-5,6-bis(4-phenylsulphonic acid)-1,2,4-triazine disodium salt as colour reagent is described. The advantages are the high sensitivity, ease of operation, good reproducibility, and simplicity of apparatus. Also, because of concentration by the ion-exchanger resin the detection limit of the method may be as low as the μg/ml level.

3-(2-Pyridyl)-5,6-bis(4-phenylsulphonic acid)-1,2,4,-triazine disodium salt ("Ferrozine", abbreviated to PPST) is a highly sensitive reagent for iron(II), usable even in strongly alkaline medium.[1] It is easily soluble in water, in which it is fully dissociated.[2] At pH 4–9 it reacts with iron(II) to form a stable magenta complex which is very soluble in water. The reaction may be expressed as

$$Fe^{2+} + 3 \, Ferroz^{2-} \rightleftharpoons Fe(Ferroz)_3^{4-}$$
The complex has its absorption peak at 562 nm, the molar absorptivity being 2.79×10^4 l.mole^{-1}.cm^{-1}.

The complex anion can be quantitatively sorbed by an anion-exchange resin, which provides the possibility of determining iron(II) by a direct colorimetric method.[3] For determination of total iron any iron(III) must be reduced to iron(II); hydroxylamine hydrochloride can be used for this purpose.

EXPERIMENTAL

Reagents

Standard iron(II) stock solution (1 *mg*/*ml*). Dissolve 0.1000 g of pure iron wire with 10 ml of hydrochloric acid (1 + 1) and dilute the solution to volume in a 100-ml standard flask.

Standard iron(II) solution (10 *μg*/*ml*). Dilute 1 ml of the standard iron(II) stock solution to volume in a 100-ml standard flask with water after addition of 2 ml of hydrochloric acid (1 + 1).

PPST solution, 0.5%.

Hydroxylamine hydrochloride solution, 10%

Anion-exchange resin. The resin (20–40 mesh, Cl$^-$ form) used was no. 717, produced by the Shanghai Resin Factory; it is a strong-base resin, equivalent to Dowex 1 or Deacidite FF. When new resin is to be used it should be soaked in water for 24 hr and then washed repeatedly. All small particles and inclusions should be removed and the resin dried with filter paper and stored in a polyethylene container.

Analytical-grade chemicals and demineralized water should be used.

Procedure for determination of iron(II)

Take 100 ml of sample solution containing not less than 0.5 μg of iron(II) and at pH 4–9 in a 250-ml Erlenmeyer flask fitted with a ground-glass or plastic stopper. Add 1 ml

of 0.5% PPST solution and mix. After 10 min the solution will be magenta in colour. Then add 1.5 g of anion-exchange resin and shake the flask mechanically for 30 min. The resin will take up the magenta colour. Withdraw the resin with a dropper and put it into a 0.5-cm glass cell, ensuring that it is evenly packed. Measure the absorbance at 575 nm against a resin blank.

Determination of iron in drinking water

Take a series of six equal samples of water (containing not less than 0.5 or more than 5 μg of iron) in 500 ml Erlenmeyer flasks fitted with ground-glass or plastic stoppers. Add 1.5 ml of 10% hydroxylamine hydrochloride solution to each to reduce iron(III). Adjust the pH to 4–9 if necessary. Add 0, 1, 2, 3, 4, 5 μg of iron(II), dilute to 250 ml, add 1 ml of PPST solution to each flask, and let the colour develop. Shake each solution with 1.5 g of resin for 30 min and complete the determination as above. Plot the absorbance against weight of iron(II) added and determine the iron(II) in the sample by extrapolation in the usual way for the standard-additions method.

Seriously polluted water samples should be digested with 5 ml of hydrochloric acid (1 + 1) for every 30 ml of water sample, then filtered before determination of the iron.

RESULTS AND DISCUSSION

Figure 1 shows that the wavelength of maximum absorption is 575 nm, a 13-nm displacement from
Fig. 1. Absorption spectra of Fe^{2+}–PPST by ion-exchange colorimetry. I, 5 μg of Fe^{2+}; II, 10 μg of Fe^{2+}; $\lambda_{max} = 575$ nm.

Table 1. Effect of foreign ions on de-
termination of $5.0\,\mu g$ of iron(II)

Ion	Added, *mg*	Fe^{2+} found, μg
—	—	5.0
Cr^{3+}	0.40	4.9
	0.80	5.0

Zn^{2+}	0.20	4.9
	0.40	4.9
Cd^{2+}	1.00	5.0
Pb^{2+}	0.20	5.0
	1.00	4.9
Al^{3+}	0.10	5.2
Ca^{2+}	10.0	5.0
Mg^{2+}	10.0	5.0

Fig. 2. Effect of shaking time.

Fig. 3. Effect of pH on the ion-exchange.

λ_{max} for the complex in solution.[2] Figure 2 indicates that the ion-exchange step takes 30 min to reach completion. Figure 3 shows that the absorbance obtained is practically independent of pH over the range 4–9, the range needed for forming $Fe(Ferroz)_3^{4-}$ in aqueous solution. The calibration graph is linear up to an iron(II) concentration of $0.1\,\mu g/ml$ in the sample solution.

The effect of various metal ions is given in Table 1. When more than 50 μg of nickel is present the colour is unevenly distributed on the resin and the measurement is adversely effected. Silver interferes if silver chloride is precipitated by the chloride released in the ion-exchange.

By this method the minimum iron content detectable is 1–2 ng/ml in the test solution. The recovery exceeds 98%.

ESTIMATION OF URANIUM IN COLUMBITE–TANTALITE SAMPLES: A METHOD FOR SAMPLE SOLUTION PREPARATION FOR FLUORIMETRIC ESTIMATION

B. K. Balaji, A. Premadas and G. V. Ramanaiah

Chemical Laboratory, Atomic Minerals Division, Department of Atomic Energy, 'Patan Bhavan', Race Course Road, Bangalore-560 001, India

Summary—A method has been developed for obtaining a clear solution of columbite–tantalite samples in nitric acid medium before the fluorimetric estimation of uranium. Ammonium hydrogen fluoride is used to keep tantalum, niobium and titanium dissolved in the acid medium. The excess of fluoride is complexed with boric acid. The method has been successfully applied to a number of synthetic and natural columbite–tantalite samples.

The fluorimetric method for the determination of uranium is widely used because of its high sensitivity. The published methods[1,2] for the determination of uranium in columbite–tantalite samples involve separation of the uranium by filtration from the gelatinous hydrous tantalum, niobium and titanium oxides that are formed in acid solution. This is a time-consuming step and there is risk of loss of uranium by retention in the precipitate. It was observed that the occluded uranium cannot be completely removed by washing. This prompted us to seek a new approach by which the tantalum, niobium and titanium would be kept in solution in the acid medium. Since all three elements form soluble fluoro-complexes, ammonium hydrogen fluoride is added to obtain a clear solution of the columbite–tantalite sample after its fusion with sodium peroxide and taking up of the cooled melt with nitric acid. The excess of fluoride is complexed with boric acid, and the uranium content is then determined by the fluorimetric method[2,3] after its separation by ethyl acetate extraction from a solution saturated with aluminium nitrate as salting-out agent.

EXPERIMENTAL

Procedures

Conventional extraction fluorimetric method. A 0.500-g synthetic sample was treated with 15 ml of concentrated hydrofluoric acid and 5 ml of nitric acid in a platinum dish, and the solution evaporated to dryness. The residue was digested with dilute nitric acid, the solution filtered and the residue washed and then ignited at 650–700°. The product was fused with 8 g of sodium peroxide and the cooled melt taken up with the original filtrate. The solution yielded a hydrolysed precipitate on acidification. This mixture was boiled for 15 min and filtered, the residue being repeatedly washed with hot 5% nitric acid (about 300 ml) in batches of 15–20 ml in order to remove the uranium from the precipitate. The filtrate was concentrated and nearly neutralized with ∼7*M* ammonia solution, then acidified with concentrated nitric acid to give a final acidity of ∼1.6*M* (∼10% v/v nitric acid) when diluted to a standard volume. The

uranium was extracted by shaking a 3-ml portion of this solution for 2 min with 10 ml of ethyl acetate after addition of 15 ml of saturated aluminium nitrate solution as salting-out agent. The uranium was determined fluorimetrically[2,3] as follows.

About 5 ml of the ethyl acetate layer was filtered through a Whatman No. 40 filter paper (7 cm) to free it from traces of moisture. Aliquots of 0.1 of this solution were taken in 5 small platinum dishes (capacity 0.5 ml, diameter 1 cm) containing a drop of water, and dried under an infrared lamp. Each residue was fused at ∼670° with a 0.4 g pellet of finely powdered flux (NaF, Na_2CO_3 and K_2CO_3 in w/w ratio 1:5:5) for 3 min in a muffle furnace. The dishes were then cooled in a desiccator to room temperature (15 min). The fluorescence of the button was measured in a fluorimeter (exciting radiation 365 nm, fluorescence radiation 555 nm) and compared with that of standard buttons (0.01–0.1 μg of uranium) prepared in a similar way. Corrections were made for the fluorescence of the flux.

Proposed method. A 0.500-g sample was fused with 8 g of sodium peroxide in a nickel crucible to give a clear red melt. The cooled fused mass was taken up in 40 ml of 8*M* nitric acid. This process resulted in hydrolysis of the tantalum, niobium and titanium present. The solution and precipitate, after boiling, were transferred into a polythene beaker and treated with just sufficient ammonium hydrogen fluoride to dissolve the hydrolysis products. The solution was warmed on a water-bath for 10 min. It was then nearly neutralized with ∼7*M* ammonia solution, and 5 ml of saturated boric acid solution were added, followed by concentrated nitric acid to give a final acidity of ∼1.6*M* after dilution to standard volume. This solution was analysed for uranium fluorimetrically, as described above.

RESULTS AND DISCUSSION

Preliminary studies to determine whether the amount of fluoride required to keep niobium and tantalum in solution would affect the extraction of uranyl nitrate into ethyl acetate from 1.6*M* nitric acid containing saturated aluminium nitrate as salting-out agent, showed that up to 10% of ammonium hydrogen fluoride would not interfere in the extraction of at least 130 μg of uranium. Under these conditions, at least 5 mg of tantalum, 2 mg of niobium, 1 mg each of iron(III) and manganese(II) and 0.5 mg of

titanium(IV), which are usually found in columbite–tantalite minerals, can be present during the extraction step, either individually or in combination, without causing significant error in the result. Furthermore, boric acid can be used to complex the excess of fluoride without interfering in the extraction of uranium. In the presence of fluoride and boric acid, the solution becomes slightly turbid on addition of the aluminium nitrate solution, but this does not affect the extraction.

Tables 1 and 2 show the results obtained when the proposed method was applied to a series of synthetic[4] columbite and tantalite samples, in which the added uranium was varied from 0.01 to 1%, and to natural samples, respectively. They also show the results obtained by the conventional ethyl acetate extraction method. The results show that the proposed method gives slightly higher results, which we ascribe to losses in the conventional method owing to occlusion of uranyl species in the gelatinous hydrolysis products. This was further confirmed by analysis of the residue for uranium, after dissolution in ammonium hydrogen fluoride solution. The occlusion found was higher for tantalite samples than for columbite samples. The

higher retention of uranyl ion by the hydrated tantalum pentoxide can be attributed to the greater cation-exchange behaviour of the latter.[5] Similar behaviour was also exhibited in the analysis of the natural columbite–tantalite samples (Table 2).

Replicate analysis, by the proposed method, of a natural sample of columbite–tantalite containing 0.183% U_3O_8, gave a standard deviation of 0.004%.

SPECTROPHOTOMETRIC DETERMINATION OF TELLURIUM AFTER ADSORPTION OF ITS MORPHOLINE-4-CARBODITHIOATE ON MICROCRYSTALLINE NAPHTHALENE

C. L. Sethi, Ashok Kumar, M. Satake*
and B. K. Puri†

Summary—A rapid spectrophotometric method has been developed for microdetermination of Te(IV) after co-precipitation of its morpholine-4-carbodithioate complex on microcrystalline naphthalene and subsequent dissolution in chloroform. The molar absorptivity at 415 nm is 9.18×10^3 l.mole^{-1}.cm^{-1}. Beer's law is obeyed over the range 5–75 μg of Te(IV); 25.0 μg of Te(IV) in 10.0 ml of final solution gives a mean absorbance of 0.180 with a relative standard deviation of 0.55%. The method has been tested for determination of tellurium in some alloys and synthetic mixtures.

Morpholine-4-carbodithioate was suggested as an analytical reagent by Beyer and Ott[1] for spectrophotometric[2,3] and titrimetric[4] determination of certain metals. In this communication, a spectrophotometric method for the determination of tellurium after adsorption of its morpholine-4-carbodithioate on microcrystalline naphthalene is described. In comparison with extraction into molten naphthalene,[5] the method is rapid, sensitive, more convenient and less expensive.

EXPERIMENTAL

Reagents

A solution of analytical grade potassium tellurite was prepared in distilled water and standardized.[6] Potassium morpholine-4-carbodithioate was prepared by the method given by Marcotrigiano *et al.*[7] and used as a 0.2% solution in distilled water. Naphthalene and chloroform of reagent grade were checked spectrophotometrically before use. Dilute solutions of ammonia and perchloric acid, and 0.2M acetate buffer, were used for pH adjustment.

Procedure

In a stoppered Erlenmeyer flask take a volume of sample solution containing up to 75 μg of Te, add 1.0 ml of 0.2% reagent solution, 2.0 ml of 0.2M buffer solution of pH 5.1, dilute to about 30 ml and add 5 ml of 1M potassium nitrate. Then add 2 ml of 20% solution of naphthalene in acetone in a fast stream and shake the mixture vigorously for 1–2 min. Collect the solid on a Whatman (No. 1042) filter paper, wash it two or three times with distilled water, drain it dry, dissolve it in chloroform and make up the solution to volume in a 10-ml standard flask. Dry the solution with 2 g of anhydrous sodium sulphate and measure the absorbance at 415 nm against a reagent blank prepared in a similar manner.

RESULTS AND DISCUSSION

The absorption spectra of the reagent and its tellurium complex in naphthalene/chloroform solution measured against water and a reagent blank respectively, are shown in Fig. 1. The Te(IV) complex absorbs at 415 nm, but the reagent absorbs negligibly at this wavelength. The absorbance remains constant for only 2 hr, so measurements should be made within that period. Co-precipitation of the tellurium complex, with microcrystalline naphthalene, is quantitative over the pH range 4.0–6.4 (Fig. 2), and for 25.0 μg of Te(IV) under optimum conditions a minimum of 0.1 ml of 0.2% reagent solution is necessary, but the volume of the aqueous phase
Fig. 1. Absorption spectra of reagent measured against water (——) and Te(IV) morpholine-4-carbodithioate complex in naphthalene/chloroform solution measured against reagent solution in water (---). Te 25.0 μg, 2.0 ml of 0.2% reagent solution, aqueous phase volume 30 ml, pH 5.16, 2.0 ml of 20% naphthalene solution in acetone.

Fig. 2. Effect of pH. Conditions as for Fig. 1.

should not exceed 30 ml. The co-precipitation of the complex with microcrystalline naphthalene is practically instantaneous. Hence a shaking time of at least 15 sec should be adequate, but shaking for 1–2 min is recommended for safety.

Effect of electrolytes

For quantitative co-precipitation the presence of an inert electrolyte such as sodium chloride, perchlorate or acetate, or potassium nitrate, seems essential. An electrolyte concentration of $0.05M$ is adequate, and higher concentrations have no further effect, so addition of 5 ml of $1M$ inert-electrolyte solution is recommended.

Under the optimum conditions the calibration graph is linear over the concentration range 5.0–75 μg of Te(IV) in 10.0 ml of the final solution.

Effect of diverse ions

The following (in the amounts shown in parentheses) do not interfere: Pb, Cd, Hg(II), Bi, As(III), Sb(III), Pd(II), Co(II) and Cr(III) (0.8 mg each); Mg, Zn, Ru, Rh, W, Mo, U(VI), Au(III), Pt(IV), V(V)

and Ag (1.0 mg each); Se (0.1 mg); Fe(III) (0.5 mg). Ni and Cu interfere but can be masked by adding 15 ml of 10% sodium cyanide solution before the co-precipitation. Sodium chloride, oxalate, acetate and sulphate and potassium bromide and tartrate (35 mg each), potassium iodide and sodium carbonate (50 mg each), sodium dihydrogen phosphate (40 mg), potassium thiocyanate and sodium citrate (30 mg each), sodium fluoride (23 mg) and disodium EDTA (10 mg) are also tolerated.

Analysis of alloys

Dissolve a 0.1–0.2 g sample of the alloy by heating for 20–30 min with 20 ml of concentrated nitric acid or of aqua regia (3:1 HCl–HNO_3), cool, dilute with water, filter, and make up to volume in a 200-ml standard flask.

Take an aliquot of this solution, containing up to 75 μg of tellurium, and adjust it to pH 5.2 with 2.0 ml of the acetate buffer and dilute ammonia solution. Add 15 ml of 10% sodium cyanide solution to mask copper (if present). Dilute to 30 ml, add 5 ml of $1.0M$ potassium nitrate and 2.0 ml of 0.2% reagent solution and complete the determination as already described.

QUALITY CONTROL IN CLINICAL CHEMISTRY: CHARACTERIZATION OF REFERENCE MATERIALS

ROBERT REJ and RICHARD W. JENNY

Summary—Reference serum preparations are key components of internal and external quality-control programmes. These materials are often poorly characterized, and use of inappropriate specimens may result in erroneous conclusions regarding quality of laboratory data. Several techniques are described that characterize specimens used in the quality-control or calibration of laboratory procedures. A characteristic approach requires detailed study of a few fundamental characteristics of reference preparations—such as steady-state kinetic properties of an enzyme—and comparison with the same parameters determined for patient specimens. Descriptive techniques—ratio methods and the multivariate statistical procedure of correspondence analysis—are used for further description of the interactions of materials in a variety of assay methods. The applications of these procedures to two clinical analytes—theophylline and alkaline phosphatase—are described.

The fundamental objective of statistical quality-control programmes in the clinical laboratory is to characterize the analytical process accurately and thereby provide information regarding the quality of results reported for clinical specimens. This information may be used for a number of purposes. An internal quality-control programme may provide information about the routine performance of an analytical technique—and thereby serve as a basis for selection of one among many procedures available—or give on-line monitoring of an analytical process in which acceptance of a result depends on whether it falls within predetermined limits. External quality-control provides a basis for independent characterization of laboratory performance and gives information on the reliability of test procedures in various locations and in laboratories with different backgrounds. External quality-control programmes serve, in some instances, for the determination of acceptability, licensing, or eligibility for reimbursement for laboratory services.

The reliability of this assessment of quality is dependent on a variety of factors, but the key to the success of all these schemes is that the reference materials used simulate as closely as possible the clinical specimens analysed. This facet of quality control is often (incorrectly) assumed or (equally erroneously) overlooked in both internal and external quality-control programmes. The scope of this paper is the review of criteria for materials used in clinical laboratory quality-control programmes and to pro-

vide a basis on which their acceptibility can be judged.

Various types of reference materials are currently used in quality control programmes,[1-9] and differ in their basic composition and physical character. Specimens may be prepared from human serum, plasma that has been "converted" into a serum-like state, various animal sera, albumin solutions, or synthetic substances, and are distributed in the dry or liquid state. Because stability is a prime requirement for such specimens, most are in lyophilized form. Unfortunately, freeze-drying alters certain physicochemical properties of biological materials;[10-12] for example, human lipoproteins are irreversibly denatured, and consequently serum viscosity may be changed, serum turbidity increased,[13,14] and the spectral properties altered.[15] Removal of lipoproteins prior to lyophilization,[14,16] or addition of sucrose[17] in order to minimize specimen turbidity, also results in materials that are fundamentally altered. Other typical treatments of quality-control sera include dialysis and addition of matrix expanders, preservatives, antimicrobial agents, surfactants, and clarifying agents.[18-20]

Concentrations of constituents are also often altered by attempts to obtain reference specimens with analyte concentrations outside the "normal" ranges. Such specimens, usually prepared by dilution or by addition of pure materials to a normal specimen, may differ from the sample sera because metabolites or other substances are lacking. Therefore, in use of a non-specific method that is influenced by one or several metabolites, the results for such a supplemented quality-control material will not be affected in the same way as those for a patient's serum. Such

effects are related to the *matrix* of the reference material—a term which in this article will be used to describe the principal constituents of the material. The major components of the matrix (serum; specific serum proteins, such as albumin; synthetic expanders such as polyvinylpyrrolidone) may differ from native serum in viscosity, physical interaction of low molecular-weight substances with proteins, and Donnan and other charge-related phenomena.[21,22] Finally, the pH of some lyophilized control materials differs significantly from that of normal or patients' sera.[9,23] Differences between the matrixes of commonly used lyophilized materials and clinical specimens are evident in Table 1.

In addition to the matrix, the analyte in the reference material may be quite different from that in the clinical specimen. Enzymes of animal origin are often added to such control preparations[26-33] and the properties of at least a portion of these enzymes are known to differ from those of human serum enzymes with respect to optimal substrate concentrations, pH, effects of inhibitors, and related factors. A simple example of errors introduced by such differences is provided in Fig. 1, where the hypothetical response of the activity of three enzymes to an assay parameter is presented. If the assay concentration of this parameter were increased by the increment shown, each material would respond differently. A negligible decrease is found for enzyme A; enzyme B (here for discussion purposes considered to be the response of the enzyme found in human serum) shows a moderate decrease, and enzyme C an exaggerated decrease. Use of enzyme A in a control material would tend to mask the effects of assay variables and would be least appropriate for quality-control reference preparations. The ideal control material would have a response similar to that of enzyme B in order to provide an accurate monitor of results obtained for patients' specimens. Use of a material characterized by enzyme C would indicate results that were "out of control"
Fig. 1. *Left*—hypothetical response of activity of three enzyme preparations to a change in an assay variable. *Right*—typical quality-control chart representation of measured response due to change in analytical conditions shown by the arrow at the left. Dashed lines represent limits of acceptability. If response B is representative of the enzyme in patient-specimens, responses A and C are inappropriate and the enzyme materials are not suitable in a routine quality-control programme.

for this material, though results for patients might be unaffected by a slight change in the assay variable. In these days of laboratory cost-effectiveness, this material might be considered by some to be equally inappropriate as material A. Certainly it does not authentically represent the clinical specimen. However, as we have suggested previously,[27] if this property of the control material was recognized by the analyst, this exaggerated response would be useful in an internal quality-control programme because of the increased sensitivity to change, and might indicate an unsuspected error that could be corrected by the laboratory before any results for patients' samples were affected.

In an external quality-control programme—where many different analytical techniques are examined—it is clear that only materials giving the same response as enzyme B would provide a fair assessment of interlaboratory results. This would also be the case for an internal quality-control programme in an institution where several methods are used for the determination of a single analyte (*e.g.*, back-up pro-

*Normally collected bovine and human serum were frozen in 10.0-ml aliquots at −60°; representative aliquots were lyophilized and reconstituted with 10.0 ml of water (this would result in a volume slightly different from the original 10 ml).

†Reference values for normal human serum are from Diem and Lentner[24] and are 95% confidence intervals; the mean value is shown for surface tension.

§Values of 1.80 and 1.62 have been obtained for commercially available lyophilized control sera; 3.82 was determined for a liquid material based on ethylene glycol.[25]

‡Particle sizes >20 *μm* have been found for commercial serum preparations.[13]

cedures, "stat" or emergency-room techniques, different analytical instruments used on different shifts) and the internal quality-control programme takes on many aspects of external surveys.

Peptide hormones and specific serum proteins also exhibit such behavioural differences between species and demonstrate effects similar to those described above.[34,35]

It is clear that such differences from clinical specimens can affect the use of reference materials in quality-control programmes. Many clinical laboratory procedures use reference materials as calibration solutions and differences between specimens and calibration standards are all the more important, since all the analytical results obtained are potentially affected by these differences. A dozen years ago, a report from our laboratory[27] pointed out these potential sources of error and we drew distinctions between the properties of reference materials that are important for their potential application in calibration (standards), and as control materials for intermethod studies (exemplified by external quality-control), intramethod controls, and precision controls. The properties of reference materials would differ in importance according to the intended use. Among the variables we considered were the effects of the matrix and the source of the enzyme. One of the properties that we suggested as important for materials used as intermethod controls and for calibration was *commutability*—a term that we coined to refer to the ability of a material to show interassay properties comparable to those of human serum. At the time we suggested that this was an indispensable property of materials used for calibration and external quality-control but an unnecessary one for within-method studies. Though this is basically true, this property is also necessary for intramethod-control materials when they are used to reflect the precision and accuracy of analysis of patients' specimens rather than as specialized tools for the analyst.

The term commutability has been accepted by others,[9,36-41] and the term *fidelity* has been suggested as a synonym for commutability.[23] There has been a suggestion by one group[28,42] that as analytical methods become more homogeneous around the world—in part because of the introduction of reference methods—the principle of commutability is no longer needed and they suggest that *representativeness* of these materials be used instead. However, they define this term in much the same way as we originally defined commutability. Furthermore, although methodology has become more uniform for some test procedures, it has become more diverse for others, owing to new technology. For example, dry-reagent systems require a much larger sample volume fraction than classical techniques do, thus exaggerating matrix effects.[36,43] It is likely that the property of commutability will become more, rather than less,

important in the future. Wilding and Wilkes[41] have attempted to quantify this property by describing a *commutability index* whereby the range of results from a variety of techniques for an analyte of a reference material is compared with an overall mean value—the larger the index value the less commutable the material for that analyte.

Another term that we have applied to describe the properties of reference materials is *behaviour*.[44] This term, formally defined as "the response to the whole range of factors constituting its environment" seems well suited to describe the interaction of materials (whether reference materials or clinical specimens) with assay variables. Thus poor reference materials would show behaviour considerably different from that of clinical specimens, whereas satisfactory materials—those that demonstrate commutability— would have given similar behaviour.

The characterization of quality-control material behaviour is crucial for a true estimate of the quality of results and an accurate evaluation of analytical methods. Otherwise, artificial biases, not encountered with patients' specimens, will also be detected, or biases existing with patients' sera will not be observed.

How should the behaviour of these reference materials be assessed? We recognize that many techniques are possible but have found three that are particularly useful and efficient.

Characteristic approach

This technique involves the descriptive characterization of the variable measured in the reference material—usually an enzyme, protein, or peptide hormone—in comparison with the same entity in human serum. This fundamental approach is of value in that the characteristics found for this analyte are relatively stable, and predictions of interassay behaviour can be made on the basis of small amounts of data such as steady-state kinetic constants for substrate and inhibitor, optimal pH, ligand affinity, *etc.* As new assay techniques are introduced, their relative bias for clinical specimens and reference materials can be predicted on the basis of assay conditions. In addition, the underlying cause for differences among assay techniques, observed for some reference materials, can be explained in terms of these fundamental differences among the species determined.

We have characterized a reference material for aspartate aminotransferase* measurements by such an approach.[31,45,46] In terms of substrate affinity, optimal pH and temperature effects, the enzyme purified from human erythrocytes has properties that are indistinguishable from those of the enzyme native to human serum. This purified material could thus serve well as a reference preparation for the quality control or calibration of aspartate aminotransferase assays. There have been several attempts to characterize similarly other human enzyme reference preparations.[39,47] Gruber *et al.*[26] systematically compared

---

*EC 2.6.1.1, L-aspartate: 2-oxoglutarate aminotransferase.

the catalytic properties of various purified enzymes of animal origin and those purified from human tissues in order to judge their acceptability as control materials. There have been several other investigations characterizing individual properties of control sera in order to assess their suitability.[28,33,48]

Although these studies provide useful and fundamental information, they are limited to characterization of the catalytic, immunochemical or molecular properties of a limited number of analytes. Matrix effects—a major source of differences in behaviour or lack of commutability–are not often demonstrated by these studies. There have been some attempts at describing the protein matrix of control materials. Clark et al.[49] have described a two-dimensional gel technique as a method for characterizing the matrix of specimens, and patterns obtained for control sera were compared with those of fresh human serum. This approach has also been recommended by Bais et al.,[50] who used a one-dimensional electrophoretic procedure.

The following techniques compensate for any shortcomings of the characteristic approach, but are purely descriptive so the underlying cause of differences must be obtained by other means (such as the characteristic approach) or by a thorough examination of variables affecting the analytical procedures.

Ratio methods

These procedures compare ratios of analyte concentrations for control materials (found by different techniques) with those similarly found for patients' specimens. As an example, simulated data are presented in Table 2 representing average patient-results and results for six quality-control specimens, by four analytical methods (A, B, C, and D). Method A is considered as the reference method, and all other results are expressed as percentages of those obtained with this method. Figure 2 shows a graphic representation (linear ratio, also called a commutability diagram)[36] for the simulated data given in Table 2. Results obtained by the four methods are displayed on a horizontal scale for each specimen or group of specimens. The positions for the reference method—

Table 2. Simulated results for an analyte in patients' specimens and six quality-control sera, as measured by four methods

Specimen	Method			
	A	B	C	D
Patients' sera, mean	100	102	106.8	102.8
SD		0.8	0.8	0.6
Quality-control sera				
1	100	102.0	107.0	103.0
2	100	102.0	103.5	103.0
3	100	106.5	107.0	103.0
4	100	102.0	110.0	103.0
5	100	100.0	105.1	101.0
6	100	102.0	103.0	107.0

Results for each method were generated by random selection ($n = 200$) from Gaussian distributions with the following characteristics: method B, mean 102, SD = 0.9; method C, mean 107, SD = 0.8; method D, mean = 103, SD = 0.7. (Adapted from reference 44, by permission).

or selected comparison method—are aligned vertically for each scale to aid in comparison of the profiles. The average intermethod bias demonstrated by the four analytical methods for patients' specimens is shown by the position of their respective letters on the reference scale (patients' specimens) in Fig. 2. Variability among the patients' specimens themselves for each method is shown by the shaded bars at each letter; in this example the bar represents ± 2 standard deviations. The behaviour pattern— reflected in the positions of the methods—for each quality-control specimen is also shown in Fig. 2 and should be compared with the corresponding pattern on the reference scale. Acceptable method-bias in this example is considered to be $\leqslant 5\%$, so results from methods B and D are considered reliable for assay of patients' specimen, but method C is not.

For a candidate reference specimen to be useful in a laboratory control programme, results obtained for it should give a pattern identical to that of the patients' specimens. An acceptable quality-control specimen will produce positions within the dispersion ranges given in the reference scale, for all the methods used.
Fig. 2. Linear ratio representation of hypothetical data presented in Table 2. The reference scale is the range of intermethod bias found with patient specimens. Adapted from reference 44 with permission.

Quality-control specimen 1 demonstrates an inter-method bias identical to that of the typical patients' specimens, but the pattern shown by quality-control specimen 6 is aberrant for methods C and D (Fig. 2). The behaviour pattern of quality-control specimen 2 differs from the behaviour of patients' specimens in such a way that the large bias of method C is lost. If this specimen were to be used in an interlaboratory quality-control program, those laboratories using method C would incorrectly be considered to give results equivalent to those of method A. The reverse situation is shown in the case of quality-control specimen 3, where an exaggerated bias is shown for method B. Use of this material in a quality-control survey would incorrectly characterize this method as one which gives unacceptable results.

Quality-control specimen 4 shows an exaggerated bias for method C, but unlike the case for the previous specimens, this difference might be considered useful in that it amplifies the already unacceptable bias of method C. However, the magnitude of this bias is greater than that shown for any patients' specimen, making the behaviour of this specimen different from that of the reference population. Quality-control specimen 5 likewise differs from the reference population because it shows a reduced bias for all methods, but it maintains the pattern of acceptability: methods B and D are acceptable in comparison with the reference technique, while method C is not.

The use of linear regression statistics offers another ratio approach to the assessment of control-material behaviour. An assumption in the linear regression model is that each of the y-populations is distributed normally and with equal variances and that the standard error of estimate (SEE) is a measure of the dispersion of data points around the least-squares line. In our application, one method is selected as a comparative or reference procedure and regression statistics are determined for each of the other methods, from data obtained from the analysis of clinical specimens. Deviation of control-material data from the least-squares line is then determined from the ratio, residual/SEE, where "residual" is the perpendicular distance between a control-material data-point and the regression line. At the 95% confidence

level, the ratio should be within ± 2.0 if the control-material behaviour is similar to that of clinical specimens. This analysis was performed with the simulated data of Table 2 and is presented in Table 3. Control specimens 3 and 5, when analysed by method B, clearly do not conform to the distribution of the clinical-specimen data, so these materials are not considered to be representative of authentic patient-samples when analysed by this method. Likewise, quality control specimens 2, 4, 5 and 6, when analysed by method C and specimens 5 and 6 when analysed by method D do not behave like clinical specimens.

This application of regression parameters was first proposed by van Helden et al.[37] Conclusions drawn from the linear ratio analysis of control-material acceptability are reinforced by this least-squares technique. Since these parameters are easily calculated, this procedure lends itself particularly well to micro-computer application.

Multivariate statistical analysis

When numerous patient-specimens are examined by several analytical methods, the ratio techniques cannot adequately and simultaneously present comparisons of specimens and methods. These data, however, can be processed by a variety of multivariate statistical techniques. The most appropriate statistical procedure would be a descriptive method that is not based on a preconceived model. It should also be able to characterize potential differences in behaviour among the clinical specimens themselves, and provision should be made for the treatment of quality-control specimens as inactive elements if desired, so that they will not distort the patterns shown by the clinical specimens as active elements.

The two statistical techniques that best meet these criteria are principal-components analysis and correspondence analysis. These procedures are frequently utilized in the social sciences and for applications in interpretation of data such as political polls[51] but are only now being actively explored by analytical scientists for their power to predict, classify and reveal the underlying structure of large data bases.[52] Although there is a similarity between these methods, we have described in detail the application of correspondence analysis[44] and our rationale for preferring it over principal-components analysis.

When the data of Table 2 are subjected to correspondence analysis the cluster diagram presented in Fig. 3 is obtained, where the data are projected onto the factorial plane established by the two most significant factors. The positioning of an individual specimen on the plane described by these two factors is representative of its behaviour. In such representations, specimens with similar behaviour are projected near one another. The twenty patient-specimens form a well-defined cluster that includes control material 1—as indicated above, it is a material exhibiting commutability. Note, however,

Table 3. Deviation (number of standard deviations) of hypothetical quality-control serum analyte concentration from the respective method regression lines determined by using patient-data of Table 2

Quality control serum	Deviation		
	Method B	Method C	Method D
1	0	0.2_4	0.3_1
2	0	-4.0_2	0.3_1
3	5.4_2	0.2_4	0.3_1
4	0	3.9	0.3_1
5	-2.4_1	-2.0_7	-3.1_3
6	0	-4.6_3	6.5_6

R. REJ et al.

that specimen 5, which has been shown to have some properties different from those of patient-specimens (Table 3, Fig. 2), is also projected near the centre of the projections for patients. This is due to the similar *profile* of intermethod response and demonstrates the need to apply more than one procedure to the characterization of material behaviour. Control materials 2, 3, 4 and 6 are projected far from the patient-samples, indicating a behaviour different from those of the patient-specimens. Correspondence analysis has the advantage of simultaneously projecting variables (here the analytical methods) onto the factorial plane. Proximity of the projections for method and material indicates an interaction between the two that often aids interpretation.

We have applied these techniques to characterize the behaviour of α-amylase* and aspartate aminotransferase reference materials in several analytical methods.[29,53] Here we describe two new applications to different areas of clinical chemistry analysis—therapeutic drug monitoring (theophylline) and enzyme assays (alkaline phosphatase†).

Case 1—Theophylline

In this application, the effects of specimen preparation, preservation, and matrix were examined. Nineteen specimens, selected at random from serum samples delivered to the laboratory for routine theophylline monitoring, were used to characterize the analytical systems included in this study; the theophylline concentration range was 6.5–18.6 mg/l.

Control materials were prepared by using commercially available normal human serum and bovine serum. Treatments of the serum included: precipitation of β- and pre-β-lipoproteins by the procedures of Proksch and Bonderman[14] (treatment A) and of Bais et al.[50] (treatment B); precipitation of α- and β-lipoproteins[16] (treatment C); and lyophilization. Theophylline was added to all pooled materials, to give concentrations of approximately 15.5 mg/l. The nature, treatment, and coding of control materials is outlined in the first column of Table 4.

The theophylline concentration in authentic patient and control specimens was determined by five methods, each differing in principle. The techniques used were: (a) the enzyme-multiplied immunoassay technique (EMIT); the Syva Emit and Theophylline Assay reagent kit was used with a Gilford Stasar III spectrophotometer controlled by a System 5 Clinical Analyzer; (b) fluorescent polarization immunoassay (FPIA); the Abbott TDx Theophylline Reagent Pack was used with the TDx Direct Reading Fluorescence Polarization Immunoassay Analyzer; (c) substrate-labelled fluorescent immunoassay (SLFIA); Optimate theophylline reagents were used with the Ames/Gilford Optimate Automated TDA and Chem-
Fig. 3. Correspondence analysis of hypothetical data given in Table 2. Projection onto the plane described by the two most significant factors. Projections on the plane are: patients' specimens (●); quality-control specimens (△) numbered as in Table 2; the four analytical methods (lettered boxes). The ellipse defines the 95% confidence area describing the multivariate variability in behaviour of the patients' specimens with respect to the four methods. Adapted from reference 44 with permission.

istry Analyzer; (d) rate-inhibition nephelometry (NIIA); Beckman theophylline reagents were used with the ICS II analyser; (e) high-pressure liquid chromatography (HPLC); the liquid chromatograph consisted of a Beckman Instruments Model 100A and a Model 110A pump, Model 210 injection valve fitted with 20-μl sample loop, a 15 cm × 4.6 mm Ultrasphere–ODS column, and a Model 155-40 variable wavelength UV–VIS detector. HPLC was used as the reference method.

All techniques exhibited excellent correlation with the reference method for results obtained from clinical specimens with the exception of NIIA, where the relative error exceeded 30%. When the buffer-diluted samples were centrifuged prior to analysis, as is recommended if the specimen has been frozen or lyophilized, the relative errror was decreased to 19%.

The regression analysis parameters were used to assess the relative behaviour of control materials by determining the "closeness-of-fit" of results for control specimens to the clinical specimen regression line (Table 4). Theophylline concentrations in lyophilized control materials analysed by FPIA were found to give greater error than the frozen sample in each treatment pair. At the 95% confidence level, controls 1L, 4L, 6L, 7L and 8L were significantly distant from the regression line defined by the clinical samples. SLFIA analysis of human-serum control specimens, both frozen and lyophilized, also resulted in significant error while bovine-serum materials all gave results within acceptable limits. The behaviour of all control materials in the EMIT assay was similar to that of clinical specimens, as was also the case with NIIA except for sample 8F.

---

*EC 3.2.1.1, 1,4-α-D-glucan glucanohydrolase.
†EC 3.1.3.1, orthophosphoric monoester phosphohydrolase (alkaline optimum).
Fig. 4. Linear ratio presentation of theophylline method bias relative to HPLC. The mean recovery and 95% confidence interval for patient-specimens is represented by the method code and horizontal bars respectively. With HPLC results representing target concentrations, the recovery of theophylline from patients' and control specimens is presented for the EMIT (E), FPIA (F), SLFIA (S), and NIIA (N) methods.

These data are presented in the linear-ratio format in Fig. 4, where results are expressed as a percentage of those obtained by HPLC. The mean recovery and 95% confidence interval for each method were determined by using the data for patient specimens. Recovery of theophylline from the control material should be within the respective ranges for the methods if matrix effects are negligible. The significantly higher theophylline recovery from human-serum con-

trols for SLFIA is clearly observed. Also, the FPIA theophylline recovery from 1L, 4L, 7L and 8L is lower than that for clinical specimens.

Correspondence analysis of these data was performed with patient-results as active elements (Fig. 5). Since the intermethod bias between NIIA and the other analytical systems was considerable, patient-data obtained from NIIA were treated as inactive elements to allow evaluation of the more subtle
Fig. 5. Correspondence analysis of theophylline data. The coded rectangles are projections of the five theophylline methods; projections of bovine (O) and human (△) serum control materials are identified by the enclosed codes. Projections of the patient-data are identified by the patients' numbers (1–19).

differences among the EMIT, SLFIA, FPIA and HPLC results. Data projected onto the plane determined by factorial axes 1 and 2 accounted for 59 and 41% respectively of the information contained in the data matrix. Along the most significant axis 1, EMIT is well-separated from the projections for SLFIA, FPIA and HPLC. Evaluation of the patient-data revealed a consistent positive bias of FPIA and SLFIA results relative to HPLC. EMIT results, on the other hand, for the cluster of patient-specimens with projections on the left of axis 1 were lower than HPLC results. Concentrations determined by EMIT were higher than those obtained by HPLC for those patient-specimens with projections on the right of axis 1. The position of the method projections on axis 1 is consistent with the intermethod bias of patient-results noted from regression analysis, and this axis probably reflects the intermethod bias of the theophylline results. Axis 2 is largely determined by the differences in behaviour of patients 2, 5 and 14 from that of patients 1, 11 and 15, and the method responsible for the dissimilarity in behaviour is SLFIA. The mean theophylline recovery from patients 2, 5 and 14 by SLFIA was 111.2%, which is significantly higher than the 100.1% recovery from specimens 1, 11 and 15. Figure 5 also demonstrates a separation of bovine-serum from human-serum materials along axis 2. As noted with the other techniques, a significant matrix effect existed in the

human-serum control material when analysed by SLFIA. Theophylline recovery from the human-serum controls by SLFIA averaged 114% and was therefore projected on axis 2 along with the results for patients 2, 5 and 14.

Of the methods currently used in clinical toxicology, NIIA appears to be most sensitive to the presence of endogenous particulate matter. These particles may conceivably act as centres at which immunocomplexes are formed, resulting in larger but fewer immunocomplexes than would occur in the absence of particulate matter. In this situation, falsely elevated drug concentrations are reported. Centrifugation of the buffer-diluted clinical specimens to remove cryoprecipitates prior to analysis resulted in improved accuracy and precision, but significant bias remained. The behaviour of control materials was similar to that of patients' serum, with the exception of the frozen human serum, which appears to have been rectified by treatment with dextran and "Aerosil" (Table 4).

Correspondence analysis dramatically illustrates the unique behaviour of human-serum control specimens when analysed by SLFIA. At least a portion of the bias is due to background fluorescence of the control specimens. The manufacturer claims that background fluorescence is rarely found in authentic clinical specimens, and that specimen blanks need not be routinely run in the clinical laboratory.[54]

*Deviation, expressed in number of standard deviations, was determined from the expression, residual/SEE, where residual is the perpendicular distance between the control-material data point and the regression line derived from clinical specimen data.
†The buffer-diluted samples were centrifuged at 8000 *g* for 5 min before analysis.

Correspondence analysis, however, demonstrates that 3 of the 19 patient-samples used in this study behaved similarly to the processed human-serum controls, suggesting that background fluorescence may frequently occur in clinical specimens.

Lyophilization appeared to have an adverse effect on specimen behaviour in analysis by FPIA. Mean theophylline recovery from patient-specimens, frozen and lyophilized controls was 105, 103 and 100% respectively. In the FPIA system, the extent of tracer polarization is inversely proportional to the concentration of endogenous drug.[55] Analytical variables which may increase rotational relaxation time, and hence decrease apparent analyte recovery, are decreased temperature and increased viscosity of the medium.[56] Temperature control is well maintained in the TDx analyser and control materials were dispersed among clinical samples in the analytical runs. The viscosity of the control material is increased both by lyophilization and by addition of dextran or colloidal silica, but the sample dilution factor in this assay is over 1000-fold, which minimizes the variability of viscosity between specimens. It is evident that the bias introduced by lyophilization, though measurable, was not of sufficient magnitude to exceed the limits of acceptability likely to be used in an interlaboratory quality-control programme. In the New York State programme, the coefficient of variation of the collective theophylline data averages 10%, and 80–120% recovery of drug is considered acceptable. The lyophilization effect, however, may contribute to an overestimation of this method's imprecision by external quality control.

Case 2—Alkaline phosphatase

The selection of a source of alkaline phosphatase for supplementing the activity of quality-control specimens is difficult, since it is not practical to use the two isoenzymes of clinical importance—those from human liver and bone. At present, manufacturers often add the enzyme derived from human placenta or intestinal enzyme of calf or chicken origin.[32,57] The purpose of this experiment was to seek an alternative source of alkaline phosphatase that would mimic more closely the behaviour of alkaline phosphatase from human liver and patient-specimens with respect to the most widely used methods of determination.

Twelve methods were chosen for measuring the alkaline phosphatase activity; essential details of these methods, and the three-letter abbreviation codes used for them in this article, are summarized in Table 5. Unless specified, these methods were applied exactly as described or according to the manufacturer's recommendations. The method of Kind and King (K&K)[58] was used in the Price and Woodman[59] adaptation using Technicon Auto-Analyzer equipment with dialysis. Three different modifications of the method of Bowers et al.[60] were used. The procedures coded AMD and AMZ followed the procedure as described[60] but the 2-amino-2-methyl-1-propanol used was pretreated; in method AMD it was distilled under reduced pressure and in method AMZ it was pretreated by addition of zinc ions with removal of the excess by cation-exchange as described previously.[61] The third modification (code CPS) used 0.1M CAPS [3-(cyclohexylamino)propanesulphonate] as the buffer[62] instead of 2-amino-2-methyl-1-propanol, since it is not transphosphorylated. Other methodological details will be reported separately.[63]

The methods were chosen to represent a wide spectrum of analytical principles characteristic of methods used in clinical chemistry laboratories throughout the world. In addition, the effects of

Table 5. Methods used for determination of alkaline phosphatase activity*

Code	Buffer	Substrate	Determination†	Temperature °	Reference or manufacturer

ATE	2A2M1P	PPMP	Two-point	30	General Diagnostics (Phosphastrate)
ABS	Tris	PPDP	Two-point	37	General Diagnostics (Phosphatabs)

*Abbreviations used: 2A2M1P, 2-amino-2-methyl-1-propanol; DEA, diethanolamine; CAPS, 3-(cyclohexylamino)-propanesulphonate; Tris, tris(hydroxymethyl)aminomethane; 4-NPP, 4-nitrophenylphosphate; TMPP, thymolphthalein monophosphate, PPMP, phenolphthalein monophosphate; PPDP, phenolphthalein diphosphate.

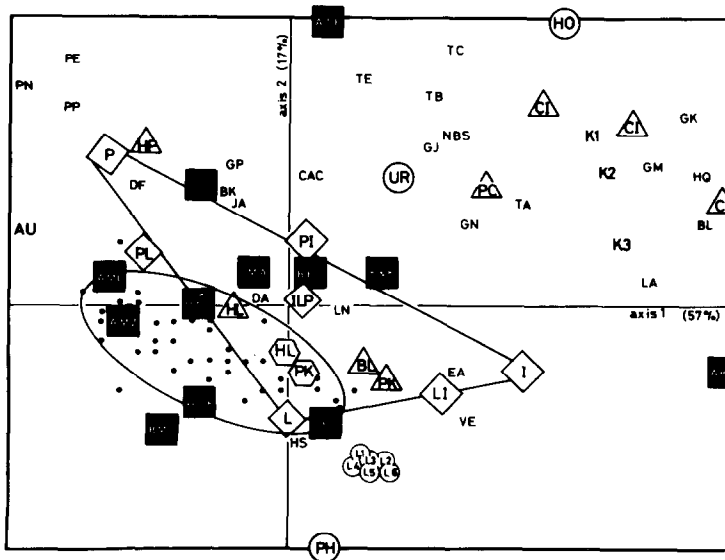
†Kinetic refers to continuous monitoring of the reaction rate, except for method SMA where the reaction rate is calculated by using three measured points.


Fig. 6. Correspondence analysis of alkaline phosphatase measurements. Projection on the plane described by axes 1 and 2. The large squares are projections of the analytical methods identified by the three-letter codes given in Table 5. Other symbols are: patient-specimens($\bullet$); purified isoenzymes ($\triangle$) identified as given in the text: letter-coded points without symbols are quality-control specimens. Large circles represent projections of results for alkaline phosphatase determined in the presence of inhibitors (see text).

homoarginine (code HO), urea (code UR), and L-phenylalanine (code PH)—all inhibitors of certain alkaline phosphatase isoenzymes—were examined under the conditions of the method coded CPS in order to better characterize the patient-specimens and candidate materials.

Patient-specimens were selected from a hospital population by use of criteria that we have described previously[44] and represented a variety of normal and pathological states with both normal and abnormal activities of alkaline phosphatase—they are shown as solid dots on the multivariate map (Fig. 6). Candidate quality-control materials were obtained commercially (shown by two- or three-character codes) or were prepared specifically for this study. These latter specimens made use of three kinds of matrixes: a native human-serum pool (shown as hexagons), a denatured human-serum pool (shown as open diamonds), and a native bovine-serum pool (shown as triangles). Enzymes of various tissue and species origin were used to supplement the matrixes. These included enzymes from calf intestine (code CI), beef liver (BL), pig kidney (code PK), and human enzymes purified from liver (code HL or L), intestine (code I), and human placenta (code P). Specimens L1–L6 (Fig. 6) differed with respect to alkaline phosphatase activity but were otherwise identical. They were made of human liver enzyme in an artificial matrix composed of polyvinylpyrrolidone, albumin and buffer.[57]

Results were processed by correspondence analysis and the projection of these data on the plane formed by factorial axes 1 and 2 is shown in Fig. 6. These two axes represent 57 and 17% respectively of the infor-

mation contained in the data, as calculated from their eigenvalues. The aggregate clustering of the patients' specimens, surrounded by the 95% confidence ellipse is in sharp contrast to most of the quality-control specimens, which have their projections outside this ellipse. A remarkable result is the similar projection of the diamond-coded specimens, which can be used as an alternative reference of behaviour. They contain either one pure human isoenzyme (code I, L or P), determining the corners of a triangle, or equal-activity mixtures of two of them (code PI, LI or PL), positioned at the middle of each corresponding side, or an equal-activity mixture of all three (code ILP), located at the centre of gravity of the triangle. The relative positions of the ellipse and the triangle are consistent with the fact that most alkaline phosphatase activity encountered in patient-specimens is of liver origin.

As we have described earlier, the differences in behaviour are directly related to the intermethod biases for different kinds of specimens. It is possible to conclude that in this experiment, a lack of correlation between methods cannot be accounted for by any biases, since the projections for the specimens L1–L6 are near each other, irrespective of the concentration.

Most quality-control specimens situated in the upper right corner of the map apparently contain intestinal alkaline phosphatase either from chicken or calf. It is interesting that they differ significantly from those containing the enzyme of human origin. This was verified for some of the control materials known to contain one of the non-human intestinal

enzymes, including that coded as NBS in Fig. 6, which is the U.S. National Bureau of Standards reference material SRM-909, for which enzyme data are available.[64] Our data suggest that this material has an intermethod behaviour demonstrably different from that of patient-specimens and is therefore of limited usefulness in intermethod comparisons. Similarly, commercial specimens PE, PP, PN, containing human placental enzymes in a semi-artificial matrix, are all located near the P diamond. Conversely, some of the commercially available specimens (e.g., DA or HS) display a behaviour similar to that of the patient-specimens, since their projections are close to the ellipse. These specimens were manufactured from human plasma to which no supplemental alkaline phosphatase was added. Finally, the behaviour of prepared specimens containing pig kidney or beef liver show a behaviour very similar to that of patient-specimens when the matrix is a denatured human-serum pool. Minor departure from behaviour can be observed when native bovine serum is supplemented with these enzymes (see triangles on the right of the ellipse in Fig. 6).

As a conclusion from this study, we recommend the use of pig kidney or beef liver alkaline phosphatase as an adequate source of the enzyme for simulating intermethod behaviour of patient-specimens.

CONCLUSIONS

The success of any statistical quality-control program is dependent in large part on the characteristics of the specimens used to evaluate the analytical system(s). In external programmes it is essential that the material has properties similar to those of patient-specimens in the methods tested. The procedures that we have outlined—and applied to two cases here— are relatively simple yet highly informative for the evaluation of control-material commutability. Correspondence analysis, in particular, is a powerful descriptive tool. It also clearly presents information regarding the interaction of patient-specimens with the analytical methods, so that matrix effects that may also influence results for certain types of patient-specimens will also be characterized (Fig. 4). Such matrix effects may be a significant source of error for patient-specimens.[65] Jansen[66] has used an alternative multivariate technique for similarly classifying methods, but possible non-commutability of the control specimens was not considered in that application.

Recognition of the limitations of certain control materials should help in the interpretation of inter-laboratory quality-control data. Procedures such as those described here will help in the design of more effective materials for quality-control in the future.

SOLID-PHASE CHEMISTRY: ITS PRINCIPLES AND APPLICATIONS IN CLINICAL ANALYSIS

ADAM ZIPP

Ames Division, Miles Laboratories Inc., Elkhart, Indiana, U.S.A.

W. E. HORNBY

Ames Division, Miles Laboratories Ltd., Stoke Court, Stoke Poges, Bucks, England

Summary—A review is given of the development of solid-phase reaction systems (test papers, impregnated-fibre systems, multi-layer film systems) for rapid field and laboratory testing in clinical analysis.

Anyone who has worked or been taught in a chemical laboratory is very familiar with the use of indicator papers for the rapid and approximate estimation of the pH of a solution. Likewise, most people who have been associated with clinical biochemistry are equally aware of the use of other types of reagent strips for the rapid estimation of certain urinary constituents such as glucose and protein. In the more specialized area of diabetology, the usefulness of reagent strips for the measurement of whole blood glucose has been recognized for more than a decade, and more recently, attention has been drawn to the use of yet more sophisticated reagent strips for the quantitative measurement of a much wider range of analytes in serum and plasma, such as enzymes, metabolites and drugs. All these test papers or reagent strips are types of solid-phase reagents which may thus be looked upon as self-contained analytical devices.

A common denominator underlying the use of these solid-phase reagents is the need to be able to perform rapid and convenient analyses without the encumbrances or impedimenta that are often associated with more conventional analytical techniques. While it is recognized today that convenience is one of the principal driving forces behind the use of solid-phase reagents, it is not widely known that such considerations prompted similar interest in and use of solid-phase reagents a century ago. Thus, in reporting on the use of test papers for the detection of urinary glucose, George Oliver in 1883 wrote "All busy practitioners must admit the clinical utility and importance of accurate, time-saving and portable tests . . . ".[1]

Since the development and manufacture today of solid-phase reagents is tightly bound up with modern and advanced technology, it is generally thought that these analytical tools are artefacts of the twentieth century and inventions of the companies which have pioneered their application in diagnostics. This is not strictly true, since solid-phase reagents of one type or another have been used as diagnostic tools for the best part of two centuries. Indeed, many of the

precepts governing the use of solid-phase reagents in diagnostics were developed during the last century and it is worthwhile to note a few of the landmarks in their evolution, before reviewing in more detail the latest developments.

Among the earliest accounts is that by Prout in 1817[2] reporting the use of litmus paper for testing the alkalinity of urine. Further applications of litmus paper, this time for measuring the alkalinity of mucus, were recorded by Babington in 1837, who reported that "bibulous paper tinged with litmus and reddened by simple exposure or by a very dilute acid solution is restored to its blue colour by fresh mucus". It is interesting that as early as 1837 Babington was able to recognize the importance of the nature of the matrix of the solid-phase reagent and the effect this can have on the performance of the test system. He reported that the sensitivity of the mucus test was modulated when the type of paper was changed: "In the shops they commonly tinge writing paper for use; but the size it contains, which cannot be soaked out by cold water, diminishes its delicacy as a test".[3] A few years later, in 1850, Maumené extended the range of application of solid-phase reagents when he described the detection of urinary glucose with test strips woven from white merino wool and impregnated with stannous chloride.[4] Maumené, too, recognized the role of the solid-phase matrix itself, and pointed out that the glucose test strips should not be made from paper, since the paper itself developed a false-positive reaction with the stannous chloride.

Another variant of solid-phase reagent was developed and reported by Oliver[1] in an attempt to render more portable and convenient some of the tests then commonly carried out by general practitioners. Oliver used reagent-impregnated papers as reagent carriers and reconstituted the liquid tests systems by leaching the reagents out of the strips immediately before their use. In this way, he managed to obviate the need to transport bulky and corrosive liquid reagents, and developed a range of assays[5] which

included tests for urinary glucose based upon its reaction with indigo carmine, and for albumen based upon its precipitation by solutions of potassium and mercuric iodides.

In this paper we will describe the principles of modern solid-phase chemistry, emphasize impregnated fibre and multi-layer film systems and attempt to convey a basic understanding of the theoretical and practical aspects of their use. We will describe in some detail the characteristics of the most popular systems and discuss future applications of this new and exciting area of clinical chemistry.

GENERAL CONSIDERATIONS

From the manner in which they are used, solid-phase reagents can be regarded as self-contained analytical devices. This description may be expanded in order to define these tools more fully. Thus, they can be described more precisely as integral analytical elements which typically take the form of thin pads or films, and contain all of the reagents required for the performance of an assay, distributed in a dry form within the pad or film. These component reagents may be distributed either homogeneously throughout the matrix of the element or may be organized, or compartmentalized, into specific domains within the infra-structure of the matrix. In either case, regardless of the geometric distribution of the component reagents in the solid-phase device, the *modus operandi* may be described schematically as follows: the analyte-containing solution, which may be urine, whole blood, serum or plasma, is applied to one of the surfaces of the solid-phase element, where it diffuses into the matrix of the element and, in so doing, dissolves the component reagents dispersed therein, as shown in Fig. 1. When the dry reagents have dissolved, they react with the analyte to give products which are used as a measure of the analyte concentration, generally through the use of chromogenic reagents and either visual or instrumental measurement of the colour generated in and on the surface of the solid-phase element. Thus, in operational terms, these analytical devices may be considered as unitized reagents that make possible the performance of certain assays, without the need to prepare, dispense and mix the component reagents of the system.

As described above, solid-phase reagents conform, in general, to one of two principal types, which will be referred to as the fibre-impregnated systems and the multilayer film systems respectively. From the standpoint of use, both systems have many features in common and in general operate as shown schematically in Fig. 1. They differ significantly, however, structurally and in composition, and accordingly will be treated separately in later sections of this review.

Solid-phase reagents of the fibre-impregnated type have been used in their current format for many years[6,7] and form the basis of the rapid diagnostic test
Fig. 1. Schematic representation of the operation of a simple solid-phase reagent.

systems commonly used in urine analysis[8] and now used routinely for the determination of whole blood glucose.[9] On the other hand, the multilayer film type of device has been in evidence for only a few years and forms the basis of a new fully-automated clinical chemistry analyser.[10] Interestingly, there is already an apparent slight divergence in the manner of application and the locus of use of these two types of solid-phase reagent. The fibre-impregnated type of system traditionally appears to have been associated more with rapid diagnostic testing away from the central laboratory, whereas the multilayer film system so far appears to have been mainly used in large central analytical laboratories, though there have been recent reports of their use in group practices and even by individual physicians. Reasons underlying their application in analysis are common and perhaps should be enumerated at this point as justification of our interest in them.

Besides their obvious advantages of simplicity and convenience, already mentioned above, the solid-phase reagents also afford a useful and efficient vehicle for stabilizing some labile analytical reagents. Because of their dry form, and also the stabilizing influence sometimes generated by the solid-phase matrix itself, some of these systems, particularly those employing cellulose fibre supports, have prolonged storage stability, often for up to two years, even at room temperature. Obviously such extended and simplified storage features further increase the convenience to the user.

At the time of writing this review, interest in solid-phase reagents is being further stimulated by extensions and improvements in the technologies of their manufacture and use, which suggest the generation of new analytical systems and novel applications employing these devices. Of particular interest is the potential development of systems for quantitative clinical analysis outside the laboratory, so that testing can be done closer to the patient.

FIBRE-IMPREGNATED SYSTEMS

General considerations

Fibre-impregnated systems have been in use for many years. Hence they represent the largest and most diverse type of solid-phase reagent, certainly in terms of the assortment of assays that can be performed with them. Even though there is an abundance of reports in the literature that both review their performance and describe their evaluation, and a wide selection of diagnostic products that utilize this technology is commercially available, there is a remarkable dearth of reports that either describe their preparation or detail their make-up and characteristics. This is not surprising, since virtually all of the research and development work on fibre-impregnated systems has been performed by industry and for obvious reasons such activities have been subject to a degree of secrecy. Consequently it is often very difficult to extract specific details describing fully many of these solid-phase devices, and in a review such as this it is equally hard to report in depth on some aspects of their make-up and characteristics. In order to try to compensate for this sparsity of information, an attempt will be made here to describe in general terms the preparation and properties of typical fibre-impregnated systems.

In general, the fibre-impregnated solid-phase systems consist of a sheet of cellulose matrix which is either porous or semi-permeable with respect to solute diffusion. In this type of solid-phase reagent, the components of the assay system, which might comprise such diverse species as group-specific chemical reagents, indicator enzymes, co-enzymes, activators and buffer salts, are distributed in a dry form both in the interstices of the cellulose matrix and on the surface of its integral structural fibres.

In the simplest form of the fibre-impregnated solid reagent, the components of the assay system are distributed homogeneously throughout the matrix, with no attempt made to segregate the different components into separate compartments within the matrix. Further insight into the make-up of this simple type of fibre-impregnated reagent is gleaned from the manner of its manufacture: the cellulose matrix, which might be a porous paper, is immersed in a single solution of the various assay components and then removed and dried under controlled conditions; upon evaporation of the solvent, the dry reagents become uniformly trapped in the matrix of

the solid-phase. From an operational viewpoint, this type of solid-phase reagent is described by the schematic in Fig. 1.

Design and manufacture

In reality, most fibre-impregnated solid-phase reagents, such as the systems described by Greyson[11] and Zipp,[12] are somewhat more complicated and sophisticated in their design and composition than that just used to illustrate the concept of these reagents, in which there was no compartmentalization of the component reagents within the matrix of the solid-phase element. Such a configuration is not suitable for a solid-phase reagent that incorporates an assay system composed of mutually incompatible component reagents. With some analytical reactions, it is necessary to introduce into the system a degree of compartmentalization, either to segregate mutually incompatible reagents, or to separate sequentially particular steps of the overall analytical reaction. Such compartmentalization can be built very efficiently into the design of the fibre-impregnated reagent. Obviously, in order to achieve this, the manufacturing process necessarily becomes both more complicated and sophisticated.

A schematic outline of a manufacturing process for the production of a fibre-impregnated reagent that allows for the compartmentalization of the different reagents is depicted in Fig. 2, which throws some light on the structure of this more complicated type of device. In this scheme, the native matrix, which might be paper-based and in the form of an extended sheet, is fed continuously from a storage spool through a sequence of operational work stations, wherein the various unit operations that make up the overall manufacturing process take place. Thus, for example, the matrix is fed at a carefully controlled speed through the first work station, where it is steeped in a solution of some of the components of the assay system, and these components become uniformly distributed in solution throughout its structure. After passing through this station, the matrix is dried in the course of its passage through the second work station, under drying conditions which are carefully controlled by regulating the temperature, relative humidity and laminar air flow. The sheet, now dry, is then fed through the third work station, where it is soaked in a solution of the remaining components of the assay system, in a solvent different from that used during the first impregnation stage. The solvent for this stage is carefully selected so that is does not dissolve the first set of reactants already deposited in the matrix of the paper during the first impregnation stage. Thus the second set of reactants is layered on top of the first set in the matrix in the course of evaporation of the second solvent during the second drying stage. The process, as described, allows for two reagent systems to be layered separately in the matrix of the cellulose, each effectively in a separate "reagent compartment". Clearly, if more reagent
Fig. 2. Schematic representation of a typical process for the continuous manufacture of a fibre-impregnated solid-phase reagent incorporating two separate reagent compartments.

compartments are required, because of a multiplicity of reagents and/or the need for segregated reaction steps, they can be accomplished by adding extra impregnation and drying work stations to the continuous process shown in Fig. 2.

Further insight into the make-up of this more complicated type of fibre-impregnated system is best gleaned, perhaps, by consideration of a specific example. Such a reagent was first reported by Turk and Zipp[13] for the quantitative measurement of urea in serum. In this example, the analyte, urea, is measured in a two-stage reaction as shown in Fig. 3 in which urea (II) first couples with the group-specific reagent o-phthalaldehyde (I) to form dihydroxy-isoindoline (III).[14,15] Then in the second reaction the dihydroxyisoindoline is complexed in strongly acidic conditions with the indicator 3-hydroxy-1,2,3,4-tetrahydrobenzo-(h)-quinoline to form a blue adduct, the concentration of which is determined photometrically.

The translation of the reaction sequence shown in Fig. 3 into the format of a fibre-impregnated reagent requires the solution of two problems. The first relates to the need to separate the indicator from the o-phthalaldehyde, because of their mutual reactivity, while the second relates to the need to overcome the known instability of cellulose in the strongly acidic conditions that prevail in the second part of the

reaction sequence. The particular configuration of solid-phase reagent developed by Turk and Zipp for the solution of these problems is depicted schematically in Fig. 4 and is achieved by a process of the type illustrated in Fig. 2, but involving three sequential impregnation and drying stages. The problem relating to the provision of acidic conditions without destroying the cellulose matrix is overcome by the incorporation into the cellulose of a cation-exchange resin, which dissociates when hydrated by the sample, thus generating strongly acidic conditions. In this way, the dry or unreacted form of the reagent is not exposed to strong acid and hence the integrity of the cellulose is preserved. The problem of segregating the two mutually incompatible reagents, indicator and o-phthalaldehyde, is resolved by depositing three layers concentrically around the cellulose fibres of the solid-phase matrix. The first, or proximal layer, which is adjacent to the fibres and contains the indicator, is laid down in the first impregnation stage and is separated from the o-phthalaldehyde, which is in the distal layer and is laid down in the third impregnation stage, by a polymeric separation layer, which is deposited in the second impregnation stage. When sample is applied to the surface of this solid-phase reagent it diffuses into the distal layer, where any urea in it reacts with the o-phthalaldehyde. Further diffusion of the sample within the infra-

(III) +1,3-DIHYDROXYISOINDOLINE ⟶ BLUE CHROMOPHORE
Fig. 3. Reactions involved in the measurement of urea according to Turk and Zipp.[13]
Fig. 4. Schematic breakdown of a fibre-impregnated solid-phase reagent containing three reagent compartments. The system shown is that for measurement of urea.[13]

structure causes disruption of the polymeric separation layer and thus permits the dihydroxy-isoindoline to gain access to the proximal layer. Thereafter complexing with the indicator takes place in the now strongly acidic conditions brought about by the dissociation of the cation-exchange resin in the water of the sample.

The nature of the matrix

Reference has already been made to the long-standing recognition[3,4] of the importance of selecting the correct type of matrix for a solid-phase reagent.

Today most solid-phase reagents of the fibre-impregnated type utilize cellulose-based materials such as paper for the support matrix. Arguably this decision was made some 25 years ago, and more than likely emanated from familiarity with the common laboratory spot-test devices, such as pH indicator papers, which can therefore be considered as the forebears of the present day solid-phase reagents. Even though the selection of cellulose in the form of paper was more by accident than design, nevertheless it turned out to be a very good choice, as will now be seen.

It will be recalled that one reason for interest in solid-phase reagents stemmed from the opportunities that these devices offer for the stabilization of some analytical reagents. It has been known for some time now that polyhydric alcohols can have a stabilizing effect on the structure of proteins. Indeed, in the industry, certain polyols are often used to stabilize

labile protein preparations.[16] Owing to its polyhydric character, cellulose also can exert a stabilizing influence on neighbouring proteins, perhaps by forming hydrogen bonds with them in such a way that a greater degree of stability is conferred upon the protein structure. Consequently, experience has shown that some biochemical systems have enhanced stability when included in solid-phase cellulose matrices,[17] Thus it is not surprising that many cellulose-based solid-phase reagents, perhaps containing labile component enzymes, are stable for many months, even when stored at room temperature.

Another factor which is associated with the cellulosic nature of the fibre-impregnated systems and which also contributes significantly to their good stability, is the high degree to which cellulose can be dried. Thus, under carefully controlled conditions, such as those prevailing during the manufacture of the fibre-impregnated systems, cellulose matrices, such as paper, can be dried to an extremely low residual water content. Since the denaturation of enzymes is a solution phenomenon, this process is dramatically arrested when these proteins are stored in the dry state, especially when they are in close proximity to the stabilizing influence of a polyhydric alcohol such as cellulose.

Cellulose also proves to be an effective and useful dry-phase matrix because of its strongly hydrophilic character, since dry cellulose structures will therefore tend to hydrate very rapidly and efficiently. The ease with which the dry cellulose structures can be wetted means that when the sample is applied, it spreads evenly and thus promotes homogeneous diffusion of analyte and reactants and results in uniform colour development.

The measurement process

Figure 1 described schematically the *modus operandi* of a typical fibre-impregnated system. With this type of solid-phase reagent, the extent of the reaction, and hence the concentration of the analyte, is determined by measuring the colour change that accompanies the reaction in the solid-phase matrix. This is done either visually by comparison of the colour of the reacted matrix with a standardized colour chart, or by recording instrumentally the reflectance of light of a defined wavelength, from the surface of the solid-phase element.

For the visual measurement, the comparison standard colour scales are typically made up of a number of discrete colour blocks, each of which corresponds to a different concentration of the analyte, and the colour of the reacted matrix is matched to that of a particular block, or interpolated between the colours of two adjacent blocks. Clearly the quality of the result depends on the ease and certainty with which the observer can discriminate between the component colour blocks of the scale. To optimize this discrimination, the colour blocks must be distinctly different
Fig. 5. Instrumental methods used for the measurement of the colour of reacted solid-phase reagents by
reflectance photometry.

but the concentration steps must be close enough for the results to be clinically meaningful.

In order to achieve this goal, the analytical reaction used must produce coloured products, the concentration and spectral characteristics of which both must change with the analyte concentration. In this way, both the intensity and wavelengths of light reflected from the reacted solid-phase reagent will change with analyte concentration and thereby maximize the visual discrimination between colours corresponding to different analyte concentrations. In practice, this can sometimes be achieved by using combinations of different chromogenic reagents or by inclusion in the solid-phase reagent of background dyes which interact spectrally with the product chromophores to achieve the desired effect.

Obviously, instrumental measurement of the colour change in the solid-phase matrix will improve the quality of the results by removing the subjective component of the visual method, but it is fair to point out that the price of better quantification has to be paid in the currency of convenience. Thus, to achieve a precision comparable with that of traditional solution-based analytical procedures, the solid-phase techniques have to forfeit their freedom from instrumental encumbrances. However, this lost benefit can be offset by decreasing the size and complexity of the instrument used. A conspicuous trend in the evolution of fibre-impregnated systems is the development of such instrumentation.

Because of the opacity of the solid-phase reagent, the colour developed can only be measured by reflectance spectrophotometry. This technique involves measuring the intensity of light reflected and scattered from a surface of the solid-phase reagent when that surface is irradiated with light of a wavelength which is absorbed by the reaction products. In principle, this is performed in one of two ways, as illustrated schematically in Fig. 5.

In the first way, the sample is applied to the top surface of the solid-phase reagent and after it has permeated into the reagent and the reaction has occurred, the resulting colour is determined by measuring the reflectance from the same surface. This approach has been the one adopted so far for measuring instrumentally the colours of reacted solid-phase reagents of the fibre-impregnated type. In the second way, the sample is applied to the top surface of the solid-phase reagent and, after the ensuing reaction, the colour is measured by monitoring the reflectance from the reverse side of the element, as shown in Fig. 5. This is the approach that has been used for measuring the reaction colours of the multilayer film systems that are described later in the review.

As shown in Fig. 5, the concentration of the reaction products formed in the fibre-impregnated systems is determined instrumentally by measuring the reflectance of light from the top side of the analytical element. In essence, this process involves irradiating the top surface of the matrix with light and measuring the intensity of light of that wavelength as it is reflected from the same surface. In reality, the light is not reflected only from the top surface, as would be the case with an ideal reflector or mirror, but penetrates into the solid-phase matrix, as shown in Fig. 6. Inside the solid-phase system the light is affected separately by the solid and liquid components of the heterogeneous matrix. Thus, the solid components, such as the fibres, scatter part of the light, and the liquid component, which contains the reaction products, absorbs part of the light. These events take place both before and after the light is reflected from the interface of the matrix and the plastic support on its lower surface; in other words, throughout the passage of the light through the solid-phase reagent. To relate the concentration of the reaction products to the intensity of the light
Fig. 6. Schematic representation of the events occurring when a light-beam irradiates a typical fibre-impregnated solid-phase reagent.

leaving the matrix, it is necessary to take all events into account. Kubelka and Munk[18] studied this model of a diffuse reflector and developed an equation which related the concentration of the light-absorbing species (C) in the reflector to the measured reflectance (R) of the light. In its simplest form:

$$C = \frac{S(1 - R)^2}{2ER} \qquad (1)$$

where S is a scattering coefficient for the effect of the solid component and E is the absorption coefficient for the liquid component, the relation pertains to a reflector with thickness such that the light is either absorbed or scattered before it can reach the lower reflected surface. In other words, equation (1) approximates the behaviour of a diffuse reflector in those cases when the difference in intensity between the incident and reflected beams is independent of the thickness of the structure. This happens to be the case with most fibre-impregnated systems and hence this equation often approximates their behaviour.

The reflectance is the ratio of the intensity of the reflected beam to that of the incident beam, and may be regarded as equivalent to the transmittance term (T), in the Lambert–Beer relation [equation (2), where L is the path-length].

$$C = \frac{\log(1/T)}{EL} \qquad (2)$$

Figure 7 shows graphically the qualitative similarity between these two relationships and suggests that reflectance measurements approach transmittance measurements in precision. A more detailed treatment of the behaviour of diffuse reflectors, together with a critical analysis of quantitative reflectometry, has been presented by Kealey.[19,20]

We should emphasize that the model developed by Kubelka and Munk provides only an approximate description of the interaction of light with a solid-phase matrix. The mathematical relationships derived from experimental data can take functional forms

different from those derived by Kubelka and Munk. A more detailed discussion of this has been given by Greyson.[11]

Clearly, the measurement potential of solid-phase reagents, predicted above, can only be realized if appropriate instrumentation is developed. Figure 6 shows what happens when the surface of a diffuse reflector, such as a fibre-impregnated solid-phase reagent, is irradiated with light. Owing to the random nature of the light-scattering events, both the incident and the reflected beams are dispersed in all directions, and hence only part of the reflected light is collected by a simple unidirectional detector such as that shown in Fig. 5. To improve the efficiency of the measuring process, the more sophisticated types of reflectance analysers use a device called an integrating sphere, the operation of which is shown schematically in Fig. 8.

In the optical arrangement shown in Fig. 8, the light issuing from the lamp undergoes multiple
Fig. 7. Relationship between transmittance and concentration (– – –) and between reflectance and concentration (——) as predicted by equations (1) and (2) respectively for $S/E = 1/EL = 1000$.
Fig. 8. Optical arrangement for measuring the colour of a reacted solid-phase reagent by reflectance photometry with an integrating sphere.

internal reflections from the inside surface of the sphere and so irradiates the surface of the reagent pad uniformly from all directions. Thus, by measuring the intensity of the reflected light normal to the pad, the same effect is achieved as would have been obtained had the pad been irradiated unidirectionally and the light reflected in all directions been collected equally.

Figure 8 also shows some other features of a reflectance photometer, such as a filter for wavelength selection, and a split-beam arrangement to compensate for variations in the intensity of the light source. Such features are incorporated in the reflectance analyser described by Zipp[12] and are essential for obtaining the type of results discussed in the next section.

Applications and performance

Visual and single-analyte systems. Although urine test papers were manufactured and sold as diagnostic devices nearly a century ago,[21] their widespread use and acceptance as analytical tools in rapid testing was not really established until the second half of this century. Without doubt, the emergence of solid-phase reagents as routine analytical tools some 25 years ago was catalysed by industry, which developed both new and improved solid-phase systems and made them widely available. Today, solid-phase reagents of the fibre-impregnated type are used for the measurement of a wide assortment of analytes, such as enzymes, metabolites and proteins in urine, whole blood, serum and plasma.

The first of the new fibre-impregnated systems, Clinistix[®] reagent strip and Tes-Tape[®], were developed by the American companies, Ames Division, Miles Laboratories Inc., and Eli Lilly respectively,

and both made their appearance in 1956 as tools for the measurement of urinary glucose. Free *et al.*[6] described the former system, which used the enzymes glucose oxidase and peroxidase, together with the chromogenic substrate *o*-tolidine, and a basic red background dye, and Comer[7] reported on the latter system, which used the same enzymes and substrate, but with a basic yellow background dye (Tartrazine, C.I. 19140).

Further tests making possible the measurement of a wider range of urinary analytes, such as protein,[22] pH,[23] blood,[24] ketones,[25] bilirubin,[26] leucocytes[27] and specific gravity[28] have been developed in more recent years and are now widely used in routine urine analysis.[8,29]

The possibility that solid-phase reagents could also be used for the measurement of blood analytes was explored by Kohn[30] who showed that the fibre-impregnated Clinistix[®] reagent strips, hitherto used for the determination of urinary glucose, could also be used for measuring the same analyte in whole blood. Thereafter, fibre-impregnated systen ~ appeared which were tailor-made for the measur ment of whole blood glucose. The first of these (Dextrostix[®] reagent strip) again used the enzymes glucose oxidase and peroxidase, together with a combination of three ancillary chromogenic indicators to generate the required visual discrimination between various glucose concentrations. The performance of this system and its utility for the measurement of blood glucose in the management of diabetes was reported by Marks and Dawson.[31]

To improve visual discrimination, more recent solid-phase reagents for blood glucose incorporate more sophisticated colour scales. Thus Kerner *et al.*[32] reported the use of Visidex[®], which uses two different reaction systems to generate two separate colour scales that measure glucose in the concentration ranges 1.1–10 mM and 11.1–44.4 mM respectively. The lower concentration scale utilizes the glucose oxidase–peroxidase system, together with the chromogenic substrate tetramethylbenzidine, and the higher concentration scale uses a Trinder-type reaction[33] involving the substrates 4-aminoantipyrine and 3,5-dichloro-2-hydroxybenzene sulphonic acid. This reagent system has recently been improved and is marketed under the trade name Visidex II[®].

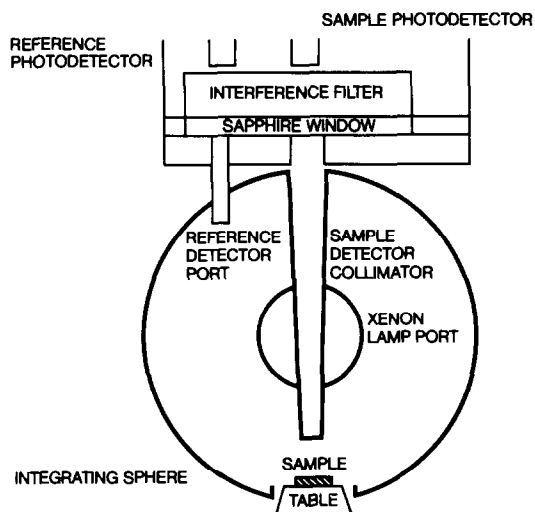
All the solid-phase reagents mentioned above were initially designed to be read visually, and various reflectance meters were subsequently developed along the lines and principles already discussed. One of the first of these instruments was developed for use with Dextrostix[®] reagent strips and the improvement in results achieved by use of this instrument–reagent system was reported by Jarrett *et al.*[34] As the usefulness of solid-phase reagents for measuring blood glucose became more widely accepted, development of cheaper and smaller yet more sophisticated meters progressed at a rapid pace. Webb *et al.* have reported on the performance of a number of these new
Fig. 9. Schematic of Seralyzer® solid-phase reagent strip. A; Side view. B; Front view.

Fig. 10. Cross-section of Seralyzer® optical system.

systems.[35] With continuing advances in microelectronics, it is expected that newer generations of meters will be even cheaper and smaller, yet more powerful in their overall capability and performance.

Multi-analyte systems: the Seralyzer® reflectance photometer. More recently, the sphere of application of the fibre-impregnated systems has been extended to a wider range of analytes, including serum enzymes and metabolites, by the development of integrated systems comprising the solid-phase reagents together with appropriate dedicated instrumentation. The first such system (the Ames Seralyzer® reflectance photometer)[13] was reported by Turk and Zipp in 1978 for the measurement of urea and later described in greater detail by Greyson[11] and Zipp.[12] This system now consists of a reflectance photometer along with solid-phase reagents for 10 traditional blood analyses [glucose, urea, uric acid, cholesterol, bilirubin, creatinine, whole blood haemoglobin, triglycerides, lactic dehydrogenase (LDH), creatine phosphokinase (CPK)], is suitable for use in any location, and does not need a skilled operator. It is also applicable as a "stat" or back-up instrument in clinical laboratories.

The solid-phase reagent strip used with the Seralyzer® system is shown in Fig. 9. A cellulose matrix is impregnated with the reagents, dried, and then bonded with a special adhesive layer onto a plastic support. A white reflective area is incorporated under the cellulose matrix to improve the reflectance efficiency. A barcode, printed directly onto the plastic support, is read by the instrument upon insertion of the strip, to avoid improper matching of reagent strip and module (see Fig. 11, below).

The Seralyzer® optical system is shown in Fig. 10. The light source is a xenon flash-tube which produces a high-intensity flash covering the entire spectral region. In particular, it provides high intensity at 340 nm, so enzyme reactions can be monitored in the ultraviolet region. The reagent strip sits on a constant-temperature table which is pushed into the integrating sphere after application of the sample.


The environment of the sphere is also thermostatically controlled. The collimator collects the reflected light and directs it through an interference filter to a solid-state detector.

The reference detector port directs light scattered from the sphere wall to the reference detector. The reflectance is the ratio of the sample and reference detector signals. This arrangement eliminates error due to changes in light intensity from flash to flash. The sapphire window which covers the sample and reference detector ports minimizes evaporation from the pad surface. The interference filter is contained in a plug-in module which is specific for each serum test and also contains a read-only memory chip which programs the processing of the reflectance signals. The module and its relationship to the optical system are shown in Fig. 11. The microprocessor also runs a series of checks and balances on system performance so that any malfunctions or operator error can be easily detected. For example, on completion of the calibration, the microprocessor checks the calibration slope to determine its validity. If the slope is

tate aminotransferase) will soon be added to the Seralyzer® system. The chemistry for these two assay systems is shown in Fig. 12. In contrast to the more conventional ultraviolet assays for these enzymes, colorimetric assays are used, based on the oxidation of an indicator system by peroxide. The choice of colorimetry stems from the sensitivity limitations encountered in use of substrates such as NADH, which have comparatively low molar absorptivities; these limitations are most apparent when reflectance spectroscopy is used, since it is inherently less sensitive than absorbance measurement. Table 3 shows some precision and correlation data for the ALT and AST assays.

Immunochemistry. Greenquist et al.[39] have reported on the performance of a number of solid-phase immunoassays utilizing the substrate-labelled fluorescent immunoassay technique first described by Burd et al.[40] Tyhach et al.[41] have described attempts to incorporate immunoreagents for the measurement of theophylline and phenytoin, into solid-phase matrices. This early work has been significantly extended, resulting in the recent report of Greenquist et al.[42] of a colorimetric solid-phase theophylline assay utilizing the ARIS™ immunoassay system. This system, first described by Morris et al.[43] is based on a competitive protein-binding reaction in which the analyte competes with an analyte-conjugate for a limited number of antibody binding-sites that are specific for the analyte. The conjugate consists of the analyte covalently linked to the prosthetic group of glucose oxidase, flavine adenine dinucleotide (FAD). In the absence of analyte, the conjugate binds to the antibody and is unavailable for further reaction. In the presence of analyte, a corresponding proportion of the conjugate remains in solution because of the competitive binding, and FAD liberated from it reacts with apoglucose oxidase to reconstitute glucose

oxidase, which is then detected through a coupled reaction with peroxidase to yield a coloured product. The theophylline assay described by Greenquist et al.[42] utilizes monoclonal theophylline antibody to ensure reproducibility of the immunochemical response.

Figure 13 shows the correlation between HPLC and Seralyzer® results for solid-phase theophylline assay. The precision is reported to be about 5% and thus comparable to that of the "wet methods".[39,42]

Litman et al.[44] have recently described a solid-phase immunoassay system for morphine detection, based on the enzyme-channelling technique. A glucose oxidase and horseradish peroxidase enzyme-pair is used to generate an insoluble coloured reaction product of an immunospecific reaction on the test strip surface. The authors claim a potential sensitivity of 5–10 μg/l., with a 20-min assay time. Although this assay time is significantly longer than that, for exam-

ple, for the Seralyzer[®] theophylline assay (80 sec), these enzyme-channelled systems should be useful when assay time is not critical and high sensitivity is demanded.

Solid-phase immunoassays, like their blood-chemistry counterparts, offer significant advantages over comparable wet systems. No reagent mixing or manipulation is required and assay times are short. These reagents are extremely stable (1 year at room temperature for Seralyzer[®] theophylline), require low sample volumes and only a minimum of skill. Hence therapeutic-drug assay testing may soon be as common and easy to perform as simple glucose determinations.

Whole blood. The multi-analyte solid-phase systems just described are used primarily with serum as the sample. Those systems designed for whole-blood samples are generally for glucose assays in diabetes cases. Some of these systems have already been briefly mentioned and a summary of those most commonly used is given in Table 4.

Although glucose is so far the only analyte conveniently measured in whole blood, a multi-analyte fibre-impregnated solid-phase system utilizing whole blood as the sample has recently been announced.[45] This system—the Reflotron/Refloquant[TM]—uses a complex reagent strip on which plasma is separated from the red cell components by a glass filter. For several analytes the system is claimed to give good correlation with other methods, but extensive field evaluation has not yet taken place.

MULTI-LAYER FILM SYSTEMS

The multi-layer film systems first appeared in the literature five years ago, when Curme *et al.*[10] described a multi-layer film reagent for measurement of glucose in serum. At the same time, Spayd *et al.*[46] reported similar types of reagent for measurement of urea, amylase, bilirubin and triglycerides. Multi-layer films are used in the same way as impregnated fibre systems, and differ from them only in construction. As the name implies, the multi-layer film systems are laminated, with the different reagents deposited in flat strata. The support material is protein-based instead of polysaccharide-based, and in most systems so far is gelatin.

The simplest configuration of a multi-layer film system is shown schematically in Fig. 14. The sample is applied to the exposed surface of the top layer (which typically is made of titanium dioxide, in order to facilitate reflectance measurements from the reverse surface), spreads quickly through its porous structure, then penetrates into the reactant layer, hydrating its contents and initiating the analytical reaction. Additional layers can be added to keep incompatible reagents separate or to provide a sequence of reactions. Such a multi-layer film is depicted in Fig. 15, which shows schematically the system described by Spayd *et al.*[46] for measurement of urea in serum, by the reaction sequence (Fig. 16) in which urea is hydrolysed by urease in a strongly buffered solution at pH 8.0, and the free ammonia formed then reacts with a protonated merocyanine dye, and changes its colour to that of the unprotonated dye.

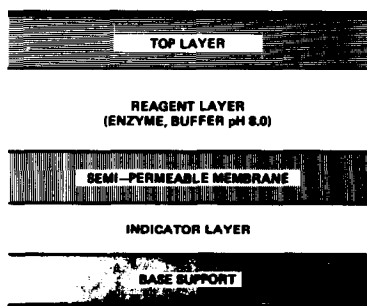
The urease and buffer are located in a gelatin-based reagent layer (Fig. 15) which is immediately below the
Fig. 14. Schematic representation of a simple multi-layer film solid-phase reagent. The sample is applied on the top layer and then diffuses into the reactant layer, where reaction takes place. Typically, the colour is measured by reflectance photometry from the reverse side and through the base support.


Fig. 15. Reactions involved in the measurement of urea with the multi-layer film solid-phase reagent described by Spayd et al.[46]

porous titanium dioxide layer, and separated from the indicator layer by a semi-permeable cellulose acetate/butyrate membrane. The ammonia produced diffuses through the semi-permeable membrane, which forms a barrier to other basic species such as the hydroxide ion, and finally into the last layer which comprises an indicator in a film of cellulose acetate. This type of multi-layer element is used in the East-man Kodak Ektachem® system.

The multi-layer film approach has been further developed by Ohkubu et al.,[47] who described a multi-layer element that could be used with whole blood. The device differs from those reported by Spayd et al.[46] and Curme et al.[10] mainly in the make-up of the surface layers. The top layer consists of a finely woven thin web, which may be cellulose-based. This layer is reported to act as a coarse filter which removes platelets and red cells as the sample diffuses through it. The sample then diffuses through a semi-permeable "blocking layer" which allows the glucose, now free from blood proteins, to gain access to the reactant layer, which is next to the base support material.

Use of the system for determination of whole-blood urea nitrogen is shown in Fig. 17. This reagent system is used in the Fuji Drichem® 1000 analyser, which is not yet commercially available, and is pack-aged as slides which are operationally equivalent to the Kodak elements described above.

Measurement

With multi-layer film systems, the reflectance mea-surement is made on the surface opposite to that of sample application. The optics of such a system are rather more complicated than those for the simpler systems already described. Williams and Clapper[48] constructed a mathematical model of the system,
Fig. 16. Schematic representation of the multi-layer film solid-phase reagent described by Spayd et al.[46] for the measurement of urea.

CHEMISTRY

$$H_2NCONH_2 + H_2O \xrightarrow[BASE]{UREASE} 2NH_3 + CO_2$$

BROMOCRESOL GREEN + NH_3 $\longrightarrow$ BLUE DYE
Fig. 17. Schematic representation of the Fuji Drichem® slide for determination of whole-blood blood-urea nitrogen. Note the "filter" layer for screening out interfering substances.

which leads to the equation

$$D_R = \log R_o/(R_{test} - R_f) \qquad (3)$$

where D_R is the so-called reflective density of the film element, which is analogous to absorbance in trans-mission spectroscopy, R_o is the intensity of light reflected from a standard reflector (e.g., a barium sulphate surface) in the beam, R_f is a correction factor for non-linear effects and R_{test} is the intensity for the test film. Like R in the Kubelka–Munk equation, D_R is a non-linear function of concentration. However, D_R can be transformed into a function D_T which is linearly related to concentration by the equation:

$$C = B (D_T - D_B) = B\left\{ tr\left[\log\left(\frac{R_o}{R_{test} - R_f} \right) \right] - D_B \right\} (4)$$

where C is the analyte concentration, tr represents the Williams–Clapper transformation, B is proportional to reciprocal absorptivity and D_B is the reflective density for the blank (i.e., $C = 0$). The effect of the transformation is shown in Fig. 18. B, D_B and D_T are
Fig. 18. Reflective density (D) as a function of glucose concentration for a multi-layer film system. D_R represents the reflective density before and D_T that after application of the Williams–Clapper transformation;[43] From Curme et al.[10]
Fig. 19. Correlation of Fuji Drichem® whole-blood blood-urea nitrogen assay with SMAC comparative method. Regression statistics are given in the figure.

determined with a three-point calibration technique. The need for three points is in contrast to the case for diffuse reflectance systems (Kubelka–Munk theory) such as an impregnated fibre, for which linear response regions can be developed and a two-point calibration is all that is required[12]. The Williams and Clapper approach is valid for both the Kodak and Fuji systems since both rely on basically the same technology.

Performance

The laboratory performance of Ektachem® clinical chemistry slides has been extensively reported by Warren et al.[49] and Dappen et al.[50] Recent reports have given the assay performance for a number of new enzyme determinations.[51,52] In general the performance is excellent, with coefficients of variation < 2% for some assays and good correlation with reference methods. It is interesting that multi-layer films appear to be less susceptible than impregnated-fibre systems to serum interferences, presumably because the various polymeric spreading and filtering layers serve as effective screens for some interfering substances.

The performance of the Fuji Drichem® whole-blood glucose assay has been reported and appears excellent.[47] Figure 19 shows correlation data for the Fuji whole-blood urea nitrogen assay, which indicate performance comparable to that of impregnated-fibre or other multi-layer film systems for serum analysis, but as, like the Reflotron/Refloquant™ system, the Fuji Drichem 1000 analyser is not yet commercially available, final judgement must await extensive field testing.

COMPARISON OF MULTI-LAYER FILM AND IMPREGNATED-FIBRE SYSTEMS

Besides the obvious structural differences between impregnated-fibre and multi-layer film systems, the differences in the nature of the matrices for these two systems can lead to significant differences in their physical properties. Thus, Haeckel et al.[54] have reported that there is an apparent dependence of the response of multi-layer film systems on the viscosity of the sample. In contrast, the fibre-impregnated systems appear to be less affected by added protein and sample viscosity, as was shown by Greyson.[11] A further difference arises from the nature of the polymer used as the matrix for the reactant layers. Most fibre-impregnated systems are cellulose-based, whereas multi-layer film systems tend to be gelatin-based. Gelatin cannot be dried as thoroughly as cellulose and the residual water content in the gelatin-based reactant layers is about 10%. Consequently, the reagents are not totally dry and any protein components are prone to solution denaturation. This property of the multi-layer films perhaps accounts for the need to store them under refrigeration for maximum stability. This higher water content may also lead to decreased stability for multi-layer film systems because of diffusion effects as well as denaturation effects. The typical "coupler–developer" type of indicator systems used in these films can react prematurely if the components come into too close contact before the main reaction has begun. This inactivation would appear as a decrease in reactivity with time for these film systems.

OTHER FILM SYSTEMS

In addition to the multi-layer film devices described above, other analytical films comprising only a single film layer have been reported and used successfully for some years. The best-known of these is the Chemstrip bG® product of Boehringer Mannheim GmbH, which is used for the visual determination of whole blood glucose.[55] The system consists of a polymer film containing the appropriate reagents, coated onto a plastic support. The blood sample can be removed after a given reaction time and there is good colour stability after sample removal.[56] The Ames Division of Miles Laboratories has recently introduced Visidex® II reagent strips for the determination of whole-blood glucose. This product is a combination of impregnated-fibre and film technology. A hardened gelatin film is coated over the cellulose matrix to impart "wipe-off" properties to the system as a whole. The blood sample can be removed by either wiping or blotting, and the system is directly competitive with the Chemstrip bG® product.

Film systems have also been designed for electrolyte determination. The most common are the Ektachem® slide systems for Na^+, K^+, CO_2 and Ca^{2+}, which utilize potentiometric measurement in combination with ion-selective membranes.[10] Charlton et al.[57] have reported a solid-phase analytical element for the determination of serum potassium. It consists of a poly(vinyl chloride) film which contains a plasticizer and valinomycin. The serum sample is diluted with an anionic dye solution and

pipetted onto the film surface. The dye molecules then partition into the film layer in order to maintain electrical neutrality. After removal of excess of dye, the resulting colour can be measured by standard absorption or reflectance techniques.

CONCLUSIONS

It is clear that the technology of solid-phase analytical systems has moved extremely rapidly in the last five years. From the initial application to blood analysis, the applications have been extended to drug detection and electrolyte determination. It might reasonably be expected that even broader applications will emerge in the years ahead as the potential of these systems for convenient testing is more fully realized, and ultimately clinical chemistry may be brought to the bedside.

FLOW-INJECTION ANALYSIS IN CLINICAL CHEMISTRY

CLIFFORD RILEY

Post-graduate Division of Biomedical Engineering, University of Sussex, Falmer, Brighton, England

BERNARD F. ROCKS and ROY A. SHERWOOD

Biochemistry Department, Royal Sussex County Hospital, Brighton, England

Summary—Flow-injection is the most recent addition to the techniques used in automatic analysis. In the simplest form, the sample is injected as a discrete slug into a stream of reagent flowing in a narrow-bore tube. Various sampling valves have been used in order to achieve full mechanization, but are not ideal for clinical analyses since they are wasteful of sample. An economical alternative has been developed which is based on the precise aspiration of sample by a probe. Applications of FIA and this modification in particular to clinical chemistry are discussed.

In technological societies innovations commonly appear in response to an obvious need. Thus it was that in 1957 Skeggs[1] introduced his bubble-segmented continuous-flow automatic analyser. This was developed in response to the intolerable pressure, caused by exponentially rising workloads, experienced by clinical laboratories all over the Western world. Soon after this the discrete analyser appeared. This was a simple concept which, despite some daunting problems in small-scale chemical engineering, was successfully developed. Subsequently, in 1969, in answer to the specific need for simultaneous analyses of cell fractions, the centrifugal analyser was developed[2] and this was soon modified for clinical work. The latest system to appear, flow-injection analysis, was developed simultaneously by Stewart and his co-workers in the United States[3] and by Růžička and Hansen in Denmark.[4] From very simple beginnings the technique has advanced rapidly. This progress has been reviewed recently by Stewart[5] and Růžička.[6]

Unlike the techniques mentioned earlier FIA has not found immediate favour with clinical chemists though it has been received enthusiastically by analytical chemists working in industry.

This indifference on the part of clinical chemists, which ignores the enormous potential of the method, arises because of the changed expectations of this group of workers. They have become used to purchasing dedicated machines with methodology fully developed and comprehensive data-handling systems included. So far no manufacturer has offered such a package based on FIA.

The preparation of a brief review such as this, aimed at two widely disparate sections of the scientific community, is difficult. The clinical chemist would possibly prefer a simple account of practical possibilities. The analytical chemist would undoubtedly prefer something more sophisticated.

In classical bubble-segmented continuous-flow systems the samples are divided and separated by gas (usually air) bubbles; at any one time several specimens are moving one behind the other through the same pipeline and the flow is to some extent turbulent.

In flow-injection the approach is quite different. The sample is injected as a discrete slug or bolus into a stream of reagent moving under conditions of laminar flow in a narrow-bore tube. No air is admitted, so the slug, flowing along the so-called reactor tube, remains intact throughout and is normally cleared completely from the system before another sample is introduced. When fast reactions are used, throughput can be high, and indeed Tijssen[7] has reported that under special conditions analytical rates of 900/hr can be achieved. Slower reactions must be dealt with differently; use is made of the lack of elasticity in the system and the sample is arrested to allow the reaction to proceed, but this of course limits the throughput. A limiting factor on throughput is the preparation of samples, if preliminary treatment is necessary.

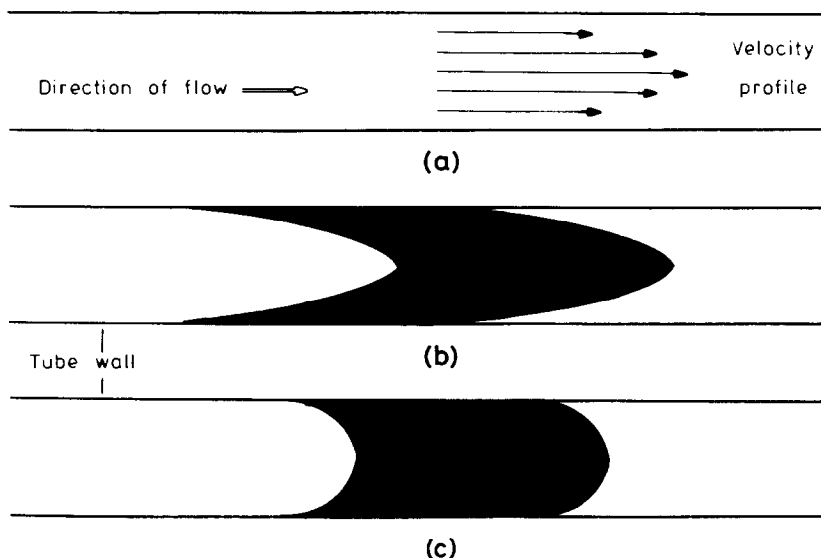
The behaviour of the slug of sample as it travels through the reactor tubing is of cardinal importance. Since it generally moves under conditions of laminar flow it may be thought of as having the classical parabolic velocity profile, progressively adopting a bullet-shaped form with a hollow tail as shown in Fig. 1. If this were the only phenomenon involved the slug would rapidly disperse into the reagent stream, but the behaviour of the slug is greatly modified by radial diffusion. The tip of the slug continually diffuses outwards, entering slower moving streams of reagent and thus being retarded; conversely, the tail of the slug diffuses inwards into more rapidly moving streams and is thus accelerated. Apart from limiting the longitudinal dispersion of the slug this must also


Fig. 1. Convection/diffusion-induced dispersion of a sample slug in a flowing stream. (a) Laminar-flow velocity profile; (b) dispersion of sample slug caused by convection; (c) sample zone modified by molecular diffusion. (The drawing is not to scale; a 10-μl sample injected into a 0.5-mm bore tube would occupy a length of about 5 cm before dispersion.)

modify its shape. Vanderslice *et al.*[8] show some estimates of shapes at various stages of development of the moving bolus. Most figures of this kind, including our own Fig. 1, are misleading in that they suggest that the slug is short and compact; in fact, a 25-μl slug injected into a 0.5-mm bore tube is immediately over 125 mm long and it may well be ten times as long by the time it leaves the system. The radial diffusion ensures efficient mixing with the reagent: the moving slug is continuously exposed to fresh boundary layer and since this is composed of undiluted reagent the latter diffuses rapidly into the slug until equilibrium is approached. These processes are rapid because of the small diameters employed. Linear diffusion has very little effect and in fact the slug can be held stationary for prolonged periods without significant sample-spreading occurring.

The classical work on the behaviour of liquids flowing in narrow-bore pipes is that of Taylor[9,10] and much of the theoretical discussion used in FIA is based on his work.

The dispersion, or spread, of the slug as it travels along the tube has been defined by Růžička and Hansen[11] as the ratio of the concentrations of the sample before and after the dispersive process has taken place. In practice this is easily determined by injecting a slug of sample and measuring the peak height obtained with the read-out device being used. The sample is then pumped continuously, without carrier solution, and the peak height at steady state measured. The dispersion coefficient $D = H^\circ/H$ where H° is the peak height at steady state and H is the peak height given by the injected slug. This is a

practical working formula, but it describes only the maximum concentration of sample in the slug.

Several factors govern the degree of dispersion.

(1) Size of sample. Large samples give smaller dispersions than small samples; the ultimate limitation is the steady state, when the sample is infinitely large and the dispersion is 1.0.

(2) Length of reactor tubing. All other things being equal, the dispersion is proportional to the square root of the length of the reactor tubing. In practice, most work is done with tube lengths of < 1 m.

(3) Tube diameter. The larger the diameter, the greater the dispersion, which increases approximately with the square of the radius. The upper limit for the internal diameter is perhaps 1.0 mm; with larger diameters it becomes difficult to maintain the integrity of the slug. The lower limit is determined by practical difficulties (high pumping pressures, tendency to blockage and so on). Tijssen[7] has worked with tubing of only 20 μm bore. In practice, tubes of internal diameter 0.5–0.8 mm are most commonly used.

(4) Flow velocity. The effects of this appear to have been insufficiently investigated. In our work with 0.5-mm tubing, the dispersion increased with flow-rate up to about 0.5 ml/min; above that rate, the dispersion decreased.

There are two other factors which should be mentioned. First, if the reactor tubing is tightly coiled the dispersion is decreased. It has been suggested that this

is a centrifugal effect, but this is not a wholly satisfying explanation. Secondly, the effect of turbulent flow can be exploited. Although most work has been done under conditions of laminar flow, Tijssen[7] and Reijn et al.[12] argue that the flat velocity profile obtained under conditions of turbulent flow should give reduced dispersion, and, working with reactor tubes packed with glass beads, have shown this to be true.

The behaviour of the travelling slug is obviously very complex; all the possible variables in the system interact with each other and are probably modified in their turn by the chemical reaction itself.[13]

Important contributions to the theory have been made by Reijn et al.[14] and Vanderslice et al.[8] These largely mathematical treatments do not, however, explain some of the phenomena encountered when working with the technique. For example, with intensely coloured samples it is occasionally possible to see the main body of the slug preceded by a fine thread; again, insoluble matter appears to travel more rapidly than material in solution, perhaps under the influence of factors suggested by Repetti and Leonard[15] for red blood cells; then, for what it is worth, there is some anecdotal evidence that a substance can pass forward through the slug without reacting with it. There seems to be a good case for making photographic studies.

Notwithstanding the uncertainty of these variables, the behaviour of the slug remains remarkably reproducible provided that the system, once set up, is undisturbed.

In general, limited dispersion ($D = 1$–3) is used where high local concentrations of sample are required, for example, with measurements by ion-selective electrodes, whereas medium dispersions ($D = 3$–10) are needed for many of the reactions used in clinical chemical analyses; however, several important clinical determinations require systems designed to produce large dispersion ($D > 10$).

FIA is remarkably versatile, and there are a number of modes in which it may be used which are particularly useful in clinical chemistry. The most fundamentally useful manoeuvre is "stopped-flow". Because the system is inelastic, when the pump is stopped the slug is immobilized and its integrity remains preserved for long periods. This is exploited in two ways. First, when a period of incubation is required, the slug can be arrested in the reaction tubing for as long as necessary; this, of course, limits the throughput. However, with careful choice of reactor tubing it is possible to arrest two or three samples, separated by uncontaminated carrier liquid. Secondly, when kinetic studies are required, the slug can be arrested in the flow-through cell of the detector and the changes recorded during the appropriate time. "Stopped-flow" operation requires precise timing.

A disadvantage of the basic system is that reagent consumption can be large (though still small in comparison with other methods). This problem has been overcome by Bergamin et al;[16] with a technique which they have named "merging zones." In this technique, the carrier liquid is distilled water, and two streams of it are pumped. A bolus of sample and a larger one of reagent are injected simultaneously into the respective streams, which join downstream at a T-junction in such a fashion that the reagent slug overlaps the sample. Once set up, this arrangement is remarkably stable, but it does give larger dispersions than the conventional approach. Other techniques reported which are applicable to clinical work include solvent extraction,[17–21] gas transfer[22] and dialysis.[23] In the case of dialysis, it should be possible to operate in a counter-current mode, with greater efficiency than obtainable with the unidirectional flowing streams required by gas-segmented systems. However, in our hands, attempts to operate with counter-flowing streams have been disappointing.

FIA IN PRACTICE

Simple flow-injection systems can be easily assembled from items of equipment usually available in clinical laboratories. A basic system requires no more than a means of propelling the stream of reagent, a coil of reactor tubing, some means of injecting the sample, and a detector with a flow-through cell together with some means of recording the output (Fig. 2).
Fig. 2. Configuration of a simple FIA system based on reaction between the sample (S) and the reagent (R). A pump (P) propels the stream through the reaction coil (RC), through the detector (D) and to waste (W). These symbols are also used in Figs. 3–6.
Fig. 3. Automated FIA. The sample is drawn from the sample turntable (T) into the bore of a motorized rotary valve (RV). The valve then rotates through 90° and "injects" the sample into the reagent stream. The valve is fitted with by-pass tubes (B) to allow flow of reagent when the valve is in the "fill" position.

The stream of reagent may be propelled in a variety of ways. In their original apparatus Stewart et al.[3] used a pressurized reservoir. This has the merit of simplicity and also provides non-pulsatory flow. Mechanical constant-flow pumps intended for HPLC have been used by some workers, for example Rocks et al.[24] Whilst these arrangements work well, a separate pump or reservoir is needed for each flowing stream. Peristaltic pumps do not have this disadvantage, but the severe pulsation produced by some models is undesirable. Least pulsation is given by pumps which have closely spaced rollers, together with platens which are designed so that the rollers lift off them gradually. Some workers have used pulse-suppressing devices[25,26] but Vanderslice et al.[8] suggest that a slight degree of pulsation may be beneficial.

The sample can be injected in a variety of ways, of which the simplest is direct injection by means of a syringe, either through a septum[4,24] or a "flap" valve.[27,28] Injection septa of the type designed for HPLC are very suitable. However, the majority of workers have favoured some form of valve capable of transferring an accurately measured volume of sample into the flowing stream of reagent. The basic principle is indicated in Fig. 3; the hole in the key of a stopcock provides the volumetric measure, and when filled with sample is rotated into the flowing stream. A by-pass is necessary to avoid interrupting the flow of reagent and this must be arranged so that it provides greater resistance to flow than the hole in the key does. A considerable number of variations on this theme have been described. Perhaps the first to be used was the slide valve activated by compressed air, devised by Stewart et al.[3] A similar principle, in a manually operated valve, was employed by Bergamin et al.[16] Most workers have preferred to use rotary valves; custom-built valves of this type have been described by Růžička and Hansen,[28] Mindegaard[29] and Anderson.[30] Riley et al.[31] have described a motorized version. Rocks et al.[32,33] have successfully used commercially available manually operated laboratory stopcocks, whilst a number of

workers, for example Pardue and Fields,[34] Fogg et al.[35] and Strohl and Curran[36] have used loop sampling-valves of the type manufactured for use in HPLC.

In the case of the custom-built rotary valves, the hole in the rotor, or alternatively a separate loop of tubing, provides the volumetric measurement of the sample. Sample is either injected into the sample valve by means of a syringe, or is passed through it by means of the peristaltic pump. If the latter approach is coupled with a motorized valve, a completely automatic system is possible[31] (Fig. 3). Rotary valves have disadvantages; the sliding surfaces are very vulnerable to wear, a problem which particularly affects the custom-built valves already mentioned, in which the stators are generally made of acrylic polymer and the rotors of PTFE. It is in any case a formidable task to machine a really flat surface on a PTFE rotor.

The introduction of injection valves greatly complicated what is fundamentally an extremely simple system. As an alternative, Růžička and Hansen[37] have proposed a technique they have named "hydrodynamic injection". The essential features are shown in Fig. 4. Two pumps are required, one pumping reagent and the other pumping sample. In practice, the reagent pump, P2, is stopped and the sample pump, P1, started to draw sample through the side-arms and fill length L of the reactor line. The sample pump is then stopped and the reagent pump started, and the segment of sample held in length L moves on into the reactor coil.

Harrow and Janata[38] have proposed a modification of this arrangement in which the sample introduction pump is replaced by a hand-operated vacuum pump. Solenoid pinch-valves are used to stop and start the carrier flow and to allow sample to be drawn into the reactor tube. By control of the operating time of the valves, different sample volumes may be drawn into the system. This method of injection is claimed to be more precise than either the use of injection valves or "hydrodynamic injection".
Fig. 4. Sample introduction by "hydrodynamic injection". A second pump (P2) is used to draw sample into the section of the reaction tube marked L.

This approach, and the previously mentioned systems employing rotary valves, all suffer from a common fault; not only must the entry and exit tubes be filled with sample over and above the volume required to fill the sample-measuring space, but also an excess of sample must be used to flush out the residue of the previous specimen. This is unacceptable in clinical chemistry, where the size of the specimen is always limited, and sample volumes of less than 50 μl are the aim. This requirement of strict economy of sample prompted Riley et al.[39] to adopt a different approach, which they call "Controlled Dispersion Flow Analysis". The simplest form of this is indicated in Fig. 5. In this system the peristaltic pump is driven by a stepping motor controlled by a microcomputer. The sample probe normally rests in a reagent container, R, so reagent is pumped through the system between samples. When a sample is offered to the machine, the pump is stopped and the probe is transferred to the sample container, S. The pump then rotates through a precise predetermined angle, and again stops. The probe is returned to the reagent container and the pump restarted. The sample slug travels up the probe, through the pump and onwards into the reactor tubing and finally the detector, no part of the sample being wasted. When this system was first constructed it was expected that the journey through the pump would increase the dispersion of the sample slug. This was tested by measuring the dispersion in the new system and

comparing it with the dispersion obtained with the pump sited downstream of the detector. Surprisingly, appreciably *less* dispersion occurred when the slug travelled through the pump.

Economy in use of expensive reagents is of only slightly less importance than economy of sample and therefore the system was subsequently modified to make use of the merging zone technique. As indicated in Fig. 6, the dipping mechanism is fitted with two probes and two pump tubes, one each for sample and reagent respectively. The probes normally rest in a container of distilled water, C. When a sample is offered to the machine the sample probe is transferred to the sample container. As in the previous example, the pump makes a precise angular movement, but this time both a sample and a reagent slug are created and subsequently pumped onwards to meet at a T-junction downstream from the pump. Typically, sample volumes of 10–20 μl and reagent volumes of 50–150 μl are used. It is, of course, possible to use two or more reagent probes, merging the sample and reagents either simultaneously or one after the other at predetermined time intervals.[40]

The earliest model of this machine was operated effectively under the control of a simple cam timer, but this was soon replaced by a microcomputer. The enormous benefits conferred by computer control make the additional expense and complications worthwhile. In particular, computer control, by feeding exactly the correct number of pulses to the
Fig. 5. Basic "controlled dispersion" analyser. The broken line represents probe movements.
Fig. 6. Merging-zone "controlled dispersion" analyser. Sample and reagent are simultaneously aspirated into independent carrier streams (C) of demineralized water. Sample and reagent zones merge at a T-connector (T).

stepping motor, ensures maximum sampling precision. The same pulse-counting technique is invaluable in stopped-flow work, ensuring that successive samples are treated identically; a peak-identification programme enables the correct conditions for stopped-flow to be set and can verify at any time that these conditions are being maintained. In addition to its control functions, the computer can deal effectively with the data output of the system.

Detectors

In clinical chemistry, most requirements for sample detectors are met by relatively simple flow-through photometers. An important requirement is that the volume of the flow-through cuvette is small; the type of cell used in HPLC detectors, typically 8 μl in volume, meets most needs. Refractive-index effects can be a problem with the small diameter light-paths used in these cells, especially if zones of liquid with widely different temperatures pass through the cell. These effects can be minimized by maintaining the reactor coil and cuvette at the same temperature. Anderson[30] suggests that refractive-index effects are unimportant at absorbances >0.05, but with the wide range of values commonly encountered in clinical chemistry, measurements at such low levels sometimes have to be made.

FIA has been used with considerable success in clinical chemistry as a means of feeding samples to various other detectors (see Table 1).

The output signal generated by the detector is conveniently displayed with a fast-response chart recorder. Because the response curves do not reach the steady-state plateau and the sample zone passes through the detector relatively quickly, the recorder trace has the form of sharp peaks (Fig. 7).

The most convenient method of calibration is to use peak heights, *i.e.*, the peak maximum is taken as the reference point from which the read-out is obtained. However, any other point on the output signal may also be used, provided all readings are taken at exactly the same place. In practice this is accomplished by taking the readings at a fixed time after sample injection. By monitoring several points on the trailing edge of the peak a multipoint calibration curve may be constructed from a single injection of sample.[6]

From the clinical chemist's point of view a useful feature of all FIA systems is that start-up and close-down times are very short. Except for detector warm-up time the FIA system is ready for operation almost as soon as the pump has been started. When the work is finished, reagent and sample are easily and quickly removed from the conduits by pumping distilled water for a short period. Hence FIA should be very suitable for stand-by or emergency applications.

Sample viscosity

When we first began to investigate FIA we became concerned that the variation in viscosity between different biological specimens would make the technique unsuitable for clinical use. In fact FIA has been used to estimate viscosity.[41–43] The greater the viscosity of the solutions the less they disperse into the carrier solution. However, in most of the assays that we have investigated, viscosity effects have not been a problem, although when manual injection techniques are used,[24,44] the rate of injection can be
Fig. 7. Recorder trace showing the characteristic shape of FIA peaks. The peaks resulted from the duplicate injection of (right to left) 0.5, 1.0, 1.5 and 2.0mM magnesium standards followed by two serum samples, into an atomic-absorption spectrophotometer by means of a simple FIA system.[33]

influenced by the viscosity of the sample, and in this case aqueous standards should be modified to have a viscosity near to that of the sample to be assayed.

There are no literature reports of viscosity problems encountered when using injection valves. In systems designed to give high dispersion, the sample soon becomes diluted with the carrier and any difference in viscosity between samples and/or standards soon becomes negligible. In low-dispersion systems, differences in viscosity may have a greater effect and aqueous and serum-based standards may not always yield comparable results.

APPLICATION OF FIA TO CLINICAL ANALYSES

Many of the most frequently requested assays in clinical chemistry laboratories can be done by FIA. Table 1 is a compilation of determinations performed on clinical specimens. Although interesting, some of the determinations involve esoteric methods and would be most unsuitable for routine hospital use. Additionally, many of these report results only for standard solutions, or a very small number of samples taken from patients (*i.e.*, real specimens), and consequently should be regarded as feasibility studies. As a crude guide to clinical usefulness, we have indicated (by an asterisk) those determinations in which more than ten different clinical specimens were assayed. We have not included systems incorporating mixing chambers or columns of immobilized enzymes, since in such systems laminar flow does not predominate. Lists of clinically relevant species determined by FIA, but not all in clinical specimens, have been previously compiled by Růžička and Hansen[28] and by Rocks and Riley.[45]

In the simplest system the sample is injected into a stream of demineralized water (or buffer) and swept by the moving stream to a detector such as an atomic-absorption spectrophotometer or an ion-selective electrode. The sample size and flow conditions can be adjusted to produce the desired degree of sample dispersion (dilution) before it reaches the detector. For example, zinc in serum is easily determined by using this approach.[44] The analytical peak is available 8 sec after injection of the 50-μl sample.

Rapid colorimetric tests can be performed by injecting the sample into a flowing stream of reagent and recording the colour intensity of the resulting products. Assays in this category include albumin, total protein, calcium and chloride. These determinations require FIA systems capable of producing high dispersion ($D > 40$). High dispersion is best achieved by using the smallest sample size consistent with adequate sensitivity. Increasing the dispersion by increasing the reactor tube length and/or radius produces peak broadening and reduces the sampling rate. However, the injection of very small volumes imposes great demands on valve design and in prac-

tice most FIA valves have a minimum delivery volume of between 5 and 10 μl. This means that most simple FIA systems work most efficiently, in terms of sampling rate and reagent consumption, when $D < 10$. A common way round this problem is to dilute the specimen appropriately before injecting it into a conventional FIA system (see Table 1 for examples). Another approach, useful for small molecules, is to use dialysis as a means of rejecting the bulk of the sample.[46] Converging streams can also be used to perform an "on-line" dilution of the sample before it encounters the reagent stream.[47,48]

Mindegaard[29] has described a novel method of dealing with concentrated samples, based on the merging-zone principle. The sample and reagent zones are put slightly out of synchronization so that when the streams converge the reagent zone overlaps the relatively dilute tail of the sample zone. By this method albumin was measured, without predilution, at a rate of 300 samples per hour.

The sample introduction system described by Riley *et al.*[39] has an advantage over the valve system, in that the sample volume is more easily varied and volumes of less than 1 μl can be easily and reproducibly sampled when required.[40] Moreover, in this system the pump tubes may be chosen to give different flow-rates, the reagent usually being pumped at a higher flow-rate than the sample. Hence the sample zone will be further diluted by the reagent zone when they meet at the mixing point. Thus this system offers a greater range of dispersion coefficients than is possible with conventional FIA.

As mentioned earlier, slower reactions are best monitored by stopping the slug of sample in the cuvette and observing the initial rate of reaction. Additionally, the amount of expensive reagents needed can be minimized by the use of merging zones. Rocks *et al.*[40] have used the combined techniques of stopped flow and synchronous merging zones to determine plasma triglycerides. The procedure used 7.5 μl of plasma and 115 μl of reagent. The sample–reagent zone was held in the cuvette for 30 sec while the rate of reaction was recorded.

For analyses involving incubations longer than about 1 min, gas-segmented flow analysis will generally yield a higher sample throughput than an equivalent FIA system. However, if a scarce or expensive reagent is involved, and sampling rate is not a priority, then FIA may still be appropriate for use with reactions requiring relatively long incubation periods. Lim *et al.*[49] have used FIA to minimize reagent consumption in a homogeneous energy-transfer fluorimmunoassay for albumin. Sample and reagent (both 36 μl) were brought together by the merging-zones technique and the carrier flow was stopped for a 6-min period before measurement. (We are not, of course, advocating this approach to routine plasma albumin estimation; the method shows that relatively long incubations are possible when necessary.)

Table 1. Assay of clinical specimens by FIA

Determination	(ref.)	Type of FIA	Carrier/reagent	Detection mode
Albumin in serum	(47)*	C	Bromocresol Green	Photometric
	(29)	M	Bromocresol Green	Photometric
	(40)*	C (CDA)	Bromocresol Green	Photometric
	(31)*	F	Bromocresol Purple	Photometric
in prediluted serum	(45)	F	Bromocresol Green	Photometric
	(56)	F	8-Anilino-1-naphthalene sulphonic acid	Fluorimetric
	(49)	M	8-Anilino-1-naphthalene sulphonic acid	Fluorimetric
	(49)	M/S	Fluorescein-labelled albumin and Rhodamine-labelled antibody	Fluorimetric (Homogenous energy-transfer immunoassay
Alcohol in prediluted whole blood and serum	(57)	C/S	Alcohol dehydrogenase + NAD$^+$	Photometric (NADH)
Ammonia in whole blood and plasma	(50)*	C/G	Donor alkali; recipient pH indicator dye	Photometric
in serum	(58)	C/G	Donor: Tris buffer, pH 7.5; recipient: Tris buffer, pH 8.5	Potentiometric (ammonia selective electrode)
Calcium in serum	(59)	F	EDTA	Flame atomic absorption
	(33)*	F	Acidic lanthanum chloride	Flame atomic absorption
	(60)	F	Tris buffer	Potentiometric (calcium ion-selective electrode)
in prediluted serum	(60)	C	o-Cresolphthalein complexone	Photometric
Chloride in serum	(46)	C/D	Mercuric thiocyanate/ferric nitrate	Photometric
	(39)*	M (CDA)	Mercuric thiocyanate/ferric nitrate	Photometric
Total CO$_2$ in plasma	(22)*	G	Donor acid; recipient pH indicator dye	Photometric
Copper in serum	(44)*	F	Water	Flame atomic absorption
in deproteinated serum	(61)*	R	Ferric thiosulphate	Photometric
Glucose in serum	(62)*	R	Glucose oxidase	Amperometric
	(23)	F;C;D	Glucose dehydrogenase/NAD$^+$	Photometric (NADH)
in prediluted serum	(63)	M	Glucose dehydrogenase/NAD$^+$	Photometric (NADH)
	(64)	C	Glucose oxidase/potassium ferricyanide/luminol	Luminometric
γ-Glutamyl transferase in serum	(39)*	M/S (CDA)	L-γ-Glutamyl-3-carboxy-4-nitroanilide	Photometric
pH of serum	(60)	F	Tris buffer	Potentiometric (pH electrode)
Immunoglobulin, IgG, in prediluted serum	(65)	C	HRP labelled antibody/LDADCF, H$_2$O$_2$	Fluorimetric
Iron in deproteinated serum	(32)*	F	Demineralized water	Flame atomic absorption
Lithium in serum at therapeutic levels	(24)*	F	Demineralized water	Flame atomic absorption
Lactate dehydrogenase in serum	(31)*	F/S	Pyruvate/NADH	Photometric
	(66)	F	Tris buffer	Amperometric (pyruvate sensor)
Lactate in deproteinated serum	(67,68)*	F	Lactate dehydrogenase NADH	Fluorimetric
α$_2$-Macroglobulin in prediluted serum	(31)*	F	N-α-Benzoyl-L-arginine ethyl ester	Photometric
Magnesium in serum	(59)	F	EDTA	Flame atomic absorption
	(33)	F	EDTA	Flame atomic absorption
Phosphate (inorganic) in serum	(46)	C	Molybdate/ascorbic acid	Photometric (molybdenum blue)
Potassium in serum	(69)	F	Tris buffer	Potentiometric (ion-selective electrode)
	(70)	F	Demineralized water	Flame atomic absorption

Table 1—*continued*

Determination	(ref.)	Type of FIA	Carrier/reagent	Detection mode
Protein (total) in serum	(48)*	C	Biuret reagent	Photometric
Sodium in serum	(70)	F	Demineralized water	Flame atomic absorption
Sulphate (inorganic) in urine	(71)*	D	Donor water; recipient acidic barium chloride solution	Turbidimetric
Theophylline in serum, therapeutic levels	(40)	M/S(CDA)	EMIT reagent	Photometric
Triglycerides in serum	(40)*	M/S(CDA)	"Triglyceride enzymatic" reagent	Photometric
Urea in serum	(72)	C	Urease/hypochlorite/phenol	Photometric (Indophenol blue)
in prediluted serum	(73)	F	Urease	Potentiometric (pH electrode used to measure pH change)
Zinc in serum	(44)*	F	Demineralized water	Flame atomic absorption
in deproteinated serum	(74)	F	Demineralized water	Flame atomic absorption
in prediluted serum, simultaneously determined with *sodium, potassium, calcium, magnesium, lithium, iron* and *copper*	(75)	F	Demineralized water	Plasma atomic emission

Type of system:	F = single-line FIA	C = confluent streams
	M = merging zones	S = stopped flow
	G = gas transfer	R = recirculating reagent
	D = dialysis	CDA = controlled-dispersion analysis

NADH = Nicotinamide adenine dinucleotide
EDTA = Disodium ethylenediaminetetra-acetate
HRP = Horseradish peroxidase
LDADCF = leuco-diacetyldichlorofluorescein
EMIT = enzyme multiplied immunoassay technique
*Publications in which more than 10 assays are reported.

Gas-transfer methods have some applications in clinical chemistry. For example, an FIA method for total CO_2 in plasma has been described.[22] The sample is injected into a stream of dilute sulphuric acid and some of the liberated carbon dioxide diffuses through a gas-permeable membrane into a stream containing a pH-sensitive indicator dye. The change in colour of the recipient stream is monitored by a photometer. Ammonia in whole blood and plasma has also been determined by a similar technique in which the sample is first made alkaline to convert all ammonium ions into ammonia.[50]

In addition to its applications listed in Table 1, FIA has been used in other ways which could be of value to the clinical chemist. For example, it has been used as an interface between a high-pressure liquid chromatograph and an atomic-absorption instrument.[51] Abdullahi *et al.*[52] have used FIA as a convenient method of studying drug–protein binding interactions and a generalized method has been proposed[53] for assessing the extent of interference by a foreign species in a given chemical reaction. Inherent in the FIA dispersion equations[8] is the ability to determine reaction-rate constants[54] and molecular-diffusion coefficients.[43,55] Gerhardt and Adams[55] have used these equations for rapid determination of diffusion coefficients of biogenic amine compounds related to neurotransmitters.

CONCLUSIONS

Despite their success in industrial applications and their very obvious potential, flow-injection instruments have so far found little use in routine hospital laboratories. There are two reasons for this. First, the sampling valves universally used in currently available machines are wasteful of sample. Secondly these machines do not possess the sophisticated sample-handling and data-processing facilities that clinical chemists have come to expect, and the pressures on the clinical chemist are such that he no longer has the time to adapt unsuitable machines. The potential is

there—rapid production of results, low reagent consumption and mechanical simplicity; what is needed is the commercial manufacture of machines specifically designed for clinical work.

ENZYME-LINKED IMMUNOSORBENT ASSAY (ELISA) OF ANTIBODIES TO EIGHT COMMON NEUROTROPIC VIRUSES

J. A. P. Earle, N. V. McFerran and G. B. Wisdom*

Department of Biochemistry, The Queen's University of Belfast, Medical Biology Centre, Belfast, U.K.

Summary—Enzyme-linked immunosorbent assay (ELISA) methods were developed for determining serum levels of antibodies to adenovirus, cytomegalovirus, Epstein-Barr virus, herpes simplex type I virus, measles virus, mumps virus, rubella virus, and varicella zoster virus. The assays were evaluated for specificity, range, precision and accuracy and found to give satisfactory performances. Serum samples from 76 blood donors were assayed for the different antibodies. The antibodies to adenovirus and the members of the Herpesviridae had wide concentration ranges, with a significant minority of the samples having zero or very low levels, whereas the antibodies to measles, mumps and rubella had narrower distributions, with very few samples having levels below the detection limit of the ELISA.

As part of an investigation of the viral aetiology of psychiatric diseases we wished to measure the levels of the antibodies to eight common neurotropic viruses in the serum of a large number of patients and controls. The enzyme-linked immunosorbent assay (ELISA) technique of Engvall and Perlmann[1] appeared to be ideally suited to this purpose. In this technique the antigen is immobilized on a solid phase, a dilution of test serum is incubated with this solid phase, and any antibody present binds to the immobilized antigen. Non-bound serum components are removed by washing, and an anti-immunoglobulin/enzyme conjugate is then added. The conjugate binds to the immunoglobulin attached to the solid phase and, after removal of excess of conjugate by washing, the amount bound is determined by measuring the product formed by incubation with substrate for the enzyme label.

ELISA has been used to identify and measure many types of antibody.[2,3] The major advantages of the technique are that it is objective, quantitative, sensitive and precise, the reagents are stable and non-hazardous, and it is relatively easy and inexpensive to apply to a large number of samples.

We decided to develop ELISA methods for the antibodies to adenovirus, cytomegalovirus, Epstein-Barr virus, herpes simplex type I virus, measles virus, mumps virus, rubella virus, and varicella zoster virus. Microtitre plates (MTPs) were chosen as the solid phase because they offered several advantages, particularly for handling large numbers of samples.[4] Alkaline phosphatase was selected as the enzyme label because of its stability and high activity and because it can be easily attached to antibody molecules with glutaraldehyde.[1] The viral antigens were prepared from cell cultures grown in our laboratory or purchased commercially. The eight assays were evaluated for their specificity, range, precision and accuracy, and applied to serum samples from blood donors.

EXPERIMENTAL

Sera

Serum samples used for assay evaluation were obtained from blood donors aged 20–65 (Blood Transfusion Service, Belfast, Northern Ireland).

Standard sera (positive and negative) for different viral antibodies were obtained from Dynatech Laboratories Ltd. (Billingshurst, Sussex, England) or Flow Laboratories Ltd. (Irvine, Ayrshire, Scotland).

Control sera for routine use in the assay were: positive control—pool of 200 human serum samples (Department of Haematology, Royal Victoria Hospital, Belfast, Northern Ireland); negative control—newborn-calf serum (Gibco Bio-Cult, Glasgow, Scotland).

Sera were stored in small portions at −70°.

Assay solutions

Coating buffer. A 0.05M sodium carbonate buffer, pH 9.6, containing 0.02% sodium azide.

Phosphate-buffered saline/Tween (PBS/T). A 0.02M sodium phosphate buffer, pH 7.2, 0.15M in sodium chloride and containing 0.05% Tween 20, and 0.02% sodium azide.

Substrate solution. A 0.05M sodium carbonate buffer, pH 9.8, containing 1 mg/ml *p*-nitrophenyl disodium phosphate, and 1mM magnesium chloride.

Conjugate

Rabbits were immunized with pure human immunoglobulin G (IgG) and the monospecific antiserum was purified by treatment with an Ultrogel AcA34–human IgG adsorbent.[5] The antibodies were conjugated to calf-intestine alkaline phosphatase of high specific activity (type VIII; Sigma Chemical Co. Ltd., Poole, Dorset, England) by use of glutaraldehyde in a one-step procedure.[1] Conjugates were stored at 4° in 2% bovine serum albumin solution containing 0.02% sodium azide.

The activity of different batches of conjugate was evaluated by reacting dilutions of conjugate with MTP wells coated with 100 μl of human IgG (5 μg/ml of coating buffer)

---

*Requests for reprints should be addressed to this author.

for 3 hr at 37°. Unbound material was washed out and the amount of bound conjugate was determined by incubation with substrate solution for 5 min as described below.

Microtitre plates

Microtitre plates (M129A; Dynatech Laboratories) were used as the solid phase. The binding characteristics of samples from each box of 50 plates were evaluated by coating the wells with 100 µl of human IgG (5 µg/ml of coating buffer) for 3 hr at 37°. The wells were washed and 100 µl of conjugate (1:500 dilution in PBST) were incubated at 4° for 18 hr. The amount of bound conjugate was determined as described below.

Antigens

Adenovirus types 3, 4 and 7 CF antigen (in Vero cells), varicella zoster strain 2591G CF antigen (in Vero cells), Epstein-Barr virus micro-ELISA antigen (in P3HR1 cells), and Vero cell control antigen were obtained from Dynatech Laboratories.

Cytomegalovirus strain AD169 CF antigen (in human embryonic fibroblast cells) and the corresponding control antigen were purchased from Flow Laboratories.

Rubella HA antigen (in baby-hamster kidney cells) and the corresponding control antigen were obtained from Wellcome Laboratories Ltd. (Beckenham, Kent, England).

Measles virus Edmonston strain, mumps virus Belfast strain and herpes simplex virus type I were grown in Vero cells supplied with Eagles BHK medium (Wellcome Laboratories). Infected cell suspensions were washed 5 times in 0.02M sodium phosphate buffer, pH 7.2, 0.15M in sodium chloride (phosphate-buffered saline, PBS), incubated in 4% paraformaldehyde solution in PBS at 4° for 15 min and washed as before. The suspension was subjected to ultrasonic radiation at 4° for four 30-sec periods. Uninfected Vero cells were used as the control antigen for these three viruses.

The antigens from commercial sources were reconstituted in 0.15M sodium chloride. Protein concentrations were determined by the Lowry method,[6] with bovine serum albumin as the standard, and the antigens were stored, in 500-µl portions, at −70°.

Each antigen preparation was screened for non-specific effects before use in the ELISA. Endogenous alkaline phosphatase activity was determined by coating MTP wells at 37° for 3 hr with 100 µl of antigen at 50 µg/ml concentration. The wells were washed, substrate solution was added, the mixture incubated at 26° for 1 hr and the product measured as described below. Non-specific binding of conjugate was measured by treating antigen-coated wells (as above) with 100 µl of conjugate (1:100 dilution in PBS/T) at 4° for 18 hr. The amount of bound conjugate was determined as before.

ELISA

To minimize variation, the edge wells of the MTPs were not used.[7] Each assay was performed in triplicate and each

half-plate (30 wells) contained positive and negative control sera together with 8 test sera. During incubation the MTP was tightly sealed with cellophane film. The concentrations of antigen preparation, serum sample and conjugate used in each assay are listed in Table 1. The procedure is as follows.

Each MTP well was treated with antigen in coating buffer (100 µl) by incubation at 37° for 3 hr. The wells were washed free from unbound material by flooding three times with PBST, followed by a 15-min soak in the same solution, and then inverted and tapped on a paper towel until dry. A 100-µl portion of a serum dilution in PBST was added to each of the coated wells, and incubated at 37° for 3 hr. Unbound serum components were washed from the wells as before and rabbit anti-human IgG/alkaline phosphate conjugate diluted in PBST (100 µl) was added to each well and incubated at 4° for 18 hr. Excess of conjugate was removed by washing as before and substrate solution (200 µl) was added and incubated at 26° for 30 min (or 60 min in the case of adenovirus, Epstein-Barr virus and varicella zoster virus antibodies). The reaction was stopped by the addition of 50 µl of 3M sodium hydroxide. The absorbance of a 100-µl sample from each well was measured at 405 nm (A_{405}) with a Vitatron DCP photometer fitted with a flow-through cell of 5 mm path-length; the measurements were semi-automated by use of an MSE Microelisa reader (MSE Scientific Instruments Ltd., Crawley, Sussex, England) connected to an Apple II microcomputer (Apple Computer Inc., Cupertino, California, U.S.A.).

Each individual absorbance measurement was transferred to the Apple microcomputer for storage on magnetic disc. The microcomputer produced a tabulated record of the assays from each MTP, each serum assay being reported as the corrected mean absorbance value and its coefficient of variation (CV). The corrected mean absorbance value was calculated by subtracting the mean value of the negative control serum from the mean test serum value and expressing the results as a percentage of the similarly corrected positive control for that particular half-plate. A suite of programs was written to allow editing of the data-base of raw absorbances and gathering together in a single record the mean absorbance values for all the viral antibodies appropriate to a particular test serum. Mean absorbances stored on disc were then converted into concentration units for each antibody, relative to the positive control values, by using a polynomial fitting procedure for the calibration data and linear interpolation between the calibration points. The resultant data-base could be interrogated to produce either the complete spectrum of responses present in a single individual or the overall population pattern of response to each viral antigen.

Evaluation of the ELISA methods

Specificity. Each assay was performed with positive and negative standard sera and with antigen and control antigen (control antigen for Epstein-Barr virus was not available).

Range. The positive control (pooled human serum) was assayed at dilutions from 1:6.25 to 1:6400.

Table 1. Concentrations of antigen preparation, serum sample and conjugate used in the ELISAs

Virus	Antigen (µg protein/ml)	Serum (dilution)	Conjugate (dilution)
Adenovirus	128	1:100	1:100
Cytomegalovirus	79	1:50	1:200
Epstein-Barr	3	1:50	1:100
Herpes simplex	28	1:500	1:200
Measles	35	1:50	1:200
Mumps	48	1:100	1:200
Rubella	80	1:100	1:200
Varicella zoster	126	1:200	1:100

Precision. Test sera with high, medium or low levels of each antibody were assayed 5 times simultaneously, and on 5 different days for the medium level.

Accuracy. Sets of 10 test sera with ELISA values covering the whole range were assayed by either a neutralization test[8] or an immunofluorescence titration using rabbit anti-human IgG and fluorescein-labelled sheep anti-rabbit IgG.[9]

RESULTS

Several batches of conjugate were used during the course of these experiments, and the preparation procedure was found to give reproducibly active conjugates. These conjugates lost a negligible amount of activity during storage at 4° for one year. The different batches of MTPs used were found to be satisfactory although the reproducibility of binding, as determined by the degree of adsorption of IgG (5 μg/ml), could have CVs as large as 8.8% for between plate measurements.

The viral antigens and control antigens employed showed negligible endogenous alkaline phosphate activity and very low direct conjugate binding.

The concentrations of the assay components (antigen preparation, serum sample and conjugate) were varied (Table 1) together with the incubation times, to optimize the assay conditions. The aim was to saturate the solid phase with antigen and to use a combination of serum and conjugate dilutions which would give: (a) the best discrimination between positive and negative serum samples, (b) a response in the appropriate range, (c) the most economical use of reagents. Incubation times and temperatures were chosen so as to allow the reactions to approach or reach equilibrium. In the case of the conjugate incubation, for convenience, 18 hr at 4° was selected rather than 3 or 4 hr at 37°.

The performance of each of the 8 ELISAs was evaluated. The *specificity* was tested by using positive and negative standard sera together with antigen and control (negative) antigen. The results (Table 2) showed that the assays could clearly distinguish between positive and negative samples. The positive and negative control sera incorporated routinely in the assays also gave the expected responses, which were stable during regular use of the 8 assays over a period of 6 months. The possibility of rheumatoid factor cross-linking the viral antibody to the conjugate was investigated by the addition of sera having high titres of rheumatoid factor to sera with known levels of viral antibody; no increase in conjugate binding was found. The ELISAs had effective *ranges* of at least two orders of magnitude and gave linear log–log calibration graphs of corrected absorbance *vs.* concentration of the positive control serum (except those for herpes simplex and mumps, which were convex with respect to the abscissa). The *precision* was determined by using sera with high, medium and low levels of antibody. The CVs found for the mid-range replicates (Table 2) had a mean of 4.8% for within-day and 7.6% for between-day assays. The CVs for within-day assays at low and high levels were larger, with means of 6.9 and 5.6% respectively. The *accuracy* was evaluated by comparison with the antibody levels found in serum samples by a neutralization test or by immunofluorescence titration. The correlation coefficients obtained (Table 2) ranged between 0.78 and 0.95.

The methods were applied to sera from a group of 76 blood donors and the distributions of the 8 viral antibody levels were determined. Two basic patterns were seen. Adenovirus and the members of the Herpesviridae (cytomegalovirus, Epstein-Barr, herpes simplex, varicella zoster) had wide concentration ranges, with a significant minority of the group having zero or very low antibody levels and a smaller minority having relatively high levels. The other viruses (measles, mumps, rubella) had narrower ranges, which contained few, if any, values that were below the detection limit of the assay. Examples of the distributions are shown in Fig. 1.

Table 2. Specificity, precision and accuracy of the ELISAs: specificity was determined by assaying positive and negative standard sera, and antigen and control antigen; precision was estimated by assaying replicates ($n = 5$); accuracy is presented as the correlation coefficient of the ELISA results for a set of samples with those of a neutralization test (*) or an immunofluorescence titration (†); ND = not determined

| | Specificity (A_{405}) | | | | Precision (CV, %) | | Accuracy (correlation coefficient) |
| | Antigen | | Control antigen | | | | |
Virus	Positive serum	Negative serum	Positive serum	Negative serum	Within-day	Between-day	
Adenovirus	1.090	0.319	0.335	0.324	5.4	8.0	0.88†
Cytomegalovirus	1.103	0.143	0.198	0.121	5.1	10.6	0.89†

DISCUSSION

The ELISAs described measured antibodies to viruses belonging to four groups: Adenoviridae, Herpesviridae, Paramyxoviridae (measles, mumps) and Togaviridae (rubella). They all gave satisfactory performance. The ranges were sufficiently wide for a single dilution of most sera to give results falling on the calibration curve. The occasional sample having a high antibody level could be analysed by assaying a higher dilution. For all the antibodies very low levels could not be distinguished from each other or from zero. The specificity of the assays, as judged by the responses given by control (negative) antigen and by positive and negative standard sera, was high despite the use of antigen preparations in which virus-specific polypeptides probably made up only a small percentage of the total protein. The positive standard sera for herpes simplex, measles and rubella did not give high ELISA values and this probably reflects relatively low levels of the antibody in these sera, as many test sera gave greater responses. The negative standard sera gave somewhat higher values than the negative control (bovine) serum used routinely in the assay; this is probably due to a small amount of non-specific binding of IgG and, in some cases, to the sensitivity of the ELISA allowing detection of low levels of antibody in sera which are negative in other tests. (The bovine serum was used as negative control in preference to control antigen or negative human serum for reasons of economy.) Interference by rheumatoid factor and other proteins did not present problems with the antigens employed. A few commercial antigens, especially rubella anti-

gens, did not give good discrimination between positive and negative sera and they were not used in this investigation. Assay precision was adequate and only a small number of assays required repetition. This was signalled by the computer when the MTPs were read, if (*a*) the CV of the difference between the positive and negative control sera exceeded 10%, in which case that half-plate of assays was rejected, or (*b*) the CV of the triplicate determinations exceeded 15%, in which case the individual assay was rejected. The accuracy of immunoassays can be difficult to determine, as different methods may have different biases; however, in the comparisons reported here the ELISA results showed reasonably high correlation with those from the alternative method of measuring antibody level.

The assays are easy to perform. The small amounts of serum required mean that many assays can be done on 1 ml of blood and the use of MTPs makes the handling of large numbers of assays relatively easy, even with only a partially automated system for reading the absorbances (with our apparatus the MTP had to be moved manually for reading the wells). Although the MTPs were coated with antigen and used immediately, pretreatment of MTPs may allow the antigen-coated solid phase to be stored before use.[10] This, together with the stability of the conjugates, adds to the convenience of ELISAs which are required for only occasional use during a period of many months. The ELISA procedures described here take a little over a day to complete, but could be accelerated if required, and viral antibody ELISAs may be completed in as little as 2 hr.[11]

Although the assays reported here and elsewhere[2,3] are already useful methods, recent developments promise to increase the scope and performance of ELISAs. High-capacity MTPs with more reproducible adsorption properties have become available and antigen preparations specifically for use in highly sensitive ELISAs are now being produced commercially. This is very important, as the quality of the antigen determines, to a large extent, the quality of the assay. Anti-immunoglobulin conjugates specific for different immunoglobulin heavy chains and with different enzyme labels are currently produced by many different firms. They are usually of high activity and can be measured by use of fluorogenic substrates, as well as the conventional ones, to give increased sensitivity. Automation of the technique has developed extensively in recent years and machines which can load, wash and read MTPs are available from several sources. In addition, ELISA kits for the determination of several important viral antibodies are now being marketed.[12]

While no extensive comparisons of ELISA with other methods for determining antibody levels were made in this study, previous reports indicate that ELISAs usually equal or exceed the sensitivity of most alternative techniques and are generally more convenient.[2,3] Our experience indicates that ELISAs can easily be set up for viral antibodies, with reagents which are available commercially, and these assays have performances adequate for most research and routine investigations.

DEVELOPMENT OF A SENSITIVE ENZYME IMMUNOASSAY FOR PLASMA AND SALIVARY STEROIDS

A. Roda*, S. Girotti, S. Lodi and S. Preti

Istituto di Scienze Chimiche, Facoltà di Farmacia, Università degli Studi di Bologna, Bologna, Italy

Summary—The development of an enzyme-labelled immunoassay (EIA) of sufficient range and sensitivity for determination of plasma and salivary steroids is described. The method is based on competition in the solid phase. A fixed amount of a specific antibody is immobilized on polystyrene beads, its amount being enough to bind about 50% of a steroid–enzyme conjugate (covalently linked steroid/horseradish peroxidase conjugate). The initial incubation at 25° of serum sample or extract with the conjugate in presence of the immobilized antibody is followed by washing and the addition of a substrate for measurement of the enzyme activity either colorimetrically by the H_2O_2/o-phenylenediamine method or by the luminescence reaction based on the use of H_2O_2/luminol. The method is precise and accurate (CV < 10% for both the intra- and inter-assay studies). The sensitivity of the colorimetric determination is similar to that of radioimmunoassay, but the luminescence method is more sensitive. Radioimmunoassay and EIA gave results in good agreement ($r > 0.97$). The method has also been applied to salivary steroids: the procedure is direct and only a few μl of saliva are required. The levels of these steroids in saliva are only about a tenth of those in serum but directly correlated with them ($r > 0.85$). The enzyme immunoassay proposed is sensitive and precise enough to measure these steroids accurately in saliva and plasma.

All steroids of diagnostic significance in the routine assessment of endocrine function can now be measured accurately both in plasma and urine samples thanks to the development of sensitive and accurate radioimmunoassays (RIA). Several methods have been described based on the use of radiolabelled tracers such as ^{3}H and ^{125}I.[1,2] These assays are mostly based on a competitive principle and require separation of the antigen–antibody complex. The results obtained on biological samples have been validated by comparison with independent methods such as GC–MS[3] and the data agree well. Most procedures still require a preliminary liquid extraction of the steroids from the serum matrix. Several kits are commercially available and wide applications have been reported.

Some problems related to methodology still remain. Data derived from different laboratories for the same specimen sometimes disagree and this seems related to differences in antibody heterogeneity and recovery in the extraction.

A factor limiting widespread application of tests using radioactive materials is the need for expensive equipment and consequently the use of these methods is mainly limited to hospital laboratories.

The limited half-life of some radioisotopes (*e.g.* ^{125}I) used in such assays is another drawback when these tests are used in small laboratories where only a few samples are analysed per day.

Alternative methods to RIA have recently been proposed, including enzyme immunoassay,[4] amplified

enzymatic methods[5] and fluorescence[6] (FIA) or luminescence[7] (LIA) immunoassay. Until now few of them have fulfilled the requisites of sensitivity and accuracy shown by RIA and few commercial kits for steroid analysis are available.

In addition, the exact definition of endocrine function requires the measurement of such steroids in urine collected over a 24-hr period or the use of dynamic tests with consequent collection of several plasma samples.

Recently Riad-Fahmy *et al.*[8] reported the measurement of steroids in saliva and demonstrated its validity by comparing the results with those obtained for plasma. They concluded that all steroids, including cortisol, oestriol, testosterone, progesterone, *etc.*, can be accurately measured in saliva and that their levels are independent of the saliva flow-rate (over a range with the highest rate 4–6 times the lowest) and reflect those in the free fraction present in plasma. A direct method without preliminary extraction from the matrix can be developed for saliva even for those steroids which require a solvent extraction from plasma samples.

For the clinician the use of saliva sampling simplifies the work and reduces stress for the patient. These factors, together with a considerable reduction in cost, make this test attractive.

Salivary levels of most steroids are very low, between about a tenth and a twentieth of those in serum. Consequently an analytical method applicable to saliva has to be highly sensitive and accurate to detect disease-related variations at picomolar levels.

---

*To whom correspondence should be addressed.

In the present paper we report the development of a highly sensitive enzyme immunoassay based on a competitive principle, able to measure steroids in plasma and saliva samples.

The method is based on the use of steroid labelled with horseradish peroxidase (HRP) as a "label" and a steroid-specific antibody immobilized on a solid support (polystyrene beads). The method is extremely simple and rapid and can be performed in a single tube. The enzymatic activity of the HRP–steroid conjugate can be measured by conventional colorimetric detection with H_2O_2/o-phenylenediamine (OPD) as substrate or by a luminescence reaction using $H_2O_2/$luminol as substrate.

The general method reported here shows a sensitivity comparable to that of RIA and sometimes better, mainly when luminescence detection is used. Here we describe the general scheme of the assay and its application in the development of sensitive immunoenzymatic assays for progesterone, testosterone, oestriol, cortisol and conjugated lithocholate (CLCA). Comparison with RIA and validation with saliva and serum samples, by an extraction procedure or a direct method, is also reported.

EXPERIMENTAL

Reagents

All the reagents used were of analytical grade and used without further purification. Steroid-carboxymethyloxime derivatives (CMO) were obtained from Makor Chemical Ltd., Jerusalem, Israel, or synthesized in our laboratory by published methods.[9]

The purity of such derivatives and steroid standards was assessed both by TLC and HPLC and found better than 98%. Horseradish peroxidase (HRP) was obtained from Boehringer GmbH, Mannheim, West Germany (Grade 1). Sephadex G-100 was obtained from Pharmacia, Uppsala, Sweden. Polystyrene beads (6.5 mm diameter) were purchased from Precision Plastic Balls, Chicago, U.S.A., and luminol from LKB, Bromma, Sweden. Tritium-labelled steroids (specific activity 80–110 Ci/mmole) were obtained from the Radiochemical Centre, Amersham, U.K. Tritium-labelled glycolithocholic acid (specific activity 17 Ci/mmole) was obtained from NEN, Worcester, Mass., U.S.A.

Antibodies

Antisera were produced in rabbits against (CMO)–bovine serum albumin (BSA) conjugated steroids; these derivatives were prepared by the previously described mixed anhydride method[10] and in the case of conjugated lithocholic acid the antigen was prepared by direct conjugation of glycolithocholic acid with BSA, by a carbodi-imide method, at the C-24 carboxyl group.[11] The molar ratio of steroid to bovine serum albumin, evaluated by adding ^{3}H-labelled steroids to the reaction mixture, ranged from 15 to 20. Unbound steroid was removed by gel-exclusion chromatography on a Sephadex G-100 column and dialysis against three changes of $0.1M$ phosphate buffer, pH 7.0.

The immunization technique was similar to that previously reported,[12] and antisera with adequate titre, affinity and specificity were obtained 3–5 months after the first immunization. BSA (0.3%) was first added to the rabbit sera in order to eliminate any anti-BSA present, by precipitation. The IgG-rich fraction was isolated by salting-out precipitation with anhydrous sodium sulphate, following a slight modification of the method described by Axen et al.[13] The IgG were then extensively dialysed against $0.1M$ phosphate buffer, pH 7.0.

Immobilization. The purified antibody was immobilized on polystyrene beads (6.4 mm diameter) previously washed with distilled water. An appropriate dilution of IgG was incubated with the beads (1 mg/100 beads) in $0.1M$ phosphate buffer (pH 8) for 4 hr at 4°. The solution was removed and BSA solution containing 0.01% of thiomersal was added and incubated for 2 hr. The solution was discarded and the beads were washed with doubly distilled water, dried under vacuum and stored at 4° until use.

Enzyme–steroid conjugate

The mixed anhydride method was selected to conjugate the steroid–CMO derivative with HRP by a slight modification of the method originally described by Erlanger et al.[10] The conjugate was freed from unreacted steroids by gel-exclusion chromatography on Sephadex G-100 and the eluate dialysed against three changes (1 litre) of $0.1M$ phosphate buffer, pH 7.0, at 4°. The molar ratio of steroid to HRP was evaluated by adding ^{3}H-labelled steroid–CMO to the reaction mixture. In the case of lithocholic acid, which already contained a carboxyl group, the reaction was performed with a water-soluble carbodi-imide as previously reported.[11]

Samples

The method developed is directly applicable to plasma samples only for cortisol and CLCA. For the other steroids a preliminary liquid extraction is still required for plasma samples. The plasma sample (500 µl) was extracted with 5 ml of diethyl ether. The ether phase was decanted and evaporated to dryness. The residue was then dissolved in 5 ml of $0.1M$ phosphate buffer (pH 7.0) and 100-µl aliquots of solution were used for the assay. In order to validate the method saliva samples were also run, with and without extraction. In the case of saliva 1-ml aliquots were extracted with 10 ml of diethyl ether. The aqueous phase was quick-frozen and the ether phase decanted off and evaporated to dryness. The residue was dissolved in 1 ml of phosphate buffer and 100-µl aliquots of solution were used for the assay.

Assay procedure

The assay buffer used was $0.05M$ phosphate/EDTA buffer (pH 7.5) containing 0.1% BSA. A 100-µl portion of steroid–HRP conjugate (diluted 10^5-fold) was added to the assay tube containing 100 µl of sample prepared as described above, or a standard solution. The final volume was adjusted to 500 µl with assay buffer. The immobilized antibody was then added to the tube. The tubes were incubated for 3 hr at 25°.

At the end of incubation the beads (bound fraction) were washed twice with 4 ml of water. The enzyme activity of the bound fraction was measured by adding 2 ml of "substrate solution" ($0.1M$ phosphate buffer, pH 6.0, containing 2 mg of OPD and 1 µl of 30% H_2O_2) to each tube. After incubation for 30 min in the dark at 25° the reaction was stopped with 200 µl of $4M$ sulphuric acid and the absorbance at 492 nm recorded.

The luminescence detection was based on the use of the luminol/H_2O_2 system. The washed beads were added to a tube containing the "luminescence solution" (1 ml of $0.01M$ phosphate buffer, pH 7.0; 0.1 ml of $0.01M$ luminol; 0.5 ml of $0.01M$ H_2O_2). The light emission occurs in a few seconds and is stable for 30–40 sec. The peak light emission was measured with an LKB luminometer, model 1250, and the output signal recorded on an LKB potentiometer recorder, model 2210.

RIA

The radioimmunoassay procedures employed for obtaining comparison results have already been published elsewhere. The main characteristics in terms of sensitivity and

CV = coefficient of variation.

precision are reported in Table 1. The same antibodies were used both for RIA and immunoenzymatic assay.

RESULTS

Antibodies

The specificities of the antibodies used are reported in Table 2. As far as the CLCA assay is concerned, the antibody is specific both for glycolithocholic and taurolithocholic acid. The cross-reactivity of the unconjugated bile acid is 5%, but other bile acids do not cross-react. The antibody titre is extremely high for all the assays: the final dilution of the antibody at 50% binding is about $1:10^5$ and the affinity constant is around 10^{10} l./mole. The stability of the immobilized antibody was checked by weekly assays of the same standard at both 4° and 25°. Figure 1 shows the results for two representative steroids, cortisol and oestriol. The reproducibility of the immobilization procedure was assessed by adding ^{3}H-labelled steroid (10 pg/tube, 10^4 dpm) to the beads and measuring the bound radioactivity after 3-hr incubation. The same procedure was repeated several times. For all immobilized antibodies the coefficient of variation was less than 5%, showing that the same amount of antibody was bound to each polystyrene bead.

Enzyme label

Approximately 1 mole of HRP is bound to 2–3 moles of steroid, as calculated by measuring the radioactivity of the ^{3}H-labelled CMO–steroid added to the reaction mixture. At the final dilution of this label in the assay tube, not more than 20 pg of steroid is present and the maximum absorbance recorded at 412 nm is between 1.0 and 2.0. When luminescence detection is used it is possible to reduce the dilution to 5 pg/tube.

These "labels" are highly stable when stored in concentrated form (1 mg/ml), at 4° and in presence of $0.1M$ gelatine. Once diluted for the assay (1 μg/ml) they are drastically reduced in stability, as shown in Fig. 2.

Immunoassay

A linear response was obtained over a wide concentration range when the fraction of antigen bound was plotted against the concentration in a logit–log plot. Representative calibration graphs obtained by colorimetric detection are shown in Fig. 3.

The detection limit, defined as the concentration resulting in a response equal to twice the standard deviation of the zero dose response, is reported in Table 1 for both detection systems used. In all assays the luminescence EIA was more sensitive than RIA and the colorimetric EIA.

The intra- and inter-assay reproducibility, expressed as the coefficient of variation, was obtained from 20 replicate determinations at low and high concentrations. In addition, various amounts of standard steroids were added to plasma and the mixtures

assayed by the three methods. The recovery is expressed as the mean range of five determinations.

Comparison of methods

Figure 4 shows the results obtained by using the colorimetric or luminescence EIA, compared with those obtained by RIA for 25 extracted plasma testosterone samples with normal or pathological levels of this steroid. The other steroid assays behave in a similar fashion. The agreement was good at both low and high levels, as shown by the correlation coefficient ($r > 0.88$).

When the plasma and salivary levels measured by EIA or LIA methods were compared, a good correlation was found, suggesting that variations in the saliva levels reflect those in the plasma (Fig. 5). The salivary levels are lower than those in the plasma by a factor of 10–20.

DISCUSSION

The solid-phase immunoenzymatic assay described here appears to be a useful alternative to RIA for measuring steroids in plasma and saliva. Its sensitivity is comparable to that of RIA and in some cases higher. For example, the RIA developed for CLCA has a sensitivity lower by a factor of 1000, probably because of the low specific activity of the ^{3}H-tracer used (17 Ci/mmole). The uncontrolled adsorption of the antibody on the solid beads when a non-covalent binding is chosen is improved by careful selection of the coating conditions, such as ionic strength, pH, antibody purity and precoating treatment of the plastic beads. The high specificity and affinity of the antibodies used seems a key parameter. Once treated with BSA so that all the remaining possible specific adsorptive sites on the bead surface are occupied, the beads are very stable, either wet or dry if stored at 4°. The non-specific binding is very low (less than 1%) and increases to only a limited extent during 2–3 months of storage.

The HRP-steroid conjugates have high specific activity, allowing them to be used at high dilution in the assay tube, with consequent increased sensitivity of the assay. The conjugates can be used at a final dilution at least 10–100 times greater than that for other conjugates.[14]

When luminescence detection is used, an even greater dilution of the conjugate is possible, and as little as 2 pg of steroid (or even less) can be assayed. The method is precise and accurate (Table 1) and the use of polystyrene beads seems ideal when colorimetric, and particularly luminescence, detection is used. The main advantages are as follows.

(1) The beads are easily washed, with consequent removal of all possible non-specific interferences in the colorimetric and luminescence reactions.

(a)

(b)
Fig. 5. Relationship between plasma and saliva levels of cortisol as measured by colorimetric (a) and luminescence (b) enzyme immunoassay.

(2) The washing difficulties and bacterial growth experienced in methods using Sepharose beads[14] are resolved.

(3) With OPD/H_2O_2 as the detection-system substrate, the sensitivity is adequate to measure disease-related variations in both plasma and saliva. The luminescence detection is faster and much more sensitive but requires the use of a luminometer, which is not widely available in clinical chemistry laboratories.

Both assays are easy to perform and require only inexpensive equipment. The reagents used, such as the enzyme–steroid conjugate and the immobilized antibody are very stable, thus simplifying storage and shipment of kits. The preliminary results reported here on the correlation between salivary and plasma levels of oestriol are in agreement with those previously published. The combination of this enzyme immunoassay with saliva sampling will make steroid tests more practicable.

Endocrinology Unit, University of Florence, Viale Morgagni 85, 50134 Florence, Italy

Summary—The application of luminescence to the development of non-isotopic immunoassay methods for steroids and urinary steroid metabolites is reviewed. On-line computer analysis of the light emission is particularly useful, as it reveals the interfering effects of biological compounds on the reaction and this can improve the quality of luminescence immunoassay (LIA) methods. The main characteristics of chemiluminescent tracers are stability, safety, speed and sensitivity of detection, and reliability. Homogeneous methods, not requiring phase separation, have also been reported and validated. Heterogeneous methods which use dextran-coated charcoal or solid-phase techniques can be used for direct determination of urinary steroids in unextracted samples.

Many compounds of clinical interest are currently determined at low levels by protein-binding assays with radioactive labels. Although radioimmunoassay (RIA) methods are sensitive and reasonably specific, they possess certain disadvantages inherent in the use of radioactive material, such as problems of stability of the tracer, radioactive waste disposal, and the availability of expensive instrumentation and reagents.

Other analytical procedures have been developed which take full advantage of the specificity and sensitivity that result from the use of an antibody, but do not employ an isotopically labelled antigen. These include the use of an enzyme and a fluorescent or chemiluminescent molecule as a label.

In this paper we survey the use of such labels in immunoassay methods for steroid hormones.

THE ANALYTICAL SIGNAL OF A CHEMILUMINESCENCE REACTION

Luminescence may be defined as the chemical production of light and involves the emission of photons from excited molecules during their return to a lower energy state. Luminescence can be applied in a wide variety of assays of biological interest and more information on the characteristics of bioluminescence (BL) and chemiluminescence (CL) reactions, instrumentation, and applications in clinical chemistry can be found in several recent reviews[1,2] and books.[3,4] Here we describe how some compounds giving chemiluminescence reactions can be used as labels for the development of luminescence immunoassay (LIA) methods for steroids.

The main difference between LIA and radioimmunoassay (RIA) procedures lies in the measure-ment of the tracer; in the case of LIA, the tracer measurement has the following characteristics:

(i) the chemiluminescence of the tracer must be activated before it can be measured, and this requires an additional step, *viz.* an oxidation reaction,[5] which can be a source of variability; radioisotopes emit spontaneously beta or gamma radiation;

(ii) the signal of a CL reaction is not easily definable in absolute terms of light emission[6] and the luminometer (the instrument used for luminescence measurements) records values in arbitrary light units; microprocessor-controlled beta- and gamma-counters can automatically evaluate efficiency and convert cpm into dpm values;

(iii) the CL signal is time-dependent whereas radioisotope tracers give an effectively constant signal which is more easily quantifiable (Fig. 1).

Consequently the measurement of the chemiluminescent tracer in LIA methods is a more critical step than the measurement of radioactivity in RIA. Further, beta- or gamma-counters are usually quite sophisticated instruments in comparison to the commercially available luminometers, which are com-
Fig. 1. Comparison between the analytical signal of a radiolabelled or a chemiluminescent tracer.

Fig. 2. Time-course of the light signal obtained on oxidation of a CL tracer with the H_2O_2–microperoxidase system at pH 13, and some of the most used measurement parameters. TLP (total light production). The integrated value of the photon emission reaching the detector during the total time of emission. PLI (peak light intensity). A fast measurement parameter often related to PI. PI (portion integration for 0–10 or 2–12 sec or other intervals). An integration value for a fixed time interval. T_{max}. Time interval from the oxidant injection to PLI. This is a "shape" index which can often reveal changes in the CL kinetics due to interfering compounds (see reference 8).

monly equipped with inadequate injection devices and crude light measurement systems.

To minimize errors due to the chemiluminescent tracer measurement, the following factors should be optimized.

Choice of the measurement parameter. The CL reaction, because of its time-dependence, can be quantified in various ways (see Fig. 2) which possess different characteristics in terms of time, reproducibility, linearity, signal to-noise ratio etc.[7] The most suitable method for the measurement depends of the kind of CL compound used and on the reaction conditions.

Evaluation of the CL kinetics. The reaction conditions (*viz.* pH, buffers, the relative concentrations of the oxidant and catalyst, and in particular the presence of materials of biological origin such as plasma or urine) can modify the kinetics and consequently the measured light output.[7] Consequently it is necessary to have a criterion for evaluating the shape or pattern of the signal. In fact, quenching corrections, analogous to dead-time corrections in radioisotope counting, can be developed by using a detailed analysis of the time course of the CL signal.

In an attempt to improve the present methods of

measurement of CL reactions with commercial lumi-nometers, we have interfaced a microcomputer to operate on-line with a luminometer (Packard PICO-LITE model 6200). The signal from the photo-multiplier of the luminometer is processed by the interface to become acceptable for the parallel port of the computer, and is then analysed in terms of light emission and shape of the signal. Details of this approach have been reported.[8]

The use of on-line computer analysis of CL reac-tions facilitates selection of the most suitable method of measurement and can characterize the reaction kinetics. Table 1 gives an example of the computer output of the most significant signal parameters of an LIA method for cortisol.

We believe that on-line use of the computer with the luminometer allows us both to monitor the CL reaction and identify and eliminate some sources of error, and thus improve the quality and consis-tency of LIA methods. In addition, we use the computer for routine analysis of RIA and LIA dose-response curves, using a weighted four-parameter logistic method.[9]

CHEMILUMINESCENT TRACERS FOR STEROIDS

Several compounds which produce chemilumi-nescence can be used as labelling reagents. In par-ticular some aminophthalylhydrazides (luminol, isoluminol and isoluminol derivatives) participate in simple oxidation reactions (e.g. the hydrogen peroxide-microperoxidase reaction at pH 8.6–13) to produce light with relatively high quantum efficiency[10] and thus can be used as universal labels for both antigens[11] and haptens.[12]

Some isoluminol derivatives have been conjugated to steroid molecules and the resulting steroid–CL tracer conjugates have been investigated in terms of both their affinity for the homologous antibody and their CL characteristics. The results of this study[12] can be summarized as follows.

(1) The preparation of the steroid–CL tracer conju-gate is a simple conjugation reaction, such as a carbodi-imide reaction, similar to those used in the synthesis of steroid-protein immunogens. Purification can be done on silica gel TLC plates and the identity of the final compound confirmed by mass spec-trometry. An example of the structure of a steroid–CL tracer conjugate is shown in Fig. 3.

(2) The CL efficiency of the conjugates is mainly determined by the isoluminol derivative used and is not significantly affected by the steroid molecule. Some isoluminol derivatives (AEEI or ABEI) are more efficient than others, and always produce CL tracers detectable at picomolar level (range 0.1–0.4 fmole/tube).

Conjugate	R$_1$	R$_2$	M.W. a.u.	FD mass spectra			
				M$^+$	(M+H)$^+$	(M+M$_2$)$^+$	(M+Na)$^+$
C–21–HS–ABEI	(CH$_2$)$_4$	—CH$_2$—CH$_3$—	720	721	722		743
C–21–HS–ABI	(CH$_2$)$_4$	—H	692	693	694		715
Fig. 3. Example of the structure of a steroid CL tracer (A) and of the mass spectrum data obtained by the field desorption (FD; B) or the fast-atom bombardment (FAB; C) ionization techniques.
Fig. 4. Homogeneous LIA for progesterone: standard curve. The continuous vertical bar represents the 2-12 sec PI value of the CL tracer in absence of antibody, and the dotted line at the zero point the PI value in presence of the homologous antibody. The enhancement phenomenon is evident. The effect of adding increasing amounts of cold progesterone to the reaction mixture, on the enhancement, is also shown.

(3) The affinity of the steroid-CL tracer conjugate for the homologous antibody can be affected by the ability of the antibody to recognize both the steroid and the bridge between the steroid and the CL molecule (e.g.) the carboxymethyloxime or the hemisuccinate bridge). Consequently the affinity can be higher or lower than that of the native steroid, or similar to it, and this can affect the sensitivity and specificity of the assay.[13,14] However, most of the steroid-CL tracer conjugates possess suitable affinity for use in LIA methods.

THE LUMINESCENT IMMUNOASSAY METHOD

Within the last few years, LIA methods have been reported for several compounds of biological and clinical interest.[4] In this paper we will discuss several types of steroid immunoassay based on monitoring chemiluminescence; these include homogeneous methods, which do not require a phase separation, and heterogeneous methods using dextran-coated charcoal or solid-phase separation systems.

Homogeneous LIA

The steroid-CL tracer conjugate emits light on oxidation by the hydrogen peroxide-microperoxidase system at pH 8.6-13.0. Use of pH 8.6 is compatible with monitoring of competitive protein-binding reactions in homogeneous medium when the presence of the specific antibody affects the light-yield from the conjugate.

A homogeneous LIA for progesterone has been developed.[15] In this assay, the homologous antibody raised in rabbits by use of an anti-progesterone-11α-hemisuccinate-BSA as the immunogen, causes an increase of the light-yield of the progesterone-11α-hemisuccinate-ABEI during oxidation. The addition of unaltered homologous steroid (progesterone) to

the reaction mixture competitively inhibits the light production and this is the basis for the assessment of the standard curve in the homogeneous phase (Fig. 4).

This approach has been used for developing homogeneous LIA methods for progesterone,[15] cortisol,[12,16] and oestriol-16α-glucuronide[16,17] which have sensitivity and specificity similar to those of conventional RIA methods. However, an extraction of the biological sample (plasma or urine) was introduced into the procedure in order to remove nonspecific compounds interfering in the CL reaction.

Recently we have developed a homogeneous LIA for total urinary oestrogens in diluted hydrolysed urine samples;[18] this direct assay was possible because only 0.5 μl of samples was used for the assay, a quantity small enough not to interfere in the CL reaction.

Homogeneous LIA methods are attractive because they can allow full automation of the assay; however, they do have some disadvantages, mainly due to incomplete knowledge of the mechanism of the antibody-enhanced chemiluminescence. Several factors are involved in the enhancement phenomenon, including the chemical structure of the tracer and the immunological characteristics of the antibody.[15] Consequently, it appears that different procedures have to be chosen according to the antibody or labelled ligand used, and this is not practical for routine work, but the situation should improve as well standardized reagents become available (especially monoclonal antibodies).

Heterogeneous LIA

In contrast to homogeneous LIA, heterogeneous LIA does not utilize the light-enhancement properties of the specific antibody, but introduces a phase-separation step into the procedure.

An example of the dose-response curves for cortisol obtained by LIA and RIA procedures is shown in Fig. 5, and a comparison between the working ranges and detection limits is given in Fig. 6.

Some heterogeneous LIA methods have been described for cortisol,[19] progesterone[20] and testosterone[9]
Fig. 5. Representative standard curves for cortisol, obtained by an LIA and an RIA procedure.
Fig. 6. Precision profiles of LIA and RIA for cortisol. Relationship between dose and precision (CV for duplicate determinations) as calculated from five LIA and RIA standard curves by a weighted four-parameter logistic analysis (program RIA004; see reference 9).

which use dextran-coated charcoal for separation of bound and free forms of the ligand, and can be readily introduced into clinicial laboratories. However, this kind of phase separation step cannot always remove interfering compounds from biological samples and consequently most of these assays, like the homogeneous LIA methods, require a preliminary extraction step.

In attempts to develop simple and reliable LIA methods for plasma steroids and urinary steroid metabolites, we have explored the possibility of using solid-phase techniques. The solid-phase separation systems can obviate the need for prior purification of the sample since non-specific compounds, which may interfere in the CL reaction, are removed by washing after the binding reaction.

A number of solid supports (polystyrene tubes, etched polystyrene beads and antibodies covalently linked to polyacrylamide beads) have been used, and solid-phase LIA methods have been developed for progesterone[21] and oestradiol[22] in plasma and for oestriol-16α-glucuronide,[23] testosterone-17-glucuronide,[24] oestrone-3-glucuronide[25] and pregnanediol-3-glucuronide[26] in urine.

These solid-phase LIA methods for urinary steroid glucuronides appear promising and the use of specific antibodies raised against urinary steroid metabolites (glucuronides) together with solid-phase techniques can avoid both the hydrolysis and the purification of urine samples, which are time-consuming and impractical methodological steps. The determination of urinary steroid metabolites can be an important tool in the investigation of several physiopathological conditions. For example, determination of oestriol-16α-glucuronide can be used in monitoring of foetal

well-being,[23,27] and testosterone-17-glucuronide is a useful index of the total androgenic secretion in man and woman in both normal conditions and under specific suppressive therapies.[24] Oestrone-3-glucuronide and pregnanediol-3-glucuronide can be used in monitoring the menstrual cycle[28,29] and in this case only daily samples of early-morning urine are required, instead of 24-hr pooled collection. An example of monitoring of a normal menstrual cycle by LIA of urinary steroid metabolites is shown in Fig. 7.

DISCUSSION

In this paper we have reviewed the application of luminescence in the development of non-isotopic immunoassays for steroids. The analytical signal from the chemiluminescent tracer can be perturbed by interfering compounds of biological origin, present in the assay tube, and this reduces the reliability of the LIA methods. On-line computer analysis of the CL reactions seems particularly useful for identifying and eliminating these sources of error.

The main characteristics of the steroid–CL tracer conjugates are stability, safety, speed and sensitivity of detection. LIA methods based on use of such reagents possess sensitivity, specificity, accuracy and precision comparable to those commonly obtained with the equivalent RIA methods. Moreover, LIA methods which use solid-phase techniques allow the direct determination of steroids in unextracted samples, making the procedures simple and easy to introduce into clinical laboratories without problems of licensing and safety.
Fig. 7. Daily excretion of pregnanediol-3-glucuronide and oestrone-3-glucuronide through a normal menstrual cycle, as measured in early morning urine samples by solid-phase LIA methods. Urinary LH was measured by RIA.

In conclusion, the application of luminescence to non-isotopic immunoassays is a very promising technique, and would be more widely used if the commercial availability of well standardized reagents and of automated instrumentation for CL reactions improved.

DETERMINATION OF HORMONES BY TIME-RESOLVED FLUOROIMMUNOASSAY

Timo Lövgren, Ilkka Hemmilä, Kim Pettersson,
Jarkko U. Eskola and Eric Bertoft
Wallac Biochemical Laboratory, P.O. Box 10, SF-20101 Turku 10, Finland

Summary—Immunoassays based on europium labels and time-resolved fluorescence as the detection method, have been developed. The specific activity of the label is several orders of magnitude higher than that of radioactive labels. Consequently, the technique provides great potential, especially in the determination of analytes which require high sensitivity. Both competitive and immunometric assays which use labelled antibodies have been worked out. In competitive assays the antigen is immobilized on a solid phase with a protein carrier. The antigen in the standard or sample then competes with the labelled antibody in solution. Separation is done simply by washing the wells in the microtitre strip where the assays are performed. Model systems are described for the measurement of testosterone and cortisol. Immunometric assays of human thyrotropin (hTSH) and luteotropin (LH) were performed with monoclonal antibodies, by either a one-step (hTSH) or two-step (LH) incubation procedure. These assays, which exploit the specific activity of the label, give a very high sensitivity and good reproducibility. The standard curves are linear and the dynamic range is at least 1000-fold. Because of the properties of the europium label and the simple assay design, the immunoassays based on time-resolved fluorescence are expected to gain wide application both in research and in routine determinations.

Since the development of RIA and related saturation assay techniques by Berson and Yalow[1] and Ekins[2] in the late 1950s, the assays have been extensively applied to numerous analytes in routine work as well as in research. The basic procedure in RIA has been refined, but at least in clinical chemistry it is still the most widely used immunoassay technique. The wide use of radioactive labels in immunoassays has, however, increased awareness of the problems involved, *e.g.*, health hazards associated with the use and disposal of radioactive material, and the limited shelf-life of the labelled reagents due to the short half-life of the radioactive label and to radiolysis. A number of alternative non-isotopic techniques have been tested with the purpose of avoiding the disadvantages of radioimmunoassays without any decrease in the potential of the immunoassay technique as such. At present the most promising alternatives to RIA are enzyme immunoassay, chemiluminescence immunoassay and fluoroimmunoassay.

The sensitivity of most fluoroimmunoassay methods reported to date is, however, far lower than that of radioimmunoassay.[3] The limited sensitivity is caused by the high background signal which is always obtained in conventional fluorometric determinations, and which seriously limits the possibilities for exploiting the inherent sensitivity of the measurement principle. A tremendous increase in sensitivity is achievable by utilizing the difference in the fluorescence lifetime of the signal originating from different fluorescent compounds.[4,5] All conventional fluorescence, including that causing the high background which limits the sensitivity, has a half-life of

decay in the range 10^{-8}–10^{-9} sec. Consequently, if a europium chelate with a fluorescence decay time of 10^{-3}–10^{-6} sec is chosen as label and its specific fluorescence is measured after the background signal has decayed, an excellent sensitivity can be achieved. When time-resolved fluorescence is used, europium concentrations as low as $5 \times 10^{-14} M$ can be measured.[5,6]

The present communication describes immunoassay methods based on the use of europium as label and time-resolved fluorescence as the technique for determining it. The new immunoassay technique has been applied both in competitive and reagent-excess measurements on systems involving labelled antibodies. Model assays using solid-phase antigens or antibodies have been worked out for steroids and peptides. The advantage of the high specific activity of the label is obvious in the reagent-excess system, as an increased sensitivity can be achieved.

EXPERIMENTAL

Materials

Eu_2O_3 was obtained from Fluka. $EuCl_3$ was prepared by dissolving the oxide in hydrochloric acid and evaporating the excess of acid. Isothiocyanatophenyl–EDTA–Eu and other corresponding polycarboxylic acid derivatives were synthesized from the amino-derivatives of the europium chelate by condensation with thiophosgene in a water–chloroform mixture. After this the chloroform was removed and the isothiocyanate derivative was recovered from the aqueous phase mixture. The aminophenyl derivative of EDTA was synthesized by a modification of the Sundberg method.[7] The enhancement solution used for europium determination by time-resolved fluorescence[6] and the assay buffer consisting of $0.05M$ Tris–HCl, pH 7.7,

containing 0.9% sodium chloride, 0.05% sodium azide, 0.5% bovine serum albumin, 0.05% bovine globulin, 0.01% Tween 40 and 20 μM diethylenetriaminepenta-acetic acid, were obtained from LKB-Wallac, Turku, Finland. The monoclonal antibodies used in the peptide assays were obtained from Medix Laboratories Ltd., Kauniainen, Finland, and the polyclonal antibodies used in steroid assays came from Farmos Diagnostica, Turku, Finland.

The europium fluorescence was measured with a 1230 Arcus time-resolved fluorometer[4] (LKB-Wallac, Turku, Finland). In all assays polystyrene microtitre strips (Labsystems Oy, Helsinki, Finland) were used.

Labelling of antibodies

Depending on the conjugation conditions and the antibody preparations, a 50–300-fold molar excess of europium isothiocyanatophenylcomplexonate was used in conjugations performed in phosphate buffer at pH 9.0–9.3 and 4°, overnight. The europium-labelled antibody was separated from excess of label by gel-filtration on a Sepharose-6B column (1.5×70 cm) and eluted with $0.05M$ Tris–HCl buffer, pH 7.4, containing 0.9% sodium chloride and 0.05% sodium azide. The number of europium ions incorporated per immunoglobulin molecule was determined by measuring the fluorescence in comparison to that of known $EuCl_3$ standards.[6] On the average, 5–15 europium ions were incorporated per protein molecule. Bovine serum albumin (1 mg/ml) was added as carrier to the labelled antibody solutions.

Coating of microtitre strips

In immunometric assays the wells of polystyrene microtitre strips were coated with the antibodies, whereas in competitive assays protein-bound haptens were used.

Coating with antibody was performed by physical adsorption. Individual wells were treated with 0.2 ml of antibody preparation (5 μg/ml) in $0.1M$ phosphate buffer, pH 4.9, for 20 hr at room temperature, washed three times with saline, then saturated by treatment for 2 hr with 0.3 ml of $0.05M$ Tris–HCl buffer, pH 7.4, containing 0.9% sodium chloride, 0.05% sodium azide, 0.5% bovine serum albumin. The coated and saturated strips were washed twice with saline and stored humid at 4° until used.

Coating with protein-bound haptens was performed with cortisol- or testosterone-3–CMO–ovalbumin conjugates (CMO = carboxymethyloxime) prepared as described by Hosoda *et al.*[8] Individual wells were coated by treatment with 0.25 ml of protein-bound hapten preparation (0.05 μg/ml) in $0.1M$ sodium carbonate buffer, pH 9.3, overnight at room temperature. After coating, the wells were washed three times with $0.15M$ saline solution containing 0.05% sodium azide, after which they were ready for use.

Measurement of europium fluorescence

When the immunoreaction is complete, the label is dissociated from the antibody bound to the solid by adding an enhancement solution (200 μl) consisting of $0.1M$ acetate buffer adjusted to pH 3.2 with potassium hydrogen phthalate, and containing $15\mu M$ 2-naphthoyltrifluoroacetone, $50\mu M$ tri-n-octylphosphine oxide and 0.1% Triton X-100.[6]

RESULTS

Immunometric assay of peptide hormones

Monoclonal antibodies for different gonadotropic hormones have recently become available, and have been applied in combination with europium labels and time-resolved fluorometric detection. These antibodies suit immunometric assays well, as the two-site concept can be utilized in tests which require either

one or two incubation steps.[9] In addition, it is possible to use the reagent-excess technique,[10] as the supply of antibody is unlimited.

In the assay of hTSH two β-chain specific monoclonal antibodies are used. The hTSH sample or standard is reacted with a β-chain specific monoclonal antibody immobilized on the surface of microtitre-strip wells. The europium-labelled second monoclonal antibody, specific against a different site on the β-subunit, is added simultaneously with the analyte. Thus the whole assay requires only one incubation step. After thorough washing of the strip, the added enhancement solution dissociates into solution the europium ions from the labelled second antibody bound to the solid phase. In solution the europium ion forms a new and highly fluorescent chelate, and the fluorescence is directly measured in the microtitre strip well. The assay procedure is outlined in Fig. 1A and a typical standard curve is shown in Fig. 2. The dose–response curve is linear after the background of the zero standard has been subtracted, and the fluorescence intensity is directly proportional to the antigen concentration over the whole standard range, which extends from 0.25 to 324 μU/ml.

A precision profile calculated from 12 replicates of each hTSH concentration is also shown in Fig. 2. The whole working range of the assay is covered by a coefficient of variation (CV) that is 5% or smaller. The minimum detection limit, defined as the hTSH concentration corresponding to the mean fluorescence signal of 12 replicates of the zero standard plus 3 times the standard deviation, is 0.03 μU/ml—far below the lowest standard concentration used in the assay.

Cross-reactions obtained for the two monoclonal antibodies separately (RIA) and in combination (time-resolved fluoroimmunometric assay), are given in Table 1.

Figure 3 shows the correlation between the time-resolved immunofluorometric assay and a conventional competitive RIA for samples with hTSH levels either above (A) or below (B) 4 μU/ml. At concentrations above 4 μU/ml correlation between the two procedures is excellent whereas samples with hTSH levels below 4 μU/ml give poor correlation. Furthermore, in a number of samples the hTSH levels were not detectable by the RIA procedure. Only 3 samples among the 27 with hTSH levels below 1 μU/ml gave a negative result in the immunometric procedure.

The LH assay is performed with β-chain and α-chain specific monoclonal antibodies, respectively. The assay is performed in either one or two steps. The two-step assay procedure is outlined in Fig. 1B and a typical standard curve is shown in Fig. 4.

The fluorescence intensity is directly proportional to the LH concentration within a range from 1 to 125 IU/l. and the standard curve is linear after subtraction of the zero standard. The CV over the whole

Fig. 2. Standard curve (A) and precision profile (B) for the one-step hTSH assay, performed according to Fig. 1A. The reference values were measured by Imagura *et al.*[12] by enzyme immunoassay with fluorescent detection.

Table 1. The cross-reactivities of the two β-specific mono-clonal antibodies (I = solid-phase antibody, II = used for labelling) used in the hTSH assay, when measured separately (RIA) or in combination (TR–FIA)

Hormone	Cross-reactivity, %		
	I (RIA)	II (RIA)	I + II (TR-FIA)
hTSH	100	100	100
hLH	<0.4	0.5	2.3
hCG	<0.1	<0.02	<0.001
hTSH β-subunit	195	<1.0	1.8
hFSH	—	—	1.8

assay range is below 8%. The detection limit (mean of the zero sample + 3 standard deviations) was found to be 0.04 IU/l. when a 100-μl sample volume was used. Table 2 shows the cross-reactivity of the two monoclonal antibodies employed, when measured separately in a conventional RIA and in combination by the assay procedure described in Fig. 1B. Cross-reactivity with hCG is rather high, and the clinical situation has to be taken into account when the assay results are evaluated. In the process of ovulation the hCG level is virtually zero and a rapid increase in the LH level occurs. There is good correlation between the time-resolved fluorescence method and a conventional RIA for LH.

Competitive steroid assays with labelled antibodies

To avoid the need to label different antigens with a europium chelate and with the intention of making the separation step required in competitive assay procedures as simple as possible, the conventional assay design was abandoned and an antibody-labelled competitive technique was designed. In this technique a known amount of antigen is immobilized on the solid phase. The standard or sample is added immediately before the labelled antibody. The immo-

bilized and free antigen will then compete for the binding sites on the labelled antibody. After a 1-hr incubation at room temperature, the microtitre strip wells where the assay is performed are washed, and the amount of europium-labelled antibodies bound to the solid phase is determined by adding the enhancement solution and measuring the europium fluorescence by time-resolved fluorometry. The assay design is outlined in Fig. 5. A standard curve similar to that obtained in a conventional competitive RIA is constructed and the analyte concentration of the samples is read. Assays as described above have been worked out for both testosterone and cortisol.
Fig. 3. Correlation between RIA and time-resolved assays of hTSH in serum samples with an hTSH concentration above (A) or below (B) 4 μU/ml.

Table 2. The cross-reactivities of the β- and α-chain specific monoclonal antibodies used in the LH assay, when measured separately (RIA) or in combination (TR-FIA)

Hormone	Cross-reactivity, %		
	Anti-β (RIA)	Anti-α (RIA)	Both antibodies (TR–FIA)
LH	100	100	100
hCG	62	28	62
hTSH	14	24	10

The effect of the amount of the solid-phase antigen and labelled antibody in the testosterone assay has been investigated in detail. Figure 6A illustrates a typical result when the amount of testosterone immobilized by physical adsorption as a testosterone-3–CMO–ovalbumin conjugate on the solid phase, is varied. A constant amount of labelled antibody was used, in the absence (B_0) and presence (B) of free steroid in solution. In absence of free testosterone, the solid phase is saturated with the steroid conjugate at a concentration of about 2 pmole per well. The signal from the europium-labelled antibody bound to the solid-phase antigen reaches a constant level. In the presence of a free testosterone concentration corresponding to the level of the highest standard in an actual assay, the signal increases as the amount of immobilized antigen on the solid phase increases. If the fraction bound is plotted against the immobilized-antigen concentration, it becomes obvious that the best replacement is obtained at a relatively low amount of antigen on the solid phase (Fig. 6B) which favours competition between the amounts of bound and free antigen. At low solid-phase antigen concentrations various amounts of labelled antibody can be used without any critical effect on the performance of the assay. A testosterone-3–CMO–ovalbumin concentration of 0.05 μg/ml for coating the microtitre-strip well and 25 ng of europium-labelled antibody preparation per well were found optimal.

A standard curve and a precision profile for the testosterone assay covering the range of clinical inter-
Fig. 6. (A) The effect of different amounts of testosterone immobilized on the solid phase (as a testosterone-3–CMO–ovalbumin conjugate) on the fluorescence signal obtained with a constant amount (25 ng, 5 Eu/IgG) of labelled antibody. The assay was done in the absence ($\triangle$) and presence ($\blacktriangle$, 300 nM, 50 μl sample volume) of free testosterone in solution. The total volume was 200 μl and the incubation time 90 min at room temperature. (B) The effect of the immobilized testosterone concentration on the fraction of labelled antibody bound to the solid-phase antigen in the presence of 300 nM free testosterone.

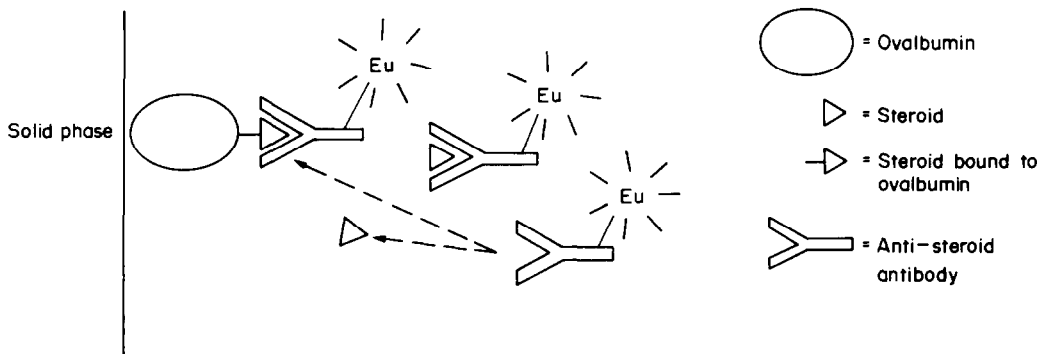
est is shown in Fig. 7. The precision over the assay range lies between 18 and 6%. Correlation between the new time-resolved fluorescence assay and conventional RIA was found to be good when extracted serum samples were used (Fig. 8).


Fig. 5. The principle of the competitive time-resolved fluoroimmunoassay of steroids, based on a europium-labelled antibody assay and a constant amount of immobilized steroid on the wall of microtitre-strip wells. After the competitive immunoreaction has been completed, the label is released into solution by addition of the enhancement solution.
Fig. 7. Dose–response curve (■) and precision profile (●) for the time-resolved fluoroimmunoassay of testosterone. The assay conditions were as described in Fig. 6A and a solid-phase antigen concentration of 0.23 pmole of testosterone per well was used.

A similar assay procedure has also been developed for cortisol. However, it is a direct test and thus no pretreatment of the serum samples is required. The assay has been optimized in the same way as the testosterone assay. Figure 9 shows the effect of three different amounts of the cortisol-3–CMO–ovalbumin conjugate on the shape of the standard curve for cortisol within the clinically relevant range. The fraction bound (B/B_0) at different standard concentrations decreases as the amount of antigen bound to the solid phase is reduced, as will of course the actual amount of labelled antibody bound to the solid phase at each concentration. The fluorescence signal level in the assay is dependent on the number of europium
Fig. 9. Standard curves for a competitive time-resolved fluoroimmunoassay of cortisol with three different amounts of cortisol-3–CMO–ovalbumin immobilized on the walls of microtitre strips: ● 3.5, ○ 1.7 and △ 0.9 pmole of cortisol per well. The assays were done with a sample volume of 20 μl and a total volume of 120 μl, with 50 ng of labelled antibody (5 Eu/IgG) in the assay buffer. Incubation was 1 hr at room temperature. B_0 was 4.05×10^5, 2.30×10^5 and 1.33×10^5 cps, for the three solid-phase antigen levels (in order of decreasing concentration).

ions conjugated to the labelled antibody, but the level can be further adjusted by varying the amount of labelled antibody within a certain limit. Consequently, the fluorescence signal in the assay is modified by varying the parameters during the optimization of assay conditions.

Figure 10 shows the correlation between a conventional RIA and the time-resolved fluoroimmunoassay of cortisol with labelled antibodies. The coefficient of variation (CV) within the assay range was below 11%.

DISCUSSION

The results obtained in immunometric and competitive assays, both of them based on a labelled-antibody technique, show that sensitive, rapid and simple assays can be developed with europium as the label and time-resolved fluorescence as the detection method. The long decay time of the europium label is utilized to eliminate the background problem which previously limited the applicability of fluorescent labels in assays requiring high sensitivity. In the assays, the europium ion is actually bound to the antibody as a non-fluorescent chelate.[6] Consequently, only the chelated metal ion is used as the label during the immunoreaction, and the europium fluorescence is developed after the ion is released by dissociation in the presence of an enhancement solu-
Fig. 8. Correlation between RIA and time-resolved fluoroimmunoassay of testosterone. Serum-based standards of unknown samples (100 μl) were extracted for 15 min with 1 ml of freshly prepared diethyl ether–ethyl acetate mixture (9:1 v/v); a 400-μl portion of the ether phase was evaporated under a stream of air, after which 120 μl of assay buffer were added and the sample was left for at least 30 min before duplicate 50-μl samples were taken for the measurement.

tion which contains the energy-absorbing ligands required for the formation of a fluorescent chelate. The situation is very favourable in regard to the measurement of fluorescence because excitation and emission occur in solution and not on a solid phase. In solution, europium concentrations as low as $5 \times 10^{-14} M$ have been determined by use of the present systems, and as a number of europium ions can be coupled per antibody molecule, prospects for obtaining assays with even higher sensitivity exist.[5,6] The specific activity of the label, calculated on the basis of the measurement in solution, is actually 10^6 times that for ^{125}I, which is most commonly used in assays employing radioactive labels.[4]

The europium label can be used as in both competitive and immunometric assays. The competitive assays are based on a labelled-antibody technique to avoid the need to label every separate antigen, and hence avoid the difficulties involved in such steps. Furthermore, the use of the immobilized-antigen technique in competitive assays greatly simplifies the procedure, and all stability problems connected with the solid phase are eliminated. The performance characteristics are at least as good as those of conventional competitive techniques employing radioactive labels.

The immunometric assay design benefits more extensively from the properties of the europium label. As shown before, assays with a higher sensitivity than that normally achieved with radioactive labels are obtained, for the same assay principle. The reason for the improved performance can be traced back to (a) the labelling, which does not affect the properties of the antibody, (b) the high specific activity of the label, and (c) the large excess of labelled antibody that can

be used in the assays with no increase in non-specific binding. Of these causes, the last is probably the most important. In principle it should be possible to obtain similar performance characteristics with the same immunocomponents by using a radioactive label such as ^{125}I, but a tremendous amount of radioactivity would have to be added, which in practice would cause several undesirable effects. The experimental results are consistent with the theoretical optimization of immunoradiometric assays.[11]

Besides high sensitivity, the immunometric assays based on europium labels have a number of other benefits. The europium concentration can be measured over a wide dynamic range and as the capacity of the antibody immobilized on the solid phase is large and a considerable excess of the labelled antibody is used, an assay with an extraordinarily wide dynamic range is obtained. The benefit of the wide range is, of course, dependent on the degree of variation in the analyte concentration in clinical samples. It will, however, be of greater importance in the future as improved sensitivity in the assays widens the detectable concentration range for a number of analytes and facilitates important research on their clinical importance; hTSH is a typical analyte belonging to this category, because in conventional methods difficulties arise in measurement of concentrations at normal levels and below.

The standard curve in immunometric assays is linear after the background signal has been subtracted. Because of this it becomes possible to reduce the number of standards required. Assays can even be performed with only one standard and a blank. This property can be utilized to full extent when a stable label-preparation is used. However, replication of the standard will improve the precision.

Both the competitive and immunometric assays have been based on use of the wells of polystyrene microtitre strips as the solid phase. In each case handling becomes simpler, since the separation step in the solid-phase assays is accomplished by washing the wells, which can be done with a variety of commercially available devices designed for the purpose. The only additional step [apart from the incubation(s) and washing] currently needed in the time-resolved fluorescence assays is the addition of enhancement solution before the 1-sec measurement in the fluorometer. The total assay time, including the immunoreaction(s), is dependent on the quality of the antibodies used. Several of the assays can be done in 1 hr or less, as the fast and easy handling eliminates the error caused by slight variations in incubation times when equilibrium is not reached. In practice, however, the number of tests in fast assays must be limited to 1 microtitre plate (8 strips). Monoclonal antibodies contribute to the simplicity of the procedure in immunometric assays, as some of the tests can often be performed with a single incubation, with all the components required added in one step. A one-incubation, multi-site, solid-phase assay of

human pancreatic phospholipase A_2, based on time resolved fluorescence, has been developed recently, and was successful even though a polyclonal antibody was used.[13]

CONCLUSIONS

Europium ions as labels and time-resolved fluorometry as the detection method have been shown to provide an alternative of high potential in the field of non-isotopic immunoassays. The high specific activity, which exceeds that of radioactive labels, makes the europium label ideal in assays requiring high sensitivity. The label can be applied both in competitive assays using a labelled-antibody technique, and in immunometric assays. In both types of assay high sensitivity and excellent precision have been obtained, and the immunometric assays give a linear range of at least 1000-fold.

The combination of solid-phase assay with the stable label and fast and sensitive detection principle results in rapid tests that are easy to handle. The technique is predicted to have a wide application in a variety of immunoassays in both research and routine determinations in the near future.

IMMUNOASSAYS IN AQUEOUS TWO-PHASE SYSTEMS

TORBJÖRN G. I. LING and BO MATTIASSON

Pure & Applied Biochemistry, Chemical Centre, P.O. Box 740, S-220 07 Lund, Sweden

Summary—Aqueous two-phase systems provide a novel and convenient method for separating bound from free fractions in a binding assay. The ease of automation of this type of procedure makes it particularly attractive for separations based on immobilized ligands or binders or on adsorbents.

In order to determine the degree of binding in a ligand:binder assay, the amount of free and/or bound reactant must be measured. This generally requires a separation step. There are exceptions to this rule, but there is no general method that avoids separation. In an effort to meet at least some of the requirements for a fast and simple assay we have developed the so-called "partition-affinity ligand assay" (PALA). The method involves a binding reaction and subsequent separation by partition in an aqueous two-phase system.

In aqueous two-phase systems, both phases contain 85–95% water together with a water-soluble polymer or a salt. The systems based on poly(ethylene glycol) (PEG), and dextran have been studied extensively. In these systems the PEG is mainly in the upper phase, and the denser phase is rich in dextran. The systems are biocompatible because of their high water content and the extremely low surface tension (in many cases less than 0.1 dyne/cm).

When a substance is added to a two-phase system, it will partition between the phases according to the surface properties of its molecules. The partition behaviour is characterized by the partition coefficient, K_{part}, which is the ratio of the concentrations in the top phase to that in the bottom phase.

The principle for studying direct binding reactions in aqueous two-phase systems is schematically illustrated in Fig. 1. The composition of the phase system is chosen so that the antigen partitions into one phase (Fig. 1a) and the antibody into the other (Fig. 1b). The degree of binding is then a function of the displacement of antigen when antibodies are added to the system and antigen is moved to the phase into which the antibodies partition (Fig. 1c). In practice, neither reactant is completely partitioned into one of the phases, but the two partition coefficients give the range for the calibration curve.

The separation step in a binding assay must be highly reproducible and preferably fast as well. This means that when phase systems are used for separation, the effects of salts and other substances that influence partitioning should be minimized. It also means that long multi-step procedures should be avoided. Both these requirements imply the use of an effective separation procedure and can be met by employing an antibody with strongly selective partitioning into one of the phases and thus low sensitivity to change in the composition of the phase system.

Requirements for separation

Proper partitioning of the antibody can be accomplished by choosing a proper phase system,[1,2] or if necessary, by modifying the surface structure of the antibody[3-5] in order to make it partition practically exclusively into one of the phases. Such modified binding structures have been called *separator molecules*.

Partition-affinity ligand assays can only be set up when the differences in partition behaviour between the reactants are sufficiently large. The character of the label used and the binding characteristics of the antigen–antibody interaction, as well as the reactant concentrations influence the overall partitioning. In general terms, however, when the ratio of the partition coefficients is greater than 10 it is possible to set up a manually interpreted assay. In this case the partition coefficient can be regarded as an approximation of the bound/free ratio. As will be discussed later, even small differences in the partition coefficients may be sufficient if an evaluation method
Fig. 1. Schematic representation of a direct binding assay between antigen and antibody. (A) The antigen partitions into the top phase and (B) the antibody partitions into the bottom phase. (C) Binding is observed as a displacement of antigen from the top phase to the bottom phase.
Fig. 2. Calibration curve for a competitive assay of digoxin. Native and iodine-labelled digoxin partitioned into the top phase, whereas the antibodies partitioned into the bottom phase. The radioactivity in the top phase is given as a function of added native digoxin. (From Mattiasson,[1] by permission of the copyright holders.)

that compensates for the incomplete separation is utilized.

In assays of haptens favouring the top phase, a very favourable situation occurs. In the case of digoxin, for example, the partition coefficient for the digoxin is 4.0 and for the antibody against digoxin 0.30. Furthermore, the reactants differ in size

sufficiently for the complex formed to partition in the same way as the native antibody. By measurement of the decrease in label concentration in the top phase and/or the concomitant increase in the bottom phase at constant concentration of antibodies and labelled digoxin, the concentration of the native digoxin can be obtained by interpolation in a calibration curve.

A typical calibration curve is shown in Fig. 2. Several haptens behaving like digoxin have been determined (Table 1). When the molecules are equally large and/or favour the same phase as the antibodies do, a much more complicated situation occurs. In such cases one of the reactants has to be modified in order to change its partition behaviour. Several possibilities for overcoming this problem are discussed in the following section.

In a study of molecules of similar molecular weights (less than one order of magnitude difference) and similar partition behaviour, the interaction between the lectin concanavalin A (Con A) and the glycoenzyme, horseradish peroxidase (HRP), was examined. The system was designed to study binding of sugars in a competitive assay where the carbohydrate competed with the carbohydrate entities of the peroxidase molecule for binding to Con A. The enzyme part of the glycoprotein was thus utilized as an enzyme label on the carbohydrate. In the phase system used, K_{part} for HRP was 0.12 and for Con A 0.031.

In order to solve the separation problem, a rather drastic change in the partition behaviour of one of the entities was necessary. The aim, besides changing K_{part}, was to make the complexes formed by binding partition into the same phase as the modified reactant. The binder, Con A, was modified, because modification of the carbohydrate was inconvenient.

Table 1. Partition-affinity ligand assay—immunoassays of different antigens

*Labelled reactant.
Label: HRP = Horseradish peroxidase.
Type: Comp = competitive assay; Dir = direct binding assay.
Time: I = reaction period (at room temperature); S = time allowed for phase separation.

Table 2. Methods used for activation of PEG

Activating agent	Time for activation	Coupling		
		Time, hr	pH range	Reference
Triazine	1 hr	3	8.7	8
Tresyl	15 min	16	7.5–9.5	9
Epichlorohydrin	16 hr	3	8.5–11.0	17
Carbonyl di-imidazole	15 min	3–5	5.5–8.5	18

The modification strategy was to introduce groups onto the surface of the molecule to make it favour one of the phases.

Modification has mostly been effected by covalent attachment of a polymer, e.g., PEG, to make the substance partition into the PEG-rich top phase.[3-5] To prevent the formation of cross-linked complexes of the binder, a monomethoxy-PEG was used. Several methods for PEG-activation and coupling to the protein have been tried (Table 2). On the other hand, addition of dextran in the form of the single polymer[6] or cross-linked in Sephadex particles,[1] enables the substance to partition into the dextran-rich (or salt-rich) bottom phase. Organic moieties such as phenyl groups and alkyl chains (octyl, dodecyl) have also been used for modification.[6] The formation of an antibody–enzyme conjugate can also be regarded as a modification of the antibody, since it is possible to change its partitioning in this way.[7]

The methods for modification with PEG have been developed at various laboratories since PEG-modification of various biological macromolecular structures became important. Abuchowski et al.[8] introduced triazine activation of PEG, a method we have used in many of our applications. The tresyl-modification method has also been successfully applied and is now our routine process.[9]

When antibodies are modified by attachment of PEG, their surface properties are altered, giving them a higher partition coefficient. However, the PEG molecules may sterically hinder binding reactions. Highly modified antibodies have a significantly decreased binding capacity and if PEG-modified antibodies are to be used in an assay, they should be able to partition predominantly into the top phase and also retain a fair amount of their binding capacity. Each batch of modified antibodies has, therefore, been tested for the ability to bind antigen and move it to the top phase.[3-5] This ability has been called the transport capacity. For most types of binding structures, the degree of modification has an optimum.

Optical properties

If the partition assay is to be done with limited facilities (e.g., in the field), it should be advantageous to use a phase system that is optically clear in order to permit use of a colorimetric assay for direct registration of the enzyme activity in one of the phases. With conventional systems, it is possible to obtain one clear phase by changing the volume ratio of the phases. It is also possible, by careful selection of polymers, to set up a system that separates directly into two optically clear phases.[10]

Immunoassay procedure

An immunoassay for use in the field must be simple, quick and easy to operate. How does the PALA method meet these demands?

A typical test is performed in a test-tube, in which the labelled antigen (in a small volume of buffer) is mixed with the sample to be assayed. A fixed amount of antibodies is added and binding takes place. The kinetics of the binding reaction are difficult to alter, but since the assay procedure involves a quick separation step, it is possible to terminate the binding step long before equilibrium is attained, without degrading the analytical result. Phase separation takes place within seconds after addition of the fine dispersion of the two phases.

If the assay is to be performed by direct reading of the distribution of enzyme activity in the phase system, then the substrates must be added with the phase system. Ultimately, all the steps—binding, separation and reading—can take place in the same test-tube. If only semiquantitative results are required, visual determination of the activity in the two phases might be enough.

Otherwise an aliquot of either phase may be removed, mixed with substrate and assayed. There are few manual steps involved in the process. In theory, at least, this should give good accuracy and also easy automation, as discussed later.

Binding analysis

The art of performing binding analyses is often the art of separating free and bound antigen. Most of the separation methods used in biochemistry have also been used in binding analyses. A good separation method must be able to separate the reactants without perturbing the binding reaction. This statement may sound superfluous, but the perturbation effect is not always easy to avoid and its consequences may be difficult to establish.

After the degree of binding has been determined in an analysis, the data may be used for calculation of the association constant or stoichiometry of the reaction. The interaction between a protein, P, and a ligand L, produces a complex, PL.

$$P + L \xrightarrow{K_{ass.}} PL$$

If the complex is completely isolated during the separation process, the complex will dissociate

slightly and after some time establish equilibrium. In practice, complete separation does not occur, but many methods are designed to remove most of the free reactants and thus introduce risk of dissociation of the complex. Another factor that governs the dissociation is, of course, the magnitude of K_{ass}. However, even if the complex is not thermo-dynamically stable, it may be kinetically stable (i.e., the dissociation is slow).

It is thus evident that a separation method that is to be used in analytical procedures must not only be highly reproducible but may also have to be precisely timed.[11]

Another problem that may occur involves inter-actions between the reactants and the material used in the separation process. Many binding reactions are studied in a very low concentration range ($pM-\mu M$) and are thus very sensitive to perturbations, e.g., adsorption on plastic reaction vessels, ultrafiltration membranes,[12,13] or gel-filtration media. Thus the com-monly used method of equilibrium dialysis has an inherent weak point. This method is often used for determining binding between a protein and a low molecular-weight ligand. Many of the ligands studied are rather hydrophobic in nature, have low solubility in aqueous buffer solutions and are prone to ad-sorption on the dialysis membrane. Such adsorption may be strong enough to completely distort the outcome of a binding analysis.[12,14] Problems of this kind are not very often discussed in the literature. The interpretation of binding data from equilibrium di-alysis experiments has, however, been found in some cases to be inadequate.[13]

The preparation of bound and free reactant in aqueous two-phase systems has, in this respect, two advantages.

1. The degree of separation can be controlled. It is reproducible between different batches of phase systems[15] and is not time-dependent after equilibrium has been reached.

2. There are generally no problems with ad-sorption of biomolecules. However, particles and very large protein aggregates may be adsorbed at the interface.

We have used a method evaluating results from binding analyses where neither reactant is completely partitioned into one phase. It is, however, required that the reactants are preferentially partitioned into different phases and that their partition coefficients are known. The interaction of a ligand, L, with a protein, P, in a two-phase system can be represented by the following scheme (the stoichiometry is not considered at this point):
The partition coefficient, K_{part}, is defined as the ratio of the concentrations in the top and bottom phases:

$$K_{part} = C^t/C^b \qquad (1)$$

The superscript t denotes the top phase and b the bottom phase. After the total amount of label in each phase has been determined the evaluation can start.

$$C^t_{L,tot} = C^t_L + C^t_{PL} \qquad (2)$$

$$C^b_{L,tot} = C^b_L + C^b_{PL} \qquad (3)$$

The total concentration of complex and concen-tration of free ligand are now to be determined. The following set of equations is used and solved by iteration.[5,10] As an initial approximation, $C^t_{L,tot}$ is used instead of C^t_L in equation (1).

$$C^b_L = C^t_L/K_{part,L} \qquad (4)$$

$$C^b_{PL} = C^b_{L,tot} - C^b_L \qquad (5)$$

$$C^t_{PL} = C^b_{PL} \times K_{part,PL} \qquad (6)$$

$$C^t_L = C^t_{L,tot} - C^t_{PL} \qquad (7)$$

In equation (7) a new value of C^t_L is obtained and can be used in equation (4). The calculations proceed until the same values are obtained in two successive steps.

This method has been used to evaluate binding analyses of the interactions between serum albumin and Cibacron Blue[12] and in competitive immu-noassays involving binding of β_2-microglobulin to antibodies.[5] A more detailed description of the evalu-ation procedure has been published.[5,12] The method is only a basic concept and can be further developed for calculations involving more complicated binding situations.

AUTOMATION

A particular advantage of using aqueous two-phase systems for separation in analysis is that the steps of the assay are mechanically simple. The separation is initiated by the mixing of the phase components and terminated by withdrawal of a sample from one of the phases. The steps of the PALA are as follows.

1. Mixing of the reactants for the binding reaction (e.g., sample, antibody and antigen–enzyme conju-gate).

2. Addition of the phase system. Enzyme sub-strates might be included. Mixing.

3. Withdrawal of sample from one of the phases for determination of enzyme activity. The sample is mixed with substrate if this was not done in the previous step.

Steps 1 and 2 are necessary for the assay. In some cases step 3 may be excluded and the result read directly, e.g., by visual determination. Each step can be automated without loss of control of the process.

$$
\begin{array}{ccccc}
P & + & L \underset{K^t_{ass}}{\rightleftharpoons} PL & & \text{top phase} \\
\updownarrow K_{part,P} & & \updownarrow K_{part,L} & \updownarrow K_{part,PL} & \\
P & + & L \underset{K^b_{ass}}{\rightleftharpoons} PL & & \text{bottom phase}
\end{array}
$$

Commercial equipment available can easily be adapted for use with the PALA-technique. A disadvantage is that such equipment is dedicated and unnecessarily sophisticated and expensive. It is, however, also possible to assemble an automatic PALA analyser from equipment commonly available in biochemical laboratories.

Design

The PALA analyser consists of a conveyor belt (or a fraction collector) having three stations, three dual-channel peristaltic pumps, a photometer and a microcomputer.

The three steps mentioned above can be executed in the following way. The samples are manually distributed in test-tubes and put on the conveyor belt. At the first pump station, antibody and antigen–enzyme conjugate are added by delivery of a controlled volume of each. After a predetermined time, set by the speed of the belt and the number of test-tube positions between the stations, the test-tube arrives at the second station. Here, the phase components are added by dual-channel pump. Each piece of tubing has a narrow outlet, thus giving a fine jet which hits the liquid forcefully, resulting in instantaneous mixing. After a second time interval, which is long enough to allow the phases to settle, the test-tube comes to the last station, where a sampling needle is brought down into one of the phases. If necessary, a dual-channel pump can be used, so that the aliquot taken can be mixed with buffer and enzyme substrate, or other reagents.

Equipment

Conveyor belts are commercially available, but rather expensive. A modified fraction collector, can be used instead. A fraction collector of carousel type, having all the test-tubes in a circle, is advantageous, since this makes it easy to have the stations in the proper positions. The timer in the collector can be used for initiating the operations at the different stations.

Pumps

Almost any type of peristaltic pump can be used. It should be checked that it can be controlled externally by a microcomputer and that tubing with diameter suitable to allow flow of the somewhat viscous phase components is available.

Photometer

Any simple spectrophotometer and many filter photometers can be used, provided the instrument can be equipped with a flow cuvette and that it has a connector for external read-out. Depending on the intended use, ruggedness of the model may be a more important consideration.

Microcomputer

Many microcomputers that can be used for control and data-acquisition are available. Important factors when choosing a system are portability, data-storage capacity and availability of interface cards for connection of external equipment. We have used an ABC80 (Luxor AB, Motala, Sweden), equipped with one interface card for controlling the conveyor belt and the pumps and one A/D-converter for reading the photometer.

DEVELOPMENT OF A LIGHT-SCATTERING IMMUNOASSAY FOR THYROXINE-BINDING PREALBUMIN IN PLASMA OR SERUM

K. SPENCER

Department of Biochemistry, Oldchurch Hospital, Romford, Essex, England

Summary—This paper describes the development of an assay for the measurement of thyroxine binding prealbumin in plasma or serum, based on the technique of fixed-time kinetic immunoturbidimetry with the Cobas Bio centrifugal analyser. The assay has good precision (coefficient of variation <5%) and a detection limit of 15 mg/l. The assay is rapid, economical, and the results compare well with those obtained by an established procedure. The technique has wide applicability to instruments which can make kinetic measurements and could prove useful in the clinical monitoring of patients receiving nutritional support and in the identification of nutritionally-at-risk groups prior to surgery. The assay further emphasises the sensitivity and usefulness of kinetic immunoturbidimetry for the measurement of low concentrations of proteins.

In the last decade there has been an increasing interest in the nutritional status of patients in hospital, both by the doctors looking after them and the pharmaceutical industry providing nutritional products. Recent North American surveys have indicated that up to 50% of such patients may be suffering from clinical and subclinical malnutrition.[1,2] Evidence directly linking malnutrition with increased morbidity and mortality is not hard to find, since loss of weight and combined nitrogen may be rapid after injury or during any illness, because of a combination of increased breakdown of body tissue and insufficient food intake. Some of this evidence has been recently reviewed by Woolfson.[3] Clearly, for a whole range of different medical and surgical conditions there are distinct advantages in improving nutrition by assisting, or replacing the patient's ordinary diet.

Total parenteral nutrition is increasingly used in the correction of nutritional deficiencies, but is expensive. Clearly a practical and sensitive method for the early detection of subclinical protein and energy malnutrition and for assessing the adequacy of dietary treatment and nutritional support, would be useful.

Measuring plasma albumin has been the mainstay of nutritional screening in clinical practice, but the long half-life (19 days) limits its usefulness in following the rapid nutritional changes that need to be monitored in patients receiving total parenteral nutrition. Plasma transferrin is also reduced in severe protein and energy malnutrition, but its usefulness in the detection of subclinical malnutrition is limited because of its relatively long half-life (8 days), the effect of iron status, its "acute phase" response to infection and stress, and the buffering ability of a good nutritional state.[4]

The use of rapid-turnover transport proteins such as thyroxine-binding prealbumin (TBPA)[4–6] and retinol-binding protein (RBP),[4–6] with biological half-lives of 48 and 12 hr respectively, has been shown to be very sensitive to changes in both dietary protein and energy over very short time periods.[4,6] It appears that these proteins will prove useful in the assessment of nutritional support and in the early detection of subclinical protein and energy malnutrition.

It must be borne in mind, however, that changes in both liver disease and chronic renal disease may influence the levels of such proteins. Furthermore TBPA is also a negative acute-phase reactant and care may be needed in some situations in interpreting the data.

The protein TBPA has a molecular weight of 5.5×10^4 and migrates faster than albumin in cellulose acetate electrophoresis. The protein also binds the smaller (m.w. 2.1×10^4) RBP and thyroxine. TBPA has usually been measured by a variety of time-consuming or imprecise immunological techniques which include radial immunodiffusion[5] and electroimmunoassay.[6,7] More recently, light-scattering immunoassay has proved to be a sensitive, precise, rapid, easily automated alternative to these time-honoured gel-precipitation methods for proteins.[8,9] The technique of light-scattering immunoassay has been based on use of dedicated analysers employing nephelometric detection[8–10] or on use of kinetic analysers and spectrophotometers, with turbidimetric detection.[8,9,11] The kinetic turbidimetric approach has much to commend it in terms of flexible use of equipment, superior precision, less effect of analyser and reagent noise, and comparable sensitivity.[12] In particular, "enzyme analysers" such as the LKB reaction-rate analyser have proved very useful,[13–17] as have centrifugal analysers.[11,18–20]

The precision and sensitivity of immunoturbidimetry now seem comparable with those of nephelometry (unless some form of sample pre-

treatment is used),[8,9,12] thus raising the question of the need for dedicated nephelometric instruments. Centrifugal analysers seem very well suited for the purpose, with their very precise control of timing, mixing and temperature, and the use of sophisticated microprocessor or computer facilities for analysing kinetic data.[21] One such commercial instrument (Cobas Bio) has a novel optical system in which absorbance measurements are made with the cuvettes lying longitudinally in the light-beam, and the light-source is a pulsing xenon tube.[22] The advantages of this type of optical arrangement over other types of photometric system have been outlined.[23]

This paper outlines the development of a fixed-time kinetic immunoturbidimetric method for the measurement of thyroxine-binding prealbumin with the Cobas Bio centrifugal analyser.

EXPERIMENTAL

Instrumentation

The Cobas Bio Centrifugal Analyser (Roche Diagnostics, P.O. Box 8, Welwyn Garden City, Hertfordshire, U.K.) was used to collect absorbance data. Data-processing of absorbances and calibration curve-fitting were done with a third-order polynomial routine on an Apple II computer.

Reagents

All reagents were obtained from British Drug Houses, Poole, Dorset, and were of "AnalaR" grade or equivalent except where stated.

Phosphate-buffered saline. Prepared by dissolving 5.85 g of sodium chloride, 9.10 g of dipotassium ethylenediaminetetra-acetate dihydrate, 7.16 g of disodium hydrogen phosphate and 1.33 g of potassium dihydrogen phosphate in 950 ml of distilled water, adjusting to pH 7.40 ± 0.02 and diluting to 1 litre with distilled water. The buffer was stable for at least three months when stored at 4°. Its composition is $0.05M$ phosphate, $0.1M$ sodium chloride and $0.0225M$ EDTA. The EDTA minimizes variation in the effect of calcium and magnesium.[8,9]

Phosphate buffer with polyethylene glycol 6000. Prepared by dissolving 40 g of polyethylene glycol 6000 (PEG) in 800 ml of phosphate-buffered saline and diluting to 1 litre with the saline. This solution was stable at 4° for at least three months.

Stock antihuman thyroxine-binding prealbumin antiserum. Rabbit antihuman thyroxine-binding prealbumin was obtained from Hoechst Pharmaceuticals, Hounslow, Middlesex, U.K. (Product Number ORCA 05). To produce a working antiserum solution, the required volume of antiserum was appropriately diluted with phosphate-buffered PEG reagent. After 15 min at room temperature the working reagent was centrifuged (1750 g, 10 min) to remove any precipitate formed.

Standards and quality-assurance materials. A stabilized standard human serum (Hoechst Pharmaceuticals, Product Number ORDT 07) was diluted stepwise with $0.1M$ sodium chloride, to provide a series of five standards covering the range 35–560 mg/l. Protein standard serum B (Hoechst Pharmaceuticals, Product Number OTFG 07) was used for quality-control of the assay.

Procedures

Kinetic immunoturbidimetry. Table 1 summarizes the final assay conditions, including the instrument settings for the Cobas Bio analyser. The antiserum was diluted 1:9 with phosphate-buffered PEG. The sample, diluent and reagent volumes and all other variables of the analyser were set by

19	Print-out mode	1

the microprocessor when the required program was called. Cuvette 1 contained a reagent blank and cuvettes 2–6 contained appropriate standards. The analyser, operating at 25° and 290 nm, took absorbance measurements every 10 sec after mixing and the change in absorbance between 1 and 300 sec after mixing was multiplied by 1000 and printed out for each cuvette.

The absorbance data from the Cobas Bio were manually fed into a microcomputer and the calibration curve computed by using a third-order polynomial; the results for test samples were then calculated from this standard curve. Alternatively the results can be calculated graphically.

Radial immunodiffusion (RID). Radial immunodiffusion assay was done with Hoechst M Partigen immunodiffusion plates (Product Number OTBW 03). The diffusion rings were evaluated with a calibration graph obtained by plotting the square of the diameter against concentration of thyroxine-binding prealbumin for standard solutions.

RESULTS

Study of immunokinetic assay conditions

Factors likely to affect the antigen–antibody reaction and its kinetics have been described in detail elsewhere.[8,9,13] The reaction of TBPA with the antiserum was studied in relation to the following variables.

pH. In contrast to previous experience[13–15] which showed no significant pH optima, the TBPA system had a distinct optimum pH of 7.40.

Sodium chloride. The ionic strength of the reaction medium and the charge-density of the ions present significantly affect the kinetics of the antigen–antibody reaction.[9] Previous studies[13–16] have demonstrated the chaotropic effect of chloride ions; increasing the chloride ion concentrations decreases the rate of reaction. The addition of sodium chloride to the TBPA system increased the absorbance change, the effect being maximum at 0.1M sodium chloride concentration in the buffered PEG. Further increase in sodium chloride concentration resulted in a marked decrease in the absorbance change.

Temperature. The effect of temperature on antibody–antigen reactions has been investigated by several authors but no clear picture has emerged. Price and Spencer,[24] in a study of over 35 antisera against 8 antigens, found temperature coefficients (Q_{10}) varying from $+40\%$ to $+120\%$ increase in reaction rate for a $10°$ temperature rise from $25°$. The data for the TBPA assay indicate a significantly increased sensitivity if the assay is run at $25°$, with a Q_{10} (25–$35°$) of $+89\%$ for the Hoechst antiserum.

Enhancement by polymer. The effect of PEG 6000 on the antigen–antibody reaction was studied by diluting the antiserum with PEG reagents of increasing concentration. The possibility of kinetic blank-reactions[16] was also investigated by studying the response in the absence of antiserum with a saline blank as reference. The results indicated an optimum PEG reagent concentration of 60 g/l. (46.9 g/l. in the final reaction mixture); however, at this concentration, non-specific precipitation, contributing to a kinetic sample-blank, was observed. It was therefore decided to choose a PEG concentration of 40 g/l. (31.3 g/l. in the final reaction mixture) since the sensitivity was reduced by only 15% and no non-specific precipitation could be detected.

Antiserum dilution. Previous experience has shown that performance characteristics given for antiserum by the manufacturer do not always provide helpful information on the use of the antiserum in a kinetic assay. Batches of antisera must therefore be tested to ascertain the dilution necessary to obtain the required sensitivity. Figure 1 shows the precipitin curve at various dilutions of the antiserum used in this study. It was decided to use a dilution of 1 part of antiserum with 8 parts of diluent in the TBPA assay. This dilution represents a compromise between the need to operate with excess of antibody and to reduce assay costs, while still maintaining adequate sensitivity and precision.
Fig. 2. Calibration curve changes at two detector wavelengths ●——● at 290 nm; ○——○ at 340 nm.

Wavelength. One factor influencing assay sensitivity is the wavelength used to measure the scattered light.[9,12] The Cobas Bio, unlike many automated kinetic analysers, uses a grating monochromator, so the influence of wavelength on the assay could be studied. Rayleigh's law of light-scattering indicates that the scattering intensity varies as the reciprocal of the fourth power of the wavelength of the incident light. Therefore, if this wavelength is decreased the intensity of the scattered light increases, hence the sensitivity increases. However, it must also be borne in mind that antibodies and proteins themselves are of sufficient size to scatter light and hence the serum and reagent blank signals will also increase. A further consideration in the choice of assay wavelength is the instrument noise at various wavelengths.[12]

The TBPA assay system was set so that a set of standards for the calibration curve was run first, followed by 20 saline samples. The absorbance data at 340 and 290 nm were collected in the usual way. The data from the 20 saline samples were used to obtain a measure of instrument noise and the absorbance changes for the calibration curve were plotted graphically (Fig. 2).

Although the initial absorbance of the reagent blank was 0.120 at 340 nm but 1.480 at 290 nm (because of the Rayleigh law effect), the instrument noise, expressed as the standard deviation (sd) of the absorbance of the 20 saline blank samples, increased only from 0.011 to 0.013. This minimal shift in instrument noise compared with the 40-fold increase in sensitivity, suggested 290 nm as the wavelength of choice.

ASSAY PERFORMANCE

Detection limits

The detection limit is the smallest value (for a single analysis) which can be distinguished with a stated probability from a suitable blank. For light-scattering assays, assuming equality of absolute pre-

Fig. 1. Hoechst antiserum precipitin curves at various dilutions in PEG 6000 (40 g/l). ●——● dilution 1:6; ○——○ dilution 1:9; △——△ dilution 1:15.

cision in measuring blanks and samples with concentrations near the detection limit, the detection limit will be equal to the mean blank result plus 3 sd.[8] The data from the wavelength experiment with saline samples as blanks were subjected to curve fitting and the sd (and hence the detection limit) was calculated. For the assay at 290 nm the detection limit was found to be 15 mg/l., corresponding to an absorbance change of 0.018 in 5 min. This is equivalent to a concentration of 90 ng per cuvette and compares well with previously published data.[8,9,12-18]

Within and between batch precision

Within-batch precision of the assay system was assessed in the usual way by measuring replicates of three samples at different TBPA levels (Table 2). Between-batch precision was assessed by running the assay on 20 separate occasions, with freshly thawed aliquots of the three samples. On each occasion a fresh dilution of the stock antiserum was prepared. Table 2 shows the precision data.

Relative accuracy

The kinetic immunoturbidimetric assay was compared with the well-established standard technique of radial immunodiffusion, for analysis of samples from patients. The regression parameters obtained according to the Deming procedure were y(RID) = 5.141 + 1.019 × (immunokinetic); $r = 0.9864$, $n = 50$.

Reference range

Heparinized plasma samples taken from 45 healthy volunteers (23 female, 22 male; mean age 31.7 years) were submitted for analysis by the new procedure. The results showed a Gaussian distribution with a mean level of 277 mg/l, and a ± 2 sd range of 160–390 mg/l. There was no difference between the population mean for women and men. This range is in close agreement with those previously obtained by use of RID[6] and electroimmunoassay;[7] however, one brief report[25] on light-scattering immunoassay with a Beckman Rate Nephelometer indicated a reference range as wide as 151–503 mg/l. (This paper also reported much wider levels for the RID technique: 131–487 mg/l.)

Excess of antigen

The various methods for detection of excess of antigen have been outlined elsewhere.[8,9] In this partic-

ular assay kinetic equivalence occurs at 600 mg/l., so only samples with antigen levels greater than this will cause problems; such high levels are extremely unlikely in clinical situations. Many authors have used the change in reaction kinetics on change from antigen excess to antibody excess as a means of detecting antigen excess. This method proves very practical for analysers with analogue recorder output, but is less practical for analysers that only store the data readings. For instances of suspected antigen excess the data points must then be plotted manually. More recently, kinetic analysers with additional computational facilities have allowed presentation of raw data for inspection on a VDU and various computations and algorithms for real-time detection of this condition have been investigated.

CONCLUSION

Turbidimetric assays for the measurement of specific proteins in clinical chemistry have been realized by use of various analytical systems, including centrifugal analysers. The potential of these analysers for multiple data-point collection allows the use of kinetic techniques, and their ability to read the absorbance at the start of the reaction allows measurement of sample blanks. Accurate timing of the data of the data collection means that the reactions do not have to run to completion and sample throughput can therefore be increased.

The assay described for TBPA is a rapid assay making use of instrumentation which is widely available in clinical chemistry departments. The precision and speed of the assay are far superior to those of conventional assays such as RID and electroimmunoassay, and also superior to those of more recently outlined kinetic nephelometric[25] and enzyme immunoassay[26] methods. The detection limit of the assay, about 100 ng in the sample in the cuvette, is comparable to that reported for use of kinetic analysers[8,9] and indicates that the novel optical arrangement of the Cobas Bio introduces no advantages or disadvantages in terms of assay sensitivity. However, the ability to use small volumes has an obvious cost implication.

Preliminary clinical studies with the TBPA assay indicate that TBPA and other short half-life proteins have considerable potential for monitoring of nutritional status in a wide range of conditions.

PHARMACEUTICAL AND CLINICAL ANALYSIS BY TANDEM MASS SPECTROMETRY

RICHARD A. YOST,* ROBERT J. PERCHALSKI,† HARRY O. BROTHERTON,§
JODIE V. JOHNSON and MARY BETH BUDD
Department of Chemistry, University of Florida, Gainesville, FL 32611, USA

Summary—Tandem mass spectrometry (MS/MS) is a promising technique for trace determination of compounds in complex mixtures. The application of triple-quadrupole MS/MS to clinical and pharmacological studies has been investigated with major emphasis on rapid screening and determination of drugs and biomolecules in physiological fluids and tissues. These techniques have been applied to a range of problems, including the determination of chlorinated compounds in humans, subpicogram analysis of neurochemicals and the detection of illegal drugs in racing animals. A new technique for determining the structures of all the metabolites of a particular drug has also been developed. It is possible to identify in a single sample all molecular ions which contain substructures characteristic of the parent drug. The structure of each metabolite can then be determined by obtaining the MS/MS spectrum of the molecular ion.

Tandem mass spectrometry (MS/MS) is a relatively new analytical technique based upon mass spectrometers that can provide two (or more) stages of mass separation in sequence. This capability makes possible the integration of the two basic operations of chemical analysis, separation and identification, in one instrumental technique. Because both operations are based upon mass analysis, the technique is rapid, sensitive and selective. Here we describe the application of MS/MS to problems in pharmaceutical and clinical analysis.

TANDEM MASS SPECTROMETRY

A conceptual diagram of a tandem mass spectrometer is illustrated in Fig. 1 and compared with the familiar gas chromatograph/mass spectrometer combination (GC/MS). Although several instrumental approaches have been employed for mass analysis in GC/MS and MS/MS, the quadrupole mass filter shown is by far the most common. Tandem mass spectrometry has its roots in the early studies of ion-molecule reactions[1] and metastable ions.[2] The earliest applications of MS/MS for mixture analysis employed double-focusing mass spectrometers.[3,4] The development of the triple-quadrupole mass spectrometer[5] made possible routine analytical applications of MS/MS and led the way to commercial introduction of MS/MS instruments.[6] Instrumentation for tandem mass spectrometry has been reviewed recently.[7]

Tandem mass spectrometry has a wide range of applicability for chemical analysis, as illustrated by the wide range of applications presented in the first book devoted to the subject.[8] These range from trace mixture analysis to structure elucidation. Here we will concentrate on clinical and pharmaceutical applications that employ the mixture-analysis capabilities of MS/MS. Before discussing those applications, however, it is important to consider why MS/MS is advantageous for trace analysis.

The unique position of mass spectrometry for trace analysis was presented recently by Cairns,[9] as shown in Table 1. The extreme sensitivity of mass spectrometric analysis provides detectable signals for minute quantities of analyte. For trace analysis, however, sensitivity is not the most critical figure of merit; rather it is the limit of detection, as shown in Table 2. The response of the detector in mass spectrometry is rarely the limiting factor; indeed, detecting a single ion is commonplace. To take advantage of this sensitivity, high selectivity must be achieved, so that the signal from the analyte can be differentiated from that due to other compounds in the sample or the mass spectrometer background. The practical figure of merit, therefore, is limit of detection, a function of both sensitivity and selectivity. The increase in selectivity provided by two stages of mass analysis in MS/MS can lead to improved (lower) limits of detection compared to traditional MS, even though some sensitivity is inevitably lost in the second stage.

The benefits of multiple stages of analysis in MS/MS were first elucidated by Cooks.[3] He pointed out that the signal due to chemical interferences is essentially "chemical noise", and that the use of two or more sequential analytical stages or "gates" can be highly effective in filtering out this noise. Figure 2

GC / MS

MS / MS

Fig. 1. Conceptual diagrams of the triple-quadrupole tandem mass spectrometer (MS/MS) and a traditional gas chromatograph/quadrupole mass spectrometer (GC/MS).

illustrates this concept. It is apparent that, as long as the signal is not decreased to the point that it cannot be detected, increasing the number of analytical stages increases the signal-to-noise ratio, and thereby improves the limit of detection. The added stages of analysis can include the second stage of mass analysis in MS/MS, the chromatographic separation in GC/MS, or both in GC/MS/MS.

A further benefit of the sensitivity and selectivity of tandem mass spectrometry is the potential for rapid analysis. This results primarily from the ability either to eliminate the chromatographic separation step, or to use rapid, limited chromatographic separation with short packed or capillary columns. The loss in chromatographic selectivity is compensated for by the gain in mass spectrometric (MS/MS) selectivity. Speed is also gained since it is often possible to

analyse complex mixtures with little or no sample preparation.

Because of the potential for rapid, sensitive and selective trace mixture analysis, MS/MS is finding increased use in pharmaceutical and clinical applications. In the sections below, we present some of these applications, taken from work in our own laboratory.

SCREENING AND TRACE ANALYSIS

Many problems in pharmaceutical and clinical analysis are best solved by a two-step screening/confirmation procedure. In this process, a rapid screening step is used to identify samples which may contain the analyte (positives) and to eliminate those which do not (negatives). The screening step should be sensitive enough to prevent false negatives,

but will generally lack the selectivity to prevent false positives. All positives are then subjected to a second, more selective, confirmation step in order to identify those samples which do contain the analyte. If the rapid screening step effectively reduces the number of samples which must be subjected to the more time-consuming confirmation step, then this two-step procedure saves time and expense. Typically, the two steps employ two different analytical techniques. Tandem mass spectrometry offers the advantage of being able to perform both steps with the same instrument.

As an example of such an analytical problem, consider the testing of athletes (both animal and human) for illegal drugs. This type of analysis is traditionally performed by use of a thin-layer chro-

matographic screening step followed by a GC/MS confirmation step.[10] We have developed an MS/MS procedure for these analyses.[11] Screening for up to 50 drugs in a serum or urine sample is accomplished by selected-reaction monitoring (SRM) of one parent-ion/daughter-ion pair for each compound [analogous to selected-ion monitoring (SIM) in MS]. Alternatively, selected neutral losses or daughter ions characteristic of particular classes of drugs can be monitored. Any positives are then confirmed by obtaining complete daughter spectra for the suspected parent ions and matching the resulting spectra with a library of daughter spectra for standards. This procedure is illustrated in Fig. 3, in which a horse serum sample, spiked with 25 ppm procaine, is screened for four drugs.

The ion-current for each selected reaction is monitored as a 1-μl sample, inserted into the chemical ionization source on a direct insertion probe, is heated to 325° in 100 sec. The screening in Fig. 3 indicated a positive for procaine. The presence of this drug is confirmed by heating a second 1-μl sample while obtaining the complete daughter spectrum for the compound's protonated molecular ion, as shown in Fig. 4. The library match (Fig. 4) confirms the presence of procaine. This procedure permits the screening of 12 serum or urine samples per hr, with detection limits in the range 0.1–100 ppm for most drugs in serum, urine, or extracts thereof. This procedure permits the sensitive and selective screening and confirmation of illegal drugs rapidly and with minimal sample preparation.

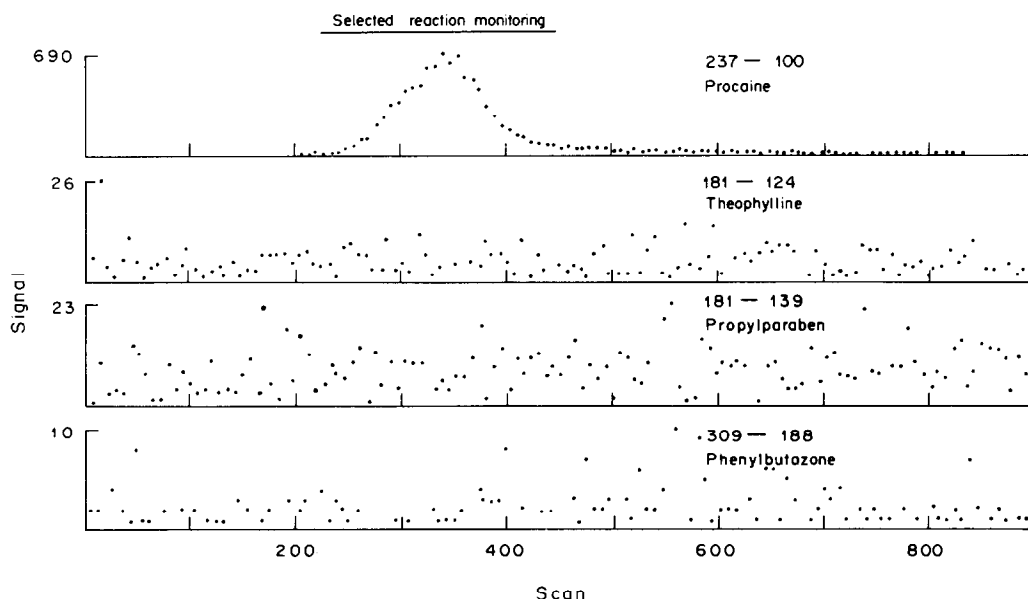
The enhanced selectivity of MS/MS over traditional MS also makes possible trace analysis with extremely low limits of detection. For example, we


Fig. 3. Screening for four drugs in horse serum spiked with 25 ppm procaine. Results are positive for procaine, negative for the other three drugs.
Fig. 4. Comparison of daughter spectrum of procaine in serum with reference library daughter spectrum (for procaine in chloroform).

have demonstrated the ability to detect hexachlorobenzene and trichlorophenol in extracts of human serum and urine with detection limits of 0.05 pg and 0.25 pg, respectively, at a rate of 100 sample injections/hr.[12] The low detection limits were made possible by the use of a short GC column for sample introduction, negative chemical ionization (NCI), and selected-reaction monitoring MS/MS. The use of the 50 cm × 0.1 cm GC column provides short retention times (< 30 sec) for rapid analysis.

A similar approach has been applied to trace analysis for neurochemicals (tryptolines in rat brain extract[13] and octopamines and synephrines in human serum and urine).[14] In order to take advantage of the sensitivity of NCI, the compounds are converted into their perfluorinated propionic or butyric acid derivatives. This approach provides extremely low limits of detection (Table 3) in standard solutions. When real brain-tissue, urine, or blood serum are analysed, however, large numbers of compounds, many present at levels significantly higher than the analytes, also form derivatives. The short GC column is not adequate to resolve these compounds from the analyte, leading to severe quenching in the electron-capture NCI process and difficulty in detecting even 10 ng of the analyte. Indeed, not even the selectivity possible in the MS/MS analysis can correct for competitive ionization and quenching from interferences in the NCI source.

One solution to this problem would be to switch to positive CI, which is much less sensitive to ionization interferences, albeit with a significant loss in sensitivity. Alternatively, longer capillary columns could be used to separate the analyte derivative from those of other sample components. This latter approach provides detection limits similar to those achieved with the short column, but with longer retention times (ca. 10 min) and therefore less rapid analysis. The real value of selected-reaction monitoring MS/MS compared to selected-ion monitoring MS, even with capillary GC separation, is illustrated in Fig. 5. Figure 5a shows the GC/MS (SIM) and 5b the

GC/MS/MS (SRM) chromatograms for a crude rat-brain extract spiked with 35 pbb of methtryptoline. The SIM chromatogram shows numerous compounds producing the m/z 362[-] ion, while the SRM chromatogram for m/z 362[-] →m/z 179[-] shows only methtryptoline. Expansion of the chromatogram time-scale in the area of the methtryptoline peak (Figs. 5c and 5d) shows that in the SIM analysis, the methtryptoline is actually an unresolved shoulder on the side of a large interference peak. SRM eliminates this interference.

Preliminary experiments[13] with 1-μl injections of crude brain extracts (corresponding to 10 mg of tissue) show tryptoline levels of 50 pg/g in rat brain. The combination of a 20-m cross-linked methyl silicone capillary column with MS/MS has provided isomer-specific detection of the o-, m-, and p- octopamines and synephrines at the 1 ppb level. The use of deuterium-labelled internal standards has permitted precise ($\pm 5\%$) determination in urine and serum extracts.[14]

These studies illustrate the potential for rapid, sensitive, and selective analysis of clinical and pharmaceutical samples. Rapid screening and confirmation is possible for large numbers of targeted compounds at the ppb–ppm level in complex mixtures, with minimal sample preparation. Trace analysis at sub-ppb levels is possible by combination of the sensitivity of negative CI with the selectivity of capillary GC/MS/MS.

DRUG METABOLISM STUDIES

The combination of gas chromatography with mass spectrometry has long been used to determine structures of drug metabolites. The methods generally involve some pretreatment of the sample to free conjugated or protein-bound species, followed by extraction to separate basic, acidic and neutral components and endogenous interferences. Since many metabolites are polar molecules, derivatives may be employed to increase volatility, thermal stability and

chromatographic compatibility. This final item is important because compounds that have dissimilar functional groups may not all be detectable under a single set of chromatographic conditions. Therefore, in a metabolite search in which the compounds sought are unknown, use of only one set of conditions may preclude the discovery of one or more species, while development of multiple chromatographic systems takes considerable time.

The capabilities of MS/MS make it ideally suited to the determination of structures of drug metabolites. Since most metabolites retain a relatively large part of the parent drug structure, it is reasonable to assume that their daughter spectra will contain peaks corresponding to one or more of the fragment ions or neutral fragments characteristic of the pure drug. Therefore, if an extract of urine or plasma from a person taking a particular drug is analysed for these

Pure drug (primidone)
Fig. 6. Spectra obtained in a study of the metabolites of the drug primidone: (a) the positive (CH₄) CI mass spectrum of the pure drug showing the (M + H)⁺ ion at m/z 219 as well as (M + 29)⁺, (M + 41)⁺, and fragment ions; (b) the summed daughter spectra of six ions in (a).

characteristic fragment ions or neutral fragments, the resulting spectrum should contain molecular ions which correspond to potential metabolites of the drug. To identify the compounds, complete daughter spectra are obtained. Because all components of a sample are ionized under a single set of conditions, there is no need to spend time developing chromatographic methods or waiting for components of interest to be eluted.

We have described a method that allows determination of metabolite structure from one extract of urine (2 ml) or plasma (1 ml) in as little as 30 min.[15] As an example, Figs. 6 and 7 illustrate the steps involved in determining the metabolites of the antiepileptic drug primidone. First a normal (positive or negative ion) CI mass spectrum of the pure drug is obtained, as shown in Fig. 6a. Secondly characteristic substructures of the drug, both daughter ions and neutral fragments, are identified by recording daughter spectra of the molecular ions and major fragment ions in the CI mass spectrum. Figure 6b shows the sum of the daughter spectra of six of these ions. Next, for a sample of serum, urine, or tissue, all ions that contain the drug's characteristic substructures are

Serum extract

Pure metabolite (PEMA)
Fig. 7. (a) Parent spectrum of an extract of a patient's serum for the m/z 162 daughter ion characteristic of primidone, showing (M + H)⁺ ions for the drug (m/z 219) and two metabolites (m/z 207 and m/z 233); (b) the daughter spectrum of the m/z 207 ion from the serum extract; (c) the daughter spectrum of the m/z 207 ion from pure phenylethylmalonamide (PEMA) for comparison with (b).

identified by acquiring a parent spectrum for each selected daughter ion and a neutral fragment spectrum for each selected neutral fragment. Each of the parent ions seen in these scans corresponds to a potential metabolite. Figure 7a shows one such scan, a parent spectrum for the characteristic 162 daughter ion, from an extract of serum from a patient being treated with the drug. The (M + H)⁺ ions are seen for the parent drug at m/z 219, and two possible metab-
Fig. 8. Primidone and its metabolites identified in serum by MS/MS.

olites at m/z 207 and 233. In addition, the $(M + 29)^+$ and $(M + 41)^+$ ions are observed for each compound. Finally, a daughter spectrum corresponding to the molecular ion of each potential metabolite is obtained in order to determine the metabolite structure. The daughter spectrum of the m/z 207 ion is shown in Fig. 7b. It may be interpreted directly, or compared with the daughter spectrum of the authentic metabolite (Fig. 7c) in order to confirm the structure. In this case two metabolites, phenylethylamalonamide and phenobarbital, are identified, as shown in Fig. 8. This example demonstrates the potential of MS/MS for rapid metabolite identification in a single physiological sample.

CONCLUSION AND FUTURE TRENDS

These studies have demonstrated that tandem mass spectrometry is a powerful tool for clinical and pharmacological studies. Rapid screening and determination at the ppb level and below are possible, since the selectivity of tandem mass spectrometry reduces the need for high selectivity in sample clean-up and chromatographic separation. Furthermore, the unique capabilities of MS/MS offer new analytical techniques, such as the metabolite identification method presented here.

Tandem mass spectrometry is a rapidly evolving field, with dramatic advances particularly apparent in

instrumentation. Although the first commercial triple-quadrupole instruments appeared barely three years ago, sophisticated MS/MS instruments are now being sold by nearly every MS manufacturer. Perhaps the most important advance in MS/MS instrumentation will involve those developments necessary to make low-cost ($50,000–150,000) instruments available. This will make tandem mass spectrometry even more attractive for rapid screening, trace analysis and metabolite studies.

PERTURBATION OF LABORATORY TEST RESULTS BY ANALYTICAL INTERFERENCES AND DRUG EFFECTS

M. M. Galteau and G. Siest

Centre du Médicament, 30 Rue Lionnois, 54000 Nancy, France
Centre de Médecine Préventive, 2 Avenue du Doyen Jacques Parisot,
54500 Vandoeuvre-les-Nancy, France

Summary—An account is given of ways in which drug treatment can influence the results of laboratory tests for certain species of clinical importance, and of methods of detecting such interferences or effects.

When interpreting laboratory test results, clinical chemists and physicians meet various problems that are due to drug intake by the test subjects. It is now well known that some drugs are able to perturb laboratory tests in two ways.[1,2] *Analytical*, in which the drug and/or its metabolites can interfere, at any stage, with the assay of a constituent. In clinical chemistry, the term "analytical interference" can be reserved for this *in vitro* effect. *Biological*, in which the drug provokes a change in a biological constituent by a physiological, pharmacological or toxicological mechanism (*in vivo* effect). This aspect includes both the primary desirable effects and also the undesirable so-called "side-effects".

In this paper we describe recent results obtained in our laboratory on both analytical interference and the biological effects of drugs on the most commonly performed routine tests.

ANALYTICAL INTERFERENCES

The studies were performed in two steps, using the procedures developed by the IFCC Expert Panel on "Drug Effects in Clinical Chemistry".[3] The first step is the detection of possible analytical interference, the second is its determination. The methods and materials used are listed in Table 1. The sample consists of one pool of sera drawn from supposedly healthy subjects taking no drug. This pool is lyophilized in 25-ml vials. Before use, two vials are reconstituted with (*a*) 25 ml of a solution in which the active principle is dissolved (this is the spiked sample) and (*b*) 25 ml of the solvent used to dissolve the drug (the control sample). The contents of the two vials are stirred for 30 min and then dispatched to the laboratory and the tests performed.

We have studied 39 active principles and the interference is considered as significant when the

results for the spiked and unspiked samples differ by more than 5% for chemical constituents and 10% for enzymes.

The results are given in Table 2.

Among the 39 drugs tested, 3 are insoluble in the solvents used, *i.e.*, water, 0.002*M* sodium hydroxide, or water–ethanol (98:2–90:10 v/v). These three drugs are fenofibrate, dipyridamole and glafenine, and they were not studied.

Of the 36 drugs left, 23 give no interference with the methods assayed, and 13 of these do not interfere when added at a concentration of less than 0.1 m*M*. It is logical to think that the higher the drug concentration, the more likely it is to produce an interference, and conversely, the lower the constituent level, the more a drug at a higher concentration can interfere, but we found no correlation between the levels of blood constituents and the concentrations at which drugs interfered. The other 13 active principles produce an analytical interference with at least one serum constituent when they are tested at concentrations 10 times the maximal therapeutic level.

To measure the interferences quantitatively, we performed a new series of tests with decreasing concentrations of the 13 interfering substances. At least two of these levels were within the therapeutic range.

Only 3 drugs, ascorbic acid, methyldopa and theophylline, still produced an analytical interference with some constituents. The results are given as a function of the concentrations in Table 3.

We found that ascorbic acid interferes with determination of glucose, cholesterol, urates and creatinine, but the interference decreases with dose level. The interference of ascorbic acid in determination of glucose and cholesterol was expected, as these tests were performed by enzymatic methods involving a

Trinder reaction (peroxidase).[5] Villatte[6] has shown that the lack of specificity of the peroxidase reaction is responsible not only for these analytical interferences with glucose and cholesterol determination but also with that of urates, phospholipids and triglycerides (Fig. 1).

Although the risk of interference is reduced by the development of more specific methods, it is always necessary to assess the possible interference of commonly used drugs in the application of new techniques, especially in measurement of very low concentrations of hormones or other molecules. Analytical interferences are particularly important in measurement of urinary constituents.

BIOLOGICAL EFFECTS

We have studied certain drugs suspected of having secondary cholestatic effects, in particular some neuroleptics, minor tranquillizers, anabolic steroids, antidiabetics and oral contraceptives. From the biological tests performed at the Centre for Preventive Medicine, we selected those using enzymes which can reflect a hepatic effect, *e.g.*, gamma-glutamyltransferase (GGT), alkaline phosphatase (AP) and alanine aminotransferase (ALT).

The "samples" were subjects who had undergone a health examination at the Centre for Preventive Medicine in Vandoeuvre-Les-Nancy (France). The test population comprised subjects being treated with at least one drug, generally on a long-term basis. The control population was composed of subjects matching the treated subjects in sex, age and weight, but taking no medication. Information concerning drug intake was collected by means of questionnaires filled up by pharmacists and nurses when blood samples were drawn, and was then computerized by classes, subclasses and trade names.[4] In some cases, the control subjects presented the same pathological characteristics as the test subjects. The 50th centiles from the two populations were compared. The methods used for measuring the enzymatic activites of GGT, ALT and AP are briefly described in Table 1.

Table 4 summarizes the results obtained for certain classes of drugs. In some cases, we have differentiated the results according to sex. Of the 3 enzymes studied, GGT is the most liable to suffer interference. The ingestion of drugs does not systematically increase the enzyme activities, and some medications are able to decrease plasma enzymes.

The procedure described is sometimes not appropriate. The example of antihypertensive agents is interesting. In this case, it is impossible to compare the treated subjects with supposedly healthy people to detect the effect of drug intake. Instead it is necessary to compare the results obtained for the treated population with those for hypertensive non-treated subjects. The results of such a study are presented in Table 5.

The ALT and AP activities do not show large variations after antihypertensive treatments. In contrast, plasma GGT is affected by each drug to an extent varying between −40 and −80%. On the basis of these results, the GGT activity is proposed as a useful test for monitoring antihypertensive drug therapy.[12]

Most of the variations described above are important and indisputable. However, in certain cases the effects of drugs are less clear, and comparison with a control population is not easy. For example, we have examined the effect of 2 hypolipidemic drugs, viz. fenofibrate and clofibrate, on GGT, ALT and AP activities.

The 50th centile of a population undergoing treatment was compared with that of a presumably healthy untreated control group (Table 6). Subjects were paired according to sex, age and weight. We also compared these centiles with those of a sample population in a "reference state", consisting of 20–30 year old subjects, taking no drugs and with none overweight.

Comparison of the results for the fenofibrate-treated patients with those for the controls, shows a decrease in the GGT and AP activities for the 50th centiles. For the clofibrate-treated patients this decrease is even bigger. For ALT, the effect is dependent on sex. In men fenofibrate produces a slight decrease, but clofibrate has no effect. On the contrary, in women the ALT activity increases after either treatment.

In contrast, if the results are compared with those for the reference state, the GGT activity increases in males and females treated with fenofibrate. No significant modification occurs with clofibrate. The ALT activity seems to be very much increased by the

Table 5. Effect of antihypertensive agents on plasma enzyme activities (per cent difference, calculated on 50th centile, referred to untreated subjects)[12]

T = treated; C = control; RS = reference state.

treatment, and the AP activity is decreased. This example illustrates the difficulties in interpretation, particularly when the dispersion of the control distribution is large. These results could be due to inclusion of overweight individuals in the control group, or to age.

Drugs can affect enzymes *in vivo* by modifying either their activity or their concentration. It is impossible to distinguish between the two effects, since only the activity is measured. The activities of plasma enzymes can be modified by a direct effect of the drug on the enzyme (either inhibitive or enhancing) or indirectly by action on a co-enzyme or on a cation necessary for the enzymatic reaction.

The changes in enzyme levels are due to more complex effects: change in enzyme metabolism by inductive processes, repression, acceleration of metabolism or catabolism. The well-known effect of anticonvulsant drugs, especially phenobarbital, on GGT results from the increase of synthesis of this enzyme in the liver. However, the change in plasma enzyme levels due to drugs can be independent of enzyme synthesis. For example, cholestatic effects of drugs can increase alkaline phosphatase. This also seems to be the case for antiepileptic drugs. Another general mechanism of drug–enzyme interactions is an effect on membrane structures.

Some results can be explained in terms of the mechanism of actions of drugs, but most of the *in vivo* effects remain unexplained. Moreover, it is difficult to interpret these effects. They must be related to other physiological variations of enzymes.[15] It is now well known that plasma GGT or ALT varies with age, sex, overweight.

CONCLUSION

As it is impossible to remember all the *in vitro* interferences, and the *in vivo* effects and simultaneously the physiological variations for each biological constituent, data banks are absolutely necessary to help clinical chemists and physicians in interpreting laboratory test results. In Nancy, we have constituted such a bank, entitled INTERMEDIC.[2,16,17] It contains information from our own results obtained at the Centre for Preventive Medicine or from the existing literature. Two other computerized drug information systems exist in Europe; a Swedish one (SWEDIS)[18] and a British one[19] (at the University of Surrey). The first data bank on drug effects was established by Young *et al.*[20]

DETERMINATION OF MICRO AMOUNTS OF URANIUM BY A MOLYBDENUM BLUE METHOD

V. K. Bhargava, M. S. Oak, A. R. Joshi and V. B. Sagar

Radiochemistry Division, Bhabha Atomic Research Centre, Trombay, Bombay-400 085, India

Summary—A new and highly sensitive spectrophotometric method has been developed for the determination of micro amounts of uranium by a molybdenum blue method. The method is based on the observation that at low acidities uranium(IV) reduces ammonium molybdate to molybdenum blue, the absorbance of which is proportional to the amount of uranium present. The variables affecting development of the colour have been investigated and the conditions optimized. Beer's law is found to hold good for uranium concentrations between 1 and 20 ppm, with a precision of 2%. The effect of diverse ions has been studied. The method is useful for the determination of uranium present as an impurity (down to 0.1%) in plutonium, neptunium or thorium.

Several methods are available for the determination of micro amounts of uranium. These include spectrophotometric methods[1-4] which involve the formation of highly sensitive coloured complexes. Fission-track registration[5,6] has also been used for the determination of micro quantities of uranium in various matrices. In all these methods plutonium interferes, if present, and a preliminary separation is needed. The present paper describes a spectrophotometric method for the determination of uranium at micro level, valid in the presence of plutonium, neptunium or thorium, by formation of molybdenum blue. The results of preliminary investigations were reported earlier.[7]

It has long been known that heteropolymolybdates of As, P, Si *etc.*, on reduction produce a blue colour which can be used either to determine the central atom incorporated in the complex or to determine the amount of reductant.[8] The blue colour is also reported to be developed when an acidified solution of molybdate is reduced by mild reducing agents.[9] It was thought of interest to see whether U(IV) [$E° = 0.33$ V for the U(VI)/U(IV) couple] could be used to reduce either the heteropolymolybdates of As, P, Si *etc.* or ammonium molybdate to form a blue colour. Attempts to reduce the heteropoly compounds did not yield the desired results, but U(IV) was found to reduce ammonium molybdate to a molybdenum blue at low acidities. The variables affecting development of the blue colour have therefore been investigated and the conditions optimized. The effect of diverse ions has been studied and is discussed.

EXPERIMENTAL

Reagents

All reagents used were of analytical-reagent grade.

Ammonium molybdate solution, 10%. Prepared in doubly distilled water and allowed to stand for 3 hr for complete dissolution.

Sulphuric acid. A 2M stock solution was prepared in doubly distilled water and used for controlling the acidity.

Ti(III) solution. Titanium sponge was dissolved in 2M sulphuric acid and the saturated solution obtained was filtered and used as the reductant.

Preparation of pure uranium solution. Nuclear-purity UO_3 was dissolved in 8M nitric acid and converted into sulphate form by repeated evaporation with 4M sulphuric acid and finally transferred with 1M sulphuric acid to a dry weighed flask, which was then weighed again. The uranium content in the stock solution was determined by the Davies and Gray method.[10]

Uranium in the stock solution was reduced to U(IV) with Ti(III) in a medium consisting of a mixture of sulphuric acid, sulphamic acid and nitric acid.

Preparation of pure plutonium solution. Plutonium(IV) oxalate was converted into the oxide by heating in a platinum boat at 900°. The absence of impurities such as vanadium and iron was checked by emission spectrography. The oxide was dissolved in concentrated nitric acid containing 0.05 mole of hydrofluoric acid per litre, in a platinum dish. The solution was evaporated to dryness, then the residue was taken up in concentrated nitric acid; this step was repeated twice more to ensure complete removal of hydrofluoric acid. The solution was then repeatedly evaporated with 4M sulphuric acid to convert the plutonium into sulphate form and finally transferred with 1M sulphuric acid to a dry weighed flask, which was then weighed again. The plutonium content of this stock solution was determined by the Drummond and Grant method.[11] Absence of uranium in the stock solution was ascertained by the present method.

Apparatus

All spectra were recorded on a Cary model 14 spectrophotometer, with 1-cm quartz cells. For studying the effect of diverse ions, temperature and time, the absorbance measurements were made with a Brinkman DC 800 probe colorimeter, with appropriate filters.

Procedure

Take the solution containing uranium in a 25-ml standard flask for reduction. Add 0.5 ml of a reaction mixture consisting of sulphamic acid (0.25M), nitric acid (1M) and sulphuric acid (0.5M), followed by the titanium(III) solution until its colour persists. The excess of titanium(III) is slowly oxidized to titanium(IV) by the nitric acid present, and the titanium(IV) does not absorb in the wavelength span of interest. Add 5 ml of 2M sulphuric acid, ~10 ml of distilled water and 7.5 ml of 10% ammonium molybdate solution, and then make up to volume with distilled water, giving a final acidity of 0.4M sulphuric acid and an ammo-

nium molybdate concentration of 3%. After 20 min, measure the absorbance at 600 nm in a 1-cm cell against a reagent blank. Prepare a calibration graph in a similar way.

RESULTS AND DISCUSSION

It was observed that when U(IV) is added to an acidified ammonium molybdate solution, a blue colour is produced, the intensity of which varies with the amount of U(IV) added. The absorption spectrum of this blue solution is dependent on the acidity and on the amount of ammonium molybdate present. A systematic study was therefore made, to optimize the conditions.

Influence of acidity and selection of wavelength

Figure 1 shows the change in the spectrum with acidity. At low acidity, i.e., 0.02–0.1M sulphuric acid, λ_{max} is between 820 and 800 nm, then gradually shifts to 600 nm at an acidity of ~0.18M sulphuric acid. At acidities between 0.18 and 0.5M sulphuric acid, λ_{max} remains fairly constant at 600 nm but the absorbance decreases at higher acidities. At sulphuric acid concentrations >0.5M, the blue colour changes to green. Beer's law is obeyed at λ_{max} at all acidities in the range 0.02–0.5M. The molar absorptivities at 0.04, 0.2 and 0.4M sulphuric acid concentration have been calculated for 820, 660 and 600 nm for comparison, and are shown in Table 1. The molar absorptivity is highest at 820 nm but the dependence of λ_{max} on acidity is very critical, making this wavelength unsuitable for quantitative work. An acidity range of 0.2–0.4M is optimal but an acidity of 0.4M sulphuric

Table 1. Molar absorptivities at different acidities and wavelengths (measurement after 20 min colour development)

λ, nm	Molar absorptivity, 10^4 l.mole^{-1}.cm^{-1} [H$_2$SO$_4$]		
	0.04M	0.20M	0.40M
600	0.7	1.3	1.2
660	1.1	1.1	1.1
820	2.0	0.7	0.7

acid is preferred, at the cost of sensitivity, as the tolerance limit for various ions is then higher and there is no precipitation. When the acidity is not accurately known, the absorbance measurements should be made at 660 nm.

Effect of ammonium molybdate concentration

Figure 2 shows the change in the spectrum with variation in molybdate concentration. At lower concentrations, i.e., from 1.8 to 2.2%, λ_{max} is at ~700 nm, and gradually shifts to 600 nm with increasing concentration of molybdate up to 2.8%. Though the absorbance at 600 nm increases with increasing molybdate concentration, high concentrations cause precipitation on standing. A concentration of 3% is therefore recommended.

Influence of sequence of addition of reagents, time and temperature

The order of addition of the reagents is immaterial. To study the effect of time and temperature, two
Fig. 1. Change in absorption spectrum of Mo blue with acidity (A.M. = ammonium molybdate)
Fig. 2. Change in absorption spectrum of Mo blue with ammonium molybdate (A.M.) concentration.

solutions were prepared, containing about 12 ppm of U(IV) and 3% ammonium molybdate in (A) 0.04M and (B) 0.4M sulphuric acid, and the absorbance was measured as a function of time (Fig. 3). Maximal absorbance is attained after ~20 min, and remains constant for ~12 hr. These solutions were also heated after constant absorbance had been reached (Fig. 4). No appreciable change in absorbance was observed until a temperature of 35° was reached. At higher temperatures the absorbance of solution (A) increased whereas that of solution (B) decreased. At above 70° the blue colour changed into green.
Fig. 3. Time dependence of absorbance.

Beer's law, sensitivity and precision

Beer's law was obeyed at all acidities from 0.04 to 0.5M sulphuric acid and at 820, 660 and 600 nm. The precision of the method was determined with 10 aliquots of an 898-μg/g stock solution of U(IV); the mean found was 911 μg/g, with a relative standard deviation of ±1.6%.

Determination in presence of plutonium

Since the method is suitable for determination of uranium in the ppm range, it was of interest to see whether it could be exploited for the determination of uranium as an impurity in plutonium samples. Synthetic mixtures of U and Pu were prepared, and analysed for uranium by the procedure described. Identical amounts of uranium were taken in separate flasks and the colour developed. Comparison of the absorbances of the two sets showed that plutonium does not interfere. In principle, as little as 5 μg of uranium can be determined in the presence of 2500 μg of plutonium per 25 ml of solution, but larger amounts of plutonium cause precipitation.

Effect of diverse ions

A known amount of potentially intefering ion was added to a known amount of uranium, the blue colour was developed by the procedure described and the absorbance compared with that of a pure uranium solution. A change of 3%, twice the relative standard deviation, in the absorbance was taken as

Fig. 4. Temperature dependence of absorbance.

by forming blue solutions themselves; their lower oxidation states [V(III), Fe(II)] are capable of reducing isopolymolybdates to molybdenum blue. Thorium, plutonium and neptunium up to 100 μg/ml did not interfere, but higher concentrations resulted in precipitation. Alkali metals and most of the rare-earth metals did not interfere. Anions such as SCN^-, NO_3^-, Cl^-, ClO_4^-, CH_3COO^-, $C_2O_4^{2-}$, $NH_2SO_3^-$ did not interfere.

Summary—The general program ABLET is a system of subprograms for non-linear regression analysis of experimental data to find an appropriate model. The structure of ABLET provides a suitable organizational framework in which just two specific subroutines have to be supplied by the user. The resulting program can estimate non-linear model parameters with their standard deviations, test the agreement between experimental data and a mathematical model, test the accuracy and reliability of the parameters found, and simulate synthetic data for preselected parametric values. Heuristic, and/or algorithmic minimization strategies aid examination of the local and overall minima. The method of construction of the program for a particular system is discussed.

The original LETAGROP VRID of Sillén and Ingri[1,2] has been rewritten in the form of the subroutine LETAG in autocode MOST F 13 for the ODRA 1013 computer,[3] in Fortran for the Hewlett-Packard 2116B,[4] and in Fortran IV for the EC 1040 or EC 1033 computers.[5] Various programs[6–15] have been based on LETAG and applied to studies of protonation and complex-formation equilibria and determination of stability constants.[7,16–27]

More than ten years of experience with the use of LETAG, and critical comparison with other up-to-date minimization algorithms, have led to the improved version, ABLET, and revision of all our previous programs based on it. Adaptation of the ABLET system to a particular equilibrium problem is now much easier. The ABLET system also makes a statistical test of the reliability of the estimated parameters, plots a curve-fitting graph by a printer routine, and provides three minimization strategies for finding not only the global minimum but also any selected one. Minimization may be done algorithmically or by trial-and-error or by a combination of the two.

The seven programs of the ABLET family[28,29] are (1) DHLET for determination of thermodynamic dissociation constants and parameters of the extended Debye–Hückel equation, (2) DCLET for determination of dissociation constants and molar absorptivities,[30] (3) NCLET for determination of stability constants from competitive titration equilibria,[11] (4) MRLET for determination of ligand purity and the stability constant of a predominant complex from mole-ratio data,[31] (5) SPLET for determination of stability constants and parameters of a chemical model from absorbance data,[28] (6) EXLET for analysis of extraction/photometric data,[28] and (7) POLET for determination of stability constants and complex stoichiometry from potentiometric titration.[28]

The ABLET system allows the minimization subroutine to be changed from LETAG to another subroutine from the library.

THEORY

Modus operandi *of the ABLET system*

In studies of chemical equilibria it is often necessary to fit a function $f(x; \vec{\beta})$ to a set of experimental data. Unknown parameters are estimated by minimizing the difference between the experimental and calculated data:

$$U = \sum_{i=1}^{n} w_i (y_{\exp,i} - y_{\text{calc},i})^2 = \text{minimum} \qquad (1)$$

where w_i represents the statistical weight, $y_{\exp,i}$ is a single observation made for x_i, and $y_{\text{calc},i} = f(x_i; \beta_1, \beta_2, \ldots, \beta_m)$ is the functional relationship assumed to exist. Each observed y_i for a given x_i is related to the calculated value of y_i by the equation $y_i = f_i + \epsilon_i$ where ϵ_i represents a random error. Random (or observational) errors are assumed to follow a Gaussian (normal) distribution expressed as

$$f(\epsilon_i) = \frac{\exp[-\epsilon_i^2/2s^2(y)]}{\pi \sqrt{2} s(y)} \qquad (2)$$

Part IV—*Talanta* 1979, **26**, 569.

where $s^2(y)$ is the variance of y. Theoretically, the assumption that the model giving minimum U is the best fit is justified only if (i) the correct form of the equation for y_{calc} is known and used, (ii) there are no errors other than random errors in y, (iii) the random errors in y have a Gaussian distribution, and (iv) w_i is an exact indication of the inherent accuracy of y_i. None of these conditions is usually strictly fulfilled, but $U = $ minimum is still widely used as a criterion because there is no better alternative.

A computer program for analysing data from equilibrium studies may usefully be constructed from logical units, each consisting of one or more subroutines. The division of the program into logical units aids the understanding of the functional structure of the whole program, Fig. 1.

The MASTER unit contains the main part of the program. The INPUT unit reads and checks data, and makes some preliminary calculations. The RESIDUAL-SQUARE SUM unit formulates the sum of squared residuals, $i.e.$, the squares of the differences between experimental and calculated values of the dependent variable. The relevant mathematical model in the form of an explicit or implicit functional relationship must be available.

$Example.$ The dissociation equilibrium of HL^z, $HL^z \rightleftharpoons L^{z-1} + H^+$, is characterized by the thermodynamic (activity) dissociation constant $K_a^T = a_H a_L / a_{HL}$. The dependence of the mixed dissociation constant $K_a = a_H[L]/[HL]$ on ionic strength, assuming that both ions HL^z and L^{z-1} have roughly

the same ion-size parameter $\mathring{a}$ (10^{-10} m) and that the overall salting-out coefficient is given by $C = C_{HL} - C_L$, is expressed by the Debye–Hückel equation in the form

$$pK_a = pK_a^T - AI^{1/2}(1 - 2z)/(1 + B\mathring{a}I^{1/2}) + CI \quad (3)$$

where

$$A = 0.5112 \, \text{mole}^{-1/2}.\text{l}^{1/2}.\text{K}^{3/2}$$

and

$$B = 0.3291 \, \text{mole}^{-1/2}.\text{m}^{-1}.\text{l}^{1/2}.\text{K}^{1/2}.10^{10}$$

for aqueous solutions and 25°. The mixed dissociation constant pK_a represents a dependent variable and the ionic strength I is taken as the independent variable, because it can be adjusted precisely so that its random error is less than that of the dependent variable pK_a. The three unknown parameters pK_a^T, $\mathring{a}$ and C are to be estimated by minimization of U:

$$U = \sum_{i=1}^{n} w_i (pK_{a,exp,i} - pK_{a,calc,i})^2 \quad (4)$$

The program used is DHLET.[8]

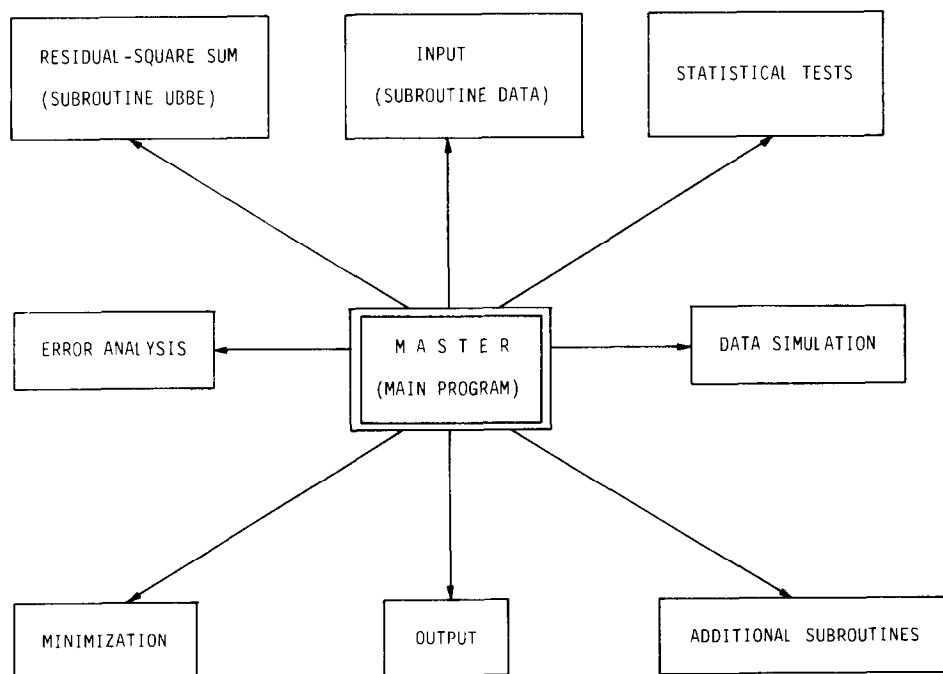
The MINIMIZATION unit contains the least-squares curve-fitting algorithm LETAG[3-5] which estimates unknown parameters by the minimization of a residual-square sum function. LETAG is based on the approach developed by Sillén and Ingri[1,2] which approximates the residual-square sum as a possible or proposed. The statistical analysis of re-


Fig. 1. The functional units of the general ABLET program. The three units to be written by the user are SUBROUTINE UBBE, SUBROUTINE DATA, MAIN PROGRAM. The rest of the ABLET system is identical for all programs.

second-degree surface of an elliptical paraboloid for one of the two parameters (*i.e.*, $m = 2$) in $(m + 1) = 3$-dimensional space. For more parameters than two ($m > 2$), it deals with a hyperparaboloid in $(m + 1)$-dimensional space.

Table 1 gives an example of a DHLET output which estimates three parameters, pK_a^T, $\hat{a}$ and C [from 20 data points (pK_a, I)] from Table 2. Key 7 calls the block LASK, which reads the initial guessed values for the parameters. Key 3 calls block STEG which reads the size of the initial minimization steps. Key 2 calls block UTTAG which calculates the residual-square sum function for an actual parameter value. Then a systematic search of parameters by block LETA, called by key 5, begins.

The minimization process starts with a "central" set $\vec{\beta}_c$ equal to initial guessed values for the parameters, supplied by the user, and calculates U for $\vec{\beta}_c$ and for sets where one or two elements in $\vec{\beta}_c$ have been changed by steps h_i. In the heuristic (trial-and-error) strategy, these steps are always supplied by the user, but in the algorithmic strategy they are supplied by the user only for the first iteration; for subsequent iterations they are calculated by the program.

From the U values for $(m + 1)(m + 2)/2$ systematically chosen points, the coefficients of the equation for a second-degree surface through these points are calculated, and hence the position $\vec{\beta}_0$ of the minimum on that surface. For brevity, the procedure described so far will be referred to as a "shot". The $\vec{\beta}_0$ obtained from the first shot may be used as the central value for the next shot, and so on. The co-ordinates of the pit, the lowest point of function U, are computed from the coefficients of the equations describing the approximate surface.

This pit-mapping method can also be employed when the parameters are inhomogeneous (*e.g.*, stability constants, molar absorptivities, concentrations, *etc.*). The U surface is very often distorted and not symmetrical. With such a cleft-like surface (a "skew pit"), or if there is a high degree of correlation between the β_i parameters, difficulties arise in the calculations. When the steps chosen are too large and the pit is deep and skew, the points are high up on the wall of the "cleft", and terms of third and higher degree become important. On the other hand, if the steps are too small, rounding errors in the computer can cause rounding errors in the calculation of $\vec{\beta}_0$.

STATISTICAL ANALYSIS OF RESIDUALS:
RESIDUAL MEAN = 1.52E-06
MEAN RESIDUAL = 0.0041
STANDARD DEVIATION = 0.0050
SKEWNESS = 0.022
KURTOSIS = 2.390
PEARSON CHI SQUARE = 3.20 and SHOULD BE 12.60
    (FOR 6 D.F. AND 0.95 PROBABILITY LEVEL)
R-FACTOR = 0.00103

The values of parameters are varied along the main axis of the pit instead of parallel to the original co-ordinate axes, in the second and subsequent refinement cycles.

For equilibrium constants and certain other types of parameters such as concentrations, a negative value has no physical meaning. LETAG[5] contains a number of safeguards to prevent such parameters from becoming negative during a shot, and at the same time to check that the calculation is not carried too far from the minimum.

If the calculated minimum $\vec{\beta}_0$ gives negative values for such parameters, they are set equal to zero, and the computer searches for the minimum of the "reduced pit". The block performing this operation, MIKO, searches the calculated second-degree surface systematically for the set $\vec{\beta}$ that gives the lowest value for U while no member of $\vec{\beta}$ is negative.

MIKO can also be used to find the set $\vec{\beta}$ that gives the lowest U value, subject to the restriction that each member β_i should have a value of either zero or not less than its standard deviation $s(\beta_i)$ multiplied by a selected factor F_s.

The ERROR ANALYSIS unit calculates the standard deviations of the estimated parameters and

dependent variable. LETAG[5] is used for calculating the residual-square sum function for the pit found, U_{min}, and the standard deviation of y, $s(y)$, which is denoted by SIGY in the output in Table 1 and is the square root of U_{min} divided by the square root of the number of degrees of freedom [$(n - m)$ where n is the number of data points and m the number of parameters]:

$$s(y) = \sqrt{U_{min}/(n - m)}. \qquad (5)$$

For defining the standard deviations $s(\beta_i)$ of the parameters, the term "D-boundary" was introduced by Sillén[1,2]. It is the curve or supercurve on which $U = U_{min} + s^2(y)$. The "D-boundary" is sometimes called the U contour. The standard deviation of each parameter $s(\beta_i)$ has a parabolic distribution and is calculated as the maximum difference between the value for β_i at any point on the "D-boundary" and the value for β_i at the minimum, $s(\beta_i) = D_i = [(\beta_D - \beta_0)_i]_{max}$. In the output of Table 1, $s(\beta_i)$ is printed under the heading DARR2 if it is available in the minimization process, otherwise −1.0 is printed.

The STATISTICAL TESTS unit identifies the "best" model when more than one hypothesis is

siduals involves examination of the differences between the experimental and calculated values of the dependent variable, $r_i = y_{exp,i} - y_{calc,i}$. The assumptions necessary for the least-squares treatment have already been mentioned. If the model represents the data adequately, the residuals should possess characteristics that satisfy or at least do not contradict the basic assumptions: thus the residuals should be randomly distributed about y_{calc}. Systematic departures from randomness indicate that the model is not satisfactory. The examination of plots of the residuals vs. x may assist numerical and/or graphical aids in the analysis of residuals. A study of the signs of the residuals ($+$ or $-$) and sums of signs can also be used.

For the analysis of residuals, graphical presentation is extremely helpful for the following tests: (i) detection of an outlier (an extreme residual), (ii) detection of a trend in the residuals, (iii) detection of sign changes, (iv) detection of an abrupt shift level of the experiment, (v) examination of residuals for normal distribution. A relative frequency plot should give approximately the familiar bell-shaped curve about a mean of zero.

For a more objective statistical analysis,[32] the set of residuals can be described by its four moments (cf. Table 2) and may be used for hypothesis testing.

(i) The first moment is the arithmetic mean of residuals $m_{r,1} = \bar{r}$, which should be equal to zero.

(ii) The second moment is the variance

$$m_{r,2} = \left(\sum_{i=1}^{n} r_i^2/n \right) - \left(\sum_{i=1}^{n} r_i/n \right)^2$$

and its square root is the standard deviation, which should have a value similar to the experimental error in the dependent variable y, $s_{inst}(y)$. The same rule is applied to the mean of the residuals which is calculated as the arithmetic mean of the absolute values of the residuals.

(iii) The third moment, the coefficient of symmetry (skewness) gives information about the symmetry of the residual distribution curve;

$$m_{r,3} = \sum_{i=1}^{n} (r_i - \bar{r})^3/nm_{r,2}^{3/2}$$

is equal to zero for a Gaussian distribution.

(iv) The fourth moment, the coefficient of kurtosis, characterizes the "peakedness" of the residual distribution curve and is defined by

$$m_{r,4} = \sum_{i=1}^{n} (r_i - \bar{r})^4/nm_{r,2}^2.$$

For a normal Gaussian shape it has the value 3.

(v) A goodness-of-fit statistic χ^2 (Pearson test) is derived from the difference between the observed and calculated probability distribution. The residuals may be divided into eight classes, each of which should contain 12.5% of all residuals. These classes are defined by the limits $-\infty$, $-1.15s$, $-0.675s$,

$-0.319s$, 0.0, $0.319s$, $0.675s$, $1.15s$, $+\infty$. Since the residuals standard deviation s is calculated from the residuals themselves, the total χ^2 has 6 degrees of freedom. A fit can be accepted at the appropriate confidence level if the experimental value χ^2 is less than the value expected.

(vi) The Hamilton R-factor is defined by the expression

$$R = \left[\sum_{i=1}^{n} w_i(y_{exp,i} - y_{calc,i})^2 \middle/ \sum_{i=1}^{n} w_i y_{exp,i}^2 \right]^{1/2}.$$

This value is compared with the limiting value R_{lim} calculated by saying $r_i = y_{exp,i} - y_{calc,i}$ is the residual in the ith equation calculated from pessimistic estimates of the errors in all experimental quantities, by using the error-propagation rules. To test alternative hypotheses, the R-factor ratio test can be applied. If, for example, a particular hypothesis H_0 gives an R-factor of R_0 and an alternative hypothesis H_1 gives the value R_1, then H_1 can be rejected at the α-significance level if $R_1/R_0 > R_{m,n-m,\alpha}$ where m is the number of parameters that have been refined and $(n - m)$ is the number of degrees of freedom of the least-squares adjustment. The value of $R_{m,n-m,\alpha}$ is found from statistical tables.[33]

Table 2 gives an example of a goodness-of-fit test for the data from Table 3 and the minimization process of Table 1.

The DATA SIMULATION unit calculates a simulated curve by the addition of generated random errors to the calculated precise curve. To test the reliability of a written program and the validity of the parameters estimated from a given type of experimental curve, simulated data are often used initially.

The user supplies values for the parameters, their standard deviations if available, the values of parametric weights if the conditioning of a particular parameter in the model is bad, and the values of the standard deviation of the dependent variable $s_{inst}(y)$, denoted by SINST. A set of n values of the independent variable x should also be given. The program then calculates precise values of "theoretical points" along the exact curve $y = f(x; \beta_1, \beta_2, \ldots, \beta_m)$. Each theoretical point is then converted into a simulated "experimental" one by the addition of a Gaussian error generated by a random-number generator. The four statistical moments, Pearson χ^2 test and Hamilton R-factor test are then applied to the "experimental" curve points, in order to check whether the errors are normally distributed.

The weight for each curve point, w_i, is calculated for m parameters

$$\vec{\beta} = (\beta_1, \beta_2, \ldots, \beta_m),$$

a vector of their standard deviations

$$\vec{s}(\vec{\beta}) = [s(\beta_1), s(\beta_2), \ldots, s(\beta_m)]$$

and a vector of their parametric weights

$$\vec{w}(\vec{\beta}) = [w(\beta_1), w(\beta_2), \ldots, w(\beta_m)]$$

Table 3. Simulation of pK_a-I curve points for pre-selected values of parameters, their standard deviations, their weights and errors s_{inst} (pK_a) for the dissociation $HL^- = L^{2-} + H^+$. Statistical analysis of the set of errors generated tests whether a distribution is Gaussian [$z = -1$, $(z-1)^2 - z^2 = 3$]

according to the general scheme

$$y_{i,0} = f(x_i; \beta_1, \beta_2, \ldots, \beta_m)$$ (6)

$$y_{i,1} = f[x_i; \beta_1 + s(\beta_1), \beta_2, \ldots, \beta_m]$$ (7.1)

$$y_{i,2} = f[x_i; \beta_1, \beta_2 + s(\beta_2), \ldots, \beta_m]$$ (7.2)

. . . .

$$y_{i,m} = f[x_i; \beta_1, \beta_2, \ldots, \beta_m + s(\beta_m)]$$ (7.m)

$$P_j = 1 / \sum_{i=1}^{n} (y_{i,j} - y_{i,0})^2$$ (8)

$$w_i = \sum_{j=1}^{m} P_j w(\beta_j) |y_{i,j} - y_{i,0}|$$ (9)

The value of the parametric weight $w(\beta_j)$ serves to increase the sensitivity of the jth parameter in the model. When all the parameters are well-conditioned in a model, their parametric weights are equal.

Table 3 demonstrates a data simulation for the program DHLET. The parametric values are $\beta_1 = 5.0$ $(=pK_a^T)$, $\beta_2 = 4.5$ $(=\mathring{a})$, $\beta_3 = 0.3$ $(=C)$. The standard deviations of the parameters can be set at any desired values; in this case the values were $s(\beta_1) = 0.02$, $s(\beta_2) = 0.3$, $s(\beta_3) = 0.01$. The statistical weight for each parameter can also be set to a suitable value to improve the sensitivity of the parameter in the model. Therefore $w(\beta_1) = 0.01$, $w(\beta_2) = 0.98$ and $w(\beta_3) = 0.01$. As the ion-size parameter $\mathring{a}$ is ill-conditioned in the model and its estimate is not so precise as the estimate of the other two parameters, its parametric weight was set at a value 98 times the parametric weights for the thermodynamic constant and salting-out coefficient. Statistical weights for each point on the pK_a-I curve are calculated according to the scheme above.

The OUTPUT unit displays the estimated results in various graphical ways: deconvolution of the experimental absorbance curve into the absorbance curves

for individual species, distribution diagrams for all the complex species in equilibrium, curves of molar absorptivities of requested species, curve fitting, fitness tests, *etc.* are possible.

The ADDITIONAL SUBROUTINES unit contains various mathematical subprograms, format-free reading subroutines, subroutines of matrix calculus, *etc.*

CONSTRUCTION OF AN ABLET PROGRAM

An ABLET program is constructed from (1) three specific units formulated by the user for the particular mathematical model of the equilibrium study and (2) six permanent units which are the same for all ABLET family programs.

Units formulated by the user

The MASTER unit contains the MAIN PROGRAM which reads in some of the organization data, keys, termination criteria, *etc.* SINST is set such that either synthetic data (SINST > 0) or experimental data (SINST = − 1.0) are treated. The present version of ABLET allows up to N = 50 curve points and M = 8 unknown parameters. Enlargement of arrays for M in single precision may lead to instability in the least-squares algorithm LETAG, and is at the risk of the user. An array for the parametric vector XK(M), parametric standard deviations SIGXK(M) and parametric weights WEI(M) should be declared. Variable arrays are transferred by COMMON/FUNC/. This contains a vector for the independent variable XEXP(50), a vector for the dependent variable YEXP(50), a vector for the generated random error ERR(50), a vector for the calculated variable YCAL(50) and a vector of weight for each curve point W(50). The input channel number NI is transferred by COMMON/KANAL/ and four numerical constants for printer-plotting subroutine PLOTT and seven keys are transferred by COMMON/PLOT/ and COMMON/ISW/.

```
MAIN
DIMENSION XK(8),SIGXK(8),WEI(8)
COMMON/FUNC/XEXP(50),YEXP(50),ERR(50),
YCAL(50),W(50)/KANAL/NI
COMMON/PLOT/MY,MX,NLS,NCL,DUMMY
  (1930)/ISW/ISSW(7)
. . .
. . .
STOP
END
```

The INPUT unit should contain a version of SUBROUTINE DATA(IOU,NB) written for the particular equilibrium problem. The subroutine reads the experimental data and does some preliminary calculations. It has two arguments: IOU is an output channel number and NB the number of curve points. All variables are transferred by labelled COMMON

blocks. The preliminary calculations must be specified by the user.

```
SUBROUTINE DATA(IOU,NB)
COMMON/FUNC/XEXP(50),YEXP(50),ERR(50),
YCAL(50),W(50)/KANAL/NI
CALL READI(NB,1)
. . .
. . .
RETURN
END
```

The RESIDUAL-SQUARE SUM unit should contain a subroutine UBBE(U,NK,XK,NB) which uses the parametric vector XK(M) and the independent variable vector XEXP(N) to calculate a dependent variable vector YCAL(N) and then the sum of squared residuals

$$\sum_{i=1}^{n} W(I)*[YEXP(I) - YCAL(I)]^2.$$

The arguments for UBBE are NB, the number of curve points; NK, the number of parameters; XK, the parametric vector; and U, the residual-square sum function. Other variables are transferred by a labelled COMMON.

```
SUBROUTINE UBBE(U,NK,XK,NB)
DIMENSION XK(NK)
COMMON/FUNC/XEXP(50),YEXP(50),ERR(50),
YCAL(50),W(50)
U = 0.0
DO 1 I = 1,NB
. . .
. . .
YCAL(I) = . . .
1 U = U + W(I)*(YEXP(I) - YCAL(I))**2
RETURN
END
```

Permanent parts of the ABLET program

The MINIMIZATION unit contains SUBROUTINE LETAG(IOU,NAUT,NK,NB,XK,UMIN, ISSW,DARK2,DATA,UBBE,SKRIK),[5] which performs a search for parameters XK and their standard deviations SIGXK. The LETAG subroutine is divided into independent logical blocks, use of which is controlled by the value of IRUR. Its arguments are IOU, the output channel number; NK, the number of parameters; NB, the number of curve points; ISSW, the vector of keys; subroutines DATA, UBBE and SKRIK; NAUT, a key; XK, a parametric vector; DARK2, a vector of parametric standard deviations calculated in LETAG; and UMIN, the minimum of U achieved.

The STATISTICAL TEST unit contains SUBROUTINE STATS(IOU,NK,NB,X,Y,EPS) which is adapted from the program MINIQUAD.[32]

The DATA SIMULATION unit contains three subprograms, SIMUL, NORAND and FUNCTION RANDOL. In the SUBROUTINE SIMUL

(X,YC,YM,NB,ISTART) X is the vector of the independent variable; YC the vector of dependent variable calculated precisely; YM the vector of dependent variable loaded with an error generated by $YM(I) = YC(I) + SINST*EPS(I)$ where $EPS(I)$ is the random error generated by subroutine NORAND;[34] SINST is the standard deviation of the dependent variable; ISTART is a starting value for generation of random numbers. SUBROUTINE NORAND(D1,D2,IS) is the routine[34] for generation of random numbers and calls internal FUNCTION RANDOL(IS).

The OUTPUT unit contains SUBROUTINE SKRIK(NB,NK,IOU,IRUR,XK,SIGXK) and outputs the estimated parameters and their standard deviations, a statistical analysis of residuals, and a printer-plot of the curve-fitting done by subroutine PLOTT.[35]

The ADDITIONAL SUBROUTINES unit contains seven subroutines: WEIGHT, PLOTT, READI, READR, INVERT, PINUS and MULLE. SUBROUTINE WEIGHT(UBBE,NB,XK,SIGXK,WEI) calculates weights for simulated curve points. SUBROUTINE PLOTT(XX,YY,NDATA,NDMAX, ISYMBL,NF,XLINE,MX,YLINE,MY,NLS,NCL, MM,LL,AREA,YSCALE) makes a line-printer plot.[35] SUBROUTINE READI(I,N) and SUBROUTINE READR(A,N) are used for format-free input. I is the identifier of the variable or array to contain N integers, and A is the identifier of the variable or array to contain N reals. The input channel is defined by COMMON/KANAL/NI, e.g., NI = 5. As separator between two numbers, blank(s) or comma(s) may be used, or any symbol(s) which cannot be interpreted as numbers by READI or READR (e.g., 1E7 is interpreted by READR as 1.0×10^7 but by READI as two different integers 1 and 7). When r numbers of the same value are to be read in, the form $r*$ number may be used, e.g., 5.52, 5.52, 5.52 may be written as 3*5.52. The form 5*b, where b is one blank, causes READI or READR to skip the next readings, leave the corresponding variables at their previous values.

Three internal subroutines of LETAG are SUBROUTINE INVERT for matrix inversion,[2] SUBROUTINE PINUS for multiplication of a vector by a matrix,[2] and SUBROUTINE MULLE for multiplication of a matrix by a matrix.[2]

CONCLUSION

Many problems in a wide variety of fields of analysis can be reduced to the problem of finding a correct mathematical model and its unknown parameters by minimizing the difference between experimental and calculated data. ABLET is a system of subprograms to solve such problems. Since in prin-

ciple ABLET is designed to handle any function $y = f(x; \vec{\beta})$ it is quite general, and it may suit the needs of quite different users, not only in the study of solution equilibria.

A listing of the ABLET system and data input instructions are available on request.

A NEW PROCEDURE FOR SEPARATION OF THE ENAMEL AND DENTIN OF HUMAN TEETH

BRUCE R. SMITH, CAROLE YOUNGBERG, DENNIS FINTON,
DAVID WILLEY and THEODORE R. WILLIAMS*

JANET B. VAN DOREN
University of Akron, Akron, Ohio 44325, U.S.A.

Summary—A new method for the separation of enamel and dentin in various types of human teeth is proposed. The separated enamel and dentin samples have been analysed for thirteen elements by inductively-coupled plasma emission-spectroscopy and also for fluoride.

Many of the recent reports on trace metals in biological tissues merely report the bulk concentrations for the sample. Such is the case with most studies involving the analysis of human teeth. There have, however, been a few efforts to separate teeth into their various components before analysis. One method[1] involves a bromoform–acetone flotation process based on the differences in density of the various components of teeth. Another involves a mechanical separation of enamel and dentin with a diamond saw.[2,3] A third suggests the use of a dental burr[4] to section the teeth. All three have significant limitations. In the flotation procedure, some of the sample tends to adhere to the bromoform surface, and there is considerable risk of contamination when the mechanical separation is used.

There have been only a few reports of multiple-element analysis of human teeth and none involves the separate analysis of dentin and enamel. Oehme *et al.*[5] determined copper, lead, cadmium and zinc in whole teeth, by anodic-stripping voltammetry, and Curzon and Crocker[6] analysed over 300 whole enamel samples for 29 elements by spark-source mass spectrometry. Our study was undertaken to develop a method for separating the enamel and dentin of human teeth before analysis for trace metals or fluoride, and to minimize the risk of sample contamination.

In our preliminary work, attempts were made to separate the enamel and dentin by mechanical means. Our experiences indicated that it was very easy to contaminate the sample when grinding or chipping techniques were used. A number of earlier studies employed the freeze–thaw technique, but, in our opinion, they do not offer any advantages over our newly proposed procedure. The freeze–thaw method requires subjecting the tooth to temperature extremes over a 2-day period, followed by mechanically chipping the tooth to separate the enamel and dentin. The cementum can only be separated from the dentin by chipping the tooth under the microscope at 40× magnification. The new method avoids this problem and the various solutions obtained are ready for immediate analysis. Several teeth can be dealt with simultaneously, so the effective working time required to separate the enamel and dentin is less than 1 hour per tooth. The solutions obtained are analysed by plasma emission-spectrometry for twelve metallic elements and boron, and by ion-selective electrode for fluoride.

EXPERIMENTAL

Tooth samples

Intact, non-carious permanent human teeth were obtained from Defiance, Ohio and the suburban Cleveland area. Following extraction, the teeth were immediately placed in polyethylene vials and frozen to retard contamination. Before analysis, extraneous blood, tissue, bone, and collagenous material were removed from each tooth by agitation in 5 ml of 3% reagent-grade hydrogen peroxide (Fisher Scientific Company) for 5 min. Next the teeth were rinsed with distilled demineralized water and any remaining tissues were removed by scraping with a Teflon spatula. The samples were rinsed again in distilled demineralized water, air-dried overnight and stored at −15° in Falcon 2070 plastic tubes until they were prepared for analysis.

Reagents

Digestion reagents. A protective coating material of "Total" denture rebase power (autopolymerizing) and "Total" acrylic rebase liquid (self-curing) was supplied by Stratford-Cookson Company of College Park, Georgia. These materials gave no appreciable trace metal signals.

Nitric acid, 0.6*M*, was prepared from "Suprapur" (Matheson-Coleman and Bell) or "Baker Instra-Analyzed" reagents which are designed for trace metal analysis.

Metal standards. Standard solutions were prepared in Nalgene standard flasks and then stored in Falcon 2070 polyethylene tubes. Most were prepared from Matheson Coleman and Bell 1000-ppm atomic-absorption standards, and the others from atomic-absorption standards available from Anderson Laboratories Inc., Fort Worth, Texas.

---

*Author for correspondence.

Solutions for fluoride determination. Sodium fluoride standards down to $10^{-5}M$ were prepared by serial dilution of a $0.1M$ stock solution made by dissolving the Baker "Analyzed grade" material in $0.6M$ nitric acid ("Suprapur"). The total ionic strength adjustment buffer (TISAB) was prepared by dissolving 57 ml of glacial acetic acid (Baker "Analyzed"), 58 of sodium chloride (Baker "Analyzed"), and 4 g of diaminocyclohexanetreta-acetic acid (ICN Pharmaceutical, Inc., Plainview, N.Y.) in 500 ml of distilled demineralized water, adjusting to pH 5.0–5.5 with $5M$ sodium hydroxide (Baker "Analyzed"), and diluting to 1 litre with distilled demineralized water.

Apparatus

Analysis for metals and boron. An ARL ICPQ-137 inductively-coupled plasma spectrometer was used, under standard operating procedures.

Digestion. Parr A 238 Teflon containers and lids were used. Each container was inserted into a Parr 4745 acid-digestion bomb or an aluminium jacket before heating on a Corning PC-35 hot-plate. Before use, all the Teflon caps and lids were cleaned with 25% nitric acid (Fisher Reagent Grade) in a Bransonic B-12 ultrasonic cleaner, and rinsed several times with distilled demineralized water.

Fluoride determination. A fluoride ion-selective electrode (Orion Model 94-09) and a silver–silver chloride reference electrode (Sargent-Welch, Model 30080-10C, platinum junction) were used in conjunction with a digital Corning 135 pH/ion-meter.

Selective sectioning procedure. To dissolve the various layers of the tooth, several acids already used for the purpose were tried. Although lactic acid, hydrochloric acid[2,8] and acetic acid[2] have been reported to be effective in achieving the separation, none was as effective as the $0.6M$ nitric acid.

Several protective coatings were tried in the initial work, including spray acrylic, paraffin wax and lucite. Dental rebase mixture, which is used as a temporary liner for dentures, was found to be the most effective. Disposable surgical gloves were worn whenever handling the teeth. Tweezers and spatulas coated with Teflon or Parafilm were used for handling the teeth, to prevent contamination.

The sample teeth were thawed at room temperature and allowed to dry in air, under a tissue-paper cover. The dry teeth were weighed and then coated with denture rebase mixture (over the cementum only). Each of the Teflon containers was inserted into the metal jacket of a Parr 4745 acid-digestion bomb and the bombs were placed on the Corning PC-35 hot-plate; 15 ml of $0.6M$ "Suprapur" nitric acid were added to each Teflon container and the lids were replaced. The acid was given 15 min to reach a steady temperature of approximately 90°, at which the enamel was to be digested. The coated sample teeth were then inserted into the Teflon containers (one in each) and these were then recapped. The temperature was kept constant throughout the digestion.

In the preliminary work, X-rays were taken to check the completeness of enamel removal. The digestion times for the dissolution of the enamel depend on the type of tooth (Table 1). Once the enamel is removed, the digestion time for the dentin is the same for all teeth.

On completion of removal of the enamel layer, the remains of the teeth were extracted from the containers with Teflon-covered forceps and the enamel solutions were poured into polyethylene tubes which were immediately transferred to a freezer (at $-15°$) to await elemental analysis. The coated tooth remains were placed in an oven at $\sim 140°$ for 5–10 min to soften the denture rebase. The coating was then peeled off with a Teflon-coated spatula and the remaining tooth parts were weighed and placed in polyethylene tubes.

The next step involved the removal of residual enamel and

Table 1. Enamel-digestion times for various tooth groups

Tooth group	Digestion time, *min*

Lower incisors	20
Cuspids	30
Bicuspids	30
Molars	60

cementum, leaving just the dentin. By the same procedure as for the enamel digestion, excepting the addition of 20 ml of $3M$ "Suprapur" nitric acid, the Teflon containers and lids were cleaned and placed on the hot-plate. After addition of the tooth remains, the capped containers were heated at 90° for 10–15 min, and then examined to see whether the remaining tooth parts floated. Flotation of the tooth remains indicated a change in density which was attributed to having only the dentin left unconsumed. However, if the surviving tooth sections did not float, the bombs were recapped and digestion continued for an additional 5 min. The additional heating consistently produced flotation. This flotation proved reproducible.

The dentin remnants were removed from the Teflon (Parr acid-digestion) containers and placed in polyethylene tubes, air-dried, and weighed. The Teflon containers were then cleaned, and the dentin samples put back into them along with 7.5 ml of $1.2M$ "Suprapur" nitric acid, preheated to 100°. The containers were placed in the Parr bombs, which were then tightly capped, and heated for 75 min on the hot-plate at 90°. After this time the dentin was completely in solution. The resultant solutions were diluted to 15 ml with distilled demineralized water and poured into polyethylene tubes, in which they were then frozen (at $\sim 15°$) and stored at the same constant temperature until analysis.

Procedure for metals and boron. Without further dilution, the whole 15 ml of solution was thawed and analysed with the ICP. This procedure results in approximately a 1:15 dilution of the original material. The enamel portion is approximately 0.6–0.8 g and the dentin 0.2–0.4 g.

Procedure for fluoride. A 2-ml portion of the 15 ml of diluted digest was pipetted into a Falcon 2076 graduated 50-ml plastic tube. Enough TISAB (6–9 ml) was added to bring the pH to 4.8–5.0 and the solution was diluted to the 15-ml mark with distilled demineralized water. The fluoride content was then measured with the ion-selective electrode.

In the early work the dilution was done by weight on a top-loading balance, but later the dilution was done as described above, when it was found that the reproducibility was adequate (2%).

RESULTS

Table 2 summarizes the results for samples obtained from the northeast Ohio area. The technique was also applied to the determination of fluoride in samples obtained from the northwest Ohio area (Table 3). Both sets of samples came from both fluoridated and non-fluoridated communities.

DISCUSSION

Most of our values are somewhat lower than those obtained in earlier studies. This may be partially due to the lower risk of contamination. In particular, the earlier values are much higher than ours for potas-

sium, sodium, iron and boron, which are normally contaminants from glassware. The use of Teflon containers for the digestion process eliminates the introduction of such elements.

Clearly, there are advantages in analysing the enamel and dentin separately. Only limited reports on the composition of these portions of human teeth exist. Often only mean values are given, with no indication of the range of the data. Table 2 provides values for some elements for which no previous results are available.

The most remarkable differences in the composition of the enamel and dentin are for magnesium, fluoride and aluminium. The magnesium concentrations were considerably greater in the dentin than in the enamel. The dentin is much more porous than the enamel, thus enabling the systemic introduction of elements. Magnesium is able to substitute easily for calcium in the structure of the tooth, which is primarily hydroxyapatite.

The fluoride levels are also much higher for the dentin than the enamel, by a factor of at least three. The literature shows almost no relation between fluoride levels in enamel and dentin. It appears that a great deal of the fluoride which is ingested from water supplies and toothpastes is concentrated in the teeth. Although aluminium is present in many foods, the levels in dentin suggest that it is not systemically concentrated in the body.

Comparison of the values from previous work with ours shows certain clear differences. The samples from the Ohio area gave somewhat higher chromium values than those of other workers. A possible explanation is that the concentration of this element in the water supplies varies with the different regions. Similar considerations apply to strontium, the content of which, in minerals, varies considerably, depending on the region of the United States.[20] This may account for the wide range of values previously found for this element in the enamel.

Several questions are raised by this study. One important issue is which elements are associated with the fluoride ingested from water or fluoride-containing dental materials. A second concern is whether there is any relationship between the number of cavities and the metal content in a person's teeth. Both of these questions are at present under study in our laboratory. A third problem is that of considerable skewness in the distributions for iron, copper, manganese, chromium, strontium and barium in both enamel and dentin. Correlations between unusually high levels of different elements would also be of interest, but were not looked for in the present work.

EXTRACTIVE SEPARATION AND SPECTROPHOTOMETRIC DETERMINATION OF PALLADIUM AND PLATINUM WITH DITHIZONE IN THE PRESENCE OF STANNOUS CHLORIDE

Z. MARCZENKO, S. KUŚ and M. MOJSKI

Department of Analytical Chemistry, Technical University, Warsaw, Poland

Summary—The conditions [acid used, presence of chloride and tin(II)] for the extractive separation and spectrophotometric determination of palladium and platinum as the dithizonates $Pd(HDz)_2$ and $Pt(HDz)_2$ have been examined. In the absence of stannous chloride platinum does not undergo extraction. Conditions for the separation and determination of these metals in the presence of mercury, gold and copper, which are also extracted with dithizone into carbon tetrachloride or chloroform under the conditions suitable for palladium (1*M* sulphuric acid/0.1*M* hydrochloric acid), have been defined. The mercury and gold dithizonates are formed quickly and can be removed before the palladium and platinum compounds have had time to form. They can be decomposed with iodide. Copper dithizonate is decomposed by reduction with tin(II). The proposed procedure has been applied to the determination of palladium in technical platinum metal.

The methods of separation of platinum metals are of considerable importance in the chemical analysis of these metals because of substantial similarities in their chemical properties. These separation methods have been reviewed.[1-3] Among the organic reagents that can be applied for extractive separation of palladium from platinum, dithizone is worthy of attention.[4-6] Several papers have been published on the spectrophotometric determination of palladium[7-11] and platinum[7,12,13] with dithizone, but some aspects of this subject still require more clarification.

The study described here was devoted mainly to extractive separation of palladium from platinum with dithizone. In solving this problem attention has been paid to the advantages of introducing stannous chloride into the aqueous phase, since for a number of other extractive reagents, *e.g.*, thiourea derivatives,[14] dioctyl sulphide,[15] triphenylphosphine,[16] the use of stannous chloride in the extraction system has made it possible to separate the platinum metals effectively.

EXPERIMENTAL

Reagents

Standard palladium solution (1 mg/ml) was prepared by dissolving 0.84 g of palladium(II) chloride in 10 ml of concentrated hydrochloric acid and diluting to volume with water in a 500-ml standard flask. The solution was standardized gravimetrically with dimethylglyoxime. Working solutions (*e.g.*, 10 μg/ml) were obtained by suitable dilution of the stock solution with water.

Standard platinum solution (1 mg/ml) was prepared by dissolving 0.5000 g of suitably pure platinum metal in 20 ml of *aqua regia*. Oxides of nitrogen were removed by three successive evaporations (almost to dryness) with hydrochloric acid. The residue was dissolved in 10 ml of concen-

trated hydrochloric acid, and the solution was transferred to a 500-ml standard flask and diluted to volume with water. Working solutions were obtained by suitable dilution of the stock solution with water.

Dithizone (H_2Dz), 0.01% solution in carbon tetrachloride or chloroform, was standardized by extractive titration of standard silver solution.[3]

A 1*M* stannous chloride solution in 2*M* hydrochloric acid was used.

Procedure

Separation and determination of palladium. From the acid test solution, *ca.* 1*M* with respect to sulphuric acid and 0.1*M* with respect to hydrochloric acid (volume *ca.* 20 ml), containing platinum and not more than 50 μg of palladium, extract palladium with two portions of $2 \times 10^{-4}M$ dithizone in carbon tetrachloride (shaking for 2 min), and reserve the aqueous phase for platinum determination. Shake the combined extracts for 30 sec with 5 ml of 4*M* hydrochloric acid plus one drop of 1*M* stannous chloride. Separate the phases and shake the organic extract with two 5-ml portions of dilute ammonia solution (1 + 50). Separate, and dilute the extract to volume with carbon tetrachloride in a 10–25 ml standard flask, according to the amount of palladium. Measure the absorbance of the $Pd(HDz)_2$ solution at 635 nm against carbon tetrachloride.

Determination of platinum. To the aqueous phase reserved from separation of palladium, add 1 ml of hydrochloric acid (1 + 1) and 0.2 ml of 1*M* stannous chloride. Extract the platinum with two portions of $2 \times 10^{-4}M$ dithizone in chloroform (shaking for 1 min). Wash the combined extracts first with 5 ml of 1*M* hydrochloric acid, and then with 5 ml of ammonia solution (1 + 50). Dilute the organic phase with chloroform to a known volume (standard flask), suitable for the amount of platinum. Measure the absorbance of the $Pt(HDz)_2$ solution at 710 nm against chloroform.

RESULTS AND DISCUSSION

Extraction and determination of palladium

When an acidic aqueous solution of palladium(II) is shaken with excess of dithizone solution in carbon
Fig. 1. Absorption spectra of: 1—dithizone, 2—Pd(HDz)₂, 3—Pt(HDz)₂ (in carbon tetrachloride).

tetrachloride or chloroform, grey-green palladium dithizonate is formed. The absorption spectrum of Pd(HDz)₂ in carbon tetrachloride has absorption maxima at 450 and 635 nm (Fig. 1).

The concentration of sulphuric acid or perchloric acid present should not exceed $4M$. It is not advisable to use nitric acid of concentration higher than $1M$, because it would readily oxidize the dithizone. The concentration of hydrochloric acid (alone or in the presence of the above-mentioned acids) should not exceed $0.1M$. As the concentration of chloride increases, the formation of Pd(HDz)₂ becomes more and more difficult because of the inertness of $PdCl_4^{2-}$ towards dithizone, and the necessary shaking time for complete extraction becomes longer.

Palladium dithizonate in carbon tetrachloride or chloroform is stable in time and when formed is resistant to hydrochloric acid (1 + 1), sulphuric acid (1 + 1) and ammonia solution (up to $3M$). A single shaking for 30 sec with dilute ammonia solution (1 + 50) will remove the excess of dithizone from the organic phase.

The completeness of extraction of palladium dithizonate is a function of the concentration of dithizone in the organic phase, the shaking time, and the nature of the aqueous medium, as shown in Figs. 2 and 3.
The rate of extraction of palladium is considerably increased by the presence of small amounts of stannous chloride in the solution, because $SnCl_3^-$ ions replace chloride ions in the chloride complex of palladium (which is rather inert towards reaction with dithizone) and are themselves easily displaced by dithizonate ligands.

The calibration graph obtained under the conditions given in the procedure is linear up to a palladium concentration of 2.5 μg/ml. The molar absorptivity is 3.55×10^4 l.mole^{-1}.cm^{-1} at 635 nm.

Extraction and determination of platinum

Platinum(IV) in acid solutions ($0.1–4M$ hydrochloric, sulphuric, or perchloric acid) does not form a dithizonate when shaken with dithizone solution in carbon tetrachloride or chloroform, and can oxidize the dithizone. Nor is platinum extracted with dithizone in the presence of ascorbic acid or sulphite, even though these reducing agents transform platinum(IV) into platinum(II). If stannous chloride is added, however, brown-yellow platinum(II) dithizonate is rapidly extracted. As can be seen from Figs. 4 and 5, the optimum conditions for the extraction of platinum are ca. $1M$ sulphuric acid and $0.1M$ stannous chloride or $1–2M$ hydrochloric acid and $0.01–0.05M$ stannous chloride. For a mixed medium ($1M$ sulphuric acid/$0.5M$ hydrochloric acid) a lower concentration of stannous chloride ($0.01M$) is sufficient. It is best to use chloroform as solvent, because platinum dithizonate is more soluble in it than in carbon tetrachloride.

Platinum dithizonate is stable in time and resistant to ammonia, which can therefore be used for removing the excess of dithizone from the extract. Before the treatment with ammonia, however, it is necessary to wash the extract with $1M$ hydrochloric acid to decompose the red tin(II) dithizonate, which forms in the pH range 5–9.[4]

The absorption spectrum of platinum dithizonate (Fig. 1) has maxima at 490 and 710 nm. Dithizone does not absorb light of the latter wavelength.

Fig. 3. Dependence of palladium extraction on shaking time, from: 1—$1M$ HCl, 2—$1M$ H₂SO₄, 3—$0.05M$ HCl.
Fig. 4. Dependence of platinum extraction on stannous chloride concentration, from: 1—$1M$ HCl, 2—$1M$ H_2SO_4.
Fig. 5. Dependence of platinum extraction on acid concentration: 1—HCl (and $0.01M$ $SnCl_2$), 2—H_2SO_4 (and $0.1M$ $SnCl_2$).

Unlike palladium (which would form the pink secondary dithizonate[10]), at high Pt:H_2Dz ratio platinum can be extracted stepwise with successive small portions of dithizone solution. This fact allows the composition of the platinum dithizonate to be determined by the spectrophotometric titration method; the compound is found to be 1:2 (Pt:HDz).

As ternary complexes of platinum metals are known which contain $SnCl_3^-$ as a ligand, it was necessary to check whether the platinum compound extracted in the presence of stannous chloride contained any tin. After evaporation of the solvent and mineralization of the residue with concentrated sulphuric and nitric acids, the spectrophotometric method for determination of tin with phenylfluorone[3] was applied but no tin was found. The correctness of the result was verified by analysing the extracts after addition of known amounts of tin before the mineralization. The tin introduced was completely recovered. Therefore platinum dithizonate can be ascribed the formula $Pt(HDz)_2$. The stannous chloride used in the procedure performs a double function: it reduces Pt(IV) to Pt(II), and then transforms the platinum chloro-complex (rather inert towards dithizone) into the more labile complex with $SnCl_3^-$ as ligand.

The calibration graph obtained according to the procedure is linear up to a platinum concentration of $5\,\mu g/ml$. The molar absorptivity is $3.50 \times 10^4 \, l.mole^{-1}.cm^{-1}$ at 710 nm, and $3.75 \times 10^4 \, l.mole^{-1}.cm^{-1}$ at 490 nm.

Separation of palladium from platinum

It follows from the investigations described above, that palladium can be separated from platinum with dithizone. The palladium can first be extracted with dithizone from ca. $1M$ sulphuric acid medium. In the absence of stannous chloride platinum remains in the aqueous phase. Low concentrations of stannous chloride (below $0.001M$ in the aqueous phase) would increase the rate of extraction of palladium and prevent dithizone from being oxidized by platinum(IV) and aerial oxygen, but would also result in extraction of small quantities of platinum. It is therefore better to extract the palladium in the absence of stannous chloride and then to wash the extract with a highly dilute stannous chloride solution in $4M$ hydrochloric acid; the tin(II) reduces the dithizone oxidation products back to dithizone, which can then be removed from the extract by washing with ammonia. Furthermore, any copper(II) dithizonate which may be present in the extract is decomposed by reduction of the Cu(II) to Cu(I) by the Sn(II).

Various mixtures of palladium and platinum were analysed by the proposed procedure. The results in Table 1 show good precision and accuracy, and indicate the possibility of determining palladium in the presence of large quantities of platinum.

Other platinum metals do not react with dithizone under the conditions used.[4,5] Silver, mercury, gold and copper can also be extracted with dithizone from acidic media, but silver does not form a dithizonate in the presence of chloride. The orange-yellow mercury(II) dithizonate forms quickly; shaking for several seconds is enough. Hence, any mercury can be preliminarily separated by extraction with small portions of dithizone solution in carbon tetrachloride. These extractions are continued until there is a change in colour between one portion of dithizone extract and the next. Any mercury in this last portion of extract can be removed by brief shaking with a dilute acid solution of potassium iodide containing a little ascorbic acid (to prevent oxidation of iodide to iodine), and the organic phase added to the subsequent palladium extracts.

Brown-yellow gold dithizonate is also extracted quickly. For larger amounts of gold it is better to use a chloroform solution of dithizone, in which gold

dithizonate is more soluble. The procedure is the same as that for removal of mercury, including the washing with potassium iodide solution.

Copper(II) (especially in larger quantities) reacts with dithizone faster than palladium does, forming a violet dithizonate. However, if the extraction is prolonged (*e.g.*, to 5 min), palladium displaces copper from its dithizonate, because palladium dithizonate is more stable than copper dithizonate.[5] As explained above, any copper present in the palladium extract can be removed by shaking with $4M$ hydrochloric acid containing a little stannous chloride.

A series of solutions containing (besides palladium and platinum) known quantities of copper, mercury and gold, separately or simultaneously, was analysed, the procedure being modified as already indicated, by prior separation of mercury and gold by shaking with small portions of dithizone solution (for a few seconds) until there was a change in colour from one extract to the next, and the last of these extracts was then washed with 5 ml of 2% potassium iodide/0.1% ascorbic acid solution in $1M$ sulphuric acid, and added to the subsequent extracts containing palladium and copper. The results shown in Table 2 were satisfactory.

The proposed method was applied to determination of palladium in technical platinum metal.

The sample was dissolved in *aqua regia* and the product was subjected to alternating evaporation almost to dryness and addition of hydrochloric acid. The residue was dissolved in $2M$ sulphuric acid. The palladium was extracted and determined in aliquots corresponding to 5 mg of the sample. The palladium content found was $0.12 \pm 0.01\%$ (for 6 determinations). The recovery was checked by addition of 5 μg of palladium to the test solution, and re-analysis, and found to be 95%.

EXTRACTION OF COBALT FROM THIOCYANATE SOLUTIONS WITH POLYURETHANE FOAM

R. F. HAMON and A. CHOW

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba, Canada

Summary—The extraction of cobalt (II) from aqueous thiocyanate solutions with polyurethane foam has been extensively investigated. The extraction is enhanced by high thiocyanate concentration, high ionic strength and low temperature. A pH of 1.0–9.0 can be used for efficient extraction. Cobalt can be extracted at low concentration and the distribution coefficient is independent of foam weight. Several foam types and foam pretreatments have been examined. The effect of various substances added to the cobalt thiocyanate solutions has been investigated. Some of these substances caused either enhanced or decreased extractions by interacting with the polyurethane foam or by changing the solution chemistry.

The thiocyanate complex has been used for several decades as a means of extracting cobalt into organic solvents.[1] The sorption of cobalt by flexible polyurethane foam from thiocyanate solutions has been reported,[2-7] although no very detailed studies were undertaken. The present paper outlines a systematic investigation of the extraction of cobalt, which was used to provide precise information on the sorption process under a wide variety of conditions. Throughout this work, cobalt-60 was used as a tracer so as to provide the most precise data possible, and extreme care was taken to eliminate or correct for as many sources of error as possible.

EXPERIMENTAL

Apparatus

Radiometric counting was done with a Baird-Atomic model 530A gamma spectrometer and spectrophotometric measurements with a Unicam model SP800B recording spectrophotometer. Pyrex cells for distribution studies were designed so that 150 ml of solution could be equilibrated with a foam sample by squeezing, this action causing reasonable stirring and minimal splashing of the sample. These cells consisted of a lower section with a side-arm and stopper for removal of samples, and an upper section with a central sleeve and glass plunger. A mechanical squeezer was made with plungers driven up and down in the extraction cells by means of large glass tubes on brass cams mounted eccentrically on a motor-driven rod. This system gave the plungers a 5-cm stroke at a rate of 25 cycles/min. A controlled-temperature cabinet was made, fitted with a heater and cooler, and a fan for circulation of the air in the system. The temperature was maintained within ± 0.05° of the preset value, and the difference between cell temperatures was approximately ± 0.01°. Details of the cells and squeezing apparatus are available on request.

Standard flasks were calibrated to contain 150 ml ± 0.06%. The Pyrex test-tubes used for gamma-counting were numbered and calibrated to contain 15.0 ml. A counting error of only ± 0.07% was caused by a variation of 0.1 ml in volume, since the sample extended well beyond the detector crystal. Slight differences in counting geometry of the tubes were corrected for by using a radioactive tracer calibration solution to obtain a correction factor (maximum 2%).

All chemicals were reagent grade and the water was doubly distilled and then demineralized. A stock solution of 1000 ppm (17 mM) Co(II) was prepared from $CoCl_2.6H_2O$ in $10^{-3}M$ hydrochloric acid. Tracer ^{60}Co (ICN Nuclear), obtained as $CoCl_2$ solution, was mixed with concentrated hydrochloric acid and evaporated to dryness, then the residue was taken up in $0.001M$ hydrochloric acid for storage. A $2.5M$ sodium acetate/acetic acid buffer (pH ~4.7) was used.

Polyether-type polyurethane foam (# 1338 from G. N. Jackson Ltd., Winnipeg, Canada) was used for all experiments except those investigating the effect of foam type. All foams were cut into cubes (1.3 cm edge), cleaned by soaking in $1M$ hydrochloric acid for 12 hr, washed in distilled water, washed in a Soxhlet apparatus with acetone for 6 hr, and dried. A foam weight of 50 ± 2 mg was generally used, with the weight measured to 0.01 mg after any static charge had been allowed to dissipate in a grounded metal container. To avoid any bias from the sample cells or position, the ten solutions were randomized with respect to numbered sample location. Observed evaporation losses of 1.8% over 24 hr were reduced to 0.3% by using a latex rubber seal over the plunger and cell neck.

Sample solutions were prepared as required and 30 or 40 μl of ^{60}Co tracer added. After rough dilution and mixing, the solutions were left overnight for temperature and solution equilibration before the final volume adjustment and mixing. A 15-ml aliquot was withdrawn from each sample, counted on the gamma-spectrometer for ten 100-sec periods, and carefully returned to its original flask. The sample was then placed in a distribution cell, with 99.70–99.75% of the 150 ml actually transferred. All gamma-spectrometer data were corrected for both background and detector drift. The background was obtained from one hundred 100-sec counting periods. A solid ^{60}Co standard was used with every counting sequence to determine any detector drift. Calibration indicated that the detector had a linear response over the normal counting-rate range.

In all cases the equipment was washed and dried before use, to prevent sample loss or dilution. Samples were usually taken after 6, 12 and 24 hr since this gave information on when equilibrium was obtained and the relative rates of equilibration.

It should be noted that in many experiments, in order to obtain meaningful data it was necessary to use conditions which were not optimum, since the distribution coefficient was so large. Calculations of the distribution coefficient (D, l./kg) and degree of extraction (%E) were done as previously discussed.[8]
Fig. 1. Time dependence of cobalt sorption. Conditions: 0.05 g of foam; 150 ml of solution $1.7 \times 10^{-6}M$ in Co(II), $0.10M$ in NaSCN, ionic strength $3.00M$, pH 4.8, 25.00°. Duplicate experiments, A and B.

RESULTS AND DISCUSSION

Time dependence

A 1.7 μM Co(II) solution at pH 4.8 containing ^{60}Co tracer, $0.10M$ sodium thiocyanate, $1.90M$ sodium and chloride and $1.00M$ sodium acetate/acetic acid buffer was used to determine the time required for equilibration between the cobalt solution and poly-urethane foam. One experiment mainly evaluated the first 2 hr of extraction, and a second experiment extended the time up to 48 hr. Typical results shown in Fig. 1 indicate that equilibrium is approached fairly slowly with the small amount of foam used. The extraction increased from 90% of its final value after 2 hr to 97% after 24 hr. The final value determined after 48 hr may be affected by small evaporation

losses which cause a gradual increase in D due to increasing thiocyanate and ionic strength. This experiment was deliberately done under conditions which ensured only a moderate extraction. Under more appropriate conditions (e.g. $1.0M$ thiocyanate and 0.4 g of foam) 99.99% extraction can be obtained, with 90% extraction in less than 2min.

Effect of pH

The pH of $1.7\mu M$ Co(II) containing ^{60}Co tracer and $0.10M$ sodium thiocyanate was adjusted with hydrochloric acid or sodium hydroxide as required and the ionic strength fixed at $3.00M$ with sodium chloride. After initial pH measurement, the solutions were equilibrated with 50 mg of foam for up to 24 hr and the pH redetermined. It was noted that at
Fig. 2. Effect of pH on cobalt sorption. Conditions: 0.050 g of foam; 150 ml of solution $1.7 \times 10^{-6}M$ in Co(II), $0.1M$ in NaSCN, pH adjusted with HCl or NaOH, NaCl added to maintain $3.00M$ ionic strength. Equilibrium pH values: measured $\bigcirc$; calculated $\bullet$.

solution acidities between $0.5M$ acid and pH 4, the foam developed a red to red-brown colour due to the presence of small specks of iron inhomogeneously distributed in the reagent-grade sodium chloride. This extraction of iron by polyurethane foam has been reported before,[3,5-7] and the iron either does not affect the cobalt extraction or is easily displaced by the cobalt species. At an acidity greater than $1M$, a yellow colour quickly developed, accompanied by the smell of H_2S. On standing overnight a small amount of yellow precipitate formed, and there was a return of cobalt to the solution from the polymer. These observations are consistent with the reported[9] instability of HSCN in acid solution, resulting in hydrolysis to give H_2S or polymerization to give the yellow isoperthiocyanic acid. At pH > 11, a precipitate was formed which was assumed to be $Co(OH)_2$.[10]

The pH values before and after the extraction were practically the same except in the range 7–11.5, where changes of up to two units occurred, probably due to decomposition of SCN^- or sorption of acid by the foam.

From the results in Fig. 2, the sorption of cobalt is quite insensitive to pH from 1 to 9. Hydrogen-ion concentrations greater than $0.1M$ affect the cobalt extraction because the available thiocyanate concentration is reduced in fairly acid solution by protonation[11] ($pK_a \sim -2.0$). In addition the decomposition of HSCN in acid further shifts the equilibrium and results in the observed decrease in cobalt extraction with time. In more basic solutions the sorption gradually decreases and there is considerably more scatter in the results, owing to the formation of $Co(OH)_2$.

Therefore most experiments were done in the middle of the optimum pH range, with sodium acetate/acetic acid buffer.

The lack of sensitivity to hydrogen-ion concentration indicates that either hydrogen ion is available in vast excess or it is involved in formation of neither the extractable species nor weakly basic anion-exchange sites on the foam (by protonation). That cobalt can be sorbed from mildly basic solutions makes it unlikely that the mechanism involves protonation of the polymer sites to form a weak-base anion-exchanger (as suggested by Bowen[12]). In addition, the small changes in pH indicate that the largest amount of hydrogen ion which could have been released from the foam is not sufficient to account for the large amount of cobalt extracted.

Effect of thiocyanate

Cobalt(II) solutions $(1.7 \mu M)$ containing ^{60}Co tracer, $0.88M$ sodium acetate/$1.00M$ acetic acid buffer and various sodium thiocyanate concentrations were adjusted with sodium chloride to a total ionic strength of $2.88M$. Extraction with 50 mg of polyurethane for up to 24 hr showed that D rises to 10^5 at $0.25M$ thiocyanate and to 3.3×10^6 at $2.00M$ thiocyanate.
Fig. 3. Effect of thiocyanate on cobalt sorption. Conditions: 0.050 g of foam; 150 ml of solution $1.7 \times 10^{-6}M$ in Co(II), $2.88M$ ionic strength, pH 4.7, 25.00°.

The latter value is equivalent to 99.9% sorption of cobalt from 3000 litres of solution by a kilogram of foam. Figure 3 shows the near linearity of a log D vs. log $[SCN^-]$ plot, at the lower thiocyanate concentrations; the slope of about 4 indicates that four SCN^- ligands are involved in the extractable species.

Control of the thiocyanate concentration provides very wide flexibility in the sorption and desorption of cobalt. Some degree of selectivity may be possible by careful choice of the thiocyanate concentration and other solution parameters, in column chromatographic or batch extraction separations.

Effect of cobalt concentration

Initial cobalt concentrations from tracer only $(\sim 1.7 \times 10^{-10}M)$ to 1.7mM were used to evaluate their effect on cobalt extraction in 24 hr from solutions containing $1.00M$ sodium acetate/acetic acid buffer, $0.10M$ sodium thiocyanate and $1.90M$ sodium chloride. A second series of experiments used $0.25M$ thiocyanate, $1.00M$ buffer and $1.75M$ sodium chloride.

The colours of the equilibrated polyurethane foams ranged from off-white through various shades of green to a dark blue-green, in parallel with the amount of cobalt sorbed. The foam pieces containing the largest amounts of cobalt became brittle and broke apart on squeezing, which has been interpreted as supporting the cation chelation mechanism for the extraction.[8]

Figure 4 shows that the distribution ratio, D, is markedly affected by thiocyanate concentration, as expected, but the fraction of cobalt extracted is
Fig. 4. Effect of cobalt concentration on distribution ratio. Conditions: 0.050 g of foam; 150 ml of solution, 3.00M ionic strength, at 25.00°. ○ 0.10M NaSCN; □ 0.25M NaSCN; △ ^{60}Co tracer only.

essentially independent (slope = 0) of the amount of cobalt present (at low concentrations), which indicates[13] that a mononuclear complex is extracted. Moreover, at high cobalt concentration, the slope is about −1.0, indicating that nearly all additional
Fig. 5. Effect of cobalt concentration on extraction. Conditions: 0.050 g of foam; 150 ml of solution, 3.00M ionic strength, 25.00°. ○ 0.10M NaSCN; □ 0.25M NaSCN; △ ^{60}Co tracer only.

cobalt added remains in the aqueous phase. Figure 5 displays the results in a different way, showing the maximum concentration of cobalt in the foam is ~0.47 mole/kg. Since a typical polyurethane foam has a surface area[14] of 81 m^2/kg and the cross-sectional area[15] of a Co^{2+} ion is about 1.63×10^{-20} m^2, the sorption process must involve the whole bulk of the polymer and be akin to a solvent extraction or ion-exchange process rather than solely a surface adsorption phenomenon.

It is apparent that the degree of cobalt extraction does not decrease even at very low cobalt concentrations, which makes polyurethane foam and thiocyanate useful either for the preconcentration of very low levels of cobalt for analysis or for the complete recovery of cobalt from radioactive wastes or spills. Further, since the distribution ratio remains constant until the foam is almost saturated, reasonably symmetrical elution peaks are expected when the system is used in column chromatography. The relatively high capacity of polyurethane foam [0.47 mole of Co(SCN)$_4^{2-}$ and hence 0.94 mole of Na$^+$/kg] is of the same order of magnitude as that of many commercially available ion-exchange resins and its cost is competitive.

Effect of phase ratio

A wide range of phase ratios was studied, to test the assumption that D is constant for different relative amounts of aqueous phase and foam. Because of the experimental difficulties in using small sample volumes for extraction, the study was done by using a wide variation in foam weight. Solutions containing 0.10M sodium thiocyanate, 0.88M sodium acetate/1.00M acetic acid buffer, 1.90M sodium chloride, 0.10 ppm Co(II) and ^{60}Co tracer were equilibrated with 1–1000 mg pieces of foam for 48 hr. Special care was taken to eliminate the effect of static charge on weighing the smaller pieces of foam and to ensure that these had the entrapped air removed by manual squeezing before the normal mechanical squeezing.

From Table 1 it appears that D remains nearly

Table 1. Effect of phase ratio on distribution coefficient

Foam weight, mg	$D \times 10^{-3}$		
	12 hr	24 hr	36 hr
1029.75	4.6 ± 0.6	4.7 ± 0.6	4.7 ± 0.6

46.473	4.71 ± 0.05	4.81 ± 0.05	4.83 ± 0.05
24.546	4.85 ± 0.03	4.94 ± 0.04	4.96 ± 0.03
10.974	4.98 ± 0.06	5.04 ± 0.06	5.08 ± 0.06
4.233	4.84 ± 0.07	4.71 ± 0.14	4.76 ± 0.12
1.780	4.84 ± 0.22	4.71 ± 0.21	4.58 ± 0.23
0.967	5.0 ± 0.5	4.4 ± 0.5	4.3 ± 0.4

Conditions: 150 ml of solution $1.7 \times 10^{-6}M$ in Co(II), 0.10M in NaSCN, with ionic strength 2.88M and pH 4.7; foam squeezed for 12.0, 24.0 and 36.0 hr at 25.00°.

constant, considering the 1000-fold range of foam weight, but there are some changes. With the larger foam pieces there is some increase in D with time whereas for the smallest foam pieces D decreases with increasing time.

It can be shown[13] that these effects can be caused by losses of water through evaporation, and that

$$D_{apparent} = D^\circ \left(\frac{V^\circ}{V^\circ - \Delta V} \right)^4 \frac{\Delta V}{W}$$

where D° is the actual distribution coefficient, $D_{apparent}$ the apparent distribution coefficient, V° the initial sample volume, ΔV the volume loss, and W the foam weight.

If the distribution ratio, D, is assumed to be completely independent of foam weight, then if even minor evaporative losses of solvent occur, small increases in the apparent distribution ratio will be observed at high foam weights and fairly large decreases will be seen at low foam weights, as was observed.

Two 0.50-g amounts of foam, in one case as a single piece and in the second as 222 small pieces, were equilibrated for 48 hr with the same solution as that above and gave D values of 4688 and 4686 l./kg respectively in spite of the drastic difference in piece sizes. Thus the squeezing behaviour, air entrapment and other physical factors associated with the various sizes of foam pieces used, did not affect the extraction.

The distribution ratio is essentially independent of cobalt concentration (when this is below the saturation limit) and of the relative quantities of the two phases. Thus large volumes of solutions may be extracted with small weights of polyurethane with no decrease in efficiency.

Effect of temperature

The extraction of cobalt was studied over the temperature range 0–95° after preliminary observations had revealed that even a 0.2° change due to normal laboratory fluctuations caused a 10% variation in D. Maloney et al.[6] have reported the large variation in cobalt extraction from 0.4M potassium thiocyanate when the temperature changes from 20° to 90°.

Five series of potassium thiocyanate solutions (0.010, 0.050, 0.25, 1.00 and 5.00M) that were 1.7μM in Co(II) were prepared, with ^{60}Co tracer. The ionic strength was adjusted to 3.00M for the 0.050M SCN$^-$ series, 5.88M for the 5.00M SCN$^-$ and 2.88M for the remainder, with sodium acetate/acetic acid buffer. Samples were extracted with 50 mg of foam in water-jacketed distribution cells for 6 hr, then the temperature was recorded and an aliquot removed for measurement (after return to room temperature). To minimize any effect of foam deterioration, or loss or contamination of the solution, the temperature of a single sample was raised in 10° increments in successive runs and then lowered to intermediate values. The data for ascending and descending temperature matched, showing the absence of such effects.

The data in Fig. 6 indicate that the cobalt sorption is very sensitive to temperature, but less so at high thiocyanate concentrations. These data can be used to help interpret the extraction process, as discussed in detail elsewhere.[13] Since D increases sharply with decrease in temperature the solution concentration of
Fig. 6. Effect of temperature on cobalt extraction. 4.80	5.00	99.38 ± 0.32	5.70 ± 0.22

Conditions: 150 ml of solution, $1.7 \times 10^{-6}M$ in Co(II), $0.10M$ in NaSCN, $0.10M$ in HCl; 0.050 g foam; 24 hr extraction.

* ± 1%.

the extractable species must correspondingly increase markedly. At low temperatures D assumes the same large value of 3×10^6 l./kg for thiocyanate concentrations of 0.25, 1.00 and $5.00M$. This suggests that the species in solution is either co-ordinatively saturated with the ligand [*i.e.*, Co (SCN)$_4^{2-}$· aq is formed] or does not contain any thiocyanate (which is improbable in view of the very high thiocyanate dependence at low cobalt concentrations).

Hence cooling the system can create considerable economy in large scale operations, and the temperature effect may be used to shift the equilibrium either to increase cobalt sorption or aid in its recovery from the foam.

Effect of ionic strength

Preliminary studies of cobalt extraction in the presence of a variety of sodium salts indicated that the extraction was somewhat enhanced by $1.0M$ sodium chloride, bromide, nitrate or acetate, somewhat decreased by sodium iodide, greatly decreased by sodium carbonate, and made slower but otherwise unchanged, by sodium sulphate. Sodium chloride was used in various amounts as an "inert" salt and $1.7\mu M$ Co(II) solutions containing ^{60}Co tracer, $0.10M$ sodium thiocyanate and $0.10M$ hydrochloric acid were extracted with 50 mg of polymer for 24 hr.

The increase in extraction (Table 2) is quite large and is due to three effects. One is the increase in dielectric constant of the aqueous phase, which favours the extraction of less polar and more hydrophobic species such as Co(SCN)$_4^{2-}$. The second is the decrease in water activity[16] as a result of solvating the added solute ions; this decreases the solubility of Co(SCN)$_4^{2-}$ and shifts the equilibrium towards its production. Finally, if the cobalt is sorbed as an ion-association complex of Co(SCN)$_4^{2-}$ with two sodium ions, as is apparently the case at high pH, then any sodium salt should increase the extraction (which would not be the case for an ion-exchange type of mechanism).

The addition of salts significantly improves the extraction of cobalt and suggests that cobalt could be

extracted efficiently from brine solutions containing small amounts of thiocyanate.

Effect of type of polyurethane foam

Several different polyurethane foams were tested for extraction of cobalt from its $1.7\mu M$ solutions containing ^{60}Co tracer, $0.100M$ sodium thiocyanate, $0.10M$ sodium acetate/acetic acid buffer and $2.80M$ sodium chloride. As usual, the colour of the foams developed rapidly, darkening during several hours in parallel with the measured sorption of cobalt.

The most striking observation from the data shown in Table 3 is that the only polyester-type polyurethane foam gave negligible sorption of cobalt, compared to the polyether-type foams under the conditions used, indicating that the polyol portion of the polymer must be very important in the sorption of cobalt and that polyesters must be largely unsuitable.

Several unknown polyether-type foams (of the kind used for upholstery) as well as one containing carbon black, showed remarkable consistency of extraction. Hypol® polyether foams, which were prepared by the manufacturer from mixtures of prepolymer and water, gave lower D values.

One difficulty in evaluating the polyurethane-foam extraction process is the general lack of simple foams with no additives and of known composition. In one case a pair of foams made from a polyethylene oxide (PEO)/polypropylene oxide (PPO) co-polymer together with a styrene/acrylonitrile co-polymer showed a 12% larger D value for the foam with the larger fraction of PEO/PPO, although the polyether content was 33% greater. Although the polyether content of the polymer is important in sorption, site accessibility or the positional requirements of the polyether may also be important. With three foams that were similar except for PPO content the cobalt extraction increased as the PEO content increased, showing that the polyethylene oxide must play an important chemical role in the sorption phenomenon.

Effect of foam pretreatment

A systematic study of foam pretreatment was made with $1.7\mu M$ Co(II) solutions with ^{60}Co tracer in $0.100M$ sodium thiocyanate at pH 4.8 ($0.10M$ sodium acetate/acetic acid buffer) and ionic strength $3.00M$ (adjusted with $2.8M$ sodium chloride). The 50-mg pieces of foam were squeezed in a solution of the given reagent and then left in contact with it for 18 hr, after which they rinsed with an appropriate solvent to remove excess of reagent, squeezed dry in filter paper and finally dried for 12 hr in a vacuum desiccator.

The results are given in Table 4. Saturated chlorine water turned the foam into a sticky mass and 45% w/w boron trifluoride solution in diethyl ether caused immediate swelling and subsequent dissolution of the foam. In the presence of several oxidizing and reducing agents there were no appreciable increases or decreases in D so preliminary

Conditions: 150 ml of solution $1.7 \times 10^{-6}M$ in Co(II), $0.10M$ in NaSCN, with ionic strength $3.00M$ and pH 4.8; 0.050 g of foam squeezed for 24 hr (* for 48 hr) at 25.00°.

observations which had shown changes with hydroxylamine and hydrogen peroxide were probably showing solution phenomena. It appears that amine-type sites on the foam are either not present in significant numbers or not involved in the sorption of cobalt, and a weak base anion-exchange type of mechanism seems doubtful.

The sorption of cobalt from solution was made markedly slower by the boron trifluoride treatment (more noticeably so with those foams exposed to the most concentrated solutions). Since BF_3 is a particularly good Lewis acid for sites such as polyether oxygen atoms, this delay must reflect strong interaction of BF_3 with the key sorption sites in the polyurethane until it is slowly displaced by other Lewis bases (e.g., water). The equilibrium value of D was increased by this treatment, however, perhaps by the generation or freeing of more sites or even formation of an adduct. Silicon tetrachloride does not have the same effect, because of its easy hydro-

Conditions: 150.0 ml of solution 1.7 × $10^{-6}M$ in Co(II), 0.10M in NaSCN with ionic strength 3.00M and pH 4.8: 0.050 g of foam rinsed and dried after pretreatment, then squeezed for 48.0 hr at 25.00°.

lysis and subsequent removal from the foam in the presence of water.

When sodium tetraphenylborate was used to pretreat the foam, or more notably, added to the solution, there was a considerable decrease in the extraction. This can be interpreted as the strongly preferential sorption of B(C₆H₅)₄⁻ in place of Co(SCN)₄²⁻ at some form of cationic site in the foam. The failure of PF₆⁻ to interfere similarly at these sites is probably because it is not a bulky, hydrophobic and highly polarizable anion [as both Co(SCN)₄²⁻ and B(C₆H₅)₄⁻ are] and so is not readily accommodated in polyurethane.

Effect of added substances

In order to simplify interpretation of the results of this study, no sodium chloride was added to the samples, although the resulting low ionic strength necessitated using 0.50M thiocyanate to obtain a reasonable cobalt extraction. The 1.7μM Co(II) solutions with ⁶⁰Co tracer were buffered with 0.1M sodium acetate/acetic acid. High concentrations of the test chemicals were used initially and then progressively lower amounts tried until the observed effect was small. In some cases where there was a significant change, the trial was repeated with 1.7mM Co(II) and the absorption spectra were taken shortly

after preparation and again after 24 hr in order to simulate the normal sample-solution preparation.

The effect of the sodium salts of various anions on the cobalt extraction by polyurethane foam is shown in Table 5. Part of the effect observed will be due to increases in ionic strength and to the presence of the additional extractable cation, Na⁺. However, the remainder may result from competitive reactions between added ligands and SCN⁻ to form other cobalt complexes [which are more or less extractable that Co(SCN)₄²⁻] destruction of the SCN⁻ ligand by chemical reaction, competitive sorption of species other than Co(SCN)₄²⁻ onto the foam or alteration of some important solution parameter such as pH. For example, sodium nitrate, chlorate and perchlorate do not alter the cobalt equilibria but do decrease the extraction from that expected for solutions with the same ionic strength. Large polarizable anions such as perchlorate are likely to be extractable and interfere by competition for sorption sites.

Stronger interferences were noted for several anions which produce stable cobalt complexes which are not extracted.

The effects of many metal ions were examined at the 1000-ppm level and at levels as low as 1 ppm if there was an interference. The results are collected in a periodic table (Fig. 7). In general the group IIa metals cause a minor increase in sorption but Be(II) forms

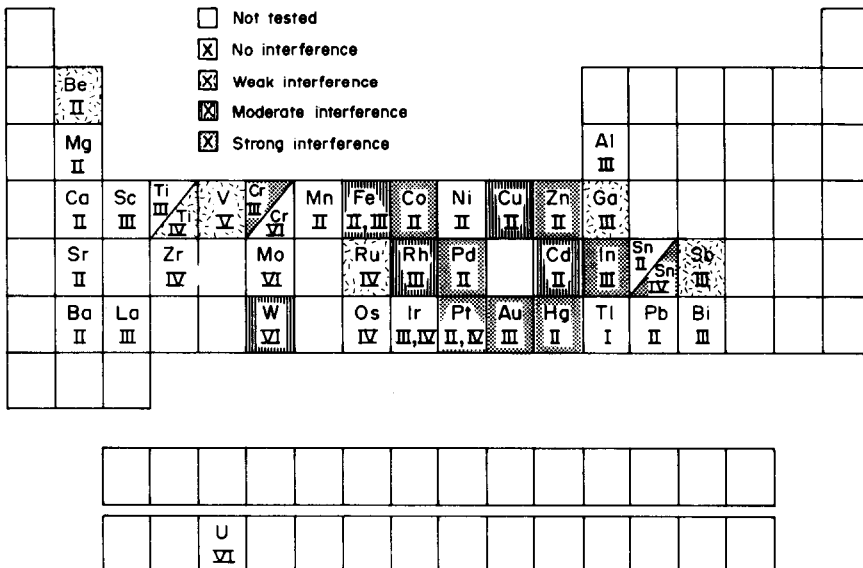
Conditions: 0.050 g of foam squeezed for 24.0 hr at 25.00°; 150 ml of solution $1.7 \times 10^{-6}M$ in Co(II), $0.10M$ in NaSCN, with initial pH 4.8 and ionic strength $0.6M$, plus the added salt.


Fig. 7. Summary of interference studies with various metal ions.

an extractable red thiocyanate complex which interferes with the cobalt sorption. The apparent increase caused by $V(V)$ was due to the ammonium ion from the salt used.

The group VIa metals differ considerably in their effect, owing to formation of extractable thiocyanate complexes.[17]

The group VIII metals give a variety of results, because of competition for the foam sites or formation of extractable complexes.

Gold causes a significant interference with the cobalt sorption even at 1 ppm. The group IIb metals form thiocyanate complexes and compete for foam sites. Of the group IIIb metals, Al(III) and Tl(I) enhance the extraction slightly, and Ga(III) interferes somewhat. Indium forms a highly extractable thiocyanate complex and greatly reduces the cobalt sorption.

Sn(IV) interferes strongly by co-precipitating cobalt with gelatinous $SnO_2 \cdot x H_2O$.

Many metals can be extracted as thiocyanate complexes under these conditions but a thorough examination would be required to optimize specific separations or particular co-extractions.

The effect of several nitrogen-containing compounds was tested, since cobalt forms a fairly large number of complexes with this type of ligand and a

number of extraction procedures make use of both SCN^- and a protonated nitrogen-containing compound. Most of these test compounds are stronger bases than acetate and so will exist in the protonated cationic form in the sample solutions (near pH 4.5 with the acetate buffer). A few, such as tetramethylammonium bromide, are ionic at any pH, and a few such as N-methylformamide are very weak bases and essentially neutral under these conditions. Pyridine and aniline are borderline cases and so both forms will be present.

The data obtained are recorded in Table 6. With $1.0M$ ammonium chloride and hydroxylamine hydrochloride an enhancement occurs, but there is no change in the spectra of these solutions so the effect must be related to some sorption characteristic of the added ions themselves. Most probably NH_4^+ and NH_3OH^+ are more extractable as counter-ions with $Co(SCN)_4^{2-}$ than is Na^+.

The progressive substitution of methyl groups in the ammonium ion leads to a steady trend from a substantial enhancement with $0.10M$ NH_4^+ to a slight depression with $0.10M$ $(CH_3)_4N^+$. Since the spectra show no substantial difference, this again suggests that NH_4^+ has some special effect on the solvation process. When n-butyl groups are substituted in the NH_4^+, the opposite effect (from that for the methyl

Conditions: 0.050 g of foam squeezed for 24.0 hr at 25.00°; 150 ml of solution $1.7 \times 10^{-6}M$ in Co(II), $0.5M$ in NaSCN with initial pH 4.8 and ionic strength $0.6M$, plus the added salt.

compounds) is seen, because two phases form in these solutions, and also these n-butylamines can act as liquid ion-exchangers. This effect is also seen with other substances, such as aniline. Ethylenediamine interferes since it is a good complexant of cobalt, and pyridine interferes by precipitating cobalt, probably as $Co(C_5H_5N)_4(SCN)_2$.

A group of very weak bases (formamide, N-methylformamide, N,N-dimethylurea and urethane) which might mimic types of N-containing groups in polyurethane foam, showed no detectable effect, indicating that the foam-nitrogen ligands are not involved in the sorption process.

In general, substances interfere with the extraction by formation of less extractable cobalt complexes, by decreasing the concentration of available thiocyanate ion, by occupying or destroying sorption sites on the foam, and/or by affecting the formation of $Co(SCN)_4^{2-}$. An enhancement of extraction occurs when more extractable cobalt complexes are formed, when the concentration of more extractable cations is increased, and/or the solution ionic strength is increased.

CONCLUSION

Cobalt(II) is extracted very efficiently from aqueous thiocyanate solutions by polyether-type polyurethane foam. Using high thiocyanate concentration, high ionic strength, low temperature and a pH between 1.0 and 9.0 gives distribution coefficients as high as 3×10^6 l./kg. The high distribution coefficient, reasonably large capacity, high flow-through, and low cost suggest that polyurethane

foam may find several industrial and analytical applications for the extraction of cobalt and other thiocyanate complexes.

DETERMINATION OF DIPHENYLTIN AND DIALKYLTIN HOMOLOGUES BY HPLC WITH MORIN IN THE ELUENT

Wenche Langseth

Department of Chemistry, The University of Oslo, Blindern, 0315 Oslo 3, Norway

Summary—A sensitive and selective method has been developed for the simultaneous determination of diphenyltin and dialkyltin compounds. The compounds were separated by HPLC on a cyanopropyl-bonded silica column with toluene containing 1–5% acetic acid, 1–5% ethanol or methanol and 0.0015% morin. The organotins were eluted as morin complexes and detected by a fluorescence spectrophotometer. Detection limits ranged from 1 to 4 pg. Data reported include capacity factors, separation efficiencies and linearity of detection.

Organotin compounds have found widespread commercial use as pesticides, fungicides and stabilizers of plastics.[1,2] Dialkyltin compounds, especially, have been used to stabilize certain plastics against heat and light. Studies have shown that both the number and kind of organic groups covalently attached to tin in the organotin species affect the toxicity.[3,4] The need for better analytical methods capable of trace speciation of various organotin compounds is apparent.

A variety of analytical techniques and procedures have been applied for the determination of organotin species. These include atomic-absorption spectrophotometry,[5,6] gas chromatography (GC)[7,8] and HPLC.[9,10] Adsorption and decomposition of dialkyltin compounds is found to be a problem in GC.[11,12] HPLC appears to be the most versatile method for these compounds. The most common and generally sensitive HPLC detectors are the spectrophotometer and fluorimeter, but in most cases these are not directly applicable to alkyltin compounds. HPLC is therefore often combined with an element-specific detector such as an atomic-absorption spectrophotometer,[13,14] flame photometer or inductively-coupled plasma-emission spectrophotometer (ICP).[15,16] These approaches need expensive equipment, however, and are often far too complicated. The separation and determination of metals in the form of chelates by HPLC, with ultraviolet or fluorescence detection, have found increased application.[17] The metal complexes can be formed either prior to injection,[18] on the column[19] or post-column.[20] Separation of dialkyltin dichlorides and post-column reaction with morin to give a fluorescent product has been described,[21] but post-column reactors are complicated and not available in most laboratories.

The aim of this study was to separate trace amounts of dialkyltin and diphenyltin compounds with ordinary HPLC equipment. This paper describes a method requiring only a single HPLC pump and a fluorimetric or photometric detector.

EXPERIMENTAL

Reagents

Dibutyltin dichloride was obtained from Fluka AG (Switzerland). Diphenyltin dichloride, diethyltin dichloride and dimethyltin dichloride were purchased from the Alfa Division, Ventron Corporation. When necessary, the alkyltin chlorides were purified by recrystallization from light petroleum (b.p. 40–60°). Morin (2′,3,4′,5,7-pentahydroxyflavone) was obtained from Fluka AG and 3-hydroxyflavone from Eastman Kodak Ltd. The toluene used was of glass-distilled grade from Rathburn Chemicals. All HPLC solvents and the morin and 3-hydroxyflavone solutions were filtered through 0.45-μm Millipore filters.

Apparatus

The HPLC equipment consisted of a Perkin–Elmer dual pump module (Series 2) with a Rheodyne injector, model 7105, a Perkin–Elmer LC-75 spectrophotometer and a Kontron spectrophotometer, model SFM-23.

Two prepacked cyanopropyl-bonded silica (5.0 μm particle size) columns were used in this study, both obtained from Brownlee Labs; one stainless-steel column 250 × 4.6 mm i.d. and one MPLC™ cartridge 100 × 4.6 mm i.d. The guard column, 30 × 4.6 mm i.d., also containing cyanopropyl-bonded silica (5 μm particle size), was of the MPLC™ type. The solvent flow-rate was 1.0 ml/min.

Procedure

The diphenyltin and dialkyltin dichlorides were injected as hexane solutions (normally 10 μl). They were eluted with toluene containing 1–5% v/v acetic acid, 1–5% v/v methanol or ethanol and 0.0015% morin. Morin is stable in alcohol for weeks, and its alcoholic solution was added to the eluent. The excitation wavelength of the fluorescence detector was set at 420 nm and the emission wavelength at 500 nm.

RESULTS AND DISCUSSION

The use of post-column derivative formation before detection requires a reaction chamber or mixer of high quality. Considerable band-broadening and a high noise level are often observed when a con-

ventional reaction coil is used. Alkyltin chlorides or similar compounds are easily adsorbed by residual silanol groups on bonded-phase columns, making tailing hard to avoid. The tin atom is, however, considerably reduced in reactivity in chelates where it is six-co-ordinated.

Complex formation in HPLC separations can be done either prior to injection or on the column. If the ligand is not incorporated in the eluent, the complex has to be very stable. No dialkyltin complexes suitable for ultraviolet or fluorescence detection were found to be stable enough.

Organotin chelates are generally unstable and nearly insoluble in aqueous media. Mobile phases containing organic solvents are therefore preferred. Cyanopropyl-bonded phase columns have found increased applicability when normal silica packing is unsuitable because of strong adsorption effects. It was therefore decided to try a cyanopropyl-bonded stationary phase. Recent works have shown that these columns are suitable for separations of alkyltins[21] and other organometallic compounds.[22]

Basic studies of the complexes formed between dialkyltins and 3-hydroxyflavone[23] and morin[24] revealed that both reagents could be used as complexing agents. Preliminary studies showed that both formed dialkyltin complexes that were sufficiently stable for HPLC determination, when the ligand was incorporated in the mobile phase. Morin was selected for further work because of the high fluorescence intensity of the complexes, giving better selectivity and sensitivity.

Toluene was found to be the best major component of the mobile phase. The sensitivity for the alkyltin complexes when hexane or methanol was used instead, was only 1 or 10%, respectively, of that when toluene was used. Toluene containing small amounts of acetic acid, methanol or ethanol and morin was found to give good selectivity, high resolution and high sensitivity.

An eluent with 0.0015% morin gave reproducible peak heights, which was not the case when only 0.0010% morin was incorporated in the eluent. Use of 0.002% did not increase the sensitivity.

Experiments proved that acetic acid was essential in the mobile phase. Hardly any selectivity was obtained for dioctyl-, dibutyl- and dipropyltin when only ethanol (containing 4% water) was used, and the peaks became broad and undetectable with water-free ethanol. The retention volume decreased with increasing amount of acetic acid for all the diorganotin chlorides examined, as shown in Fig. 1.

The alcohol was necessary to obtain reasonable sensitivity, which was found to decrease appreciably for ethanol content $<1\%$. A high degree of tailing was observed when the alcohol was replaced by another modifier such as ethyl acetate.

Table 1 shows the capacity factors and resolutions when methanol, ethanol and propan-1-ol were used as modifiers of the mobile phase. A high degree of
Fig. 1. Effect of the acetic acid content in the mobile phase on the separation of diphenyl- and dialkyltin compounds. Column: 30 × 4.6 mm bore + 250 × 4.6 mm bore cyanopropyl-bonded column (Brownlee Labs.) Mobile phase: toluene, $x\%$ acetic acid, 3% ethanol (4% water), 0.0015% morin. ■, Oc_2SnCl_2; ☐, Bu_2SnCl_2; ●, Pr_2SnCl_2; ○, Ph_2SnCl_2; ×, Et_2SnCl_2; ▲, Me_2SnCl_2.

tailing and low sensitivity were observed for diethyltin and especially for dimethyltin with propan-1-ol. Methanol and ethanol (4% water) gave about the same resolution (Figs. 2 and 3), but the sensitivity was about 50% higher with methanol, except for
Fig. 2. Chromatogram of diphenyl- and dialkyltin compounds. Column as for Fig. 1. Mobile phase: toluene, 3% acetic acid, 2% methanol, 0.0015% morin, flow-rate 1.0 ml/min. Peaks: 1 = Oc_2SnCl_2 (60 ng); 2 = Bu_2SnCl_2 (60 ng); 3 = Pr_2SnCl_2 (60 ng); 4 = Ph_2SnCl_2 (20 ng); 5 = Et_2SnCl_2 (60 ng); 6 = Me_2SnCl_2 (120 ng). Amounts of each compound injected are given in parentheses.
Fig. 3. Chromatogram of diphenyl- and dialkyltin compounds. Column: 30×4.6 mm bore $+ 100 \times 4.6$ mm bore cyanopropyl-bonded column (Brownlee Labs.). Mobile phase: toluene, 3% acetic acid, 2% ethanol (water-free), 1% ethanol (4% water), 0.0015% morin, flow-rate 1.0 ml/min. Peaks: $1 = Oc_2SnCl_2$ (3 ng); $2 = Bu_2SnCl_2$ (3 ng); $3 = Pr_2SnCl_2$ (3 ng), $4 = Ph_2SnCl_2$ (1 ng); $5 = Et_2SnCl_2$ (3 ng); $6 = Me_2SnCl_2$ (8 ng). Amounts injected are given in parentheses.

dimethyltin, for which a threefold increase in peak height was observed. The capacity factor for diphenyltin was particularly sensitive to the water content. Maximum resolution can be obtained by regulation of the water content, though the optimal conditions may vary from one column to another, even with the same packing material. Change in the resolution is also observed with both methanol and ethanol after prolonged use of the column.
Fig. 4. Effect of the ethanol content of the mobile phase on the separation of diphenyl- and dialkyltin compounds. Column as for Fig. 1. Mobile phase: toluene, 2% acetic acid, x% ethanol (4% water), 0.0015% morin. ■, Oc_2SnCl_2; □, Bu_2SnCl_2; ●, Pr_2SnCl_2; ○, Ph_2SnCl_2; ×, Et_2SnCl_2; ▲, Me_2SnCl_2.

The retention volume decreased with increasing ethanol content for all the diorganotin chlorides examined, except dimethyltin (Fig. 4). The capacity factor for dimethyltin was halved when the ethanol level was raised from 1 to 2% (2% acetic acid). With higher ethanol content less reduction was observed, and the retention volume increased again at ethanol concentrations above about 5%.

Very good resolution of diphenyltin and all the dialkyltins examined can be achieved within less than 10 min with isocratic elution on a 10-cm analytical column containing only 2700 theoretical plates (Fig.

3), (flow-rate 1.0 ml/min). Increasing the flow-rate to 2.0 ml/min gave band-broadening. Better resolution within the same time can be obtained with gradient elution, with increasing acetic acid content of the mobile phase. A broad band is often observed, however, because of the alteration of the equilibrium of adsorbed morin on the column.

Thorough deaeration of the mobile phase is normally recommended, when using fluorescence detection, because of the quenching effect of oxygen, but it increased the noise-level in this case, because of an increase in the fluorescence intensity of the morin, so deaeration was omitted.

The relative fluorescence intensities of the diphenyltin- and dialkyltin-morin complexes are given in Table 2. The dialkyltin complexes all produced about the same fluorescence per mole, but only about 30% of that of the diphenyltin complex.

The linearity of the calibration graphs was checked by injecting 10 μl of standard mixtures of diphenyltin and dialkyltin chlorides (0.001–100.0 μg/ml) in hexane. They were linear up to at least 1 μg. The correlation coefficients were in all cases found to be >0.998.

Detection limits ranged from 1.0 pg for diphenyltin dichloride to 4.0 pg for dimethyltin dichloride, when the "High HV" mode of the detector was used and the detection limit taken as twice the noise level. An MPLCTH 10-cm cartridge was then used with a mobile phase of toluene, 3% acetic acid, 2% water-free ethanol, 1% ethanol (4% water) and 0.0015% morin.

The dialkyltin dichloride solution could be prepared in hexane or toluene. Hexane seemed to be the best choice. The solvent peak was then well separated from the dioctyltin peak. This was not the case for toluene, the capacity factor being close to that for dioctyltin. No higher sensitivity or better resolution could be observed when the morin complexes were prepared before injection. The complexes seemed to remain stable for days, except the diphenyltin com-

plex, which decomposed after some hours. Hexane solutions of diphenyltin and dialkyltin chlorides, (1000 μg/ml), however, were stable for weeks.

Conclusion

The proposed method using an eluent containing morin or some other complexing agent appears to have considerable potential for the examination of different organotin compounds. No special equipment is required, only a single HPLC pump, an injector and a fluorescence detector (or ultraviolet detector). The utilization of a cyano-bonded silica stationary phase and normal-phase elution allows complete resolution of diphenyltin and dialkyltin homologues. The dialkyltins are eluted in order of decreasing molecular weight. The selectivity offered by the reported HPLC conditions, coupled with the linearity of the calibration graph and the detection limits of a few picograms, demonstrates the possibility of trace analysis for diphenyltin and dialkyltins.

INTERFERENCES IN THE DETERMINATION OF TOTAL NITROGEN IN NATURAL WATERS BY PHOTO-OXIDATION TO NITRATE–NITRITE MIXTURE

Lilly Gustafsson

Department of Analytical Chemistry, University of Uppsala, P.O. Box 531, S-751 21 Uppsala, Sweden

Summary—The method proposed by Armstrong, Williams and Strickland for the photo-oxidation of total nitrogen in sea-water to nitrate and nitrite has been studied in some detail, to extend its use to fresh and brackish waters, applying a more accurate method for the determination of the reaction products. Variables influencing the yield of nitrate and nitrite are irradiation time, pH and type of buffer, kind of nitrogen compound and its concentration, and the concentrations of oxygen, carbon dioxide, organic matter and salts, especially bromides, even at the low concentrations found in brackish waters. All these variables interact in a rather complicated way. Interferences from halides, organic matter and carbon dioxide are considerably reduced by ensuring that the pH is kept at 8.5–9 during the irradiation. Because pure solutions of many substances give quantitative yields ($\geqslant 98\%$) in the pH-range 7–9 usually recommended, whereas others require lower pH for maximal oxidation, a method has been developed involving photo-oxidation first at pH 2.1 and then at pH 8.5–9. In the absence of interfering concentrations of halides the relative increase in yield by an initial irradiation at low pH is especially large (10–36%) for proteins, organic nitrogen in fresh waters, uric acid and urea. A comparison is made between determination of total nitrogen in some natural waters by using photo-oxidation and by a Kjeldahl method modified to give total nitrogen. By making use of the optimal conditions presented in this paper, a negative error of less than 8% is expected in the determination of total nitrogen in fresh waters. For saline waters the error will probably be larger, at least at a high ratio of organic to inorganic nitrogen.

Armstrong *et al.*[1] proposed a method for the determination of nitrogen and phosphorus in sea-water, based on photo-oxidation of the sample by ultra-violet radiation from a 1200-W high-pressure mercury-arc lamp. In the presence of an excess of oxygen ensured by addition of hydrogen peroxide, ammonia and many organic nitrogen compounds were quantitatively oxidized after 3 hr of irradiation, to give a mixture of nitrate and nitrite. Strickland and Parsons[2] recommend this method for sea-water "even although there are some inherent errors and a doubt exists as to its applicability to certain nitrogenous compounds". Photo-oxidation by means of a mercury-arc lamp of lower power (380 W) was studied by Armstrong and Tibbitts.[3] They reported 98% oxidation of the nitrogen compounds in sea-water after irradiation for 12 hr. Henriksen[4] adapted the photo-oxidation method to the determination of nitrogen, phosphorus and iron in fresh water. Also working with fresh water, Afghan *et al.*[5] observed that certain nitrogen compounds were quantitatively oxidized within a reasonable time only in acid solution, while others required an alkaline medium. This led to the development of methods[5,6] based upon irradiation in two steps, first in acid and then in alkaline solution. Contrary to these authors, Manny *et al.*[7] irradiated the samples only at pH 4 and made separate determinations of the oxidation products formed, ammonia, nitrite and nitrate.

Some problems arose when we wanted to apply the photo-oxidation method to brackish water. There

seemed to be some interferences not observed by other authors.[1-7] We soon found that the large range of pH recommended by Strickland and Parsons (6–8.5) and Henriksen[4] (6.5–9) may lead to large errors because the interference from some substances is very dependent on pH. We also wanted to know whether the method mentioned above, using irradiation in two steps, could be adapted to sea-water analysis. Using a thoroughly investigated method[8,9] for the determination of the nitrate–nitrite mixture formed we undertook a detailed investigation of the factors influencing the photo-oxidation and made a comparison between irradiation at a certain pH and the more laborious method involving irradiation first in acid and then in alkaline medium.

EXPERIMENTAL

Equipment

The photo-oxidation was performed with equipment similar to that described by Henriksen, consisting of a 900-W high-pressure mercury-arc lamp mounted axially in an aluminium-sheet cylinder provided with a cooling fan at its lower end. Twelve silica tubes (27 mm outside diameter), each containing 100 ml of sample, were placed in a circle about 70 mm from the lamp. The temperature stabilized at 80–85° in the upper part of the solutions after prolonged irradiation.

Reagents

Water. For dilution of solutions intended for irradiation the ordinary distilled water was further purified by passing it through a column of Dowex 50 W cation-exchanger, H^+-form. Its nitrogen (N) concentration was thus reduced from 0.4 to 0.15 μM.

"Double sea-water" (*DSW*). This was prepared from specially purified reagents and had the following composition: $0.960M$ Na^+, $0.0212M$ Ca^{2+}, $0.109M$ Mg^{2+}, $0.0227M$ K^+, $1.121M$ Cl^-, $0.060M$ SO_4^{2-} and $0.00168M$ Br^-. Diluting this solution with an equal volume of water gives a synthetic sea-water of 3.5% salinity, containing the major constituents except strontium, bicarbonate, borate and fluoride.

Hydrogen peroxide, 30%. Perhydrol, Merck No. 7210, stabilized for higher storage temperature was preferred to the ordinary reagent grade, No. 7209, because it had a considerably lower nitrogen content, only 0.016–0.025 μmole of N per ml compared to 0.29 μmole of N per ml in Perhydrol No. 7209. The nitrogen content was determined after decomposition of the hydrogen peroxide by boiling an acid solution (5 ml of Perhydrol in 40 ml of $0.002M$ sulphuric acid) for about 1 hr in the presence of a platinum grid.

Regarding *solutions used in the reduction of nitrate* and *the spectrophotometric determination of nitrite*, see Nydahl.[8,9] In *solutions of undefined substances*, e.g. meat peptone and proteins, the nitrogen content was determined by Kjeldahl digestion according to the A.O.A.C.[10] before the final dilution. Tests of the Kjeldahl procedure on *p*-aminobenzoic acid and glycine gave relative errors within $\pm 0.2\%$.

Blanks. The total blank for the whole procedure (Method A) was 0.026 μmole of N ($s = 0.006$, $n = 14$) with use of purified water and 0.039 μmole of N ($s = 0.012$, $n = 8$) with synthetic sea-water of 3.5% salinity.

Procedures

Method A—One-step photo-oxidation. To each of the samples, generally containing 2 μmoles of N, were added 50 μmoles of borax and 0.30 ml of Perhydrol. followed by dilution to 95 ml and mixing. The tubes were then covered with glass caps, irradiated for 3 hr, and allowed to cool to room temperature. The solutions were quantitatively transferred to 100-ml standard flasks each containing 1 mmole of Tris-buffer and the calculated amount of alkali or acid to adjust the pH to 8.2, and were diluted to volume. The nitrate–nitrite mixture produced was then analysed according to Nydahl,[8,9] with use of electrolytically precipitated cadmium for the reduction of nitrate to nitrite before the differential spectrophotometric determination.[8,11] The absorbance of the solutions was measured against a standard nitrate solution, usually $20\mu M$, which contained the same buffer and salts as the samples and was reduced in the same column.

Method B—Two-step photo-oxidation. The irradiation was performed in two steps, first at pH 2.1 (0.50 mmole of sulphuric acid added) for 1 hr and then at pH 9 for 3 hr after addition of 0.30 ml of Perhydrol and a buffer solution containing 50 μmoles of borax and enough sodium hydroxide to neutralize the previously added sulphuric acid and the acids (H_2CO_3 etc.) formed during the irradiation. The analysis was continued as in Method A.

RESULTS AND DISCUSSION

Reduction-step errors

To obtain rapid photo-oxidation it is essential to use an adequate amount of hydrogen peroxide in order to produce a high concentration of oxygen. Irradiation accelerates the decomposition of the hydrogen peroxide; it was found that less than 0.01% remained after 1 hr. Notwithstanding the high temperature the solution may remain supersaturated with oxygen even after prolonged irradiation time and this large excess must be removed before the reduction in the cadmium column. Otherwise the reduction of

oxygen would lead to a deleterious production of cadmium ions, and cadmium hydroxide would precipitate and decrease the efficiency of the column (*cf.* Nydahl[8]). With use of 0.30 ml of Perhydrol and an irradiation time of 3 hr, interfering concentrations of oxygen were occasionally observed if the solutions were rapidly cooled after irradiation and immediately analysed for nitrate and nitrite, but if the solutions were left in the reactor until the next day no such problems arose. If necessary, an excess of oxygen can easily be removed by shaking and aeration. Contrary to other authors,[2-4] it was found that reagent-grade hydrogen peroxide may contain significant concentrations of nitrogen compounds.

Without due attention to pH, chloride concentration and flow-rate, the errors introduced in the reduction step may be quite large (*cf.* Nydahl[8]), especially for copperized cadmium, which is commonly used on account of its high rate of reduction. Differences in composition (pH, concentration of chloride and nitrite) between the irradiated sample and the nitrate standard used for calibrating the reduction step may lead to errors, positive or negative depending on the differences and on the flow-rate used. The thoroughly investigated reduction method used in the present paper gave for both nitrate and nitrite a nitrite yield of $\geqslant 99.5\%$ at low salt content, and about 99% for synthetic ocean water. The error in the determination of nitrate + nitrite did not exceed 0.3% for 1–2 μmoles of nitrogen and any larger errors found can therefore be attributed to the photo-oxidation step.

One-step photo-oxidation

Effect of pH and buffer type. In our experiments, generally with boric acid–borax buffer, irradiation for 3 hr gave quantitative ($\geqslant 98\%$) yields from ammonia, glycine, EDTA, 8-hydroxyquinoline and n-butylamine within the pH-range 7–9, but the yield was reduced at lower pH. Other substances, e.g., urea and *p*-aminobenzoic acid, required lower pH for quantitative oxidation and therefore gave large negative errors at pH > 7. Nitrogen compounds containing nitrogen-to-nitrogen bonds gave extremely low yields—Methyl Orange only 35% (and hydrazine sulphate only 5% by Method B)—presumably on account of losses as free nitrogen. Natural waters, however, are not likely to contain significant concentrations of such compounds. The behaviour of urea is particularly interesting. Armstrong *et al.*,[1] who performed the irradiation of sea-water at pH 8, state that urea is only partly oxidized to give nitrate. Using a similar apparatus, Semenov *et al.*[6] found that urea was 80% oxidized at pH 4, whereas hardly any nitrate–nitrite mixture was formed at pH 9. The remarkable resistance of urea to photo-oxidation is also shown by Armstrong and Tibbitts,[3] who report that urea required 24 hr for nearly complete oxidation, double the time necessary for other nitrogen compounds. We obtained quantitative oxidation

of urea at pH 4–6, but low and erratic yields at higher pH. The great influence of pH in the presence of halides is described later on.

It is usually recommended to buffer the solution with sodium bicarbonate. For some substances (urea, creatinine and guanidine) the yields were 15–45% lower with 50–100 μmoles of this buffer than with borax buffer of the same pH.

Effect of organic matter. Organic matter may interfere in various ways. Apart from a conceivable specific effect, it consumes oxygen, which may lower the oxidation rate, and carbon dioxide is formed which lowers the pH, the more so the more poorly the solution is buffered; at low pH carbon dioxide also lowers the oxidation rate, as shown by other experiments. It might be expected that addition of still more hydrogen peroxide would increase the oxidation rate, partly on account of the higher concentration of oxygen and partly by partial removal of carbon dioxide with the excess of oxygen escaping from the hot solution.

To test these predictions some experiments were performed with sucrose as model organic matter. The results are given in Fig. 1. Theoretically, 0.30 ml of Perhydrol should be sufficient for the complete oxidation of as much as 120 μmoles of sucrose. In spite of the large excess of oxygen there was a decrease in yield for the oxidation of glycine in the presence of even moderate amounts of sucrose (curve A). The effect of increasing the irradiation time to 5 hr (curve B) was slight, but if at the same time the amount of Perhydrol was doubled (curve C), the

Fig. 2. Effect of salt concentration and pH on the photo-oxidation of 2 μmoles of ammonium chloride. DSW added: 0, 2, 10 and 50 ml.

values became considerably higher. Still more sucrose could be tolerated if the pH was kept higher during the irradiation by using 150 instead of 50 μmoles of borax (curve D). Unfortunately it is possible to use this large quantity of borax only in samples low in calcium and magnesium, e.g., most lake waters, because at higher levels their borates will precipitate. Further experiments showed that the interference from sucrose was similar for meat peptone and also for glycine in synthetic sea-water of 3.5% salinity.

Effect of bromide and chloride. In this study five test substances were chosen as representatives of different groups of nitrogen compounds in natural waters (meat peptone as a representative of the decomposition products of proteins). Different dilutions of DSW were used to obtain solutions of various salinities.

(i) *Ammonia.* As shown in Fig. 2, the yield was very dependent on pH in saline solutions. Pure solutions of ammonium chloride gave quantitative yields in the whole pH-range tested. In saline solutions the yield was about 98% at pH 9–9.5 at all three dilutions of DSW, but the yield decreased with decreasing pH, the more the lower the salinity. Obviously, there must be a salinity that will cause a minimum in yield in the lower pH-range. Figure 3B shows that such a minimum was obtained at a salinity of about 0.15% (2 ml of DSW added) when irradiation was performed at pH 7. In Fig. 3 a comparison is made between the yields found at pH 7 and 9 for sodium chloride solutions and synthetic sea-waters. At pH 9 the yield was fairly independent of the salt concentration but at pH 7 large negative errors were obtained, especially in the presence of DSW.

Experiments proved that these low yields were caused by losses of nitrogen, presumably as free nitrogen, and not by a decrease in the rate of photo-oxidation. The difference between the effects of sodium chloride and synthetic sea-water are fully explained by the bromide content of the latter. Figure

Fig. 1. Effect of sucrose on the photo-oxidation of 2 μmoles of glycine (10 μmoles of sucrose in 95 ml corresponds to a COD of 40 mg of oxygen per litre). Curves A and B: 0.30 ml of Perhydrol, 50 μmoles of borax; (A) 3 hr, (B) 5 hr irradiation. Curves C and D: 0.60 ml of Perhydrol, 5 hr irradiation; (C) 50 μmoles, (D) 150 μmoles of borax. Curve E: 0.30 ml of Perhydrol, 150 μmoles of borax, 3 hr irradiation.
Fig. 3. Photo-oxidation of 2 μmoles of ammonium chloride at pH 7.0 and 9.0 in the presence of 0.02–50 ml of 1.12*M* NaCl (A) or DSW, 1.12*M* in Cl⁻ (B). The insert is an enlargement of the first part of curve B, pH 7.

4 shows the yields obtained when 2 μmoles of ammonium chloride were irradiated in solutions of chloride and bromide. Generally a certain concentration of bromide caused increased losses of ammonia-nitrogen as the chloride content decreased. The values agree well (within 2%) with the corresponding yields obtained in the presence of synthetic sea-water of the same halide content. Thus the other salts in synthetic sea-water have insignificant effect in this respect. At least part of the negative errors obtained without any addition of potassium bromide may be attributed to traces of bromide in the sodium chloride reagent used. It is well known that hypobromite may oxidize ammonia and amino groups to free nitrogen and it seems probable that a similar reaction may cause the losses found here. At the minimum shown in Fig. 3B, the concentrations of bromide and nitrogen are of the same order of magnitude. Hydrogen peroxide had no specific effect on the bromide-nitrogen reaction, as shown by irradiating saline solutions saturated with oxygen as a substitute for addition of hydrogen peroxide. This gave about the same losses at pH 7 as in the presence of hydrogen peroxide.

The necessity of maintaining sufficiently high pH during the irradiation of saline waters is less pronounced at lower concentration of ammonia, as demonstrated in Fig. 5 where the yields for 0.1–2 μmole amounts of ammonia at pH 7.2 and 9.0 are shown.

(*ii*) *Glycine.* The influence of halides and nitrogen concentrations at different pH-values (7 and 9) on glycine was similar to that on ammonia, although the minimum in yield at pH 7 for a salinity of 0.15% was less pronounced (78% compared to 73% for ammonia).

(*iii*) *Meat peptone.* The photo-oxidation of meat peptone in synthetic sea-water was fairly independent of pH and of the concentration of peptone-nitrogen (Fig. 5).

(*iv*) *Urea.* In contrast to other substances investigated, urea gave much higher yields at pH 7 than at pH 9 in the presence of halides. At pH 7 the negative influence of halides was smaller, the lower the concentration of urea. As with meat peptone, there was a general decrease in yield with increasing salinity; no minimum was observed.
Fig. 4. Effect of chloride and bromide on the photo-oxidation of 2 μmoles of ammonium chloride at pH 7; 1.12*M* NaCl added: 0 (□), 0.5 (●), 2 (■) and 50 (▲) ml.
Fig. 5. The yield as function of the nitrogen concentration in the presence of 2 ml of DSW; 0.1-2 μmole amounts of ammonia-nitrogen (A) or peptone-nitrogen (B) irradiated at pH 7.2 and 9.0.

(v) *Nitrate.* For nitrate, small losses of nitrogen, proportional to the irradiation time, were observed in spite of the high oxygen content. These losses (1% for irradiation for 4 hr) were independent of salinity.

Two-step photo-oxidation

Method A with irradiation for 3 hr at pH 9 gave low yields (85-88%) for some proteins (gelatine, milk, white of a hen's egg, pepsin). This is of special interest, as to a large extent organic nitrogen compounds in natural waters may be proteins or their decomposition products. Attempts to increase the yield by using longer irradiation times, more hydrogen peroxide or pH 7 instead of pH 9 were unsuccessful, nor did dilution of the samples (0.2 μmole of N taken) significantly increase the yield.

Preliminary experiments. Preliminary experiments on gelatine showed that it was possible to increase the yield by performing the irradiation in two steps, first in acid medium and then at pH 9 for 3 hr after addition of hydrogen peroxide. When the first irradiation (for 1 hr) was performed in the presence of 0.01, 0.05, 0.1, 0.2 or 0.5 mmole of sulphuric acid, the final yields were 92.8, 94.6, 95.1, 94.5 and 97.2%, respectively. The positive effect of a decreasing pH in the first step was still more pronounced if the solution contained halides. At a salinity of 0.15% acidification with 0.05, 0.2 and 0.5 mmole of sulphuric acid gave final yields of 70.5, 85.0 and 90.8%. Other experiments showed that not much was gained by using still larger amounts of acid. For practical reasons 0.5 mmole of sulphuric aid was therefore found to be adequate. Addition of hydrogen peroxide before the

irradiation in acid medium decreased the yield if halides were present.

Reaction products found after irradiation at pH 2.1. Ammonia, glycine, *N*-acetylglycine, meat peptone and caffeine were irradiated for 1 or 3 hr at pH 2.1 (0.5 mmole of sulphuric acid added) in the absence or presence of hydrogen peroxide (29 experiments). After cooling, the solutions were analysed for ammonia by an indophenol blue method,[12] and for nitrate and nitrite. Only 0.3% of the nitrogen added was found as nitrite. Ammonia remained as such. Glycine-nitrogen was mostly converted into ammonia; only 2-5% was found as nitrate. When the amino group was protected by acetylation (*N*-acetylglycine) the yield of nitrate was increased to 27-33%. The sum of inorganic nitrogen was 98-100% for ammonia, glycine and *N*-acetylglycine, the higher values generally being obtained with the longer irradiation time. For the more complicated substances caffeine and meat peptone, the formation of ammonia and nitrate proceeded more slowly, their relative amounts varied, and the sum of inorganic nitrogen was only 84-95%.

These experiments show that nitrogen remaining after irradiation in acid medium is present as ammonium, nitrate and incompletely mineralized organic nitrogen. A second irradiation at high pH is therefore necessary (Method B).

Comparison between Method A and Method B

In Table 1 a comparison is made between methods A and B for some well-defined chemical compounds and for some proteins or their partial decomposition products in the absence of interfering substances. In all cases method B gave higher yields, the relative increase being especially large for caffeine (35%), uric acid (31%), urea (36%) and proteins (about 10%). Experiments proved that the lower yield obtained with method A could not be caused by the shorter total irradiation time.

As might be expected from our earlier results (one-step photo-oxidation) an initial irradiation in acid medium caused large losses of ammonia-nitrogen if halides were present (see Table 2). These losses could be prevented by the addition of 1 μmole of sucrose and it seems probable that organic matter present in natural waters is also beneficial in this respect. For the other substances listed in Table 2 the yields were about the same with both methods (A and B) in the presence of halides.

Experiments not recorded here showed large interference from halides if hydrogen peroxide was added before the irradiation at pH 2.1.

In order to elucidate the applicability of photo-oxidation to natural waters, some samples, filtered through 0.45-μm Millipore filters, were analysed by both photo-oxidation and a Kjeldahl method[13] modified to give the sum of nitrate, nitrite, ammonia and organic nitrogen. The principal features of this method were: oxidation of nitrite to nitrate with bromate, added before the sulphuric acid, reduction

Table 1. Comparison between methods A and B in the absence of interfering substances: 2 μmoles of N taken; s indicates standard deviation, n number of determinations

Irradiated substance	Method A			Method B		
	Mean yield, %	s	n	Mean yield, %	s	n

p-Aminobenzoic acid	90.5	2.2	2	97.3	0.1	2

of nitrate to ammonia with Cr(II)–Ti(III) in the absence of oxygen, evaporation and Kjeldahl digestion. As the method permitted large samples to be taken, the ammonia formed could be determined by acidimetric titration after distillation. The results are presented in Table 3, which also includes values for Cl^-, COD, NH_4^+, NO_3^- and NO_2^-. For two of the samples (10 and 14) it was found that addition of 0.05 ml of Perhydrol before irradiation at pH 2.1 increased the yield considerably but, as expected from earlier experiments, such an addition led to rather large relative losses of nitrogen for the brackish samples. Compared to the values for total nitrogen obtained with the thoroughly tested Kjeldahl method used, photo-oxidation gave for the fresh water samples a mean yield of 89.7% with method A and 95.4% with method B modified by addition of 0.05 ml of Perhydrol before the irradiation at pH 2.1 (method B* in Table 3). As the fresh water samples are essentially

of the same kind it is possible to treat the results obtained for them statistically. Applying the t-test shows that the photo-oxidation methods gave significantly lower values (confidence level about 99%) than the modified Kjeldahl method. Besides, the difference between the means obtained by method B* and either of methods A and B is significant at the 95% confidence level. For the brackish samples, which were very low in ammonia and nitrate, the relative errors were larger with both photo-oxidation methods. If the effect on organic nitrogen is considered, the advantage of method B* for fresh waters is even more apparent. The mean relative change in yield of organic nitrogen by use of method B* instead of method A was +13% for the fresh water samples in Table 3. As it is possible to determine ammonia and nitrate + nitrite with fairly high accuracy, the error in organic nitrogen will mostly depend on the analysis for total nitrogen.

Table 2. Effect of salinity on methods A and B; 2 μmoles of N taken

Irradiated substance	DSW added, ml	Yield, %

*As for method B but with addition of 0.05 ml of Perhydrol before irradiation at pH 2.1.

The water samples analysed in Table 3 were about 20 μM in total nitrogen when irradiated. A greater dilution before irradiation would presumably have led to higher yields.

CONCLUSIONS

Experimental conditions such as intensity and spectral composition of the radiation, as well as pH and concentration of nitrogen and salts, especially halides, in the irradiation step have a large influence on the yields of the photo-oxidation. It is therefore difficult to compare results obtained by different authors, especially as the information given about the parameters used is often incomplete.

The low results obtained when solutions of proteins, urea and some other substances were irradiated according to method A led to the development of method B. In the absence of interfering concentrations of halides method B gave considerably higher yields for many of the substances investigated. A drawback of method B, however, is the difficulty in adjusting the pH before the final irradiation, as the form of the irradiation vessels prohibits the use of a glass electrode. Because only small amounts of borax can be used, the relatively large quantity of sulphuric acid requires that the amount of sodium hydroxide added should be adequate to increase the pH to the desired value, due regard being given to the extra acids (H_2CO_3 etc.) formed by oxidation. Other authors[5,6] have also used irradiation in two steps, but at pH 4 and 9. For fresh waters it might be advantageous to do the first irradiation at pH 4 instead of 2.1, because the adjustment to pH 9 before the final irradiation would be less difficult. In our experience, however, the losses caused by even rather low concen-

trations of halides are far larger in solutions of lower acidity than pH 2.1.

Provided the concentration of halides is sufficiently low, a small addition of hydrogen peroxide before the first irradiation (at pH 2.1) is recommended. The gain in yield may be considerable, especially at high concentrations of organic nitrogen and/or organic matter.

If the concentration of nitrogen is high it is advisable to dilute the sample to ⩽ 20 μM in N before irradiation, thus also reducing the concentrations of any interfering substances that may be present.

It is evident from the results of this investigation that the different variables interact in a rather complicated way. The method chosen must be a compromise, and dependent on the kind of water sample and also on the accuracy desired. To minimize interferences from halides and organic matter the final irradiation should be performed at fairly high pH, 8.0–8.5 for sea-waters and 8.7–9 for samples low in calcium and magnesium. Borax was chosen as buffer because the generally recommended bicarbonate buffer led to low results for some compounds. In practice, however, naturally occurring bicarbonates must be tolerated and may then, if in sufficient concentration, as in ocean water and hard waters, serve as the buffer; addition of borax is then preferably omitted, as involving a certain risk of formation of precipitates.

In the absence of interfering concentrations of halides the advantage of an initial irradiation at pH 2.1 according to method B is clearly shown. For saline solutions, however, the gain in yield by using method B instead of method A is usually slight and may not warrant the extra work involved. For practical reasons it may therefore be preferable to analyse brackish and sea-waters with method A.

On account of the low blank and the high sensitivity of the spectrophotometric finish, the photo-oxidation method is particularly suitable for samples (fresh as well as saline waters) of low nitrogen content.

From the results obtained it seems probable that the determination of total nitrogen in filtered fresh waters according to method B may have a negative error of 2–8%, the larger error being expected for samples relatively high in organic nitrogen. For saline samples the errors will probably be larger, at least at high ratio of organic nitrogen to inorganic nitrogen.

The photo-oxidation of particulate matter was not investigated.

CONTRIBUTIONS TO THE THEORY OF CATALYTIC TITRATIONS—I*

COMPLEXOMETRIC CATALYTIC TITRATIONS

Ferenc F. Gaál and Biljana F. Abramović

Institute of Chemistry, Faculty of Sciences, University of Novi Sad, V. Vlahovića 2, YU-21000 Novi Sad, Yugoslavia

Summary—Complexometric catalytic titrations with both volumetric and coulometric addition of the titrant have been simulated. By taking into consideration the equilibrium concentration of the catalyst during the titration, general mathematical equations have been set up. The influence of several factors on the shape of the simulated catalytic titration curve has been investigated and is discussed. The work also deals with the conditions under which the approximate mathematical expressions (equilibrium concentration of the catalyst being neglected) can be applied to simulate the catalytic titration curves with a satisfactory accuracy.

As with other analytical procedures, in the development of catalytic titrations the methodological and experimental foundations were laid before the corresponding theoretical relations were derived. From our own research in the field[1,2] and the results of other authors,[3–9] it seems that the experimental conditions have hitherto been chosen on the basis of extensive experimentation, which is a rather tedious job. However, by further development of the theory of catalytic titrations it should be possible, in a relatively easy way (with the aid of computers), to determine the optimal titration conditions. It should also be possible, on the basis of the reaction kinetics, to decide in advance whether a certain indicator reaction would be suitable for determination of particular analytes. After an experimental check, simulated catalytic titration curves might also be used for determination or revision of the indicator reaction kinetics, as well as for determination of all other quantities influencing the shape of the catalytic titration curves.

In catalytic titrations the titrant can be added either continuously or discontinuously, but in both cases the titration curve is obtained by plotting the change in some physical parameter (which is a function of an indicator-reaction rate, *i.e.*, the catalytic activity of a component of the solution to be titrated) against the amount of titrant added. Since methods with a continuous addition of the titrant are of greater importance, and experimentally much simpler, their mathematical interpretation has attracted more attention.

In 1970 Mottola[10] gave the first mathematical treatment of catalytic titration curves, starting from some general expressions, but without particular

solutions for the titration curves. Goizman[11] in 1971 derived equations for the catalytic thermometric curves, but his work was restricted to volumetric addition of the titrating reagent, and the volume change of the solution during titration was neglected. Simpson[12] in 1973 was the first to simulate catalytic spectrophotometric titration curves by using a computer, introducing a new quality into these investigations, but he, also, neglected the solution volume changes during titration. Gaál[1] in 1977 formulated some general mathematical equations as a basis for interpretation of the shape of catalytic titration curves, obtained by means of different techniques, for both coulometric and volumetric addition of the titrating reagent.

However, all these authors have assumed that the catalyst concentration before the equivalence point can be neglected. This approximation is acceptable provided the reaction product formed in reaction (1)

$$
\begin{array}{ccccc}
A & + & K & \rightleftharpoons & AK \\

\text{(inhibitor)} & & \text{(catalyst)} & &
\end{array}
\tag{1}
$$
is, for example, a sparingly soluble compound with a very low solubility product, or a complex with a very high stability constant. This is not always the case, however. For this reason we have formulated a mathematical description of catalytic titration curves, taking into account the equilibrium concentration of catalyst in the course of titration. In this article we derive the mathematical expressions for simulation of complexometric catalytic titration curves for both volumetric and coulometric addition of the titrant. We consider indicator reactions of first or pseudo-first and second order. Since the mathematical expressions obtained in this way are rather complex, we have also determined the conditions under which the equilibrium concentration of catalyst can be neglected.

---

*Dedicated to Professor. V. J. Vajgand, Faculty of Sciences, University of Belgrade, on the occasion of his 60th birthday.

THEORY

To simplify derivation of the mathematical expressions, we consider it advisable to introduce several approximations, namely

(1) titrant is added to the ideally stirred solution;

(2) temperature changes during titration do not affect the thermodynamics and kinetics of the reactions;

(3) the indicator reaction has an incubation period short enough to be neglected;

(4) the rate constant of the titration reaction is high, and need not be taken into account;

(5) changes caused in the measured parameter by the titration reaction are negligibly small compared to the changes due to the indicator reaction.

The procedure for obtaining expressions for simulation of catalytic complexometric titrations consists of deriving an equation for the catalyst concentration during the titration. The expression obtained is then introduced into the one for the rate of the indicator reaction and, this expression is integrated for the limiting conditions.

In deriving the equation for the catalyst concentration in the course of titration, we start from the expression for the instability constant K_N of the catalyst–inhibitor complex (assumed to have 1:1 stoichiometry):

$$K_N = \frac{c(K)c'(A)}{c(AK)} \quad (2)$$

where $c(K)$ is the molar concentration of catalyst K, $c'(A)$ that of inhibitor A and $c(AK)$ that of the complex AK.

After introduction of the appropriate expressions for $c'(A)$ and $c(AK)$ into expression (2), a relation is obtained for the equilibrium concentration of the catalyst during the titration.

Simulation of volumetric complexometric catalytic titrations

If $c'(A)$ and $c(AK)$ during the titration are taken as

$$c'(A) = \frac{V_r c(A)}{V_r + jt} - c(AK) \quad (3)$$

and

$$c(AK) = \frac{jtc(T)}{V_r + jt} - c(K) \quad (4)$$

where $c(A)$ is the initial molar concentration of the inhibitor, $c(T)$ the concentration of the titrant, V_r the initial volume of the titrated solution (l.), j the rate of addition of titrant (l./sec), and t is time (sec), then introducing these expressions into equation (2) gives the following relation for the catalyst concentration during the titration:

$$c(K) = \frac{[c(T) - K_N]jt - E_k^{1/2} + (E_k + F_k t + G_k t^2)^{1/2}}{2(V_r + jt)} \quad (5)$$

where

$$E_k = \{V_r[c(A) + K_N]\}^2;$$
$$F_k = 2V_r j\{K_N[c(A) + K_N] - c(T)[c(A) - K_N]\};$$
$$G_k = j^2[c(T) + K_N]^2$$

In order to obtain equations for the catalytic titration curves we start (similarly to other authors[1,10-12]) from the corresponding expressions for the rates of the indicator reactions.

First-order indicator reaction. If the indicator reaction

$$X + (Y) \overset{K}{\rightleftharpoons} L + (O) \quad (6)$$
proceeds according to first or pseudo-first order kinetics with respect to the indicator reaction component X, then its rate can be expressed as:

$$-\frac{dc(X)}{dt} = [k_0' + k_k'c(K)]c(X) + \frac{c(X)j}{V_r + jt} \quad (7)$$

where k_0' is the rate constant of the first-order spontaneous reaction (sec^{-1}), k_k' the rate constant of the first-order catalysed reaction (l.mole^{-1}.sec^{-1}) and $c(X)$ the molar concentration of the indicator reaction component. The last term in equation (7) describes the change in the rate of the indicator reaction due to the increase in volume of the reaction mixture during the titration.

With the catalyst concentration expressed by equation (5) and integration of equation (7) for the limiting conditions $c(X) = c_0(X)$ at $t = 0$, an expression is obtained for describing the concentration of component X at time t:

$$c(X) = c_0(X) \frac{V_r}{V_r + jt} \exp(-M_k) \quad (8)$$

where $c_0(X)$ is the initial molar concentration of the indicator reaction component, and

in which

$$M_k = k_0't - \frac{k_k'V_r}{2j}[c(A) + c(T)]\ln\frac{V_r + jt}{V_r} + \frac{k_k't}{2}[c(T) - K_N] + \frac{k_k'}{2j}R_k \quad (9)$$

$$R_k = [A_k + B_k(V_r + jt) + C_k(V_r + jt)^2]^{1/2} - (A_k + B_kV_r + C_kV_r^2)^{1/2}$$
$$+ \frac{B_k}{2C_k^{1/2}}\ln\frac{2C_k(V_r + jt) + B_k + 2\{C_k[A_k + B_k(V_r + jt) + C_k(V_r + jt)^2]\}^{1/2}}{2C_kV_r + B_k + 2[C_k(A_k + B_kV_r + C_kV_r^2)]^{1/2}}$$
$$- A_k^{1/2}\ln\frac{V_r(2\{A_k[A_k + B_k(V_r + jt) + C_k(V_r + jt)^2]\}^{1/2} + B_k(V_r + jt) + 2A_k)}{(V_r + jt)\{2[A_k(A_k + B_kV_r + C_kV_r^2)]^{1/2} + B_kV_r + 2A_k\}} \quad (10)$$

where

$$A_k = \{V_r[c(A) + c(T)]\}^2;$$

$$B_k = 2V_r\{K_N[c(A) - c(T)] - c(T)[c(A) + c(T)]\};$$

$$C_k = [c(T) + K_N]^2$$

Since the concentrations of the reaction products are often measured during the titration, it can be suitable to express the reaction rates as a function of these concentrations. If product L is formed from component X in equation (6), in 1:1 ratio, then the concentration of X remaining at time t will be:

$$c(X) = c_0(X)\frac{V_r}{V_r + jt} - c(L) \qquad (11)$$

where $c(L)$ is the molar concentration of the indicator-reaction product.

On the basis of equations (8) and (11) it follows that the concentration of L at time t is:

$$c(L) = c_0(X)\frac{V_r}{V_r + jt}[1 - \exp(-M_k)] \qquad (12)$$

Second-order indicator reaction. If the indicator reaction is second order, the reaction rate will be maximal when the initial concentrations of the reacting components, $c(X)$ and $c(Y)$, are equal. The rate of the indicator reaction can then be written in the form:

$$-\frac{dc(X)}{dt} = [k_0 + k_k c(K)]c(X)^2 + \frac{c(X)j}{V_r + jt} \qquad (13)$$

where k_0 is the rate constant for the second-order spontaneous reaction ($1.mole^{-1}.sec^{-1}$), and k_k the rate constant for the second-order catalytic reaction ($1^2.mole^{-2}.sec^{-1}$).

After introduction of equation (5), describing the catalyst concentration, and integration of equation (13), the following expression is obtained for the concentration of component X at time t:

$$c(X) = \frac{c_0(X) V_r}{[1 + c_0(X)Q_k](V_r + jt)} \qquad (14)$$

The concentration of product L is

$$c(L) = \frac{c_0^2(X)Q_k V_r}{[1 + c_0(X)Q_k](V_r + jt)}. \qquad (17)$$

Simulation of coulometric complexometric catalytic titrations

The concentrations of the inhibitor, $c'(A)$, and of complex, $c(AK)$, in coulometric addition of the titrant are:

$$c'(A) = c(A) - c(AK) \qquad (18)$$

$$c(AK) = \frac{It}{nFV_r} - c(K) \qquad (19)$$

where I is the generating current (A), F the Faraday constant (C/mole), n the number of electrons in the half-reaction for electrochemical generation of the titrant, and their introduction into expression (2) leads to an equation for the catalyst concentration:

$$c(K) = \frac{It - (E_k')^{1/2} + [E_k' + F_k't + (It)^2]^{1/2}}{2nFV_r} \qquad (20)$$

where

$$E_k' = \{nFV_r[c(A) + K_N]\}^2;$$

$$F_k' = 2nFV_r I[K_N - c(A)]$$

First-order indicator reaction. In coulometric addition of the titrant the rate of an indicator reaction of first or pseudo-first order with respect to component X is given by

$$-\frac{dc(X)}{dt} = [k_0' + k_k' c(K)]c(X) \qquad (21)$$

Expression (21) differs from (7) by the absence of the term describing the volume changes during the titration.

After introduction of equation (20) into (21), and integration for the limiting conditions $c(X) = c_0(X)$ at $t = 0$, expression (22) is obtained for the concentration of component X at time t:

$$c(X) = c_0(X) \exp(-M_k') \qquad (22)$$

where

$$M_k' = k_0't + \frac{k_k'It^2}{4nFV_r} - \frac{k_k'[c(A) + K_N]t}{2}$$
$$+ \frac{k_k'}{2nFV}R_k' \qquad (23)$$

where

$$Q_k = \frac{k_0 V_r}{j}\ln\frac{V_r + jt}{V_r} + \frac{k_k V_r}{2j}[c(T) - K_N]\left(\ln\frac{V_r + jt}{V_r} - \frac{jt}{V_r + jt}\right) - \frac{k_k V_r^2}{2j}[c(A) + K_N]\left(\frac{1}{V_r} - \frac{1}{V_r + jt}\right) + \frac{k_k V_r}{2j}S_k \qquad (15)$$

in which

$$S_k = \frac{-[A_k + B_k(V_r + jt) + C_k(V_r + jt)^2]^{1/2}}{V_r + jt} + \frac{(A_k + B_k V_r + C_k V_r^2)^{1/2}}{V_r}$$

$$+ C_k^{1/2}\ln\frac{2C_k(V_r + jt) + B_k + 2\{C_k[A_k + B_k(V_r + jt) + C_k(V_r + jt)^2]\}^{1/2}}{2C_k V_r + B_k + 2[C_k(A_k + B_k V_r + C_k V_r^2)]^{1/2}}$$

$$- \frac{B_k}{2A_k^{1/2}}\ln\frac{V_r(2\{A_k[A_k + B_k(V_r + jt) + C_k(V_r + jt)^2]\}^{1/2} + B_k(V_r + jt) + 2A_k)}{(V_r + jt)\{2[A_k(A_k + B_k V_r + C_k V_r^2)]^{1/2} + B_k V_r + 2A_k\}} \qquad (16)$$

in which

$$R'_k = \frac{(2I^2t + F'_k)[E'_k + F'_k t + (It)^2]^{1/2} - F'_k(E'_k)^{1/2}}{4I^2}$$

$$+ \frac{4E'_k I^2 - (F'_k)^2}{8I^3} \ln$$

$$\times \frac{2I[E'_k + F'_k t + (It)^2]^{1/2} + 2I^2t + F'_k}{2I(E'_k)^{1/2} + F'_k} \quad (24)$$

From the relation

$$c(L) = c_0(X) - c(X) \quad (25)$$

and (22), an expression is obtained for the concentration of product L at time t:

$$c(L) = c_0(X)[1 - \exp(-M'_k)]. \quad (26)$$

Second-order indicator reaction. The expression for the rate constant of the second-order indicator reaction in coulometric addition of the titrant $[c(X) = c(Y)]$ is

$$-\frac{dc(X)}{dt} = [k_0 + k_k c(K)]c(X)^2 \quad (27)$$

and combination of this with relation (20) for the catalyst concentration during the titration, gives, after integration of equation (27) for the limiting conditions $c(X) = c_0(X)$ $t = 0$, the following relations for the concentration of component X and product L:

$$c(X) = \frac{c_0(X)}{1 + c_0(X)Q'_k} \quad (28)$$

$$c(L) = \frac{c_0^2(X)Q'_k}{1 + c_0(X)Q'_k} \quad (29)$$

where Q'_k is analogous to M'_k in equation (23) but with constants k_0 and k_k instead of k'_0 and k'_k.

Calculations

As can be seen, the equations obtained for simulation of catalytic titration curves are rather complex, so to treat the data numerically it is necessary to use a computer. We have employed a Univac 1100 and a Varian 73, with FORTRAN IV as the programming language. Also, the expressions to be used for calculation of the concentration of the indicator-reaction product depend on the nature of the indicator reaction [equations (12) and (17), or (26) and (29)]. Moreover, we have planned to simulate precipitation, redox and neutralization catalytic titration curves in our further work. For this reason we wished to construct a program by means of which we could simulate all types of catalytic titration curves, regardless of the order of the indicator reaction and the type of titration reaction. We have achieved this in the following way: we have written a program which in fact contains two programs. The flow-diagrams of both are given in Figs. 1 and 2. As can be seen, the first program (Fig. 1) contains a great number of subroutines (one for each type of catalytic titration). Therefore we first introduce the "number of the

subroutine", IP, in order to supply the computer with the information on the type of catalytic titration and which subroutine, PP_i, is to be used in the calculations. We then introduce the data on the number of curves as well as all necessary data for calculation of the concentration of the indicator-reaction product at various stages of the titration. The results are then calculated with the derived expressions (by calling for the corresponding subroutine) and tabulated on a disc. We have constructed this program in such a way that besides putting the data on a disc, we can simultaneously list them with the corresponding headings, on the basis of which it is possible to recognize the particular catalytic titration. From such a list it is then possible to plot the catalytic titration curves. Since hand-plotting is time-consuming we have constructed a program to do it. This program (Fig. 2) is written in such a way that after introducing the data from the disc, the text for figure headings and the co-ordinates of the figures, besides listing the results, the computer prints the graph of the corresponding simulated catalytic titration curves together with the headings containing all the pertinent data: type of catalytic titration curve, order of the indicator

Fig. 1. Flow diagram for program.

factors affecting the shape of simulated titration curves is discussed below.

Effect of the complex instability constant

One of the most interesting effects, which has not been considered in previous works (Fig. 3, curves 1–4), is certainly that of the value of the complex instability constant. As can be seen from Fig. 3, determination of the titration end-point is difficult when the complex instability constant is $> 10^{-7}$ (curve 2) under the given working conditions. However, if the rate constant of the catalysed reaction is lower, it may be possible to determine the end-point even for values of the complex instability constant $> 10^{-7}$.

It is also interesting to find the limiting value for the complex instability constant for which it is necessary to apply the derived expressions, i.e., the lowest value of the constant, for which the catalyst ions are practically not present in the solution before the equivalence point. It is evident from Fig. 3 that with decrease in the complex instability constant, the differences between complexometric catalytic titration curves become smaller and smaller. Thus, for example, for values of 10^{-8} and 10^{-10} for the complex instability constant (curves 3 and 4) the difference in shape of the titration curves is very small. Furthermore, with further decrease of the constant, the differences between the simulated curves practically disappear. Hence, it can be concluded that for complex instability constants of about 10^{-8} or below, it is possible to use an approximative expression, neglecting the equilibrium concentration of the catalyst. The error will be relatively small, as will be shown later on.

Since the approximative equations are much simpler (see Appendix 1) we have examined and presented graphically a broad range of conditions for which it is possible to neglect the equilibrium concentration of the catalyst. The procedure was as follows: the curves obtained on the basis of the complete and the approximative expressions were compared, and the conditions determined for which the difference in shape of the titration curves, i.e., in the concentrations of component X and product L, respectively, does not exceed a prescribed value. We have examined the conditions for which the approximation error is not higher than $0.03c_0(X)$ or $0.05c(L)$. Since these calculations were also relatively complex, we wrote suitable programs in FORTRAN IV and used a Univac 1100. Figures 4 and 5 present the diagrams for deciding in advance whether it is necessary to apply the complete expression or an approximative one for simulation of the volumetric complexometric catalytic titration with a first-order indicator reaction, so that the error does not exceed $0.03c_0(X)$ (Fig. 4) or $0.05c(L)$ (Fig. 5).

It is necessary to use the complete expression for all conditions on the left-hand side of each curve, but not for those on the right-hand side. Thus, for

Fig. 2. Flow diagram for program.

reaction, concentrations of the titrant and titrand, concentration of the indicator-reaction component, initial volume of the solution, rate constants for both the spontaneous and the catalysed reaction, the equilibrium constant, rate of addition of the titrant in the volumetric method or the generating current in a coulometric determination, as well as the number of electrons in the equation for the electrochemical generation of the titrant (in the coulometric method). On each graph several catalytic titration curves are plotted, differing only in the value for the parameter being investigated. The listings of the programs are available on request.

RESULTS AND DISCUSSION

As pointed out in the introduction, by simulation of catalytic titration curves it is possible to choose, in a relatively simple way, the optimal experimental conditions. Therefore the effect of a number of

Fig. 3. Simulated curves for catalytic complexometric titrations obtained with volumetric addition of titrant and a first or pseudo-first order indicator reaction, under the following conditions: $V_r = 3 \times 10^{-2}$ l.; $c_0(X) = 10^{-3}M$; $k'_0 = 10^{-3}$ sec^{-1}; $k'_k = 10^3$ l.mole^{-1}.sec^{-1}; $c(T) = 5 \times 10^{-3}M$; $c(A) = 5 \times 10^{-4}M$; $j = 10^{-5}$ l./sec. Curves 1–4—equilibrium catalyst concentration taken into account [according to equation (12)]; 5—on the basis of the expressions obtained by Goizman[11] and Simpson;[12] 6—according to the expressions obtained by Gaál.[1] Values for K_N are: 1, 10^{-6}; 2, 10^{-7}; 3, 10^{-8}; 4, 10^{-10}. Equivalence point 3.00 ml.

example, if K_N is 10^{-9}, $k'_0 = 10^{-4}$ sec^{-1}, $k'_k = 10^4$ l.mole^{-1}.sec^{-1}, $c(A) = 5 \times 10^{-4}M$ and $c(T) = 5 \times 10^{-3}M$, it is possible to use the approximative expression, for an approximation error $<0.03c_0(X)$, because the point is on the right-hand side of the corresponding curve (Fig. 4, curve 2'). However, if we choose an error not exceeding $0.05c(L)$, then use of the approximative expression is not possible, because the point is on the left-hand side of the corresponding straight line (Fig. 5, curve 2').

Similar diagrams have been obtained for a second-order indicator reaction with the rate constants of both the spontaneous and the catalysed reaction 1000 times those for a first-order reaction. This will be discussed further, below.

Very similar diagrams have been obtained for the case of coulometric addition of the titrant, so the same diagrams can be applied (under the given working conditions) regardless of the mode of titrant addition.

Figure 3 also shows catalytic titration curves obtained on the basis of the approximative expressions derived by Goizman[11] and Simpson[12] (curve 5) and Gaál[1] (curve 6). As mentioned before, curves 1–4 differ from curves 5 and 6 by taking into account the concentration changes of the indicator-reaction product, due to dilution, and the equilibrium concentration of the catalyst during the titration. These two parameters have opposite effects, i.e., the first causes a decrease and the second an increase in the concen-
Fig. 4. Range of applicability of approximative equations for simulation of volumetric complexometric catalytic titrations with an approximation error not exceeding $0.03c_0(X)$ (first-order indicator reaction) under the following conditions: $V_r = 3 \times 10^{-2}$ 1.; $c_0(X) = 10^{-3}M$; $j = 10^{-5}$ 1./sec. 1-3, $c(A) = 5 \times 10^{-3}M$; $c(T) = 5 \times 10^{-2}M$; $1'-3'$, $c(A) = 5 \times 10^{-4}M$; $c(T) = 5 \times 10^{-3}M$; $1''-3''$, $c(A) = 5 \times 10^{-5}M$; $c(T) = 5 \times 10^{-4}M$; $1'''-3'''$, $c(A) = 5 \times 10^{-6}M$; $c(T) = 5 \times 10^{-5}M$; $1,1',1'',1'''$, $k_0' = 10^{-3}$ sec^{-1}; $2, 2', 2'', 2'''$, $k_0' = 10^{-4}$ sec^{-1}; $3, 3', 3'', 3'''$, $k_0' = 10^{-5}$ sec^{-1}.

tration of L, as could be expected. Which of the two effects will prevail depends on the value of the complex instability constant and the concentration of the titrant. If, for example, the instability constant is 10^{-7} or higher (for given other conditions), the effect of the equilibrium concentration of the catalyst is larger in the period before the equivalence point. Consequently, curves 1 and 2 are then above curves 5 and 6. On the other hand, if the complex instability constant is below 10^{-8} the effect of dilution of the solution has a greater influence, hence curves 3 and 4 lie below curves 5 and 6. However, after the equivalence point, when the indicator-reaction components have completely reacted, curves 1–4 have the same shape, i.e., only the effect in volume increase of the reacting mixture is noticeable, so that all the curves, irrespective of the complex instability constant, are below curves 5 and 6. It is evident that when the concentration of the titrant is ten times that of the titrand it is necessary to take into account concentration changes of the indicator-reaction product, due to dilution of the solution.

However, it should be mentioned again that under certain working conditions (for example, at a small value of the instability constant and at a high ratio of the concentration of titrant to that of titrand) satisfactory agreement is obtained between the experimental and simulated catalytic titration curves even when the expressions derived by Goizman,[11] Simpson[12] and Gaál[1] are used.

Effect of initial concentrations of the indicator reaction components

In the case of the first-order indicator reaction, the reaction rate, i.e., the rate at which the measured parameter changes during the titration, is a linear function of the initial concentrations of the indicator-reaction components. This can be concluded on the basis of equations (12) and (26) and of the experimental results. A further conclusion is that increasing the initial concentrations of the indicator-reaction components or decreasing the sensitivity of the monitoring instrument (or vice versa) will have the same effect on the shape of the titration curve. Whether a higher or lower concentration is chosen in the experimental work depends on the measuring instrument (recorder) available. If we have a sensitive recorder we shall certainly choose a lower starting concentration of the indicator-reaction components. In the case of the second-order indicator reaction this effect is somewhat more complex. As can be concluded on the basis of equations (17) and (29), under given working conditions the dependence on this parameter can vary from linear to quadratic (limiting cases). If $c_0(X)Q_k < 1$ or $c_0(X)Q_k' < 1$, which happens either at a low $c_0(X)$ or k_0, k_k, $c(K)$, or t (all these last four quantities being included in Q_k and Q_k'), the dependence is practically quadratic. However, with increase in $c_0(X)Q_k$ or $c_0(X)Q_k'$ it becomes less and less quadratic with a tendency to linearity (which is achieved in the limiting case). Since Q_k (or Q_k') is also changing during the titration [the values for both t and $c(K)$ show an increase] the effect of changing $c_0(X)$ on the rate of the indicator reaction (i.e., on the shape of the titration curve) is decreasing. The optimal starting concentration of the indicator-reaction components depends on several factors. If the value for k_0 is small, curves of a better shape will be obtained with higher starting concentrations of the indicator-reaction components, especially if the value for k_k is small. However, for a higher k_0 value, it will be more convenient to use a lower starting concentration of the indicator-reaction components, which is in agreement with the experimental results.

Effect of the mode of titrant addition

If complexometric catalytic titration curves obtained by volumetric and coulometric addition of the titrant are compared, it can be noticed that (under the working conditions as in Fig. 3) they are similar to each other in the period before the equivalence point. With decrease of the titrant concentration and the generating current, respectively, the differences in shape of the titration curves, and hence, the concentration changes for the indicator-reaction component in coulometric addition of the titrant, will become larger and larger. However, in the pretitration period a significant difference is noticeable even at a titrant concentration ten times that of the titrand. This is because there is no volume change during the
Fig. 5. Range of applicability of approximative equations for simulation of volumetric complexometric catalytic titrations with an approximation error not exceeding $0.05c(\mathrm{L})$ (first-order indicator reaction) under the following conditions: $V_\mathrm{r} = 3 \times 10^{-2}$ l.; $c_0(\mathrm{X}) = 10^{-3}M$; $j = 10^{-5}$ l./sec. 1–3 $c(\mathrm{A}) = 5 \times 10^{-3}M$; $c(\mathrm{T}) = 5 \times 10^{-2}M$; $1'{-}3'\, c(\mathrm{A}) = 5 \times 10^{-4}M$; $c(\mathrm{T}) = 5 \times 10^{-3}M$; $1''{-}3''\, c(\mathrm{A}) = 5 \times 10^{-5}M$; $c(\mathrm{T}) = 5 \times 10^{-4}M$; $1'''{-}3'''\, c(\mathrm{A}) = 5 \times 10^{-6}M$; $c(\mathrm{T}) = 5 \times 10^{-5}M$; $1,\, 1',\, 1'',\, 1''',\, k_0' = 10^{-3}$ sec^{-1}; $2,\, 2',\, 2'',\, 2''',\, k_0' = 10^{-4}$ sec^{-1}; $3,\, 3',\, 3'',\, 3''',\, k_0' = 10^{-5}$ sec^{-1}.

coulometric titration so that the concentration of product L at some moment becomes equal to the initial concentration of component X. After that, with further generation of the titrant, there is no change in the concentration of product L. However, in the volumetric addition method, owing to the dilution of the solution the concentration of product L cannot reach the value for the starting concentration of the indicator-reaction component X, so a maximum appears on the titration curve, after which the concentration of product L decreases with further addition of the titrant. For this reason, the total concentration change of product L is somewhat larger in the coulometric method and hence this mode is more suitable, especially in titration of smaller amounts of substances, and when higher generating currents are used. Since we are considering further development of coulometric complexometric catalytic titrations, the conclusions derived from this work may be of great help in choosing the proper experimental conditions.

Effect of the rate constant of the catalysed reaction

An increase in the rate of the catalysed reaction (Fig. 6) does not show a significant effect before the equivalence point (under the given working conditions), but has a very pronounced effect after the equivalence point. However, for higher values of the instability constant, the effect is more conspicuous in the period before the equivalence point. It can also be concluded that the titration end-point can be easily determined when k_k' is > 10 l.mole^{-1}.sec^{-1} (curve 4), for given other conditions. If $c(\mathrm{T})$ or j is larger, it might also be possible to employ an indicator reaction with a somewhat lower value for k_k'. On the basis of Fig. 6, it can be concluded that the best way of determining the end-point is by direct graphical

extrapolation of the linear parts of the titration curve before and after the equivalence point, since the concentration of L changes gradually. However, the results obtained in this way would be slightly higher than the theoretical values, so it is necessary to correct them with the corresponding results from blank titrations. Simulation of these titrations will be described in a future article.

However, if the indicator reaction is second order, it is possible to determine the titration end-point in a satisfactory way if k_k is $> 10^4$ l^2.mole^{-2}.sec^{-1}, under the same working conditions as in the case of the first-order indicator reaction. These differences in the effect of the k_k values on the shape of the catalytic titration curves can be easily understood by comparing expression (12) with (17), and (26) with (29), respectively.

Under such conditions, in the case of the second-order indicator reaction the dependence of $c(\mathrm{L})$ on $c_0(\mathrm{X})$ is practically quadratic. For this reason it is necessary to have a thousandfold higher Q_k in order to obtain a curve of the same shape as in the case of the first-order indicator reaction. This is best achieved by a thousandfold increase in k_k.

Effect of the rate constant of the spontaneous reaction

This effect is very significant, even in the period before the equivalence point (under the same working conditions, Fig. 6), which is quite understandable. Under the given experimental conditions, which are those most often used in practice, it is possible to determine satisfactorily the titration end-point if $k_0' \leqslant 10^{-3}$ sec^{-1} in the case of a first-order indicator reaction, and $k_0 < 1$ l.mole^{-1}.sec^{-1} in the case of a second-order indicator reaction. These differences in the maximal values for k_0' and k_0 can be explained in the same way as in the case of k_k.
Fig. 6. Effect of rate constant for the first, or pseudo-first order catalysed reaction, k_1', on the shape of the simulated volumetric complexometric catalytic titration curves obtained under the following conditions: $V_r = 3 \times 10^{-2}$ l.; $c_0(X) = 10^{-3}M$; $k_0' = 10^{-3}$ sec^{-1}; $c(T) = 5 \times 10^{-3}M$; $c(A) = 5 \times 10^{-4}M$; $j = 10^{-5}$ l./sec; $K_N = 10^{-8}$. Values for k_1' (l.mole^{-1}.sec^{-1}) are: 1, 10^4; 2, 10^3; 3, 10^2; 4, 10; 5, 1. Equivalence point 3.00 ml.

Effect of concentrations of the titrant and titrand

It appears possible to determine the titration endpoint if the concentrations of the titrant and titrand are not lower than 5×10^{-4} and $5 \times 10^{-5}M$ respectively (under the same working conditions as in simulated curve 2, Fig. 6). If the rate constant for the catalysed reaction were higher, it would be possible to titrate even more dilute solutions and with a more dilute titrant, but the complex instability constant would have to be lower, in order to have a reaction proceeding quantitatively at the equivalence point.

Other effects

The following effects have been also investigated: rate of titrant addition, magnitude of the generating current, and the number of electrons involved in the electrochemical generation of the titrant. These pa-

rameters all had the expected effect on the shape of the simulated titration curves.

The conclusions reached in this work explain and confirm, to a great extent, our experimental results, as well as those of other investigators in the field. Also, the optimal experimental conditions have been predicted for realization of further experimental studies on the subject.

SPECTROPHOTOMETRIC DETERMINATION OF GERMANIUM IN ORES, CONCENTRATES, ZINC-PROCESSING PRODUCTS AND RELATED MATERIALS WITH PHENYLFLUORONE AND CETYLTRIMETHYLAMMONIUM BROMIDE AFTER SEPARATION BY IRON COLLECTION AND HEPTANE EXTRACTION OF GERMANIUM TETRACHLORIDE

Elsie M. Donaldson

Mineral Sciences Laboratories, Canada Centre for Mineral and Energy Technology, Department of
Energy, Mines and Resources, Ottawa, Canada

Summary—A method for determining ~ 0.2 μg/g or more of germanium in ores, concentrates, zinc-processing products and related materials is described. The sample is decomposed by fusion with sodium peroxide and the cooled melt is dissolved in dilute sulphuric acid. Silica, if > 50 mg, is removed by volatilization with hydrofluoric acid. Germanium is separated from sodium salts by co-precipitation with hydrous ferric oxide, the precipitate is dissolved in $3M$ hydrochloric acid and germanium is subsequently separated from iron(III) and other co-precipitated elements by a single heptane extraction of germanium tetrachloride from $\sim 9.4M$ hydrochloric acid. The extract is washed with $12M$ hydrochloric acid to remove residual iron(III), then germanium is stripped with water and determined spectrophotometrically with phenylfluorone in a $1.4M$ hydrochloric acid–$0.002M$ cetyltrimethylammonium bromide medium in the presence of ascorbic acid as a reductant for co-extracted chlorine. The apparent molar absorptivity of the complex is 1.71×10^4 $1.\text{mole}^{-1}.\text{mm}^{-1}$ at 507 nm, the wavelength of maximum absorption. Up to 5 mg of tin(IV), 10 mg of antimony(V) and tungsten(VI) and ~ 50 mg of silica do not interfere. Germanium values are given for some Canadian certified reference ores, concentrates and iron-formation samples and for a metallurgical dust.

A current long-term CANMET project involves a study of the behaviour, form and distribution of silver in conventional hydrometallurgical processes or circuits designed to recover metallic zinc from zinc ores and concentrates. The objective of this project is to increase the recovery of silver in Canadian zinc plants. As part of this project, solvent extraction/atomic-absorption spectrophotometric (AAS) methods[1,2] and a direct AAS[3] method have been developed for the determination of small and moderate amounts of silver, respectively. In addition, an improved solvent extraction/flame atomic-emission method[4] has been developed for the determination of indium, which is also a valuable by-product and which affects the behaviour of silver in the zinc circuit. Because the intermediate products from the processing of zinc ores are a primary source of germanium,[5] which might also affect the recovery of silver, a reliable, simple and reasonably rapid method was required for the routine determination of microgram-quantities of germanium in these and related materials.

In the past, the two most widely used methods for the determination of small amounts of germanium were those based on its separation by distillation or

extraction of germanium tetrachloride from strongly acidic hydrochloric acid media, followed by spectrophotometric measurement of its complex with phenylfluorone or other chromogenic reagents.[5–7] Currently, however, the extraction method has almost completely replaced the distillation method because of its greater selectivity, convenience, speed and simplicity and because the germanium can be more readily concentrated into a small volume.[7,8] Furthermore, the distillation method yields low results in the presence of large amounts of sodium chloride and insoluble material such as lead sulphate and amorphous silica.[5,6] In recent years the AAS determination of germanium by electrothermal atomization[9] and by hydride-evolution techniques coupled with both flame[10–13] and electrothermal finishes[14] has been studied and direct methods have been reported for coal[14] and coal ash.[11] However, these methods are strongly subject to interference from matrix elements[10–12,14] and, although the finishes used are relatively sensitive, they are more complicated and time-consuming than a simple spectrophotometric phenylfluorone finish. Several investigators have found that with these finishes the accurate determination of trace amounts of germanium necessitates its preliminary separation from matrix elements by extraction as the chloride.[9,12] The

literature shows that most of the published methods for the determination of germanium in ores, concentrates and related materials appear in obscure Soviet and other journals not readily accessible to Western readers. Recently, however, methods published up to ~ mid-1971 were reviewed by Nazarenko.[15a] Most of these and the later methods[16-20] involve spectrophotometric finishes, usually with phenylfluorone and generally after the separation of germanium by a double or triple extraction of the tetrachloride into carbon tetrachloride. Some also involve a preliminary collection step with iron to separate germanium from large amounts of zinc or from sodium salts resulting from decomposition of the sample by fusion with an alkaline flux. In most of these methods, gum arabic, gelatin and poly(vinyl alcohol)[15b] are used as dispersing agents to stabilize the suspension of the germanium–phenylfluorone complex. However, Shijo and Takeuchi[21] found that cetyltrimethylammonium bromide (CTAB) acts as a surface-active agent and greatly increases the sensitivity and rate of the reaction between germanium and phenylfluorone. Since the publication of their work, other quaternary ammonium salts and analogous compounds have been found to react in a similar manner.[22-24] Because of the simplicity and speed of the spectrophotometric phenylfluorone finish and the high sensitivity obtained in the presence of these surfactants, it was considered that this type of finish would be advantageous for the routine determination of small amounts of germanium in diverse ores, concentrates, zinc-processing products and related materials after suitable separation of germanium from the matrix elements.

The proposed method, which is a modification of other published methods,[15a] involves the separation of germanium from sodium salts, introduced during fusion of the sample, by co-precipitation with hydrous ferric oxide from an ammoniacal medium, followed by its separation from iron and other co-precipitated matrix elements by a single heptane extraction of germanium tetrachloride from $\sim 9.4M$ hydrochloric acid. The germanium is stripped from the extract with water and determined spectrophotometrically with phenylfluorone in $\sim 1.4M$ hydrochloric acid in the presence of CTAB. Some potential sources of error in existing methods are described and germanium values are given for some Canadian certified reference materials.

EXPERIMENTAL

Reagents

Standard germanium solution, 100 μg/ml. Dissolve 0.1441 g of pure germanium dioxide by heating gently with 20 ml of 2% sodium hydroxide solution (Note 1). Transfer the solution to a 1-litre standard flask and dilute to volume with water. Prepare a 10-μg/ml solution by diluting 10 ml of this stock solution to 100 ml with water. Prepare this diluted solution fresh as required.

Phenylfluorone, 0.001M solution. Transfer 0.160 g of 2,6,7-trihydroxy-9-phenylisoxanthene-3-one (9-phenyl-2,3,7-

trihydroxy-6-fluorone) to a 400-ml beaker containing a Teflon-coated magnetic stirring bar. Add ~200 ml of ethanol and 2 ml of concentrated hydrochloric acid, stir on a magnetic stirrer until the reagent has dissolved, then transfer the solution to a 500-ml standard flask and dilute to volume with ethanol. This solution is stable for at least one month.

CTAB, 0.9% solution. Add ~300 ml of water to 4.5 g of CTAB, mix thoroughly and place the beaker in a pan of warm water (Note 2). When the salt has dissolved, dilute the solution to 500 ml with water. Prepare a fresh solution every 4 weeks.

Iron(III) sulphate solution, 10 mg of iron/ml. Dissolve 25 g of ferric sulphate nonahydrate in ~300 ml of hot water containing 5 ml of concentrated sulphuric acid, cool and dilute to 500 ml with water.

Ascorbic acid, 10% solution. Prepare a fresh solution every 2 days.

Sulphuric acid, 50% v/v.

Hydrochloric acid, 25% v/v. Store in a plastic squeeze-type wash bottle.

Ammonia, 5% v/v solution. Store in a wash-bottle.

Heptane. Analytical reagent-grade.

Calibration curves

Transfer a 20-ml aliquot of 10-μg/ml standard germanium solution to a 250-ml separatory funnel and add 15 ml of water, 150 ml of cold (~0°) (Note 3) concentrated hydrochloric acid and 75 ml of heptane. Stopper the funnel and shake it for 2 min. Allow the layers to separate, then drain off and discard the lower (aqueous) layer. Wash the heptane phase by shaking it gently for ~30 sec with 5 ml of cold concentrated hydrochloric acid. Drain off and discard the acid layer and wash the stem of the funnel with water. Add 10 ml of water to the extract, stopper the funnel and shake it for 1 min. Allow the layers to separate, then drain the lower (aqueous) layer into a 200-ml standard flask with the aid of a small funnel placed in the neck of the flask. Wash the stem of the separatory funnel with water and collect the washings in the flask. Repeat the stripping step twice more by shaking the extract for ~30 sec each time with 10-ml portions of water. Wash the stem of the separatory funnel with water each time. Dilute the solution to volume with water and mix thoroughly.

From a burette, add 1, 2, 3, 4, 5 and 6 ml of the resulting 1-μg/ml germanium solution to six 25-ml standard flasks and dilute each solution to ~10 ml with water. Add 10 ml of water to a seventh flask, to prepare the blank. To each flask, add in succession 2 ml of 10% ascorbic acid solution, 3 ml of concentrated hydrochloric acid and 2 ml of 0.9% CTAB solution, mixing thoroughly after each addition, then add 2 ml of 0.001M phenylfluorone solution, dilute to volume with water and mix. Add 5, 10, 15, 20 and 25 ml of the 1-μg/ml germanium solution to five 100-ml standard flasks and dilute each solution to ~50 ml with water. Add 2 ml of 10% ascorbic acid solution to each flask, then proceed with the complex formation as described above, but with four times the volumes of concentrated hydrochloric acid and CTAB and phenylfluorone solutions (Note 4). Allow the resulting solutions to stand for ~5 min to complete the complex formation, then measure the absorbance, at 507 nm, of the blank and each of the six solutions in the first series against water as the reference solution, using 10-mm cells. Measure the absorbance of each of the five solutions in the second series in a similar manner. Correct the absorbance value obtained for each germanium–phenylfluorone solution by subtracting that obtained for the blank. Plot μg of germanium vs. absorbance for each series of measurements.

Analysis of ores, concentrates, zinc processing products and related materials

Silica ≤ 50 mg. Depending on the expected germanium content, transfer up to 0.5 g of powdered sample, containing

not more than 200 μg of germanium and up to ~ 150 mg of iron (Note 5), to a 50-ml zirconium crucible. Add 4 g of sodium peroxide, mix thoroughly (Note 6) and cautiously fuse the mixture over a low-temperature flame (Note 7) and keep it molten for ~ 30 sec to ensure complete decomposition (Note 8). Allow the melt to cool for several min, then transfer the crucible to a covered 400-ml beaker containing ~ 80 ml of water and 20 ml of 50% sulphuric acid. When the melt has dissolved, remove the crucible after washing it thoroughly with water, then cover the beaker (Note 9), boil the solution vigorously and allow it to evaporate to ~ 100 ml to ensure the complete destruction of hydrogen peroxide. Cool to room temperature, then add 5 ml of concentrated hydrochloric acid and, if necessary, add sufficient iron(III) sulphate solution for at least 100 mg of iron to be present.

Add sufficient concentrated ammonia solution to precipitate iron as the hydrous oxide, then add 5 ml in excess and boil the solution for ~ 1 min to coagulate the precipitate. Allow it to settle, then filter (Whatman No. 541 paper) and wash the beaker twice with 5% ammonia solution. Wash the paper and precipitate twice with the ammonia solution, followed by water, then discard the filtrate and washings. Place the funnel containing the precipitate in the neck of a 250-ml separatory funnel marked at 50 ml. Wash down the sides of the precipitation beaker with ~ 10 ml of cold (Note 3) 25% hydrochloric acid added from a plastic squeeze-type wash-bottle and add the solution to the funnel containing the precipitate. Carefully, to avoid tearing the paper, break up the gelatinous precipitate with a glass rod to aid dissolution. Wash the beaker twice more with ~ 5-ml portions of cold 25% hydrochloric acid, then wash the paper at least three times with small portions of the acid solution to dissolve any remaining precipitate. Discard the paper and, if necessary, dilute the solution to the mark with cold 25% hydrochloric acid. Add 135 ml of cold concentrated hydrochloric acid (Note 3) and 75 ml of heptane, stopper the funnel, then proceed with the extraction of germanium as described for the calibration. Wash the heptane phase with 5 ml of cold concentrated hydrochloric acid as described above, then drain off and discard the acid phase.

If the sample contains ~ 5 μg or less of germanium, add 5 ml of water to the extract, stopper the funnel and shake it for ~ 1 min. Allow the layers to separate, then carefully, without washing the stem of the funnel after the draining step, collect the aqueous phase in a 25-ml standard flask with the aid of a small funnel placed in the neck of the flask (Note 10). Wash the extract twice by shaking it for ~ 30 sec with 3 ml and then with 1 ml of water and add the washings to the flask (Note 11). Remove the small funnel from the flask and proceed with the addition of ascorbic acid solution and the subsequent determination of germanium as described above.

If the sample contains between 5 and 25 μg of germanium, shake the extract with three 10-ml portions of water as described for the calibration. Collect the solutions in a 100-ml standard flask, dilute to ~ 50 ml with water and proceed with the determination of germanium as described above.

If the sample contains more than 25 μg of germanium, strip the extract with three 10-ml portions of water as described above and dilute the resulting solution to volume with water in a 100-ml standard flask. Transfer a suitable aliquot (up to 50 ml) of the solution to a 100-ml standard flask, dilute to ~ 50 ml with water, if necessary, and proceed with the determination of germanium as described above.

Silica > 50 mg. Decompose a suitable weight of sample as described above and dissolve the melt as described, using a covered 400-ml Teflon beaker. Evaporate the solution to ~ 100 ml, then remove the cover, add 10 ml of concentrated hydrofluoric acid and evaporate the solution until copious fumes of sulphur trioxide are evolved. Cool, wash down the sides of the beaker with water and evaporate the solution to

fumes of sulphur trioxide again to ensure the complete removal of hydrofluoric acid. Cool, add ~ 100 ml of water and heat to dissolve the salts. Cool the solution, add 5 ml of concentrated hydrochloric acid and, if necessary, add sufficient iron(III) sulphate solution for at least 100 mg of iron to be present, then proceed with the co-precipitation, extraction and determination of germanium as described above.

Notes

1. If the germanium dioxide does not dissolve completely, the standard solution can be prepared by fusing the compound with ~ 4 g of sodium carbonate in a covered platinum crucible, with a high-temperature blast burner. The cooled melt should be dissolved in water and the resulting solution should be diluted as described.

2. The beaker should not be placed in hot water or on a hot-plate because a gelatinous substance, not readily soluble, forms under these conditions. If crystals form in the solution on standing they can be readily redissolved by placing the container in a pan of warm water.

3. The concentrated hydrochloric acid used for extraction and the 25% solution employed for the dissolution of the hydrous ferric oxide precipitate are most conveniently kept in a freezer. The extraction should be done without too much delay because germanium may be lost by volatilization as the chloride if the solution is allowed to warm to room temperature.[7,15a]

4. A second blank can be prepared in a similar manner or the first can be used for correction purposes. In this work the absorbance of the blank for the same batch of phenylfluorone varied from ~ 0.14 to 0.16.

5. More than ~ 0.5 g of sample is not recommended, because the amount of iron(III) used in the co-precipitation step may not be sufficient for the complete co-precipitation of germanium if the total concentration of other co-precipitated elements is too great. Samples containing more than 150 mg of iron can be taken but the filtration and/or dissolution steps may become unduly slow because of the bulk of the precipitate.

6. It is not necessary to run a reagent blank.

7. A bunsen burner, not a high-temperature blast burner, should be used. Too hot a flame causes the molten sodium peroxide to attack the crucible and results in the presence of too much zirconium in the final solution. This can cause difficulty in the co-precipitation step.

8. Ores containing very little sulphide minerals may be decomposed more readily by fusion with ~ 4 g of sodium carbonate as described in Note 1. The cooled melt should subsequently be dissolved in dilute sulphuric acid as described.

9. The solution should be kept almost completely covered during the initial evaporation, to avoid loss by spray.

10. Care should be taken that no heptane accompanies the aqueous phase, or the final solution obtained after the addition of phenylfluorone solution may be cloudy.

11. The heptane can be used continually for subsequent extractions if the stripped extracts are combined in a large separatory funnel and washed once by shaking with ~ 100 ml of water.

RESULTS AND DISCUSSION

Spectrophotometric determination of germanium with phenylfluorone

Recent work has shown that various quaternary ammonium salts and compounds [benzalkonium chloride,[22] dodecyltrimethylammonium bromide (DTAB)[23] and sodium lauryl sulphate[24]] other than CTAB, which is a commonly used surfactant, also sensitize and hasten the formation of the neutral 1:2

complex formed between Ge(OH)$_2^{2+}$ and phenylfluorone.[15c] However, none of these reagents appears to offer any particular advantages over CTAB. Consequently, CTAB was used in this work. Initial tests with $1M$ hydrochloric acid media showed that, for up to ~0.25 µg of germanium per ml, the optimum concentration of CTAB required for rapid complex formation is $\geq 0.0016M$. The optimum range of hydrochloric acid concentration is ~1–1.8M. Therefore, CTAB and hydrochloric acid concentrations of 0.002 and 1.4M, respectively, were chosen for subsequent work. Under these conditions, the optimum concentrations of phenylfluorone and ethanol, which is required to keep the reagent in solution, are ~8 × 10^{-5}M and ~8% v/v, respectively. Except for the phenylfluorone concentration, these conditions are in good agreement with those reported by Shijo and Takeuchi.[21] More than ~12% v/v ethanol inhibits the reaction. Higher concentrations of phenylfluorone are not recommended because of the magnitude of the reagent blank; at lower concentrations the reaction is incomplete. Beer's law is obeyed for up to ~0.25 µg of germanium per ml. Complex formation is complete in 2 or 3 min and the absorbance of the complex remains constant for at least 4 hr.

Except for the greater intensity of the main spectral band for a given amount of germanium, the spectrum of the complex formed in the presence of CTAB is essentially the same as the spectra obtained in the presence of poly(vinyl alcohol) and other dispersing agents.[21] The apparent molar absorptivity of the complex is 1.71 × 10^4 l.mole^{-1}.mm^{-1} at 507 nm, the wavelength of maximum absorption. This is in excellent agreement with the value reported by Shijo and Takeuchi,[21] viz. 1.71 × 10^4 l.mole^{-1}.mm^{-1} at 505 nm, and with that reported recently by Kurihara and Kuwabara[23] for the complex formed in the presence of a similar compound, DTAB, viz. 1.72 × 10^4 l.mole^{-1}.mm^{-1} at 503 nm. However, neither the results obtained in this work nor those obtained by the investigators above agree with those reported for CTAB by Burns and Dadgar.[24] These investigators found that in the presence of CTAB ~2 hr were required for complex formation and that the wavelength of maximum absorption shifted from 504 to 528 nm. Because the use of surfactants or other dispersing agents does not cause a significant shift in the absorption maximum of the germanium–phenylfluorone complex,[15b] this suggests that either the reagent used by these workers was not CTAB or that its composition had altered in some manner. Burns and Dadgar recommend the use of sodium lauryl sulphate as a dispersing agent. However, the apparent molar absorptivity value they obtained in the presence of this compound (1.18 × 10^4 l.mole^{-1}.mm^{-1}) shows that it is not nearly as effective a solubilizing agent as CTAB, DTAB or benzalkonium chloride (which gives a molar absorptivity of 1.81 × 10^4 l.mole^{-1}.mm^{-1}).

Separation of germanium by co-precipitation with hydrous ferric oxide

Acid attack involving the use of hydrofluoric and sulphuric acids or hydrofluoric and phosphoric acids, in the absence or presence of nitric acid, has been recommended for the decomposition of ores and related materials containing germanium before its separation by extraction as the tetrachloride and ultimate determination with phenylfluorone or other chromogenic reagents. However, under these conditions, if the sample contains an appreciable amount of chloride some germanium be lost by volatilization as the tetrachloride. In addition if the decomposition is incomplete, some germanium may remain in the insoluble residue.[7,15a] Furthermore, as mentioned later, phosphoric acid inhibits the extraction of germanium, and evaporation with sulphuric acid can produce low results. Because fusion with an alkaline flux, which usually results in complete decomposition of the sample, causes no loss of germanium as the tetrachloride,[7,15a] fusion with sodium peroxide was chosen for this work. However, because the large amount of sodium chloride formed when the hydrochloric acid concentration of the solution is adjusted to $\geq 9M$ before the extraction step interferes mechanically with the extraction of germanium,[15a,17,25] it is necessary to make a preliminary separation of germanium from the sodium salts by co-precipitation with hydrous ferric oxide from ammoniacal medium (pH ~7–10) as recommended by many previous investigators.[6,15a,15d] However, in initial tests involving 5–50 µg of germanium and 50 mg of iron(III) (as sulphate), low results (~85–90% recovery) were obtained when the precipitates were dissolved in cold (0°) $\geq 9M$ hydrochloric acid before the extraction step, as recommended by some previous workers.[15a,18,26–28] Some of these investigators also obtained low results under these conditions.[18,26,28] Ultimately, tests in which germanium was completely recovered when the precipitate was dissolved in 10% hydrochloric acid, followed by the direct determination of germanium in the resulting solution, showed that the loss when $\geq 9M$ hydrochloric acid was used occurred in the dissolution step. Presumably, the local heat generated during the dissolution of the precipitate, even in very cold 9–12M hydrochloric acid, results in some loss of germanium by volatilization as the tetrachloride. Tests showed that there is no advantage in using a hydrobromic acid system for the extraction. Although germanium tetrabromide is considered to be less volatile than the tetrachloride because of its higher boiling point, low results (~85–95% recovery), which were not due to incomplete extraction, were also obtained when the hydrous oxide precipitate was dissolved in concentrated hydrobromic acid before the extraction step. Further work showed that no loss by volatilization occurs if the precipitate is dissolved in ~3M hydrochloric acid, followed by the adjustment of the hydrochloric

acid concentration of the resulting solution to ~9.4M with cold concentrated hydrochloric acid just before the extraction step.

Previous investigators[29] showed that for the quantitative co-precipitation of germanium with the hydrous oxides of tervalent metallic elements, which results in the formation of the corresponding germanates, the metal ion to germanium ratio should be greater the lower the concentration of germanium. For the co-precipitation of ~0.01 μg of germanium per ml with hydrous ferric oxide, this ratio should not be less than ~1000:1.[15d] Although, as determined experimentally with pure germanium solutions, the amount of iron(III) (50 mg) used in the initial tests was sufficient for the complete co-precipitation of ≤ 1 μg of germanium, subsequent work showed that this amount is not sufficient when germanium is co-precipitated in the presence of ≥ 50 mg of aluminium, 25 mg of arsenic(V) or vanadium(V) or moderately large amounts of other co-precipitated elements and compounds such as antimony(V) and silica. This is because they compete with germanium to form ferric aluminates, arsenates, vanadates, antimonates and silicates.[15d] In further work 100 mg of iron(III) was found to be suitable for co-precipitation purposes. Under these conditions, up to 0.5 g of sample containing moderate amounts of aluminium and other co-precipitated elements can be used.

Separation of germanium by extraction as the tetrachloride

Carbon tetrachloride is the most commonly used solvent for the extraction of germanium tetrachloride and most investigators recommend a double or triple extraction to ensure complete extraction.[7,15a,15c,30] Extraction from $\geq 8M$ hydrochloric acid is reported to be essentially complete under these conditions.[15e,25,30,31] However, Luke and Campbell[32] found that germanium is only ~95% extracted in one extraction from ~8.5M hydrochloric acid when the volume ratio of organic to aqueous phase is ~1:1 and that additional extractions do not improve the recovery. These findings were confirmed in the present work, with carbon tetrachloride, benzene and heptane as extractants. Presumably this loss of germanium could be due to its volatilization as the tetrachloride before or during extraction. However, a more probable explanation is that the Ge(OH)$_2^{2+}$ present in the initial solution is not all completely converted into GeCl$_4$ when the hydrochloric acid concentration of the solution is adjusted to $\geq 8M$ before the extraction step. According to previous investigators,[33,34] some germanium can be present as an unextractable, partly hydrolysed anionic oxychloride complex under these conditions. Similar results (~98 and 0% recovery for the first and second extractions, respectively), which also suggest the formation of such species, were obtained when germanium was extracted as the less volatile tetrabromide from 8.6M hydrobromic acid into heptane.

On the basis of these findings, it was considered that one extraction with a non-polar solvent of specific gravity <1 would be advantageous for the separation of germanium from iron and other co-precipitated elements after its separation by collection with hydrous ferric oxide. Unlike extraction with carbon tetrachloride and other heavy solvents, which requires the use of three separatory funnels for the extraction and subsequent washing and stripping steps, this would result in a quicker and simpler method because all these operations could be carried out in the same funnel. Although many non-polar solvents of low specific gravity can be used to extract germanium tetrachloride, heptane was chosen because it is readily available and has a favourable extraction capacity with respect to germanium tetrachloride.[15e] It is also not as unpleasant to use as benzene or cyclohexane. Tests showed that up to at least 200 μg of germanium is ~98% extracted from $\geq 9M$ hydrochloric acid in one extraction with heptane in 1:1 or 2:1 aqueous/organic phase-volume ratio. To avoid error in the germanium result, the loss of germanium must be compensated for in the calibration curve. This is usually accomplished by taking all the solutions used for calibration purposes through the extraction step.[32] However, it is only necessary to extract one solution of relatively high germanium content (*e.g.*, 200 μg) and then to use the resultant strip solution for the preparation of the calibration curve.

Effect of diverse ions

Previous investigators found that only arsenic(III) as the chloride, and osmium and ruthenium as the tetroxides, are co-extracted into carbon tetrachloride from high concentrations of hydrochloric acid.[5,15e,30,33] Osmium and ruthenium are rarely present in ores and related materials in amounts sufficient to interfere during complex formation and, after sample decomposition by fusion with sodium peroxide, arsenic will be present in the quinquevalent state. However, it was considered necessary to investigate the possible interference effects of various elements that would be completely or partly co-precipitated with germanium or occluded by the precipitate during the iron collection step. These tests showed that, when 100 mg of iron(III) is used for co-precipitation, up to at least 75 mg of phosphate, 50 mg of aluminium, 25 mg of bismuth, manganese(II), molybdenum(VI), titanium(IV), arsenic(V) and vanadium(V) and 2 mg of selenium(VI) and tellurium(VI) can be present during the co-precipitation step without interfering in the co-precipitation or subsequent extraction of germanium. More than 10 mg of antimony(V) and tungsten(VI) will cause low results for germanium and more than ~5 mg of tin(IV) causes a high result. The interference of tin is due to its reaction with phenylfluorone[32] because, at the 5-mg level, tin(IV) is ~0.6% co-extracted under the conditions used for the extraction of germanium. More than ~50 mg of

silica causes a low result. Presumably, it interferes by competing with germanium to form ferric silicate and by forming a silicic acid gel when the hydrous oxide precipitate is dissolved in $3M$ hydrochloric acid before the extraction step. This gel adsorbs germanium and prevents its extraction as the tetrachloride.[15d] Interference from silica can readily be avoided by volatilizing it with hydrofluoric acid after dissolution of the melt in dilute sulphuric acid. However, under these conditions, more than microgram-quantities of chloride should not be present, because some germanium will be lost by volatilization as the chloride when the solution is evaporated to fumes of sulphur trioxide to remove the excess of hydrofluoric acid. At the 50-μg level, the loss of germanium in the presence of 1 mg of chloride is ~ 10–20%. Conversely, if the hydrofluoric acid treatment is not required, up to at least 2 g of chloride can be present in the solution of the melt without causing loss of germanium when the

solution is boiled to destroy the hydrogen peroxide produced.

Interference from co-extracted chlorine, which oxidizes phenylfluorone, is avoided by reducing it with ascorbic acid just before complex formation. This also reduces any iron(III) remaining after the extract is washed with concentrated hydrochloric acid. In the presence of the recommended amount of ascorbic acid, up to at least 5 mg of iron(III) will not interfere during complex formation.

Applications

Table 1 shows that the results obtained by the proposed method for a series of synthetic zinc concentrates in which the added germanium was varied from 2 to 200 $\mu g/g$ agree favourably with the calculated amount present. Similarly, Table 2 shows that the results obtained for five diverse Canadian Certified Reference Materials Project (CCRMP) ores

and concentrates and for three typical zinc-processing products, to which 2–100 $\mu g/g$ of germanium was added, are also in good agreement with the calculated values. In these tests, the required volumes of appropriate standard alkaline germanium solution were added to the zirconium crucibles and the solutions were gently evaporated to dryness before the addition of the sample and sodium peroxide. Table 3 shows that the results obtained for four CCRMP iron-formation samples agree reasonably well with the "usable" germanium values reported by Abbey et al.[35] These "usable" values, which are the approximate means of the sets of values obtained by automated d.c. arc optical emission and spark-source mass spectrometry, are only approximate interim germanium values because too few data were reported during the interlaboratory certification programme for firm values to be assigned.

Table 4 shows that the precision for germanium at about 2–26 $\mu g/g$ is reasonably good. The non-ferrous dust, PD-1, is a composite of metallurgical dusts collected on electrostatic precipitators from zinc and copper roaster stacks.

In many existing methods for the determination of germanium in silicates and related materials, in which the extraction step follows the decomposition step, mixtures of hydrofluoric and sulphuric acids and

hydrofluoric and phosphoric acids, in the absence or presence of nitric acid, are recommended for the decomposition of the sample.[6,7,15a,30] This is followed by the evaporation of the solution to fumes of sulphur trioxide and to a syrupy state, respectively, to ensure the complete removal of the excess of hydrofluoric acid which interferes in the extraction of germanium. Although these methods yield reasonably accurate results for samples containing microgram-quantities of germanium, tests in which solutions containing 100 μg were evaporated to fumes of sulphur trioxide as described above, followed by the extraction of germanium, yielded considerably low results. Presumably, this could be caused by the formation, during prolonged evaporation with sulphuric acid, of crystalline germanium dioxide which is insoluble in hot water or cold $9M$ hydrochloric acid. Heating with hydrochloric acid is required for its dissolution.[15a,36] In the proposed method for samples of high silica content, in which silica is removed by evaporation with hydrofluoric and sulphuric acids, the large amount of sodium salts present after fusion of the sample possibly inhibits the formation of this insoluble compound. Low results were obtained in similar tests with phosphoric acid, which was found to inhibit the extraction of germanium. As mentioned previously, a further disadvantage of both methods of acid attack is that the decomposition may not be complete.[7,15a]

The proposed method has several advantages over older methods based on carbon tetrachloride extraction and a phenylfluorone finish. It is quicker and simpler because only one extraction is required and because the extraction, washing and stripping steps are all done in the same separatory funnel. In addition, sample decomposition is complete and the phenylfluorone finish in the presence of CTAB is more rapid and about twice as sensitive as finishes involving the use of gelatin, gum arabic or poly(vinyl alcohol) as dispersing agents. The method is suitable for samples containing ~ 0.2 $\mu g/g$ or more of germanium. It should also be directly applicable to zinc-

process solutions. The mean values obtained for the CCRMP materials in Tables 2–4 should be of value to analysts for comparison purposes.

SHORT COMMUNICATIONS

CONSTRUCTION AND EVALUATION OF A POTASSIUM-SELECTIVE TUBE-MOUNTED MEMBRANE ELECTRODE

R. E. FARRELL and A. D. SCOTT

Department of Agronomy, Iowa State University, Ames, Iowa 50011, U.S.A.

Summary—A simple procedure for the rapid construction of inexpensive potassium-selective electrodes with valinomycin-based PVC membranes is described. Potassium-selective membranes were formed on the end of Parafilm- or Tygon-covered glass tubes by dipping the tubes into a mixture of PVC, valinomycin, and dioctyl sebacate dissolved in tetrahydrofuran. Small internal Ag/AgCl reference electrodes were made with silver wire and placed inside the tubes with AgCl-saturated potassium chloride solution. This procedure yields tube-mounted membrane electrodes that perform as well as commercially available potassium-selective electrodes in terms of their response characteristics and practical applications with soil extracts. Moreover, it facilitates the evaluation of membranes with different compositions, for making ion-selective electrodes.

Potassium-selective electrodes incorporating the neutral carrier valinomycin in PVC membranes have become extremely popular during the past decade.[1,2] These electrodes, which can be constructed with either an internal reference solution[3,4] or a solid internal contact,[5] have proved to be both reliable and versatile. Construction of these electrodes, however, can be quite cumbersome and, in some instances, may require specially designed membrane housings.[4,5] Furthermore, although potassium-selective PVC membrane electrodes are commercially available from several manufacturers,[6,7] they are relatively expensive, as are the membrane replacements periodically required. Here, we report on a simple, rapid and inexpensive method of constructing potassium-selective tube-mounted membrane electrodes with valinomycin-based PVC membranes and Ag/AgCl internal reference elements.

EXPERIMENTAL

Electrodes

The membrane material was a PVC–valinomycin–plasticizer mixture[4] prepared by dissolving 5 mg of valinomycin in 0.92 ml of dioctyl sebacate (DOS) in a screw-cap centrifuge tube, adding 150 mg of PVC and 2 ml of tetrahydrofuran (THF) as solvent, and mixing thoroughly with a vortex mixer. Twenty or more electrodes can be prepared from this amount of material, which, if refrigerated, will keep for several months.

The Ag/AgCl internal reference electrodes were prepared by a modification of the procedure described by Bailey.[8] A 2.5-cm length of 20-gauge silver wire was welded to a 20-cm length of 18-gauge copper wire, dipped into a solution of PVC (500 mg dissolved in 3–4 ml of THF) several times, and air-dried. Approximately 1.5 cm of the PVC coating was removed from the tip end of the silver wire, which was then dipped into concentrated ammonia solution for 30 sec, rinsed with demineralized water, dipped into 50% nitric acid until an even white colour developed (~ 60 sec), and rinsed again. With a 500-kΩ, 10-turn, 0.75-W potentiometer to regulate the current from a 9-V battery, the silver wire was

first made cathodic (platinum anode) in 0.1M hydrochloric acid for 15–30 sec at a current density that just produced bubbles at the cathode (~ 0.3 mA/mm^2). The battery connections were then reversed, and the same current density held for 5–10 min. Properly prepared electrodes had a uniform purple-grey colour and were stored in AgCl-saturated 10^{-3}M potassium chloride.

The membrane electrodes were constructed as follows. Membranes were formed on the ends of glass tubes (2 mm bore) by dipping the tubes in the PVC mixture and air-drying overnight. Because of the poor adhesion between glass and PVC and the non-availability of rigid small-diameter PVC tubing, a 5-mm length of the end to be dipped was wrapped with Parafilm or covered with Tygon tubing (3 mm bore) before dipping. The THF in the PVC mixture dissolved enough of the Parafilm or Tygon to glue the PVC to the glass covering and thereby achieve a good seal between the membrane and the tube. When the membranes had dried, the tubes were partly filled with AgCl-saturated 10^{-3}M potassium chloride, in which the internal Ag/AgCl reference electrodes were then immersed, and the upper ends of the tubes were sealed with Parafilm. The electrodes thus prepared were conditioned in 10^{-5}M potassium chloride for 1–2 hr and calibrated.

An Orion (model 93–19) and a Corning (model 476132) potassium-selective electrode were similarly conditioned and calibrated. An Orion (model 90–02) double-junction sleeve-type reference electrode with a saturated lithium acetate salt bridge was used in the calibration.

Measurements

Cell e.m.f. valves (E) were measured with a Corning (model 135) pH/Ion meter and recorded when the rate of change was ≤ 0.1 mV/min. All measurements were performed at 22.0 ± 0.1° in plastic beakers, with the test solutions mixed at constant speed. The potassium-selective electrodes were stored in 10^{-3}M potassium chloride when they were not to be used for periods of 2 days or more, and otherwise in 10^{-5}M potassium chloride. Calibration measurements were made in sequence from dilute to more concentrated solutions, the electrodes being rinsed with 10^{-6}M potassium chloride and lightly blotted dry between measurements. Before and after each complete calibration sequence, the electrodes were soaked in 10^{-6}M potassium chloride for 15–20 min.
Fig. 1. Calibrations with tube-mounted membrane electrode A, 1 day, 1 week and 5 weeks after construction.

RESULTS AND DISCUSSION

Typical calibration results are shown in Fig. 1. The cell e.m.f. decreased by ~ 1.5 mV/day during the first week, then at only ~ 0.2 mV/day over the next month. Most of the rapid initial change was due to

drift in the potential of the internal Ag/AgCl reference electrode as it equilibrated with the internal solution. This drift can be eliminated by equilibrating the Ag/AgCl electrode in AgCl-saturated $10^{-3} M$ potassium chloride for 3–5 days before use. The later changes are probably due to the effect of aging on the asymmetry potential of the PVC membrane. Similar but smaller changes were observed with the Orion and Corning electrodes.

The response characteristics of our electrodes (after 1 week of use) were very similar to those of the Orion and Corning electrodes (Table 1). The variations in cell constants ($E^{\circ\prime}$) are presumably due to differences between various internal reference solutions and asymmetry potentials. The response times, i.e., the times needed for ΔE to become ≤ 0.1 mV/min, for the electrodes were about the same: 3–5 min at low ($\leq 10^{-5} M$) potassium concentrations and 1–2 min at higher concentrations. The characteristics of all the electrodes were relatively unaffected by changes in pH from 5 to 11.

Our electrodes performed as well as or better than the commercial electrodes in practical determinations of potassium in soil extracts. A comparison of the results obtained for potassium determinations in $0.5 M$ barium chloride extracts of 10 soil samples with our electrode C (TM-C), the Orion electrode, and standard atomic-absorption (AAS) procedures is given in Table 2.

Our electrode provides an excellent alternative to

the more expensive commercial electrodes, especially when the risk of damage to the membrane is high. Since the tube holding the membrane is quite small and can be even smaller, the electrodes are well suited for determination of potassium in small samples. Furthermore, many electrodes can be prepared at one time and the membranes can be easily removed and replaced. Accordingly, our technique for construction of PVC membrane electrodes is particularly useful when a variety of membranes with different compositions is to be prepared and compared for specific applications.

DETERMINATION OF NICKEL BY FLAME ATOMIC-ABSORPTION SPECTROPHOTOMETRY AFTER SEPARATION BY ADSORPTION OF ITS NIOXIME COMPLEX ON MICROCRYSTALLINE NAPHTHALENE

Tohru Nagahiro and Bal Krishan Puri

Summary—A method has been developed for the determination of nickel in alloys by flame atomic-absorption spectrophotometry after formation of a water-insoluble complex, its adsorption on microcrystalline naphthalene, and dissolution of the complex and naphthalene in nitric acid and xylene.

Nioxime forms a water-insoluble, thermally stable red complex with nickel, which can be determined spectrophotometrically in the presence of gum arabic in aqueous medium,[1,2] but the complex is only partially soluble in the common organic solvents and so cannot be determined by extraction and spectrophotometry. Like may other complexes,[3–8] nickel nioximate is readily and quantitatively adsorbed on microcrystalline naphthalene, however, and thus easily separated from the aqueous phase. The nickel can then be stripped by dissolving the solid with nitric acid and xylene, and determined by atomic-absorption.

EXPERIMENTAL

Reagents

Standard nickel solution, 5 ppm.
Nioxime solution in ethanol, 0.1%.
Acetic acid/ammonium acetate buffer, 1*M*, pH 4.0.
Naphthalene solution in acetone, 20%.

Procedure

To a known volume (up to 40 ml) of sample solution containing 5–100 μg of nickel, in an 80-ml stoppered Erlenmeyer flask, add 2.0 ml of pH 4.0 buffer and 1.5 ml of nioxime solution, mix, then after a few minutes add 2.0 ml of naphthalene solution and shake the mixture vigorously for 30 sec. Filter off the naphthalene on a filter paper (No. 5C, Toyo Roshi Co., Japan) placed flat on a perforated Teflon disc (3 cm in diameter) placed in an ordinary filter funnel or on a sintered glass filter (porosity 2). Wash with water, then add 13 ml of 3*M* nitric acid and 2 ml of xylene to the filter to dissolve the naphthalene and nickel complex. The nickel is then in the aqueous phase and the naphthalene in the xylene. Filter the aqueous phase into a 20-ml standard flask, and wash the paper with water until the solution is diluted to the mark. Aspirate the solution into an air–acetylene flame and measure the absorbance at 232.0 nm, using a nickel hollow-cathode lamp.

RESULTS AND DISCUSSION

The optimum pH range is 3.2–11.2. The adsorption of the complex is quantitative with use of 0.3–6.0 ml of the nioxime solution, and 1–5 ml of buffer can be used. The nickel complex forms completely in a few minutes. Adsorption is complete with 0.5–4.0 ml of the naphthalene solution and takes only a few seconds of shaking. Mineral acids of various concentrations were tried for dissolution of the nickel complex and 3*M* nitric acid was found the most suitable. The adsorption yield with the 0.4 g of naphthalene is constant for aqueous phase volumes up to 200 ml, but decreases for larger volumes. Beer's law is obeyed for nickel up to 5 μg/ml in the final aqueous solution. For ten replicate determinations of 40 μg of nickel, the relative standard deviation was less than 1.4%.

Effect of diverse ions

In determination of 40 μg of nickel the following compounds did not interfere, even at the 100-mg level: KI, NaClO$_4$, KNO$_3$, NaCl, CH$_3$COONa·3H$_2$O, NH$_4$Cl, sodium tartrate, Na$_2$SO$_4$, KSCN, NaF, KH$_2$PO$_4$·12H$_2$O. Only relatively low amounts (1 mg) of sodium citrate and oxalate could be tolerated. EDTA and KCN interfered seriously. Mg, Mo(VI), Ca, W(VI), Mn(II), Pb, Cd, Hg(II) and Ag (adsorbed at pH 11.2), could be tolerated even at the 1000-mg level. Pd(II) can be removed by prior extraction into molten naphthalene at pH 1.0. The following metal ions (amounts, mg, in parentheses) could be tolerated: Al (150), V(V) (100), Zn (50), Cr(VI) (20), Pt(VI) (15), Bi(III) (2), Fe(III) (1.5) and Co (0.1). Cu(II) (4 mg) could be completely masked with 5 ml of 5% thiourea. In analysis of steels, if the iron concentration is higher than the tolerance limit, it can be lowered by extraction from 6*M* hydrochloric acid medium with methyl isobutyl ketone or diethyl ether. Generally, metal ions such as Fe(III), Co and Cu(II), which form complexes, interfere with the determination, and hence they must be eliminated with masking agents or by prior extraction with organic solvents.

*Cobalt was removed from $8M$ HCl medium by extraction with three 30-ml portions of 5% tri-n-octylamine solution in xylene.[9]

Analysis of alloys

This method has been successfully applied to the analysis of nickel-containing alloys and metal salts. The results (Table 1) are in reasonable agreement with the certified values or those obtained by direct AAS determination. The method is not really suitable for alloys containing $> \sim 2\%$ nickel, on account of the comparatively high relative standard deviation.

COMPARISON OF TWO DIGESTION METHODS USED IN THE DETERMINATION OF SELENIUM IN MARINE BIOLOGICAL TISSUES BY GAS CHROMATOGRAPHY WITH ELECTRON-CAPTURE DETECTION

K. W. Michael Siu* and Shier S. Berman

Division of Chemistry, National Research Council of Canada, Montreal Road, Ottawa, Ontario, Canada

Summary—The performance of two decomposition procedures, with (*a*) nitric/perchloric/sulphuric acid and (*b*) nitric acid/magnesium nitrate, in the determination of selenium in marine biological tissues by gas chromatography with electron-capture detection was compared. Both methods were found satisfactory and performed equally well for sample dissolution, but method (*b*) was judged to be more convenient.

Selenium is an essential element. During the course of analyses in establishing a reliable value for it in the newly issued lobster hepatopancreas reference material for trace metals, TORT-1, it was felt necessary to compare some existing digestion methods and evaluate their relative merits for use in conjunction with gas-chromatographic determination. Two decomposition procedures, namely with nitric/perchloric/sulphuric acid and nitric acid/magnesium nitrate, were chosen because of their popularity and success with other types of materials.

Acid digestion is generally used for decomposing biological materials for selenium determination. Within this category, nitric/perchloric acid digestion with or without sulphuric acid is most widely employed.[1–4] It has been used in conjunction with a variety of instrumental methods, including gas chromatography with electron-capture detection.[2] Nitric acid/magnesium nitrate digestion has also been used with the gas-chromatographic determination of selenium.[5,6] It was the preferred decomposition method in one study and reportedly yielded cleaner chromatograms.[5]

Gas chromatography with electron-capture detection has been used to determine selenium in a variety of materials, after its reaction with *o*-phenylenediamine and conversion into piazselenol.[7] In this study, the commercially available 4-nitro-*o*-phenylenediamine was selected as reagent. It reacts with selenium(IV) to form 5-nitropiazselenol. This reaction is highly selective and suffers from few, if any, known interferences.

TORT-1 is issued by the National Research Council of Canada's Marine Analytical Chemistry Standards Program. The material was prepared from commercial edible tomalley paste, considered a gas-tronomic delight by many. The sample was homogenized, spray-dried, extracted with acetone, vacuum-dried, sieved, blended, bottled, and sterilized with gamma-radiation. The metal levels in tomalley are relatively high, and even more so in TORT-1 because of the concentration factors inherent in the processing steps.

EXPERIMENTAL

Instrumentation

A Varian 6000 gas chromatograph equipped with a constant-current electron-capture detector was used. The column was a 12-m fused silica capillary coated with SE-30. Splitless injection was used. Nitrogen (oxygen content < 10 ppm), further purified by passage through molecular sieve 5A and a heated oxygen-scavenger unit (Supelco), was used as carrier and make-up gas, at flow-rates of about 1 and 60 ml/min respectively. The injector temperature was held at 220°. In the temperature programme, the column was held at 120° for 2 min, and then heated at 20°/min to 200°, and held at that temperature for 11 min. The detector temperature was 300°.

Reagents

All reagents were of analytical grade. To minimize contamination, acids were further purified by sub-boiling distillation.[8] Demineralized distilled water (DDW) was produced by passing distilled water through a demineralizer consisting of a charcoal cartridge and two mixed-bed demineralizers (Cole-Palmer). Toluene was "distilled-in-glass" grade (Caledon).

A 1000-ppm selenium(IV) stock solution was prepared by dissolving sodium selenite (B.D.H.) in 1*M* hydrochloric acid, and standardized gravimetrically by precipitation of selenium with sulphur dioxide.[9] Similarly, a 1000-ppm selenium(VI) stock solution in 2*M* nitric acid was prepared from sodium selenate (B.D.H.). Working solutions were made by dilution of the Se(IV) and Se(VI) stock solutions with 1*M* hydrochloric acid and 2*M* nitric acid, respectively.

A 1% 4-nitro-*o*-phenylenediamine hydrochloride solution in 1*M* hydrochloric acid was prepared as previously described.[10]

Sample digestions

In addition to TORT-1, another reference material, NBS-1566 oyster tissue, was used. They were both vacuum-dried before weighing, as recommended.

---

*Author for correspondence.
NRCC 23549.

Nitric/perchloric/sulphuric acid digestion. Approximately 1 g of sample was weighed and placed in a 100-ml glass beaker, 25 ml of concentrated nitric acid were added and the beaker was covered. The mixture was allowed to stand for at least 2 hr. Then 5 ml each of concentrated perchloric and sulphuric acids were added, plus a few glass spheres to minimize bumping. The beaker was placed on a hot-plate and gradually heated until the nitric acid boiled gently. When the volume was reduced to about 25 ml, the temperature was raised to drive off nitric acid rapidly. The beaker was removed from the hot-plate when the volume had been reduced to 15 ml, and allowed to cool for 1 min. Then 3 ml of concentrated nitric acid were added. The digest was heated until dense white fumes of perchloric acid appeared and its volume was reduced to 5 ml. The solution was cooled and 5 ml of 10M hydrochloric acid were added. It was then heated to 95° for 15 min, cooled, transferred into a 50-ml standard flask and diluted to the mark with DDW.

Nitric acid/magnesium nitrate digestion. Ten ml of concentrated nitric acid and 4 g of magnesium nitrate hexahydrate were added to a 1-g sample in a 100-ml beaker. The mixture was allowed to stand at room temperature for at least 2 hr. The beaker was then put on a hot-plate and heated at 95° for 3 hr, after which the contents were slowly evaporated to dryness overnight. The next morning, the hot-plate was kept at its maximum temperature until volatilization of nitrogen dioxide ceased. The beaker was then placed in a cold muffle furnace, heated up to 500° and held at that temperature for 30 min. The beaker was cooled, 5 ml of 10M hydrochloric acid were added and the solution was heated at 95° for 15 min. The digest was allowed to cool and transferred into a 50-ml standard flask. Finally 5 ml of 40% urea solution were added, followed by dilution to volume with DDW.

Analytical procedure

Determinations were done by the method of standard additions. A 0.1-ml portion of the digest solution and the appropriate amount of Se(IV) spike were allowed to stand with 0.1 ml of 1% 4-nitro-o-phenylenediamine hydrochloride solution in a 5-ml "Reacti-vial" (Chromatographic Specialities Ltd.) for 2 hr, then 1 ml of toluene was added. The vial was shaken vigorously for 5 min to extract the 5-nitropiazselenol into the organic phase, and 1 μl of the toluene layer was injected into the chromatograph. The injection was repeated at least three times for each extract, and the average taken.

RESULTS AND DISCUSSION

Figure 1 shows chromatograms resulting from both digestion methods. They were all reasonably clean, with the piazselenol peak the most prominent; the extra peaks were due to excess of 4-nitro-o-phenylenediamine, its reaction side-products, and impurities in the toluene. In this respect both procedures were equally satisfactory. This apparently contradicts an earlier report which judged the nitric acid/magnesium nitrate digestion the more favourable.[5] However, that comparison was made with a nitric acid and a nitric/perchloric/sulphuric acid/hydrogen peroxide digestion, and the experimental conditions were different from ours.

In terms of convenience and ease of use, the nitric acid/magnesium nitrate digestion is preferred. It requires minimal attention, and because the digest is taken to dryness, constant volume checks are not necessary, in contrast to the nitric/perchloric/sulphuric acid decomposition, where the digest vol-
Fig. 1. Chromatograms of piazselenol prepared from acid digest of TORT-1: (*a*) nitric/perchloric/sulphuric acid digestion; (*b*) nitric acid/magnesium nitrate digestion; (*c*) blank for (*b*).

ume at each stage is moderately critical (control to $\pm 20\%$ is needed). Further, unattended overnight heating reduces the man-hours of labour.

In both decomposition procedures, the temperature and its rate of change were controlled to minimize charring, which usually results in low selenium recoveries.[3,5,7] Heating with 10M hydrochloric acid was used to convert Se(VI) into Se(IV) [necessary because only Se(IV) reacts to form the piazselenol].

Both digestion methods were judged satisfactory for selenium determination by gas chromatography. Table 1 shows both decomposition procedures gave

Table 1. Selenium concentrations in marine biological tissues

		Se concentration, $\mu g/g$	
Sample	Digestion method*	Found†	Certified values§
TORT-1	a	$7.3_8 \pm 0.4_5$	6.88 ± 0.47
	b	$7.0_7 \pm 0.4_8$	
NBS-1566	a	$2.1_8 \pm 0.2_5$	2.1 ± 0.5
	b	$2.2_3 \pm 0.2_6$	

*a = nitric/perchloric/sulphuric acid digestion; b = nitric acid/magnesium nitrate digestion.

†Mean ± standard deviation ($n = 5$).

§Mean ± 95% confidence limit. Certified values were derived from results of at least two independent analytical techniques: for TORT-1, atomic-absorption spectrometry, isotope-dilution spark-source mass spectrometry and gas chromatography; for NBS-1566, atomic-absorption spectrometry, isotope-dilution spark-source mass spectrometry and neutron-activation analysis.

results in good agreement with the certified values, with no significant difference between them.

A limited recovery study with $10\,\mu g$ of Se(IV) or Se(VI) added to 1 g of biological material before the digestion showed quantitative recovery of both [$98 \pm 5\%$ for Se(IV) and $102 \pm 6\%$ for Se(VI), 8 replicates for each]. No organoselenium compounds were tested for recovery, but the results in Table 1 suggest that decomposition of such compounds would be complete.

The gas chromatographic determination was simple but sensitive, the detection limit, calculated as twice the reagent blank, being 0.5 pg of injected Se, or 250 ng per g of sample. The latter figure could easily be lowered by increasing the volume ratio of digest to toluene in the extraction. The precision for 15 pg of injected Se was better than 7%; the main source of variation was drift in the detector sensitivity.

Both methods were found to decompose the samples satisfactorily (giving accurate results and quan-titative recoveries) and yield clean chromatograms. Convenience is the only criterion in which they differ, the nitric acid/magnesium nitrate digestion being superior.

A SENSITIVE SPECTROPHOTOMETRIC METHOD FOR THE DETERMINATION OF HYDROXYLAMINE BY USE OF p-NITROANILINE AND N-(1-NAPHTHYL)-ETHYLENEDIAMINE

Pratima Verma and V. K. Gupta*
Department of Chemistry, Ravishankar University, Raipur, 492010 India

Summary—A sensitive method for the spectrophotometric determination of hydroxylamine is described, based on known diazotization and coupling reactions. Hydroxylamine is oxidized by iodine in acetic acid medium to nitrite which then diazotizes p-nitroaniline to form a diazonium salt which is later coupled with N-(1-naphthyl)ethylenediamine to give a purple dye which has an absorption maximum at 545 nm, with a molar absorptivity of 6.6×10^4 $l.mole^{-1}.cm^{-1}$. Beer's law is obeyed over the hydroxylamine concentration range 0–8 $\mu g/25$ ml (0.0–0.32 ppm) in the final solution.

The determination of hydroxylamine is important in studies of biological processes and for industrial purposes. It has been detected in bacterial media and in the tissue of a number of organisms. It is produced during the reduction of nitrites.[1] Hydroxylamine is often found in biological materials in combined forms, *e.g.*, as hydroxamic acids or oximes.[2] The toxicity of hydroxylamine and its derivatives has been described.[3]

Earlier methods for the spectrophotometric determination of hydroxylamine were based either on the Griess–Ilosvay reaction,[4,5] after oxidation to nitrite[6] or on direct reaction with hydroxylamine.[7] Other spectrophotometric methods reported[8–11] are less sensitive and suffer from common interferences. Titrimetric methods[12–14] reported are generally based on oxidation of hydroxylamine. Electrochemical methods[15–17] utilize the redox properties of hydroxylamine. A coulometric method[15] is based on reduction of Fe^{3+} to Fe^{2+} by hydroxylamine. There is a potentiometric titration[16] of Fehling's solution with hydroxylamine, and also a chronopotentiometric method.[17]

The present communication describes a sensitive method based on combination of two well-tried reactions: oxidation of hydroxylamine to nitrite by iodine in acetic acid medium,[6] and nitrite determination with p-nitroaniline (PNA) and N-(1-naphthyl)ethylenediamine dihydrochloride (NEDA).[18] The purple product has an absorption maxima at 545 nm. The reaction is very sensitive and Beer's law is obeyed over the hydroxylamine range 0–8 $\mu g/25$ ml of the final solution (0.0–0.32 ppm). The molar absorptivity is $(6.60 \pm 0.01) \times 10^4$ $l.mole^{-1}.cm^{-1}$.

EXPERIMENTAL

Reagents

Standard hydroxylamine solution, 4 µg/ml. Prepared by appropriate dilution of stock solution.

Sodium acetate solution, 2.5%.

p-*Nitroaniline solution, 0.05%.*

Iodine reagent. Iodine (1.3 g) dissolved in 100 ml of glacial acetic acid.

Sodium thiosulphate solution, 2.5%.

N-(*1-Naphthyl*) *ethylenediaminedihydrochloride (NEDA) solution, 0.2%.*

All reagents used were of anlytical grade, and doubly distilled water was used throughout.

Procedure for hydroxylamine

To an aliquot of sample solution containing 0–8 µg of hydroxylamine, in a 25-ml standard flask, add 1 ml of sodium acetate solution, 1 ml of p-nitroaniline solution and 0.5 ml of iodine reagent, shake and allow to stand for 2–5 min. Remove the residual iodine by dropwise addition of sodium thiosulphate solution (avoid excess). Add 2 ml of N-(1-naphthyl)ethylenediamine solution and let stand for 10 min for complete development of the purple colour, then make up to the mark with 25% v/v acetic acid solution. Measure the absorbance at 545 nm against a reagent blank.

Procedure for benzohydroxamic acid

To 1 ml of sample solution containing 10–80 µg of benzohydroxamic acid in a 25-ml standard flask add 0.5 ml of sodium acetate solution, 1 ml of p-nitroaniline solution, and 0.2 ml of iodine solution, shake and let stand for 2–5 min. Then add thiosulphate solution dropwise and continue as for hydroxylamine.

RESULTS AND DISCUSSION

The absorption spectrum of the product shows λ_{max} at 545 nm. The absorbance was maximal and independent of pH in the range 2.2–3.0. This pH range is obtained by adding 0.5 ml of the iodine reagent and subsequently diluting with 25% acetic acid solution. (The colour is not stable if water is used for the final dilution.)

Table 1. Effect of foreign species on determination of 0.16 ppm of hydroxylamine

Tolerance limits*, ppm	
Phenylhydrazine, 2000	Hydrazine, 2000
2,4-Dinitrophenylhydrazine, 2250	Hydrocarbons, 5000
Alcohols, 2000	Aldehydes, 1500
Cd^{2+}, 2000	Pb^{2+}, 2000
Zn^{2+}, 2500	Hg^{2+}, 1500
Cu^{2+}, 600	Fe^{3+}, 1000
Ca^{2+}, 600	Mg^{2+}, 650

*Concentration which causes a 2% error.

The oxidation of hydroxylamine to nitrite is fast, and complete in 2 min. The excess of iodine should be removed within the next 5 min, or lower absorbances will be obtained. Sodium thiosulphate solution is added dropwise to remove the iodine, but excess must be avoided or low absorbances will be obtained. However this effect can be prevented by addition of bromobenzene solution, as reported by Lee and Roughan.[19]

The time required for full colour development at pH 2.2–3.0 is 10 min after addition of the NEDA solution. The best results are obtained if the reaction is done at 10–30°. Higher temperatures reduce the rate of the reaction.

The colour system was found to obey Beer's law over the hydroxylamine concentration range 0–8 μg/25 ml (0.0–0.32 ppm) in the final solution. The reproducibility of the method was determined by 10 replicate determinations of 4 μg of hydroxylamine over a period of 10 days. The mean absorbance was 0.400, standard deviation 0.0037. The molar absorptivity was found to be 6.60×10^4 l.mole^{-1}.cm^{-1}.

Effect of foreign species

Hydroxylamine (4 μg) was determined in the presence of known amounts of various species likely to accompany it. Excess of hydrazine, 2,4-dinitrohydrazine and phenylhydrazine did not interfere provided sufficient excess of iodine was used in the oxidation. Several common organic species and several metal ions also did not interfere. The tolerance limits are shown in Table 1. Nitrite interfered

but could be removed by adding 1 ml of 3% sulphamic acid solution before the iodine oxidation.

Application to determination of benzohydroxamic acid

Primary hydroxamic acids are quantitatively oxidized to nitrite by the iodine reagent. Benzohydroxamic acid is directly oxidized to nitrite by iodine at pH 5.0–6.5. At pH 2.2–3.0 no colour is formed. Benzohydroxamic acid is oxidized at pH $\sim$5.5, then estimated by following the procedure described earlier. Beer's law is obeyed in the range 0.0–80.0 μg of benzohydroxamic acid/25 ml of solution. The molar absorptivity (referred to benzohydroxamic acid) is 2.50×10^4 l.mole^{-1}.cm^{-1}. For 40 μg/25 ml concentration the mean absorbance is 0.281, standard deviation 0.003.

SIMULTANEOUS DETERMINATION OF DEXTROPROPOXYPHENE NAPSYLATE, CAFFEINE, ASPIRIN AND SALICYLIC ACID IN PHARMACEUTICAL PREPARATIONS BY REVERSED-PHASE HPLC

I. M. Jalal
Al-Hikma Pharmaceuticals, P.O. Box 182400, Amman, Jordan

S. I. Sa'sa'
Yarmouk University, Irbid, Jordan

Summary—The official compendial method for the determination of dextropropoxyphene napsylate, caffeine, aspirin and salicylic acid involves a lengthy extraction by gas chromatography and spectrophotometry. The analytical scheme reported here provides a fast, sensitive, and stability-indicating reversed-phase HPLC assay for all these components concurrently. The total elution time is 10 min. The accuracy of the method has been tested on commercial products. The method can easily detect low levels of salicylic acid.

Dextropropoxyphene napsylate (DPN) is a widely prescribed analgesic for mild to moderate pain, either alone or in combination with caffeine, aspirin or acetaminophen. Several methods for the detection of DPN have been reported. The colorimetric[1,2] and TLC[3] methods lack the sensitivity necessary for determination of low concentrations. In biological fluids, DPN has been determined by gas chromatography (GC),[4–8] but there have been conflicting opinions about the stability of DPN under various GC conditions. The amounts of decomposition have been found to be dependent on column temperature, sample size and flow-rate.[9] Numerous methods have been reported for the determination of aspirin, including colorimetry,[10] fluorimetry[11] and GC.[12,13] Aspirin in combination with caffeine, phenacetin or acetaminophen has been determined by HPLC.[14,15] Determination of DPN and aspirin by the National Formulary (13th Ed.) method (NF XIII) involves conventional extraction of the two drugs. The concentration of each is then determined by infrared spectrometry. DPN and aspirin have also been determined by ultraviolet spectrophotometry after separation by partition chromatography.[16] A mixture of propoxyphene hydrochloride, aspirin, caffeine and phenacetin has been analysed similarly[17] but the method is slow.

The current official method[18] for determining DPN, caffeine, aspirin and salicylic acid in a mixture involves separation of salicylic acid by column partition chromatography followed by ultraviolet spectrophotometry, separation by gas chromatography with nitrogen as carrier gas for determination of

DPN and caffeine, and colorimetry for aspirin. This method, while specific, is lengthy and requires three samples. The analytical scheme described in this paper provides a fast, sensitive and reliable reversed-phase HPLC method for simultaneous separation of the four compounds.

EXPERIMENTAL

Reagents

Glacial acetic acid, salicylic acid (B.D.H) and sodium pentane sulphonate (Fluka) were reagent grade. HPLC-grade methanol (Fluka) and distilled demineralized water were used. Standard DPN (Siegfried, Basle), caffeine (Boehringer, Ingelheim, West Germany), and aspirin (Graesser Salicylates, Deeside, England), were used as received; their purities were certified as 99.7, 99.9 and 99.85%, respectively. The Varian 5000 LC HPLC system, equipped with a Valco manual loop injector (Valco Instruments Co., Houston, Texas) was connected to a Varian UV-50 variable wavelength detector (λ 229 nm) and Varian 9176 chart recorder. A 300 × 4 mm reversed-phase octadecylsilane column (Varian Micropak MCH-10) was used.

Chromatographic conditions

The mobile phase was prepared by dissolving 0.1922 g of sodium pentane sulphonate in 700 ml of water and 300 ml of methanol and adjusted to pH 3.9 with glacial acetic acid. It was always filtered through a Gelman 0.45-μm filter and degassed by vacuum before use. The flow-rate was 2.0 ml/min and pressure about 2000 psi. The detector sensitivity was 0.1 absorbance full-scale for DPN, caffeine and aspirin and 0.02 for salicylic acid. The chart speed was 0.5 cm/min.

Standard preparation

A four-component standard methanolic solution was prepared containing 50 μg of DPN, 30 μg of caffeine, 375 μg of aspirin and 3.75 μg of salicylic acid per ml. The solution was filtered through a 0.45- μm filter before use.

Sample preparation

Twenty capsules were emptied and their contents weighed. The average content per capsule was weighed out and dissolved in 100 ml of methanol. The solution was filtered through a 0.45-μm filter, and 5 ml of the filtrate were diluted to 50 ml with methanol.

Assay method

Equal volumes (10 μl) and approximately equal concentrations of freshly prepared standard and sample preparations were injected into the HPLC and chromatographed under the conditions described above. The peak heights were measured for each component in both samples and standards, and the content in the sample was calculated by simple proportion. The quantity of each component injected was always within the linearity range.

RESULTS AND DISCUSSION

Calibration standard solutions of DPN, caffeine, aspirin and salicylic acid were prepared and the following quantities of each compound were injected: 0.2, 0.4, 0.6, 0.8, 1, 2, 3, 4 and 5 μg. A plot of peak height *vs.* amount injected was linear up to 3 μg for DPN, and up to 5 μg for the other three, with correlation coefficients of 0.999 or better.

Each standard was doped with pharmaceutical excipients and subjected to HPLC analysis. In all cases, satisfactory recoveries and reproducibility of peak heights were obtained (Table 1). No interference due to excipients was detected in the chromatograms produced.

The specificity of the method is shown by the complete separation of DPN, salicylic acid, aspirin and caffeine, with retention times of 2.5, 4.3, 5.5 and 9.4 min, respectively (Fig. 1).

The detection limit was determined by diluting the standard solution with methanol and injecting 1 μl of each solution into the column. The amounts that produced a signal equal to twice the noise were 4.8, 30, 6, and 7 ng, for DPN, caffeine, aspirin and salicylic acid, respectively.

The reproducibility was checked by analysing a commercial product on four separate days. The results listed in Table 2 show reproducibility with no statistical difference at the 5% level, and the accuracy is shown by the agreement between the amounts nominally present ("label claim") and those found.

Stability studies

To determine the stability-indicating capability of the procedure, samples of caffeine and aspirin, and also samples of a commercial product, were stored in tubes at 50° in a humid atmosphere. A sample was
Fig. 1. (a) A typical chromatogram for a 10 μl injection of a synthetic mixture containing 0.50, 0.01, 3.75, and 0.30 μg of DPN, salicylic acid (SA), aspirin (ASA) and caffeine, respectively. Full-scale deflection = 0.10 absorbance. (b) The same chromatogram with full-scale deflection = 0.02 absorbance. Chromatographic conditions as described in the text.

taken daily and assayed. It should be noted that DPN was not studied individually because it had been shown in an earlier study to be stable.[19]

The results in Table 3 show the stability of caffeine and the partial degradation of aspirin, with an increase in salicylic acid content after seven days. Moreover, the results in Table 4 show that when the commercial product is stored for the same period of time it yields essentially the same results. This clearly illustrates that the method is specific. In conclusion, the HPLC method described here is applicable to individual bulk drugs as well as commercial combina-

TITRIMETRIC MICRODETERMINATION OF SILVER, LEAD AND CADMIUM WITH THIOGLYCOLLIC ACID AND OF MERCURY(II) WITH 2-MERCAPTOPROPANOIC ACID

K. K. Tiwari and R. M. Verma*
Department of Post-Graduate Studies and Research in Chemistry, University of Jabalpur, Jabalpur
(M.P.), 482001, India

Summary—A simple and rapid titrimetric method is described for the microdetermination of Ag^+, Cd^{2+} and Pb^{2+}, based on their formation of mercaptides with a measured excess of 2-mercaptopropanoic acid, and similar determination of Hg^{2+} with thioglycollic acid. Univalent and bivalent metal ions release one and two thiol protons respectively, which along with the carboxyl protons of the thiol reagent are titrated with standard alkali. The difference from the blank titration gives the increase in acidity which is a function of the metal-ion concentration. The proposed procedure is applicable to samples containing 0.025–0.25 mmole of these ions, the average deviation being in the range 0.2–0.5%.

Silver and mercury(II) have been extensively used as reagents in the determination of mercaptans.[1] Organomercuric salts have generally been employed but some authors have recommended the use of mercuric chloride.[2,3] Though a number of titrimetric procedures are available for determining ionized mercuric salts,[4] these fail when applied to weakly ionized Hg(II) salts such as mercuric chloride. The latter is usually determined by titration with potassium iodide or by reduction to mercury(I) chloride, which can be collected and weighed,[5] or titrated with iodine[4] or potassium iodate.[6] It was, therefore, thought worthwhile to study the reaction of mercuric chloride with certain mercaptans with a view to developing a rapid and convenient titrimetric procedure for its determination. Our earlier work[7] on the determination of certain mercaptans was based on their treatment with an excess of mercuric chloride and titration of the acid liberated. Under these conditions the molar reacting ratio was 1:1. If the mercaptan is in excess, however, a 1:2 reacting ratio was observed:

$$Hg^{2+} + 2RSH \rightarrow (RS)_2Hg + 2H^+$$
This reaction has now been utilized in a simple and accurate method for determining mercuric chloride. A micro procedure has been evolved for determining mercury(II), and also silver, cadmium and lead. 2-Mercaptopropanoic acid is suitable for the mercury determination, but gives an insoluble mercaptide with silver, cadmium and lead, and this interferes

with detection of the end-point. Though thioglycollic acid also gives a precipitate with these three metals, the precipitate dissolves just before the equivalence point during the titration, and does not impair the phenolphthalein end-point. The dissolution of the precipitate can serve as a guide to the approach of the end-point. In the blank titration only the carboxyl proton is titrated, whereas for the samples the protons released from the thiol group and the carboxyl protons of the reagent are titrated. The difference in the volume of alkali used (ΔV ml, molarity M) corresponds to the metal concentration in the test solution:

$$\text{mg of metal ion} = \left(\frac{\text{atomic weight}}{\text{ionic charge}}\right) M \Delta V$$

EXPERIMENTAL

Reagents

All solutions were prepared with analytical-reagent grade chemicals and conductivity water.

2-Mercaptopropanoic acid. Standardized with potassium iodate solution,[8] and diluted to give 0.025, 0.020, 0.0125 and 0.01M solutions.

Thioglycollic acid. Standardized by titration with iondine solution[9] and diluted to give 0.05, 0.025, 0.0125 and 0.01M solutions.

Sodium hydroxide. Standardized with oxalic or preferably furoic acid solution; 0.05, 0.025 and 0.0125M solutions were prepared by dilution.

Phenolphthalein. A 1% solution in 1:1 v/v ethanol–water mixture.

Metal salt solutions. Silver nitrate and mercuric chloride solutions were prepared by dissolving a known weight of the salt and diluting to known volume with water. Solutions of lead nitrate and cadmium sulphate were standardized by titration with EDTA[6] and then suitably diluted.

Table 1. Determination of some metal salts with mercaptans

Compound	Amount of metal, mg		Average deviation, %	Relative standard deviation, %
	Taken	Recovered*		
Silver nitrate	26.97	27.02	0.2	0.2
	13.49	13.54	0.4	0.3
	6.74	6.77	0.5	0.3
Mercuric chloride	20.06	20.10	0.2	0.1
	10.03	10.06	0.3	0.2
	5.01	5.03	0.4	0.2
Cadmium sulphate	22.48	22.55	0.3	0.2
	11.24	11.27	0.3	0.2
	5.62	5.64	0.4	0.3
Lead nitrate	25.90	25.95	0.2	0.1
	10.36	10.40	0.4	0.2
	5.18	5.20	0.4	0.3

*Average of 6 determinations.

Procedure

Pipette 5 or 10 ml of metal salt solution containing 0.025–0.25 mmole of the substance and add about 100% excess of mercaptan solution (2-mercaptopropanoic acid for mercuric chloride and thioglycollic acid for silver, cadmium and lead salts). With mercuric chloride a precipitate appears initially but eventually dissolves when all the reagent has been added and the mixture is shaken. With silver, cadmium and lead salts, the dissolution of the mercaptide occurs just before the end-point.

Add 5–10 drops of phenolphthalein solution and titrate with standard sodium hydroxide solution. Run a blank with the same volume of mercaptan solution as that added to the sample. From the difference between the volumes of alkali needed for the blank and sample calculate the amount of metal: 1 ml of $0.02M$ sodium hydroxide $\equiv 2.006$ mg of mercury, 2.158 mg of silver, 1.124 mg of cadmium or 2.072 mg of lead.

RESULTS AND DISCUSSION

Silver nitrate, mercuric chloride, cadmium sulphate and lead nitrate were used for testing the proposed method at three concentration levels between 0.005 and $0.025M$. The results recorded in Table 1 are the averages of six determinations. The recovery studies showed that the average deviation is between 0.2 and 0.5% and the relative standard deviation between 0.1 and 0.3%.

Several gravimetric methods have been proposed for the determination of mercury(II) but the most suitable weighing form is the sulphide.[10] However, it is difficult to keep volatilization losses within reasonable limits.[4] Titrimetric methods for determining mercury(II) involve neutralization, precipitation or redox reactions. The Volhard titration with thiocyanate, using iron(III) as indicator,[11] has the disadvantage that the reaction is not quite stoichiometric,[12] and halides interfere. The EDTA titration can be done in presence of chloride and even small amounts of bromide, with Eriochrome Black T as indicator, at $pH \geqslant 10$. Because the mercury cannot be kept initially in solution at such high pH values without the aid of auxiliary complex-forming substances (which will interfere in the EDTA titration)[13] a back-

titration method is generally used. Most of these titrimetric procedures are applicable only to ionized mercury salts and cannot be used for determining mercuric chloride. Most of the redox methods involve reduction of mercury(II) to mercury(I), followed by oxidimetric titration of the latter, which is time-consuming.

The most extensively used methods for the determination of silver are precipitation as silver chloride or bromide, or the so-called[14] Volhard titration, which is satisfactory only at macro levels. Several organic reagents have been used for gravimetric determination of cadmium, and there are several procedures in which cadmium is precipitated by suitable reagents and the precipitate analysed titrimetrically. In most cases cadmium has to be separated from interfering elements before a titrimetric method is feasible. Only the EDTA complex is suitable for the direct titrimetric determination of cadmium, but there is extensive interference from other elements. However, a combination of pH control and masking reactions will eliminate most interferences.[15] The gravimetric determination of lead is based on its precipitation as sulphate, chromate, molybdate, iodate, salicylaldoximate *etc*. The chromate precipitate can be analysed iodometrically. The best titrimetric method is with EDTA.

The procedure proposed here is simple, rapid and accurate. No unusual reagent or indicators are required and the reaction conditions are not critical. It has been observed that addition of 100–300% excess of mercaptan solution or letting the mixture stand for 2–30 min before the titration does not affect the results. There will obviously be interference by the presence of any metals which react with mercaptans.

STUDIES ON THE APPLICATION OF Fe–Zr MIXED HYDROUS OXIDE MEMBRANES IN ION-SELECTIVE POTENTIOMETRY

S. K. Srivastava and C. K. Jain

Department of Chemistry. University of Roorkee, Roorkee-247667, India

Summary—A solid membrane electrode selective to chloride ions has been prepared from Fe–Zr mixed hydrous oxide (with iron as a major constituent) with polystyrene as binder. Although the response of the electrode is non-Nernstian it can be utilized to estimate chloride in the concentration range 10^{-4}–$10^{-1}M$. The potentials generated across the membrane are reproducible within ± 0.2 mV and the response time is a few seconds. The standard deviation of the potential measurements is 0.4 mV at the $0.1M$ level. The useful pH range is 4–7 and the electrode can also be used in partially non-aqueous systems. The electrode exhibits fairly good selectivity for chloride.

Hydrous oxides of zirconium, thorium, tin *etc.*, are known to possess anion- as well as cation-exchange properties, depending on the pH of the environment. These oxides can be used as ion-sensors when combined with an appropriate membrane and suitable support matrix,[1] because they have fixed ionic groups in their structure, ensuring selective ion-exchange reactions. Various ion-selective electrodes are available for the determination of chloride in milk,[2] boiler water,[3] gaseous mixtures,[4] water and industrial wastes,[5–10] but do not have high precision and accuracy at very low chloride levels, and are susceptible to interference by various ions.

We have been working on the sorption characteristics of some mixed oxide systems and have also investigated the electrochemical performance of membranes made with them. We have found that a mixed hydrous oxide of iron and zirconium (with iron as a major constituent) exhibits much greater capacity for anion uptake than either the pure iron or zirconium oxide. Polystyrene-based membranes made with this product also possess better anion-selectivity than those made with the individual oxides. Earlier, we described the use of a zirconium oxide membrane for estimation of molybdate,[11] and here we report the use of the mixed oxide membrane as an ion-selective electrode for chloride.

EXPERIMENTAL

All reagents were of analytical grade.

Preparation of mixed and doped oxides

Iron(III) chloride ($0.2M$) and zirconyl chloride ($0.2M$) solutions were mixed in 8:1 volume ratio, then $1.0M$ ammonia solution was added with constant stirring; the precipitate obtained was aged in the mother liquor for two days at room temperature, then filtered off, washed with water and dried at 80° for 24 hr.

A doped oxide was prepared by adding 50 ml of a solution containing 0.075 g of tin(II) chloride to 450 ml of the 8:1

mixed iron/zirconium solution, and precipitating *etc.* as just described.

Preparation of the ion-selective membrane

Unsupported membranes of the oxides could not be prepared, but membranes made with polystyrene as binder were found to be quite stable. They were obtained by thoroughly mixing 1.275 g of the oxide with 0.225 g of polystyrene and heating the mixture in a 2.5-cm diameter die at 120° under a pressure of 6500–7000 psi. By this method, membranes that were both mechanically and chemically stable were obtained and were checked under an electron microscope for deformities or cracks. Membranes thus obtained were equilibrated in $0.1M$ sodium chloride for 2–3 days, the solution being changed four or five times at intervals during this period. The minimum equilibration time was determined in a preliminary investigation, and it was observed that membranes equilibrated for shorter times did not give stable potentials.

Potential measurements

The electrode assembly used for potential measurements was the same as that reported earlier[12] and the reference solution was $0.1M$ sodium chloride. Ionic strength was adjusted by adding 5 ml of saturated potassium nitrate solution to 50 ml of test solution. All e.m.f. measurements were made at $25 \pm 0.1°$ with a Radiometer (model PHM64) millivoltmeter coupled with a Servoscribe recorder. Ceramic-junction calomel reference electrodes were used.

RESULTS AND DISCUSSION

The response of the electrode is relatively fast. The response time (static) was found to be 15 sec for dilute solutions ($10^{-3}M$) and a little more (20 sec) for concentrated solutions ($0.1M$), the potentials reaching a value constant within ± 0.2 mV, with no deviation for 30 min, after which a slow drift in potential occurred. Ten replicates at two concentration levels gave a standard deviation of 0.4 mV in the higher concentration range ($0.1M$) and 0.5 mV in the lower concentration range ($10^{-3}M$).

The potentials obtained with mixed and doped

Table 1. Selectivity coefficient values for Fe–Zr and Sn(II)-doped Fe–Zr mixed hydrous oxide membrane electrodes at $10^{-3}M$ concentration of interfering ion, determined by the fixed interference method

Ion	$k_{A,B}^{pot}$	
	Mixed oxide membrane	Doped oxide membrane
Br^-	1.75×10^{-2}	1.34×10^{-2}
I^-	1.64×10^{-2}	1.29×10^{-2}
NO_3^-	1.05×10^{-2}	1.01×10^{-2}
ClO_4^-	1.07×10^{-2}	1.02×10^{-2}
SCN^-	1.14×10^{-2}	1.08×10^{-2}
$S_2O_4^{2-}$	1.29×10^{-3}	1.12×10^{-3}
$C_2O_4^{2-}$	6.44×10^{-4}	6.23×10^{-4}
SO_4^{2-}	8.5×10^{-4}	8.25×10^{-4}
WO_4^{2-}	1.13×10^{-3}	1.02×10^{-3}
MoO_4^{2-}	1.16×10^{-3}	1.08×10^{-3}
PO_4^{3-}	9.79×10^{-4}	9.42×10^{-4}
AsO_4^{3-}	4.36×10^{-4}	4.12×10^{-4}
$Fe(CN)_6^{3-}$	7.65×10^{-4}	7.43×10^{-4}
$Fe(CN)_6^{4-}$	3.36×10^{-5}	3.18×10^{-5}

Fig. 1. Potential $vs.$ $-\log[Cl^-]$ with the mixed oxide membrane (a), and doped oxide membrane (b).
Fig. 2. Variation of membrane potential with pH.

oxide membranes in contact with chloride ions are shown in Fig. 1. In both cases the potential response is linear in the range 10^{-4}–$10^{-1}M$ chloride, with a non-Nernstian slope of 29.5 mV/decade. Coetzee and Basson have reported an even lower response for a caesium-electrode based on caesium phosphomolybdate.[13]

The effect of pH was investigated at two chloride concentrations (Fig. 2). The useful pH range was found to be 4–7. Below pH 4 hydrogen ions interfere and above pH 7 hydroxide ions interfere.

The membrane electrodes can also be applied to the determination of chloride concentration in an aqueous medium containing up to 25% v/v ethanol, methanol or acetone, the response being the same as in purely aqueous medium. The stability of response decreases at higher levels of the non-aqueous component and there is a drift in potential.

The performance of the electrode in the presence of other ions has been assessed and the selectivity coefficients determined by the fixed interference[14] method (Table 1). The selectivity is fairly good.

The effect of cations was also examined. The potential values for chloride were independent of the presence of various cations such as Na^+, K^+, Li^+, Ca^{2+}, Ba^{2+}, Sr^{2+}, Mg^{2+}, Zn^{2+}, Al^{3+} at concentrations equivalent to that of the chloride, but Ag^+, Hg^{2+} and Pb^{2+} interfere at levels at which they will decrease the

chloride concentration by precipitation or complex formation.

The electrode system is also tolerant of the presence of low concentrations $(10^{-4}M)$ of cationic surfactants (cetyltrimethylammonium bromide or cetylpyridinium chloride). Proteins (albumin, gelatin), if present in traces $(10^{-5}$–$10^{-6}M)$ also do not cause any disturbance but higher levels $(10^{-3}M)$ of proteins poison the membrane surface. Anionic surfactants (sodium dodecyl sulphate) cause significant interference, but if the membrane is preconditioned by soaking for 4 hr in a solution of the anionic surfactant, this effect disappears (Table 2).

The membrane electrode can be used in the temperature range 20–40° without correction to the potential. The electrode can be used for 4 months

Table 2. Potentials for sodium chloride and SDS $(10^{-4}M)$ mixtures

[Cl⁻], M	Potential from calibration plot, mV	Potential when SDS is also present, mV	
		Original membrane	Membrane treated with SDS
10^{-2}	32.9	39.8	33.0
10^{-3}	59.0	67.1	59.1
10^{-4}	85.0	97.6	85.2

without showing any drift in potential, but the linear range and slope decrease slowly after continuous use for about 6 months. If contamination occurs, it can be removed by equilibrating the membrane with $0.1M$ sodium chloride for 2–3 days. If this treatment fails, it is advisable to discard the electrode and prepare a new one.

DUAL-WAVELENGTH SPECTROPHOTOMETRIC DETERMINATION OF TRACE SULPHIDE IN DOMESTIC WATER THROUGH ITS LIGAND-EXCHANGE REACTION WITH SILVER–CADION 2B–TRITON X-100

Wei Fu-sheng, Teng En-jiang and Rui Kui-sheng
China National Environmental Monitoring Centre, Beijing, China

Summary—Trace amounts of S^{2-} can be determined by means of the exchange reaction with the Ag^+–Cadion 2B complex in presence of Triton X-100 and $Na_2B_4O_7$ solution, by dual-wavelength spectrophotometry. Beer's law is obeyed for the sulphide range 0–2.0 μg/25 ml. The apparent molar absorptivity is 2.65×10^5 1.mole^{-1}.cm^{-1}. The effect of diverse ions in the presence of EDTA has been studied. The interferences produced by some anions in water samples can be eliminated by precipitation with zinc acetate.

In the presence of Triton X-100 and sodium tetra-borate solution (pH 9.2), Ag^+ forms a purplish red complex with Cadion 2B which has been used for determination of silver and cyanide in water.[1,2] In those experiments we noticed that sulphide can discharge the purplish red of the Ag^+-Cadion 2B complex. This paper reports the exchange reaction of S^{2-} with the Ag^+–Cadion 2B complex and the optimum conditions for the determination of trace amounts of sulphide in water. By the dual-wavelength method the apparent molar absorptivity for sulphide is 2.65×10^5 1.mole^{-1}.cm^{-1}. The method is more sensitive than the standard Methylene Blue method[3] and the other indirect spectrophotometric methods for the determination of sulphide with Ag^+–phen–BPR,[4,5] Cu^{2+}–DDTC,[6] Cu^{2+}–STTA,[7] Cu^{2+}–(2′-amino-3′-hydroxypyridyl-4′-azo)-benzene-4-sulphonic acid (AHD-4S),[8] Cu^{2+}–oxine,[9] Hg^{2+}–chloranilic acid,[10] Hg^{2+}–DPC,[11] Hg^{2+}–AHD-4S,[12] Fe^{2+}–bathophen.[13] The accuracy and precision of this method are quite good.

EXPERIMENTAL

Reagents

Standard silver solution, 1.000 mg/ml. Dissolve 0.1578 g of analytical-reagent grade silver nitrate in distilled water and dilute to 100 ml.

Standard sulphide solution, 1.0 mg/ml. Use $Na_2S.9H_2O$ of analytical-reagent grade, and standardize it.[3] Before use dilute it with cooled boiled water to give a 1.00-μg/ml working standard.

Cadion 2B solution, 0.04%, in ethanol.

Triton X-100 solution, 5%, in distilled water.

Sodium tetraborate solution, 5%, in distilled water.

Coloured complex solution. To a 200-ml standard flask containing 400 μg of Ag^+, add 40 ml of the sodium tetraborate solution, 20 ml of the Triton X-100 solution and 30 ml of the Cadion 2B solution, dilute to volume with distilled water and mix well.

General procedure

To a 25-ml standard flask add a known volume of sample containing less than 2.0 μg of sulphide and then 10.0 ml of the coloured complex solution, dilute to volume with distilled water, and mix well. After 10 min, measure the absorbance at 446 nm for the sample and 556 nm for the reference (1-cm cells) with a dual-wavelength double-beam recording spectrophotometer (*e.g.*, a Shimadzu model UV 3000).

Procedure for determination of the sulphide in domestic sewage

Pipette an aliquot of water sample containing less than 2.0 μg of sulphide into a beaker, dilute to 25 ml with water, then add 1 ml of 1% zinc acetate solution and 1.25 ml of 0.1M sodium hydroxide and mix well. Allow the precipitated ZnS and Zn(OH)$_2$ to settle out, and then decant the supernatant liquid. Wash the precipitate with sufficient distilled water and separate again. Add 1.5 ml of 0.05M EDTA, and mix well. After 3 min, add 10.0 ml of the coloured complex solution and dilute to 25 ml with distilled water. Measure the absorbance according to the procedure above.

RESULTS AND DISCUSSION

The principle of the method and selection of wavelength

The absorption spectra of Cadion 2B, and of Ag^+-Cadion 2B complex alone and in the presence of sulphide at pH 9.2 in borax buffer solution, are shown in Fig. 1. The absorbance of the Ag^+–Cadion 2B system at 556 nm is decreased by the presence of sulphide and that at 446 nm is increased. The sensitivity for sulphide will be increased by measuring the difference in absorbance at these wavelengths by dual-wavelength spectrophotometry.

Experiments showed that the best linearity for the calibration graph was obtained by taking 446 nm as the "sample" wavelength and 556 nm as the "reference" wavelength. The apparent molar absorptivity for sulphide is 2.65×10^5 1.mole^{-1}.cm^{-1}.
Fig. 1. Absorption spectra: 1, $1.6 \times 10^{-5}M$ Cadion 2B; 2, 10.0 ml of the coloured soln. + 2.0 μg of S^{2-}; 3, 10.0 ml of the coloured soln. + 1.0 μg of S^{2-}; 4, 10.0 ml of the coloured soln. (water as reference).
Fig. 2. The molar ratio method: $[Ag^+] = 7.4 \times 10^{-6}M$.

Figure 2 shows the reacting molar ratio of sulphide to silver in this system is 1:2.

The apparent molar absorptivity of the Ag^+–Cadion 2B complex is 1.41×10^5 $1.mole^{-1}.cm^{-1}$ by the dual-wavelength method, approximately half that for the sulphide.

The basis of the method is obviously the ligand exchange reaction

$$2Ag^+(\text{Cadion 2B})_4^* + S^{2-} \longrightarrow Ag_2S + 8 \text{ Cadion 2B}$$

<div align="center">purplish red   yellow</div>
Effect of the amount of Ag⁺-Cadion 2B coloured complex

It does not matter whether the sulphide is added before or after formation of the silver–Cadion 2B complex. To simplify operations and reduce error, use of the coloured complex solution was selected. The effect of the amount of coloured complex solution used is given in Fig. 3. Beer's law is obeyed in

*See Reference 1 for the molar ratio of silver to Cadion 2B.
Fig. 3. Effect of the amount of the coloured complex solution: 1, 7.0 ml; 2, 10.0 ml; 3, 13.0 ml.

the sulphide range 0–80 ng/ml for 10.0 ml of the coloured complex solution, and the only effect of adding more or less reagent is to shift the calibration graph along the absorbance axis.

Effect of other ions and elimination of interferences

All the anions that react with Ag^+ to form stable compounds would interfere and so would all metal ions that form coloured complexes with Cadion 2B or hydrolyse under the conditions used, so the effects produced by some ions generally present in water samples, on determination of 1.0 μg of sulphide in the presence of EDTA, were examined. The following ions [in the amounts (μg) given in parentheses] do not interfere: PO_4^{3-}(1000), SO_4^{2-}(1000), NO_3^-(1000), Cu^{2+}(100), Fe^{2+}(50), Pb^{2+}(25), Ni^{2+}(25), Cd^{2+}(25), Al^{3+}(25), Cr^{3+}(25), Cl^-(10), Br^-(10). Cyanide and iodide cannot be tolerated at all.

To separate sulphide from large amounts of Cl^-, and from SO_3^{2-}, $S_2O_3^{2-}$, I^-, CN^-, which may appear in some water samples, it is precipitated with zinc acetate. The recovery is between 95 and 104% (shown by adding standard sulphide solution to distilled water and tap water, see Table 1).

Table 1. Recovery obtained by adding standard sulphide solution

No.	System	Added, μg	Found, μg
1	25 ml of	0.50	0.50
2	distilled	1.00	0.99
3	water	2.00	1.91
4	25 ml of	2.00	1.96
5	tap water	2.00	2.08

Table 2. Analysis of water samples

No.	Source	Concentration of S^{2-}, mg/l.	
		Present method	Methylene Blue method
1	Domestic	0.009	Undetected
2	sewage	0.018	0.017
3		0.084	0.088
4	Waste water	0.55	0.54
5		2.00	2.07

Precision

The coefficient of variation obtained according to the procedure above was 5% for 0.21 μg/25 ml (8 determinations) and 1.4% for 0.91 μg/25 ml (6 determinations).

Results for water samples analysed

Some domestic sewage samples were analysed by the new method and the results compared well with those of the Methylene Blue method (Table 2).

DETERMINATION OF QUINONES BY A CHEMILUMINESCENCE REACTION IN SOLUTION

J. L. BURGUERA and M. BURGUERA

Departamento de Química, Facultad de Ciencias, Universidad de Los Andes, Apartado Postal 542, Mérida 5101-A, Venezuela

Summary—Oxidation of *p*-benzoquinone by hydrogen peroxide in an alkaline medium gives chemiluminescence emission with maximum intensity at 660 and 560 nm. 1,4-Naphthaquinone gives only a single maximum at 660 nm. These emissions can be used for the determination of μg amounts of the quinones. The interference effect of some organic compounds is described.

Quinones present in waste waters from the paper industry[1] and in airborne diesel-engine exhaust particulate samples[2] are considered to be potential warfare agents, because of their high toxicity to mammals[3,4] and insects.[5] Accordingly, analytical methods for the detection of such compounds should be as sensitive as possible. The methods recommended are based on polarographic measurements,[6] reaction with substrates and detection by thin-layer chromatography,[7] determination by ion-selective electrode and a Gran plot,[8] and reaction with 8-hydroxyquinoline and colorimetric measurements.[9] All these methods may be applied for the detection, identification or determination of quinones, but are not satisfactory in all respects. For example, the polarographic method is reproducible but time-consuming, and the thin-layer chromatographic method is sensitive but most quinones produce similar colours.

The chemiluminescence accompanying redox reactions of some quinones has been observed on reacting *p*-benzoquinone and adrenochrome with hydrogen peroxide in concentrated alkaline solutions.[10] Although some kinetic studies have been made of these systems, no analytical applications have yet been reported. A number of quinones were therefore tested for chemiluminescence emission with hydrogen peroxide in alkaline medium to evaluate the analytical potentialities. Some mono and binuclear quinones, soluble in alkaline media, were tested for chemiluminescence emission in the wavelength range 400–700 nm. No emission was observed from tetrafluoro-1,4-benzoquinone, tetrahydroxy-1,4-quinone and 1,2-naphthaquinone-4-sulphonic acid, but emission was given by *p*-benzoquinone and 1,4-naphthaquinone. This paper describes the use of these observations for determining these two compounds.

EXPERIMEMTAL

Apparatus

A standard Bausch & Lomb Spectronic 20 spectrophotometer with a working range from 340 to 950 nm,[11]

was converted for measuring chemiluminescence by the pulse technique.[12] The signal was recorded on a Hewlett-Packard 680M chart recorder. The experimental technique used was that described previously.[13]

Reagents

All reagents were analytical grade, unless otherwise, stated. The water was twice distilled from an all-glass apparatus.

Hydrogen peroxide (1.2–0.1M). Prepared by appropriate dilution of 100-volume hydrogen peroxide with water.

Stock quinone solutions ($10^{-2}M$). Prepared daily in 3mM phosphate buffer. Working solutions were prepared before use by appropriate dilution with buffer solution of the chosen pH.

Procedure

The quinone solution (1.2 ml) was injected into the hydrogen peroxide solution (1.2 ml). The emission intensity was recorded at 560 or 660 nm for *p*-benzoquinone and at 660 nm for 1,4-naphthaquinone, over a period of 65 sec. Each measurement was repeated 3–5 times. The same procedure was used for calibration or the determination of unknown samples.

RESULTS

Injections of a quinone solution into an alkaline hydrogen peroxide solution produces a chemiluminescence emission after ~35 sec. Typical emission *vs.* time curves for the two quinones studied are shown in Fig. 1. The spectral distribution of the chemiluminescence emission for *p*-benzoquinone and 1,4-naphthaquinone in the alkaline hydrogen peroxide system is shown in Fig. 2. The spectra were obtained by measuring the emission intensity produced at various wavelengths by a constant amount of quinone. The spectrum from the 1,4-naphthaquinone system has not hitherto been reported; it reveals a strong emission band in the spectral range from 600 to 700 nm with a maximum at 660 nm, indicating the formation of a single emitter. The spectrum from the *p*-benzoquinone system showed two broad bands in the range 400–700 nm with maxima at 560 and 660 nm, indicating formation of two emitters. This spectrum resembled that obtained previously by Slawinska.[10] Although
Fig. 1. Intensity vs. time profile obtained for (1) p-benzoquinone at 660 nm, (2) p-benzoquinone at 560 nm, (3) 1,4-naphthaquinone at 660 nm. a, b and c refer to quinone concentrations, in the final solution, of 4.5, 13.6 and 27.3 μg/ml. pH 12.0; $0.3M$ H_2O_2; 1.2 ml of sample and of hydrogen peroxide solution.

the spectra give no evidence on the nature of the emitters, it is likely that the chemiluminescence observed from both quinones at 660 nm is due to emitters of similar structure. This emission may arise by addition of O_2^- to the quinone, followed by decomposition to an excited orthoquinone. The chemiluminescence at 560 nm from p-benzoquinone could be attributed to the formation of a different excited complex between a p-benzoquinone free radical and a sensitized quinone molecule.[14-16]

The effect of hydrogen peroxide concentration on the maximum intensities is shown in Fig. 3. The chemiluminescence intensity at 660 nm increases with hydrogen peroxide concentration up to $0.3M$ for both quinones. The chemiluminescence intensity at 560 nm (from p-benzoquinone) shows similar behaviour up to a final hydrogen peroxide concentration of $0.4M$. In all cases excess of hydrogen peroxide (up to $0.6M$) produces no further increase in chemiluminescence intensity.

The effect of pH (8.0–13.0) on the chemiluminescence intensity is shown in Fig. 4, and was the same irrespective of the quinone and wavelength of maximum emission. The greatest intensity was observed at pH 12.0, which was therefore used in subsequent studies.

Calibration graphs for both quinones were linear and had the equations: $I_1 = 1.008 + 0.498X_1$, $r_1 = 0.9995$; $I_2 = 1.087 + 0.419X_2$, $r_2 = 0.9999$; $I_3 = -0.163 + 0.442X_3$, $r_3 = 0.9991$, where I_1, I_2 and I_3 are the intensities (in arbitrary units) for p-benzoquinone at 660 nm, p-benzoquinone at 560 nm, and 1,4-naphthaquinone at 660 nm, respectively, X_1 and X_2 are the p-benzoquinone concentrations in the

†Concentration in final solution.
§I, II, III indicate values for p-benzoquinone at 660 and 560 nm, and for 1,4-naphthaquinone at 660 nm, respectively. pH 12.0, sample and hydrogen peroxide solution volumes 1.2 ml each.

ranges 1.8–36.4 and 2.3–29.5 μg/ml, respectively, and X_3 is the naphthaquinone concentration (3.2–27.3 μg/ml), and r_1, r_2 and r_3 are the correlation coefficients (10 results). The detection limits were 1.0, 1.5 and 3 μg/ml for p-benzoquinone at 660 and 560 nm, and 1,4-naphthaquinone at 660 nm, respectively. The coefficients of variation for 6 measurements at the 9.1 μg/ml level were 3.0, 3.1 and 3.4% for p-benzoquinone (at 660 and 560 nm), and 1,4-naphthaquinone at 660 nm, respectively.

Interferences

The effects of some organic compounds on the chemiluminescence intensity from both quinones were investigated. An interference is defined as significant if it causes a change of more than two standard deviations in the chemiluminescence emission intensity. The results are shown in Table 1. Several organic compounds depress the emission from both quinones (*e.g.*, 8-hydroxyquinoline, 1,2-chloranilic acid, hydroquinone, tetrahydroxy-1,4-quinone and tetrafluoro-1,4-benzoquinone), whereas others increase the chemiluminescence emission (*e.g.*, formaldehyde, gallic acid and 2,6-dimethyl-benzoquinone). These effects can be reduced or eliminated by increasing the hydrogen peroxide concentration to 0.6M. The depressive effects are reduced probably because at high concentrations of hydrogen peroxide there are sufficient O_2^- radicals present for the two quinones to be oxidized despite quenching by the inhibitors.[17] The strong stimulating effect of formaldehyde and gallic acid is less sensitive to hydrogen peroxide concentration, possibly due to the intervention of other processes of sensitized chemiluminescence.[18–20]

Conclusion

The chemiluminescence measurements have demonstrated the possibility of the determination of p-benzoquinone and 1,4-naphthaquinone at μg/ml level. The method is simple and rapid (1 measurement/min) and the detection limits are simi-lar to those for many other techniques.[6,7,9] The equipment used is simple and may be adapted to flow-injection analysis.[21–23]

ANALYTICAL DATA

SOLVENT EXTRACTION OF THE ION-PAIRS OF CHROMIUM(VI) AND MOLYBDENUM(VI) WITH TRIOCTYLMETHYLAMMONIUM CHLORIDE AND BENZYLDIMETHYLCETYLAMMONIUM CHLORIDE

Kousaburo Ohashi, Keiko Shikina, Hiroyuki Nagatsu,
Izumi Ito and Katsumi Yamamoto
Department of Chemistry, Faculty of Science, Ibaraki University, Mito 310, Ibaraki, Japan

Summary—The number of capriquat molecules per chromium(VI) atom in the chromate–capriquat ion-association complex has been found to be between one and two. The distribution ratio in the extraction of chromium(VI) with capriquat is dependent on the dielectric constant of the organic solvent, with a minimum at a dielectric constant of about 8. The absorption spectra of the ion-pair extracted into cyclohexane, carbon tetrachloride, benzene and n-butanol are very similar to that of chromate in aqueous solution. The absorption spectra of the chromium(VI)–capriquat extracts in these organic solvents gradually change to an absorption spectrum similar to that of $HCrO_4^-$ in aqueous solution. Chromium(VI)–capriquat extracted into chloroform and 1,2-dichloroethane gives absorption spectra similar to that of $HCrO_4^-$ in aqueous medium. The chromium(VI)–capriquat species extracted into 1,2-dichloroethane may be $(Q^+)_2 \cdot CrO_4^{2-}(H_2O)_n$. In contrast, chromium(VI) is extracted with capriquat into the other organic solvents from ammoniacal medium as a mixture of $(Q^+)_2 \cdot CrO_4^{2-}(H_2O)_n$ and $Q^+ \cdot NH_4^+ \cdot CrO_4^{2-}(H_2O)_n$. The spectral change is ascribed to the change of the extracted species from $(Q^+)_2 \cdot CrO_4^{2-}(H_2O)_n$ and $Q^+ \cdot NH_4^+ \cdot CrO_4^{2-}(H_2O)_n$ to $Q^+ \cdot HCrO_4^{2-}(H_2O)_{n-1}$. The chromium(VI)–zephiramine species extracted is formulated as $(Q^+, NH_4^+)_2CrO_4^{2-}(H_2O)_n \cdot (Q^+ \cdot Cl^-)_m$. Molybdenum(VI) is extracted with capriquat into the same organic solvents as a mixture of $(Q^+)_2 \cdot MoO_4^{2-}(H_2O)_n$ and $Q^+ \cdot NH_4^+ \cdot MoO_4^{2-}(H_2O)_n$.

Several studies have been made of the solvent extraction of ion-association complexes of chromium(VI)[1–3] and molybdenum(VI)[4–7] with organic cations, to obtain detailed information about the complexes and the extraction mechanism, because chromium(VI) and molybdenum(VI) exist as various species in aqueous solution. The study of the extraction of chromium(VI) from weakly acid solution with organic cations (Q^+) such as triphenyltetrazolium,[3] tetraphenylarsonium[3] and n-propyltriphenylphosphonium[3] suggested that chromium(VI) was extracted as an ion-pair ($Q^+ \cdot HCrO_4^-$). Winkhaus and Uhring[2] found that chromium(VI) was extracted in the pH range 1–3 with the di-π-cyclopentadienyltitanium cation (Q^{2+}) as $Q^{2+} \cdot CrO_4^{2-}$. In this pH range the main species of chromium(VI) is probably $HCrO_4^-$. They proposed that extraction of the 1:1 ion-pair is more favourable.

There have been few detailed investigations of the mechanism of solvent extraction of chromium(VI) with long-chain quaternary ammonium ions. The solvent extraction of low concentrations of chromium(VI) from alkaline solution with capriquat and zephiramine is described here.

Most of the work on the extraction of molybdenum(VI) with amines and quaternary ammonium salts has been done in acid media, and the influence of acidity and diluents on the extraction investigated.[6,7]

The extraction of molybdenum(VI) from alkaline solution with capriquat and zephiramine has therefore also been investigated, to compare it with that of chromium(VI) .

EXPERIMENTAL

Apparatus

A Hitachi 170-30 type atomic-absorption spectrophotometer was used for determination of chromium(VI) and molybdenum(VI). A Hitachi EPS-3 type spectrophotometer was used to measure the absorption spectra. A Hitachi Horiba F-7 type pH-meter was used for pH measurements.

Reagents

Standard 0.1M chromium(VI) solution was prepared from potassium chromate and redistilled water. Standard 0.1M molybdenum(VI) solution was made by dissolving sodium molybdate in sodium hydroxide solution (pH 9). Working solutions were prepared by diluting these stock solutions with redistilled water, and buffered with ammonia/ammonium chloride solution.

Capriquat (Kanto Co. Ltd.) and zephiramine (Dojin Co. Ltd. GR grade) were used without further purification. Organic solvents were distilled before use. All other reagents were of analytical grade.

Procedure

A 10-ml portion of $1.50 \times 10^{-5}M$ chromium(VI) and 10 ml of a given concentration of quaternary ammonium chloride in the selected organic solvent were pipetted into a 50-ml separatory funnel. A shaking time of 10 min gave a constant degree of extraction. After separation of the phases, chromium(VI) in the aqueous phase was determined. The pH of the aqueous phase was measured after the extraction, and found to change negligibly during the extraction. The number of quaternary ammonium ions per chromium(VI) atom in the ion-pair was determined from the slope of the straight line obtained by plotting log D vs. log $[Q^+ \cdot Cl^-]$, where D and $[Q^+ \cdot Cl^-]$ are the distribution ratio and the concentration of free quaternary ammonium chloride. A large excess of quaternary ammonium chloride was used, so that the amount extracted could be neglected and $[Q^+ \cdot Cl^-]$ taken as the concentration added.

RESULTS AND DISCUSSION

Extraction of chromium(VI) with capriquat

The plots of log D vs. log $[Q^+ \cdot Cl^-]$ for extraction of chromium(VI) with capriquat into the organic solvents were linear up to 90% extraction. Table 1 gives the number (n) of capriquat ions per chromium(VI) atom in the ion-pairs extracted into cyclohexane, carbon tetrachloride, benzene, chloroform, n-butanol, 1,2-dichloroethane and methyl isobutyl ketone (MIBK); n varied between 1.3 and 2.0.

The equilibria for the proton-dissociation and dimerization of chromium(VI) in aqueous solution are well characterized and are as follows:[8]

$$H_2CrO_4 \rightleftharpoons H^+ + HCrO_4^- \ (K_1 = 1.2)$$

$$HCrO_4^- \rightleftharpoons H^+ + CrO_4^{2-} \ (K_2 = 3.2 \times 10^{-7})$$

$$HCr_2O_7^- \rightleftharpoons H^+ + Cr_2O_7^{2-} \ (K_3 = 0.85)$$

$$2HCrO_4^- \rightleftharpoons Cr_2O_7^{2-} + H_2O \ (K_4 = 98)$$
At a chromium(VI) concentration of $10^{-4}M$, CrO_4^{2-} is the main species in alkaline solution. The fact that the number of capriquat ions per chromium(VI) atom is between 1.3 and 2.0 in these extractions suggests that chromium(VI) may be extracted as a mixture of $(Q^+)_2 \cdot CrO_4^{2-}$ and other ion-pair species.

Absorption spectra of extracted chromium(VI)–capriquat species

Figures 1 and 2 show the absorption spectra of the chromium(VI)–capriquat species extracted into cyclohexane and carbon tetrachloride, and Fig. 3 the spectra of CrO_4^{2-} and $HCrO_4$ in aqueous solution. The spectrum of the extracted chromium(VI)–capriquat species, measured immediately after sepa-
Fig. 1. Absorption spectra of the chromium(VI)–capriquat species extracted into cyclohexane. [Cr(VI)]:$1.00 \times 10^{-4}M$; [capriquat]:$0.1M$; pH 9.2; 94% extraction; 17 hr standing after extraction; spectra (A) and (B) were measured 3 min and 100 hr, respectively, after separation.

ration, is very similar to that of CrO_4^{2-} in aqueous solution. When benzene and n-butanol were used, similar absorption spectra were obtained. On the other hand, the absorption spectra of
Fig. 2. Absorption spectra of the chromium(VI)–capriquat species extracted into carbon tetrachloride. Conditions as for Fig. 1; 90% extraction; 4 hr standing after extraction; spectra (A), (B) and (C) were measured 3 min, 11 hr and 62 hr, respectively, after separation.

Table 1. Number (n) of capriquat ions bonded per chromium(VI) atom, as a function of the dielectric constant (ε) of the organic solvent (extraction at pH 9.2)

Solvent	CCl_4	C_6H_6	C_6H_{12}	$CHCl_3$	$1,2\text{-}C_2H_4Cl_2$	MIBK	$n\text{-}C_4H_9OH$
n	1.5	1.5	1.3	1.5	2.0	2.0	1.6
ε	2.2	2.3	2.3	4.9	10.4	13.1	16.4
Fig. 3. Absorption spectra of $1.00 \times 10^{-4}M$ chromium(VI) in aqueous solution: (A) pH 9.5, (B) pH 3.0.

Fig. 5. Absorption spectra of the chromium(VI)–zephiramine species extracted into chloroform. [Cr(VI)]: $1.00 \times 10^{-4}M$; [zephiramine]: $0.05M$; 79% extraction; pH 9.2; 2 hr standing after separation; (A), (B), (C) and (D) measured 2 min, 1 hr, 6 hr and 13 hr, respectively, after separation.

chromium(VI)–capriquat species extracted into 1,2-dichloroethane (Fig. 4) and chloroform are very similar to that of $HCrO_4^-$ in aqueous solution. The absorption spectra of the chromium(VI)–capriquat species extracted into benzene, cyclohexane, carbon tetrachloride and n-butanol gradually changed into an absorption spectrum similar to that of $HCrO_4^-$ in aqueous solution. The rate of the spectral change increases in the order cyclohexane < benzene < carbon tetrachloride < n-butanol < MIBK. The molar absorptivity and wavelength of maximum absorption for the cyclohexane extract are in good agreement with those of CrO_4^{2-} in aqueous solution, suggesting that the chromium(VI) species in the ion-pair is CrO_4^{2-}. The number of capriquat ions extracted per chromium(VI) atom with cyclohexane was 1.3. As an ammonia buffer was used to adjust the pH, ammonium ions may also participitate in the

extraction, and the chromium(VI) be extracted as a mixture of $(Q^+)_2 \cdot CrO_4^{2-}$ and $Q^+ \cdot NH_4^+ \cdot CrO_4^{2-}$. The same could apply to the benzene, carbon tetrachloride and n-butanol systems, although the molar absorptivities for these extracts are slightly smaller than that of CrO_4^{2-} in aqueous medium. The corresponding data for the 1,2-dichloroethane system ($n = 2.0$, absorption spectrum, immediately after separation, similar to that of $HCrO_4^-$ in aqueous solution) suggest that $(Q^+)_2 \cdot CrO_4^{2-}$ is extracted but rapidly changes into $Q^+ \cdot HCrO_4^-$, the proton possibly coming from a water molecule attached to the chromium(VI) in the ion-pair.

Extraction of chromium(VI) with zephiramine

The plots of log D vs. log [zephiramine] were linear with a slope of 2.7. The absorption spectrum of the species extracted into chloroform is shown in Fig. 5. The spectrum measured immediately after the separation is very similar to that of CrO_4^{2-} in aqueous medium and changes much more slowly than that of the chromium(VI)–capriquat species in chloroform. The chromium(VI) may be extracted with zephiramine as $(Q^+,NH_4^+)_2CrO_4^{2-}(H_2O)_n \cdot (Q^+ \cdot Cl^-)_m$ where (Q^+, NH_4^+) indicates vicarious substitution of NH_4^+ for Q^+. The spectral change may be ascribed to the formation of $Q^+ \cdot HCrO_4^-(H_2O)_{n-1}$.

Chromium(VI) has been found[2] to be extracted at pH 1–3 with the di-π-cyclopentadienyltitanium cation (Q^{2+}) into chloroform as $Q^{2+} \cdot CrO_4^{2-}$, though the dominant species of chromium(VI) in aqueous solution at pH 1–3 is $HCrO_4^-$.

In the present work, it was found spectrophotometrically that the chromium(VI)–capriquat species extracted into organic solvents as

Fig. 4. Absorption spectra of the chromium(VI)–capriquat species extracted into 1,2-dichloroethane. [Cr(VI)]: $1.00 \times 10^{-4}M$; [capriquat]: $0.05M$; pH 9.2; 84% extraction; 3 min standing time after shaking; (A) and (B) measured 3 min and 15 hr, respectively, after separation.

Table 2. Number (n) of capriquat ions bonded to one molybdenum(VI) atom

Solvent	CCl_4	C_6H_6	C_6H_{12}	$CHCl_3$	$1,2-C_2H_4Cl_2$	$n-C_4H_9OH$
n	1.3	1.4	1.1	1.0	1.5	1.8
ε	2.2	2.3	2.3	4.9	10.4	16.4

$Q^+ \cdot NH_4^+ \cdot CrO_4^{2-}(H_2O)_n$ and/or $(Q^+)_2 \cdot CrO_4^{2-}(H_2O)_n$ changes to $Q^+ \cdot HCrO_4^-(H_2O)_{n-1}$. It therefore seems likely that there are thermodynamic factors that favour extraction of 1:1 charge-matched species rather than 2:1 species formed from components with different charges.

Extraction of molybdenum(VI) with capriquat and zephiramine

The number of capriquat ions per molybdenum(VI) in the molybdenum(VI)–capriquat species extracted was determined by the procedure used for chromium(VI). As shown in Table 2, n for the capriquat system was between 1.0 and 1.8. For the zephiramine system it was 2.7. The extraction of molybdenum(VI) from alkaline solution with capriquat and zephiramine seems essentially the same as the extraction of chromium(VI) with capriquat and zephiramine. At pH 9.2, molybdenum(VI) exists as MoO_4^{2-} because the proton-dissociation constant (pK_a) of $HMoO_4^-$ is 4.1, and polymerized species can be neglected for $10^{-4}M$ Mo(VI) in alkaline medium. The ion-association species of $(Q^+)_2 \cdot MoO_4^{2-}(H_2O)_n$ and $Q^+ \cdot NH_4^+ \cdot MoO_4^{2-}(H_2O)_n$ are proposed for the capriquat system and $(Q^+, NH_4^+)_2MoO_4^{2-}(H_2O)_n \cdot (Q^+ \cdot Cl^-)_m$ for the zephiramine system.

The absorption spectra of the molybdenum (VI)–capriquat and molybdenum(VI)–zephiramine species extracted were not obtained, because of their very small molar absorptivities.

Effect of organic solvent on the distribution ratio

Figure 6 shows the relationship between log D and the dielectric constant of the organic solvents for the
Fig. 6. Relationship between log D and the dielectric constant (ε) of the organic solvent. ○: $5.00 \times 10^{-5}M$; Cr(VI); pH 9.2; $0.01M$ capriquat. ●: $1.00 \times 10^{-4}M$; Mo(VI); pH 10.5; $0.01M$ capriquat. Organic solvent: 1, cyclohexane; 2, carbon tetrachloride; 3, benzene; 4, toluene; 5, chloroform; 6, tributyl phosphate; 7, 1,2-dichloroethane; 8, MIBK; 9, n-butanol; 10, nitrobenzene.

extraction of chromium(VI) and molybdenum(VI) with capriquat. The value of log D exhibits a minimum at a dielectric constant of about 8. Though the dielectric constants of n-butanol and nitrobenzene are 16.1 and 34.8 respectively, the distribution ratios are not very different. Similar solvent effects were obtained for the molybdenum(VI)–capriquat system.

The degree of extraction of chromium(VI) with triphenyltetrazolium at pH 4.0–4.2 decreases according to the solvent used, in the order[3] nitrobenzene > chloroform > benzene > carbon tetrachloride > cyclohexane. It is noteworthy that the long-chain quaternary ammonium ion seems to have a different effect from that of triphenyltetrazolium ion on the extraction of chromium(VI).

The influence of organic solvents on the extraction of molybdenum(VI) with tri-iso-octylamine from hydrochloric acid has been reported.[6] The degree of extraction of molybdenum(VI) from $1.0M$ hydrochloric acid decreases according to the solvent used, in the order 1,2-dichloroethane > 1,2-dichlorobenzene > carbon tetrachloride. In contrast, the distribution ratio for the extraction of molybdenum(VI) with capriquat into carbon tetrachloride is larger than that for use of 1,2-dichloroethane (Fig. 6). The molybdenum(VI) species extracted with tri-iso-octylamine was reported[6] to be $MoO_2Cl_4^{2-}$ or MoO_2Cl_2. We cannot discuss these results in detail, because of the limited number of studies on the solvent effect on these extraction systems.

As mentioned above, the number of zephiramine ions bonded per molybdenum(VI) is greater than that needed to give electroneutrality with MoO_4^{2-}. A similar result was obtained for the extraction of molybdenum(VI) with capriquat into kerosene at pH 2.2–2.5,[7] and it was proposed that for $[Mo(VI)] > [Q^+ \cdot Cl^-]$ the reaction was

$$3Q^+ \cdot Cl^- + Mo_6O_{19aq}^{2-} \rightleftharpoons (Q^+)_2Mo_6O_{19}^{2-} \cdot Q^+ \cdot Cl^- + Cl^-_{aq}$$
The same process was proposed for the extraction into chloroform.

Sato et al.[9] investigated the extraction of molybdenum(VI) with capriquat from sodium hydroxide solution into benzene and suggested the extracted species had the composition $Q^+:Mo(VI):H_2O = 2:1:14$. It is interesting that it was proposed that molybdenum(VI)–capriquat is solvated with water. The molybdenum(VI)–capriquat species extracted into carbon tetrachloride, n-butanol, 1,2-dichloroethane, chloroform and benzene from an alkaline ammonia buffer may also be solvated with water.

We have therefore examined the extraction of chromium(IV) and molybdenum(VI) with capriquat from sodium hydroxide medium. Extraction of

chromium(VI) into chloroform or 1,2-dichloroethane gave a solution with an absorption spectrum similar to that for CrO_4^{2-} in aqueous medium, in contrast to the spectra of extracts from ammoniacal medium. The number of capriquat ions bound per chromium(VI) or molybdenum(VI) in the extracts from sodium hydroxide medium (pH 11.7; $0.01M$ NaOH) is shown in Table 3. The result for molybdenum(VI) differs from that found by Sato et al.,[9] but this may be due to differences in experimental conditions. However, it appears that sodium ions may be involved in this extraction of chromium(VI) and molybdenum(VI).

Table 3. Number (n) of capriquat ions bonded per Cr(VI) or Mo(VI) atom

Solvent	CCl_4	C_6H_6	$CHCl_3$	$1,2\text{-}C_2H_4Cl_2$
n for Cr(VI)	2.0	2.0	0.9	1.5
n for Mo(VI)	1.0	1.2	1.4	1.1

THE SOLUBILITY OF ALKALI-METAL FLUORIDES IN NON-AQUEOUS SOLVENTS WITH AND WITHOUT CROWN ETHERS, AS DETERMINED BY FLAME EMISSION SPECTROMETRY

David A. Wynn*, Marie M. Roth and Bruce D. Pollard†

Chemistry Department, Marquette University, Milwaukee, WI 53233, U.S.A.

Summary—The solubilities of LiF, NaF, KF, RbF and CsF in acetonitrile, acetone, tetrahydrofuran, dimethylformamide, benzene and cyclohexane have been determined with and without a crown ether (usually $0.1M$ 18-crown-6) present. Flame emission spectrometry was the determination method. Three procedures, selected according to the miscibility of the solvent with water, and the solubility of the fluoride, are described. Samples, standards and blanks were matrix-matched. The precision varied between 1 and 10% RSD. Although extensive drying procedures were applied, moisture present in the solvents and salts had some effect on the results.

The solubility of inorganic salts in non-aqueous media, though usually very low, is of concern in corrosion and wear studies,[1,2] in environmental and toxicological problems and in studies of organic reactions in which the rate or outcome of the reaction is affected by traces of salts. Reliable solubility data, obtained by methods carefully designed to give good reproducibility and accuracy, are essential for interpretation of these studies.

Fluoride ions are useful in organic synthesis for cleavage of carbon–silicon bonds,[3,4] in displacement and elimination reaction[5-7] and as catalysts,[8] but the low solubility of metal fluorides in organic solvents[9] is a problem. The addition of crown ethers which form complexes with alkali-metal cations can enhance the solubility of alkali-metal fluorides in organic solvents.[5,10] The resultant increased availability of fluoride ion may affect its reactivity as a participating reagent or as a catalyst.[11,12] Solubility data for alkali-metal fluorides in organic solvents in the presence of crown ethers must be considered when interpreting and optimizing the effect of fluoride ion on the reactions.

In the present study, flame spectrometry was applied to the determination of solubilities of alkali-metal fluorides in non-aqueous media in the absence and presence of crown ethers. Flame spectrometry is a convenient, rapid and accurate method for these determinations if several conditions are met. The solubility must be sufficient to provide signals in the high-precision part of the linear calibration. The matrix for the standards and blanks must match the sample matrix exactly, because the analyte signal is

not only a direct function of the nebulization flow-rate, which depends on the physical properties, *e.g.*, viscosity, of the solution, but is also governed by the degree of atomization and ionization produced at the flame temperature (which is modified by the combustibility of the organic solvent in the matrix). Standards should bracket the concentration of the sample so that a linear signal/concentration relationship is ensured.

If a suitable matrix can be found, aqueous standards are the most convenient to use. An aqueous/organic solvent mixture must be a true solution to be suitable for nebulization and combustion in the burner. A water-miscible solvent presents no problem; if the solvent is not miscible with water, addition of a common solvent to produce a single-phase system is sometimes possible. Non-aqueous solutions can be analysed directly but present problems with flame techniques, and require organometallic standards which are not always available or may be difficult to handle.

The solubilities reported here for alkali-metal fluorides in particular organic solvents have been obtained by procedures based on flame spectrometric determination. The procedures can be extended to other salts and solvents and adapted for use whenever trace metals in solvents must be determined.

EXPERIMENTAL

Equipment

Alkali-metal concentrations were determined with an IL 251 flame atomic spectrophotometer (Instrumentation Laboratory, Andover, MA) in the atomic-emission mode. Wavelengths (nm) used were: Li, 670.8; Na, 589.0; K, 766.5; Rb, 780.0; Cs, 852.1. A special red-sensitive photomultiplier (R446, Hamamatsu, Middlesex, NJ) was installed because several of the wavelengths were outside the range of the original photomultiplier of the equipment. The standard

†Author to whom correspondence should be addressed.

slot-burner was operated off-axis and carefully cleaned after each series of determinations. The acetylene/air flame was slightly fuel-rich and had a typical fuel/oxidant flow ratio of 5.5/19. For each element/solvent system the instrumental parameters, including slit-width, flame position, nebulization rate and integration time, were optimized on the basis of signal-to-noise ratios.

Samples and reagents

The salts [lithium fluoride (Aldrich Chem., Milwaukee, WI, 99.999% pure), sodium fluoride (Fisher Scientific, certified A.C.S.), potassium fluoride (Allied Chem., reagent grade), rubidium fluoride (Cerac, Milwaukee, WI, 99.9% pure), and caesium fluoride (Alfa, Danvers, MA, 99.9% pure)] were dried for two days at 120° under vacuum and stored over phosphorus pentoxide in a desiccator.

A solution of 25 g of 1,4,7,10,13,16-hexaoxacyclo-octadecane (18-crown-6)[13] (Aldrich Chem., Milwaukee, WI) in 200 ml of dichloromethane was dried overnight with 2 g of anhydrous magnesium sulphate in a nitrogen atmosphere and pressure-filtered under nitrogen. After distillation of the dichloromethane, the residue was dried at 76 mmHg pressure. 1,4,7,10-Tetraoxacyclododecane (12-crown-4) and 1,4,7,10,13-pentaoxacyclopentadecane (15-crown-5) (Aldrich Chem., Milwaukee, WI) were used without further purification.

Acetonitrile (reagent grade dried with calcium hydride and filtered, or Aldrich gold label 99+% pure) was fractionally distilled from phosphorus pentoxide in a nitrogen atmosphere, stored over 3A molecular sieve and freshly distilled before use. Benzene was fractionally distilled under nitrogen from sodium/benzophenone ketyl and stored over 3A molecular sieves. Tetrahydrofuran (THF) was fractionally distilled under nitrogen from sodium–potassium/benzophenon ketyl and used immediately. Dimethylformamide (DMF) was shaken with potassium hydroxide, fractionally distilled from barium oxide under reduced pressure and stored over 3A molecular sieve. Cyclohexane (<0.002% water) and acetone (<0.2% water) were of spectrophotometric grade (MCB Mfg. Chemists Omnisolv Reagents).

All water used was ultrapure, prepared from distilled water and demineralized by passage through a SYBRON/Barnstead Nanopure water system (Model 02782). Stock solutions of standards (1000 ppm) were prepared from the dry solid alkali-metal fluorides; the

---

*The very fine suspensions settled with difficulty. Repetition of decantation and centrifugation resulted in more complete removal of suspended solid metal fluoride, and the later centrifugates did not show higher alkali-metal concentrations.

lithium fluoride solution was also 0.3M in hydrochloric acid. Aqueous standards in the proper concentration ranges were prepared by dilution.

General procedure

Saturated solutions of the metal fluorides were prepared by stirring an excess of the salt (usually less than 0.2 g) with 15 ml of solvent for 30 min in a closed system at a constant measured temperature ($\pm 0.2°$). It was important that the salt was as dry as possible; otherwise, the care in solvent preparation was negated. The suspension was decanted and centrifuged* at 5000 rpm (International Equipment Co., Clinical Centrifuge, Model CL) for 10–15 min. Varying periods of refluxing, stirring and ultrasound treatment were evaluated as methods for ensuring saturation and found to give identical results. For water-miscible solvents (acetonitrile, acetone, THF and DMF), 1-ml aliquots of centrifugate were transferred to 50-ml beakers and diluted with 5 ml of water to give a sample with a 16.7% solvent/83.3% water matrix. One-ml amounts of pure solvent diluted with 5 ml of aqueous standard or water provided matrix-matched standards and blanks, respectively. Use of PMP (polymethylpentene) beakers was preferred, to avoid exchange of metallic ions with a glass surface, and improved the reproducibility of the results. Kimax-glass beakers were used for cyclohexane solutions, however, since cyclohexane causes immediate decomposition of the PMP beakers.

For solubility systems which, by the procedure above, gave samples with concentrations below the limit of detection, a known volume (6 ml) of the saturated solution was preconcentrated by evaporation and the residue was dissolved in 1 ml of water to provide a sample for direct comparison with aqueous standards. Blanks for this procedure were prepared from a similar volume of pure solvent, evaporated in a similar vessel.

When the solvent was immiscible with water (benzene, cyclohexane), a modification employing a common solvent in the matrix was employed. For benzene, dilution of the 1 ml of centrifuge to 20 ml with 95% ethanol gave a sample in a 5% benzene/90% ethanol/5% water matrix. For cyclohexane, dilution of the 1-ml aliquot of centrifuge with 5 ml of 95% ethanol produced a sample in a 16.7% cyclohexane/79.2% ethanol/4.2% water matrix. Blanks and standards were matched to these matrices.

In studies on the effect of crown ethers on saturation solubility, similar procedures were followed, with the crown ether added at a known concentration to the solvent used for the preparation of the saturated solution and the corresponding blanks and standards. It was important to match the matrix exactly, because the crown ether caused noticeable broad-band enhancement of the blank signal, which was attributed to a change in flame conditions.

§Common solvent method.

RESULTS AND DISCUSSION

The present method produced consistent solubility data (Table 1), with good standard deviations, for alkali-metal fluorides in several organic solvents in the presence and absence of crown ethers. In general, the values obtained were lower than the solubilities previously reported, which differed over a wide range.

Evaluation of the results must take account of how the sample was prepared and how the solubility was measured. The importance of controlled procedures and reproducibility cannot be overemphasized.

High values for the solubility of very slightly soluble salts can result from traces of very finely divided solid present in the saturated solution samples. In investigations of solubility in non-aqueous solvents, trace amounts of water present in the solvents used or introduced during the preparation of the saturated solutions can increase the amount of solute dissolved. Inconsistent and inaccurate data can also result if standards are improperly matched; in flame spectrometry, organic solvents and other components can affect the flame temperature and rate of nebulization and thereby the degree of ionization. The present method has provided for separation of the solution from the finely divided solid phase, and for the use of dry solvents in a controlled atmosphere. The standards were chosen to provide an identical matrix and to bracket sample concentrations in a range of linear response.

The effect of traces of moisture is probably the major factor influencing such solubility data.[20] The results in Table 1 represent the solubilities in dry solvents under laboratory working conditions normal for moisture-sensitive materials. The effect of moisture on the solubility of potassium fluoride in acetonitrile is illustrated by the following comparison. For one group of samples extreme precautions were taken to ensure dryness; the acetonitrile was dried for several days over phosphorus pentoxide and redistilled under nitrogen immediately before use;[21] its moisture content was monitored by modified coulometric Karl Fischer titration;[22,23] the potassium fluoride was dried under vacuum at 120° for 2 hr; refluxing, cooling to room temperature, two-step centrifugation and Acro-disc® filtration were all performed in a closed system (glove-bag) under dry nitrogen. This resulted in a 0.014 ± 0.002mM saturated solution of potassium fluoride in acetonitrile with a water content of 100 ± 20 μg/ml, which may be compared with the value 0.031 ± 0.004mM obtained for a saturated solution of potassium fluoride in normally dried acetonitrile containing 400 ± 40 μg/ml water. Obviously, the solubility of potassium fluoride in the organic solvent is dependent on the amount of water present. Although it would be possible to extrapolate to a solubility at zero water content, this would represent a condition that does not exist under experimental conditions. The solubility of real experimental significance is that obtained under normal anhydrous operating conditions, such as those employed for the solubilities reported in Table 1.

The solubilities recorded in the literature for alkali-metal fluorides in acetone[14] are lower than those obtained by the present method for lithium, sodium and potassium fluorides. These literature values were obtained by conductance measurements, which depend on free ions in solution; any ion-pair formation or solvation would result in lower apparent solubility. The solubilities of the more soluble rubidium and caesium fluorides were probably determined by weight, but no details were given; they are in agreement with the values obtained by our flame photometric method.

The ability of a crown ether to enhance solubility in non-aqueous solvents depends not only on the cavity size of the crown ether and the cation radius but also on the inherent solubility of the particular inorganic salt in the pure solvent.[10] 18-Crown-6 was found to enhance the solubility of potassium, rubidium and caesium fluorides in all the solvents tested—acetonitrile, acetone, THF, DMF, benzene and cyclohexane; a smaller degree of enhancement was observed for sodium fluoride in acetone, THF, DMF and benzene, and only a very slight enhancement for lithium fluoride in benzene, with no enhancement in the other solvents. The cavity diameter in 18-crown-6 (2.6–3.2 Å)[10] can accommodate the potassium ion (ionic diameter 2.66 Å) or rubidium ion (2.94 Å) in a 1:1 complex. The increased solubility of a caesium fluoride can be attributed to the caesium ion being sandwiched between two 18-crown-6 molecules in a 1:2 complex. The smaller sodium ion (1.94 Å) and lithium ion (1.36 Å) can be complexed by 18-crown-6 but the poorer fit of ion to cavity results in a smaller degree of complex formation and less enhancement of solubility.

The effect of the smaller crown ethers, 15-crown-5 (cavity diameter 1.7–2.2 Å[10] or 1.72–1.84 Å[24]) and 12-crown-4 (cavity diameter 1.2–1.5 Å[10]) on the solubility of sodium and lithium fluorides, respectively, was investigated since these would seem to provide good cavity sizes for complexing the cations, but the result is not always as expected.[25] For benzene as solvent, in which 18-crown-6 had caused a slight enhancement of lithium fluoride solubility, only the same degree of enhancement was observed with 12-crown-4, although it would seem to give an ideal fit for lithium ions. Neither crown ether produced any enhancement of the solubility of lithium fluoride in acetone. The sodium ion may be slightly large for the 15-crown-5 ether cavity but there a slight enhancement of the solubility of its fluoride in both benzene and acetone was found. The 18-crown-6 ether was found to be ineffective with sodium fluoride in benzene, but was more effective than 15-crown-5 in acetone. A similar anomaly in effect of crown cavity size on effectiveness of ion-complexing was noted by Hopkins and Norman[25] who observed that the equilibrium constants for complexation with a fixed concentration of lithium iodide were in the order 18-crown-6 > 15-crown-5 > 12-crown-4.

CONCLUSIONS

The solubilities of alkali-metal fluorides in non-aqueous solvents have been determined with and

without crown ether present. The results compare favourably with those in the literature. A discussion of the solubilities, based on ion-size, ion-pair formation and solvent donor-power can be found elsewhere.[26] Water present in the solvent, air and salts has a marked influence on the solubility. Crown ethers increase the solubility of some alkali-metal fluorides, particularly when the ion-size matches the cavity in 18-crown-6. The methods of determination, based on flame emission spectrometry, are simple and result in good precision. The importance of matrix-matching samples, standards and a proper blank, cannot be overemphasized.

2-(8-QUINOLYLAZO)-7-PHENYLAZOCHROMOTROPIC ACID AS AN ANALYTICAL REAGENT*

Ru-Qin Yu, Zhi-Hua Zhang and Ya-Wen Li

Department of Chemistry and Chemical Engineering, Hunan University, Changsha, People's Republic of
China

Summary—2-(8-Quinolylazo)-7-phenylazochromotropic acid (QAPAC) has been synthesized by coupling diazotized 8-aminoquinoline with 2-phenylazochromotropic acid as well as by coupling diazotized aniline with 2-(8-quinolylazo)chromotropic acid. The properties of QAPAC and the spectrophotometric characteristics of some metal–QAPAC complexes are reported.

Quinolylazo derivatives are promising analytical reagents for spectrophotometric determination of trace elements. So far the number of published works on reagents derived from diazotized 8-aminoquinoline is limited.[1-5] We have tested 23 compounds derived from this compound and find that 2-(8-quinolylazo)-7-phenylazo-1,8-dihydroxy-naphthalene-3,6-disulphonic acid [2-(8-quinolylazo)-7-phenylazochromotropic acid, QAPAC] has the best analytical characteristics. Our studies on its synthesis and properties are now reported.

EXPERIMENTAL

Synthesis of the reagent

Dissolve 7.9 g of 8-aminoquinoline in 60 ml of 2M hydrochloric acid and cool to 0°. With stirring, add drop-wise 60 ml of ice-cold water containing 4.2 g of sodium nitrite. Cool the mixture for 1 hr in an ice-bath. In a separate vessel suspend 42.5 g of calcium oxide in 200 ml of hot water. Dissolve about 45 g of Chromotrope 2R (disodium salt of phenylazochromotropic acid) in the minimum amount of water and chromatograph it on a Polyamide 6 column with water as effluent. Collect the red fraction and pour it into the cooled calcium hydroxide suspension. To this mixture add the diazotized 8-aminoquinoline solution, followed by 63 g of sodium chloride. Stir the mixture for 1 hr, then dilute with 1 litre of water. Add 100 ml of concentrated hydrochloric acid to precipitate the QAPAC. Collect the precipitate and wash it with hydrochloric acid of decreasing concentration, then with water. Dry the crude product under vacuum at 45° (yield 12.9 g). Dissolve the product in 1M sodium hydroxide, and reprecipitate it three times with concentrated hydrochloric acid. For further purification, prepare a chromatographic column of Poly-amide 6 sorbent (6–7 cm in length, 2–4 cm diameter). Dissolve the crude product in the minimum amount of 1M sodium hydroxide, apply it to the column, elute with 0.2M sodium hydroxide and discard the red fraction of the eluate. Collect the blue fraction and precipitate QAPAC from it with concentrated hydrochloric acid. Filter off under suction and dry under vacuum. Evaluate the purity of the product

by paper chromatography with 2:1:1 (v/v) butan-1-ol–glacial acetic acid–water. The best product shows a blue spot remaining at the start. Analysis: $C_{25}H_{17}O_8N_5S_2$ requires 12.08° N, 11.06° S; found 12.0° N, 10.7, S. The principal infrared bands are at 1030, 1190, 1275 and 1445 cm^{-1}.

RESULTS AND DISCUSSION

Purification and identification of QAPAC

The commercially available Chromotrope 2R contained blue impurities which were left on the Poly-amide 6 column when the red fraction was eluted with water. When QAPAC was precipitated with hydro-chloric acid, most of the unreacted phenyl-azochromotropic acid remained in solution. For the chromatographic separation of QAPAC from im-purities on a Polyamide 6 column, ammonia or sodium hydroxide solutions of various concentration were tried as eluents, and 0.2M sodium hydroxide was found to be the best.

Theoretically, QAPAC can be synthesized by two different routes (an example of so-called "meeting synthesis"[6]) (Scheme 1).

Both routes were used, in order to confirm the nature of the product obtained. Diazotized 8-amino-quinoline was first coupled with chromotropic acid in sodium carbonate medium to give 2-(8-quinolylazo)-1,8-dihydroxynaphthalene-3,6-disul-phonic acid. The second coupling reaction was done in calcium hydroxide medium with diazotized aniline. The crude product was reprecipitated and further purified by column chromatography. QAPAC ob-tained in this way was examined by paper chro-matography and infrared spectroscopy, and gave the same results as the product obtained by the first reaction route.

Properties of QAPAC

QAPAC is a dark-purple amorphous powder, slightly soluble in water and ethanol, readily soluble

---
Scheme 1.

in N,N-dimethylformamide and strongly acidic or alkaline solutions.

In strongly alkaline solutions QAPAC is assumed to exist in a blue dissociated form (R^{4-}, $\lambda_{max} = 630$ nm). The absorption spectrum of QAPAC shows a

$$*k_i = \frac{[H_i R^{i-4}]}{[H^+][H_{i-1} R^{i-5}]}$$

hypsochromic shift when the pH is decreased. The protonation data for R^{4-} were obtained by means of pH–absorbance measurements.[7] The protonation constants found for the two naphthol oxygen atoms and the quinolyl nitrogen atom are: log $k_1 = 14.30$; log $k_2 = 11.27$; log $k_3 = 1.66$.* The log k value for protonation of the quinolyl group is fairly close to that for 1-(8-quinolylazo)-2-hydroxy-

naphthalene-3,6-disulphonic acid (1.48) reported by Basargin et al.[3]

Colour reactions of QAPAC with metal ions

QAPAC forms water-soluble, intensely coloured complexes with various metal ions. The reaction conditions and spectrophotometric characteristics of the complexes are presented in Table 1. The photometric sensitivity for certain metals is higher than that with other reagents. Calcium, for instance, can be determined with excellent sensitivity, the molar absorptivity of the 1:1 Ca-QAPAC complex in the absence of sensitizing agents being 2.46×10^5 $1.mol^{-1}.cm^{-1}$ at 726 nm. In the presence of dodecyl-dimethylaminoactic acid and 1,10-phenanthroline the molar ratio of Ca and QAPAC in the complex changes from 1:1 to 1:2, with better colour stability

and broader optimum pH-range (pH 4–10 instead of pH 4.3–4.9 in the absence of auxiliary agents), but the molar absorptivity falls slightly to 2.1×10^5. The selectivity is comparable with that of the Arsenazo III method. The QAPAC method has been applied to the determination of calcium in rain and snow samples; the experimental details are described elsewhere.[8]

Savvin et al. have described three types of colour reactions of alkaline-earth metal and some other elements with 2,7-bisazo derivatives of chromotropic acid. The absorption curve of the Ca–QAPAC complexes exhibits two humps at 726 and 660 nm (Fig. 1) and is quite similar to those of the third type of colour complexes reported by Savvin et al.[9,10] These authors interpreted the presence of two absorption maxima in the metal-complex spectrum as a consequence of a 1:2 sandwich structure, with two isolated reagent molecules in the complex.[10] However, according to our experimental results, QAPAC forms calcium complexes with a metal to ligand ratio of 1:1. Hence, in this instance the mechanism of the colour development requires to be examined further.

DETERMINATION OF SCANDIUM, YTTRIUM AND LANTHANIDES IN SILICATE ROCKS AND FOUR NEW CANADIAN IRON-FORMATION REFERENCE MATERIALS BY FLAME ATOMIC-ABSORPTION SPECTROMETRY WITH MICROSAMPLE INJECTION

J. G. Sen Gupta

Geological Survey of Canada, Ottawa, Ontario, Canada

Summary—Enhancement of sensitivity by factors of up to 1.5 by use of the microsampling technique, coupled with the advantage of using small samples in small solution volumes, permits rapid flame AAS determination of traces of Sc, Y, Nd, Eu, Dy, Ho, Er, Tm and Yb in ultramafic and most other rocks of low rare-earth content, which would be either impossible or very difficult to analyse by direct aspiration because of the need for much larger sample weights and solution volumes. The rare-earths are separated by a modified ion-exchange or a double calcium oxalate and single hydrous ferric oxide co-precipitation procedure, and ultimately determined in an ethanolic perchlorate solution, buffered with 1% lanthanum, by the flame microsample injection technique, with a nitrous oxide–acetylene flame. The results obtained by this technique for six international reference rocks SY-2 (syenite), BCR-1 (basalt), BHVO-1 (Hawaiian basalt), SCo-1 (cody shale), MAG-1 (marine mud) and STM-1 (syenite) are compared with those obtained previously by the direct aspiration method and with other reported data. Results are given for four new Canadian iron formation reference materials FeR-1 to FeR-4.

Abundance-studies on the rare-earths for petrogenetic modelling require their rapid determination in a variety of igneous and sedimentary rocks and rock-forming minerals. An earlier publication[1] described an atomic-absorption spectrometric (AAS) method for the determination of Y, Nd, Eu, Dy, Ho, Er, Tm and Yb in some minerals and rocks, by direct aspiration of the sample solution (in ethanolic perchlorate medium containing 1% lanthanum as spectroscopic buffer) into a nitrous oxide–acetylene flame. The rare-earth elements (REE) were separated from a relatively large sample (3–10 g) by double co-precipitation with calcium oxalate followed by a co-precipitation with hydrous iron oxide to remove calcium. Although this method is applicable to rare-earth minerals and to certain rocks of relatively high rare-earth content (*e.g.*, syenites, carbonatites, tuffs, foyaites, some basalts and granites), it is not suitable for ultramafic and some common rocks and rock-forming minerals (*e.g.*, peridotites, gabbros, basic gneisses, anorthosites, tonalites, certain shales and altered granites, atzites, sandstones, iron formations and pyroxenes) containing only a few ppm of REE, because of the difficulties in the decomposition and subsequent handling of the large amount (10–15 g) of sample required for preconcentration of the rare-earths. Use of a smaller sample (2–3 g) for the flame AAS determination of these rare-earth elements in these materials would require a small final solution volume (2–3 ml) after preconcentration of the ele-

ments as described previously,[1,2] so use of a flame microsample injection technique[3–5] has been investigated. This AAS finish has not been used before for the determination of the rare-earths in rocks. The ion-exchange procedure used previously for britholite[2] was modified in this work by using smaller volumes and higher concentrations of hydrochloric acid for rapid elution.

The microsampling method is easier to use than the graphite-furnace AAS technique normally favoured for trace element determinations, suffers less interference from associated elements and is much faster for routine work. The results obtained for six international reference rocks by this technique are compared with those obtained previously by the direct-aspiration flame method and with other reported data. Results are also given for four new Canadian iron-formation reference materials, FeR-1, FeR-2, FeR-3 and FeR-4.

EXPERIMENTAL

Apparatus

A Techtron model AA-3 spectrometer fitted with a Goguel-type water cooled burner[1] and a variable-flow nebulizer with an uptake rate of 4 ml/min, and equipped with some Techtron model AA-5 accessories such as a modulated lamp-current supply (Type MLS-5), lamp turret assembly and an indicating module (Type IM-5), was used for atomic-absorption measurements. Eppendorf multivolume micropipettes (100–1000 μl) and a Varian model 66 microsampler were used for sample dilution and for dispensing solutions into the flame. Up to 10-fold scale expansion on the IM-5 unit was used and the absorbance peaks were recorded on a Varian model 9176 strip-chart recorder with

§Varian hollow-cathode lamp.

a chart-speed of 200 cm/hr. The supply of compressed air or nitrous oxide and acetylene to the burner head was controlled by a Beckman gas-control unit.

Sensitivities and instrumental operating parameters are given in Table 1. An improvement of sensitivity by factors of up to 1.5 for most elements was obtained by using microsample injection instead of direct aspiration.

Ion-exchange column. Pack a 30-cm long Dowex 50W-X8 cation-exchange resin (50–100 mesh) column in the borosilicate glass apparatus shown in Fig. 1. Wash the column with 6M hydrochloric acid until the effluent is free from Fe^{3+} (test with ammonium thiocyanate solution), and then
Fig. 1. Ion-exchange column.

with demineralized water until the washings are neutral to blue litmus paper.

Reagents

Standard solutions. Prepare stock solutions (1000 ppm) of Sc, Y and the lanthanides by dissolving appropriate quantities of the pure oxides in hot dilute nitric acid. Remove the excess of acid by evaporation, dilute the solutions to known volume with 1M nitric acid and store them in Nalgene bottles. To standardize, transfer 5 ml to a 10-ml platinum crucible previously ignited to constant weight at 1000°, evaporate to dryness on a steam-bath, heat the crucible gently with a low Bunsen flame until no more fumes are evolved, then strongly with the full flame, and finally ignite in a muffle furnace at 1000° for 30 min. Cool in a desiccator for 30 min and weigh. Prepare working solutions (0.1–100 ppm) by appropriate dilution of the stock solution with 0.1M nitric acid and store them in Nalgene bottles.

Lanthanum buffers, 5% solutions. Prepare an aqueous solution by dissolving 5.85 g of high-purity lanthanum oxide in hot dilute nitric acid. Dilute to 100 ml with demineralized water and store in a 125-ml Nalgene bottle. To prepare an ethanolic solution, evaporate 25 ml of the aqueous solution to dryness on a hot-plate, add 10 ml of concentrated perchloric acid, evaporate to a moist residue, cool the covered beaker to room temperature, and add 10–15 ml of absolute ethanol. Warm on a steam-bath and stir to dissolve the salts, then transfer the solution to a 25-ml standard flask, dilute to volume with ethanol and store in a 30-ml Nalgene bottle.

Other reagents. Ferric nitrate solution (Fe 5 mg/ml in 1M nitric acid; ferric perchlorate solution (Fe 5 mg/ml in absolute ethanol); 10% nitric acid—5% hydrogen peroxide solution; 1.85M and 6M hydrochloric acid; 0.1M and 1M nitric acid.

Procedures

Calibration solutions. Using 100-ml standard flasks, prepare three stock standard solutions, diluted to volume with 1M nitric acid, containing Sc, Y, Th and the REE in amounts approximating those found in a 25-g sample of the international reference rocks GA (granite[6,7]), SY-2 and SY-3 (both syenites[7,8]) (see Table 2 and Note 1). Store the solutions in Nalgene bottles.

To 20-ml beakers, transfer 5, 10 and 15 ml of synthetic standard GA solution, 2.5, 5 and 7.5 ml of synthetic standard SY-2 solution, and 2, 3 and 4 ml of synthetic standard SY-3 solution. Add 1 ml of aqueous 5% lanthanum buffer solution to each beaker, evaporate the solutions to dryness, then add 2 ml of concentrated perchloric acid and evaporate to a moist residue. Cool each beaker, cover with a watch-glass

and dissolve the salts in 2–3 ml of absolute ethanol, stirring with a glass rod. Transfer the solutions to 5-ml standard flasks, dilute to volume with ethanol, then transfer to 8-ml glass vials and close the screw-caps tightly.

Prepare a blank for correction purposes after the ion-exchange separation of the rare earths, by diluting 1 ml of ethanolic 5% lanthanum buffer solution to volume in a 5-ml standard flask with absolute ethanol. Prepare a similar blank containing 6–10 mg of iron(III), as perchlorate, for correction purposes after the separation of the rare earths by co-precipitation. Transfer to 15-ml glass vials and close the screw-caps tightly.

Sample decomposition. Depending on the type of sample and the quantity available, transfer 2–3 g, accurately weighed, of the finely powdered sample to a 50- or 100-ml platinum dish and moisten with water. Cover the dish with a platinum lid and gradually, while stirring with a platinum rod, add 10–20 ml of concentrated hydrofluoric acid. Heat on a steam-bath for 2–3 hr, then remove the lid and rinse it in with water, and evaporate the solution to dryness. Add 10–20 ml of concentrated nitric acid to the residue, stir to break up any lumps, and evaporate to dryness.*

Add 15–20 ml of concentrated perchloric acid, stir the mixture until a thin slurry is produced, then cover the dish, and heat gently on a sand-bath until fumes of perchloric acid start to appear. Remove the lid, rinse in with water, stir to mix, then evaporate the solution to a syrupy consistency.

Cool the dish, add 25 ml of 10% nitric acid–5% hydrogen peroxide solution, cover and, with occasional stirring, heat on a steam-bath to dissolve the salts. Transfer the solution to a 400-ml beaker, rinse the dish thoroughly with water, cover the beaker with a watch-glass and boil vigorously to decompose the excess of hydrogen peroxide. If insoluble material is present or a precipitate forms on cooling, filter the solution through a Whatman No. 40 paper, wash with hot 10% nitric acid–5% hydrogen peroxide solution, then transfer the paper and residue to a platinum crucible and burn off the paper at ~400° in a muffle furnace. Ignite the residue at ~800° for 15 min, cool the crucible and, depending on the quantity of residue, add 0.5–1 g of potassium pyrosulphate. Mix thoroughly, then fuse the mixture over an open flame and keep the melt at red heat for a short time to ensure complete decomposition. Cool the crucible, add 15 ml of water, loosen the cake with a glass rod, then transfer to a 50-ml beaker. Heat on a hot-plate and add 50% sulphuric acid dropwise, if necessary, until a clear solution is obtained. Add this solution to the main solution.

Ion-exchange separation. Using a pH-meter, adjust the pH of the solution to 1.2 ± 0.2 by dilution with demineralized water, then transfer the solution to a 250-ml separatory funnel clamped at the top of the cation-exchange resin column. Pass the solution through the column at about 2.5 ml/min. Wash the beaker three times with 10-ml portions of acidulated water (pH 1.2 ± 0.2) and add the washings to the column.

Elute the common ions from the column with 250–300 ml of 1.85M hydrochloric acid (at 2.5 ml/min) until the effluent is free from Fe^{3+} (test with ammonium thiocyanate solution). Discard the effluent.

Elute the rare-earths, scandium and yttrium by passing 500 ml of 6M hydrochloric acid through the column at 2.5 ml/min. Collect the eluate in a 600-ml beaker, and evaporate it to about 5 ml. Transfer the solution to a 20-ml beaker, rinsing the original beaker with hot 6M hydrochloric acid. Evaporate the solution to a syrupy liquid on a hot-plate and finally to dryness on a steam-bath. Add 5 ml of concentrated nitric acid and 1 ml of 30% hydrogen

peroxide, cover the beaker with a watch-glass and heat on a steam-bath to decompose any resin and convert the chlorides into the nitrates. When the reaction has subsided, raise the watch-glass by means of glass hooks and evaporate the solution to dryness. Repeat the nitric acid–peroxide treatment and subsequent evaporation twice more to ensure complete decomposition of the organic material and conversion of the salts into nitrates. Dissolve the final residue in 5 ml of 0.1M nitric acid by stirring and warming briefly on a steam-bath, then transfer to a 10-ml standard flask and dilute to the mark with 0.1M nitric acid. If necessary, filter the 5 ml of solution through a 5.5-cm glass-fibre paper in a 58° funnel 35 mm in diameter, rinsing the beaker and washing the paper with 0.1M nitric acid, collecting the filtrate and washings in a 10-ml standard flask. This 10 ml of solution is Solution A.

Alternative preconcentration by oxalate and hydroxide co-precipitations. Preconcentrate the rare-earths by double oxalate co-precipitation with 0.2 g of added calcium, followed by a single hydrous oxide co-precipitation with 5 mg of added iron to remove the calcium.[1] After destruction of the paper containing the hydrous oxide residue, by three evaporations with concentrated nitric acid and 30% hydrogen peroxide, evaporate the solution to dryness on a steam-bath. Dissolve the salts in 5 ml of 0.1M nitric acid, stirring with a glass rod and briefly warming on a steam-bath, and make up to volume with the same acid in a 10-ml standard flask (filtering *etc.*, if necessary, as just described) to obtain Solution A.

Preparation of ethanolic perchlorate solution. If the sample weight was 3 g, transfer 8 ml (Note 2) of Solution A to a 10-ml beaker, add 0.6 ml of aqueous 5% lanthanum buffer solution and evaporate to dryness, then add 2 ml of concentrated perchloric acid and evaporate on an asbestos-covered hot-plate to a moist residue. Cool until no fumes are visible, then cover the beaker with a watch-glass. Add 1 ml of absolute ethanol and stir the mixture with a small glass rod to dislodge the solids and dissolve the salts. Transfer the solution to a 3-ml standard flask (available from Mandel Scientific Co. Ltd., Rockwood, Ontario), dilute to volume with absolute ethanol, then transfer the solution to a 5-ml glass vial and close the screw-cap tightly (Note 3).

If the original sample weight was <3 g, transfer 8 ml of Solution A to a 10-ml beaker, add 0.4 ml of aqueous 5% lanthanum buffer solution and evaporate with perchloric acid as above. Dissolve the salts in 1 ml of absolute ethanol, transfer the solution to a 2-ml standard flask, dilute to volume with ethanol, then transfer the solution to a 5-ml glass vial. In order to have sufficient volume for determination of the specified elements, transfer 0.5 ml to a 1-ml standard flask, add 0.1 ml of ethanolic 5% lanthanum buffer solution, dilute to volume with absolute ethanol, then transfer the solution to a 5-ml glass vial (Note 4). Close the screw-caps tightly to prevent evaporation losses.

AAS determination of Sc, Y, Nd, Eu, Dy, Ho, Er, Tm and Yb by flame microsample injection. After adjustment of the solution uptake into the lean nitrous oxide–acetylene flame (3–4 cm red feather) to 4 ml/min, with absolute ethanol as the test liquid, and optimization of the vertical and horizontal burner positions with 10-fold scale expansion and an ethanolic perchlorate solution of the appropriate element (containing ethanolic lanthanum buffer), connect one end of the uptake tubing to the burner nebulizer and the other end to the bottom of the injection funnel of the microsampler, which is firmly held on the vial tray by a mounting bracket.

With the AAS instrument set at 10-fold scale expansion and the strip-chart recorder at appropriate sensitivity, successively aspirate (Note 5) 200-μl portions of the blank, calibration and sample solutions by means of the injection funnel, in the following order: blank, low calibration solution (*e.g.*, synthetic GA), sample solution, blank, high calibration solution (*e.g.*, synthetic SY-2 or SY-3). Between each aspiration, wash the funnel and the capillary tube with

---

*For shale samples of high carbon content (2–8%), place the dish on a silica triangle supported on a tripod, cover and heat gently with a Bunsen burner until all acid fumes are expelled and all organic material is destroyed. Heat briefly to red heat, cool, then proceed as described.
Fig. 2. Absorbance peaks and calibration curve (inset) for erbium: A, blank (1% La buffer solution); B, 1 ppm Er; C, 2 ppm Er: D, 3 ppm Er; E, capillary tube and spray chamber cleaned with absolute ethanol between injection of samples. Approximately 10-fold scale expansion was used.

a jet of absolute ethanol from a wash bottle until the flame shows no colour due to sample salts and lanthanum. Use a fresh pipette tip for each solution (Note 6).

Correct the absorbance value obtained for each calibration solution and plot absorbance of the particular rare-earth element vs. its concentration. Determine the corresponding rare-earth content of the sample solution by reference to the calibration curve, after correction for the blank. Monitor the recovery by determination (in the same run) of the same element in two international reference rocks for which "usable values"[7] for the REE are available.

Notes

1. Since in the flame AAS determination of REE there are no interelement interferences among the rare-earths in
Fig. 3. Absorbance peaks and calibration curve (inset) for ytterbium: A, blank (1% La buffer solution); B, 0.4 ppm Yb; C, 0.8 ppm Yb; D, 1.2 ppm Yb; E, capillary tube and spray chamber cleaned with absolute ethanol between injection of samples. Approximately 10-fold scale expansion was used.

the presence of 1% lanthanum spectroscopic buffer,[1] such solutions provide handy standards for the specified elements for preparation of calibration curves.

2. The remaining 2 ml of Solution A can be used for the determination of other rare-earths by electrothermal AAS.[9-12]

3. For a sample of high scandium or REE content it may be necessary to dilute the initial solution to a suitable volume with absolute ethanol before the AAS determination. Sufficient ethanolic 5% lanthanum solution must be added for the final concentration of lanthanum to be 1% by weight.

4. The determination of Sc (see Note 3 above), Dy and Yb should be completed from this diluted solution, and the original sample solution should be used for determination of Y, Nd, Eu, Ho, Er and Tm.

5. For recording absorbances of most standards and sample solutions use the recorder set at 10 mV full-scale deflection. Additional scale expansion may be obtained by using 5 mV full-scale deflection (useful for very low Nd, Eu and Ho contents).

6. Do not discard the blue pipette tips after use. Wash them thoroughly in tap water, followed by demineralized water, then dry at room temperature overnight.

RESULTS

Figures 2 and 3 show that for the concentration ranges tested the absorbance peaks obtained for erbium and ytterbium with the microsampling technique are reasonably reproducible, and linear calibration graphs are obtained. Similar results were obtained for Sc, Y, Nd, Eu, Dy, Ho and Tm in suitable concentration ranges.

The reliability of the proposed method was tested by applying it to the analysis of the synthetic GA, SY-2 and SY-3 solutions prepared for calibration purposes. It was also applied to various Canadian and U.S.G.S. reference rocks for which published data on the REE are available for comparison, and to four new Canadian iron formation reference materials FeR-1, FeR-2, FeR-3 and FeR-4. The results of these determinations are given in Tables 2–4.

DISCUSSION

Table 2 shows that complete recovery ($100 \pm 5\%$) of the added REE was obtained after their separation by double calcium oxalate and hydrous ferric oxide co-precipitation. Tables 3 and 4 show that the results obtained for six international reference rocks, in which the REE were preconcentrated by double calcium oxalate and hydrous ferric oxide co-precipitation for all six and by ion-exchange for four of them, are in reasonably good agreement with those obtained by the author by direct-aspiration flame AAS.[1,9,13,14] There is also satisfactory agreement with the author's graphite-furnace AAS and emission spectrographic values,[9,10,14] and the "usable values" reported in compilations of data by Abbey[7,8] (the value with a question mark indicates uncertainty about the "usable value" because it represents the *median* of only 5–9 available results[7]) and the "mean values ± standard deviations" reported in compilations of data by Gladney *et al.*[15,16] Where sufficient values are not available in such com-

pilations, other published values[17-19] are included for comparison purposes.

The results obtained by the proposed method for the Canadian iron formation reference materials either compare well with the "usable value?" reported in a recent compilation of data by Abbey *et al.*[20] or fall within the range of other values (Table 4). Values for neodymium (except FeR-2), erbium and thulium have not hitherto been reported.

Although the results obtained by the two separation methods are in good agreement with each other and with published values, the ion-exchange method is somewhat the faster. The proposed method is also applicable to the determination of large amounts of lanthanum and samarium in some rocks rich in rare-earths. It is considerably quicker than methods based on direct aspiration of the sample solution, particularly for ultramafic and other common rocks containing trace rare-earths, because of the saving of time in preconcentration of REE from a relatively small sample. It has been applied to the routine determination of the specified REE in shales and mafic dykes.

The use of the microsampling technique has resulted in significant saving of time and simplification of the sample dissolution and preconcentration procedures for the determination of traces of rare-earths in ultramafic and many common rocks and rock-forming minerals. The results are in reasonably good agreement with those of direct flame aspiration and graphite-furnace AAS methods which require a much longer time for such determinations.

DETERMINATION OF CERIUM IN SILICATE ROCKS BY ELECTROTHERMAL ATOMIZATION IN A FURNACE LINED WITH TANTALUM FOIL

APPLICATION TO 19 INTERNATIONAL GEOLOGICAL REFERENCE MATERIALS

J. G. Sen Gupta

Geological Survey of Canada, Ottawa, Ontario, Canada

Summary—A 40-fold increase in sensitivity obtained by using a tantalum foil lining in a pyrolytically-coated graphite furnace permitted determination of low ppm levels of cerium in most silicate rocks. A preliminary preconcentration by oxalate and hydroxide co-precipitations was used before determination by use of a Varian GTA-95 atomizer coupled with an AA-475 spectrometer. The results for 3 synthetic and 19 international reference materials, including 4 new Canadian iron-formation reference materials, showed good recovery and satisfactory agreement with other published values.

The determination of cerium by atomic-absorption spectrometry has always been a baffling problem because of the low sensitivity for the element, whether a flame or a graphite furnace is used. Attempts to determine this element by use of an oxy-acetylene[1] or nitrous oxide–acetylene flame[2] were not successful. The detection limit of 150 ppm of Ce obtained by Thomas[3] by use of a fuel-rich N_2O–C_2H_2 flame is of hardly any use in rock analysis. This poor detection limit was attributed to the complexity of the low-intensity cerium spectra, more than 60% ionization of the cerium atoms, and the tendency to form CeO molecules in the gas phase.[3] When the graphite furnace is used, there is difficulty in volatilizing cerium because of the formation of its carbide or an interlayer compound with graphite. Although L'vov and Pelieva[4] noted a significant increase in sensitivity for most rare-earth elements when a graphite furnace lined with tantalum foil was used, cerium was not included in that study. In a subsequent publication[5] these authors reported a detection limit of 3–5 ng for cerium by use of the furnace lined with tantalum foil, after evaporation of the cerium and excess of lanthanum from a tungsten probe. Although mention was made of the application of a tungsten probe soaked in a solution of iron, in the determination of 0.05–0.23% cerium in some low-alloy steels, no data were reported. No other information is available on the application of a tungsten probe or simply a tantalum-foil lined furnace to the determination of cerium in geological materials.

After our acquisition of a Varian graphite-tube atomizer (GTA-95) and a Westinghouse hollow-cathode cerium lamp, it was possible to test the

sensitivity for cerium by electrothermal atomization. With use of an argon gas purifier and a tantalum foil lining to the furnace, an average sensitivity of 5 ng was obtained at 567.0 nm and a temperature of 2600°. In concurrence with the observation of L'vov and Pelieva,[5] the 567.0 nm line was found to be slightly more sensitive than the 520.1 nm line and relatively free from incandescence effects from the furnace at 2600°. However, addition of lanthanum (2.5 μg) to enhance the cerium signal and linearize the calibration, as done by L'vov and Pelieva,[5] complicated the problem of determination of very small amounts of cerium, because the lanthanum gave significant absorption at 567.0 nm. Therefore, all determinations were done without addition of lanthanum.

The method developed was tested with synthetic solutions and a number of international reference samples of established cerium contents, and applied to the determination of cerium in four new Canadian iron-formation reference materials.

EXPERIMENTAL

Apparatus and operating parameters

A Varian graphite-tube atomizer (GTA-95) equipped with a programmable sample dispenser and memory storage for 8 operating-parameter programmes, and coupled with a Varian AA-475 spectrometer fitted with IEEE communication, was used for all atomic-absorption studies. Other accessories included an Epson MX-82 Type III printer with IEEE interface, pyrolytically-coated tubes, tantalum foil (99.95% pure, 0.05 mm thick, A.D. Mackay, Darien, Conn., U.S.A.), argon gas (99.999% pure) connected through a gas purifier (Matheson, Model 6406), and a Radiometer 22 pH-Meter.

The AA-475 spectrometer was operated on single beam with restricted 0.5-nm bandpass, in the peak-height mode; a 1-sec integration-time was used in setting zero absorbance

*$0.1 M$ nitric acid.

on the instrument. A Westinghouse cerium hollow-cathode lamp was used, operated at 10 mA. The signal, at 567.0 nm, was maximized in the usual way. Other operating parameters are given in Tables 1 and 2.

Preparation of furnace lined with tantalum foil

A 2-mm hole was drilled in a 12 × 14 mm piece of tantalum foil (Fig. 1). The foil was wrapped on a 4-mm glass rod as a former (short side parallel to the rod) and the tube thus made was inserted into the centre of a new pyrolytically-coated graphite tube (PCGT) so that the holes in both tubes coincided. A metal rod (3 mm diameter) was inserted into the tube, and firmly rolled inside it (on the bench top) to attach the tantalum foil smoothly to the inner lining of the graphite tube, over the "hump" at the centre of the tube. This was the only way found for fitting the liner so that no blockage of the light-path was caused by distortion of the foil on heating. A further step to prevent distortion (and embrittlement of the foil) was a careful annealing. For this, the tantalum-lined graphite tube was placed in the GTA-95, and before first use, it was heated in a current of argon according to the following programme. The tube was brought to 1000° in 10 sec, held at that temperature for 10 sec, and then cooled down in 16 sec. This

operation was repeated for temperatures of 1500° and 2000°, followed by a blank run according to the heating programme in Table 1.

Sensitivity

The characteristic amounts found for cerium (i.e., weight producing 1% absorption) are given in Table 3. The memory effect after atomization from the tantalum surface at 2600° for 4.3 sec was negligible. Although atomization at 2700° gave a further increase in sensitivity, there was more rapid deterioration of the liner so 2600° is recommended as the maximum temperature to be used.

Reagents

Stock solution of cerium (~ 1000 ppm). Prepared by dissolving an accurately weighed quantity of CeO_2 (99.999% pure, Spex Industries Inc.) in hot dilute nitric acid with the addition of few drops of 30% hydrogen peroxide. The solution was evaporated to dryness on a steam-bath, and the salts were dissolved in $1 M$ nitric acid and diluted to known volume with the same acid. A 5-ml aliquot was evaporated in a 10-ml weighed platinum crucible on a steam-bath, the nitrate was decomposed by gentle heating with a Bunsen burner, and finally the crucible and contents were ignited to constant weight at 1000° to determine the CeO_2 content. Solutions of lower concentration (100 or 10 ppm) were prepared by appropriate dilution with $0.1 M$ nitric acid.

Stock solutions of other rare-earth elements. Prepared by dissolving the high-purity oxides (Spex Industries Inc.) in dilute nitric acid, and standardized as for the cerium solution.

Synthetic standard mixtures. Synthetic standard mixtures approximating the compositions (except for the common elements) of three international reference samples [GA (granite), SY-2 (syenite) and Sy-3 (syenite)] were prepared by mixing the standard solutions in appropriate amounts (see Table 4).

Interferences

In order to determine cerium in rocks it was necessary to separate the rare earths from common elements. Although no interference from the associated rare earths from common rocks was noticed, addition of 2.5 μg of lanthanum (as recommended[5] for enhancing the cerium signal) was found

Fig. 1. Shape and dimensions of the tantalum foil.

Table 3. Sensitivities for cerium in pyrolytically-coated and tantalum-foil lined furnace (GTA-95)

Atomization temperature, °C	Sensitivity*		
	Pyrolytically-coated graphite tube (PCGT)	Ta-foil lined furnace (TaF)	Sensitivity enhancement factor (PCGT/TaF)

*These values were derived from the author's own published and unpublished works as well as those found in the literature.

to increase the signal at 567.0 nm because of absorption by the lanthanum. Since this complicated the problem of determination of very small amounts of cerium (0.1–0.6 μg) because of uncertainty as to the cerium contribution to the total absorbance value, no additional lanthanum was added in this work. The La:Ce ratio in most rocks is about 1:2, but it was found that lanthanum could be tolerated up to a ratio to cerium of 1:1. No interferences were noticed from the presence of relatively large amounts of iron (up to 500 ppm). Therefore, rare earth concentrates obtained by double oxalate co-precipitation with calcium, followed by a hydroxide co-precipitation with iron,[6-8] were found to be suitable for

the electrothermal atomic-absorption determination of cerium.

Recommended procedure

Decompose a 3-g sample and separate the lanthanides from the common elements by double co-precipitation with calcium oxalate and then from excess of calcium by single co-precipitation as hydroxide with 5 mg of iron, as described earlier.[6-8] Destroy the filter paper by heating with concentrated nitric acid and 30% hydrogen peroxide and evaporating to dryness on the steam-bath, then dissolve the salts in 0.1M nitric acid and, depending on the concentration of cerium expected, dilute the solution to exactly 5 or 10 ml with the same acid. For solutions containing higher amounts of cerium (*e.g.*, for samples of SY-3 type) dilute further with 0.1M nitric acid to bring the cerium concentration within the range 10–30 ppm. Store all sample solutions in glass vials tightly closed with screw-caps. Using the operating parameters mentioned earlier and those in Tables 1 and 2, prepare the calibration graph by atomization of 0.1–0.6 μg of cerium in the furnace lined with tantalum foil. Use up to 5× scale-expansion, and take the average reading from two atomizations.

RESULTS AND DISCUSSION

The results for 3 synthetic solutions and 19 international reference rocks are given in Table 5 and compared with the expected or published values. Quantitative recoveries were obtained for the synthetic solutions and the results for the reference samples either agreed with the recommended values or fell within the mid-range of other values.

The condition of the tantalum-foil liner was checked by running a standard after every five samples, and if necessary a correction was applied to the adjacent sample. The tantalum foil was changed after

ETUDE DE LA CAPACITE COMPLEXANTE DES EAUX DE L'ESTUAIRE ET DE LA BAIE DE SEINE

Jean-Claude Fischer, René Nganou et Michel Wartel
Université des Sciences et Techniques de Lille, Laboratoire de Chimie Analytique et Marine,
Bâtiment C 8, Station Marine de Wimereux, 59655 Villeneuve d'Ascq Cedex, France

Résumé—Le dosage des métaux Cd, Pb et Cu dans l'estuaire et en Baie de Seine a été effectué. Le site a été choisi en raison du régime macrotidal fortement marqué qui régit les déplacements des masses d'eau. Une répartition des métaux en trois classes est proposée (métal libre, métal engagé dans des complexes détruits par abaissement du pH, métal engagé dans des complexes stables détruits par irradiation ultraviolette en milieu acide). Les propriétés particulières du cuivre ont été utilisées afin d'établir une capacité complexante apparente des différentes eaux étudiées. En faisant l'hypothèse simplificatrice de l'existence d'un équilibre du type (charges omises)

$$Cu + L \rightleftharpoons CuL$$

(L symbolisant le ligande), les concentrations totales du ligande ainsi que les constantes de stabilité des complexes CuL ont été déterminées. Les résultats obtenus sont discutés.

Notre attention s'est portée, dans ce travail, sur le comportement du cadmium, du plomb et surtout du cuivre dissous dans les eaux de l'estuaire de la Seine, afin de contribuer à une meilleure connaissance des modes de transport et du devenir des métaux lourds au sortir d'un fleuve débouchant dans une mer soumise à un régime macrotidal. Peu de mers, à l'échelle planétaire, possèdent des amplitudes et des circulations de marée aussi importantes.

La répartition du métal entre ses différentes formes solubles influence non seulement la biodisponibilité de ce métal, mais joue également un rôle important dans son devenir en raison de l'existence de complexes qui peuvent induire des phénomènes de co-précipitation, des retards à la précipitation ... *etc.*, et entraîner ainsi des modifications des temps de résidence.

Il nous a donc paru judicieux d'établir un classement des divers complexes dans lesquels sont engagés les métaux étudiés. Dans l'état actuel des connaissances des processus qui permettent au milieu marin de conserver son équilibre, il est illusoire de prétendre établir un classement rigoureux rendant compte de tous les phénomènes. C'est la raison pour laquelle notre choix s'est porté sur une méthode simple qui a de plus l'avantage de limiter les risques de pollution accidentelle.[1] C'est ainsi que nous avons, par la technique de redissolution anodique en mode impulsionnel différentiel, effectué les analyses des métaux cadmium, plomb et cuivre dans les différents échantillons au pH naturel, puis en milieu acide avant et après irradiation ultraviolette. Nous pouvons ainsi proposer un classement du type:

—métal "libre"

—métal engagé dans des complexes détruits par abaissement du pH

—métal engagé dans des "complexes stables" détruits par irradiation ultraviolette en milieu acide.

Un tel classement met bien en évidence le relargage des métaux lors du mélange des eaux douces et salées.

Dans un second temps, nous nous sommes intéressés à la capacité complexante apparente des eaux étudiées. Le métal, retenu pour cette étude, a été le cuivre en raison de sa faculté de former généralement des complexes avec la quasi-totalité des ligandes organiques présents dans les eaux naturelles, plus stables que ceux formés par les autres métaux étudiés. La méthode employée de détermination de la capacité complexante apparente des eaux de l'estuaire de la Seine est dérivée de celles proposées dans la littérature.[2-4]

PARTIE EXPERIMENTALE

Quatre sites de prélèvements ont été choisis en Seine et dans l'estuaire de la Seine: Saint-Aubin (en amont de la ville de Rouen), Quilleboeuf, Honfleur et au Cap de la Hève (Figure 1). Tous les prélèvements ont été effectués en septembre 1982 à 1 m au-dessous de la surface. Les échantillons ont été filtrés sur membrane Sartorius de porosité 0,45 μm. La conservation a été assurée par acidification à l'aide d'acide nitrique (pH $\sim$ 1,0) et par congélation pour les eaux non acidifiées. Tous les récipients utilisés sont en polyéthylène haute densité et ont été conditionnés avant utilisation.

Les métaux cadmium, plomb et cuivre ont été dosés par redissolution anodique en mode impulsionnel différentiel (technique analytique parmi les plus sensibles[5,6]) à l'aide de l'ensemble (Tacussel) suivant: unité polarographique UAP 4, potentiostat PRT 20.2X, unité Polaromax, électrode tournante EDI CVJ á disque de carbone vitreux (le film de mercure est formé in situ: addition de nitrate mercurique préparé par attaque de mercure métallique), cellule de mesure étanche en quartz.

Toutes les manipulations sont effectuées sous une hotte à flux laminaire.
Fig. 1. Sites de prélèvements. ①: Cap de la Hève ②: Honfleur ③: Quilleboeuf ④: Saint-Aubin *: limite amont de l'intrusion saline.

L'irradiation ultraviolette des échantillons a été effectuée à l'aide d'un appareillage construit au laboratoire selon le modèle décrit par Gillain.[1] Cet appareillage comporte une série de tubes de quartz horizontaux entourés de lampes ultraviolettes (lampes Philips, 15 W puissance maximum entre 2482 et 2753 Å). Les tubes de quartz, contenant l'échantillon (1/3 du volume du tube), sont soumis à une lente rotation afin d'augmenter le rendement de l'irradiation (formation d'un film de liquide sur les parois du tube). La durée d'exposition est de 12 hr. Une addition de peroxyde d'hydrogène Normapur Prolabo est effectuée avant irradiation (0,025 ml pour 50 ml d'échantillon).

Pour la préparation des échantillons destinés à l'étude de la capacité complexante, nous avons respecté la méthode suivante:

—additions de cuivre en quantité connue et croissante dans différents échantillons (généralement 10) provenant d'un même site le plus rapidement possible après le prélèvement et la filtration;
—congélation dans l'attente de l'analyse;
—décongélation programmée avant l'analyse, afin de laisser aux échantillons le même temps de mise à l'équilibre; chaque échantillon a ainsi été analysé 24 hr après la décongélation.

RÉSULTATS ET DISCUSSION

Parmi les diverses méthodes de classement des métaux en leurs différentes formes solubles décrites dans la littérature,[7,8] nous avons retenu celle qui nécessite le moins de manipulations de l'échantillon et le moins d'additions de réactifs afin de minimiser les risques de pollution.[1] Cette technique de spéciation consiste à doser les métaux Cd, Pb et Cu contenus dans la colonne d'eau (échantillons filtrés sur membrane 0,45 μm) au pH naturel puis en milieu acide avant et après irradiation ultraviolette (l'acidification des échantillons est faite sur les lieux du prélèvement).

Nous avons reporté dans le Tableau 1 les résultats d'analyse, par redissolution anodique en mode impulsionnel différentiel, des métaux Cd, Pb et Cu pour les différents sites de prélèvement. La colonne I représente la concentration en métal dit libre, c'est-à-dire directement accessible par la méthode de dosage. Il est clair que cette concentration dépend de la technique analytique choisie et dans notre cas particulier, elle dépend également de la valeur du potentiel appliqué à l'électrode indicatrice pendant la phase de dépôt (−1,2 V par rapport à l'électrode au calomel pour le dosage du plomb et du cadmium et −0,8 V pour le dosage du cuivre). La répartition que l'on pourra déduire par la suite ne pourra donc être qu'arbitraire. On peut noter que pour les sites de Saint-Aubin, de Quilleboeuf et de Honfleur, aucun pic de redissolution n'a pu être détecté au pH naturel, c'est-à-dire qu'aucun complexe métallique n'a été détruit pendant la phase de dépôt. Nous avons là un premier indice du caractère complexant marqué de ces eaux naturelles. La colonne II donne les valeurs des concentrations métalliques obtenues en milieu acide (acide nitrique, pH ∼ 1,0). La différence entre ces deux colonnes permet d'obtenir la quantité de métal engagé dans des complexes détruits par un abaissement du pH. Pour les sites de Saint-Aubin et de Quilleboeuf, les dosages manquent de reproductibilité. L'accroissement des teneurs métalliques peut être dû:

—à la dissolution d'oxydes (comme MnO_2) ou d'hydroxydes (surtout ceux de fer), composés jouant un rôle important dans le transport des métaux en raison de leur forte capacité d'adsorption;
—à la désorption de colloïdes d'origine minérale ou organique;
—à la protonation de certains complexes organiques.

La colonne III donne les teneurs métalliques après irradiation ultraviolette en milieu acide. Nous observons une nouvelle augmentation des concentrations des différents métaux, augmentation imputable à la destruction par l'irradiation ultraviolette de formes non électroactives essentiellement d'origine organique. Les teneurs métalliques figurant dans cette dernière colonne sont considérées comme représentatives de la concentration totale des différents métaux.[9]

Nous avons reporté sur la Figure 2 la répartition du cadmium, du plomb et du cuivre dans les trois classes:

—métal "libre";
—métal engagé dans des complexes détruits par abaissement du pH (origine minérale essentiellement);
—métal engagé dans des complexes détruits par irradiation ultraviolette en milieu acide (principalement d'origine organique).

Ce classement, bien que dépendant de la technique analytique utilisée, montre bien le relargage des métaux d'amont en aval. Pour les sites de Saint-

Aubin et de Quilleboeuf, la distinction des différents groupes n'a pu être réalisée en raison du caractère très complexant des eaux. C'est la raison pour laquelle nous avons, pour ces deux sites, regroupé les deux classes:

—métal engagé dans des complexes détruits par acidification;
—métal engagé dans des complexes détruits par irradiation en milieu acide.

Ces résultats nous ont conduit à étudier l'évolution de la capacité complexante apparente des eaux le long de l'estuaire de la Seine (la limite amont de l'intrusion saline est située bien au-delà du site de Quilleboeuf), et à nous intéresser plus particulièrement à la dernière classe de complexes: les complexes métalliques détruits par irradiation en milieu acide. En effet, ces derniers sont directement liés à la quantité des complexants organiques dissous, principaux responsables du pouvoir complexant des eaux naturelles. Pour effectuer cette étude, nous avons, comme de nombreux auteurs, utilisé le cuivre qui a la propriété de former des complexes stables avec la plupart des ligandes organiques.[10] Nous avons donc considéré l'équilibre $Cu + L \rightleftharpoons CuL$, où L symbolise le ligande organique susceptible de former le complexe CuL "stable". Les charges ont été omises pour plus de clarté. La concentration du cuivre "libre" supposée accessible par la technique analytique utilisée (redissolution anodique en mode impulsionnel différentiel) a été suivie lors d'ajouts connus de cuivre à différents échantillons provenant d'un même site de prélèvement. Le cuivre ajouté a été laissé en contact 24 hr avec la solution afin de permettre aux équilibres de s'établir (voir partie expérimentale). Nous avons reporté sur la Figure 3 les courbes obtenues en traçant concentration de cuivre trouvée en fonction de la concentration ajoutée de cuivre, pour les différents sites de prélèvement. Toutes les courbes tendent vers une asymptote (droite dont la pente est égale à l'unité—droite en pointillés sur la figure). Nous avons déterminé les points d'intersection des différentes asymptotes avec l'axe des abscisses par la méthode décrite par Plavsic et al.[11] En posant $K = [CuL]/[Cu][L]$, $(Cu)_T$ = concentration totale en cuivre, c'est-à-dire concentration initiale + concentration ajoutée, et $(L)_T$ = concentration totale en ligande, on montre que:

$$\frac{[Cu]}{(Cu)_T - [Cu]} = \frac{[Cu]}{(L)_T} + \frac{1}{K(L)_T}$$

Nous avons reporté, sur la Figure 4, les courbes obtenues en traçant:

$$\frac{[Cu]}{(Cu)_T - [Cu]} = f[Cu]$$

Nous obtenons des droites dont la pente permet de déterminer $(L)_T$ et l'ordonnée à l'origine le produit $K(L)_T$. Cette méthode permet donc également de déterminer les constantes de stabilité K. Les concen-

Fig. 2. Répartition des métaux Cd, Pb et Cu dans les sites de prélèvements: A: Cap de la Hève; B: Honfleur; C: Quilleboeuf et Saint-Aubin. ▦ Métal engagé dans des complexes non différenciables détruits par abaissement du pH et par irradiation ultraviolette. ▦ Métal engagé dans des complexes détruits par irradiation ultraviolette en milieu acide. ▦ Métal engagé dans des complexes détruits par abaissement du pH. ▦ Métal libre.

trations des ligandes et les différentes constantes ainsi déterminées sont reportées dans le Tableau 2. Il faut noter que les valeurs des coefficients de correlation relatifs aux droites obtenues confirment la validité de l'approximation faite quant à la formation d'un complexe 1:1 du type CuL.

Les valeurs des concentrations totales de ligande $(L)_T$ trouvées permettent de tracer les asymptotes aux courbes de la Figure 2. Ce sont ces valeurs que retiennent certains auteurs comme estimation de la capacité complexante des eaux naturelles.[3] Pour notre part, nous avons préféré utiliser un autre critère. En effet, l'examen des valeurs de $(L)_T$ semblerait montrer que les eaux du site de Honfleur sont, des eaux

étudiées, les plus complexantes, ce qui est en désaccord avec les résultats obtenus lors de notre ébauche de "spéciation" (Tableau 1 et Figure 2). Nous avons préféré utiliser à la fois la concentration du ligande et la valeur de la constante de stabilité du complexe correspondant. Nous avons donc reporté dans le Tableau 2 les valeurs du produit $K(L)_T$. Nous obtenons ainsi un classement des capacités complexantes apparentes en accord avec nos résultats de spéciation. Dans les sites étudiés, en général la concentration initiale en cuivre est petite devant la concentration totale en ligande, ce qui entraîne:

$$K(L)_T \sim [CuL]/[Cu]$$

Le produit $K(L)_T$ nous renseigne donc directement, dans la plupart des cas, sur la valeur du rapport: métal complexé/métal libre.

Nous avons reporté également dans le Tableau 2 les valeurs, concernant d'autres sites, calculées à partir de résultats relevés dans la bibliographie.[11] Les concentrations de ligande et les constantes de stabilité relatives aux sites "Lac Huron" et "Onaping river" ont été déterminées par une méthode basée sur l'adsorption des métaux par le dioxyde de manganèse. Il faut noter que les résultats obtenus ne semblent pas dépendre de la méthode utilisée, tout au
Fig. 3. Courbes obtenues en traçant: Cu trouvé en fonction de Cu ajouté (indices des courbes: voir légende de la figure 1) la droite en pointillés correspond à la droite de pente égale à l'unité. Détermination des asymptotes: voir texte.

ultraviolette. La répartition obtenue le long de l'estuaire montre que dans la détermination de la capacité complexante apparente des eaux étudiées, on ne peut se limiter à la seule détermination de la concentration totale du ligand comme l'ont préconisé certains auteurs. Il est nécessaire de tenir compte de la valeur de la constante de stabilité du complexe formé. Nous proposons donc d'utiliser le produit de la concentration du ligand par la constante de stabilité du complexe comme grandeur définissant la capacité complexante apparente.

Nous nous proposons, dans un prochain travail, d'étudier l'influence des particules en suspension sur le pouvoir complexant des eaux naturelles.

moins en ce qui concerne les eaux de rivière "Onaping river" et "Saint Aubin". Pour ces derniers sites les capacités complexantes sont tout à fait comparables.

CONCLUSION

L'étude du comportement des métaux Cd, Pb et Cu dans la colonne d'eau de l'estuaire de la Seine a été effectuée par redissolution anodique en mode impulsionnel différentiel. Les différentes formes métalliques solubles ont pu être classées en trois groupes: métal libre et métal engagé dans des complexes détruits en milieu acide avec ou sans irradiation

Summary—Analyses for the metals Cd, Pd and Cu in the estuary and bay of the Seine have been made. The site was chosen because of the very high tides, which produce considerable water displacement. For the purpose of analysis the metals have been divided into three categories: free metals, metals forming complexes that are unstable at low pH, and metals forming stable complexes that are destroyed in an acidic medium by ultraviolet radiation. The special properties of copper have been used to establish a "complexing capacity" of the different water samples studied. By making the simple hypothesis of the existence of an equilibrium of the type $Cu + L \rightleftharpoons CuL$, where L represents the ligand, the total ligand concentration, as well as the stability constants of the CuL complexes, has been determined. These results are presented and discussed.

PRECISE AND ACCURATE DETERMINATION OF HIGH CONCENTRATIONS OF SULPHUR BY ISOTOPE-DILUTION THERMAL-IONIZATION MASS-SPECTROMETRY

W. R. Kelly and P. J. Paulsen

Center for Analytical Chemistry, National Bureau of Standards, Washington, D.C. 20234, U.S.A.

Summary—An isotope-dilution thermal-ionization mass-spectrometric procedure has been developed for the accurate and precise determination of sulphur in steels and organic-based materials. The sample and isotopically enriched sulphur spike are dissolved in a sealed tube to prevent loss of sulphur and the sulphur isotopes are measured as AsS^+ ions, with silica gel as an emitter. This technique has been applied to the determination of sulphur in 13 NBS Standard Reference Materials ranging in concentration from 0.03 to 5% S. The relative uncertainty for a single determination is typically 0.5% (95% confidence interval) and arises primarily from the uncertainty in the spike calibration and from sample inhomogeneity.

The precise and accurate determination of the total sulphur (S) content in some materials is of great importance. The S content in coal is important because many states have laws which forbid the burning of coal which has more than a certain S content, typically 1%. The S concentrations in the SRM coals reported here cover the range typical of coals used in industry and power generation. The S content of fly-ash is important for the measurement and control of particulate S emissions. The S content of plants can reflect their exposure to atmospheric SO_2.[1-3] The determinations of S in the diverse materials in this study provide the S standards needed for calibration of automated S analysers and provide quality assurance for these important environmental measurements.

We have recently reported on a new procedure for the determination of S at concentrations below 0.01% in copper and iron-based materials.[4] In this procedure ^{34}S enriched tracer is added to a sample and all the S is oxidized to sulphate in a closed system. Subsequently, the sulphate is reduced to H_2S and the sulphur precipitated as As_2S_3. A small portion of an ammoniacal solution of this compound, equivalent to 1.5 μg of S, is added to a flat rhenium filament coated with silica gel, used as an emitter. The S isotopes are measured as the AsS^+ ions. We showed that the analytical blank of about 0.3 μg of S was the largest source of uncertainty in the determination of low S concentrations.[4] In this study these techniques have been applied to materials of high S concentration.

The inherent high precision of thermal ionization makes this technique the method of choice for accurate and precise S determinations at high levels where the uncertainty due to the blank is negligible. The chemical procedure for isolating S is matrix-independent.[4,5] Once the samples have been dissolved, they are all processed identically to obtain the As_2S_3 precipitate. In this paper we demonstrate the wide application of this technique by determining high S concentrations in such diverse materials as steels, coal, fly-ash, bovine liver, powdered milk and citrus leaves.

EXPERIMENTAL

Reagents

NBS sub-boiling distilled nitric acid and hydrochloric acid were used to dissolve samples. The reducing solution consisted of ACS reagent grade hypophosphorous acid (61 ml), hydriodic acid (125 ml) and hydrochloric acid (205 ml), as described by Thode *et al.*[5]

The ^{34}S-enriched spike in the form of elemental S was obtained from Mound Laboratory (Mosanto Research Corporation*). Standard solutions of known S concentration were prepared from high-purity anhydrous sodium sulphate and potassium sulphate. Aqueous ammonia solution was prepared by bubbling high-purity ammonia into distilled water. An As(III) solution (1000 μg/ml) was prepared by dissolving NBS SRM 83c (As_2O_3) in aqueous ammonia solution.

The silica gel used for the mass-spectrometric loading was premixed with phosphoric acid and this mixture was neutralized with aqueous ammonia solution. The details of the preparation of these reagents and solutions were reported earlier.[4]

Apparatus

All glassware and the modified Carius tubes were made of borosilicate glass. The reduction apparatus consisted of a 100-ml flask fitted with a 15-cm water-cooled condenser, a 25-ml bubbler and a Pasteur pipette. The flask had a side-arm through which nitrogen was injected into the flask to sweep the H_2S from the reducing solution in the flask, through the condenser, into the bubbler, and then into the centrifuge tube containing 1 ml of the As(III) solution.

---

*Certain commercial equipment, instruments, or materials are identified in this report to specify adequately the experimental procedure. Such identification does not imply recommendation or endorsement by the National Bureau of Standards, nor does it imply that the materials or equipment identified are necessarily the best available for the purpose.

The sample-loading for mass spectrometry was performed with a 5-cm length of 0.76 mm bore intermedic tubing attached to a 21-gauge hypodermic needle fixed to a syringe. Flat filaments were fabricated from zone-refined rhenium. Samples were loaded in a small glove box in a dry nitrogen atmosphere. Isotopic ratio measurements were performed with a single-sector 12-in. radius mass spectrometer of NBS design. Ion currents were measured with a Cary 401 MR vibrating-reed electrometer and a Faraday cup detector.

Procedure

The same chemical procedure was used for all samples and has been discussed in detail by Paulsen et al.,[6] Burke et al.[7] and Paulsen and Kelly.[4] A brief outline of the procedure is given below and any changes are noted.

Preparation of spike. The ^{34}S-enriched spike in the form of elemental S was oxidized to sulphate in a sealed Carius tube. High-purity sodium carbonate was added to yield an Na/S atom ratio of 4. The spike was stored in 2M hydrochloric acid. The S content of the spike was calibrated by comparison with gravimetrically prepared solutions of high-purity sodium and potassium sulphates.

Spiking and dissolution of samples. Sample, spike and nitric and hydrochloric acids were added to a Carius tube. The typical sample size was 0.1–0.2 g for the organic samples. This sample size was used to conserve spike and minimize the internal pressure produced in the Carius tube from CO_2 and NO_2 formed during oxidation. Sample sizes for steels were about 0.5 g. Approximately 1 μg of ^{34}S-enriched spike was added for every 3 μg of S in the sample.

The sealed Carius tubes were placed in closed steel shells with approximately 50 g of solid CO_2 to equalize the pressure. The organic samples were heated to 240° for 24 hr to ensure complete oxidation of organic matter and equilibration of the S isotopes. In all cases clear solutions were obtained, except for the coal and fly-ash samples which contained residues. Small portions of these residues were analysed by spark-source mass-spectrometry and shown to be silicate material inherent in the samples. Steel samples were heated for 12 hr. The solutions were repeatedly heated with hydrochloric acid and evaporated to dryness under a nitrogen atmosphere to destroy nitrates.

Reduction of sulphate to H_2S and conversion into As_2S_3. The dried samples were dissolved in 5 ml of hydrochloric acid and an aliquot equivalent to approximately 500 μg of total S was reduced in the reduction apparatus to H_2S. The H_2S was trapped in an ammoniacal As(III) solution cooled in an ice-water bath, then precipitated as As_2S_3 by the addition of hydrochloric acid and the As_2S_3 precipitate was

washed repeatedly with distilled water. The chemical yield of these steps is greater than 80%.[4] The As_2S_3 was dissolved in ammoniacal As(III) solution to yield an S concentration of 100 μg/ml with an As/S atom ratio of 2. This solution was stored at $-16°$ and not used until at least 16 hr had elapsed.

Mass spectrometry. A small portion of the solution prepared as just described, equivalent to 1.5 μg of total S, was added to an outgassed flat rhenium filament coated with ~ 100 μg of silica gel and phosphoric acid. The sample and silica gel were dried, heated to 700° for 5 sec and immediately loaded into the mass spectrometer. When a pressure of 2×10^{-7} mmHg was obtained, the filament was heated to 800° (time = 0). The temperature was increased by 50° each time at 5-min intervals until a temperature of 950° was obtained. After 30 min the ^{32}S/^{34}S ratio was measured at m/z 107 and 109 for the AsS$^+$ ions. The total ion current rose typically to 3–5 $\times$ 10^{-11} A and then decayed. Three sets of 5 ratios were obtained, with a 15-sec integration time. The observed change in the ratio during data collection was less than 0.1%. Typical precision for 3 sets was 0.1% relative standard deviation (r.s.d.).

Sulphur concentrations were calculated from the measured ^{32}S/^{34}S ratios by using the equation:

$$S\% = \frac{WK}{m} \frac{(A_{sp} - B_{sp}R)}{(BR - A)} \times 10^4 \tag{1}$$

where R is the measured ^{32}S/^{34}S ratio, A_{sp} and B_{sp} are the ^{32}S and ^{34}S abundances in the spike, A and B are the natural abundances of ^{32}S and ^{34}S in the sample, W is the amount of S spike (in μg) added to the sample, m is the sample weight (g), and K is the ratio of the atomic weight of natural S to the atomic weight of the S spike.

Caution. Great care should be used in handling the pressurized tubes. The Carius tubes should be annealed at 560° and checked for fire cracks before use. A small hole in the tube is potentially very dangerous. When a tube with a leak is used, the CO_2 in the closed steel shell will equilibrate with the atmosphere inside the tube. If this occurs, liquid CO_2 will be visible in the tube at room temperature when the tube is removed from the steel shell, and indicates that internal pressure is at least 60 atm. Such tubes should be isolated and not handled until the liquid CO_2 phase has bled off, which may take several days. The most common cause of a leak is improper sealing of the neck of the tube after addition of the sample. After sealing, the Carius tube should be handled behind a blast shield. Before opening with a torch the tube should be cooled to 0° or below.

Hypophosphorous acid and some metals can form an explosive mixture if taken near to dryness. The refluxing of our reduction mixture has never resulted in any measurable loss of volume, but this could occur during prolonged heating or breakage of the flask.

RESULTS AND DISCUSSION

From equation (1) it is seen that only isotopic ratios need to be measured for an accurate S determination. For almost all elements, the natural isotopic abundancies are invariant. Sulphur is one of a few elements which shows measurable variations in composition as a result of isotopic fractionation, principally during the biological oxidation and reduction of sulphur.[8] Therefore the isotopic composition of S in all samples and calibration solutions was measured to preclude bias from this source, which could be 1% or greater if IUPAC values were assumed for all compositions.[9] The measured S isotopic ratios for all samples are given in Table 1.

The relative abundances of ^{32}S, ^{33}S and ^{34}S were calculated from these data, assuming the abundance of ^{36}S to be 0.015%. Since the ^{36}S abundance is very low, its variability has a negligible effect on the calculated abundances of the other isotopes. The

calculated ^{32}S and ^{34}S abundances for each material were used in equation (1) to calculate the sulphur concentration.

Calibration of ^{34}S-enriched spike

The ^{34}S spike was calibrated against solutions prepared from two high-purity sulphates. Previously, it was shown that solutions gravimetrically prepared from these salts yielded a spike calibration value within a few parts in 10^4 of that determined from three different solutions of coulometrically titrated sulphuric acid.[4] Therefore these two salts can be used reliably as primary S standards. About 300 μg of S from a solution of natural S composition was accurately weighed into a Teflon beaker along with a known weight of spike solution. The resulting solution was mixed thoroughly, added to the reduction flask and treated in the same way as a sample. The S concentration determined in the spike for the individual mixes is given in Table 2. The uncertainty (r.s.d.) for the grand mean is 0.13%. For the high S concentrations reported in this paper, the uncertainty in the spike calibration is a significant source of uncertainty in the values for homogeneous SRMs.

S determinations in steel

The S concentration was determined in three SRM steels, which were in the form of chips. The individual values are given in Table 3 for replicate determinations on SRM 133b. The 1.4% (relative) range observed for the six bottles indicates sample inhomogeneity among bottles, since much smaller ranges have been observed for materials of comparable S concentration (see Table 6). Three separate samples were taken from bottles 2, 3 and 4. The range in S concentration in all three bottles was about 0.6% relative and may indicate slight sample inhomogeneity within individual bottles. A one-way analysis of variance of the twelve replicates, grouped according to their bottle designation, showed that there was a statistically significant difference ($\alpha = 0.03$) among the bottles. The significant difference is caused by the low values for bottle No. 4. Table 4 summarizes the S determinations on steels analysed in this study. The S values determined

for SRMs 133b and 1132a are in good agreement with previously certified values.

S determinations in organic-based materials

Sulphur was determined in a number of organic Standard Reference Materials ranging from powdered milk (0.35%) to a bituminous coal (4.8%). All organic materials measured in this study had to be dried to remove moisture. The drying procedure must effectively reduce all materials to the same dry weight basis. Two approaches have commonly been used at NBS. One involves drying a sample from each bottle to determine the weight loss, but performing the actual analysis on an undried sample. The weight loss from the dried material is then used to correct the data obtained from the undried material. The second method uses the dried material directly for the analysis. Because of the possibility that sulphur could be lost during the drying, both dried and undried SRM 1572 (Citrus Leaves) was analysed. Replicate determinations on five bottles of SRM 1572 are shown in Table 5. Five weighing bottles containing citrus leaves were dried at 85° for 2 hr as instructed in the certificate. The weight losses given in column 2 have an average value of approximately 5%. Samples denoted by "U" were taken directly from the SRM bottle without drying, and the corresponding drying weight-loss correction was applied. Dried samples, denoted by "D" were taken from the weighing bottles that had been heated. A comparison of the S content of the undried and dried material by a one-sided t-test indicates no detectable S loss during drying for this material. The mean S value for each bottle is given in the last column. The total range in S content was 0.25% relative, which is much smaller than the 9% spread in weight loss. This indicates that in spite of large differences in moisture content, the drying procedure reduces all bottles to the same dry weight basis. The standard deviation for the means of the five bottles was 0.098% relative. This small uncertainty in the mean demonstrates the high precision

capability of this technique and indicates that this SRM is homogeneous for S to this degree or better for the sample weights analysed.

Table 6 summarizes the thermal-ionization determinations of S in the organic materials. In all cases sample sizes were 0.1–0.3 g of the dried material, except for SRM 1572 (Citrus Leaves) where both dried and undried material was analyzed (see Table 5). In all cases the samples were spiked with ^{34}S-enriched tracer and decomposed in a sealed Carius tube; an aliquot equivalent to 300–500 μg of total S was reduced. Blank corrections were negligible in all cases. The relative observed ranges for single determinations from six different bottles are shown in the last column. The powdered milk, bovine liver and citrus leaves show very small S ranges, indicating good sample homogeneity for S, and the high precision of this technique. For these three SRMs, the spike calibration uncertainty is a large component (approximately half) of the total uncertainty given in the penultimate column.

The relatively large uncertainties for the coal determinations are a result of sample inhomogeneity, which in turn is primarily responsible for the large ranges observed. The certified values for SRM coals 2682, 2683, 2684 and 2685 are based on three independent techniques: gravimetry, ion chromatography and the isotope-dilution values from this study.

S determinations in SRM 1633a, Fly Ash

Sulphur was determined in four different bottles of Fly Ash SRM 1633a, with sample sizes of about 0.2 g of dried material. This particular fly-ash has the following major element composition (%): Si 22.8, Al 14, Fe 9.4, K 1.88, Ca 1.11. After sealed-tube dissolution with hydrochloric and nitric acids, the insoluble portion of two unspiked samples was centrifuged, washed repeatedly with distilled water and dissolved in 10 ml of concentrated nitric acid and 1 ml of concentrated hydrofluoric acid in a Teflon jar equipped with a threaded cap (Savillex Corporation).

*Sample sizes were 0.1–0.3 g of dried material.
†Isotope-dilution values determined by this technique were used with values from other techniques to arrive at the values given here.
‡SRMs not yet certified.
§The concentration given for each SRM is the mean of a single determination for dried material from six different bottles except for citrus leaves (see Table 5). The total uncertainty is computed as the linear sum of the uncertainty (ts, 95% confidence interval) in the spike calibration, the sample reproducibility, and the absolute value of the blank divided by the sample weight. The contribution from the blank was negligible.

The S concentrations found in the two fractions are given in Table 7. The insoluble residues represented 47.7% and 46.0% of the total sample. The sum of the values for the soluble and insoluble fractions gives the total S content per gram of fly-ash. A comparison of the values shows that more than 99% of the S in this fly-ash is present in the soluble fraction, but this may not be the case for other fly-ash samples.

metric technique described in this paper satisfy the need for a highly precise and accurate technique for producing certified S standards and for the measurement of S concentrations in environmental samples. For materials that are sufficiently homogeneous, this method can determine the S concentration with a total relative uncertainty of 0.5% (95% confidence interval) or better. The capability now exists to certify standards with total uncertainties that are smaller than the measurement precision of the automated instruments that use them for calibration. Therefore, investigators making S determinations will be in the favourable position of having accurate standards with uncertainties that have a negligible effect on the overall measurement uncertainty.

The high precision of this technique allows small changes in S concentration to be observed. This capability could be useful for the detection of small changes in S content in plants living in SO₂-polluted environments. For example, a relative increase of 0.5% S content in leaves could be easily detected in sample sizes of 0.1 g or less.

The upper limit to the amount of sulphur that can be determined by this technique is governed by the cost of the enriched spike. Sample sizes of high-sulphur materials have been kept at the 0.1-g level to conserve spike. The recent availability of less expensive spike in large quantities makes the cost factor less prohibitive. The lower limit on sample size is governed by the homogeneity of the sample for S.

DIRECT DETERMINATION OF SUB-NANOMOLAR LEVELS OF ZINC IN SEA-WATER BY CATHODIC STRIPPING VOLTAMMETRY

CONSTANT M. G. VAN DEN BERG

Department of Oceanography, University of Liverpool, Liverpool, England

Summary—A novel technique for the determination of nanomolar levels of zinc in aqueous solution is presented. The zinc complex with ammonium pyrrolidine dithiocarbamate is adsorbed on a hanging mercury-drop electrode and the reduction current of zinc is measured by voltammetry. The detection limit for zinc is $3 \times 10^{-11}M$, with 10-min collection time. A procedure is suggested for the simultaneous determination of Ni and Zn in a single sample.

The conventional electrochemical determination of trace amounts of zinc in aqueous solution is by anodic stripping voltammetry (ASV). The working electrode is then either a hanging mercury-drop electrode (HMDE), or a solid electrode covered with a mercury film.[1,2] The limit of detection for zinc is $2–4 \times 10^{-9}M$ after a plating time of 15–60 min with an HMDE,[3,4] and lower by a factor of about ten if a rotating disk electrode (RDE) is used, with *in situ* plating of mercury.[5] The determination of zinc is adversely affected by the formation of intermetallic compounds with Cu, Ni and Co,[1,6] especially when thin-film techniques are used. The half-wave potential of Zn^{2+} is at -1.1 V (*vs.* SCE) in non-complexing electrolytes,[6] so the solution needs to be maintained at pH > 4 to prevent masking of the zinc oxidation current by the hydrogen wave.

Recently it has been found possible to determine low concentrations of several trace metals in aqueous solution by means of adsorption voltammetry (AV). This technique is based on the tendency of certain complexes to adsorb on the surface of the HMDE. The reduction current of the metal ions in the adsorbed complex is used as a sensitive measure of the solution concentration. Thus low concentrations of Cu(II), U(VI), V(V) and Fe(III) can be determined by complexation with catechol,[7,8] and of Ni(II) and Co(II) by complexation with dimethylglyoxime (DMG),[9,10] with limits of detection typically near $10^{-10}M$.

The results of a study of the possible determination of trace quantities of Zn in sea-water by means of AV are reported in this paper. Several complexing ligands were tested in preliminary experiments and it was found that reduction peaks for both zinc and nickel in sea-water are obtained with 8-hydroxyquinoline as complexing agent. However, the concentration–reduction current relationship was non-linear for both metals, although the sensitivity (reduction current/metal concentration) was sufficient for analysis of unpolluted sea-water. Com-

plexes of zinc with catechol were also found to adsorb on the HMDE but the sensitivity was low (no peak from clean sea-water). Aqueous solutions of ammonium pyrrolidine dithiocarbamate (APDC) were found to produce a marked reduction peak in the presence of low concentrations of zinc. It is proposed in this paper to use this property for the detection of dissolved zinc in water and sea-water.

EXPERIMENTAL

Equipment

Voltamperograms were recorded with a PAR 174 A polarograph in conjunction with a PAR 303 static mercury-drop electrode in the stationary-drop mode; the surface area of the mercury drop was 2.83 mm². The internal clock of the polarograph was altered to allow for a faster pulse rate of 10 Hz. The reference electrode was Ag/saturated AgCl, KCl. For some experiments a home-made water-jacketed electrochemical cell was used, containing 60 ml of liquid, which allowed simultaneous pH-measurement. The solution was stirred with a Teflon-coated magnetic stirring bar. The pH was measured with a Radiometer PHM 64 Research pH-meter with a combined pH/calomel reference electrode, calibrated for the free hydrogen-ion scale with a solution of $0.01M$ hydrochloric acid in $0.69M$ sodium chloride. The experiments were performed in a "clean room", equipped with filtered-air conditioning.

Reagents

An aqueous $0.1M$ APDC ("Spectrosol", BDH) stock solution (100 ml) was prepared and traces of metal ions were removed by extraction with three 10-ml portions of 1,1,2-trichlorotrifluoroethane. A stock aqueous $0.1M$ DMG solution was prepared in $0.2M$ sodium hydroxide. Buffer solutions were prepared from *N*-2-hydroxyethylpiperazine-*N'*-2-ethane sulphonic acid (HEPES), piperazine-*N,N'*-bis(2-ethane sulphonic acid) (monosodium salt) (PIPES), and *N,N'*-bis(2-hydroxyethyl)-2-aminoethane sulphonic acid (BES): each stock buffer solution contained 1 mole of buffer agent and 0.5 mole of ammonia ("Aristar") per litre. Metal contamination in these buffers was removed by addition of $10^{-3}M$ APDC and extraction with 1,1,2-trichlorotrifluoroethane. A stock buffer solution ($1M$ boric acid/$0.4M$ ammonia; pH 8.5) was used without further purification. Stock aqueous solutions of zinc, nickel and cobalt were prepared by dilution of BDH atomic-absorption ("Spectrosol") standard solutions. Sea-water used for these

experiments was collected from the Menai Straits (and filtered through a 0.45 μm Oxoid filter) and from the eastern North Atlantic (used unfiltered, supplied by courtesy of I. Butler, M.B.A., Plymouth). Distilled water was produced by a quartz double-distillation unit. Interfering dissolved organic material was removed from the sea-water by ultra-violet irradiation.[7]

Procedure

A 10-ml sample is pipetted into the electrochemical cell and 0.1 ml of 0.1M APDC and 0.075-ml of 1M BES are added; the solution is then purged with argon to remove oxygen. The magnetic stirrer is switched on and a new mercury drop is extruded; this is the beginning of the collection period of 2 min. The collection period (E_{col}) is set at -1.3 V, and the scan is started at -0.9 V: the "hold" facility of the polarograph is therefore used during the collection period. The stirrer is stopped, then after 10 sec the potential is switched to -0.9 V ("initial potential" setting) and after a further 20 sec the potential scan is started. The scanning parameters are: differential pulse modulation 25 mV, 10 pulses/sec, scan-rate 10 mV/sec. The scan is stopped at -1.3 V by using the "hold" facility. The procedure is repeated after standard additions of zinc. The reduction-current/Zn-concentration relationship is linear up to about $10^{-7}M$ Zn under the given conditions. Zinc concentrations greater than about $5 \times 10^{-8}M$ can best be determined by using a reduced collection period (1 min or less), and a higher solution pH (boric acid buffer, pH 8.5): at this pH the sensitivity is slightly reduced and the hydrogen wave is shifted to more negative potentials. At high zinc concentrations ($>5 \times 10^{-8}M$) the analysis time can be further reduced by using a linear sweep (LS) potential scan of 50 mV/sec instead of the DP modulation.

RESULTS

A potential scan from -0.1 V in the negative direction, with an HMDE in an aqueous $10^{-3}M$ APDC solution (pH 7.3), is characterized by a large reduction current between -0.5 and -0.8 V. This wave is caused by reduction of adsorbed APDC molecules and its magnitude is not affected by varying the zinc concentration. At potentials more negative than about -0.8 V the background current is very low until the hydrogen wave is reached. A reduction peak for the adsorbed zinc complex is present at -1.18 V. The reduction of ADPC takes place in at least two steps, as revealed by the presence of two major, irregularly shaped peaks at -0.5 and -0.6 V (current measurements by adsorption linear sweep voltammetry, ALSV, after 1.5 min collection at -0.1 V, with stirring, scan-rate 50 mV/sec). The peak at -0.5 V is predominant until an APDC concentration of $\sim 10^{-4}M$ is reached (Fig. 1), whereas the second peak becomes predominant at higher concentrations. In $10^{-3}M$ APDC medium the reduction current of APDC is about 25 times that of $4 \times 10^{-8}M$ zinc; reduction of APDC therefore produces a massive background current between -0.4 and -0.85 V.

Adsorption of zinc on the HMDE depends on the APDC concentration, as shown in Fig. 1: the experimental solution was irradiated sea-water (UV-SW) containing $3 \times 10^{-8}M$ Zn and 0.01M BES (pH 7.3). Each scan was preceded by collection for 1.5 min while the potential was held at -0.3 V, and the
Fig. 1. Reduction currents of Zn and APDC as a function of APDC concentration.

reduction of Zn was measured by ADPV (10 pulses/sec and 10 mV/sec). It was found that the adsorption of zinc (as indicated by the reduction current) continued to increase with the APDC concentration up to $\sim 10^{-3}M$. This concentration was therefore selected for the following experiments.

Effect of variation of pH

Adsorption of $3 \times 10^{-8}M$ Zn was measured as a function of the pH of UV-SW that had been made $10^{-3}M$ in APDC. The collection time was 1 min at a potential of -0.3 V. The reduction current was measured by ALSV at a sweep-rate of 50 mV/sec. It was found (Fig. 2) that the peak height was maximal at about pH 6.8. The zinc peak is preceded by that for nickel at -1.12 V, the reduction current for which, as a function of pH, is also shown in Fig. 2.

The peak-height for zinc was greatest at pH 6.3–6.8. It was found, however, that addition of a pH buffer in this range (such as PIPES at pH 6.9) caused the hydrogen wave to shift in the positive direction and tests showed that the baseline was sufficiently flat for low concentrations of Zn to be determined at pH 7.3 in the presence of BES buffer, whereas 0.01M HEPES (pH 7.8) shifted the hydrogen
Fig. 2. AV reduction currents of Zn and Ni as a function of pH. Experimental conditions: sea-water containing $3 \times 10^{-8}M$ Zn, $1 \times 10^{-8}M$ Ni, $10^{-3}M$ APDC; stirred collection during 1 min at -0.3 V, sweep-rate 50 mV/sec.

wave to more positive potentials. BES buffer was therefore selected for the following experiments.

Effect of variation of collection time

The reduction current of zinc in sea-water medium buffered at pH 7.3 with 0.01M BES and containing $10^{-3}M$ APDC was measured by ALSV (scan-rate 50 mV/sec) as a function of the collection period. It was found (Fig. 3) that the reduction current increased linearly with the collection time up to about 7 min for $3 \times 10^{-8}M$ zinc, but only up to a collection time of 3 min for $2 \times 10^{-7}M$ zinc. The maximum in the reduction current for $2 \times 10^{-7}M$ zinc ($\sim 3\,\mu A$), obtained after collection for 7 min was similar to the maximum current obtainable by increasing the zinc concentration and using a fixed collection period of 1.5 min. This means that the electrode was then completely covered with zinc–APDC complex. Increasing the collection period decreased the current, indicating that some of the adsorbed zinc was displaced, probably by other metals present as traces in the sample (APDC is a general complexing agent). A similar effect has been shown for the AV determination of Cu and Fe with catechol.[7,8]

Effect of variation of the collection potential

The adsorbed film of metal–APDC complex can form in two ways: (a) the metal ions react with APDC molecules that are already adsorbed on the mercury surface, or (b) the complex species is formed in solution and then adsorbed. The potential of the HMDE during the collection period is important, since it determines the sign of the electrical charge on the electrode surface. The charge is zero at the electrocapillary maximum (ecm) which is located at ~ -0.52 V in electrolyte solutions similar to sea-water.

The effect of the electrical surface charge was studied by measuring the reduction current for both $3 \times 10^{-8}M$ zinc and $1 \times 10^{-8}M$ nickel in irradiated sea-water by ALSV after collection for 1.5 min at various potentials, at pH 7.3 (0.01M BES buffer), with $10^{-3}M$ APDC (scan-rate 50 mV/sec). Scans with collection potentials more negative than -0.9 V were
Fig. 4. Adsorption of Zn and Ni on the HMDE as a function of collection potential. Current measurement by ALSV, 50 mV/sec sweep-rate after 1.5 min collection, from sea-water containing $3 \times 10^{-8}M$ Zn, $1 \times 10^{-8}M$ Ni, $10^{-3}M$ APDC and 0.01M BES (pH 7.3); peak potentials of Zn and Ni are indicated on the x-axis.

initiated at -0.9 V as described in the experimental section. It was found (Fig. 4) that the effect of the surface charge on the adsorption was generally small, except for the sharp drop in adsorption of zinc at ~ -0.5 V where the surface charge reverses, which suggests that (b) is the operative mechanism. The dip in the curve at the ecm could possibly be explained by the dipolar nature of the Zn–APDC complex(es). This property is useful as it allows for selective collection of nickel with respect to zinc.

The peak potentials for zinc and nickel are also indicated in Fig. 4. The metallic zinc produced by reduction is amalgamated and diffuses into the mercury drop when the collection potential is kept more negative than the reduction potential (-1.14 V). When the potential is switched to -0.9 V the amalgamated zinc is oxidized, then is complexed by the adsorbed APDC and remains at the surface of the HMDE. This procedure permits selective collection of zinc without interference by nickel and high concentrations of cobalt (as shown below).

Maximum adsorption capacity of the HMDE

At any given collection time the relationship between the reduction current of zinc and its concentration in solution is linear only until a certain maximum degree of surface coverage has been reached. A linear response was found, for instance, up to $2 \times 10^{-7}M$ zinc, with a collection period of 1 min. The maximum adsorption capacity of the HMDE was determined by measuring the total charge (in μC) corresponding to the reduction of zinc, as a function of its concentration in irradiated sea-water, in a collection period of 1.5 min. This charge was calculated from the area under the Zn peak obtained by ALSV, with a scan-rate of 50 mV/sec and a collection potential of -0.3 V. The results were fitted to a linear form of the Langmuir equation.[7] It was found that under saturation conditions the

Fig. 3. Adsorption of Zn on the HMDE as a function of collection time. Experimental conditions: sea-water containing $3 \times 10^{-8}M$ Zn (1) and $2.3 \times 10^{-7}M$ Zn (2), $10^{-3}M$ APDC, 0.01M BES (pH 7.3); ALSV, sweep-rate 50 mV/sec.

charge was $2.3\,\mu C$, equivalent to adsorption of 4.1×10^{-10} mole of zinc complex per cm^2 of surface (calculated from charge/$2 \times F \times$ surface area, where F is the Faraday constant). This adsorption density is approximately twice that of the complex of Cu(II) with catechol $(2 \times 10^{-10}$ mole/cm$^2)$,[7] but less than half that of the Ni(II) complex with DMG $(1 \times 10^{-9}$ mole/cm$^2)$.[10]

Interferences

Metal ions can interfere with the determination of Zn if their complexes are adsorbed on the electrode and their reduction potential is near that of zinc. It was found by making standard additions of Cu, Fe, V, U, Ni, Pb and Co, that only Ni(II) and Co(II) produced reduction peaks near that of zinc. The sensitivity for cobalt was only about a tenth of that for zinc and nickel, so it is not expected to interfere, as its concentration is of the order of $10^{-10}M$ in unpolluted sea-water,[11] whereas the concentrations of nickel and zinc in sea-water are in the range 10^{-9}–$10^{-8}M$.[12] The zinc concentration can be determined selectively by using a collection potential of -1.3 V (Fig. 4) and differential pulse (DP) modulation. The height of the zinc reduction peak was found to be increased by a factor of about 10 relative to that of nickel by use of DP modulation (10 pulses/sec), as a result of the irreversible reduction of nickel.[13]

Natural waters are known to contain low concentrations of surface-active organic material. Such material may reduce the sensitivity of this technique by competitive adsorption onto the HMDE. The reduction currents of zinc and nickel in irradiated sea-water were therefore measured before and after additions of Triton-X-100, a non-ionic surfactant which has been used as a calibration standard for surfactant activities in natural waters.[14] It was found that the coastal sea-water samples had a surfactant activity equivalent to a 0.01–0.5 mg/l. concentration of Triton-X-100. When this surfactant was added to irradiated sea-water (containing $10^{-3}M$ APDC and $0.01M$ BES) the peak-heights for zinc and nickel were reduced by 40 and 80% respectively, by a 0.5-mg/l. level of surfactant, and both by about 90% by a 1-mg/l. level. The sensitivity for Zn was found to be lower in untreated water from the Irish Sea than for an irradiated sample, whereas no significant effect was observed for water from the N. Atlantic. It is therefore advisable to irradiate samples which may be suspected to contain significant amounts of surfactants.

Organic complexing material present in natural water samples could interfere by competition for dissolved zinc. The concentrations of such ligands are normally low $(10^{-8}$–$10^{-7}M)$, but their zinc complexes are about as strong as the Zn–EDTA complex.[15,16] Addition of 10^{-6}, 10^{-5}, 3×10^{-5} and $7 \times 10^{-5}M$ EDTA to irradiated sea-water (containing $3.9 \times 10^{-8}M$ Zn, $8.88 \times 10^{-4}M$ APDC, and $0.01M$

BES, pH 7.3) reduced the ALSV peak height of zinc by 0, 11, 45 and 86% respectively. At the APDC concentration $(8.88 \times 10^{-4}M)$ used, the effect was therefore significant only at ligand concentrations much greater than those normally present in natural waters. Ultraviolet irradiation of water samples, as recommended for the removal of surfactants, should also remove high concentrations of strongly complexing ligands possibly occurring in interstitial waters.

The stability constant of the zinc–APDC complex is not known, but can be estimated from the competitive effect of EDTA. A 50% reduction in the ALSV peak height of zinc in the presence of $8.88 \times 10^{-4}M$ APDC should be caused by the presence of $3.47 \times 10^{-5}M$ EDTA (calculated by interpolation in the data above). Under these conditions the concentration ratio of zinc complex to free zinc must be the same for both complexes, so $C_{EDTA}K'_{ZnEDTA} = C_{APDC}K'_{ZnAPDC}$ where C_{EDTA} and C_{APDC} are the concentrations of free EDTA and APDC respectively and K'_{ZnEDTA} and K'_{ZnAPDC} are the conditional stability constants for the complexes. For sea-water medium at pH 7.3 it can be calculated that $\log K'_{ZnEDTA} = 7.71$ (from the stability constants quoted by Martell and Smith[17] so K'_{ZnAPDC} is approximately 2×10^6. A $10^{-4}M$ concentration of APDC in sea-water would give an α-coefficient for the side-reaction with zinc $(\alpha_{ZnAPDC} = 1 + K'_{ZnAPDC}C_{APDC})$ of about 200, and for $10^{-3}M$ APDC, $\alpha_{ZnAPDC} \sim 2000$. These values can be compared with those (40–100) for complexes of zinc with natural organic complexing material in sea-water and interstitial waters,[15] and with that (2) for inorganic complexes.[18] No significant interference by natural organic complexing material is therefore to be expected when $10^{-3}M$ APDC is used.

Determination of zinc in sea-water

From the experiments reported it was concluded that optimal sensitivity was obtained by using a solution containing $0.01M$ BES buffer (pH 7.3) and $10^{-3}M$ APDC, but that a better baseline at higher zinc concentrations would be obtained at pH 8.5. The effects of various experimental conditions on the peak current are shown in Fig. 5. The zinc peak is much reduced (scan 3) after collection at -0.5 V (see also Fig. 4), and the peaks of nickel and cobalt at -1.08 and -1.2 V respectively are readily discernible. The nickel and zinc peaks are both improved by collection at -0.1 V, whereas cobalt is completely, and nickel substantially, masked by collection at -1.3 V (scan 1). The reduction current of zinc is much increased by using differential pulse modulation (scan 4). By standard additions it was found that the zinc concentration was $3 \times 10^{-8}M$ in the sample from the N. Atlantic. This concentration was confirmed by DPASV at pH 4.5 with the HMDE.

The detection limit was evaluated from scan 5 in Fig. 5. The peak-height of 5 nA for $2 \times 10^{-9}M$ zinc had a relative standard deviation (RSD) of 2.3% (8
Fig. 5. ALSV and ADPV scans of water containing $3 \times 10^{-8}M$ Zn and $10^{-3}M$ APDC after 1.5 min collection. Scans 1–4: sea-water, pH 8.5; scans 1–3: ALSV, sweep-rate 50 mV/sec, collection potentials of *1*, -1.3 V; *2*, -0.1 V; *3*, -0.5 V; scan 4: ADPV, 10 pulses/sec, sweep-rate 10 mV/sec, collection at -1.3 V. Scans 5–7: $10^{-3}M$ APDC in distilled water, pH 7.3; 1.5 min collection at -1.3 V; ADPV with 10 pulses/sec and sweep-rate 10 mV/sec; *5*, $2 \times 10^{-9}M$ Zn; *6*, $3.8 \times 10^{-9}M$ Zn; *7*, $6.9 \times 10^{-9}M$ Zn.

degrees of freedom). The detection limit was calculated as 3 times this standard deviation, giving a value of $1.4 \times 10^{-10}M$. This limit was obtained with a collection period of only 1.5 min. A collection period of 10 min would reduce the limit of detection to about $3 \times 10^{-11}M$. This is comparable to that for nickel by similar AV techniques,[7,10] but about a hundreth of that for determination of zinc by DPASV with an HMDE,[3,4] and a tenth of that by DPASV with an RDE.[5] Application of this technique allows determination of zinc in sea-water with a collection period of only 1–2 min, with an HMDE. This type of electrode is easier to handle than the RDE, as its surface is readily renewed before each measurement and no polishing is needed.

Simultaneous determination of nickel and zinc

Peaks for both elements are obtained from a single ALSV scan of sea-water containing $10^{-3}M$ APDC, but the sensitivity for nickel is much lower than that for zinc. Comparative measurements on sea-water at pH 8.5 showed that about 10 times better sensitivity was obtained for nickel with $2 \times 10^{-5}M$ DMG than with $10^{-3}M$ APDC. DMG is selective for Ni,[10] and at $2 \times 10^{-5}M$ concentration in $10^{-3}M$ APDC medium has no effect on the peak-height for zinc. Hence

nickel can be determined first by addition of $2 \times 10^{-5}M$ DMG and use of a collection potential of -0.7 V, followed by determination of zinc by addition of $10^{-3}M$ APDC and use of a collection potential of -1.3 V. The solution is buffered at pH 8.5 with $0.01M$ boric acid. A pH of 8.5 is selected rather than 9.2 as recommended for nickel,[10] because of the possible precipitation of magnesium hydroxide and because of the lower sensitivity for zinc at a higher pH. DP modulation was used in both cases (10 pulses/sec, 10 mV/sec) and a collection period of 1.5 min. A reduction current of 57 nA was obtained for $10^{-8}M$ nickel (RSD 2%) and a limit of detection of $6 \times 10^{-10}M$. The sensitivity under the given conditions is therefore sufficient to determine Ni and Zn simultaneously, given that the levels of these metals in unpolluted sea-water are typically 10^{-9}–$10^{-8}M$.[3,12]

1,2- AND 1,3-CYCLOHEXANEDIONE BIS(2-HYDROXYBENZOYLHYDRAZONE)S AS ANALYTICAL REAGENTS

M. Gallego, M. Silva and M. Valcarcel

Department of Analytical Chemistry, Faculty of Sciences, University of Córdoba, Córdoba, Spain

Summary—The synthesis, characteristics and analytical properties of 1,2- and 1,3-cyclohexanedione bis(2-hydroxybenzoylhydrazone)s are described. Spectral characteristics, pK values, hydrolysis resistance, reactions with common cations and their potential use in kinetic analysis are reported.

Hydrazones have been widely used for spectrophotometric and spectrofluorimetric determination of metal ions, and their analytical applications have been reviewed[1,2]. Bis(aroylhydrazones) have recently been proposed as analytical reagents. Lever[3] reported the photometric and fluorimetric properties of the bis(4-hydroxybenzoylhydrazone)s of glyoxal, methylglyoxal and dimethylglyoxal. The photometric reactions of other bis(aroylhydrazones) with several metal ions have been investigated by us.[4-8]

In this paper, studies of the synthesis and properties of the 1,2-cyclohexanedione and 1,3-cyclohexanedione bis(2-hydroxybenzoylhydrazone)s (1,2-CHDSH and 1,3-CHDSH respectively) and their reactions with common cations and use in kinetic analysis are described.

Scheme 1.
EXPERIMENTAL

Reagents

All reagents were of analytical-reagent grade and all solutions were prepared with distilled water. The 1,2- and 1,3-cyclohexanedione bis(2-hydroxybenzoylhydrazone)s were used as 0.1% solutions in dimethylformamide; the solutions were stable for at least 1 week.

Procedures

Synthesis of bis(aroylhydrazones). The 1,2- or 1,3-cyclohexanedione (0.37 g) and the stoichiometric amount of

2-hydroxybenzoylhydrazine (1.00 g) were dissolved in 15 ml of absolute ethanol, several drops of concentrated hydrochloric acid were added and the mixture was heated under reflux for 15 min for synthesis of 1,2-CHDSH and for 30 min for 1,3-CHDSH. After cooling to room temperature, the products were filtered off and recrystallized from ethanol. The melting points were 243° and 253° respectively. Elemental analysis gave C 62.9%, H 5.4%, N 14.5% for 1,2-CHDSH, C 63.2%, H 5.4%, N 14.8% for 1,3-CHDSH; $C_{20}H_{20}N_4O_4$ requires C 63.16%, H 5.26%, N 14.74%.

Photometric reactions. The solutions were prepared in 25-ml standard flasks from appropriate amounts of the cation, 5 ml of 0.1% reagent solution in dimethylformamide, 10 ml of dimethylformamide, and enough dilute hydrochloric acid or sodium hydroxide solution to give the selected pH value, and diluted to volume with distilled water. The absorbances were measured at 350–500 nm against a blank solution.

Oxidation reactions. The reactions with several oxidizing agents and the catalytic effects of several cations were investigated. To a solution containing 0.5 ml of reagent solution in dimethylformamide, in a 10-ml standard flask, were added 2 ml of oxidizing agent solution (0.3% v/v hydrogen peroxide, 0.1M potassium persulphate or 0.1M sodium periodate) and 2 ml of 0.14M ammonia solution, and the mixture was made up to the mark with distilled water. In the study of the catalysed reactions appropriate amounts of the catalysts were also added. The absorbances were measured at 350–500 nm and the spectrofluorimetric measurements were made in the range 200–500 nm.

RESULTS AND DISCUSSION

The synthesis of these bis(aroylhydrazones) is very easy and the reaction needs only slight heating. Bright yellow crystals appear when the reagents are mixed.

The solubilities of the two reagents were found to be very low in organic solvents except for dimethylformamide (Table 1). Therefore, water–dimethylformamide (4:6 v/v) mixtures were used. The most important characteristics of the reagents in several solvents are shown in Table 1.

The infrared spectra (potassium bromide discs) were analogous, with bands assigned to the stretching vibrations of NH (3200 cm^{-1}), C=N (1650 cm^{-1}),

Table 1. Characteristics of both compounds in several solvents

*Measured by the method of Wittenberger.[10]

OH (1310 cm^{-1}) and *ortho*-substitution in the aromatic ring (760 cm^{-1}).

The ultraviolet spectra of the reagents show analogous absorption maxima at 300 and 310 nm (Fig. 1) with bathochromic shifts in alkaline medium (λ_{max} 350 nm). Aqueous solutions of 1,2-CHDSH do not fluoresce at any pH, but alkaline solutions of 1,3-CHDSH exhibit a blue fluorescence (λ_{ex} 350 nm, λ_{em} 430 nm). This behaviour can be attributed to interaction between the two aroylhydrazone chains, enhancing the rigidity and planarity of this compound. This effect could also explain the reactivity of this reagent relative to that of 1,2-CHDSH (see Table 2).

A combined potentiometric and photometric method[9] was used to determine the ionization constants, the first for ionization of the enolic hydroxyl group and the second for the ionization of the phenolic group. The ionization constants of 1,3-CHDSH have also been calculated from the fluorescence measurements. The average pK values are:

	1,2-CHDSH	1,3-CHDSH	
		Photometric	Fluorimetric
pK_1	6.3 ± 0.1	5.6 ± 0.1	6.3 ± 0.1
pK_2	10.8 ± 0.1	10.1 ± 0.1	10.1 ± 0.1

Solutions of these compounds in dimethylformamide are stable for at least one week and the reagents are resistant to hydrolysis at any pH.

The characteristics of the chelates formed in water–dimethylformamide (4:6 v/v) medium are shown in Table 2. 1,2-CHDSH is superior in sensitivity, but in both cases preliminary separations or masking reactions must be used to improve selectivity. However, molybdenum(VI), titanium(IV) and tin(II) react with 1,2-CHDSH at much lower pH than the other cations do, and it should be possible to

determine both tin(II) and tin(IV) in a mixture. No fluorescence was found for any of the complexes, but the fluorescence of 1,3-CHDSH is quenched by the cations that react with this reagent.

Oxidation studies

Ammoniacal solutions of 1,2-CHDSH do not show native fluorescence, but when treated with an oxidizing agent such as hydrogen peroxide, potassium persulphate or sodium periodate exhibit a blue fluorescence (λ_{ex} 310 nm and 350 nm, λ_{em} 430 nm). Figure 2 shows this behaviour as well as the slight

effect of dissolved oxygen on this compound in ammoniacal medium. If alkali-metal hydroxides are used for the pH adjustment, the effect of these oxidants is less. Potassium persulphate produces a brown oxidation product (λ_{max} 420 nm) after 48 hr, which is not fluorescent.

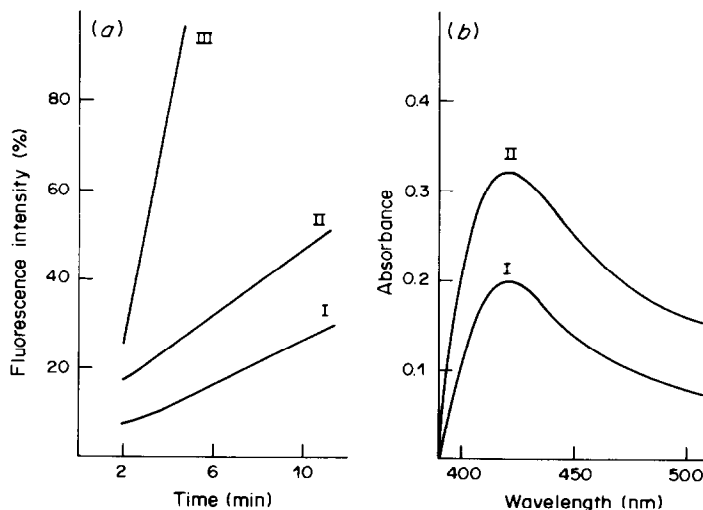
The most important catalytic effect on the oxidative production of fluorescence from 1,2-CHDSH is that of manganese(II) (Fig. 3a), when hydrogen peroxide, potassium persulphate or dissolved oxygen is the oxidant. The effect of dissolved oxygen was confirmed by measurements in an inert atmosphere


Fig. 3. (*a*) Plots of fluorescence *vs.* time for the kinetic determination of manganese at the 5.0 ng/ml level in the presence of several oxidants: I, potassium peroxodisulphate; II, dissolved oxygen and III, hydrogen peroxide. ($1.3 \times 10^{-4} M$ 1,2-CHDSH, $8.8 \times 10^{-3} M$ H_2O_2 or $10^{-2} M$ $K_2S_2O_8$, $0.4M$ ammonia, 25°C, sensitivity ×0.3). (*b*) Absorption spectra of 1,2-CHDSH in the presence of several oxidants, catalysed by manganese(II) (100 ng/ml): I, potassium peroxodisulphate and II, dissolved oxygen. Conditions as described in the procedure. In both cases, the reagent blank was negligible.

Table 3. Influence of iron(III) and silver(I) on the kinetic determination of Mn at the 5.0 ng/ml level

Metal ion	Tolerance ratio, [Ion]/[Mn^{2+}]*		
	Hydrogen peroxide	Potassium persulphate	Dissolved oxygen
Iron(III)	20	10	20
Silver(I)	100	8	50

*Experimental conditions as for Fig. 3a.

on solutions made with oxygen-free reagent solutions. The reagent blanks do not show fluorescence. The catalytic effect of manganese(II) is maximal with hydrogen peroxide as the oxidant, and manganese can be determined at sub-ng/ml levels. Iron(III) and silver(I) are the only other cations to show catalytic action (at about the μg/ml level) with hydrogen peroxide and potassium persulphate as the oxidant. The tolerance levels for these ions are shown in Table 3. Hydrogen peroxide is the oxidant of choice for the catalytic determination of manganese, owing to the greater sensitivity and selectivity.

In the photometric study and when potassium persulphate or dissolved oxygen is the oxidant, only the catalytic effect of manganese(II) has been found. This behaviour is shown in Fig. 3b.

1,3-CHDSH is similarly oxidized, to a product with blue fluorescence (λ_{ex} 315 nm, λ_{em} 415 nm). Only manganese(II) and iron(III) show a catalytic effect (a slight one) when hydrogen peroxide is the oxidant.

1,2-CHDSH is of more potential use than 1,3-CHDSH in kinetic analysis.

SYNTHESIS AND PROPERTIES OF A CHELATING RESIN CONTAINING TRIAZOLETHIOL GROUPS

ATSUSHI SUGII, NAOTAKE OGAWA and YOSHIHISA HAGIWARA
Faculty of Pharmaceutical Sciences, Kumamoto University, Kumamoto 862, Japan

Summary—A macroreticular poly(acrylic acid)-based resin with triazolethiol as the functional group has been synthesized. The stability of the resin in acidic media and the behaviour in sorption and desorption of various metal ions have been investigated and compared with those of the acylthiosemicarbazide resin which is an intermediate in synthesis of the triazolethiol resin. Both resins show high affinity for copper(II) silver, cadmium and mercury(II), and high selectivity for silver and mercury(II) at low pH (1–2), and even at pH 7 if EDTA is present. The triazolethiol resin sorbs metal ions faster than the acylthiosemicarbazide resin does and sorbs mercury(II) from high concentrations of acids and neutral salt solutions. This resin has been applied to the concentration of silver and mercury(II) from sea-water samples by column operation.

Chelating resins having a sulphur atom in their functional group should show high affinity for "soft" metal ions, and several have been synthesized and investigated. In particular, the chelating resins containing thiol groups[1-15] have been extensively investigated because of their high reactivity towards heavy metal ions. The thiol groups, however, are likely to be oxidized by oxygen during usage and/or storage of the resin, resulting in decrease in capacity, so it is worthwhile trying to synthesize new chelating resins having stable thiol groups. The present paper describes a resin containing triazolethiol groups, which is resistant to air-oxidation. The characteristics of the acylthiosemicarbazide resin which is an intermediate in the synthesis of the triazolethiol resin are also described.

EXPERIMENTAL

Apparatus and reagents

The infrared spectra and surface properties of the resins, and the radioactivity of the tracers used, were measured with the apparatus described earlier.[16] A Shimadzu AA-610S atomic-absorption spectrophotometer was used for the determination of nickel, copper and silver. The stock metal ion solutions, approximately $0.1M$, were standardized by complexometric titration. The solutions used for the sorption studies were prepared by diluting aliquots of the stock solutions with the desired background acid (hydrochloric acid or nitric acid in $1M$ acetic acid) or buffer solution ($1M$ acetic acid–sodium acetate). The radioisotopes ^{60}Co, ^{65}Zn, ^{109}Cd, ^{110m}Ag and ^{203}Hg, as nitrate or chloride, were obtained from the New England Nuclear Corp. and the Radiochemical Centre, Amersham.

Preparation of resins

Resin I. To 450 ml of 0.5% aqueous hydroxyethylcellulose solution containing 45 g of sodium chloride, 120 ml of ethyl acrylate, 30 ml of 50% divinylbenzene solution and 150 ml of iso-octane, 2.25 g of benzoyl peroxide were added, and the mixture was stirred. After dispersion of the monomers, the mixture was heated to 70–75° and kept at this temperature for 8 hr with constant stirring. The product was

filtered off and washed with hot water and methanol. After drying in a vacuum desiccator, the 35–60 mesh fraction was collected.

Resin II. To 60 g of resin I, 220 ml of anhydrous hydrazine were added and the mixture was heated at 120° for 10 hr, then the reaction mixture was poured into 2 litres of water, and the product was filtered off, and washed with water and methanol. After vacuum drying, about 55 g of a white resin was obtained.

Resin III. To 200 ml of 50% aqueous ethanol, 50 g of resin II and 30 g of methyl isothiocyanate were added, and the mixture was refluxed for 8 hr with stirring. The reaction product was filtered off, washed with methanol, and dried under vacuum. A white resin (about 73 g) was obtained.

Resin IV. Resin III (50 g) was suspended in 400 ml of 50% aqueous dioxan containing 30 g of potassium hydroxide, and the mixture was refluxed for 8 hr with stirring. The product was filtered off, washed with water, 10% acetic acid, water and methanol, and finally dried under vacuum. A white resin (about 46 g) was obtained.

Stability of resins

Portions (1 g) of resins III and IV were shaken with 50 ml of acid solutions of various concentrations ($1-5M$) for 5 days, then filtered off and washed with water, $1M$ sodium hydroxide, $1M$ acetic acid and water until the washings were neutral. After vacuum drying, the nitrogen and sulphur contents were determined.

Sorption of metal ions by batch operation

Unless otherwise stated, aliquots (10 or 100 ml) of $0.01M$ metal ion solutions were mechanically shaken with 100 mg of dry resin III or IV for a selected time at room temperature. The amount of metal ion sorbed was determined by radiochemical or spectrophotometric measurement of equal portions of the solution, before and after sorption of the metal ions.

Recovery of metal ions

Resins III and IV, loaded with metal ions, were shaken with various desorbents for 3 hr, then filtered off, and the amounts of the metal ions in the filtrates were determined.

Breakthrough

The metal solution (0.2 mg/ml, pH 7) was passed through a glass tube packed with 1 g of resin III or IV (0.5 × 15 cm)

at a flow-rate of 2 ml/min, and the effluent fractions were analysed for the metal.

RESULTS AND DISCUSSION

Preparation and stability of resins

The resins were synthesized from macroreticular (MR) poly(ethyl acrylate) cross-linked with 10% divinylbenzene as shown in Scheme 1.

Scheme 1.
The elemental analyses of resins II–IV are shown in Table 1. Resins III and IV contain nitrogen and sulphur in 3:1 molar ratio and the higher nitrogen and sulphur content of resin IV corresponds to the dehydration of resin III. The absorption band at 1680 cm^{-1} ($\nu_{C=O}$) observed for resins II and III is absent for resin IV. These facts suggest that the conversion from resin II into resin IV proceeds almost quantitatively.

The physical properties of the resins are listed in Table 2; resins III and IV show the characteristic MR structure. The specific surface area of both resins is nearly the same, but the pore volume and diameter of resin III are larger than those of resin IV. It is also clear that the thiol group in resin IV increases the hydrophilicity.

The chemical stability of resins III and IV was assessed from the change in nitrogen and sulphur content on exposure to acids. Resin IV was stable in 1–5M hydrochloric acid but not in 1M nitric acid, which caused about 97% desulphurization of the original resin (cf. preparation of 1,2,4-triazole from its thiol derivative[17]). The thiol groups of resin IV were stable for about a year on exposure to air, however. Resin III, which contains acylthiosemicarbazide groups, was stable in both nitric and hydrochloric acid media.

Sorption of metal ions

Metal chelates with 1,2,4-triazole-5-thiol have been

Table 1. Analytical data of resins

Resin	Nitrogen, % (mmole/g)	Sulphur, % (mmole/g)	Molar ratio N:S
II	17.31 (12.36)	—	—
III	18.13 (12.95)	13.65 (4.26)	3.04
IV	19.86 (14.19)	15.14 (4.72)	3.01

characterized by Gupta et al.[18] and the usefulness of thiosemicarbazide derivatives in inorganic analysis has also been reviewed.[19] It was expected that resins III and IV would have the same reactivity as their monomeric compounds towards metal ions. The sorption of metal ions on resins III and IV at various pH values was investigated, and the results are shown in Fig. 1. The sorption of silver and mercury(II) was similar on both resins at pH below 7, but for copper(II) and cadmium the affinity of resin IV was higher than that of resin III.

The maximum capacities for the four metal ions which showed the highest affinity in the preliminary experiment are listed in Table 3. The order of sorption is Ag > Hg > Cu > Cd on both resins. The sorption mechanism is still not completely elucidated. The high capacity for silver, however, suggests that the nitrogen atom as well as the sulphur atom in the functional group contributes to the sorption of metal ions. This was confirmed experimentally; the capacity at pH 7 of resin IV (desulphurized with 1M nitric acid) for copper and silver was still 1.87 and 3.50 mmole/g, respectively.

The rate of sorption was determined for copper, silver, cadmium and mercury at pH 7 by batch operation with resins III and IV, and the results are shown in Fig. 2. The equilibration is faster on resin IV; the times required for 50% uptake of copper, silver, cadmium and mercury were 15, 2, 20 and 6 min, respectively.

The effect of diverse ions on the sorption of the four metal ions with resins III and IV was studied. The presence of 10^{-2}M chloride, nitrate, thiocyanate, thiosulphate and sulphate did not interfere with sorption of metal from 10 ml of 1 × 10^{-3}M metal solution (pH 4) except for mercury(II) in thiosulphate solution, in which the mercury was reduced. Figure 3 shows that mercury(II) is effectively sorbed in the presence of high concentrations of various acids and salts. This suggests that resin IV is applicable to the concentration of mercury from highly saline solutions and/or acids widely used as reagents. The presence of 100-fold amount of cobalt(II), nickel, copper(II), zinc, cadmium, lead and iron(III) showed no significant interference with the sorption of silver(I) and mercury(II) with resins III and IV at pH 7.

Table 2. Physical properties of resins

Resin	Specific surface area, m^2/g	Pore volume, ml/g	Average pore diameter, nm	Water regain, g/g
III	39.4	0.109	111	0.98
IV	40.0	0.081	81	1.09
Fig. 1. Effect of pH on the sorption of metal ions with resins III and IV. Resin: 100 mg. Metal solutions: 0.01M, 10 ml. Shaking time; 24 hr. □: Co; ■: Ni; ○: Cu; ●: Zn; △: Ag; ▲: Cd; × : Hg.

Mercury(II) was found to be 99.9% sorbed on resin IV in the presence of silver (in 100:1 ratio to mercury) in 0.001M nitric acid medium. The amounts of silver and mercury used corresponded to 10 and 0.1 mmole per g of resin IV, respectively, so the result indicates that the resin thiol group has much higher affinity for mercury(II) than for silver.

Table 4 shows the degree of sorption of the four metal ions in the presence of EDTA, selected as a typical chelating agent. The results suggest that the resins may be useful for the concentration and recovery of silver and mercury from natural water, which contains several chelating substances. The time required for 50% uptake of silver and mercury is not affected by the presence of EDTA. As shown in Fig. 1, resin IV sorbs mercury and silver selectively at

low pH but the selectivity decreases with increasing pH. When EDTA is present, however, resin IV sorbs only mercury and silver.

In general, desorption of the metal ions from the resins was rather difficult, probably because of formation of stable metal complexes with the functional groups on the resin matrix. Quantitative recovery was achieved only by using 0.1M hydrochloric acid containing 1–10% thiourea.
Fig. 2. Effect of shaking time on the sorption of metals in acetate buffer (pH 7). Resin: 100 mg. Metal solutions· 0.01M, 10 ml. Symbols are the same as those in Fig. 1. ----: resin III ——: resin IV.

Table 3. Total capacity ($mmole/g$) for copper, silver, cadmium and mercury

Resin	Cu(II)		Ag(I)		Cd(II)		Hg(II)	
	pH 3	pH 7	pH 3	pH 7	pH 3	pH 7	pH 3	pH 7
III	0.91	1.85	6.39	7.56	0.49	0.61	3.97	3.23
IV	1.05	2.81	7.13	7.77	0.42	1.89	3.76	3.70

Metal solutions: 0.01M, 100 ml. Shaking time: 24 hr.
Fig. 4. Breakthrough curves with resin IV column.

The breakthrough curves for copper, silver and mercury on resin IV are shown in Fig. 4. About 20, 70 and 600 bed-volumes of 200-ppm copper, mercury and silver solutions respectively could pass through the column without leakage into the effluent. With resin III, however, leakage of mercury was observed after passage of about 3–5 bed-volumes of the feed solution. Although resin III is superior to resin IV in stability, its rate of equilibration is too slow for use in column work.

Resin IV was applied to concentration of mercury and silver from sea-water. Mercury was concentrated on a resin IV column from 1 litre of sea-water spiked with mercury tracer (^{203}Hg) under the same conditions as in the breakthrough experiment, and was recovered quantitatively with less than 8 bed-volumes of $0.1M$ hydrochloric acid containing 10% thiourea. Silver was also concentrated on a resin IV column (resin 1 g, 1 × 3.7 cm) from 15 litres of sea-water at a flow-rate of 20 ml/min. The silver retained

Table 4. Sorption of metal ions from acetate buffer (pH 7) in the presence of EDTA with resin IV

$\dfrac{[\text{EDTA}]}{[\text{Metal}]}$	Metal sorption, %			
	Cu(II)	Ag(I)	Cd(II)	Hg(II)
—	100	99.9	100	99.9
1	11.3	100	4.0	99.9
3	1.3	100	0	99.9
5	0	100	0	99.9
10	0	99.9	0	99.8

Metal solutions: $1 \times 10^{-3}M$, 10 ml. Shaking time: 24 hr.

was eluted with 20 ml of $0.1M$ hydrochloric acid containing 1% thiourea, and determined by atomic-absorption spectrophotometry. It was found that the sea-water contained 0.02–0.05 μg of silver per litre, in reasonable agreement with published data $(0.04 \ μg/l.)$.[20]

MULTIPARAMETRIC CURVE FITTING—VI.
MRFIT AND MRLET, COMPUTER PROGRAMS FOR ESTIMATION OF THE STABILITY CONSTANT OF THE PREDOMINANT M_pL_q COMPLEX AND THE LIGAND PURITY BY ANALYSIS OF PHOTOMETRIC TITRATION CURVES

MILAN MELOUN

Department of Analytical Chemistry, College of Chemical Technology, 532 10 Pardubice, Czechoslovakia

and

MILAN JAVŮREK

Computing Centre, College of Chemical Technology, 532 10 Pardubice, Czechoslovakia

Summary—MRFIT and MRLET, two FORTRAN computer programs, can analyse a photometric mole-ratio curve (photometric titration curve) to estimate the stability constant β_{pq} of the predominant complex M_pL_q, the ligand concentration factor f_L, the extrapolated absorbance A_{ext} and the stoichiometric coefficient q (p is usually 1). MRFIT uses algorithmic minimization of a residual-square sum to reach, usually, the global minimum or the lowest of several local ones. MRLET, an ABLET system program based on LETAG, allows algorithmic and/or heuristic minimization. A local minimum described by parametric co-ordinates with a definite physical meaning might be found by the heuristic process.

The mole-ratio method introduced by Yoe and Jones[1,2] for spectrophotometric investigation of complex-formation equilibria has been frequently used,[3–9] and is known as photometric titration in analytical chemistry. It is based on graphical interpretation of the absorbances observed when the concentration of one component of the complex is varied while that of the other is held constant.

If the system forms a sufficiently stable complex, such a plot gives a sharp break and the mole ratio at the break corresponds to the composition of the complex. If, however, a weak complex is formed, only a curved plot results (Fig. 1). Previous papers in this area have been reviewed by Momoki *et al.*[9] who also suggested a new generalized approach to the mole-ratio method to allow computer-assisted treatment.

We introduce here two FORTRAN programs that use different mathematical approaches to the minimization of a residual-square sum function. The program MRFIT is easy to apply because its algorithmic strategy works completely automatically, and minimization always leads to the global minimum or to the lowest of several minima. The parametric co-ordinates of the minimum always have mathematical meaning, although in some cases they may have no physical one.

The program MRLET, part of the ABLET system,[10] allows application of an algorithmic strategy or a heurisitic strategy, or a combination of the two.

Part V. *Talanta*, 1984, **31**, 947.

This makes it possible to find a local minimum with parametric co-ordinates with definite physical meaning.[10] Heuristic minimization requires some intervention by the user, to set the initial size of the minimization steps, the initial guesses for the parameters to be estimated or the value of the parametric steps for the final refinement of parameters.

THEORY

Mathematical model—equation of a photometric titration curve

A photometric titration curve is a graphical representation of the mole-ratio method. It shows how the
Fig. 1. Photometric mole-ratio curves shown in original (A; V_M) and normalized (α; q_M) co-ordinates for complex M_2L. Curves for strong (s), medium (m) and weak (w) complexes are shown.

absorbance changes as the mole ratio of the two components M and L of the complex M_pL_q is changed when the concentration of one is varied and the concentration of the other is held constant. Let us consider the formation of a single complex M_pL_q by the reaction

$$pM + qL \rightleftharpoons M_pL_q \qquad (1)$$
with (concentration) formation constant

$$\beta_{pq} = [M_pL_q]/([M]^p[L]^q) \qquad (2)$$

$$\beta_{pq} = [M_pL_q]/\{(c_M - p[M_pL_q])^p(c_L - q[M_pL_q])^q\} \qquad (3)$$

If the total concentrations of M and L are denoted by c_M and c_L, the mass-balance equations are

$$c_M = [M] + p[M_pL_q] = c_{M,b}V_M/V_0 \qquad (4)$$

$$c_L = [L] + q[M_pL_q] = c_{L,w}f_L \qquad (5)$$

where $c_{M,b}$ is the molar concentration and V_M the volume of the metal-ion solution added from the burette, V_0 is the initial titrand volume, $c_{L,w}$ is the nominal ligand concentration, calculated from the weight of reagent used and volume of solution made from it, and f_L is a concentration factor to allow for impurity in the reagent.

The mole ratio is $q_M = c_M/c_L$ and the normalized absorbance α is defined by the expression[9]

$$\alpha = [A(1 + V_M/V_0) - A_0]/(A_{ext} - A_0) \qquad (6)$$

where A_0 is the initial absorbance and A_{ext} is the absorbance of a solution in which an excess of metal ion has been added to suppress dissociation of the complex. For constant ligand concentration the following function may be derived:

$$F = \alpha p/q$$
$$+ \alpha^{1/p}/[q\beta_{pq}c_L^{(p + q - 1)/p}(1 - \alpha)^{p/q}] - q_M = 0 \qquad (7)$$

This describes the experimental relation $A = f(q_M)$ or the photometric titration curve $A = f(V_M)$. This mathematical model contains the dependent variable (A), the independent variable (V_M), and three unknown parameters, the overall stability constant (β_{pq}), the absorbance of the complex $M_pL_q(A_{ext})$, and the ligand concentration factor (f_L). The two stoichiometric coefficients of the complex, p and q, are usually suggested by the user and then validated by calculation; p is usually 1.

The relationship between absorbance and mole ratio is measured for constant total ligand concentration, and varied metal ion concentration, so the method is known as the "metal-changing method" (MCh). When the ligand concentration is varied and the metal-ion concentration is kept constant, the method is known as the "ligand-changing method" (LCh).[9]

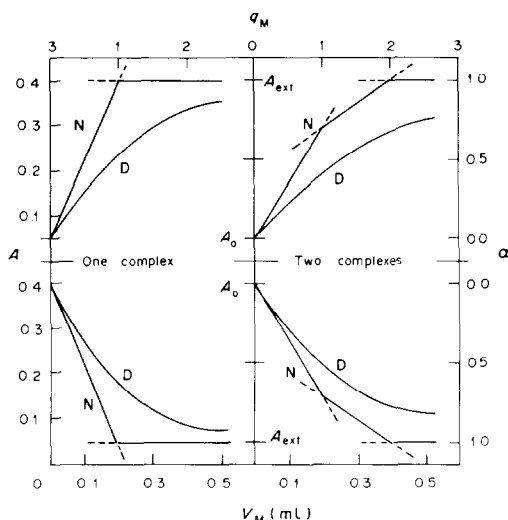
If only one complex is formed (and it is very stable), the graph of $A = f(q_M)$ consists of two intersecting lines (Fig. 2). The ratio of the total concentrations of metal and ligand at the point of inter-


Fig. 2. Photometric mole-ratio curves shown in original (A; V_M) and normalized (α; q_M) co-ordinates for a single prevailing complex ML in solution (left half of figure) and a mixture of complexes ML and M_2L (right half), for strong (N) and weak (D) complexes in solution. The photometric titration curve is shown for the wavelength at which the complex absorbs (upper part) or at which the ligand absorbs (lower part).

section gives the metal-to-ligand ratio in the complex. If the complex is only moderately stable, a steep curve is obtained and the intersection of tangents to the initial and final sections can still give this ratio, but the uncertainty increases with decreasing stability. For weak complexes, this simple graphical method fails to give any reliable information. If N complexes are formed and the successive formation constants are sufficiently high for there to be little overlap of the equilibria, the curve consists of $(N + 1)$ segments. If a single complex predominates, regression evaluation of the mole-ratio curve can be used to estimate the three parameters β_{pq}, f_L, and A_{ext}.

Regression analysis

Regression analysis consists of the estimation of unknown parameters by minimizing the difference between experimental and calculated data. The theoretical justification for the procedure has recently been discussed.[10]

The experimental error in reading the burette is usually less than the error in the absorbance reading. Because an explicit expression of the absorbance $A = f(V_M)$ is not possible, the calculated absorbance A_{calc}, is obtained by the Müller approximation[11] in both MRLET and MRFIT. The sum of weighted squared residuals

$$U = \sum_{i=1}^{n} w_i(A_{exp,i} - A_{calc,i})^2 = \text{minimum} \qquad (8)$$

where w_i is the statistical weight, usually taken as unity, can be minimized by use of the least-squares procedure LETAG[12] for MRLET, and FIT[13] for

MRFIT. The FIT subroutine uses only algorithmic minimization, and always finds the global minimum. The normal equations are linearized in FIT and transformed to the principal axis system. The subroutine contains a main loop for calculating alterations to parameters from the eigenvalues and eigenvectors of the normal equations, with reduction of the alterations if the linearity range is exceeded, and a minor loop for reducing the linearity ranges if it is found that the squared error obtained with the new parameters is greater than that for the old ones. The termination criterion is tested only in normal iterations.

The MRLET program, from the ABLET system,[10] uses the pit-mapping algorithm LETAG,[12] and does the minimization with heuristic (steps controlled by the user) or algorithmic (steps controlled automatically by the program) control. Heuristic minimization may reach a local minimum with definite physical meaning, but the algorithmic process always finds the global minimum or lowest minimum of several, but this does not necessarily have a physical meaning. In the heuristic process, the user must decide whether it is sufficient to know the location of some local minimum or whether knowledge of the global minimum is required. The user has to supply initial guesses of the values of the parameters and the minimization steps, and an organizational framework to control the process from iteration to iteration.

For all the parameters involved here, a negative value has no physical meaning. For such parameters the MRLET program contains a safeguard to stop them from becoming negative during the minimization, and at the same time to check that the calculations are not carried too far from the minimum. The block doing this is called MIKO; it searches systematically, over the calculated second-degree surface, for the set of three parameters that gives the lowest value for U with no parameter negative.

DATA INPUT INSTRUCTIONS
MRFIT

The data cards required for MRFIT are as follows, and each photometric titration requires this sequence of cards.

1. *Title card*: TITLE (20A4)
2. *Termination card*: STOP, SINST.
3. *Titration conditions card*: NB, CMB, VO, AL, CLW, CORM, ALFMIN, ALMAX, P, Q.
4. *Data card*: for simulated data set: VM(I), I = 1, NB; for experimental data set: VM(I), AEX(I), I = 1, NB.
5. *Initial guess card*: BETAO, FLO, AEXTO.
6. *Simulation card*: for a simulated data set: BETA, FL, AEXT; for an experimental data set this card is omitted.

The *termination card* contains STOP values (the algorithm FIT terminates when the sum of squares of parameter alterations divided by their variances is less than the STOP value), and SINST, the standard deviation of the absorbances measured with the spectrophotometer used: SINST > 0 indicates that a simulated data set is used, and SINST ≤ 0 that the experimental data are used.

The *titration conditions card* contains ten experimental quantities: NB is the number of data points, CMB is the

molar concentration of metal solution in the burette, $c_{M,b}$, VO is the initial volume of titrand solution V_0, AL is the initial absorbance of the ligand in the titrand before the titration is started, CLW is the total molar concentration of the ligand in the titrand, $c_{L,w}$, CORM is a correction factor relating the burette volumes $V_{M,i,read}$ to true volumes delivered [so $V_{M,i}$ = VM(I)*CORM], ALFMIN is the lower limit α_{min} of the curve interval to be analysed numerically and ALFMAX is the upper limit α_{max}, and P and Q are stoichiometric coefficients p and q of the complex M_pL_q.

The *data card* contains experimental pairs of titration-curve points; VM(I) is the volume $V_{M,i,read}$ of metal solution added and AEX(I) is the measured absorbance (when NB is written with a minus sign, transmittance is read in instead of absorbance). With simulated data, only the independent variable VM(I) is read here, and the dependent variable, absorbance, is generated by MRFIT.

The *initial guess card* contains the initial guesses of the three parameters to estimated: $\beta_{pq}^{(0)}$, $f_L^{(0)}$, $A_{ext}^{(0)}$.

The *simulation card* contains preselected values BETA, FL, AEXT for the parameters β_{pq}, f_L, and A_{ext}. For experimental data, this card is omitted.

MRLET

Programs of the ABLET system all use similar data decks, as discussed previously.[10] Only the three specific cards (the *simulation card*, *titration conditions card* and *data card*) are commented on in detail here.

1. *Title card*: TITLE (20A4).
2. *Keys card*: ISSW(I), I = 1, 6.
3. *Termination card*: EPS, PSI, SINST.
4. *Simulation card*: for a simulated data set: (XK(I), I = 1, 4), (SIGXK(I), I = 1, 4), (WEI(I), I = 1, 4). For an experimental data set this card is omitted.
5. *Titration conditions card*: for a simulated data set: NB, CMB, VO, AL, CLW, CORM, ALFMIN, ALFMAX, P, Q, FLO, AEXTO; for an experimental data set: 6, plus the same deck as for a simulated data set.
6. *Data card*: for a simulated data set: VM(I), I = 1, NB; for an experimental data set: VM(I), AEX(I), I = 1, NB.
7. *Initial guess card*: 7, 4, 4, AEXTO, FLO, LBETAO, QO.
8. *Matrix card*: ISKIN, (I(K), J(K), S(I(K), J(K)), K = 1, ISKIN.
9. *Step card*: 3, N, (I(K), STEK(I(K)), K = 1, N).
10. *Process card*: IRUR, IRUR, IRUR, ... (e.g., 2, 5, 13).

This set of cards constitutes one data block, and as many data blocks as desired may be executed, one after the other. The *simulation card* reads preselected values of four parameters in sequence (A_{ext}, f_L, log β_{pq}, q) followed by their standard deviations $s(A_{ext})$, $s(f_L)$, $s(\log \beta_{pq})$, $s(q)$ and their weights $w(A_{ext})$, $w(f_L)$, $w(\log \beta_{pq})$, $w(q)$.

The *titration conditions card* contains the same quantities as for MRFIT. FLO and AEXTO here represent the initial guesses $f_L^{(0)}$, $A_{ext}^{(0)}$. For an experimental data set, this card must begin with the integer key 6.

The *data card* has the same content as for MRFIT.

The *initial guess card* contains the key 7 followed by the number of parameters to be refined and the number of positive parameters. Values of the initial guesses for particular parameters in the sequence $A_{ext}^{(0)}$, $f_L^{(0)}$, log $\beta_{pq}^{(0)}$, $q^{(0)}$ follow.

The remaining cards have been described previously.[12]

EXPERIMENTAL

Photometric titration techniques

The mole-ratio curve for a complex-forming system may be measured by two methods.

(1) *The MCh (metal-changing) method*. The concentration of the ligand in the titration vessel is kept constant

and this solution is titrated with the metal-ion solution added from a burette.

(2) *The LCh (ligand-changing) method.* The concentration of metal-ion solution in the titration vessel is kept constant and the amount of ligand is gradually increased by addition from a burette.

There are two distinct experimental techniques for doing photometric titrations.

(1) *Titration done in the cell (internal MCh technique).* A known volume of ligand solution (2–30 ml) is placed in the spectrophotometer cell. For the total increase in volume during the titration to be small enough for the ionic strength and some equilibrium properties not to be seriously affected, the volume of metal solution added should be in the range 100–300 μl. A stirrer and the capillary tip of the micro-burette are inserted in the cell (and a glass electrode if it is desired to check the pH during the titration). The geometric arrangement should be unchanged throughout the titration. If necessary, polyethylene inlet tubes are also inserted into the cap to allow the cell to be flushed with a solvent-saturated stream of inert gas.

(2) *Titration done outside the cell (external MCh technique).* A 150-ml double jacket titration vessel is connected to the photometer cell by polyethylene tubes or glass capillary tubes fitted with glass ball-joints. Tubes pass through the Teflon cell-stopper, one of them connecting the bottom of the cell to a 100-ml glass syringe. The titration of the ligand solution is done in this titration vessel, the reagents being mixed by passage of inert gas or by a mechanical stirrer. After each addition of metal ion solution and establishment of equilibrium, some solution is trans-ported into the cell by overpressure of inert gas or by use of a syringe. The cell is rinsed several times with the solution from the titration vessel, the absorbances at various wave-lengths are measured, and the solution is transported back into the vessel. The concentration of metal is then changed by adding solution from a microburette and the whole procedure is repeated.

APPLICATIONS

Some examples are given below of systems in which a predominant complex exists at equilibrium, and which were studied with the aid of MRFIT and MRLET.

Example 1. SNAZOXS–zinc complex, studied by the internal MCh technique.

The stability constant of the ML_2 complex and the ligand concentration factor are estimated by the MCh data-evaluation procedures of MRFIT and MRLET. The two minimization strategies, algo-rithmic and heuristic, are illustrated.

Experimental conditions. An initial volume of 4.00 ml (= VO) of $1.65 \times 10^{-4} M$ (= CLW) SNAZOXS, was titrated with $2.0 \times 10^{-3} M$ (= CMB) zinc added from a home-made microburette having a correction factor of 0.988 (= CORM). The titration was done in acetate buffer at pH 5.5, with $I = 0.1$ (NaClO$_4$), with measurement at 575 nm in a 1.000 cm cell at 25°; these experimental conditions are given in the title card. The absorbance before the titration was started was 0.670 (= AL).

Input data for MRFIT (Table 1). Program MRFIT will test the proposed chemical model and verify or reject the existence of complex ML_2, the input data being P = 1, Q = 2, and the initial guesses $\beta_{12}^{(0)} = 10^8$ (= BETAO), $f_L^{(0)} = 1.0$ (= FLO), and $A_{ext}^{(0)} = 0.01$ (= AEXTO). Selected points from the total 24 (= NB) points of the photometric titration curve, between $\alpha_{min} = 0.01$ (= ALFMIN) and $\alpha_{max} = 0.99$ (= ALFMAX) will be used. The experimental data are executed, so SINST must be equal to -1. The MRFIT algorithmic minimization is limited to 100 iterations (program code) or by the termination criterion 10^{-9} (= STOP) in the input.

Input data for MRLET (Tables 2 and 3). Program MRLET can perform an algorithmic (Table 2) or a heuristic (Table 3) minimization. In each iteration a print of the parameter values and the residual-square sum function is requested [ISSW(1) = 1] and also a print of the elements of the twist matrix [ISSW(2) = 1] and the determinant [ISSW(3) = 1]. When an algorithmic process is used, [ISSW(6) = 0], the minimization step in the next iteration is calcu-lated either as a PSI fraction (PSI = 0.3) of the previous step [STEP(I) = PSI* STEP(I)], in which case ISSW(4) is equal to 0, or as a PSI fraction of the parametric standard deviation DARK2(I) calculated in the previous iteration [STEP(I) = PSI* DARK2(I)], in which case ISSW(4) is equal to 1. The key ISSW(5) is used for simulated data only. The minimization process is terminated when $|(U^{(i)} - U^{(i+1)})/U^{(i)}| \leqslant$ EPS (here EPS $= 10^{-6}$) or when 40 iterations have been performed. As experi-mental data are to be used, SINST is -1.0. When no twist matrix elements are available, ISKIN is equal to 0 and the rest of the card may be omitted. The step card contains IRUR = 3 which calls the block STEG,

followed by the number of parameter steps ($N = 3$) and the number, $I(K)$, and numerical value STEK($I(K)$) of each parameter step. This STEK($I(K)$) step value is used in the first iteration only; in following iterations it is calculated as indicated above. The process card lists three IRUR numbers (2, 5, 13) which call three blocks; 2 calls UTTAG, i.e., the starting value of the first central point of the residual-square sum function; 5 calls LETA for systematic variation of parameters and the minimization process; 13 calls SKRIK for output of the results and fitness test.

When a heuristic minimization is required the key ISSW(6) is set equal to 1 (cf. Table 3), and minimization steps and process keys IRUR are read from data cards in each iteration. One iteration is executed after reading in IRUR = 5, which calls the block LETA. The parameters do not all need to be refined at once. They are estimated one at a time, then in the final iteration all are refined together. This heuristic strategy is recommended, for example, when there are some ill-conditioned parameters in the model or when the pit-shape is skew or plate-like.

Example 2. The 7-(2-carboxyphenylazo)-8-hydroxyquinoline-5-sulphonic acid–copper(II) complex studied by the external MCh technique.

The stability constant of ML and the ligand correction factor are estimated by MRFIT analysis of mole-ratio curves measured at various wavelengths.

Experimental conditions. An initial volume of 20.00 ml (= VO) of $1.102 \times 10^{-4}M$ (= CLW) ligand solution, was titrated with $3.39 \times 10^{-3}M$ (= CMB) copper(II) added from a home-made syringe microburette with a correction factor of 0.01947 ml/mm (= CORM). The titration was done in acetate buffer at pH = 4.901, and $I = 0.1$ (NaClO$_4$) with measurement at 510 nm in a 1.000-cm cell at 25°. The initial absorbance was 1.210 (= AL).

Input data for MRFIT (Table 4). MRFIT will test the proposed chemical model ML, the parameters being $P = 1$, $Q = 1$, $\beta_{11}^{(0)} = 10^6$ (= BETAO), $f_L^{(0)} = 0.9$ (= FLO), $A_{\text{ext}}^{(0)} = 0.56$ (= AEXTO). Selected points from the total of 13 (= NB) on the photometric titration curve between $\alpha_{\text{min}} = 0.01$ (= ALFMIN) and $\alpha_{\text{max}} = 0.99$ (= ALFMAX) will be used for curve fitting. Because experimental data are used, SINST is

-1.0. The MRFIT minimization is algorithmic, limited to 100 iterations or by the termination criterion 10^{-9} ($=$ STOP).

Example 3. Data simulation. The influence of the instrumental error of the spectrophotometer used, $s_{inst}(A)$, on the estimated parameters can be investigated by the use of simulated data, by MRFIT.

Experimental conditions. For parameters $\beta_{11} = 10^6$, $f_L = 1.0$, $A_{ext} = 1.0$ and various preselected values of the instrumental error, *viz.* $s_{inst}(A) = 10^{-6}$, 10^{-4}, 10^{-3}, 0.002, 0.004, 0.006, ($=$ SINST), and with the rest of the experimental conditions kept constant (NB $= 28$, CMB $= 0.001$, VO $= 20.0$, AL $= 0.0001$, CLW $= 0.00001$, CORM $= 1.0$, ALFMIN $= 0.01$, ALFMAX $= 0.99$, P $= 1$, Q $= 1$, BETAO $= 1.5E6$, FLO $= 0.9$, AEXTO $= 0.95$) six mole-ratio curves are generated. After data simulation, a MRFIT minimization is done. The input data for simulation and minimization process are given in Table 5.

DISCUSSION

Table 6 shows the MRFIT output for Example 1. The first part lists the experimental conditions and the calculation conditions. All 24 experimental points are used in the regression analysis because they lie between α_{min} and α_{max}. TITRATION DATA lists the original co-ordinates $\{V_{M,read}; A_{read}\}$ of the photometric titration points and SELECTED POINTS lists the transformed co-ordinates $\{c_M; A\}$, the ith point having the co-ordinates $c_{M,i} = c_{M,b} * V_{M,read,i} * \text{CORM}/V_0$ and $A_i = A_{i,read}$ $(1 + V_{M,i,read} * \text{CORM}/V_0)$. MRFIT solves equation (7) by using equations (5) and (6) and the mole-ratio curve in transformed co-ordinates $\{c_M; A\}$.

INTERMEDIATE RESULTS gives the residual-square sum for the initial guesses of the parameters and for the fitted values found at the end of minimization.

OUTPUT lists the values of the parameters and their absolute and relative standard deviations. When the elements of the covariance matrix are negative, they are not printed, and the standard deviations of the parameters are also not defined. CURVE FITTING lists the experimental and calculated points of the photometric tritration curve in the original $\{c_M; A\}$ and normalized $\{q_M; \alpha\}$ co-ordinates. The re-

siduals demonstrate the quality of the fit achieved. The degree of fit is tested objectively by the statistical analysis of the residuals.

MRFIT verified the proposed chemical model, that the ML_2 complex is formed in the photometric titration of zinc with SNAZOXS, when excess of ligand is present. The statistical tests show that the calculated and experimental points are very close: the mean value of the absorbance residuals is only 0.0012 (*i.e.*, the arithmetic mean of the absolute values of the residuals), less than the instrumental error for the spectrophotometer used $[s_{inst}(A) = 0.002$ for the Zeiss VSU2-G spectrophotometer], and the standard deviation 0.0020 of the residual mean is of the same magnitude as the instrumental error. The other statistical tests also prove that the degree of fit is sufficiently good for the parameter estimates found to be considered reliable.

The statistical test of the degree of fit used here is an efficient diagnostic tool when a chemical model is sought, and it may be used as a criterion for comparison and selection of the best model from several plausible proposed ones.

From the numerical analysis of the photometric titration of zinc with SNAZOXS, it may be concluded that for the range from excess of ligand in solution to nearly equimolar solutions ($q_L = c_L/c_M = 31.6$–1.54) the ML_2 complex prevails in solution. This complex has a stability constant $\beta_{12} = 3.05 \times 10^9$, the concentration factor of SNAZOXS is $f_L = 0.947$ (this means that the SNAZOXS has a purity of 94.7%) and the extrapolated absorbance is $A_{ext} = 0.01205$ (Table 6).

Table 8 shows a MRLET output for Example 1. Experimental conditions and curve-point selection are the same as for MRFIT. Most of the MRLET output is self-explanatory, but some comments are appropriate. The control label RURIK indicates the sequence of operations in the minimization process. RURIK $= 6$ introduces block DATA, which reads the titration conditions card and data card and prints their content in the output. RURIK $= 7$ calls block LASK which reads the initial guesses of the four parameters to be refined, and RURIK $= 3$ reads and writes the minimization steps for the first iteration. RURIK $= 2$ causes calculation of the residual-square sum U_c for the central point in the first iteration, *i.e.*, for the initial guesses of the parameters.

Systematic variation of m particular parameters is done in block LETA, called by RURIK = 5. The label SKOTT introduces the "shots" fired for individual parameters in a particular step, and the relevant values of U are printed in tabular form. In each iteration $(m + 1)$ $(m + 2)/2$ shots are performed, and after each iteration, current estimates of the parameters and statistics are printed: SIGY means the value of the standard deviation of the dependent variable $s(A)$ in the given iteration, KBOM lists the refined values of the parameters, and DARR2 their standard deviations.

The twist matrix is interpreted as a rotation of the axis to coincide with the long axis of the ellipse. When parameters are varied along the direction of the main axes of the ellipsoidal cross-section of the pit, the convergence will be improved. For this purpose the axes of the trial parameters must be transformed, and the elements above the diagonal of a new (twist) matrix are printed after the label SIK. The PROVA block performs a test of the U value reached in a particular iteration. The lowest value of U, once found, is stored. If the calculated set of trial parameters in the ith iteration gives a lower value of the U function than any previously found, it is accepted as the best set; if, however, the preceding $(i − 1)$th iteration gave a lower value of U, this previous set is accepted and printed by the label GAMLA KONSTANTER. If some earlier iteration gave the lowest U value, then *that* set of parameters is accepted and printed by the label SLUMPSKOTT.

The most efficient minimization strategy seems to be a combination of a heuristic and an algorithmic process. The ill-conditioned parameters, for example, are heuristically refined at the beginning of the minimization, and later an algorithmic refinement of all the parameters is performed.

When one of the termination criteria is fulfilled, the minimization process terminates. Label SKRIK produces a table of final estimates of the refined parameters, with their standard deviations and the degree-of-fit table produced by the statistical analysis of residuals. These tables are the same as in MRFIT.

The purpose of studying simulated data is (1) investigation of the influence of the instrumental error of the spectrophotometer used on the estimates of parameters refined, or (2) investigation of ill-conditioned parameters, or (3) testing the program validity and the reliability of parameter estimation. In the simulated data, the random error generated is used to load precise absorbance values. The resulting spread of points along the A vs. q_M curve is a good representation of real experimental data.

Table 9 shows how the calculated estimates of the three parameters depend on the simulated instrumental error, $s_{inst}(A)$. The set of generated random errors is statistically tested in order to find whether its distribution is Gaussian. The reliability of the calculated parameter estimates may be classified according to the agreement between the statistical characteristics of the set of random errors and the set of residuals. The original mole-ratio curve, along which the random errors are spread, should be identical with the calculated mole-ratio curve, so each residual should be of the same magnitude as the corresponding random error of the particular point but of opposite sign.

Because all the computational conditions were kept constant, and only $s_{inst}(A)$ was changed, Table 9 illustrates the effect of randomization. Well-conditioned parameters are estimated accurately within the tolerance of their standard deviations but ill-conditioned parameters are estimated with a great deal of uncertainty and not accurately. This illus-

A NEW EXPERIMENTAL TECHNIQUE FOR VALIDATING EXCHANGE MODELS OF CARBON DIOXIDE BETWEEN THE ATMOSPHERE AND SEA-WATER

Sam Ben-Yaakov and Hugo Guterman
Department of Electrical and Computer Engineering, Ben-Gurion University of the Negev, Beer-Sheva, Israel

Summary—The mechanism of CO_2-exchange between the atmosphere and sea-water was re-examined by simultaneously measuring pH and pO_2 in artificial sea-water exposed to CO_2 and air atmospheres. The data were fitted to an exchange model by using both the differential and integral forms of the diffusion equation. It was found that the pH and pO_2 data support the assumption that the exchange for these gases is driven by the gradient of the partial pressure of the gas across the imaginary solution-gas boundary layer (the z layer) and is not affected by chemical reaction or hydration rate under the experimental conditions used, *viz.* 1–100 meq/l., alkalinity, pH 4.5–8.3 and z-layer thickness 2–500 μm. It is concluded that the rate of hydration of CO_2 plays an insignificant role in the exchange mechanisms between the atmosphere and the oceans.

Exchange of CO_2 between the gas and liquid phases is a fundamental process in many scientific and technological disciplines. The process is crucial in regulating CO_2 concentration in the oceans and atmosphere, a topic which has recently been of much concern in connection with the very high production of CO_2 due to the utilization of fossil fuel by modern technology.[1,2] The fact that dissolved CO_2 undergoes hydration to produce carbonic acid and that the acid further dissociates into bicarbonate and carbonate ions, raises the question of possible effects of these reactions on the exchange process. The simplified model generally used to describe gas exchange between the gas and liquid phases is the film model.[3] It consists of an imaginary stagnant solution layer (the z layer) separating the gas phase from the bulk of solution, both of which are assumed to be well mixed. The exchange process between the two phases is thus assumed to be controlled by molecular diffusion of the dissolved gas through the z layer. In the case of CO_2, this simple model is complicated by the fact that CO_2 reacts with the water and the transport process might therefore be dependent on the hydration kinetics as well as the migration rates of a number of species, such as HCO_3^- and CO_3^{2-}. A number of investigators have studied this question analytically and experimentally. The proposed methods differ with regard to the assumptions made concerning the carbonate chemistry within the layer. Bolin,[4] and Hoover and Berkshire[5] assumed the pH to be constant within the layer, Quinn and Otto[6] assumed electroneutrality, whereas Emerson's approach[7,8] permitted alkalinity and ionic gradients within the z layer. The different models predict similar behaviour: a transport rate which is dependent on pH and the thickness of the boundary layer. Attempts to verify

the proposed models experimentally were made by Hoover and Berkshire[5] and Liss.[9] In both cases exchange of CO_2 was monitored by tagging the dissolved CO_2 with ^{14}C and monitoring the residual radioactivity in solution after loss of CO_2 to the atmosphere. The experiments were done with solutions buffered at low and high pH ($\sim$5 and $\sim$8 respectively).

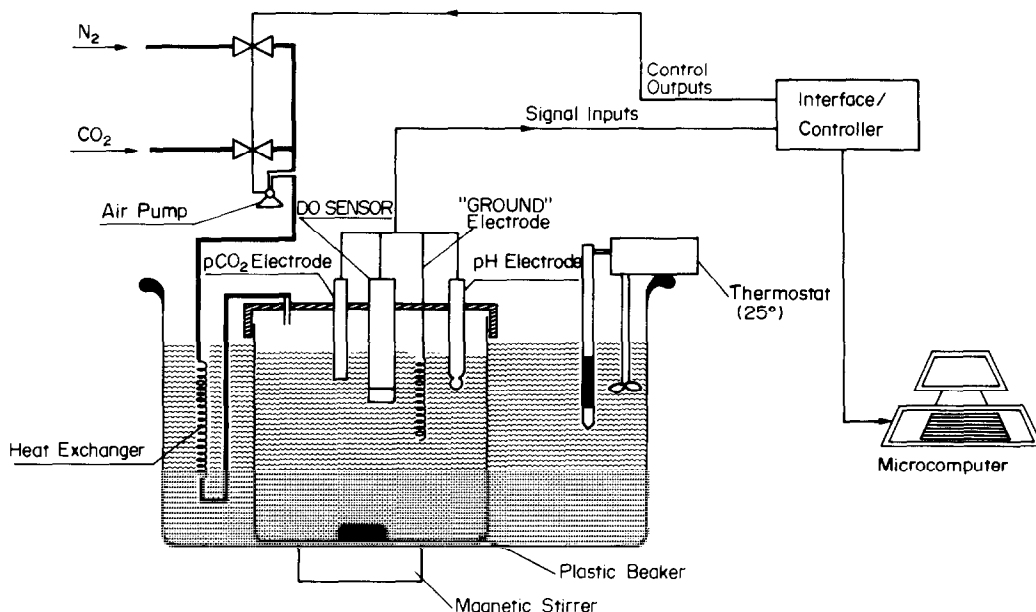
It is questionable whether the experimental procedures used in previous studies are capable of simulating natural processes, for at least two reasons. First, it is unknown whether a tracer diffusion ($^{14}CO_2$) is indeed quantitatively equal to bulk diffusion of CO_2.[10] Secondly, application of a buffer to control the pH introduces an artificial restriction not found in natural environments such as oceans and lakes, in which the pH is mainly controlled by the carbonate system.[10] A constant pH implies a constant H_2CO_3/HCO_3^- ratio independent of total CO_2 in sea-water, which is contrary to the behaviour of the oceans. Consequently, the results of these experiments may not reflect the actual behaviour of a solution such as sea-water in which the carbonate system is the main buffer. The purpose of the present study was to examine the process of CO_2 exchange between the atmosphere and sea-water over a large pH range under solution-chemistry conditions which simulate those of the oceans. This was accomplished by measuring simultaneously the partial pressures of CO_2 and O_2 in sea-water solutions which were exposed to overlying atmospheres of air and CO_2. The purpose of simultaneously monitoring pO_2 and pCO_2 was to permit the comparison of an inert gas (O_2 under these exchange conditions) and a chemically reactive gas (CO_2).


Fig. 1. Experimental assembly (DO SENSOR = dissolved oxygen sensor).

EXPERIMENTAL

The apparatus (Fig. 1) consisted of a covered beaker kept at constant temperature, pH and dissolved-oxygen electrodes, and a computerized data-acquisition system.[11] The experiments were done at 25° on 2-litre samples of artificial Mediterranean sea-water[12] with alkalinity in the range 1–100 meq/l. The solutions, stirred by a magnetic stirrer, were exposed to a CO_2 and air atmosphere at atmospheric pressure (ca. 980 mbar) and the resulting changes in pH and dissolved O_2 were monitored, with reading every 0.5–2 min. In some experiments, the exchange between the gas and liquid phases was accelerated by bubbling the gas through the solution. The pH change during the experimental runs was from pH 4.5 to pH 8.3. The dissolved-oxygen electrode was similar in design to the one described earlier.[13,14] The membrane was a 2.4×10^{-3} cm (1 mil) thick Teflon film.

In some experiments pCO_2 was also measured directly with a membrane electrode (ORION, type 9502), but the results were not used in the regression analysis.

RESULTS AND DISCUSSION

The partial pressure of CO_2 (pCO_2) and concentration of total CO_2 (TCO_2) solution, during the experimental runs, were calculated from the carbonate alkalinity and pH by using the apparent constants of the carbonate system at the given salinity:[10]

$$pCO_2 = \frac{CA \times a_H^2}{K_1' \alpha_s [a_H + 2K_2']} \quad (1)$$

and

$$TCO_2 = CA \left[\frac{a_H K_1' + K_1' K_2' + a_H^2}{a_H K_1' + 2K_1' K_2'} \right] \quad (2)$$

where CA = carbonate alkalinity; K_1' = first apparent dissociation constant of carbonic acid, K_2' = second apparent dissociation constant of carbonic acid, α_s = solubility of CO_2, a_H = hydrogen-ion activity.

The CO_2 and O_2 data for the transition from low to high pH (Fig. 2), were fitted to the simple gas-exchange model:[3]

$$\frac{dC}{dt} = -\frac{D_c}{z}(pc_b - pc_s)\alpha_c A/V \quad (3)$$

where C = concentration of the gas (mole/ml), D_c = diffusion coefficient of the gas c (cm^2/sec), z = thickness of stagnant diffusion layer (cm), α_c = solubility of the gas c (mole.cm^{-3}.atm^{-1}), pc = partial pressure of gas c (atm), A = area of the solution (cm^2) in direct contact with the atmosphere, V = volume of solution (cm^3) and the subscripts b and s denote the bulk solution and boundary layer respectively.

The model assumes that the driving force of the exchange process is dependent on the partial-pressure gradient of the pertinent gas across the z layer (or the
Fig. 2. Typical response of pH, pO_2 and pCO_2 of solutions to a change in the overlying atmosphere, in the sequence air–CO_2–air.

concentration gradient of $H_2CO_3^* = [CO_2(aq) + H_2CO_3])$ and neglects kinetic effects, and migration of ionized species such as HCO_3^-. It is also assumed that pCO_{2_b} at any instant can be calculated from the pH and carbonate alkalinity. That means that hydration and ionization-rate effects are assumed to be insignificant in comparison with the overall time constant of the exchange process, i.e., the carbonate system in the bulk solution can be considered to be in equilibrium at any instant.

The explicit equations for O_2 and CO_2 exchange are:

$$\frac{dO_2}{dt} = -\frac{D_{O_2}\alpha_{O_2}}{zh}pO_{2_b} + \frac{D_{O_2}\alpha_{O_2}}{zh}pO_{2_s} \quad (4)$$

$$\frac{dTCO_2}{dt} = -\frac{D_{CO_2}\alpha_{CO_2}}{zh}pCO_{2_b} + \frac{D_{CO_2}\alpha_{CO_2}}{zh}pCO_{2_s} \quad (5)$$

where

$$O_2 = pO_{2_b}\alpha_{O_2} \quad (6)$$

and h = height of solution in beaker (Fig. 1).

The parameters D/z and pc_s were estimated for each experimental run by fitting the data to the linear equation:

$$y = ax + b \quad (7)$$

where $y = dTCO_2/dt$, $x = pc_b$, $a = -D_c\alpha_c/zh$, $b = D_c\alpha_c pc_s/zh$, from which we obtain

$$\frac{D_c}{z} = \frac{ah}{\alpha_c}$$

and

$$pc_s = b/a$$

where c denotes O_2 or TCO_2.

The derivatives for each point were obtained by using a modified numerical differentiation method with an inherent smoothing effect,[15,16] to reduce differentiation noise. The equation for the ith value for a backward numerical differentiation was established as

$$\frac{dC}{dt}(i) = \frac{1}{10\,t_s}[-2C(i-2) - C(i-1)$$

$$+ C(i+1) + 2C(2+i)] \quad (8)$$

where t_s is the sampling time.

A second approach to reduce the fitting scatter further was also used. It was based on the integral form of equations (4) and (5), which can be represented by:

$$TC = -\frac{D\alpha_c}{zh}\int pc_b dt + \frac{D\alpha_c}{zh}pc_s\int dt \quad (9)$$

or, in its numerical form:

$$TC_i = -\frac{D\alpha_c}{zh}\sum_0^i pc_{b_i}i + \frac{D\alpha_c}{zh}pc_s\sum_0^i i \quad (10)$$

In this case, the data were fitted to a two-variable
Fig. 3. Typical regression of $dTCO_2/dt = f(pCO_{2_b})$ in the derivative form.

equation of the form:

$$y = ax_1 + bx_2 \quad (11)$$

with

$$y_i = TC_i,$$

$$x_{1_i} = \sum_0^i pc_{b_i}i,$$

$$x_{2_i} = \sum_0^i i,$$

$$a = D\alpha_c/zh,$$

$$b = d\alpha_c pc_s/zh.$$

Typical fitting curves for the differential and integral forms are depicted in Figs. 3 and 4.

The data from all the experiments were found to fit the simple model of equation (1) for both O_2 and CO_2, which assumes that the flux is controlled solely by the partial-pressure gradient between the solution and gas phases (Tables 1 and 2). The excellent fit of the data to the model suggests that kinetic effects associated with the hydration rate of CO_2 are negligible over the range of conditions used in the experiments. It was found that by using this model along with the derived numerical values of D_{CO_2}/z for a given experiment, the change in TCO_2 during the experimental cycle can be accurately simulated (Fig.
Fig. 4. Measured TCO_2 vs. predicted (TCO_2 calculated) during a typical experimental run.

4). We conclude therefore that this model represents to a high degree of accuracy the process of gas exchange for both CO_2 and O_2. It is also found that the diffusion coefficients of the two gases (when expressed as a function of partial pressures) is numerically identical, within 3% (Table 3).

Rigorous statistical analysis of typical experimental runs did not reveal any significant difference between the data points at low pH and those at high pH (Table 4). Such a difference should have been observed if previously suggested models were accepted.[4,5]

The results of the present study seem to conflict with the conclusions of previous investigations although a direct comparison between our data and previous results is impossible owing to the difference in the experimental techniques used. Previous studies seem to suggest that a kinetic enhancement should be

observed at high pH for experiments with a z layer about 300 μm thick. Our results do not support such a conjecture, as we did not observe any difference between the results for high and low pH even for a z layer about 500 μm thick. Therefore, the question of kinetic enhancement can be excluded in discussion of CO_2 exchange between the atmosphere and the oceans, for which the z layer has been estimated to be in the range 30–70 μm thick.[17,18] Hence the only CO_2 flux that should be considered in this case is the one directly associated with, and linearly proportional to, the pCO$_2$ gradient across the z layer. However, the time constant of the response of the oceans to change in atmospheric pCO$_2$ will none the less be dependent on the chemical reactivity of CO_2 in sea-water.[19] As a result of hydration of CO_2 and subsequent ionization, the increase in pCO$_2$ due to CO_2 invasion is much smaller for the pH range of normal sea-water than the increase at low pH. It can be calculated, for example, that at pH 8.2 an increase of 1 μmole/l. in the TCO$_2$ concentration in sea-water will result in an increase of 2.2 ppm in pCO$_2$, whereas the same increase in TCO$_2$ will cause a change of 36 ppm in pCO$_2$ at pH 5. Consequently, the decrease in CO_2 flux due to increase in TCO$_2$ in the ocean will be slower, reducing the time required for reaching equilibrium.

Although the experimental results of the present study disagree with the results of previous investigations, the general conclusion concerning the minor effect of hydration rate on exchange of CO_2 between the atmosphere and the oceans, has already been stated by a number of investigators. The estimated thickness of the z layer in the oceans is about 70 μm, for which previous models also suggest a negligible kinetic enhancement. However, augmentation of the hydration rate could be important in other areas. It has been suggested, for example, that reflux of CO_2 from the urinary tract to the blood could be highly dependent on the kinetics of hydration of CO_2.[20] In this case, the thickness of the

membranes through which the CO_2 diffuses is considerably larger than that of the z layer in the oceans, and the effect of rate of hydration could be important. A better assessment of the exchange mechanism may be obtainable when more experimental data for thick diffusion layers are available.

BEITRÄGE ZUR FRAGE DER EXISTENZ EINES TAUTOMERENGLEICHGEWICHTES IN LÖSUNGEN VON DITHIZON IN ORGANISCHEN SOLVENZIEN—I

DIE KORRELATION ZWISCHEN DEN LÖSUNGSMITTELABHÄNGIGEN REAKTIONSUNTERSCHIEDEN IN DEN SYSTEMEN PALLADIUM/DITHIZON UND KUPFER/DITHIZON UND DEN LÖSUNGSMITTELABHÄNGIGEN UNTERSCHIEDEN DER SPEKTREN DER DITHIZONLÖSUNGEN

H. Wagler und H. Koch
Zentralinstitut für Isotopen- und Strahlenforschung der AdW der DDR, Leipzig, DDR

Zusammenfassung—Beim Einsatz substöchiometrischer Reagenzmengen zeigten signifikante lösungsmittel- und milieuabhängige Reaktionsunterschiede in den Systemen Palladium/Dithizon und Kupfer/Dithizon differenziertes Reaktionsverhalten von Dithizon gegenüber Metallen an, was zunächst qualitativ auf die Existenz eines Tautomerenpaares in Dithizonlösungen hindeutet. Die Reaktionsunterschiede korrelieren eindeutig mit den Unterschieden in den Spektren der Dithizonlösungen. Gestützt auf diese Differenzen konnten die Aussagen zur Tautomerie über ein mathematisches Optimierungsverfahren zur Bandentrennung quantifiziert werden und erstmalig die Einzelspektren der beiden tautomeren Formen ermittelt werden.

Dithizon (Diphenylthiocarbazon, H_2Dz) wurde von Fischer[1] als photometrisches Reagens für Schwermetallspuren in die Analytik eingeführt und ist seitdem ein bekanntes und bewährtes Reagens geworden,[2] obwohl einige grundlegende Fragen des Reaktionsverhaltens bis heute noch nicht endgültig geklärt sind.

Die Frage bezüglich möglicher Tautomerie in Lösungen von Dithizon in organischen Solvenzien wurde von Irving[3] noch unter die Rubrik der ungelösten Probleme eingeordnet.

Fischer[4] hatte auf Grund des Reaktionsverhaltens von Dithizon gegenüber Metallen Thioketo–Thiol-Tautomerie angenommen, wogegen die Ergebnisse von IR-Untersuchungen, MO-Berechnungen, NMR-Untersuchungen und das Fehlen einer signifikanten Temperaturabhängigkeit der Spektren als Hinweis bzw. Beweis für das Vorliegen nur einer Spezies angesehen werden.[5-9]

Jedoch ist und bleibt die auffällige mit bekannten tautomeren Systemen korrelierende Lösungsmittelabhängigkeit der Spektren der Dithizonlösungen (Abb. 1) bei Verneinung eines Tautomerengleichgewichtes *das* Problem,[3,8-10] so daß die Frage bezüglich möglicher Tautomerie weiter im Disput ist.

Auf die Problematik der Tautomerie in Lösungen von Dithizon in organischen Solventien wurden wir beim Einsatz von Dithizon als Chelatbildner für substöchiometrische Abtrennungen aufmerksam.[11]

Ausgangspunkt war die Aufgabenstellung gewesen, Kupferspuren in Halbleitermaterialien und Palladiumspuren in Katalysatormaterialien mittels quantitativer Isotopenverdünnungsanalyse durch Solventextraktion von Metallchelaten zu bestimmen.

Voraussetzungen für diese radiochemische Methode sind das Vorhandensein eines Radionuklides hoher spezifischer Aktivität des zu bestimmenden Elementes und eines Reagenses, das im Spurenbereich noch zu quantitativ einheitlichem und exakt stöchiometrischem Umsatz mit den Metallionen befähigt ist. Im Gegensatz zur Photometrie wird bei dieser Methode mit substöchiometrischen Reagensmengen gearbeitet. Es gibt nur wenige geeignete Reagenzien für substöchiometrische Abtrennungen. Dithizon wurde von Růžička und Starý als geeignetes Reagens empfohlen und auch schon vielfach bei substöchiometrischen Bestimmungen angewandt,[12-15] wobei stillschweigend vorausgesetzt wurde, daß Dithizon quantitativ einheitlich reagiere, das heißt, kein Tautomerengleichgewicht vorliege bzw. die Reaktivität gegenüber Metallen auf die Thiol-Form beschränkt sei.

Bei unseren Voruntersuchungen zu den substöchiometrischen Bestimmungen deuteten Besonderheiten im System Palladium/Dithizon (siehe Tabelle 1) und signifikante Reaktionsunterschiede zu dem System Kupfer/Dithizon auf differenziertes Reaktionsverhalten von Dithizon gegenüber Metallen hin, so daß zunächst der Frage der Tautomerie
Abb. 1. Spektren $2 \cdot 10^{-5} M$ Dithizonlösungen: 1, H_2Dz in Chloroform; 2, H_2Dz in 2-Propanol; 3, H_2Dz in Tetrachlorkohlenstoff; 4, H_2Dz in Cyclohexan.

verdünnter Ammoniaklösung, Wiederausfällen durch Einleiten von SO_2 (unter Kühlung), Neutralwaschen des Dithizon-Niederschlages mit bidest. Wasser und Wasserfrei-Waschen mit gekühltem Methanol. Anschließend wird mit dem organischen Solvenz methanolfrei gewaschen, das zur Bereitung der Stammlösung verwendet werden soll (gekühltes Lösungsmittel!), und die Stammlösung hergestellt. Die Arbeitslösungen, meist $2 \cdot 10^{-5} M$, wurden unmittelbar für jede Versuchsserie durch Verdünnen bereitet.

Die Titerbestimmung erfolgte photometrisch und radiometrisch unter Einsatz von [110m]Ag. Für die photometrische Titerbestimmung wurden nicht nur die Extinktionen im Maximum aufgenommen, sondern das gesamte Spektrum zwischen 400 und 670 nm.[11]

Die Stammlösungen wurden im Kühlschrank aufbewahrt und bis zu 14 Tagen verwendet. In dieser Zeit wurden keinerlei Titerverschiebungen beobachtet. In den verdünnteren Arbeitslösungen konnten dagegen zum Teil Veränderungen (nicht oxydativer Art) beobachtet werden: bei H_2Dz in CCl_4 zu $E_{620}/E_{450} < 1.65$ und bei H_2Dz in C_6H_{12} zu "Rosa-Dithizon" mit λ_{max} bei 530 nm.[25]

nachgegangen werden mußte, bevor die Erarbeitung fundierter substöchiometrischer Bestimmungen in Angriff genommen werden konnte; wobei vor allem die substöchiometrische Pd-Bestimmung mit Dithizon nicht unproblematisch ist.[16]

EXPERIMENTELLES

Reaktionsunterschiede in den Systemen Pd/H_2Dz und Cu/H_2Dz

Da auch geringe Reaktionsunterschiede erfaßt werden sollten, ergaben sich hohe Reinheitsanforderungen an alle verwendeten Glasgeräte und Chemikalien.

Für die *Reinigung von Dithizon* und das Herstellen der Stammlösungen hat sich die folgende Prozedur bewährt: Lösen des Dithizons in Chloroform, Reextrahieren mit

ERGEBNISSE

Zu den Reaktionsunterschieden in den Systemen Palladium/Dithizon und Kupfer/Dithizon

Auf deutliche Unterschiede in den beiden Systemen wiesen bereits Meriwether und Mitarbeiter[26] hin.

Die milieuabhängige Gleichgewichtsverschiebung zwischen dem 1:2 und dem 1:1 Cu-Dithizonat verlief quantitativ:

$$2CuDz + 2H^+ \rightarrow Cu(HDz)_2 + Cu^{2+}$$

$$Cu(HDz)_2 + OH^- \rightarrow CuDz + HDz^- + H_2O$$
wogegen die Umwandlung des 1:1 Pd-Dithizonates durch Veränderung des pH-Wertes nur partiell und die des 1:2 Pd-Dithizonates in das 1:1 Pd-Dithizonat überhaupt nicht gelang:

$$2PdDz + 2H^+ \rightleftharpoons Pd(HDz)_2 + Pd^{2+}$$
$$\text{nur zu } ca. \ 25\% \ (H_2Dz \text{ in } CHCl_3)$$

$$Pd(HDz)_2 + OH^- \nrightarrow PdDz + HDz^- + H_2O$$

Tautomerengleichge-
wichtsverschiebung
zugunsten der
Thioketo-   Thiol-Form

Meriwether und Mitarbeiter fanden auch charakteristische Unterschiede in den IR-Spektren der 1:1 Dithizonate. Im IR-Spektrum des 1:1 Cu-Dithizonates konnte keine NH-Bande gefunden werden, wogegen im IR-Spektrum des 1:1 Pd-Dithizonates noch eine NH-Bande nachweisbar war.

Wie wir feststellen konnten, passen die Reaktionen zwischen Pd^{2+} und Dithizon, im Gegensatz zu denen von Cu^{2+} und Dithizon, nicht in das allgemeine Schema, das Iwantscheff[2] für alle zweiwertigen Schwermetalle angibt: saures Medium und Reagensüberschuß→Bildung der 1:2 Dithizonate; alkalisches Medium und Reagensmangel→Bildung der 1:1 Dithizonate.

Meriwether und Mitarbeiter gehen davon aus, daß alle 1:1 Dithizonate zweiwertiger Metalle Verbindungen des Dianions von Dithizon seien, während Iwantscheff beschreibt alle 1:1 Dithizonate mit einem Anion als Zweitligand.

Bei den 1:1 Dithizonaten müssen aber zwei Komplextypen unterschieden werden:

die Sub-Dithizonate: Beteiligung von Anionen an der Komplexbildung bei Reagensmangel, saures Medium, z.B. PdHDzX,

die sekundären Dithizonate: Verbindungen des Dianions, Bildung im alkalischen Milieu bei Reagenzmangel, z.B. CuDz.

Die intensiven Studien zum Extraktionsverhalten in den Systemen Pd/H$_2$Dz in der Kombination Radiotracertechnik/Photometrie bei Vorgabe substöchiometrischer Reagensmengen (Einsatz äquimolarer Lösungen von Dithizon in verschiedenen organischen Solvenzien) bestätigten das differenzierte Reaktionsverhalten von Dithizon gegenüber Metallen. Die Milieu- und Lösungsmittelabhängigkeit verläuft umgekehrt proportional, woraus gefolgert werden kann, daß die beiden Metalle mit verschiedenen Tautomeren von Dithizon reagieren (Tabelle 2).

Auf Grund des chemischen Verhaltens von Dithizon, gestützt auf eigene NMR-Untersuchungen und unter Einbeziehen der Literaturangaben, wurde eine Zuordnung der Reaktionen zu denen der Thioketo- und denen der Thiol-Form möglich.[11]

Im alkalischen Milieu liegt das Tautomerengleichgewicht ganz auf der Seite der Thiol-

Form, im sauren Medium verschiebt es sich zugunsten der Thioketo-Form.[11,16] (Signifikante Strukturunterschiede der Säure–Base-Formen des Dithizons wurden kürzlich auch über Ramanspektroskopische Untersuchungen offenkundig.[27])

Schlußfolgerungen aus den Reaktionsunterschieden

Die Reaktionsunterschiede in den Systemen Palladium/Dithizon und Kupfer/Dithizon korrelieren eindeutig und unverkennbar mit dem Intensitätsverhältnis der beiden Maxima der VIS-Spektren der Dithizonlösungen (Abb. 1); demnach muß das Intensitätsverhältnis $R = E_{610}/E_{450}$ eine charakteristische Größe für die Tautomerenverteilung sein.[11,17,28,29]

Präzisierung der Tautomerenverteilung in Lösungen von Dithizon in Chloroform, Tetrachlorkohlenstoff, Cyclohexan und 2-Propanol über die VIS-Spektren

Zu qualitativen als auch zu quantitativen Aussagen bezüglich der Lage eines Tautomerengleichgewichtes können chemische und verschiedene physikalische Methoden herangezogen werden. Konkrete Aussagen zu erhalten bereitet jedoch Schwierigkeiten, da durch chemische Reaktionen das Tautomerengleichgewicht verschoben werden kann und auch nicht alle physikalischen Methoden, wie z.B. IR-, NMR- und UV/VIS-Spektrometrie für jedes tautomere System mit gleichem Erfolg eingesetzt werden können.

Sowohl IR- als auch NMR-Untersuchungen bleiben für Dithizon auf Chloroformlösungen beschränkt, da die Löslichkeit in den anderen Lösungsmitteln zu gering ist (in Cyclohexan nur $\sim 0{,}05$ mM, in Tetrachlorkohlenstoff ~ 2mM und in Chloroform ~ 70mM). Allein die VIS-Spektrometrie bietet gute Untersuchungsmöglichkeiten.

Ausgehend von den charakteristischen lösungsmittelabhängigen Unterschieden in den VIS-Spektren können Aussagen zur Lage des Tautomerengleichgewichtes gewonnen werden.

Bisher wurde bei Annahme der Existenz eines Tautomerengleichgewichtes in Dithizonlösungen je eine Bande des sichtbaren Spektrums je einem Tautomeren zugeordnet.[3,10,28–32]

Tabelle 3. Tautomerenverteilung nach der (in diesem Fall unbefriedigende Ergebnisse liefernden) Methode von Fabian

Organische Solvenzien für Dithizon	λ_{max1}, nm	ε_{max1}, $l.mole^{-1}.cm^{-1}$	λ_{max2}, nm	ε_{max2}, $l.mole^{-1}.cm^{-1}$	$\varepsilon_1/\varepsilon_2$	Thioketo-Form, %

Tetrachlorkohlenstoff	620	3.3×10^4	450	2.0×10^4	1.65	62.1 (3)
Cyclohexan	630	2.6×10^4	450	2.35×10^4	1.1	52.6 (4)

Berechnungsversuch der Tautomerenverteilung bei Zuordnung je einer Bande zu je einem Tautomeren

In Anlehnung an die Berechnung des Prozentgehaltes an Enol in Monothioacetylaceton in verschiedenen organischen Solvenzien, wie sie von Fabian[33] ausgeführt wurde, soll die Berechnung über die Extinktionen der Maxima erfolgen. Für Dithizon müßte die Zuordnung des Maximums 1 (ε_1) zur Thioketo-Form und des Maximums 2 (ε_2) zur Thiol-Form erfolgen. Es ergäbe sich:

$$\% \text{ Thioketo-Form} = \varepsilon_{max1}/(\varepsilon_{max1} + \varepsilon_{max2}).$$

Fabian weist darauf hin, daß diese Berechnungsmethode nur dann befriedigende Ergebnisse liefert, wenn 3 Voraussetzungen erfüllt sind.

1. Bei den einzelnen Maxima darf nur eine tautomere Form absorbieren.
2. Die molaren Extinktionskoeffizienten beider Tautomerer müssen gleich sein.
3. Die lösungsmittelabhängigen Unterschiede in der molaren Absorption jedes einzelnen Tautomeren müssen vernachlässigbar sein.

Zur Überprüfung der Gültigkeit der in die Rechnung eingegangenen Voraussetzungen wurden die nach der Formel von Fabian berechneten Prozentgehalte an Thioketo-Form (Tab. 3) in Abhängigkeit der Extinktionen in den Maxima (für $1 \cdot 10^{-5} M$ Lösungen)
Abb. 2. Überprüfung der Zuordnungsmöglichkeit je einer Bande der VIS-Spektren von Dithizonlösungen zu je einem Tautomeren.

aufgetragen (Abb. 2), wobei sich zeigt, daß die ersten beiden Voraussetzungen nicht erfüllt sind, da die Geraden in Abb. 2 weder durch Null noch durch 100% (Koordinatenursprung) gehen, noch die Achsen bei gleichen Extinktionen schneiden.

Die Zuordnung je einer Bande zu je einem Tautomeren ist demnach für Dithizon nicht zulässig und die somit berechneten Prozentgehalte sind unkorrekt.

MATHEMATISCHES OPTIMIERUNGSVERFAHREN ZUR BANDENTRENNUNG

Berechnung der prozentualen Tautomerenverteilung in den vier verwendeten Dithizonlösungen und Ermittlung der Einzelspektren der Thioketo- und der Thiol-Form

Die VIS-Spektren der Dithizonlösungen werden hierbei als Linearkombination der entsprechenden Anteile der Einzelspektren der Thioketo- und der Thiol-Form aufgefaßt. In die Rechnung werden die Extinktionswerte der vier verwendeten Dithizonlösungen ($2 \cdot 10^{-5} M$) zwischen 400 und 670 nm in Schritten von 10 nm (28 Meßwerte) eingegeben, gesucht sind die Extinktionen für die Einzelspektren und die prozentuale Verteilung der beiden tautomeren Formen in den vier Dithizonlösungen.

In die Berechnung geht nur noch die eine Annahme ein, daß die Unterschiede in der molaren Absorption jedes Tautomeren in den verschiedenen organischen Lösungsmitteln vernachlässigbar sind.

Wären die molaren Absorptionen sowohl der Thioketo- als auch der Thiol-Form in allen organischen Lösungsmitteln voll identisch, müßten die Spektren verschiedener äquimolarer Lösungen exakt ausgeprägte isosbestische Punkte aufweisen.

Die Spektren der Lösungen von Dithizon in Chloroform, Tetrachlorkohlenstoff und Cyclohexan weisen auch zwei isosbestische Punkte auf (Abb. 1), wobei allerdings der Punkt um 630 nm etwas verwischt ist, da er sich in diesem Bereich aus Schnittpunkten von 3 Kurven mit etwa gleich großem $dE/d\lambda$ zusammensetzt und demzufolge sowohl gegen Abweichungen in E als auch in λ sehr empfindlich ist.

Dagegen wird deutlich, daß das gesamte Spektrum von Dithizon in 2-Propanol zu kleineren Wellenlängen hin verschoben ist. Wird eine entsprechende Korrektur vorgenommen (Verschieben des gesamten Spektrums um 10 nm), geht auch dieses Spektrum durch die isosbestischen Punkte (Abb. 3). In die Rechnung wurden für Dithizon in 2-Propanol diese korrigierten Extinktionswerte eingegeben. Als Richt-

werte für entsprechende Korrekturen solcher "reinen" Lösungsmitteleffekte kann der isosbestische Punkt im Minimum dienen.

Zur Verfügung stehen die folgenden Gleichungen:

$$E_{400(CHCl_3)} = E_{400(keto)} \cdot C_{keto(CHCl_3)} + E_{400(thiol)} \cdot C_{thiol(CHCl_3)}$$

$$E_{410(CHCl_3)} = E_{410(keto)} \cdot C_{keto(CHCl_3)} + E_{410(thiol)} \cdot C_{thiol(CHCl_3)}$$

$$\vdots$$

$$E_{670(CHCl_3)} = E_{670(keto)} \cdot C_{keto(CHCl_3)} + E_{670(thiol)} \cdot C_{thiol(CHCl_3)}$$

$$E_{400(CCl_4)} = E_{400(keto)} \cdot C_{keto(CCl_4)} + E_{400(thiol)} \cdot C_{thiol(CCl_4)}$$

$$\vdots$$

$$E_{670(CCl_4)} = E_{670(keto)} \cdot C_{keto(CCl_4)} + E_{670(thiol)} \cdot C_{thiol(CCl_4)}$$

$$E_{400(C_6H_{12})} = E_{400(keto)} \cdot C_{keto(C_6H_{12})} + E_{400(thiol)} \cdot C_{thiol(C_6H_{12})}$$

$$\vdots$$

$$E_{670(C_6H_{12})} = E_{670(keto)} \cdot C_{keto(C_6H_{12})} + E_{670(thiol)} \cdot C_{thiol(C_6H_{12})}$$

$$E_{400(2\text{-}Prop.)} = E_{400(keto)} \cdot C_{keto(2\text{-}Prop.)} + E_{400(thiol)} \cdot C_{thiol(2\text{-}Prop.)}$$

$$\vdots$$

$$E_{670(2\text{-}Prop.)} = E_{670(keto)} \cdot C_{keto(2\text{-}Prop.)} + E_{670(thiol)} \cdot C_{thiol(2\text{-}Prop.)}$$

Verallgemeinert mit $C_{thiol} = 1 - C_{keto}$, ergibt sich

$$E_{ij} = E_{ik} \cdot C_{kj} + E_{ith} \cdot (1 - C_{kj})$$

wobei i = Wellenlängen von 400 bis 670 nm; j = Lösungsmittel (CHCl$_3$, CCl$_4$, C$_6$H$_{12}$, 2-Propanol); k = Thioketo-Form; th = Thiol-Form.

In diesen Gleichungen sind also zunächst sowohl die C_{kj}-Werte (Prozentgehalte Thioketo-Form in den verschiedenen Lösungsmitteln) als auch die E_{ik}- und E_{ith}-Werte (Extinktionen der Einzeltautomeren bei verschiedenen Wellenlängen) unbekannt.

Anhand unserer chemischen Experimente können Richtwerte gewisser Varianzbreite für die Prozentgehalte an Thioketo-Form vorgegeben werden (Tab. 4), so daß man für je eine Wellenlänge ein lineares Gleichungssystem aus 4 Gleichungen mit den beiden Koeffizienten $E_{\lambda_{keto}}$ und $E_{\lambda_{thiol}}$ erhält. Dieses Gleichungssystem läßt sich nach der Methode der kleinsten Fehlerquadrate lösen, wobei die beiden Koeffizienten $E_{\lambda_{keto}}$ und $E_{\lambda_{thiol}}$ allerdings noch von den vorgegebenen Prozentgehalten an Thioketo-Form abhängen. Die Aufgabe besteht nun darin, solche prozentuale Verteilungen der Tautomeren für die 4 Dithizonlösungen zu finden, die für den gesamten betrachteten Spektralbereich eine befriedigende Übereinstimmung zwischen den gemessenen Spektren und den aus den Einzelspektren der Thioketo- und der Thiol-Form und den entsprechenden Prozentgehalten berechneten Spektren ergeben.

Läßt sich ein eindeutiges Minimum der Fehlerquadratsumme S_G

$$S_G = \sum_{i=1}^{28} \sum_{j=1}^{4} [E_{ij} - (E_{ik} \cdot C_{kj} + E_{ith} \cdot (1 - C_{kj}))]^2$$

finden, was gleichbedeutend mit bestmöglicher Übereinstimmung der berechneten und gemessenen Spektren ist, gilt als bewiesen, daß die Spektren der Dithizonlösungen in verschiedenen Lösungsmitteln eine Linearkombination der entsprechenden Anteile
Abb. 3. Spektren $2 \cdot 10^{-5} M$ Dithizonlösungen. 1, H$_2$Dz in Chloroform; 2, H$_2$Dz in 2-Propanol, Korrektur um 10 nm; 3, H$_2$Dz in Tetrachlorkohlenstoff; 4, H$_2$Dz in Cyclohexan.

der zwei verschiedenen Spektren der Einzeltautomeren sind.

Mit Hilfe eines Optimierungsverfahrens (parabolisches Extrapolationsverfahren nach Jacob[34]) wurden die C_{kj}-Werte für den vorgegebenen Pro-
Abb. 4. Berechnete Einzelspektren der beiden tautomeren Formen $(2 \cdot 10^{-5} M)$. – – – Spektrum der Thioketo-Form; —— Spektrum der Thiol-Form.

Tabelle 4. Richtwerte für den Thioketo-Anteil, abgeleitet aus Reaktionsabstufungen[11]

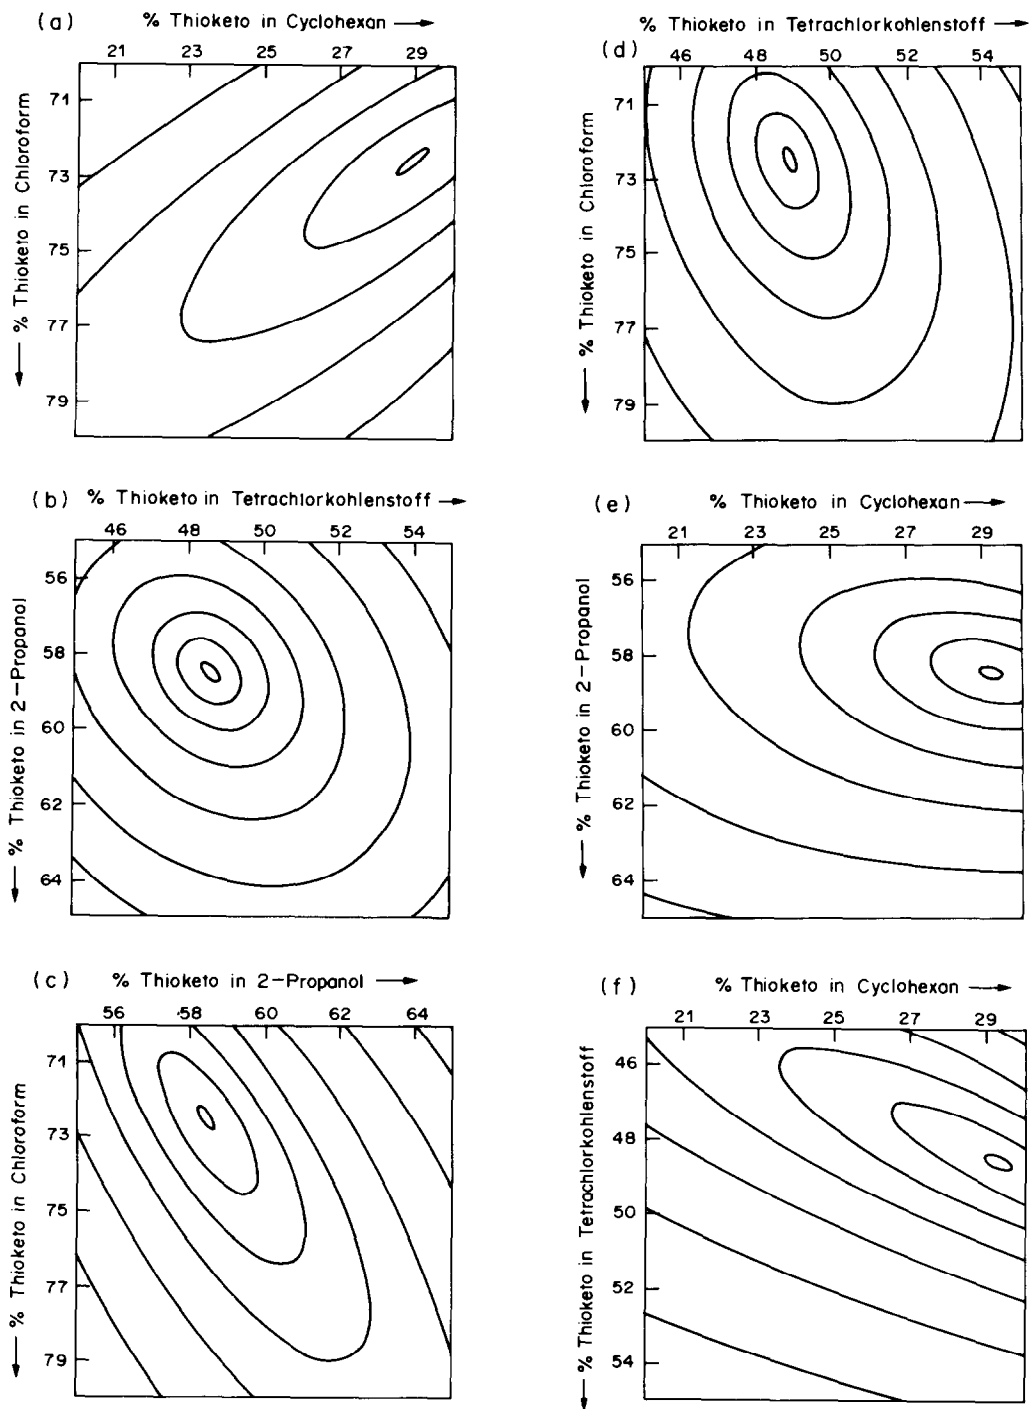
H$_2$Dz, gelöst in	Richtwert für Thioketo-Anteil, %	vorgegebene Varianzbreite, %
Cyclohexan	*ca.* 25	20–30
Tetrachlorkohlenstoff	*ca.* 47.5	45–55
Chloroform	*ca.* 75	70–80
2-Propanol	*ca.* 60	55–65


Abb. 5. Abhängigkeit der globalen Fehlerquadratsumme von den Prozentgehalten an Thioketo-Form.

Tabelle 5. Berechnete Tautomerenverteilung

	Thioketo-Anteil, %	Thiol-Anteil, %
H_2Dz in Chloroform	72.5	27.5
H_2Dz in 2-Propanol	58.5	41.5
H_2Dz in Tetrachlorkohlenstoff	48.5	51.5
H_2Dz in Cyclohexan	29.3	70.7

zentbereich systematisch so verändert, daß die globale Fehlerquadratsumme (S_G) über das gesamte Spektrum minimiert wird.

Als Lösung erhält man sowohl die Einzelspektren E_{jk} und E_{jth} der beiden tautomeren Formen (Abb. 4) als auch die prozentuale Verteilung der Tautomeren in den 4 verwendeten Dithizonlösungen (Tab. 5).

In Abb. 5 wird veranschaulicht, daß die Optimierungsprozedur das Minimum der Fehlerquadratsumme gefunden hat. In den Abbildungen ist die Fehlerquadratsumme S_G als Funktion von je zwei Prozentgehalten C_{kj} dargestellt, wobei die Prozentgehalte für 2 Lösungsmittel variiert und für die übrigen 2 Lösungsmittel die optimalen Prozentgehalte eingesetzt werden. Die Niveaulinien geben von innen nach außen folgende Fehlerquadratsumme wieder: $6.3 \cdot 10^{-3}$; $6.5 \cdot 10^{-3}$; $7.0 \cdot 10^{-3}$; $8.0 \cdot 10^{-3}$; $1.0 \cdot 10^{-2}$; $1.4 \cdot 10^{-2}$ und $2.0 \cdot 10^{-2}$.

Durch die Tatsache, daß die berechneten Prozentgehalte innerhalb der vorgegebenen Varianzbreite liegen, wird bestätigt, daß die über chemische Methoden (Einsatz unterstöchiometrischer Reagensmengen) ermittelten Prozentgehalte gute Richtwerte darstellten. Die sehr gute Übereinstimmung der gemessenen Spektren mit den aus den

Abb. 6. Beispiele für die gute Übereinstimmung der am Cary 118 gemessenen Spektren (———) von Dithizon und den aus den entsprechenden Anteilen der Einzeltautomeren berechneten Spektren ($\times \times \times$). (1) H_2Dz in Cyclohexan; (2) H_2Dz in Chloroform.

Einzelspektren und den Prozentgehalten berechneten Spektren wird in Abb. 6 an zwei Beispielen gezeigt.

DISKUSSION DER ERGEBNISSE

Neben der prozentualen Verteilung der Tautomeren in den vier betrachteten Dithizonlösungen konnten auch die Einzelspektren der Thioketo- und Thiol-Form ermittelt werden. Beiden tautomeren Formen kommt ein VIS-Spektrum mit zwei Maxima zu. Im Wellenlängenbereich zwischen 600 und 640 nm überlagern sich die Banden der beiden Tautomeren dargestalt, daß das Maximum 1 der Dithizonspektren sich mit steigendem Thiol-Gehalt zu höheren Wellenlängen hin verschiebt und die Bande bei Verlust an Höhe breiter wird.

Bisher dominierten bei der Interpretation der VIS-Spektren 2 Varianten.

Bei Variante 1 wurde der Charakter der Dithizonspektren als gleich definiert, da die Spektren aller grünen Dithizonlösungen zwei ausgeprägte Maxima aufweisen. Die markanten Unterschiede im Intensitätsverhältnis der Maxima der Spektren wurden als "reine" Lösungsmitteleffekte angesehen und das gesamte Spektrum einer Spezies zugeordnet. Als Schlußfolgerung aus dieser Interpretationsvariante ergeben sich unzulässige Verallgemeinerungen der Einzelergebnisse, so z.B. die Schlußfolgerungen aus den MO-Berechnungen von Spěváček und Spěváčková[6] und die der IR-Untersuchungen von Kemula und Mitarbeiter.[5]

Bei Variante 2 wurde dagegen gerade das Auftreten dieser zwei gut ausgeprägten Maxima als Hinweis für das Vorliegen eines Tautomerenpaares gewertet, wobei dann Zuordnung je einer Bande zu je einem Tautomeren erfolgte.[3,28-32] Widersprachen experimentelle Details dieser Zuordnungsmöglichkeit je einer Bande zu je einem Tautomeren, wurde dann als Schlußfolgerung die Existenz eines Tautomerenpaares verneint.

Die signifikante Korrelation zwischen den lösungsmittelabhängigen Reaktionsunterschieden in den Systemen Palladium/Dithizon und Kupfer/Dithizon und den charakteristischen lösungsmittelabhängigen Unterschieden in den VIS-Spektren, sowie die Tatsache, daß die Dithizonspektren als Linearkombination der entsprechenden Anteile an Thioketo- und Thiol-Form aufgefaßt werden können, sprechen dafür, daß sich die Bindungen der Dithizonmolekel (hochsymmetrische Struktur mit weitestgehend delokalisierten π-Elektronen[35]) in organischen Lösungsmitteln entsprechend
der Polarität der Lösungsmittel lokalisieren und Tautomerie vorliegt:
Festsubstanz in organischen Lösungsmitteln

Unter Berücksichtigung der neuen Erkenntnisse über die Einzelspektren der Thioketo- und der Thiol-Form (Abb. 4) und der Milieu- und Lösungsmittelabhängigkeit des Tautomerengleichgewichtes (Tab. 2) ergeben sich für viele experimentelle Daten neue Interpretationsvarianten und Tatsachen, die bisher als widersprüchlich angesehen wurden, fügen sich in das Gesamtbild ein.[5-10,36-40]

Summary—Significant differences have been observed in the reactions of substoichiometric amounts of reagent for the extraction of palladium dithizonate and of copper dithizonate. These differences depend on both the organic solvent and the composition of the aqueous phase, and suggest that dithizone can react with metals in two ways, and can exist as a mixture of tautomeric forms in organic solvents. Moreover the differences in the reactions show a clear correlation with the differences in the visible absorption spectra of dithizone in various organic solvents. A mathematical analysis of these spectra has allowed calculation of the spectra of the individual thione and thiol forms of dithizone, and also estimation of the position of the tautomeric equilibrium in the different solvents.

SHORT COMMUNICATIONS

POTENTIOMETRIC DETERMINATION OF PLUTONIUM BY SODIUM BISMUTHATE OXIDATION

M. M. Charyulu, V. K. Rao and P. R. Natarajan

Radiochemistry Division Bhabha Atomic Research Centre Trombay, Bombay-400085, India

Summary—A potentiometric method for the determination of plutonium is described, in which the plutonium is quantitatively oxidized to plutonium(VI) with sodium bismuthate in nitric acid medium, the excess of oxidant is destroyed chemically and plutonium(VI) is reduced to plutonium(IV) with a measured excess of iron(II), the surplus of which is back-titrated with dichromate. For 3–5 mg of plutonium the error is less than 0.2%. For submilligram quantities of plutonium in presence of macro-amounts of uranium the error is below 2.0%.

Plutonium in mg amounts is usually determined by titrimetric methods based on the Pu(III)/Pu(IV) and Pu(IV)/Pu(VI) couples.[1-4] Methods based on oxidation of plutonium to plutonium(VI) with silver(II) oxide are widely used. The method of Rao et al.[5] is more versatile than those reported by Drummond and Grant[6] and by Milner et al.[7] However, a disadvantage of the method is that the excess of iron(II) added for reduction of the plutonium(VI) is rather critical. Linder and Baeckman[8] reported that addition of more than 50% excess of iron(II) causes a positive error due to reduction of silver(I) to metallic silver.

This paper describes an alternative method based on the use of sodium bismuthate to oxidize the plutonium to the sexivalent state.[9,10] The excess of bismuthate is destroyed chemically before the usual back-titration procedure for plutonium, in which a considerable excess of iron(II) can be tolerated.

EXPERIMENTAL

Reagents

Analytical grade reagents were used. Potassium dichromate solutions (0.05 and 0.001 meq/g) were prepared by dissolving accurately weighed amounts of the reagent (dried at 110°) in doubly distilled water. Ammonium ferrous sulphate ($\sim 0.1M$) was prepared, and standardized by potentiometric weight titration with standard dichromate solution.

Standard plutonium nitrate solution was prepared by dissolving high-purity plutonium dioxide in concentrated nitric acid plus a few drops of 0.05M hydrofluoric acid, followed by repeated evaporation to remove hydrogen fluoride and final dilution to known weight with 1M nitric acid. The solution was standardized by mass spectrometry and by the silver(II) oxide method.[5] The fluoride concentration in the plutonium standard was measured with an ion-selective electrode and found to be less than that in the reagent blank. Standard uranium solution was prepared by dissolving the oxide in nitric acid and standardized by a modification of the Davies and Gray method.[11]

Apparatus

The potentiometric titrations were performed with a digital potentiometer with a readability of 1 mV. A 50-ml beaker was used as titration cell, with a saturated calomel electrode and platinum working electrode. The standard potassium dichromate and iron(II) solutions were added from polythene weight-burettes with suitably finely drawn jets.

Recommended procedure

A suitable accurately known weight (~ 0.2 g) of sample solution containing 3–4 mg of plutonium in 1M nitric acid medium was transferred to the titration cell with 5 ml of 1M nitric acid solution, and sodium bismuthate powder (80–100 mg) was added and stirred with the sample for 5 min to oxidize the plutonium quantitatively to plutonium(VI). Then 2 ml of 6M hydrochloric acid were added and the mixture was stirred for 10 min to ensure complete destruction of the excess of bismuthate. Ten ml or 2M sulphuric acid were then added followed by a drop or two of 1.5M sulphamic acid solution to destroy any nitrous acid. Finally enough iron(II) solution was added to give a potential of ~ 450 mV, indicating complete reduction to plutonium(IV), and the excess of iron(II) was titrated potentiometrically with dichromate, first with the more concentrated solution and then with the dilute titrant when the end-point was near.

The amount of plutonium (mg) present was calculated from the expression

$$Pu = [W_f A - (W_I + W_{II} B)] C_I E$$

where W_f is the weight of iron(II) solution added, A is the weight of concentrated dichromate solution equivalent to 1 g of iron(II) solution, W_I and W_{II} are the weights used of the concentrated and dilute dichromate solutions respectively, B is the concentration ratio of dilute to concentrated dichromate solution, C_I is the concentration (meq/g) of the concentrated dichromate solution and E is half the atomic weight of plutonium.

RESULTS AND DISCUSSION

Oxidation of plutonium with sodium bismuthate

Sodium bismuthate is a powerful oxidant in acidic medium, with $E° = 1.6$ V for reduction to Bi(III).[12] The conditional potential for the Pu(IV)/Pu(VI) couple[13] in 1M nitric acid is 1.054 V, so bismuthate will quantitatively oxidize Pu(IV) to Pu(VI). Hindman and Holland[14] reported that the oxidation in 5M nitric acid medium is quantitative at room temperature. In sulphuric acid medium, however, it is

essential to heat the solution to complete the oxidation.[9,10] We have found that in $1M$ nitric acid medium, the oxidation to plutonium(VI) is complete at room temperature in 5 min with 80–100 mg of bismuthate per 3–5 mg of plutonium.

Destruction of excess of sodium bismuthate

The excess of sodium bismuthate had to be destroyed before the titration. Markov[9] removed the excess by filtration but this is undesirable in high-precision work because the slight solubility of sodium bismuthate in acidic solutions leads to positive bias. A chemical method was therefore sought. Of several reagents tried, $6M$ hydrochloric acid was found to be the most effective. It reduces the bismuthate in nitric acid medium at room temperature in less than 3 min, with liberation of chlorine.[15] Most of the chlorine escapes as gas and the residual amount does not affect the subsequent titration significantly. This was established by adding a known amount of iron(II) to nitric acid in which bismuthate had previously been destroyed with hydrochloric acid, and titrating with dichromate; the amount found agreed within 0.01–0.04% with the amount found by direct titration of the same amount of iron(II).

Reduction of plutonium(VI) by iron(II), and back-titration

Direct titration of plutonium(VI) with iron(II) is sluggish, which is why a back-titration procedure is invariably used. The end-point was detected from the maximum of the first derivative. Analysis of 20 replicate samples of standard plutonium solution gave a relative standard deviation of 0.2% and zero bias for 3–5 mg of plutonium. Determination of 50–200 μg of plutonium (20 replicates) by the same method [but with more dilute iron(II) and dichromate solutions] gave an RSD of 2.0%.

The advantage of using sodium bismuthate instead of silver(II) oxide is that much larger quantities of iron(II) are tolerated. Amounts corresponding to as much as 1000% excess had no effect on the plutonium values found.

Effect of uranium

The method has been tested for the determination of plutonium in presence of uranium. Up to 28-fold w/w ratio of uranium to plutonium had no significant effect on the results.

Interference of various impurities

The effect of the relevant impurities has been investigated. The cations examined were those likely to be associated with plutonium, e.g., high-yield fission products such as Sr(II), Ru(III), Zr(IV) and Mo(VI) or impurities such as Al(III), Ni(II) and Hg(II). Corrosion products such as Cr(III), Mn(II) and V(IV) were found to interfere quantitatively because of their oxidation by sodium bismuthate.

Among the anions, fluoride is of most interest,

Table 1. Study of interferences

Substance	Amount added to 3–5 mg of plutonium, mg	Error, %
Strontium(II)	2.0	−0.2
Cadmium(II)	2.0	−0.1
Ruthenium(III)	2.0	−0.2
Zirconium(IV)	2.0	+0.2
Molybdenum(VI)	1.0	+0.1
Aluminium(III)	28.8	+0.2
Nickel(II)	5.0	+0.2
Copper(II)	1.6	+0.1
Mercury(II)	8.4	+0.1
Fluoride	0.005	+0.2
	0.010	−5.9
	0.130	−20.8
Nitrate	3200	−0.2
Sulphate	19.6	−1.5

since preparation of standard plutonium nitrate solution involves the use of a little hydrofluoric acid. Hydrogen fluoride is quantitatively driven off by repeated evarporation, however, and its concentration in the plutonium working standards was found to be negligible. Tests showed that up to 5 μg of fluoride had no effect on the plutonium determination. The amount present in the test solutions prepared as described was less than 2 μg per aliquot used.

Tests showed that up to 50 mmoles of nitric acid in 5 ml of sample solution (which includes the aliquot and wash solution) can be tolerated. It may be noted that the volume of the solution is about 17 ml before the addition of iron(II) solution, which means that such a solution would be about $3M$ in nitric acid at this stage. Our observation shows that nitric acid of higher concentration would oxidize iron(II) and therefore lead to positive error.

Regarding chloride, small amounts in the sample would cut down the amount of bismuthate available for the plutonium oxidation, but the plutonium should be oxidized preferentially according to the potentials involved. However, larger amounts of chloride would interfere unless the sample has already been subjected to repeated evaporation, which is normally the case to remove the small quantities of fluoride added when the solution is prepared from plutonium oxide.

Sulphate was found to inhibit the oxidation of plutonium to plutonium(IV) at room temperature. Table 1 gives the tolerance limits for the interfering ions studied.

Summary—Trace iron(II) is determined spectrophotometrically after adsorption of its ternary complex with 3-(4-phenyl-2-pyridyl)-5,6-diphenyl-1,2,4-triazine and tetraphenylborate on microcrystalline naphthalene at pH 5.1–7.4. The absorption maximum is at 567 nm; the molar absorptivity is 2.9×10^4 l.mole^{-1}.cm^{-1}.

Extractive spectrophotometric determination of iron(II) with 3-(4-phenyl-2-pyridyl-5,6-diphenyl-1,2,4-triazine (PPDT) has been reported by Schilt and Hoyle[1]. The complex Fe(PPDT)$_3^{2+}$ is only slightly soluble in water, but soluble in ethanol, ethanol–water, isoamyl alcohol, benzene and nitrobenzene. The complex forms slowly at room temperature, but rapidly in presence of perchlorate or relatively large amounts of ethanol. The perchlorate salt of the complex is extremely insoluble in water but readily extracted into isoamyl alcohol.

The spectrophotometric determination of metals after adsorption of their complexes on microcrystalline naphthalene is now well established.[2-9] In the present work the technique is applied to the ion-association complex produced by Fe(PPDT)$_3^{2+}$ and tetraphenylborate (TBP), which is not extractable into the usual organic solvents. The complex is quantitatively adsorbed on microcrystalline naphthalene and is freely soluble in dimethylformamide and acetonitrile, which are miscible with water.

EXPERIMENTAL

Reagents

Standard iron(III) solution, 2 ppm. Prepared by diluting 1000-ppm standard iron(III) solution with water.
PPDT solution in ethanol, 0.04%.
Hydroxylammonium chloride solution, 2%.
TPB solution, 1%.
Naphthalene solution in acetone, 20%.
*Buffer solutions, 1*M. Acetic acid/ammonium acetate; ammonia/ammonium acetate.

Procedure

Place the sample solution [containing 1–20 μg of iron(III)] in an 80-ml stoppered Erlenmeyer flask and dilute it to about 40 ml with water. Add 1.0 ml of 2% hydroxylammonium chloride solution, 3.0 ml of 0.04% PPDT solution, and 2.0 ml of acetate buffer (pH 5.8) and mix. Add 3.0 ml of 1% TPB solution. Heat on a water-bath (60°) for 50 min to precipitate the complex completely. Cool to room temperature, add 2.0 ml of 20% naphthalene solution and shake vigorously for 30 sec. Collect the naphthalene on a filter paper (Toyo Roshi No 5C) placed flat on a Teflon plate in a funnel, or on a sintered-glass filter (porosity 2). Wash it with water and dry it at 55–60°. Dissolve the mixture in dimethylformamide and dilute with the solvent in a 10-ml standard flask. Measure the absorbance at 567 nm against a reagent blank.

RESULTS AND DISCUSSION

The complex has its absorbance maximum at 567 nm, where there is practically no absorption due to the reagent blank. The absorbance is unaffected by the pH of precipitation in the range 5.1–7.4; pH 5.8 is a convenient choice for the buffer. The absorbance is constant when 1.5–8.0 ml of 0.04% PPDT solution and 0.01–6.0 ml of 1% TPB solution are used. From 0.1 to 10 ml of 2% hydroxylammonium chloride and 1.0–5.0 ml of pH 5.8 buffer solution can be used.

The formation of the complex is relatively slow at room temperature, but considerably faster above 60°, and the complex is stable for a considerable period. A digestion time of 30–90 min is enough for complete formation of the complex.

As usual, 0.4 g of naphthalene is convenient for the adsorption and shaking for 30 sec is adequate.

The volume of the aqueous phase can be varied in the range 20–60 ml without effect on the absorbance,

Table 1. Tolerance limits for diverse salts and ions in determination of
10 μg of iron

Salt	Tolerance limit	Ion	Tolerance limit
NaI	11 g	Mg^{2+}	48 mg

*Average of five determinations.
†μg/ml.
§ng/ml.

but with 60 ml a digestion time of 60 min and a shaking time of 2 min are recommended. The mixture of the complex and naphthalene can be dissolved in dimethylformamide, acetonitrile, dimethyl sulphoxide or propylene carbonate. Dimethylformamide is preferred and the complex is stable in it for 60 min.

The calibration graph is linear over the range 0.1–2.0 μg of iron per ml of dimethylformamide. The molar absorptivity is 2.90×10^4 l. mole^{-1}. cm^{-1}. Ten replicate determinations of 10 μg of iron gave a mean absorbance of 0.523 with a relative standard deviation of 1.3%.

Effect of diverse ions

The tolerance limits (error < 2%) for various ions

in determination of 10 μg of iron are summarized in Table 1. If the iron content in practical samples is low and interfering metal ions are present, a preliminary extraction of iron with methyl isobutyl ketone (MIBK) or diethyl ether from 6M hydrochloric acid is necessary.

Analysis of practical samples

The results in Table 2 are in reasonably good agreement with those obtained spectrophotometrically with 2,4,6-tri(2-pyridyl)-1,3,5-triazine[10,11] and 1,10-phenanthroline.[12] The aluminium alloy (1-g sample) was dissolved with 40 ml of hydrochloric acid (1 + 1) and 2 ml of 30% hydrogen peroxide, then the excess of peroxide was decomposed by heating. After

cooling, the solution was made up accurately to 500 ml with water, a 2-ml aliquot was transferred to a 100-ml separatory funnel, 40 ml of hydrochloric acid $(1 + 1)$ were added, and the iron was extracted by vigorous shaking for 5 min with 20 ml of MIBK. The iron was stripped with 25 ml of water, and determined by the proposed method.

The standard silicon bronze alloy (100 mg) was dissolved with 10 ml of hydrochloric acid $(1 + 1)$, 1 ml of concentrated nitric acid and 3 ml of concentrated sulphuric acid. The excess of acid was evaporated and the residue dissolved and diluted accurately to 1000 ml with water. An aliquot was analysed.

Magnesium powder (10 g) and aluminium powder (2 g) were analysed in the same way as the aluminium alloy.

Water samples, made $0.1M$ in nitric acid immediately after collection, were filtered through paper to remove suspended particulates, and the filtrates were analysed for total iron as described above.

DETERMINATION OF URANIUM IN PHOSPHOGYPSUM

Helena Górecka and Henryk Górecki

Institute of Inorganic Technology and Mineral Fertilizers, Technical University of Wrocław, Poland

Summary—A method for determination of uranium in phosphogypsum is based on extraction of uranium from phosphoric acid in which hydration transformations of calcium sulphate hydrates have occurred. The uranium is extracted with a kerosene solution of a mixture of mono- and dinonylphenylphosphoric acids, then stripped with concentrated phosphoric acid, and determined spectrophotometrically with Arsenazo III.

Production of wet phosphoric acid, which is in common use for the production of phosphate and mixed fertilizers, is associated with the creation of very large amounts of phosphogypsum waste (in about 2:1 weight ratio to the phosphate raw material used). About 4.5–6 tons of phosphogypsum waste are created in producing one ton of P_2O_5 in fertilizer products.[1] On account of its enormous amount, its mineral impurities and high water content, the waste is at present utilized only to a very small degree.[2] Phosphogypsum is generally stored near fertilizer works or dumped in rivers or the oceans. This is of danger to the natural environment since the waste contains toxic components such as fluorine, uranium and radium. Utilization of the waste for the production of building materials requires reduction of the amount of these contaminants, as well as of the phosphorus compounds.[2]

Uranium is recovered on a commercial scale more and more often from wet phosphoric acid,[3-5] and requires increased efficiency of the uranium recovery process.

A chemical analysis of the uranium content of phosphogypsum waste will make it possible to determine the proper conditions for the production of wet phosphoric acid with simultaneous uranium recovery, and allow control of the uranium content of phosphogypsum that is to be used as a raw material or an intermediate in the production of building materials.

Physicochemical reasons for presence of uranium in phosphogypsum

The uranium content of phosphogypsum depends on the type of the phosphate raw material, the technology of decomposition, and on crystallization of the phosphogypsum as well as on various technological parameters.

The uranium balance in the wet method is generally thought to depend on the liquid phase composition when the calcium sulphate crystallizes.[5-9] The uranium content depends mainly on the degree of hydration of the calcium sulphate.[6] The phos-

phogypsum obtained as calcium sulphate dihydrate contains 5–25 μg of U per g. A much greater amount of uranium (50–110 μg/g) is contained in phosphogypsum produced by applying the hemihydrate method (the main component is α-$CaSO_4 \cdot \frac{1}{2}H_2O$). The reason for this large difference lies in the different structure of the unit cells, the fact that the hemihydrate forms agglomerates and clusters, and that the co-ordination of uranium depends on the temperature and the concentration of phosphoric acid.

A significant role is also played by the relative concentrations of U(IV) and U(VI) in the liquid phase. It is thought[6] that in phosphate raw materials about 40–91% of the uranium (mean about 65%) is in the quadrivalent form.

In the decomposition of phosphate raw materials with sulphuric acid U(IV), U(VI), Fe(II) and Fe(III) are transferred into the liquid phase, where the equilibrium

$$2Fe(II) + U(VI) \rightleftharpoons 2Fe(III) + U(IV)$$
is established. Fe(III) and U(IV) form stable co-ordination compounds with F^- and HPO_4^{2-} ions, which is why the liquid phase contains more U(IV) than was in the raw material.[10]

Many authors have proved[6-8] that the higher the U(IV) content (*i.e.*, under strongly reducing conditions), the higher the amount of uranium in the phosphogypsum. Under oxidizing conditions, up to 90% of the uranium can pass to the liquid phase, and even 95% if some nitric acid is added.[8]

Decomposition under the usual technological conditions transfers about 25–30% of the uranium into the phosphogypsum, whereas addition of a large amount of iron(II) increases this to as much as 80%.

The uranium is transferred into the phosphogypsum by substitution of U^{4+} for Ca^{2+} in the crystal lattice of calcium sulphate, the probability of substitution being 3.75×10^{-5}. The process is possible because of the similarity in the ionic radii of U^{4+} (0.97 Å) and Ca^{2+} (0.99 Å). This substitution is dependent on the course of the calcium sulphate crystallization, and thus on the local concentrations
Fig. 1. The recrystallization scheme used in the analysis of phosphogypsum, shown as a phase scheme comprising domains of existence of calcium sulphate in various hydration forms in phosphoric acid solution.

of Ca^{2+}, SO_4^{2-}, HPO_4^{2-}, and F^-, as well as on the hydrodynamic conditions. It is also presumed that the presence of organic compounds in the phosphate raw material and application of organic defoamers to lower the stability of the foam in the decomposition process will increase the uranium content in the phosphogypsum. It has been experimentally proved that calcination may reduce the uranium content in phosphogypsum by about 30%.[8]

Another process significantly affecting the uranium content in phosphogypsum is adsorption of uranium(VI) as UO_2HPO_4 on the surface of the gypsum or by substitution of one UO_2^{2+} ion for $2\,Ca^{2+}$ ions in the terminal nodes of the crystal lattice.[6]

We have proved experimentally[9] that phosphogypsum particles with average weight $< 10\,\mu$g contain 30–40% more uranium than particles with mean weight $> 50\,\mu$g.

Principle of the analysis method

During the crystallization of phosphogypsum there is a non-uniform distribution of the uranium: about 80–90% in the liquid phase, and the remainder in the phosphogypsum. The distribution can be controlled by making a slight addition of oxidizing reagents, which results in a lower uranium content in the phosphogypsum.

Thus if phosphogypsum recrystallizes in a pure phosphoric acid solution, the liquid phase is separated and the recrystallization repeated, then at least

96% of the uranium can be removed from the phosphogypsum.

Depending on the phosphoric acid concentration and the temperature, there are three phase areas delimited by the lines of the phase transition. From Fig. 1 it appears that only 2 stable modifications exist: $CaSO_4 \cdot 2H_2O$ (area 1) and $CaSO_4$ (areas 2 and 3). Particular hydrate forms may undergo changes according to the temperature and concentration conditions:[1]

$$\underset{\textcircled{C}}{\underset{\textcircled{A}\qquad\qquad\qquad\textcircled{B}}{CaSO_4 \cdot 2H_2O \rightleftharpoons \alpha\text{-}CaSO_4 \cdot \tfrac{1}{2}H_2O}}{CaSO_4II}$$
For the analysis the phase transition $A \rightarrow C$ is used. The metastable transition $A \rightleftharpoons B$ is utilized in the production of wet phosphoric acid by the dihydrate–hemihydrate or hemihydrate–dihydrate methods.[1] This transition requires exact adjustment of the technological conditions.

In the analysis, the sample of dry phosphogypsum is placed in a 0.1% w/w solution of sodium chlorate in concentrated phosphoric acid (this corresponds to point 1 in Fig. 1) and heated to 90–100°, which results in transformation of $CaSO_4 \cdot 2H_2O$ into $CaSO_4II$ (point 2 in Fig. 1) with 75–85% of the uranium passing into the liquid phase. After filtering off from the concentrated acid, the wet phosphogypsum is added to a volume of water that is half that of the concentrated acid introduced initially. This lowers the concentration of P_2O_5 in solution and the

CaSO₄II is transformed back into $CaSO_4 \cdot 2H_2O$ (point 1 in Fig. 1) with simultaneous further release of uranium compounds to the liquid phase. After filtration and washing, the two filtrates and the washings are combined, and the uranium is extracted with a kerosene solution of a mixture of mono- and dinonylphenylphosphoric acids (NPPA). The aqueous phase should contain 20–30% P_2O_5 and ferrous sulphate. The uranium is stripped from the organic phase with $10M$ phosphoric acid containing sodium chlorate.[11,12] The uranium content of the strippings is determined by the Korkisch spectrophotometric method with Arsenazo III.[13,14]

EXPERIMENTAL

Reagents

Kerosene solution of NPPA, 0.2M.

Phosphoric acid, 85% H_3PO_4, pure for analysis,

Calcium sulphate dihydrate. Pure for analysis, for preparing the calibration curve.

Procedure

Prepare 100 ml of phosphoric acid of 40% P_2O_5 content (about 55% H_3PO_4) and 0.1% sodium chlorate. Weigh the sample of phosphogypsum (about 50 g) into a beaker and add the phosphoric acid. Heat to 90–100° and keep at temperature for about 1 hr. Check by examination under the microscope that transformation to CaSO₄II has taken place, and if it has, filter the suspension hot on a Buchner funnel and wash with 10 ml of water. Return the sediment to the beaker, add 50 ml of water, and let stand for at least 12 hr for reconversion into $CaSO_4 \cdot 2H_2O$. When the change is complete (microscopic observation), filter the suspension and combine the filtrates.

Add 2 g of $FeSO_4 \cdot H_2O$ to the combined filtrates. Shake the solution with 10 ml of 0.2M NPPA solution in kerosene at 20–30° for 1 hr. After phase separation, strip the kerosene phase at 55° with three 25-ml portions of $10M$ phosphoric acid containing 0.2% sodium chlorate, shaking for 30 min in each extraction. Combine the three extracts and analyse for uranium spectrophotometrically as for uranium in wet phosphoric acid.[11]

The calibration graph is prepared by adding known amounts of UO_2SO_4 to 50-g samples of pure calcium sulphate, and analysing as just described.

CONCLUSIONS

The procedure permits chemical analysis for uranium in phosphogypsum samples arising from the production of wet phosphoric acid. The method makes use of change in pattern of the distribution of uranium between the liquid and solid phases when calcium sulphate is recrystallized from phosphoric acid of different concentrations. The effect is utilized by applying a double recrystallization and knowledge of the phase transitions of particular forms of calcium sulphate. In this way 92–96% of the uranium originally present in the phosphogypsum is extracted, and then determined by extraction with a mixture of mono- and dinonylphenylphosphoric acids, and use of a modified spectrophotometric method with Arsenazo III.

Test analyses gave an error of ±6% in determination of uranium in phosphogypsum in the range 4–100 μg/g, the relative standard deviation being 9% at the 18.8 μg/g level.

Twenty samples of phosphogypsum containing 30–60 μg of U per g were analysed by the method described and by X-ray fluorescence. The results obtained by the latter method were higher by an average of 2%.

Use of the phase equilibrium diagram for calcium sulphate in phosphoric acid makes it possible to apply the procedure for analysis of the phosphogypsum produced in the hemihydrate and anhydrite methods.

STANDARD-ADDITION PROCEDURE FOR THE DETERMINATION OF TRACES OF LEAD IN SOLID SAMPLES BY X-RAY FLUORESCENCE SPECTROMETRY

Niels Pind

Department of Chemistry, Aarhus University, Langelandsgade 140, 8000 Aarhus C, Denmark

Summary—A standard-addition procedure for analysis of powdered solid samples by energy-dispersive X-ray fluorescence is described. Different amounts of the element to be determined are added to 4–6 specimens of the unknown sample. The spiked samples are prepared by mixing the powdered sample with an aqueous standard solution and drying the mixture. Homogeneously spiked samples are thus obtained with analyte and spike concentrations at the ppm level. The procedure has been investigated theoretically, and it is found suitable for the quantitative determination of lead at the ppm level. The accuracy of the technique for traces of lead has been tested on solid reference materials for the determination of lead. The quantitative results obtained compare well with those found by potentiometric stripping analysis.

X-Ray fluorescence spectrometry (XRF) is well suited for direct elemental analysis of solid samples. Quantitative analysis, however, is often hampered by interelement effects.[1] Ways of correcting for these effects can be divided into two main groups: (1) mathematical methods, *e.g.*, those based on fundamental parameters or "influence coefficients", which are applicable when a complete elemental analysis is done; (2) comparative methods, *e.g.*, those using an external standard, internal standard, double dilution or standard addition. The comparative methods are better suited for partial analysis of a sample. For single-element determinations, a comparative method is often chosen. In trace element determination, the dilution technique should be avoided, in order not to decrease the count-rate of the analyte line. Thus the main methods left for single-element determination are those using (1) an external standard; (2) an internal standard; (3) standard addition.

With the external-standard method, the general sample composition is assumed to be constant for all specimens of nearly identical composition. This allows the use of a calibration graph. However, the production of single-element calibration graphs requires a large number of standards of known composition, which must be close to that of the sample. Therefore, this approach can be quite cumbersome.

With the internal-standard and the standard-addition (spiking) methods, a known amount of a standard is added to the sample. For the internal-standard method, the element added must not be present in the sample. Thus problems arise when the internal-standard method is to be applied to complex samples, e.g., coal fly-ash. Furthermore, the difficulty is increased if more than one internal standard is used.

The standard-addition method uses addition of the analyte itself and is frequently used in conjunction with instrumental methods of trace analysis. In principle, the technique can be applied to any sample and in effect produces its own calibration graph. However, for successful application of the method, the spiked samples must be homogeneous. This condition is easy to meet for liquid samples and standards. Thus, standard addition is often used in conjunction with flame atomic-absorption spectrometry and electroanalytical techniques. The method has also been used in an XRF study on sulphur in gasoline.[2] The sulphur standard used in this investigation was di(tert-butyl)disulphide in sulphur-free iso-octane, which could be dissolved in the gasoline samples. When the sample is a solid, it is less easy to employ the standard-addition technique. If the analyte concentration is low, only minute amounts of standard should be added, and an even distribution within the sample volume can then be difficult to achieve. To determine the germanium content of low-germanium coal-ash, Campbell *et al.*[3] used a solid standard for spiking. This standard was a germanium-rich lignite ash with a known content of germanium. These workers were thus able to obtain results accurate to within ±10% relative for ashes with a germanium-content exceeding 0.1%. For lower concentrations the accuracy decreased, probably because of non-homogeneous distribution of the solid spike.

The present paper describes a spiking procedure for quantitative XRF determination of trace elements in powdered solid samples: a dilute aqueous solution of the standard is mixed with the powdered sample, and the mixture is dried. In this manner, an even distribution of the spike is obtained. Apparently, despite its simplicity, this approach has not yet been reported in the literature. The procedure has been used for the XRF determination of lead in a number of solid materials, and accurate results have been obtained.

THEORY

The X-ray fluorescence intensity, I, of an analyte line excited by monoenergetic radiation, from a specimen of infinite thickness, can be expressed as:[4]

$$I = GA(1 + H)W$$

where G includes the primary intensity for the exciting radiation, the geometry factor and the detection efficiency for the analyte, A corrects for absorption of both excitation and fluorescence radiation, and H corrects for enhancement effects. Both A and H depend on the excitation energy and the specimen composition. W is the concentration of the analyte, expressed as a weight fraction.

The analyte concentration of a spiked specimen is given by

$$W = W_0 W_p + W_s$$

where W_0 is the analyte concentration of the original sample, and W_p and W_s are the weight fractions of the original sample and of the pure elemental standard in the spiked specimen. The standard-addition procedure is based on the assumption that $GA(1 + H)$ is an unknown constant K. Since $W_p + W_s = 1$, there is a linear relationship between the intensity and the concentration of analyte in the spiked specimen:

$$I = B_0 + B_1 W_s \qquad (1)$$

where $B_0 = KW_0$ and $B_1 = K(1 - W_0)$. For each sample several spiked specimens with known W_s are prepared. Hence a set of fluorescence intensities and added concentrations is obtained. This set of intensities and corresponding weight fractions is used to establish a set of simultaneous equations of type (1), from which B_0 and B_1 are found by a least-squares procedure. The concentration of analyte in the original sample is then:

$$W_0 = B_0/(B_0 + B_1) \qquad (2)$$

EXPERIMENTAL

Apparatus

The X-ray spectrometer used is equipped with a DTG Si(Li) detector with pulsed optical feed-back (crystal dimensions 30 mm^2 × 4 mm, resolution 160 eV at 5.9 keV). The main amplifier is a Canberra model 2020 spectroscopy amplifier with pulse pile-up rejection, and the analogue-to-digital converter is a Canberra model 2070. The digitized signals are stored by a Motorola 68000 microcomputer, which also performs on-line control of the spectrometer, data-acquisition, spectrum-display and data-transmission to the central computer, a VAX 11/780.

Samples were excited by the $K\alpha$ and $K\beta$ radiation of a secondary target, which was irradiated by an X-ray tube powered by a Philips PW 1732/10 high-voltage generator (60 kV, 80 mA, maximum power 4 kW). The irradiation chamber contained six secondary targets (Ti, Se, Mo, Ag, Te and Gd), which allow effective excitation of a wide range of fluorescence energies. Except for a few minor changes, the chamber is that described in detail by Christensen *et al.*[5]

For the determination of lead the spectrometer was operated at 40 kV, the Mo secondary target being used. The

current was set at 20–45 mA and chosen so that the dead-time of the detector system was less than 40% of the total measurement time. The counting time was 200–600 sec and chosen to give about 10^4 counts for the Pb-$L\beta$ line for the unspiked samples. For each specimen, the spectrum was recorded three times, and the Pb-$L\beta$ line intensity was calculated by a simple summation procedure, with linear background subtraction. The Pb-$L\beta$ line was used because the As-$K\alpha$ line interferes with the Pb-$L\alpha$ line.

Reagents

Prepare standard solutions of lead (100 and 1000 ppm) by diluting a commercial standard solution (*e.g.*, Merck Titrisol No. 9969) with triply distilled water.

Preparation of spiked samples

Weigh accurately approximately 1 g of powdered solid sample. Transfer it into a 25-ml polyethylene test-tube, add the appropriate amount of standard solution, and mix carefully. Dry the spiked sample in a desiccator. Add four glass beads (5 mm diameter) to the dried sample and shake for 10 min. Finally, transfer the powder to the XRF sample-holder.

For each unknown sample, prepare 4–6 spiked specimens, such that the spiked sample with the highest analyte concentration will yield an analytical signal which is about three times the signal for the unspiked sample. Typically, 1–10 ml of 100-ppm lead solution should be added to a 1-g sample.

Measurements and calculations

Measure, at constant spectrometer settings, the analytical signals (Pb-$L\beta$ line-intensities) for the unspiked and spiked samples. For each measurement, set up an equation of type (1). From the resulting set of simultaneous equations, determine the constants B_0 and B_1 by linear regression. Finally, calculate W_0 from equation (2).

RESULTS AND DISCUSSION

Maximum amount of spike

The standard-addition method is valid provided that equation (2) holds, *i.e.*, the analytical signal is linearly proportional to the concentration of analyte in the spiked sample. The maximum amount of spike which can be added and still result in a linear signal/concentration relationship was estimated as follows. The procedure outlined by Christensen and Pind[6] was used to calculate the Pb-$L\beta$ line intensity, I, for a spiked fly-ash. The standard chosen was elemental lead. The elemental composition of a representative model coal fly-ash was established in the following manner. The element concentrations certified by the National Bureau of Standards for NBS SRM 1633a trace elements in coal fly-ash were used, and the non-certified concentrations were taken to be correct. The remainder was arbitrarily assumed to be the oxygen in the ash. The compositions of samples made by spiking this were calculated. Hence for any ash of these spiked samples W_s was known, and the analytical signal, I, could be calculated. In this manner, a number of simultaneous equations of type (1) were established, and solved for B_0 and B_1 by a least-squares procedure. The quantity W_0 could then be found from equation (2). From the linear range of the relationship between concentration and intensity for this model fly-ash it was found that an

Table 1. Concentrations of lead (*ppm*) in solid materials found by XRF and the proposed standard-addition technique; the results are compared with those obtained with potentiometric stripping analysis (PSA) and, for the reference material, the NBS certified value

*Christensen *et al.*[9]

accurate value for W_0 could be obtained by spiking with not more than 5 times the amount of lead present in the sample itself.

The lead in the standard solution added is in practice most probably deposited in the sample as lead nitrate. The maximum amount of solid material derived from the added spike is small ($<0.1\%$ of the sample weight), so the change in sample weight and the change in the Pb-$L\beta$ intensity caused by the nitrate and other species in the spike will be negligible; in other words, the addition of the standard lead solution is equivalent to spiking with elemental lead.

The standard-addition procedure described above was used to determine the lead content of NBS SRM 1571 orchard leaves, NBS SRM 1632a trace elements in coal (bituminous), NBS SRM 1633a trace elements in coal fly-ash, two unspecified coal fly-ashes (1 and 2) and one unspecified oil fly-ash. For all materials, linear calibration relationships were obtained (correlation coefficient better than 0.99). Table 1 shows the lead concentrations found by the proposed method, and the certified concentrations. Potentiometric stripping analysis[7] has recently been used to determine the amount of lead in the materials investigated here,[8,9] and the results found are also given in Table 1.

The results in Table 1 indicate that an aqueous standard solution is suitable as spiking agent in the XRF determination of lead (and, by inference, of other trace elements) at the ppm level in solid powdered samples. The results presented here were obtained with an energy-dispersive spectrometer and secondary target excitation. However, equation (2) is valid even when direct excitation and a wavelength-dispersive spectrometer are used, and the standard-addition method ought to perform equally well for quantitative work with such equipment.

ANALYTICAL DATA

PYROCATECHOLSULPHONPHTHALEIN COMPLEXAN AS AN ANALYTICAL REAGENT*

Ru-Qin Yu, Zheng-Qi Zhang and Zhi-Hua Zhang

Department of Chemistry and Chemical Engineering, Hunan University, Changsha, People's Republic of China

Summary—Pyrocatecholsulphonphthalein complexan (PSC) has been synthesized from Pyrocatechol Violet (PV), iminodiacetic acid and formaldehyde by Mannich condensation. Its acid dissociation equilibria have been studied potentiometrically. Some characteristic properties of Xylenol Orange (XO) and PV are found in PSC, which is slightly superior to XO and PV in sensitivity as a chromogenic reagent for bismuth. The spectrophotometric characteristics of some metal ion–PSC complexes are reported.

Körbl *et al.*[1] reported that a number of chelating agents can be obtained from Pyrocatechol Violet (PV), Pyrogallol Red and rosolic acid by condensation with iminodiacetic acid and formaldehyde according to the procedure described by Schwarzenbach *et al.*,[2] but the synthesis and analytical application of these products have not been described. The acid–base indicator Cresol Red, from which Xylenol Orange (XO) is derived, is structurally related to PV. The structure of the product derived from condensation of PV and iminodiacetic acid therefore seems likely to be
Scheme 1.

This compound, pyrocatecholsulphonphthalein complexan (PSC), is in essence XO with its methyl groups replaced by phenolic groups, so PSC has the functional groups of both XO and PV. The question then is whether PSC possesses the characteristic properties of both XO and PV. For complexometric titration of bismuth, a mixture of PV and XO has been recommended as the indicator.[3] PSC may therefore give even better results for such titrations. In this paper the synthesis of PSC and its characteristic properties as an analytical reagent are reported.

EXPERIMENTAL

Synthesis of PSC

Finely powdered PV (4.0 g) and iminodiacetic acid (5.4 g) were dissolved in 15 ml of water containing 3.2 g of sodium hydroxide, and 80 ml of glacial acetic acid were added, with

stirring. The mixture was transferred into a 250-ml three-necked, round-bottomed flask fitted with a reflux condenser, stirrer and dropping funnel containing 40% aqueous formaldehyde. After addition of 2.4 ml of formaldehyde the mixture was heated at 55–60° for 12 hr, with stirring. A further 2.4 ml of formaldehyde were added and the mixture was stirred for a total of 7 days at 55–60°. The formation of PSC was checked before proceeding further. To do this, a few drops of reaction mixture were added to 5 ml of acetone; the dark-green precipitate produced was separated and dissolved in a small amount of water. The solution gave a purple-red colour with La(III) in acetate buffer at pH 5.0. Completion of the Mannich reaction was identified by paper chromatography with butan-1-ol–glacial acetic acid–water (3:1:1, v/v). The reaction was considered complete if the chromatogram showed only a green spot at $R_f = 0$. The hot reaction mixture was then filtered by suction, and the filtrate was poured into 1 litre of acetone, with stirring. After standing for 1 hr the dark-green precipitate was filtered off under suction and washed with a small amount of acetone. The product was dried at 40° under vacuum. The yield was about 5.6 g of crude product (56%).

Purification and analysis of PSC

A 2.0-cm bore chromatographic column 80 cm long was prepared with Polyamide 6 (Beijing). About 5 g of the crude product was dissolved in the minimum amount of water, applied to the top of the column, and eluted with water at a flow-rate of 0.5 ml/min. The green fraction of the eluate (*ca.* 50 ml) was evaporated to dryness at 40° under vacuum. The product was evaluated by paper chromatography as described above, and also by thin-layer chromatography. A 9:1 w/w mixture of Polyamide 6 and cellulose powder slurried with methanol was spread on a 6.5 × 18 cm glass plate to give a layer 0.3–0.5 mm thick. The sample, dissolved in water, was applied to the air-dried plate and the chromatogram developed with 0.05*M* sodium hydroxide ($R_f = 0.83$). The product was a dark green hygroscopic solid with metallic lustre. Analysis: $C_{29}H_{38}N_2O_{15}S$ requires 4.08%N, 4.66%S; found, 4.2%N, 4.5%S. The principal infrared bands were at 525, 700, 900, 1380, 1590, 2980 and 3350 cm^{-1}.

Solutions

All solutions were prepared with demineralized water and analytical-reagent grade chemicals unless otherwise stated.

The stock solution of 10^{-2}*M* PSC was prepared from the purified reagent and diluted as required. Cetyltrimethylammonium bromide (CTMAB, Fluka) was used

without further purification. Standard solutions of rare-earth ions were prepared from the corresponding spectrally pure oxides (except La_2O_3, 99.99% and Y_2O_3, 99.999% pure). Solutions of other metal ions were standardized, when necessary, by EDTA titration. The carbonate-free hydroxide solutions used in the potentiometric titrations

protonated tertiary amino groups $(K_{a,1}-K_{a,3})$ takes place in acidic medium. The constants $K_{a,4}-K_{a,11}$ are related to the dissociation of the carboxyl and phenol groups. The Bjerrum formation function $\bar{n}$ for the protonation of L^{9-} may be written as

$$\bar{n} = \frac{K_{a,1}[H^+] + 2K_{a,1}K_{a,2}[H^+]^2 + \ldots + 11K_{a,2}K_{a,2}\ldots K_{a,11}[H^+]^{11}}{1 + K_{a,1}[H^+] + K_{a,1}K_{a,2}[H^+]^2 + \ldots + K_{a,1}K_{a,2}\ldots K_{a,11}[H^+]^{11}} \tag{1}$$

were prepared by passing $0.2M$ potassium chloride through a column (8 mm bore, 10 mm long) of Zerolit FF (OH$^-$ form, 200 mesh). The potassium hydroxide solution obtained was collected in a flask protected with a soda-lime tube, and standardized by acid–base titration.

Potentiometric studies of dissociation equilibria

PSC solutions were potentiometrically titrated with potassium hydroxide under an atmosphere of nitrogen.[4] The flow of nitrogen was stopped during readings. The degree of neutralization a and average number of bound protons $\bar{n}$ were calculated and the $\bar{n}$–pH curves constructed. The ionization constants were calculated by the Bjerrum method.[5]

RESULTS AND DISCUSSION

Synthesis and purification of PSC

Preliminary experiments showed that in aqueous alcohol medium the Mannich reaction was difficult to control, owing to the tendency to polymerization. Of the tested reaction media, glacial acetic acid gave the best yield. The paper chromatography described showed that the spot of crude product remained at the starting point $(R_f = 0)$ and did not contain unreacted PV $(R_f = 0.45)$.

For the separation on the Polyamide 6 column, water was used as the eluent to avoid introducing alkali-metal ions. A blue fraction of impurities appeared before the green fraction for some batches of crude product. The blue fraction was discarded and only the green fraction collected. The main part of the impurities (brown in colour) remained on the column.

Dissociation of PSC

Under strongly acidic conditions PSC can take up two protons to give a form that will be represented by $H_{11}L^{2+}$. The acid–base equilibria of PSC are:

$$H_{11}L^{2+} \underset{pK_{a,1}}{\overset{-H^+}{\rightleftharpoons}} H_{10}L^+ \underset{pK_{a,2}}{\overset{-H^+}{\rightleftharpoons}} H_9L \underset{pK_{a,3}}{\overset{-H^+}{\rightleftharpoons}}$$

$$H_8L^- \underset{pK_{a,4}}{\overset{-H^+}{\rightleftharpoons}} H_7L^{2-} \underset{pK_{a,5}}{\overset{-H^+}{\rightleftharpoons}} H_6L^{3-} \underset{pK_{a,6}}{\overset{-H^+}{\rightleftharpoons}}$$

$$H_5L^{4-} \underset{pK_{a,7}}{\overset{-H^+}{\rightleftharpoons}} H_4L^{5-} \underset{pK_{a,8}}{\overset{-H^+}{\rightleftharpoons}} H_3L^{6-} \underset{pK_{a,9}}{\overset{-H^+}{\rightleftharpoons}}$$

$$H_2L^{7-} \underset{pK_{a,10}}{\overset{-H^+}{\rightleftharpoons}} HL^{8-} \underset{pK_{a,11}}{\overset{-H^+}{\rightleftharpoons}} L^{9-}$$

The dissociation of the sulphonate group and the two

and can be calculated from the equation:[6]

$$\bar{n} = \frac{(9-a)T_{psc} + [OH^-] - [H^+]}{T_{psc}} \tag{2}$$

where T_{psc} is the total PSC concentration and a is the degree of neutralization, defined as ratio of moles of sodium hydroxide added to moles of PSC taken.

The formation curves for protonation of L^{9-} in the absence and presence of CTMAB ($1.5 \times 10^{-3}M$) are shown in Fig. 1. The $pK_{a,i}$ values calculated are presented in Table 1.

The presence of CTMAB inhibits the dissociation of the first carboxylic acid group $(K_{a,4})$, but promotes the remaining steps.

Figure 2 shows the absorption spectra of PSC at various pH values. The equilibrium corresponding to constant $K_{a,7}$ is mainly responsible for the colour change of the indicator from yellow to blue. On addition of CTMAB to the yellow PSC solution at pH 5.0, the $K_{a,7}$ value increases remarkably and the solution turns blue. The values of $K_{a,7}$ and $K'_{a,7}$ can easily be determined spectrophotometrically. From the pH–absorbance curves at 620 nm (for $K_{a,7}$) or 610 nm (for $K'_{a,7}$), $pK_{a,7}$ and $pK'_{a,7}$ have been found to be 5.36 and 4.49, respectively. These values are in good agreement with those obtained from potentiometric measurements.
Fig. 1. The formation curves for protonation of PSC (L^{9-}): I, in the absence of CTMAB; II, in the presence of CTMAB ($1.5 \times 10^{-3}M$).

Table 1. Acid dissociation constants of PSC

i	4	5	6	7	8	9	10	11

$pK'_{a,i}$	2.60	2.95	3.30	4.50	8.25	9.65	10.60	11.70

$$K_{a,i} = \frac{[H_{11-i}L][H^+]}{[H_{11-i+1}L]};$$ ionic strength $= 0.1$ (KCl); the $K'_{a,i}$ values are the apparent acid dissociation constants determined in the presence of CTMAB.

Colour reactions of PSC with metal ions

PSC forms intensely coloured water-soluble complexes with many metal ions. The characteristics of these reactions are summarized in Table 2.

The complexation reaction of Bi(III) with PSC has been taken as an example for more detailed investigation. In 0.10M nitric acid medium, at least two Bi(III)–PSC complex species are formed. In the presence of excess of Bi(III), a blue 1:1 complex is formed, with absorption maximum at 620 nm. When PSC is in excess, a red complex with metal:ligand ratio of 1:2 is formed, with an absorption maximum at 505 nm. The stepwise stability constants of the 1:1 and 1:2 complexes, determined by the method of corresponding solutions modified by Guan et al.[7] are log $K_1 = 5.45$ and log $K_2 = 3.89$ (in 0.1M nitric acid/0.1M potassium nitrate medium). The apparent molar absorptivity of the 1:2 complex is 2.15×10^4
Fig. 2. Absorption spectra of PSC at various pH values: 1, 2.41; 2, 3.30; 3, 4.00; 4, 6.10; 5, 9.46; 6, 10.50; 7, 11.80; 8, 13.00.

$l.mole^{-1}.cm^{-1}$. The sensitivity of PSC as a colorimetric reagent for Bi(III) is better than that of XO ($\varepsilon_{530} = 1.6 \times 10^4 \, l.mole^{-1}.cm^{-1}$)[8] or PV($\varepsilon_{580} = 1.37 \times 10^4 \, l.mole^{-1}.cm^{-1}$).[9] PSC is a useful indicator for the EDTA titration of bismuth, giving a colour change from blue to yellow in 0.5M nitric acid medium. A transient purple-red colour develops just before the equivalence point, and is a useful signal of the approaching end-point. The relative standard devi-

ation is found to be 0.06%. Details will be published elsewhere.

In acetate solution buffered at pH 4.2, lanthanum(III) forms a 1:2 red complex with PSC, apparent stability constant 1.23×10^9 (pH 4.2, ionic strength $0.1M$). Similarly, yttrium give a 1:2 complex with an apparent stability constant of 6.17×10^7 (pH 4.2, ionic strength $0.1M$). In the presence of CTMAB, lanthanum and yttrium form blue ternary complexes with PSC, the molar absorptivities of the La(III) and Y(III) complexes being 6.5×10^4 (650 nm) and 7.31×10^4 $1.\text{mole}^{-1}.\text{cm}^{-1}$ (640 nm), respectively (for [metal] $= 1 \times 10^{-5}M$, [PSC] $= 3.5 \times 10^{-4}M$). A preliminary investigation shows that the increase in sensitivity seems to be the formation of complexes with unusual metal-to-ligand molar ratios. It is interesting that addition of an organic solvent such as ethylene glycol depresses the formation of the lanthanum ternary complex but remarkably enhances the absorptivity of the Y(III)–PSC–CTMAB species. This effect can be utilized for the determination of yttrium in the presence of lanthanum.

When PSC solution is mixed with an aged zirconium(IV) solution, a slow complexation reaction takes place. Trace amounts of fluoride catalyse this reaction, even at a fluoride concentration as low as $5.0 \times 10^{-10}M$. This provides a promising means of kinetic assay of traces of fluoride. It is difficult to detect fluoride in water at levels below $10^{-7}M$ with a lanthanum fluoride electrode, because traces of fluoride are released from the membrane surface itself into the test solution, and the PSC–Zr(IV) reaction will easily distinguish between two samples of demineralized water, one of which has been in brief contact with a lanthanum fluoride electrode. This is a very sensitive qualitative test, but its analytical characteristics depend on the history of the zirconium solution, and quantitative application will require further investigation.

ETUDE DE LA PURETE DES ECHANTILLONS COMMERCIAUX D'EOSINE

D. Fompeydie et P. Levillain

Laboratoire de Chimie Analytique, UER des Sciences Pharmaceutiques et Biologiques,
4, avenue de l'Obervatoire, 75270 Paris Cedex 06, France

Résumé—L'étude de 8 échantillons commerciaux d'éosine montre que l'utilisation de ce colorant comme médicament se heurte à 3 problèmes: hydratation et teneur en composés minéraux très variables selon les échantillons, mais surtout complexité importante de la fraction xanthènique qui peut contenir jusqu'à 8 constituants. Cette étude a nécessité la mise au point d'un certain nombre de méthodes d'analyse décrites dans cet article.

Deux colorants xanthèniques ont été inscrits comme médicaments à différentes Pharmacopées. La fluorescéine y figure depuis longtemps sous diverses formes [1–3] et des critères de pureté ont également été définis par l'Association of Official Analytical Chemists.[4] Enfin il est possible de s'en procurer des échantillons commerciaux suffisamment purs.[5]
fluorescéine

Par contre, l'éosine (tétrabromo-2,4,5,7 fluorescéine) n'a été inscrite que récemment à la IXe édition de la Pharmacopée Française, et Marshall[5] a déjà signalé l'hétérogénéité des échantillons commerciaux de ce colorant.

Lors d'études antérieures sur les propriétés des colorants xanthèniques,[6–10] l'obtention d'éosine pure s'est révélée difficile. Il peut donc être intéressant de rapporter les résultats observés lors de l'étude d'échantillons commerciaux d'éosine, ces résultats différant notablement de ceux déjà publiés et pouvant aider à mieux cerner les problèmes de la monographie de la Pharmacopée.

PARTIE EXPERIMENTALE

Préparation des colorants bromés sur le cycle xanthènique

Les dérivés bromés sur le cycle xanthènique sont préparés par action du mélange bromate–bromure sur la fluorescéine en milieu mixte eau–acétone acide. Cette technique évite la formation d'esters du groupement carboxylique.[11] On utilise une quantité de bromate double de celle stoechiométriquement nécessaire pour obtenir le dérivé recherché. On obtient un mélange de colorants qu'on sépare sur colonne d'échangeurs d'ions DEAE Trisacryl M[12] à

l'aide d'un gradient eau–méthanol puis méthanol–acide formique.

Préparation des esters des colorants xanthèniques bromés

Ils peuvent être obtenus par deux voies. (1) Préparation et purification de l'éthylfluorescéine par synthèse en milieu acide dans l'alcool correspondant,[13] puis bromation et séparation chromatographique du mélange obtenu selon les techniques décrites au paragraphe précédent. (2) On peut estérifier individuellement chacun des colorants xanthèniques en milieu alcoolique acide.[13] Il reste toujours une petite quantité de colorant xanthènique non estérifié qu'on peut éliminer par chromatographie sur Sephadex LH 20, en éluant au méthanol, ou sur DEAE Trisacryl M, à l'aide du mélange utilisé pour la séparation du colorant xanthènique correspondant.[12]

Préparation des produits bromés sur le cycle C

Nous avons préparé la bromo 3'-4'-5'-6' fluorescéine par action du résorcinol sur l'anhydride phtalique tétrabromée selon la méthode classique de préparation de la fluorescéine.[14] La bromation du cycle xanthènique et la séparation des colorants formés s'effectuent comme précédemment, l'élution de la colonne étant réalisée par un gradient de 0 à 15% d'acide formique dans le méthanol.

Caractérisation des produits formés

La caractérisation des produits formés a été obtenue:

—par RMN[1]H à 270 MHz sur un appareil Brucker WH 270 FT;
—par détermination des maximums d'absorption dans le visible sur un appareil Beckmann Acta III;
—par détermination du R_M en chromatographie sur couche mince de gel de silice avec un mélange éluant toluène–acide acétique (65:35 v/v) en cuve saturée.

Etude de la pureté des échantillons commerciaux

L'étude de l'hydratation des échantillons a été effectuée par dessication à 135°.[4] La fraction minérale a été étudiée par la méthode des cendres sulfuriques de la Pharmacopée et le sodium dosé par photomètrie de flamme. Le pourcentage en colorant dans les échantillons a été obtenu par précipitation en milieu acide puis dessication du précipité.[4] La séparation chromatographique a été effectuée sur couche mince de gel de silice avec un mélange toluène–acide acétique (65:35 v/v) en cuve saturée.[15]

En HPLC, nous avons utilisé une colonne de silice greffée C_{18} (longueur 10 cm) avec un appareil Varian 5000 équipé d'un détecteur Varichrom. Le mélange éluant est constitué

d'un gradient méthanol–eau (allant de 10 à 20% d'eau) renfermant une concentration constante $0,05M$ d'acide perchlorique.

L'analyse qualitative des échantillons a été effectuée par chromatographie sur couche mince par comparaison des R_f avec ceux obtenus pour des produits purs de référence.

Le dosage des fractions a été effectué:

(1) après séparation chromatographique sur couche mince
—par densitométrie des taches à l'aide d'un intégrateur Sebia "Cellomatic" par rapport à un étalon interne d'érythrosine;
—par élution des spots dans l'ammoniaque à 0,5% et mesure de l'absorption à l'aide d'un spectrophotomètre Beckmann Acta III;
(2) par HPLC, en étalonnant l'appareil à l'aide des produits de référence;
(3) par spectrophotométrie des solutions à l'aide d'un appareil Hewlett-Packard 8450 A. Le calcul des concentrations est effectué par rapport à des solutions étalons des différents constituants des mélanges et à partir des courbes dérivées.

Le brome a été dosé par le laboratoire de microanalyse du CNRS. L'étude a été effectuée sur huit échantillons commerciaux d'éosinate de différentes origines: éosinate de sodium *1*, Y RAL n° 18; *2*, Aldrich (numéro de lot non précisé); *3*, Merck 25 89282; *4*, Flucka 19637187; *5*, RAL extra cristallisée; *6*, Merck 2520149; *7*, Flucka (lot non précisé); *8*, éosinate de potassium RAL.

Deux échantillons ont été étudiés dès l'ouverture du flacon (n° 3 et 4) alors que les autres étaient plus anciens.

Nous avons également analysé un échantillon de dibromo 4,5 fluorescéine moléculaire, Koch and Light, n° 65491.

RESULTATS

Caractéristiques des produits purs

Les caractéristiques des produits obtenus sont rassemblés dans le tableau 1 pour la RMN ^{1}H dans le DMSO d_6 et dans le tableau 2 pour les propriétés d'absorption dans le visible. En RMN ^{1}H on observe en outre deux signaux à $\delta = 0,89$ et 4,05 ppm pour les esters éthyliques.

La figure 1 représente les courbes reliant les R_M, en
Fig. 1. R_M de la fluorescéine et de ses dérivés en fonction du nombre d'atomes de brome fixés sur le cycle xanthénique: *fluorescéine; + éthylfluorescéine; ○ fluorescéine bromée sur le cycle C.

chromatographie sur couche mince, au nombre d'atomes de brome fixé sur le cycle xanthénique.

Pureté des échantillons commerciaux

Le tableau 3 regroupe les résultats d'ensemble obtenus pour les échantillons étudiés.

DISCUSSION

Préparation des produits de référence

Les produits purs de référence ont été obtenus par application ou modification de méthodes classiques de synthèse, les mélanges obtenus étant séparés sur échangeur d'ion DEAE Trisacryl M. La pureté de ces produits a été vérifée par chromatographie sur couche mince. La nature des colorants isolés peut être déduite de la réaction ayant servi à les préparer et vérifiée par des propriétés simples.

Pour les produits substitués sur le cycle xanthénique, la RMN ^{1}H montre la disparition progressive des protons en fonction du nombre

d'atomes de brome fixés en 4,5 puis en 2,7 (tableau 1). Le spectre des esters possède en outre les signaux du groupement éthyle ($\delta = 0,89$ et 4,05 ppm). Enfin pour les dérivés bromés sur le cycle C, on observe la disparition des massifs situés entre 7 et 8 ppm en même temps qu'un déblindage des protons H_{1-8} sous l'influence de la modification du noyau C.

En chromatographie sur couche mince, la courbe reliant le R_M au nombre d'atomes de brome fixés sur le cycle xanthènique est sensiblement une droite pour les trois classes de composés. Comme prévu d'après la valeur de l'énergie d'adsorption du brome sur silice ($Q = -0,17^{16}$) l'augmentation de la teneur en cet élément entraîne une accélération de la migration du colorant (figure 1).

Les spectres d'absorption dans le visible sont d'aspect semblable. Leur maximum subit un effet bathochrome lié à la présence de brome sur le noyau xanthènique. L'estérification entraîne en outre un déplacement de +4 nm alors que la bromation du cycle C augmente de 20 nm la position du maximum (tableau 2).

Pureté des échantillons commerciaux

Cette étude met en évidence l'importance et la variabilité de la teneur en eau des éosinates, teneur qui peut atteindre 15% pour des échantillons anciens. D'autre part, la conservation des sels augmente fortement leur hydratation: pour l'échantillon n° 3 la perte à la dessication passe de 2,5 à 6,6% après deux mois de conservation. Enfin les formes moléculaires sont beaucoup moins solvatées que les sels: nous le vérifions ici pour la dibromofluorescéine étudiée, comme nous l'avions observé pour la fluorescéine.[7] Ce caractère fortement hygroscopique des sels pose le problème de leur conservation.

La concentration en sodium, supérieure à celle attendue de la teneur réelle en colorant, est liée à l'existence d'impuretés minérales et de dérivés moins bromés que l'éosine renfermant un pourcentage plus important de cet ion. Enfin, par différence avec les résultats obtenus par photométrie de flamme, les cendres sulfuriques—dont les résultats sont ici exprimés en sodium—montrent que les échantillons contiennent sans doute de faibles quantités d'autres cations.

La teneur globale en colorant, déterminée par gravimétrie de la forme moléculaire précipitée en milieu acide, dépend essentiellement de l'hydratation. La somme des concentrations en sodium et en colorant et de la perte à la dessication est en effet assez proche de 100%, montrant ainsi que la teneur en éléments minéraux est généralement faible.

L'analyse qualitative de la fraction xanthènique, effectuée par chromatographie sur couche mince, montre la complexité des produits étudiés, le nombre de composants pouvant varier de 2 à 8. Il semble donc difficile d'obtenir des échantillons commerciaux purs. On peut noter que le rapport des absorbances à 516 et 490 nm—égal à 2,81 pour un échantillon d'éosine pure—paraît constituer un test valable de la pureté de l'éosine (tableau 3).

L'étude quantitative des différentes fractions a été effectuée sur trois échantillons, par quatre techniques différentes avec une bonne concordance des résultats. Les valeurs du tableau 3 ont été obtenues par chromatographie sur couche mince suivie d'élution et mesure de l'absorbance des solutions. Les résultats montrent que la teneur globale en éosine est généralement faible et comprise entre 50 et 70% des échantillons. On peut remarquer que la complexité des échantillons rend inapplicable la méthode de spectrophotométrie à trois longueurs d'onde proposée par Marshall[5] car elle ne prend en compte que trois colorants (éosine, tribromofluorescéine, fluorescéine) qui ne reflètent pas la composition de la plupart des échantillons.

Cette complexité des éosinates commerciaux

confirme que la bromation de la fluorescéine est très délicate: elle présente en effet deux difficultés importantes. Selon la densité électronique calculée sur le cycle xanthènique[7] la bromation s'effectue en 4,5 puis en 2,7 enfin beaucoup plus difficilement sur le cycle C désactivé par le groupement carboxylique. Toutefois les réactions sont assez lentes et la vitesse diffère notablement selon la position. L'excès de réactif peut donc attaquer le produit formé avant que le produit initial ait entièrement réagi. On retrouve donc systématiquement dans le milieu plusieurs composés à différents stades de bromation (fluorescéine, dérivés mono, di, tri et tétrabromés sur le cycle xanthènique et, en présence d'un excès important de brome destiné à accélérer la réaction, dérivés de l'éosine bromés sur le cycle C). Ceci est confirmé par la teneur moyenne en brome par molécule, toujours inférieure à 4 (tableau 3). Par ailleurs la réaction se produit plus régulièrement en milieu acide mais alors les colorants sont insolubles dans l'eau. On évite leur précipitation en ajoutant au milieu un solvant organique miscible à l'eau. Ce sont les alcools qui sont le plus souvent employés mais leur présence entraîne la formation d'esters du groupement carboxylique qui augmente la complexité des produits commerciaux.

CONCLUSION

La complexité des échantillons commerciaux d'éosinate de sodium pose le problème de la pureté des produits à utiliser en pharmacie. Il est certes possible de synthétiser de l'éosine très pure[11] ou de

séparer par chromatographie les produits commerciaux[12] mais le prix de revient devient alors très élevé. Il semble donc nécessaire de préciser la nature et la teneur limite en impuretés admissibles, en tenant compte des difficultés de la synthèse et en se basant sur leur efficacité thérapeutique et leur toxicité éventuelle.

Summary—Eight commercial samples of eosin have been analysed. Three problems were encountered in selecting material for use as a drug: the degree of hydration, the inorganic content and, above all, the composition of the xanthene moiety, which could contain up to 8 dyes.

SPECTROPHOTOMETRIC DETERMINATION OF FORMATION CONSTANTS OF 1:1 COMPLEXES OF LANTHANIDES WITH 4-(2-PYRIDYLAZO)RESORCINOL (PAR)

EMIKO OHYOSHI

Yatsushiro College of Technology, Hirayamashinmachi 2627, Yatsushiro, Kumamoto, 866 Japan

Summary—Complex formation (1:1) between lanthanides(III) and 4-(2-pyridylazo)resorcinol (PAR or H_2R) has been studied by spectrophotometry. The method is based on indirect estimation of the protonated (MHR) and the normal (MR) complexes by measuring the absorbance at the peak for the ligand, which decreases with increasing metal concentration at a constant pH. Similar experiments were made at various pH values. Both MHR and MR complexes were found to be formed in the pH range 5–6. Their formation constants, $\log K_{MHR}$ and $\log K_{MR}$, determined by graphical analysis, ranged from 3.78 ± 0.02 (Ce) to 4.39 ± 0.02 (Lu), and from 9.61 ± 0.06 (Ce) to 10.70 ± 0.05 (Lu), respectively. The acidity of the MHR complexes parallels the order of stability of the MR complexes.

4-(2-Pyridylazo)resorcinol (PAR or H_2R) forms intensely coloured complexes with many metal ions and is widely used in analytical chemistry.[1,2] The formation of these complexes is known to be very dependent on pH but little information on the complexation equilibria has been obtained. Such information will aid in choosing experimental conditions so as to increase the selectivity. The system is rather complicated because of simultaneous formation of the protonated and normal type of complexes with many metal ions. In a previous paper[3] we proposed a method for facilitating the spectrophotometric analysis of these two types of 1:1 complex, and applied it to the zinc and lanthanum PAR complexes. The results showed that the method was more applicable to the lanthanum system because a larger variation in absorbance with change in metal concentration could be obtained, owing to the lower absorptivity of LaHR at the absorption peak for the free ligand, PAR. This suggests that the method should also be applicable to the system of PAR and the other lanthanides(III). Sommer and Novotna[4] have studied the PAR complexes of several lanthanides(III) and found no simple relation between the stability of the complexes and the atomic number or radius of the lanthanide ions. To establish such a relationship the complexation should be studied for all the lanthanides(III).

In the present work, we investigated the complexation of PAR with all the lanthanides(III) by applying the method developed previously,[3] and have compared the results with those reported by Sommer and Novotna.[4]

EXPERIMENTAL

Reagents

All chemicals used were of analytical-reagent grade. PAR was obtained from Dojindo Chemical Co., and purified by recrystallization. The purity was checked by thin-layer chromatography.[5] The concentration of PAR in its aqueous stock solution was calculated from its weight. The lanthanide(III) nitrate solutions, except for cerium(III), were prepared by dissolving the calculated amounts of the respective oxides in nitric acid. The cerium(III) nitrate solution was prepared by dissolving $Ce(NO_3)_3 \cdot 2(NH_4NO_3) \cdot 4H_2O$ in $0.01M$ nitric acid, and standardized by EDTA titration. Sodium acetate and hexamine solutions ($0.02M$) were used to maintain the pH in the range 4.8–6.3. The ionic strength was maintained at 0.1 with sodium nitrate.

Procedure

The metal solution was added in small increments (50 μl), by μl pipette, to 10 ml of buffered PAR solution (2.0–$3.0 \times 10^{-5}M$), to give concentrations increasing from 10^{-4} to $5 \times 10^{-3}M$. Before and after each addition of metal the absorbance at the wavelength for the absorption peak of PAR (which depends on the pH, and varies from 390 to 413 nm) was measured with a Shimadzu UV 200s spectrophotometer. No precipitation occurred under these experimental conditions.

RESULTS AND DISCUSSION

Absorption spectra of the complexes

The absorption spectra of PAR solutions containing excess of each lanthanide(III) were measured over the range 350–600 nm. The variation in the spectrum with metal concentration (C_M) was investigated at constant pH values in the range 4.8–6.3. The absorbance at the peak for PAR was observed to decrease with increasing C_M. After addition of sufficient metal there was no observable change in the spectra, indicating practically complete formation of the 1:1 complexes. The spectra varied according to the lanthanide(III) used and the pH. The spectra obtained for different lanthanides(III) at pH 4.83 showed two maxima, at 410 and 495 nm. The apparent molar absorptivities at 410 nm decreased from 1.48 to 1.28×10^4 l.mole^{-1}.cm^{-1} and those at 495 nm in-

creased from 0.95 to 1.15×10^4 l.mole^{-1}.cm^{-1} with atomic number of the lanthanide. The isosbestic points also varied from 428 to 442 nm. As the pH increased, the peak at 410 nm decreased and the one at 495 nm (which was slightly shifted to 500 nm at pH 6.3) increased remarkably with atomic number. To study the latter peak more extensively we further increased the pH by adding a small amount of $1.0M$ sodium hydroxide. As a result, the peak was further shifted to 505 nm and showed nearly the same limiting absorptivity of 3.0×10^4 l.mole^{-1}.cm^{-1} for all the lanthanides, though this value was reached at different pH values for the different lanthanides, ranging from pH 6.7 (Lu) to 7.5 (Ce). From these facts, the peaks at 410 nm and 495 nm are attributed to the MHR complex and that at 505 nm is attributed to the MR complex.

Determination of the formation constants of MHR and MR

As described previously,[3] the stability constants of the metal complexes of PAR (H_2R), MHR and MR, can be indirectly estimated by utilizing the ligand absorption peak. The absorbance at the peak for the free ligand, measured in the absence (A_0) and the presence (A) of the metal, under conditions where $C_M \gg C_R$ (C_R = ligand concentration), can be related to the formation constants, K_{MHR} and K_{MR}, of the 1:1 complexes MHR and MR assumed to be formed as follows (charges are omitted for simplicity):

$$C_R = [MHR] + [MR] + [R'] \qquad (1)$$

$$A = \varepsilon_{MHR}[MHR] + \varepsilon_{MR}[MR] + \varepsilon_{R'}[R'] \qquad (2)$$

where R' is the free ligand not combined with any metal, and ε_{MHR}, ε_{MR} and $\varepsilon_{R'}$ are the molar absorptivities of MHR, MR and R' respectively, at the wavelength of the free-ligand peak. With the aid of

Fig. 1. Plots according to equation (5) for the system of PAR and different lanthanides(III) at a constant pH of 5.70. (1) Lu, Yb; (2) Tm; (3) Er; (4) Ho; (5) Dy; (6) Tb, Gd, Eu, Sm; (7) Nd; (8) Pr; (9) Ce.

the formation constants, $K_{MHR} = [MHR]/[M][HR]$ and $K_{MR} = [MR]/[M][R]$, the acid dissociation constants of H_2R, $K_1 = [H][HR]/[H_2R]$ and $K_2 = [H][R]/[HR]$, and the Ringbom α-coefficient,[6] $\alpha_R = [R']/[R]$, equations (1) and (2) can be converted into the following expressions:

$$[M] (K_{MHR}K_1[H]$$
$$+ K_{MR}K_1K_2)/(\alpha_R K_1 K_2) = C_R/[R'] - 1 \quad (3)$$

$$A/\varepsilon_{R'} = [R']\{1 + (\varepsilon_{MHR}K_{MHR}K_1[H]$$
$$+ \varepsilon_{MR}K_{MR}K_1K_2)[M]/(\varepsilon_R \alpha_R K_1 K_2)\} \quad (4)$$

Combining equation (3) with equation (4), and substituting C_M for [M] (since $C_M \gg C_R$), and A_0 for $C_R \varepsilon_{R'}$, we obtain

$$\frac{K_{MHR}K_1[H] + K_{MR}K_1K_2}{\alpha_R K_1 K_2}$$

$$- \frac{\varepsilon_{MHR}K_{MHR}K_1[H] + \varepsilon_{MR}K_{MR}K_1K_2}{\varepsilon_R \cdot \alpha_R K_1 K_2} \times \frac{A_0}{A}$$

$$= (A_0/A - 1)/C_M \quad (5)$$

From equation (5), a linear relation between $(A_0/A - 1)/C_M$ and A_0/A should be obtained at constant pH (where $\varepsilon_{R'}$ remains constant). The product of the intercept y_0 on the y-axis $[y = (A_0/A - 1)/C_M]$, at a fixed pH, and $\alpha_R K_1 K_2$ is a function of [H]:

$$y_0 \alpha_R K_1 K_2 = K_{MHR}K_1[H] + K_{MR}K_1K_2 \quad (6)$$

According to equation (6), a plot of the left-hand side of equation (6) vs. [H] should be linear in a pH-range where no hydrolysis of the metal ion occurs. From the slope and the intercept of the line, both K_{MHR} and K_{MR} can be determined.

From the measured absorbance decreases at the peak for PAR with increasing metal concentrations and constant pH, we plotted the relation expressed by equation (5). All the plots at different pH values for the different lanthanides(III) were linear with a negative slope as expected. The intercepts on the y-axis, which indicate the degree of complex formation, increased with either increasing pH or atomic number. There is no observable difference in the values for Lu(III) and Yb(III) and for Tb(III), Gd(III), Eu(III) and Sm(III) at any pH studied, and for Er(III), Ho(III) and Dy(III) at relatively low pH values in the range studied. The intercept x_0 on the x-axis (A_0/A) at pH 4.83, which might be nearly equal to the ratio $\varepsilon_{R'}/\varepsilon_{MHR}$ at 390 nm at such a low pH, slightly increased with atomic number (from 1.5 to 1.7). This is in accord with the decrease in the molar absorptivities of the MHR complexes at 410 nm with atomic number ($1.48-1.28 \times 10^4$ l.mole^{-1}.cm^{-1}). At the higher pH of 5.70, as illustrated in Fig. 1, both x_0 and y_0 values increase with atomic number to a greater extent, to give some detectable differentiation between Er(III), Ho(III) and Dy(III). This would be

due to formation of MR complexes as well as the MHR complexes. The stabilities of the MR complexes of the heavy lanthanides(III) must differ more than those of the MHR complexes. The slope given by $-(\varepsilon_{MHR}K_{MHR}K_1[H] + \varepsilon_{MR}K_{MR}K_1K_2)/(\varepsilon_R \alpha_R K_1 K_2)$ varies with the K_{MHR} value if it can be assumed that $\varepsilon_{MHR} \gg \varepsilon_{MR}$ and $\varepsilon_{MHR} \sim \varepsilon_{M'HR}$ (M and M' being different lanthanides), suggesting that the K_{MHR} values for Sm(III)–Tm(III) are not so much different from each other.

To determine the formation constants of the MHR and MR complexes we plotted the relationship expressed by equation (6), for various lanthanides(III). The values, $K_1 = 10^{-5.50}$ and $K_2 = 10^{-12.30}$,[7] were used for calculation of $\alpha_R K_1 K_2$. All the plots were linear, with intercepts indicating the presence of both the MHR and MR complexes. It was generally observed that the greater the slope of the line the greater the intercept, and that both increased with atomic number, though the extent of the two increases was not the same. The lanthanides heavier than Sm(III) showed greater difference in the intercept than in the slope. The slopes for Sm(III)–Er(III) were very similar, as is to be expected. Table 1 shows the formation constants of K_{MHR} and K_{MR} obtained from the slope and intercept of the plot of equation (6), and the proton dissociation constant of MHR, K_{MHR}^H, calculated from $K_{MHR}^H = K_2 K_{MR}/K_{MHR}$. The values were obtained by the least-squares method. For comparison the values reported in the literature[4] are included. Sommer and Novotna[4] assumed existence of the protonated complexes, MRH* where H* denotes the proton of the p-hydroxy group of PAR, and calculated the K_{MRH}^* values by using K_3 as an approximation to K_2^*, where K_1 is the dissociation constant of H_3R^+. The resulting values for K_{MRH}^* were larger than those for K_{MR}. However, Chalmers[8] has stated that the use of k_2 is preferable to use of K_3 for the approximation, because the o-hydroxy group should be regarded intrinsically as at least as acidic as the p-hydroxy group, its lower acidity being due to internal hydrogen-bonding. For the MR complexes,

our results mostly agree with those reported by Sommer and Novotna. Although they offered no explanation for the unusual relation between complex stability and atomic number, this could result from the different values of the molar absorptivity of MR (1.48–4.1 × 10^4 l.mole^{-1}.cm^{-1} at 530 nm) estimated for the different lanthanides(III). From our results, however, the ε values of MR at 505 nm are nearly the same (3.0 × 10^4 l.mole^{-1}.cm^{-1}) for all the lanthanides(III).

Comparison of complexation trends of HR^- and R^{2-}

The dependence of the formation constants, K_{MHR} and K_{MR} on the reciprocal of the ionic radius r is plotted in Fig. 2. The two curves show a similar complexation trend for the light lanthanides(III). For the heavy lanthanides(III), however, there are different trends between the HR^- and the R^{2-} ligands. These two trends are often observed in lanthanide chemistry. According to Moeller et al.[9], who divided the ligands into three types showing different complexation trends, the R^{2-} and the HR^- ligand belong to the first and the second group, respectively. Although the similarity among the li-
Fig. 2. Plots of the formation constants of the lanthanide(III)–PAR complexes, MHR and MR, vs. the reciprocal of the radius of the metal ions.

gands in the respective groups has not been clearly indicated, the ligands in the first group are capable of forming at least one chelate ring in the complexes.

In an attempt to elucidate the co-ordination structure of the protonated and the normal type of PAR complexes, detailed studies on extraction of the 1:2 Ni–PAR complexes were made by Hoshino et al.[10] They suggested that in the chelation of $Ni(HR)_2 \cdot 2H_2O$ and NiR_2^{2-}, the ligands, HR^- and R^{2-}, are acting as bidentate and terdentate, respectively. They stated that the basic change of the chelate structure from $Ni(HR)_2 \cdot 2H_2O$ to NiR_2^{2-} and deprotonation of HR^- ligand both caused a remarkable increase in the absorptivity (from 3.73 × 10⁴ to 8.08 × 10⁴ l.mole⁻¹.cm⁻¹). Although the lanthanide–PAR complexes (1:1) differ in type from the Ni–PAR complexes, a considerable increase in the absorptivity (from 0.95–1.15 × 10⁴ to 3.0 × 10⁴ l.mole⁻¹.cm⁻¹) was similarly observed with increasing pH. The LnR complexes (Ln = lanthanide) may have a more stable chelate structure which gives rise to a larger difference in stability between the heavy lanthanides(III) than that for the LnHR complexes. The acidity of the LnHR complexes parallels the stability order of the LnR complexes (Table 1).

CONCLUSIONS

The complexes MHR and MR can be differentiated by spectrophotometric means and their formation constants, K_{MHR} and K_{MR}, determined. Both values regularly increase with increasing atomic number up to Sm(III). For the heavy lanthanides(III), the K_{MR} values also increase but the K_{MHR} values are nearly the same.

Résumé—Revue sur les ferrocyanures de nickel et de zinc durant la période 1922–1983, avec une attention particulière à leur composition et leur structure en relation avec les méthodes de préparation.

During the last two decades, inorganic ion-exchangers have attracted chemists because they seemed to be very useful in separative chemistry. A rapid development in nuclear energy, hydrometallurgy, and recovery of valuable materials from industrial wastes has enforced attempts to synthesize highly selective ion-exchange materials resistant to chemicals and ionizing radiation.[1,2] Among them, insoluble ferrocyanides have been studied mainly in connection with the removal of caesium in decontamination of radioactive liquid wastes.[3] The ferrocyanides of bivalent metals have been the most extensively studied. It has been shown that zinc[4,5] and nickel ferrocyanides[6] in particular have an exceptionally strong affinity for caesium ions.

Before undertaking a systematic study of the exchange properties of these ferrocyanides, we needed a good knowledge of their chemical composition and structure in relation to the methods used for their preparation. We therefore made a thorough literature survey, and tried to make a synopsis of what was published on these topics, which we hope will be helpful to all those who want to use these products for laboratory studies or industrial applications. In order to make appraisal easier, the collected information is summarized in Table 1 for zinc ferrocyanides and in Table 2 for nickel ferrocyanides.

PREPARATION METHODS

The main purpose of this survey was to specify which preparation procedure should be used in order to obtain a product of controlled composition and structure. In the first three columns of Tables 1 and 2 we indicate the main experimental features, when details are available. In most cases the ferrocyanide

precipitate is obtained by mixing a ferrocyanide solution (alkali-metal ferrocyanide or ferrocyanic acid) with a solution of a nickel or zinc salt. Sometimes a solution of another alkali-metal salt is also added. The ratio of cations to ferrocyanide ions is an important factor. In some cases it varies continuously during the preparation, when one of the solutions is slowly added to the other. In other cases it remains constant, when the solutions are added simultaneously at the same rate.

The grain size of the precipitates and even the preparation yield are seldom indicated in the literature, so we cannot give any precise indications on these subjects. With such sparingly soluble products as zinc and nickel ferrocyanides, the particles are always very small and may even be colloidal. Most authors suggest dropwise addition of the solutions, because it should avoid formation of too small particles. According to some authors the proportion of colloidal particles depends on the reactant ratio. The colloidal character of nickel ferrocyanide is said to decrease when the Ni/Fe ratio increases from 1 to 1.5.[7] Kourim[8] recommends a 50% excess of zinc in order to avoid colloidal $Zn_2Fe(CN)_6$. In contrast, Kawamura[4] recommends using the stoichiometric ratio, in order to obtain a well crystallized $Na_2Zn_3[Fe(CN)_6]_2$ precipitate. Aging of the precipitate in the solution is used by some authors to increase the grain size.

We also indicate the conditions for drying the precipitate, whenever they were given. They vary widely: the temperature ranges from ambient to 140° and the drying is done in air or in vacuum. The drying conditions may influence the structure and composition of the ferrocyanide.

The exchange properties of the ferrocyanides have

been used by some authors for changing the composition of already precipitated products.[9-13] In some cases, the structure is also modified during this process.[9]

Single crystals of composition $M_2^I Zn_3[Fe(CN)_6]_2$ have been prepared by slow diffusion of $M_4^I Fe(CN)_6$ (M^I = Na or K) and $ZnCl_2$ through silica gel.[14,15] This preparation took about three months and led to 0.05 mm crystals, which were used for accurate X-ray analysis. The analogous $Cs_2 Zn_3[Fe(CN)_6]_2$ single crystals were obtained by ion-exchange of $Na_2 Zn_3[Fe(CN)_6]_2$ crystals with caesium ions.[16]

COMPOSITION AND STRUCTURE

We first looked at the methods used for determination of the chemical formulae, and in the tables have indicated these methods in footnotes. Often, however, the methods were not given by the authors and we do not know whether the formulae given were based on analysis or simply assigned from theoretical assumptions. The methods that *are* given may be divided into two types: (1) chemical analysis of the products or the residual solutions; (2) potentiometric or conductimetric measurements during the precipitation. It should be noted that the formulae deduced from measurements of the second type do not necessarily reflect the composition of the product which is achieved after filtration and drying. The crystallographic structures were deduced from X-ray diffraction work.

Zinc ferrocyanides

The compositions obtained are summarized in Fig. 1. We first notice that a stoichiometric formula is nearly always given for all the series. Pure zinc ferrocyanide $Zn_2 Fe(CN)_6$ is produced when the ratio of zinc cations to ferrocyanide anions used is >2, in presence of either sodium or hydrogen ions. According to Bellomo[17] this also holds when potassium ferrocyanide is used. It should be noted, however, that this author did not analyse the product obtained, but used potentiometric measurements during the precipitation. More recent studies,[5,14] with accurate analyses of the precipitates, indicated that with potassium ferrocyanide, pure $Zn_2 Fe(CN)_6$ ferrocyanide could not be obtained even with high Zn/Fe ratios and concentrated solutions.

The structure of this compound was found to be orthorhombic by Cola and Ganzerli-Valentini.[10] A more recent study by Siebert et al.[18] finds a trigonal lattice for the $Zn_2 Fe(CN)_6 . 2H_2O$ hydrate and gives an explanation for the earlier interpretation.

If the Zn/Fe ratio used is <1.5, in the presence of sodium,[19,20] ammonium[6,19] or hydrogen[19,21] ions, a mixed ferrocyanide is obtained. The formula assigned is $M_2^I Zn_3[Fe(CN)_6]_2$ where M^I is the alkali-metal ion. In presence of potassium ions, according to

a Potentiometric measurements.
b Non-stoichiometric compound. Possibility of ferricyanide ions.
c Conductivity measurements.
d Electron diffraction from deposited colloidal solution.
e No definite salt: may contain less $K_4Fe(CN)_6$ than in the formula.
f Zn determined in supernatant solution by complexometry.
g Air-dried at 140° or under vacuum at 100°.
h Chemical analysis given for Zn, $Fe(CN)_6$ and alkali metals.
i Chemical analysis given for Zn, Fe, C.
j See procedure given.[41]
k Chemical analysis given for Zn, Fe, H_2O, Cs, K.
l The X-ray diffraction pattern corresponds to those given by Kawamura et al.[4,9]
m Formula deduced from radiotracer and atomic-absorption measurements.
n Chemical analysis given for Zn, Fe, C, N, H, NH_3.
o Powders of the same compounds were obtained according to Vlasselaer et al.[5] and Kawamura et al.[9] X-ray spectra of powders are consistent with single-crystal structures.

the most recent studies, a mixed ferrocyanide is obtained whatever the Zn/Fe ratio. In most cases the formula K$_2$Zn$_3$[Fe(CN)$_6$]$_2$ is assigned.[5,17,20,22,23] MgZn$_3$[Fe(CN)$_6$]$_2$ and CaZn$_3$[Fe(CN)$_6$]$_2$ belong to the same series.[19]

The structure of this series was accurately determined by X-ray diffraction methods with powder and single crystals.[14,15,16,24] It belongs to the rhombohedral system R3c. The parameters vary very slightly according to which alkali metal is present.

For the products obtained in presence of potassium ions, other compositions are sometimes given: cubic K$_2$ZnFe(CN)$_6$ by Rigamonti[23] and Ayers et al.[25] or tetragonal K$_{0.5}$Zn$_{1.75}$Fe(CN)$_6$ by Vol'khin et al.[12].

Precipitation in the presence of caesium ions leads to a product with formula Cs$_2$ZnFe(CN)$_6$.[19,22,26,27] and a cubic structure.[10,26,27]

Kuznetsov et al.[27] proposed another composition, also with a cubic structure.

Ion-exchange has been used in order to obtain mixed zinc–caesium ferrocyanides. Starting from Zn$_2$Fe(CN)$_6$, the exchange leads to Cs$_2$ZnFe(CN)$_6$.[9,11] Starting from the M$_2^I$Zn$_3$ series (M^I = Na, K), the exchange leads to Cs$_2$Zn$_3$[Fe(CN)$_6$]$_2$ which belongs to the same R3c space group.[5,16]

According to Ganzerli-Valentini et al.,[11] sodium ions cannot be retained on Zn$_2$Fe(CN)$_6$ by ion-exchange.

Nickel ferrocyanides

The compositions found in the literature are reported in Fig. 1. In contrast to zinc, the compounds are mostly non-stoichiometric.

Pure Ni$_2$Fe(CN)$_6$, nickel ferrocyanide, was prepared by Tananaev,[28] Kuznetsov,[29] and Kawamura[30] with the aid of lithium or sodium ferrocyanide and a nickel:ion ratio close to 2. Rigamonti[23] recommends the use of potassium ferrocyanide.

In general, however, products made in the presence of an alkali-metal ion contain various proportions of the starting cations. Some examples of the variations observed are given in Table 3. Owing to the wide range of compositions, most of the proposed stoichiometric formulae are included in the limits given in Table 3:

Na$_2$Ni$_3$[Fe(CN)$_6$]$_2$,[28,31,32] K$_2$Ni$_3$[Fe(CN)$_6$]$_2$,[32-34]

K$_2$NiFe(CN)$_6$,[23,25] Cs$_2$Ni$_3$[Fe(CN)$_6$]$_2$[26] and

Cs$_2$NiFe(CN)$_6$.[27].
A few compositions do not have the general formula, such as Na$_2$NiFe(CN)$_6$ found by Kawamura.[30] The alkali-metal ion content increases in the order Na < K < Rb < Cs.

The preparation of nickel ferrocyanides by exchange has been studied by only one group.[12,13] According to these investigators, the exchange does not alter the alkali-metal to nickel ratio.

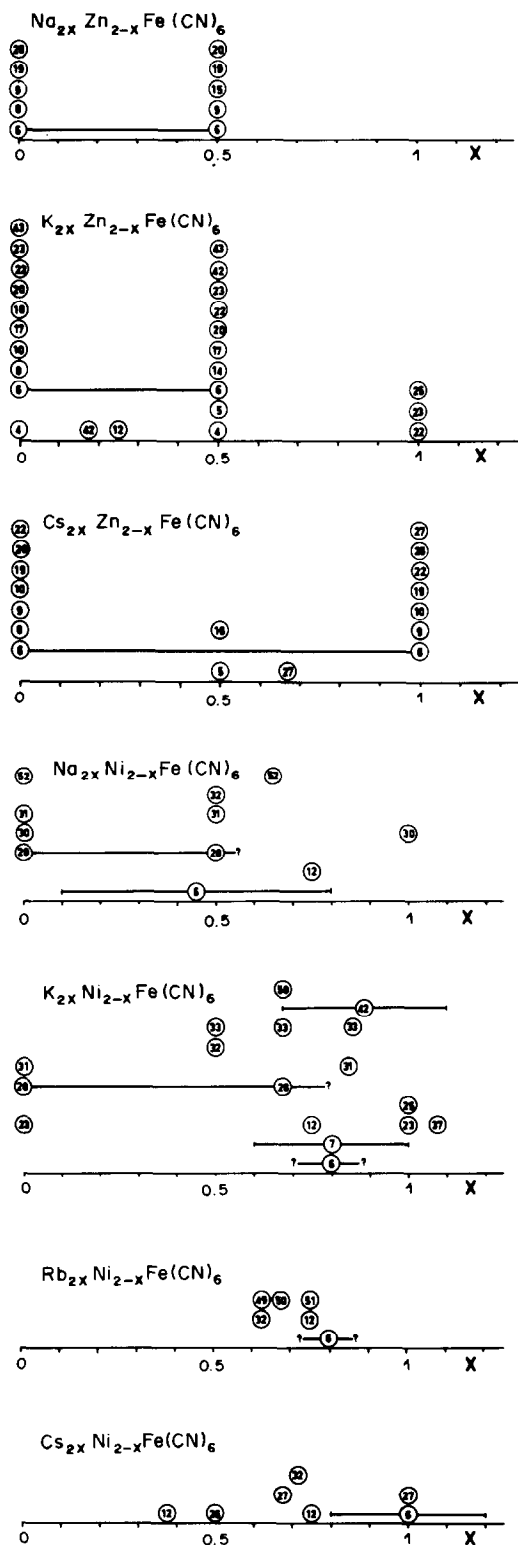
All the investigators who have studied the crystallographic structure of nickel ferrocyanides have


Fig. 1. Composition of ferrocyanides, according to various authors. The formula is taken as $M^I_{2x}M^{II}_{2-x}Fe(CN)_6$, where M^I is an alkali metal and M^{II} is Zn or Ni. The number refers to the literature and is placed at the x value indicated in the paper referred to. If x varies, its range is indicated by a straight line.

Table 3. Domain of validity of the formula $A_{2x}Ni_{2-x}Fe(CN)_6$ for various alkali-metal ions (A)

Element	x, range	$\bar{x}$
Na	0.1–0.8	0.52
K	0.5–1.1	0.82
Rb	—	0.70
Cs	0.66–1.2	0.84

found a cubic cell, whatever the composition. The unit cell parameter is between 9.9 and 10.2 Å.

Water content

The water content received little attention in the earlier studies and there are discrepancies between values reported.[5,10,25–27,29,35–37] No general conclusion was reached concerning the occurrence of definite hydrates.

Recently the problem was more accurately studied for some zinc ferrocyanides. Siebert *et al.*[18] showed that heating $Zn_2Fe(CN)_6 \cdot xH_2O$ leads to a compound with two molecules of water per formula unit. In the $M^I_2Zn_3[Fe(CN)_6]_2$ series (M^I = Na, K, Cs) the water is zeolitic.[14–16,24,38] The uptake of water may reach a very high value (9 molecules per formula unit for M^I = Na) in agreement with the microporous character of the structure.

CONCLUSIONS

Too rapid an approach to the literature on ferrocyanides could lead to a very confused idea of their composition. However, after a more systematic and synoptic review, certain general features may be found. First, the two types of ferrocyanides dealt with here appear to be quite different in composition and structure. Almost all zinc ferrocyanides seem to belong to two families, having definite formulae: $Zn_2Fe(CN)_6 \cdot xH_2O$ and $M^I_2Zn_3[Fe(CN)_6]_2 \cdot xH_2O$. The methods leading to each of these two types of compound are well defined. In contrast, nickel ferrocyanides seem not to have definite formulae, but always belong to the cubic system.

However, many points cannot be fully understood even after this review, and should be the subject of futher investigations. It would be interesting to examine the conditions for existence of some zinc ferrocyanides departing from the two families mentioned, such as $Cs_2ZnFe(CN)_6$ and $K_2ZnFe(CN)_6$. In the case of nickel, the stability domains of the M^I:Ni ratio should be studied for each alkali metal, as well as the nature of the water molecules bound in the compounds. A more accurate knowledge of the structure should be obtained by using single crystals, as already done for the $M^I_2Zn_3[Fe(CN)_6]_2$ series.

A very important point is the preparation of products usable as ion-exchangers. The ferrocyanides generally obtained have very small particle size and cannot be easily used for column work. Some au-

thors have made attempts to prepare products more suitable for that purpose.

Better mechanical properties have been obtained by mixing the ferrocyanide with silica gel[39] or an organic binding agent.[40] In both cases the capacity for caesium is lowered. Another attempt consisted in growing nickel ferrocyanide crystals at low temperature.[41]

The development of the use of ferrocyanides seems to depend on the low-cost manufacture of a product suitable for industrial applications.

Summary—A review is given of work on nickel and zinc ferrocyanides during the period 1922–1983 with an emphasis on their compositions and structures in relation to the methods of preparation.

ANNOTATIONS

ALKALI-METAL ION COMPLEXATION WITH LARIAT ETHERS POSSESSING A CHROMOGENIC GROUP

B. P. BUBNIS and G. E. PACEY

Department of Chemistry, Miami University, Oxford, Ohio 45056, U.S.A.

Summary—The extraction and complexation abilities of chromogenic alkyl crown-ether reagents were compared with those of their chromogenic benzo crown ether analogues. Improvements in the extraction efficiency and stability of the complexes were observed, and can be attributed to various factors such as increased lipophilic character and decreased charge separation. The spectral separation caused by the deprotonation of the amine-group was significantly decreased, so the usefulness of these compounds will be limited, until improved spectral separation can be achieved.

Ion-pairing with picrate as counter-ion was the first method used for colorimetric determination by means of complexation with crown ethers. Later, Ueno reported the synthesis and complexation behaviour of a chromogenic crown ether (**I**) which formed an intramolecular ion-pair with alkali-metal ions.[1] This molecule incorporated a secondary amino-group, which conferred acid/base character on the chromogenic crown ether. When the extraction system was buffered at a sufficiently high pH, the protonated ligand (HL) dissociated, resulting in a shift in λ_{max} and an increase in the molar absorptivity (ϵ). The dissociated crown ether species (L$^-$) complexed alkali-metal ions in the aqueous phase and the complex was extracted into chloroform. Absorbance measurements at an appropriate wavelength were linear with respect to [K$^+$] from 10 to 700 ppm in the presence of 2300 ppm Na$^+$. The selectivity of the reagent for K$^+$ in the presence of a large excess of Na$^+$ made it ideally suited for K$^+$ determinations in blood serum.[1,2]

Alkali-metal ion complexation by crown ethers has been shown to be governed largely by the relative fit of the alkali-metal ion in the crown ether cavity.[3-5] Experimental evidence has shown that other factors need to be considered when developing new crown ether molecules to be used for alkali-metal ion determination.[2] For example, changing the chromogenic tag altered the complexation behaviour of these new analytical reagents.[2] The replacement of the *p*-nitro group in compound I with a cyano group shifted λ_{max} of HL to longer wavelengths (390→420 nm) and decreased ϵ_{max} (1.3 × 10^4→1.1 × 10^4 l.mole^{-1}.cm^{-1}). $\Delta\lambda_{max}$ [*i.e.*, λ_{max}(L$^-$) − λ_{max}(HL)] was increased from 55 to 130 nm, and the formation constant for the potassium complex (K_{ML}) was lowered (80.5→22.5). Interestingly, this evidence showed that the chromophore structure also had an effect on the strength of the metal–ligand complex.
Scheme 1.

Our experience with chromogenic crown ether reagents in extraction analysis has led us to conclude that to improve the extraction efficiency an increase in the lipophilic nature of the compound is needed. Hence reagents II and III were prepared from the aminomethyl derivatives of 15-crown-5 and 12-crown-4.

This paper reports data on the visible spectra, extraction constants, dissociation constants, and formation constants for complexes of compounds II and III with alkali-metal ions.

EXPERIMENTAL

The dichloromethene and chloroform used were of spectral analysis quality. All water was distilled, and demineralized with Barnstead Nanopure system. All alkali-metal salts were purchased from Alfa Chemical Co. and dried at 110°. Absorption spectra were recorded with a Hewlett-Packard 8450-A spectrophotometer. All pH measurements were made with a Corning 12 pH-meter.

The aminomethyl derivatives were synthesized in good yield from the hydroxymethyl precursors described in the literature.[6] The aminomethyl crown ether molecules were synthesized from the hydroxymethyl molecules by either of two pathways: (1) the use of thionyl chloride and subsequent reaction of the product with the potassium salt of phthalimide; (2) generation of a phosphonium salt intermediate by the addition of an equivalent each of triphenylphosphine, diethylazodicarboxylate, and phthalimide to an equivalent of the hydroxymethyl compound. Both methods yielded the phthalimidomethyl compounds which was then reacted with hydrazine hydrate. Details of the synthesis have been given elsewhere.[7]

General method for the preparation of chromogenic lariat ethers

Approximately 2 mmoles of the appropriate aminomethyl crown ether hydrochloride were placed in 25 ml of tetrahydrofuran (THF) containing one equivalent of sodium hydroxide and the mixture was stirred at room temperature for 1 hr. An equivalent of chromophore [4-chloro-3,5-dinitrobenzotrifluoride (Aldrich) or 1-chloro-2,4,6-trinitrobenzene (Fairfield)] was then added along with an additional equivalent of base. The stirring was continued for 1 hr. The solution was filtered and the THF removed in a rotary evaporator. Water (25 ml) was then added to the residue and the mixture was extracted with three 30-ml portions of chloroform. The extracts were dried over anhydrous magnesium sulphate and filtered, and the chloroform was removed in a rotary evaporator. The products were obtained as yellow powders in 60% yield following recrystallization from ethanol. 2,4,6-Trinitrophenylaminomethyl-15-crown-5 hydrochloride (II), m.p. 187–188°, $C_{17}H_{25}N_4O_{11}Cl$ requires 41.09% C, 5.07% H, 11.27% N; found 41.8% C, 5.5% H, 11.3% N. 2,4-Dinitro-6-trifluoromethylphenylaminomethyl-12-crown-4 (III), m.p. 86–88°; $C_{16}H_{20}F_3N_3O_8$ requires 43.74% C, 4.58% H, 12.97% F, 9.56% N; found 43.8% C, 4.6% H, 13.0% F, 9.4% N.

Visible region spectra

Spectra for II and III were obtained for solutions in 20% acetonitrile/80% water mixture. Two spectra were recorded, one at pH 2 and the other at a pH at which the amine proton was dissociated.

Determination of extraction constants

A 5-ml portion of $0.1M$ alkali-metal ion solution was extracted with 5 ml of $1M$ triethylamine solution in chloroform, which contained a known concentration of crown ether. The organic and aqueous layers were analysed spectrophotometrically.

Determination of K_a, K_{ML}, K_{MHL}

The crown ether reagent was dissolved in a 40% acetonitrile/60% water mixture to give a final concentration of approximately $2.5 \times 10^{-4}M$. A 10-ml portion was diluted to 25 ml with demineralized water. K_a was determined experimentally with the diluted solution containing a constant concentration of an alkali-metal ion which does not readily complex with the crown ether. K_a^{app}, K_{ML}, and K_{MHL} were determined experimentally by varying the concentration of the alkali-metal salt (0.1, 0.08, 0.06M) in the solution. The absorbance was measured at the wavelength of maximum apparent molar absorptivity, at varying [H^+], with hydrochloric acid and a weakly or non-complexing alkali-metal hydroxide to adjust the pH.[8]

RESULTS AND DISCUSSION

Visible region spectra

The spectral data for reagents II and III are given in Table 1. The $\Delta\lambda_{max}$ resulting from dissociation of the monobasic amine proton was relatively small (2 and 12 nm), because an extended conjugated system was not created by the deprotonation. The changes in molar absorptivity (($\Delta\epsilon$) at λ_{max} for II and III were 1.52×10^3 and 4.96×10^3 l.mole^{-1}.cm^{-1}, and the largest $\Delta\epsilon$ for reagent III was found to be at 377 nm ($\Delta\epsilon = 6.47 \times 10^3$ l.mole^{-1}.cm^{-1}). The visible-region spectra for both reagents indicate that their usefulness as alkali-metal ion sensors would be limited, since there was extensive spectral overlap of the (HL) and (L^-) species. This was confirmed when reagent III was tested for determination of potassium. Although the $\Delta\epsilon$ was adequate for extraction analyses,[1]

Table 1. Wavelengths of maximum absorption and molar absorptivities of the test compounds

Compound	HL		L^-	
	λ_{max}, nm	ϵ, 10^4 l.mole^{-1}.cm^{-1}	λ_{max}, nm	ϵ, 10^4 l.mole^{-1}.cm^{-1}

the very small $\Delta\lambda_{max}$ on deprotonation reduced the analytical usefulness of the larger $\Delta\epsilon$.

Extraction

The selectivity of chromogenic crown ethers for alkali-metal ions can be described in terms of their extraction constants. The appropriate plot gave a straight line with slope equal to the extraction constant, K_{ext}.[1]

Table 2 lists the pK_{ext} values. The alkyl chromogenic crown ethers exhibited better overall extraction of alkali-metal ions. This could be partly due to the absence of the benzene ring giving the molecule a more lipophobic nature and better solubility in water. Also, the charge separation between the intra-molecular ion-pair was smaller than in the case of reagent I. A tight ion-pair or chelate-type interaction between the anion and metal ion would improve extraction. Although the improvement in extraction efficiency was beneficial, there was also reduced selectivity. An additional change was that the alkyl reagents extracted lithium. It is interesting that the 15-crown-5 molecule (II) extracted lithium better than the 12-crown-4 reagent did. The hydrated lithium ion is larger than the unhydrated ion and therefore requires a larger cavity. The data in Table 2 also indicate that solvent interaction plays an important role in the ability of crown ethers to extract alkali-metal ions into an organic phase. Comparison of the extraction constants for reagent II revealed that dichloromethane improved the extraction efficiency in most cases, although the gain in efficiency was offset by a significant loss in selectivity.

The selectivity sequence with I was found to be $K^+ > Rb^+ > Na^+ \sim Cs^+$. The selectivity (Table II) for the alkyl analogue under the same experimental conditions was $K^+ > Li^+ > Cs^+ > Na^+ > Rb^+$. In each case K^+ was the alkali-metal ion extracted most efficiently. The reported data for I indicate that the preferred stoichiometry is the 1:2 metal–ligand complex.[1] The selectivity data for reagent II showed that factors other than cation/cavity diameters need to be considered in order to explain the experimental results. If cation/cavity diameters were solely responsible for complexation then the extraction selectivity would be $K^+ > Li_{aq}^+ > Rb^+ > Na^+ \sim Cs^+$.

Although the degress of extraction of Na^+ and Cs^+ were similar, Rb^+ was extracted less efficiently than either.

The predicted selectivity of the 12-crown-4 analogues, based solely on cation/cavity diameters, is $Na^+ > K^+ > Li_{aq}^+ > Rb^+ > Cs^+$. The experimentally determined extraction selectivity of III was $K^+ > Na^+ > Rb^+ > Li_{aq}^+ > Cs^+$. This experimental evidence, along with the 15-crown-5 data, indicated that the nature of the ligand (aryl vs. alkyl, side-chains, etc.) was also a factor, though to a lesser degree, in the selectivity of crown ethers towards alkali-metal ions.

Complexation in aqueous medium

K_a, K_a', K_{ML} and K_{MHL} values for II and III were experimentally determined, by use of equations previously reported.[2]

The pK_a values for reagents I–III and 2″,4″-dinitro-6″-trifluoromethylphenyl-4′-aminobenzo-15-crown-5 are given in Table 3. The pK_a value for II was determined with rubidium hydroxide used to adjust the pH; for III lithium hydroxide was used. Dilute hydrochloric acid was used to lower the pH in both cases. These hydroxides were chosen because the extraction data in Table 1 indicated that these metal cations interacted the least with the respective reagents. The experimentally determined pK_a values were 11.6 for II and 11.4 for III, 1.0 pK_a unit higher than those for the benzo type crown ethers were in both cases. These experimentally determined data agreed with the theoretical prediction that the pres-

Table 4. Formation constants for complexes of reagents II and III

	Reagent	Li[+]	Na[+]	K[+]	Rb[+]
$\log K_{ML}$	II	2.28	2.05	2.28	
$\log K_{MHL}$	II	1.09	1.47	1.12	
pK_a'	II	10.3	11.01	10.4	
$\log K_{ML}$	III		1.66	2.93	1.64
$\log K_{MHL}$	III		1.17	1.33	1.01
pK_a'	III		10.9	9.8	10.8

ence of a benzene ring adjacent to an amino group should decrease the pK_a of the dissociable proton.[9]

Table 3 also shows the effect of presence of the benzene ring on alkali-metal complexation. With potassium reagent I had a formation constant of $10^{1.91}$. The reagent without the benzene ring gave a formation constant of $10^{2.28}$, in agreement with the literature[10] in showing that the introduction of a benzo-group in the crown ether ring decreased the stability of the metal complex.

The complexation data for aqueous medium were in good agreement with the extraction data presented in Table 2. The extraction efficiencies with reagent II were $K^+ > Li^+ > Na^+$. The order of strengths of the crown ether–alkali-metal ion complexes, from the formation constants, was $K^+ \sim Li^+ > Na^+$. Similarly, with reagent III the extractability order was $K^+ > Na^+ > Rb^+$, and the formation constants followed the same trend. The K_{ML} values were larger than the K_{MHL} values, indicating that the overall negative charge of the molecule was influencing the formation of the metal complex. The selectivity of complexation also agreed with the literature in that the interaction was not strictly a charge-interaction.[8]

The absence of the benzene ring also had an effect on the pK_a' values of the molecule. When the benzene ring was present, as in the case of I, the complexation of various alkali-metal ions in the crown-ether cavity had little effect on the pK_a' value. The benzene ring acted as an insulator which protected the monobasic amine proton from the electron-withdrawing effects of the complexed cation. Removing the righ produced pK_a' values which depended on the cation and the strength of the complex. Table 3 indicates that as the formation constants (K_{ML}) increase, the pK_a' values decrease.

CONCLUSION

Complexation with crown ethers is a selective and sensitive method for determining alkali metals. The usefulness of these reagents is determined largely by the spectral characteristics of the molecule. Future attempts to use crown ether chromogenic reagents must deal with the problem of the large spectral overlap for reagent and complex or suffer from exceptionally high blank values.

The extraction and complexation data are better for the alkyl reagents than for their benzo analogues. The improvement can be attributed to numerous factors. As expected, the chromogenic activity does not appear to be useful in current methods of determination of alkali metals, but the knowledge gained has encouraged us to investigate alkyl crown ethers which incorporate fluorogenic tags.

DISSOLUTION OF GEOLOGICAL MATERIAL WITH ORTHOPHOSPHORIC ACID FOR MAJOR-ELEMENT DETERMINATION BY FLAME ATOMIC-ABSORPTION SPECTROSCOPY AND INDUCTIVELY-COUPLED PLASMA ATOMIC-EMISSION SPECTROSCOPY

Philip Hannaker and Hou Qing-Lie*
Department of Geology, School of Earth Sciences, University of Melbourne, Victoria 3052, Australia

Summary—An analytical procedure has been developed for the determination of major elements in geological material by both flame atomic-absorption spectrometry and inductively-coupled plasma atomic-emission spectrometry. Condensed phosphoric acid was used for the decomposition of 70 natural minerals containing sulphide, oxide, silicate or carbonate constituents. The results were compared with those obtained when a perchloric acid and orthophosphoric acid mixture was used for the decomposition, to ensure dissolution of even the most acid-resistant minerals. The procedure can be applied to rocks, ores, soils, slags and refractory material as a means of rapid and complete dissolution for the analysis of even the most insoluble material.

Atomic-absorption spectrometry (AAS) is now widely used to analyse a wide range of geological material for major and trace elements.[1–5] Recent years have seen an impressive increase in the application of inductively-coupled plasma atomic-emission spectroscopy (ICP–AES) for the determination of major, minor and trace elements in geological material.[6,7] One of the advantages of ICP–AES is its speed, which is due to simultaneous measurement of several elements. When automated AAS[8–11] and ICP–AES are used, the slowest step in the analysis is dissolution of the sample.

The usual procedure for dissolution of geological material[1] involves evaporation to dryness with a mixture of hydrofluoric, nitric and perchloric acids, followed by two evaporations with perchloric acid and dissolution of the resulting residue in dilute hydrochloric or nitric acid; this procedure, however, is both time-consuming, as it requires at least 20 hr of continuous heating, and incomplete, as certain minerals such as chromite and ilmenite are very resistant to such acid mixtures.

More rapid dissolution techniques using reagents such as nitric acid,[12] nitric acid–hydrogen peroxide,[13] hydrochloric acid–nitric acid[13,14] or ammonium acetate[15,16] to leach soluble material generally produce low results on account of incomplete attack on silicate material, and possibly high results (when AAS is used) due to light scattering by suspended particles in the solution.

Many analysts have found it necessary to resort to fusion techniques for the complete dissolution of geological material and the determination of silica

(which is lost by volatilization with hydrofluoric acid, when this is used in acid dissolution techniques).

Fusion with alkaline mixtures such as sodium hydroxide/sodium peroxide,[17] however, produces a high salt concentration, with consequent light-scattering,[18] which is a considerable disadvantage with AAS. It has also been reported that the plasma torch is easily fouled when solutions with high salt concentrations are used.[19] The use of these mixtures also presents difficulties because of the formation of colloidal silicic acid when the solutions are acidified. Fusion with sodium carbonate results in similar problems with the precipitation of silicic acid, and completeness of decomposition of certain refractory oxides has been questioned.[20]

Heating with hydrofluoric acid under pressure gives rapid dissolution of silicate material,[22–24] but the excess of hydrofluoric acid must be complexed with boric acid, again resulting in high light-scattering, owing to the aspiration of highly concentrated salt solutions. Also, the technique has been observed to give incomplete decomposition of minerals such as tourmaline and of some titanium and aluminium compounds, which limits its use for geological samples.[25]

To reduce the errors associated with determination of the major components of geological material, alternative dissolution techniques have been investigated.

Use of condensed phosphoric acid

On heating, orthophosphoric acid undergoes a succession of condensation reactions, giving pyrophosphoric acid ($H_4P_2O_7$), tetrapolyphosphoric acid ($H_6P_4O_{13}$) and metaphosphoric acid ($H_4P_4O_{12}$). It is convenient to call the product "condensed" phos-

*Visiting Research Fellow from Baiyin Research Institute of Mining and Metallurgy, Lanzhou, China.

phoric acid (the Japanese workers[26,27] who first developed its use called it "strong phosphoric acid").

Because of the complexing ability and the strength of the condensed phosphoric acid, and its ability to form a stable soluble silica compound SiP_2O_7,[28] heating with this acid should dissolve a large number of geologically interesting materials.

In the 1930s phosphoric acid was used to dissolve chrome[29] and iron ores.[30] Also at this time concentrated phosphoric acid was used to dissolve many silicates such as kaoline, mica and feldspar from clay minerals.[31] Perchloric and phosphoric acid mixtures have been studied for the dissolution of iron ores.[32] A mixture consisting of equal volumes of these two acids was found to be superior to hydrochloric acid when iron was determined by titration after reduction.

So far, condensed phosphoric acid has found limited use in the analysis of chrome ores[33] and some of the more difficultly soluble refractory oxides.[34] The potential of this acid used alone or combined with other acids as a means of dissolution for rapid major and trace multi-element analysis in geological material has been underestimated by many workers.

Condensed phosphoric acid was fully investigated in these laboratories for the solution and subsequent determination of major element components for oxide, silicate, sulphide and carbonate materials of a geological nature.

EXPERIMENTAL

Reagents

The reagents used were of analytical reagent grade and all water used was distilled and demineralized (DDW).

Standard solutions

Appropriate metals or stoichiometric salts were dissolved to prepare stock 1000-ppm standard solutions. The working standards for AAS contained 10% v/v orthophosphoric acid, and those for ICP-AES calibration and analysis contained 5% v/v orthophosphoric acid.

Instrumentation

The ICP-AES system is described in Table 1. The working conditions are listed in Table 2. A Techtron Model AA-3 with Varian Techtron 1m-6D indicator module was used for all AAS determinations.

Dissolution of minerals with condensed phosphoric acid

Natural minerals of oxide, silicate, sulphide and carbonate type (150-mg samples) were treated with 10 ml of orthophosphoric acid in a platinum crucible at a temperature of 290° on a hot-plate, with swirling at regular intervals.

The reaction mixtures were inspected at 15-min intervals to check completeness of dissolution. For rapid dissolution, in most cases it was found necessary to grind the sample in a mortar and pestle to 300 mesh grain-size. Finely ground silicate, oxide and carbonate minerals were rapidly dissolved, but attack on sulphides was slow, and in some cases $(Cu_5FeS_4, CuFeS_2, MoS_2, FeS_2)$ dissolution was still incomplete after continuous heating for 3 hr, reflecting the poor oxidizing power of phosphoric acid. The combined use of

Table 1. ICP–AES instrumentation

RF generator:	air-cooled, 3-kW rating, 27.12 MHz
Spectrometer:	ARL 34000, grating ruled 1080 lines/mm; primary slit-width 20 μm
Nebulizer:	glass pneumatic concentric nebulizer designed by ARL
Torch:	quartz, 18 mm outer diameter, two-turn coil surrounding the torch

0.5 ml of 70% perchloric acid with 10 ml of 85% phosphoric acid, however, provided a strongly oxidizing solution capable of dissolving the most resistant sulphide material in 45 min.

Table 3 illustrates the usefulness of phosphoric acid, especially in combination with perchloric acid, for rapid dissolution of natural minerals, including the more acid-resistant minerals such as ilmenite, chromite and tourmaline.

Dissolution of standard rocks, ores, slags and refractory materials

Each of a series of 5 NIM standard rocks and 5 BCS standard materials was treated with 10 ml of 85% phosphoric acid as described above. The solutions obtained were cooled, and then diluted to 100 ml (for AAS) or 200 ml (for ICP) with DDW. The major elements (Al, Ca, Fe, Si, Mg, Na, Ti) were determined by both ICP-AES and flame AAS, calibration being done with standards prepared in a similar manner. The experiment was repeated with the perchloric–phosphoric acid mixture (see above) for further comparison of the two acid treatments.

The completeness of dissolution was established by comparing the experimental values with the certified values for the standard material.

All materials tested were completely dissolved in less than 1 hr, without precipitation on cooling or dilution. However, for higher Ti concentrations in the prepared standards a precipitate appeared on standing, probably $Ti(OH)PO_4$, which can be eliminated by the addition of 0.5 ml of 30% w/w hydrogen peroxide before dilution.

Tables 4 and 5 show the completeness of attack for all material tested.

Precision

An internal department rock standard, DCB-1 (basalt), was used for checking the reproducibility of the method. Table 6 shows the results. The coefficients of variation ranged from 0.5% (Mn) to 3.6% (K).

Note

It should be noted that phosphoric acid, especially in the presence of perchloric acid, may slightly attack platinum crucibles at elevated temperatures. This will only become of consequence if heating is prolonged.

For samples containing high levels of organic carbon, care is needed to avoid possible explosive reactions in the presence of perchloric acid. When analysing such samples it is always advisable to pretreat the samples with concentrated nitric acid.

PAPERS RECEIVED

Determination of trace elements in American cigarette paper by neutron-activation analysis: F. Y. ISKANDER, T. L. BAUER and D. E. KLEIN. (25 September 1984)

Spectrophotometric determination of iron and copper in milk, foodstuffs and body tissues with 1-(2-quinolylazo)-2,4,5-trihydroxybenzene: ISHWAR SINGH, MRS. POONAM and P. S. KADYAN. (26 September 1984)

Performance characteristics of differential pulse polarography and voltammetry with an automated microprocessor-based polarograph and a static mercury drop electrode: WEE TEE TAN and GAIK SEE TAN. (26 September 1984)

Contributions to the theory of catalytic titrations—IV: Neutralization catalytic titrations: FERENC F. GAÁL and BILJANA F. ABRAMOVIĆ. (26 September 1984)

Determination of gold, indium, tellurium and thallium in the same sample digest of geological materials by atomic-absorption spectroscopy after a two-step solvent extraction: A. E. HUBERT and T. T. CHAO. (27 September 1984)

A modified oxygen-flask combustion technique: THURAYAH M. KARADAKHI, FADHIL M. NAJIB and FAHMI A. MOHAMMAD. (27 September 1984)

A selective method of qualitative analysis for the copper–tin group cations: SALAH M. SULTAN. (1 October 1984)

A method for the determination of vanadium and iron oxidation states in naturally occurring oxides and silicates: RICHARD B. WANTY and MARTIN B. GOLDHABER. (21 September 1984)

Formation equilibria of copper(II) complexes with some pyridinols in various solvents: R. BUCCI, V. CARUNCHIO, A. M. GIRELLI and A. MESSINA. (2 October 1984)

Reversed-phase liquid chromatographic retention behaviour of catechol amino-acids: T. ISHIMITSU, S. HIROSE and H. SAKURAI. (3 October 1984)

A new fluorogenic thiol-selective reagent: N-{p-[2-(6-dimethylamino)benzofuranyl]phenyl}maleimide: KENICHIRO NAKASHIMA, HIROYUKI AKIMOTO, KEN'ICHI NISHIDA, SHIN'ICHI NAKATSUJI and SHUZO AKIYAMA. (3 October 1984)

The synthesis and complexing ability of fluorogenic crown ethers: J. L. STEGER and G. E. PACEY. (4 October 1984)

Automated flow-injection pseudotitrations fo strong and weak acids, ascorbic acid and calcium, with a microcomputer controlled analyser: Catalytic pseudotitrations of aminopolycarboxylic acids: M. A. KOUPPARIS, P. ANAGNOSTOPOULOU and H. V. MALMSTADT. (5 October 1984)

Calculation of equilibrium constants from multiwavelength spectroscopic data—II. SPECFIT: two user-friendly programs in basic and standard FORTRAN 77: HARALD GAMPP, MARCEL MAEDER, CHARLES J. JEYER and ANDREAS D. ZUBERBÜHLER. (5 October 1984)

PAPERS RECEIVED

The manganese(IV) oxide electrode as a manganese(II) sensor: DEREK MIDGLEY and DENNIS E. MULCAHY. (13 July 1984)

Acid–base titrations in methanol: Acetylsalicyclic acid: ROBERT D. BRAUN and SCOTT A. RESWEBER. (26 June 1984)

The use of di-2-pyridinyl-methylene-2-furoylhydrazone as a fluorogenic reagent for the determination of low concentrations of aluminium: M. SALGADO ORDOÑEZ, A. GARCIA DE TORRES and J. M. CANO PAVON. (17 July 1984)

Ion-exchanger phase absorptiometry for trace analysis: KAZUHISA YOSHIMURA and HIROHIKO WAKI. (17 July 1984)

A timed solenoid injector for flow analysis: S. D. ROTHWELL and A. A. WOOLF. (17 July 1984)

A chemical phase-analysis method for the oxidation states of uranium in phosphate samples: L. A. GUIRGUIS. (20 July 1984)

Corrosion measurements by potential-step chronoamperometry: R. VON WANDRUSZKA, S. W. ORCHARD and A. GREEFF. (20 July 1984)

2-(2-Picolyliminomethyl)pyrrole: A new analytical reagent: F. CAPITAN, L. F. CAPITAN-VALLVEY, F. MOLINA and P. ESPÍNOSA. (23 July 1984)

Studies on the extraction of the mercury(II)–phenanthroline–Rose Bengal ternary system—selective separation of mercury(II) from various bivalent metal ions: Y. ANJANEYULU, P. CHANDRAMOULI, K. CHANDRA SEKHAR and M. RAVI PRAKASA REDDY. (23 July 1984)

Fluorimetric determination of tautomeric equilibria in 8-aminoquinolines: PEDRO J. ZAVALA, MARC D. RADCLIFFE and STEPHEN G. SCHULMAN. (28 June 1984)

The application of tetrazolium salts in analytical chemistry: ALEXANDER V. ALEXANDROV. (24 July 1984)

New metal ion buffer for standardization of copper ion-selective electrode: H. A. AZAB, R. M. HASSAN and S. A. IBRAHIM. (24 July 1984)

Application of pyrolysis–chemical ionization mass spectrometry to lichenology: JOSEPH B. ADDISON. (24 July 1984)

Express automatic potentiometric method for analytical control in the manufacture of extraction phosphoric acid: GEORGI VELINOV. (25 July 1984)

Spectrophotometric determination of oxyphenbutazone by a chelate-forming reaction: SAIED BELAL, AFAF A. ELKHEIR and ABDULLA M. ELSHANWANI. (25 July 1984)

Spectrophotometric determination of silicon in silicates by flow-injection analysis: ROKURO KURODA, IWAO IDA and HIDEKI KIMURA. (25 July 1984)

Application of dicarbollylcobaltate(III) anion in the water–nitrobenzene extraction system: EMANUEL MAKRLÍK and PETR VAŇURA. (25 July 1984)

Application of organic solvent-soluble membrane filters to the preconcentration and determination of trace elements: Spectrophotometric determination of phosphorus as phosphomolybdenum blue: SHIGERU TAGUCHI, EIYUKI ITO-OKA, KEIKO MASUYAMA, ISSEI KASAHARA and KATSUMI GOTO. (25 July 1984)

Deconvolution techniques for rapid flow-injection analysis: JAMES T. DYKE and QUINTUS FERNANDO. (28 May 1984)

The fluorometric determination of biacetyl: A promising method for the determination of biacetyl in foodstuffs: A. J. MAROULIS, A. N. VOULGAROPOULOS and C. P. HADJIANTONIOU-MAROULIS. (1 August 1984)

A software package for computer-controlled flow-injection analysis: L. T. M. PROP, P. C. THIJSSEN and L. G. G. VAN DONGEN. (1 August 1984)

Fluorometric determination of the complexation of amino crown ethers with alkali-metal ions: G. E. PACEY and B. P. BUBNIS. (1 August 1984)

Phosphate determination using molybdoantimonylphosphoric acid on polyurethane foam: A. S. KHAN and A. CHOW. (1 August 1984)

The role of thiourea as additive for medium modification problems in potentiometric stripping analysis (P.S.A.): C. LABAR and L. LAMBERTS. (2 August 1984)

LOUIS GORDON MEMORIAL AWARD

Presentation of the Louis Gordon Memorial Award for 1982 to Mr. N. A. Dimmock (right)
and Dr. D. Midgley (centre) by Dr. R. A. Chalmers. (See *Talanta* 1982, **29,** 557.)

PAPERS RECEIVED

Solid membrane electrode for the determination of La(III) in presence of other rare-earth cations: P. S. THIND and S. K. MITTAL. (9 May 1984)

Ionic-strength dependence of formation constants—V: Protonation constants of some cationic acids at different temperatures and ionic strengths: PIER G. DANIELE, CARMELO RIGANO and SILVIO SAMMARTANO. (9 May 1984)

The effect of EDTA/NaF solutions on the Cu(II) ion electrode: H. F. STEGER. (9 May 1984)

Determination of fluorine in mineral samples through decomposition with alkali-metal hydroxides and spectrophotometric analysis: J. V. GIMENO ADELANTADO, V. PERIS MARTINEZ, A. CHECA MORENO and F. BOSCH REIG. (9 May 1984)

Amperometric titration of cadmium, copper, lead, mercury and zinc with diethyldithiocarbamate at zero applied voltage with a rotated platinum-wire micro electrode: MAHMOUD GHANDOUR. (10 May 1984)

Pollution profile of Damodar River sediment in Raniganj–Durgapur Industrial Belt, West Bengal, India: ANIL K. DE, ASIT K. SEN, MD. REAZUL KARIM, K. J. IRGOLIC, DIPANKAR CHAKRABORTY and R. A. STOCKTON. (14 May 1984)

Etude de la pureté des échantillons commerciaux d'éosine: D. FOMPEYDIE and P. LEVILLAIN. (15 May 1984)

Etude de la capacité complexante des eaux de l'estuaire et de la Baie de Seine: JEAN-CLAUDE FISCHER, RENÉ NGANOU and MICHEL WARTEL. (15 May 1984)

Analysis of some phenolic co-polymer mixtures by electrometric titration techniques: S. K. CHATTERJEE and ANITA KATYAL. (15 May 1984)

Determination of iron and cyanides in cyanoferrate complexes: NICOLETTA BURGER. (16 May 1984)

Derivatives of imidazole as spectrophotometric analytical reagents: C. F. PEREIRA and J. GASCH. (16 May 1984)

Fluorimetric determination of μg of boron: J. M. MIR and M. C. MARTÍNEZ. (16 May 1984)

Thionalide as titrant for several metals: J. O. N. REIS, A. M. M. AMORIM and A. C. SPÍNOLA COSTA. (17 May 1984)

Comment on "Laser-excited fluorescence line-narrowing: An analytical study": J. D. WINEFORDNER. (2 March 1984)

The determination of simple and complex iodides with ferric chloride: an alternative to Andrews titration; M. CARTWRIGHT and A. A. WOOLF. (18 May 1984)

Extraction of cadmium with poly(acrylonitrile) and acrylonitrile–charcoal composite: M. A. DIAB, M. A. KABIL, A. M. ABDALLAH and Y. A. AGGOUR. (18 May 1984)

Highly sensitive and selective microdetection of iron(III) with desferrioxamine B by the "resin spot test" technique: SVJETLANA LUTEROTTI and VLADIMIR GRDINIĆ. (21 May 1984)

Chemical destruction of carcinogenic aromatic amines in laboratory wastes, monitored by HPLC with electrochemical detection: JIŘÍ BAREK, VĚRA PACÁKOVÁ, KAREL ŠTULÍK and JIŘÍ ZIMA. (21 May 1984)

Effects of microscopic surface roughening on the voltammetric response of gold electrodes: KENNETH W. PRATT. (21 May 1984)

Thin-layer technique in spark-source mass spectrometry: I. R. SHELPAKOVA, A. I. SAPRYKIN, T. A. CHANYSHEVA and I. G. YUDELEVICH. (22 May 1984)

Highly sensitive micellar solubilization spectrophotometric method for determination of microamounts of titanium(IV) with the system Ti–phenylfluorone–Triton X-305-emulsifier op: QIANFENG WU. (23 May 1984)

Bidentate pyrimidine-2-thiols as spectrophotometric reagents for palladium and osmium. Determination in alloys, minerals and catalysts: AJAI K. SINGH, BANI ROY and R. P. SINGH. (24 May 1984)

Organic ion-exchange beads as indicators in acid–base titration: M. F. EL-HADI and M. S. METWALLY. (24 May 1984)

Spectrophotometric determination of triacetyloleandomycin and some tetracyclines with 2,3,5-triphenyltetrazolium chloride: EL-SEBAI IBRAHIM, M. ABDEL SALAM, Y. BELTAGY and M. KHOLIEF. (24 May 1984)

Precise and accurate determination of high concentrations of sulphur by isotope-dilution thermal-ionization mass spectrometry: W. R. KELLY and P. J. PAULSEN. (24 May 1984)

PAPERS RECEIVED

Investigations for trace analysis of A^{III}B^{V} semiconductor microsamples by atomic spectroscopy—VII: Investigations for trace and thin-layer analysis of doping elements (Ag, Au, Bi, Cd, Sn, Tl) in InAs by atomic absorption with electrothermal evaporation: K. DITTRICH, W. MOTHES, I. G. JUDELEWITSCH and T. S. PAPINA. (9 April 1984)

The effect of organic colloids on the ASV signals of Cd, Pb and Cu: T. UGAPO and W. F. PICKERING. (10 April 1984)

Determination of the rare earths, yttrium and scandium in silicate rocks and four new geological reference materials by electrothermal atomization from graphite and tantalum surfaces: J. G. SEN GUPTA. (11 April 1984)

Studies on the electroanalytical chemistry of rare-earth elements—XVII: Polarographic study on Sm(III)–tetracycline complex: XIANZHEN YE and XIAOXIA GAO. (11 April 1984)

Studies on the electroanalytical chemistry of rare-earth elements—XVIII: Polarographic study on Eu(III)–tetracycline complex: ZIWEI JIANG and XIAOXIA GAO. (11 April 1984)

Pharmaceutical and clinical analysis by tandem mass spectrometry: RICHARD A. YOST, ROBERT J. PERCHALSKI, HARRY O. BROTHERTON, JODIE V. JOHNSON and MARY BETH BUDD. (11 April 1984)

Complexometric determination of citric acid by use of a specific copper(II) indicator: E. SZEKELY. (13 April 1984)

Formation of ternary complexes of Pb(II) with Pyrocatechol Violet and cetyltrimethylammonium bromide: JOSÉ VALERO. (13 April 1984)

Calculation scheme for acid–base titration: YOSHITSUGU HASEGAWA and NAOYA NAKAGAWA. (13 April 1984)

***N*-Chlorophthalimide as a new oxidimetric titrant for potentiometric determination in aqueous acetic acid medium:** N. JAYASREE and P. INDRASENAN. (16 April 1984)

Classification of experimental methods in solution chemistry: PATRICK MacCARTHY. (14 November 1983)

The solubility of alkali metal fluorides in non-aqueous solvents with and without crown ethers, as determined by flame emission spectrometry: DAVID A. WYNN, MARIE M. ROTH and BRUCE D. POLLARD. (17 April 1984)

Studies on semicrystalline tin(IV) selenophosphate—II: Separation and determination of chromium, nickel and iron in super alloys: SYED ASHFAQ NABI and ZIA MAHMOOD SIDDIQI. (18 April 1984)

Spectrophotometric determination of palladium with 4,4'-bis(diethylamino)thiobenzophenone and Triton X-100: YUN-XIANG CI, WEN-BAO CHANG and FENG-JI YAO. (19 April 1984)

A simple titrimetric method for determination of aldehydes and ketones: EMTITHAL EL-SAWI and NADIA KANDILE. (24 April 1984)

Optimization of parameters in the determination of iron and vanadium in petroleum fractions by atomic-absorption spectrophotometry with a graphite furnace: M. C. GONZALEZ, A. R. RODRIGUEZ and V. GONZALEZ. (24 April 1984)

AC Polarographic assay of penicillin V benzathine: J. A. SQUELLA, M. M. SILVA and LUIS J. NUNEZ-VERGARA. (4 April 1984)

Preparation and analytical characterization of 1-(2-pyridylazo)-2-naphthol-coated chelating resin: J. CHWASTOWSKA and E. MOZER. (25 April 1984)

Electrochemical studies on the oxidation of oxohydroxotetracyano-molybdate(IV) and -tungstate(IV) with Ce(IV), Cr(VI) and Mn(VII): S. I. ALI and SEEMA SHARMA. (26 April 1984)

A novel and sensitive spot-test for *m*-dinitroaromatics and their derivatives with sodium sulphite and dimethylsulphoxide: SAEEDUZZAFAR QURESHI, PUSHKIN M. QURESHI and SEEMA HAQUE. (27 April 1984)

Fluorimetric determination of sulphate ion by ternary complex formation with zirconium and diacetylmonoxime nicotinylhydrazone: S. RUBIO, A. GOMEZ-HENS and M. VALCARCEL. (30 April 1984)

Arsenic speciation in soil pore waters from mineralized and unmineralized areas of South West England: STEPHEN J. HASWELL, PETER O'NEILL and KEITH C. C. BANCROFT. (1 May 1984)

Analytical interferences and drug effects on laboratory test results: M. M. GALTEAU and G. SIEST. (2 May 1984)

New chelate-forming sorbents for noble metals: G. V. MYASOEDOVA, I. I. ANTOKOLSKAYA and S. B. SAVVIN. (2 May 1984)

A new method for the determination of total lead blended as lead alkyls in motor spirit, by atomic-absorption spectroscopy: SAMARESH BANERJEE. (2 May 1984)

Relationship of pH and potential: K. L. CHENG. (3 May 1984)

Determination of hormones by using time-resolved fluoroimmunoassay: TIMO LÖVGREN, ILKKA HEMMILÄ, KIM PETTERSSON, JARKKO U. ESKOLA and ERIC BERTOFT. (3 May 1984)

Solvent extraction separation of rubidium with dicyclohexeno-18-crown-6: B. S. MOHITE and S. M. KHOPKAR. (8 May 1984)

PAPERS RECEIVED

Determination of thermodynamic ionization constants for eight medicinal benzylimidazolines: J. E. KOUNOURELLIS, N. POPADOPOULOS and A. RAPTOULI. (19 March 1984)

Direct determination of sub-nanomolar levels of zinc in sea-water by cathodic stripping voltammetry: C. M. G. VAN DEN BERG. (19 March 1984)

Positive feed-back compensation of iR-drop in modified normal pulse polarography of sodium ion in acid solution: MINORU HARA. (19 March 1984)

Spectrofluorimetric assay of tetracycline and anhydrotetracycline in combination: M. ABDEL-HADY ELSAYED, M. E. BARARY and H. MAHGOUB. (19 March 1984)

A new polarographic catalytic method for the determination of micro quantities of tungsten (VI): H. RAMACHANDRA MURTHY, G. VENUGOPAL and V. SURYANARAYANA RAO. (19 March 1984)

Reversed-phase partition high-pressure liquid chromatography of trace amounts of inorganic and organic mercury with silver diethyldithiocarbamate; SADANOBU INOUE, SUWARU HOSHI and MUTSUYA MATSUBARA. (24 March 1984)

Determination of rare-earth elements in geological samples by thin-film X-ray fluorescence and inductively-coupled plasma atomic-emission spectrometry: HOU QING-LIE, T. C. HUGHES, MAUNU HAUKKA and PHILIP HANNAKER. (24 March 1984)

Construction and evaluation of a potassium-selective tube-mounted membrane electrode: R. E. FARRELL and A. D. SCOTT. (6 March 1984)

Investigation of industrial di(alkylphenyl)dithiophosphoric acids: ZS. WITTMANN, Z. DÉCSY and E. PUDMER. (26 March 1984)

Rapid spectrophotometric determination of some phenothiazine derivatives with *N*-chlorosuccinimide: RANGASWAMY, H. S. YATHIRAJAN, P. NAGARAJA, JAYARAMA and B. M. MOHAN. (26 March 1984)

Calculation of the formation constants of the Cu(II)–thiosemicarbazone complexes by a modification of the Deford and Hume method applicable to quasi-reversible and irreversible processes: M. ARGÜESO, M. DOLORES LUQUE DE CASTRO and MIGUEL VALCARCEL. (27 March 1984)

Pyridylazo compounds as analytical reagents: A review: ALI Z. ABU-ZUHRI. (27 March 1984)

5,5'-[-(2-Pyridyl)-1,2,4-triazine-5,6-diyl]-bis-2-furanesulphonic acid, disodium salt, as a novel chromogenic reagent for ruthenium: M. C. MEHRA and A. ARSENEAU. (28 March 1984)

Photometric complex-formation titration of submicromole amounts of uranium: J. KRAGTEN and W. OZINGA. (28 March 1984)

Study on the synergistic extraction of cobalt(II) with lower fatty acids in the presence of heterocyclic amines, and some metal-ion separations: S. K. GOGIA, D. SINGH, O. V. SINGH and S. N. TANDON (29 March 1984)

The application of internal electrolysis to determination of the equivalence point of a reaction, based on the variation in the current flowing: precipitation determination of chloride and chromate: W. RZESZUTKO and E. SOMOGYI. (29 March 1984)

Spectrophotometric study of the ineraction of tris-[2,4,6-(2-hydroxy-4-sulpho-1-naphthylazo)]-*s*-triazene, trisodium salt, with silver, and use of the silver complex for indirect determination of bromide and iodide: ISHWAR SINGH and PRATAP SINGH KADYAN. (30 March 1984)

Indirect determination of trace phenol in water by atomic-absorption spectrophotometry: XU BO-XING, XU TONG-MING, SHEN MING-YENG and FANG YU-ZHI. (30 March 1984)

Atomic-absorption and flame-photometric analysis of Nigerian crude oils and the associated water, for sodium, potassium, calcium, magnesium and arsenic: C. A. NWADINIGWE and P. C. ACHILIKE. (2 April 1984)

Rapid and selective chelatometric titration of aluminium in non-ferrous alloys: ZHOU NAN, GU YUAN-XIANG, LU ZHI-REN and CHEN WEI-YONG. (4 April 1984)

Indirect spectrophotometric determination of silicate: I-WEN SUN and FREDRICK BET-PERA. (4 April 1984)

The solubility and acid dissociation constants of fluorescein in water solution: HARVEY DIEHL and RICHARD MARKUSZEWSKI. (4 April 1984)

Fluorimetric determination of catecholamines: FATMA B. SALEM and I. W. MOHAMED (6 April 1984)

Analytical applications of semicarbazones and thiosemicarbazones: Recent advances: AJAI K. SINGH. (6 April 1984)

Potentiometric studies on the chelates of Al(III), Ga(III) and In(III) with some disubstituted pyridines: R. S. SINDHU and R. P. SINGH. (6 April 1984)

PAPERS RECEIVED

A new and very rapid indirect method for determination of stability constants of 1:1 complexes: P. H. TEDESCO, V. B. DE RUMI, L. B. DE CORDO, A. PIRO and A. IGEA. (3 January 1984)

Sensitive flotation-spectrophotometric determination of gold, based on the gold(I)–iodide–Methylene Blue system: Z. MARCZENKO and K. JANKOWSKI. (18 February 1984)

Spectrophotometric and potentiometric determination of the protonation constants of dithiocarbazates: Studies on some of their metal chelates: A. IZQUIERDO, J. GUASCH and F. X. RIUS. (22 February 1984)

Analytical application of a macroreticular hydroxamic acid resin: CHUEN-YING LIU. (22 February 1984)

Spectrophotometric determination of nitrate and nitrite in natural water and sea-water: S. J. BANJIC and B. JASELSKIS. (24 February 1984)

Reaction of iron(III) with tiron in the presence of ferrozine, and determination of tiron: N. SIMONZADEH and B. JASELSKIS. (24 February 1984)

The spectrophotometric determination of the platinum metals—VIII: Highly sensitive extraction determination of palladium with 4-(2-pyridylazo)-resorcinol in the presence of cetylpyridinium bromide: O. COUFALOVÁ and L. ČERMÁKOVÁ. (24 February 1984)

The determination of chlorpromazine and thioridazine by differential pulse voltammetry in acetonitrile medium: N. ZIMOVÁ and I. NĚMEC. (24 February 1984)

Chromatic evaluation of pyridine-2-aldehyde and 6-methylpyridine-2-aldehyde-*p*-nitrophenylhydrazones as indicators: A. M. CAMEAN FERNANDEZ, J. BATISTA PALOMA and M. GUZMAN CHOZAS. (1 February 1984)

Alkali-metal ion complexation with lariat ethers possessing a chromogenic group: B. P. BUBNIS and G. E. PACEY. (28 Febraury 1984)

Determination of diphenyltin and dialkyltin homologues by high-performance liquid chromatography incorporating morin in the eluent: W. LANGSETH. (28 February 1984)

Critical study of some metallochromic indicators for lead: J. CACHO, C. NERIN and A. GARNICA. (28 February 1984)

Flow-injection analysis in clinical chemistry: C. RILEY, B. F. ROCKS and R. A. SHERWOOD. (20 December 1983)

The development of a light-scattering immunoassay for plasma thyroxene binding prealbumin: K. SPENCER. (8 December 1983)

Enzyme-linked immunosorbent assay (ELISA) of antibodies to eight common neurotropic viruses: J. A. P. EARLE, N. V. McFERRAN and G. B. WISDOM. (5 January 1984)

Luminescent immunoassay (LIA) methods for steroids: M. PAZZAGLI, G. MESSERI, A. L. CALDINI, P. L. VANNUCCHI, A. TOMMASI and M. SERIO. (4 January 1984)

Immunoassays in aqueous two-phase systems: TORBJÖRN G. I. LING and BO MATTIASSON. (24 January 1984)

Development of a sensitive enzyme immunoassay for plasma and salivary steroids: A. RODA, S. GIROTTI, S. LODI and S. PRETI. (4 January 1984)

Zinc and nickel ferrocyanides: preparation, composition and structure: C. LOOS-NEKOVIC, M. FEDOROFF, E. GARNIER and P. GRAVEREAU. (12 March 1984)

Thermodesorptive analysis of GaAs and ZnSe surfaces: I. A. KIROVSKAYA, G. M. ZELYEVA and A. V. YURYEVA. (12 March 1984)

Thin-layer chromatography of some aliphatic aldehyde–MBHT derivatives: V. CARUNCHIO, G. DE ANGELIS, A. M. GIRELLI and A. MESSINA. (12 March 1984)

Simultaneous determination of arsenic, selenium, tin and mercury by non-dispersive atomic-fluorescence spectrometry: A. D'ULIVO, R. FUOCO and P. PAPOFF. (12 March 1984)

Catalytic titration of iodide, bromide and thiocyanate by use of the silver-catalysed phloxin–persulphate reaction: C. SANCHEZ-PEDRENO, M. HERNANDEZ CORDOBA and P. VINAS. (12 March 1984)

A kinetic method for trace mercury determination: K. MALLIKARJUNA RAO, T. SREENIVASULU and S. BRAHMAJI RAO. (12 March 1984)

Spectrophotometric determination of aliphatic primary and secondary amines by reaction with *p*-benzoquinone: SAAD S. M. HASSAN, K. L. ISKANDER and N. E. NASHED. (12 March 1984)

Voltammetric interpretation of potential at the ion-selective electrode, based on current-scan polarograms observed at the aqueous/organic solution interface: S. KIHARA and Z. YOSHIDA. (12 March 1984)

Polarographic behaviour of some substituted arylhydrazones of acetylacetone: K. RAM and S. BRAHMAJI RAO. (12 March 1984)

Extractive spectrophotometric determination of molybdenum as an ion-association complex with thiocyanate and Adogen: F. SALINAS, J. J. BERZAS NEVADO and M. I. ACEDO VALENZUELA. (12 March 1984)

Ultraviolet spectral structure correlations of five amidines of pharmaceutical interest: JOHN E. KOUNTOURELLIS and JOHN T. R. OWEN. (12 March 1984)

Hydroxide complexes of lanthanides—VII: neodymium(III) in perchlorate medium: J. KRAGTEN and L. G. DECNOP-WEEVER. (12 March 1984)

A comparative study of some hydroxyanthraquinones as acid–base indicators: J. BARBOSA, E. BOSCH and R. CARRERA. (12 March 1984)

Standard addition procedure for the determination of traces of lead in solid samples by X-ray fluorescence spectrometry: NIELS PIND. (12 March 1984)

Spectrophotometric determination of germanium in ores, concentrates, zinc processing products and related materials with phenylfluorone and cetyltrimethylammonium bromide after separations by iron collection and heptane extraction of germanium tetrachloride: ELSIE M. DONALDSON. (13 March 1984)

The stability of metal complexes with 8-mercaptoquinoline and alkyl-substituted 8-mercaptoquinolines in dimethylformamide: N. A. ULAKHOVICH, H. C. BUDNIKOV, T. S. CORBUNOVA and A. P. STURIS. (13 March 1984)

Synthesis and characterization of 1,2-cyclohexanedione bis-benzoylhydrazone and its application to the determination of titanium in minerals and rocks: M. GARCIA-VARGAS, S. TREVILLA and M. MILLA. (13 March 1984)

PAPERS RECEIVED

The spectrophotometric evaluation of acidity constants: The double incomplete colour change: A. G. ASUERO, M. J. NAVAS and D. ROSALES. (26 November 1984)

Urea as basic component in pyridine-free Karl Fischer reagent: M. BOS. (6 December 1983)

Comment on laser-excited fluorescence line-narrowing: An analytical study: J. M. HAYES and G. J. SMALL. (7 December 1983)

Factors that influence the first-order kinetics and completeness of deposition in the electro-deposition of trace amounts of metals: RAGNAR BYE. (8 December 1983)

Determination of cerium in silicate rocks by electrothermal atomization in a furnace lined with tantalum foil: Application to 19 international geological reference materials: J. G. SEN GUPTA. (8 December 1983)

Estimation of uranium in columbite–tantalite samples: A method for sample-solution preparation for fluorometric estimation: B. K. BALAJI, A. PREMDAS and G. V. RAMANAIAH. (14 December 1983)

Study of the potential response of solid-state chloride electrodes in low concentration ranges: E. G. HARSÁNYI, K. TÓTH, E. PUNGOR, YOSHIO UMEZAWA and SHIZUO FUJIWARA. (14 December 1983)

A new colorimetric determination of DDA: 2,2-bis(4-chlorophenyl) acetic acid: B. D. BANERJEE, M. RAMACHANDRAN and Q. Z. HUSSAIN. (15 December 1983)

Extractive separation and spectrophotometric determination of palladium and platinum with dithizone in the presence of stannous chloride: Z. MARCZENKO, S. KUŚ and M. MOJSKI. (15 December 1983)

Chemiluminescent reaction of lucigenin with reducing sugars: ROBERT L. VEAZEY, HOWARD NEKIMKEN and TIMOTHY A. NIEMAN. (15 December 1983)

Use of a simple monitored thermometric technique for reaction-rate determination of inorganic species: System based on the iodide-catalysed cerium(IV)–arsenic(III) reaction: F. GRASES, R. FORTEZA, J. G. MARCH and V. CERDA. (20 December 1983)

Étude polarographique du niobium dans les mélanges eau–fluorure d'hydrogène en présence d'ions tétraalkylammonium: HUGHES MÉNARD and RÉJEAN BEAUDOIN. (28 June 1983)

Extraction of cobalt from thiocyanate solutions with polyurethane foam: R. F. HAMON and A. CHOW. (23 December 1983)

A partial deproteination technique for simplifying whole-blood and related matrices for flame atomic spectrometry: E. J. EKANEM. (31 December 1983)

Spectrophotometric determination of cyanide by unsegmented flow methods: A. RIOS, M. D. LUQUE DE CASTRO and M. VALCARCEL. (31 December 1983)

Ion-pair extraction of lithium ion with cryptand 211 and resazurin: YUN PEI WU and GILBERT E. PACEY. (31 December 1983)

Determination of nickel by flame atomic-absorption spectrophotometry after separation by adsorption of its nioxinate on microcrystalline naphthalene: TOHRU NAGAHIRO, BAL KRISHAN PURI, MOHAN KATYAL and MASATADA SATAKE. (31 December 1983)

Precipitate-polished electrode: New voltammetric method with the solid electrode: TAITIRO FUJINAGA and TAKASHI KIMOTO. (6 January 1984)

PAPERS RECEIVED

Titrimetric determination of aminobenzoic acids: D. AMIN, F. M. EL-SAMMAN and H. ABDULAHED-MALALLA. (7 November 1983)

Extraction–spectrophotometric determination of small amounts of boron in copper metal and copper-base alloys with Methylene Blue: ZDENĚK ČÍŽEK and VLASTA ŠTUDLAROVÁ. (7 November 1983)

Exchange equilibria between bicarbonate, carbonate, chloride, and bromide on Dowex 1-x8: ULLA LUNDSTRÖM and ÅKE OLIN. (8 November 1983)

Standard-addition ammonia-electrode determination of nitrogen in coal: T. D. RICE, V. SWEENEY, R. SEMITEKOLOS and G. J. RHYDER. (8 November 1983)

Selective complexometric determination of tin, with mercaptans as masking agents: Its estimation in alloys: K. N. RAOOT and SARALA RAOOT. (9 November 1983)

Preparation of a new complexing resin modified by SPADNS: MARIA LUISA MARINA, VENERANDO GONZÁLEZ and ADELA ROSA RODRÍGUEZ. (9 November 1983)

Application of anion-exchange technique to the determination of traces of molybdenum in sea-water: TETSUYA KIRIYAMA and ROKURO KURODA. (9 November 1983)

Radiochemical determination of technetium-99: NORTON Y. CHU and JERRY FELDSTEIN. (3 November 1983)

Linear titration plots for the resolution of mixtures of three weak acids or bases: DEREK MIDGLEY and COLIN MCCALLUM (14 November 1983)

Signal-to-noise characteristics of optical polarimeters: JOUKO J. KANKARE and ROGER STEPHENS. (17 November 1983)

Differential pulse polarographic determination of molybdenum after separation by 8-hydroxyquinoline extraction into dichloromethane: YUKIO NAGAOSA and KATSUNORI KOBAYASHI. (21 November 1983)

Potentiometric studies on the chelates of Al(III), Ga(III) and In(III) with 2'-hydroxychalkone: R. S. SINDHU and R. P. SINGH. (24 November 1983)

Ultraviolet spectrophotometric determination of lead and bismuth with ammonium 1-pyrrolidinecarbodithioate: YOSHIKAZU YAMAMOTO, HIDENAO SAITO and KAZUMASA UEDA. (24 November 1983)

Effect of surface-active compounds on voltammetric stripping analysis at the mercury film electrode: JOSEPH WANG and DEN-BAI LUO. (24 November 1983)

Spectrophotometric determination of lead with 2-(5-bromo-2-pyridylazo)-5-diethylaminophenol and cetyltrimethylammonium bromide: ALI Z. ABU-ZUHRI and JAMAL SHALABI. (25 November 1983)

Solvent extraction of zirconium(IV) from acidic sulphate–acetate medium with bis-(2-ethylhexyl) phosphoric acid in benzene: R. K. BISWAS and M. A. HAYAT. (25 November 1983)

Titrimetric microdetermination of Ag(I), Hg(II), Cd(II) and Pb(II) with 2-mercaptopropanoic acid and thioglycollic acid: K. K. TIWARI and R. M. VERMA. (25 November 1983)

Polyurethane foam for the extraction of rhodium and its separation from iridium: S. J. AL-BAZI and A. CHOW. (28 November 1983)

Electro-deposition of traces of metals applied for analytical preconcentration and preseparation: ROMAN E. SIODA. (29 November 1983)

Protonation constants of some organic acids: ZS. WITTMANN. (29 November 1983)

Chromatographic analysis of phospholipid and cholesterol oxidation: ULRICH J. KRULL, MICHAEL THOMPSON and ANITA ARYA. (29 November 1983)

Extraction of arsenic(III) from chloride–iodide solutions by diphenyl-2-pyridyl methane/benzene: M. EJAZ, R. SIDDIQUE and SUHAIL AHMED. (1 December 1983)

Colorimetric determination of carazolol with 3-methyl-2-benzothiazolone hydrazone hydrochloride: M. A. KORANY, F. A. EL-YAZBI and M. H. ABDEL-HAY. (2 December 1983)

Contribution to the theory of catalytic titrations—I: Complexometric catalytic titrations: FERENC F. GAÁL and BILJANA F. ABRAMOVIĆ. (2 December 1983)

Voltammetric study of the redox behaviour of the Hg(II)/Hg(I)/Hg system at a rotating metal-ring/glass-carbon disk electrode: P. KIEKENS, E. TEMMERMAN and F. VERBEEK. (5 December 1983)

Ion chromatographic determination of chloride and fluoride in electrolyte from the halogen tinplating process: W. KORTH and J. ELLIS. (5 December 1983)

Lead sulphide as a sorbent for preconcentration of mercury from air and determination of mercury by atomic-emission spectroscopy: S. ALEXANDROV. (5 December 1983)

PAPERS RECEIVED

The pK_a values of imidazole in water–ethanol mixtures: JANUSZ OSZCZAPOWICA and MAŁGORZATA CZURYŁOWSKA. (11 October 1983)

Extraction of zinc with the high molecular-weight amine Amberlite LA-2: UDAY SANKAR RAY and SUNIL BARAN KAR. (13 October 1983)

Effect of pH on chromium(VI) species in solution: R. K. TANDON, P. T. CRISP, J. ELLIS and R. S. BAKER. (14 October 1983)

Platinum metals—solution chemistry and separation methods: Ion-exchange and solvent extraction: SARGON J. AL-BAZI and ARTHUR CHOW. (14 October 1983)

A comparison of cationic polymerization and esterification for end-point detection in the catalytic thermometric titration of organic bases: EDWARD J. GREENHOW and PILAR VIÑAS. (17 October 1983)

Determination of Ni in serum of occupationally exposed workers, by means of flame atomic-absorption spectroscopy—I: The analytical method: ANNA MARIA GHE, MARIA TERESA LIPPOLIS and LUCIANA PASTORELLI. (19 October 1983)

Determination of Ni in serum of occupationally exposed workers, by means of flame atomic-absorption spectroscopy—II: Study of some interferences: ANNA MARIA GHE, LUCIANA PASTORELLI and MARIA TERESA LIPPOLIS. (19 October 1983)

Method for the prediction of the behaviour of a single flow-injection manifold: MIGUEL ANGEL GOMEZ-NIETO, MARIA DOLORES LUQUE DE CASTRO, ANTONIO MARTIN and MIGUEL VALCARCEL. (19 October 1983)

Simultaneous separation of copper, cadmium and cobalt in sea-water by co-flotation with octadecylamine and ferric hydroxide as collectors: L. M. CABEZON, M. CABALLERO, R. CELA R and J. A. PEREZ-BUSTAMANTE. (20 October 1983)

Reactivity and chelate effect of triethanolamine complexes derived from cobalt(II), nickel(II) and copper(II) salts: MAMDOUH S. MASOUD and MOHAMED A. EL-DESSOUKY. (20 October 1983)

Use of ammonium molybdate in the colorimetric assay of cephalosporins: M. M. ABDEL-KHALEK and M. S. MAHROUS. (20 October 1983)

Sulphuric acid extraction of chlorinated hydrocarbons from marine organisms: VITTORIO CONTARDI, BIANCA COSMA, MARILISA MATTACE RASO and GILDA ZANICCHI. (25 October 1983)

Determination of cadmium by differential pulse anodic-stripping voltammetry after salting-out extraction with acetonitrile as solvent: YUKIO NAGAOSA and TOSHIHIRO YAMADA. (26 October 1983)

Studies on extraction of thorium from nitrate solutions by quaternary ammonium halides: I. S. EL-YAMANI and E. I. SHABANA. (28 October 1983)

Studies on extraction of indium(III) by tributyl phosphate from thiocyanate solutions: I. S. EL-YAMANI and E. I. SHABANA. (28 October 1983)

Flow-injection analysis: Epidemiology and origin of a revolution within a revolution: T. BRAUN and W. S. LYON (1 November 1983)

Separation and determination of arsenic(V) and arsenic(III) in sea-water by solvent extraction and atomic-absorption spectrophotometry by the hydride-generation technique: SAMUEL A. AMANKWAH and JAMES L. FASCHING. (25 October 1983)

2-[2-(5-Chloropyridyl)azo]-5-dimethylaminophenol as indicator for the complexometric determination of zinc: E. MARCHEVSKY, R. OLSINA and C. MARONE. (13 October 1983)

The colours of co-ordination compounds: Methods of classification: FRANZ LUDWIG WIMMER and LAURENCE PONCINI. (2 November 1983)

Diffusion coefficients and complex equilibria in solution—IV: Experimental determination and manipulation of diffusion data: D. R. CROW. (4 November 1983)

PAPERS RECEIVED

Polarographic determination of zirconium at trace levels: Y. CASTRILLEJO, R. PARDO, E. BARRADO and P. SANCHEZ BATANERO. (16 August 1984)

Spectrophotometric determination of some 1,4-benzodiazepines by use of orthogonal polynomials: M. A. KORANY, F. A. EL-YAZBI and M. H. ABDEL-HAY. (16 August 1984)

Application of microcomputers in the analytical laboratory—III: On-line monitoring of a blue-green algae (*spirulian platensis*) culture: HUGO GUTERMAN and SAM BEN-YAAKOV. (20 August 1984)

Nuclear magnetic resonance spectrometry of chemically and physically altered porous silica surfaces under gas chromatographic conditions: R. K. GILPIN and M. E. GANGODA. (20 August 1984)

Fluorometric determination of nitrite: P. DAMIANI and G. BURINI. (20 August 1984)

A new polarographic catalytic method for the determination of micro quantities of tungsten(VI): R. RAMACHANDRA MURTHY and V. SURYANARAYANA RAO. (20 August 1984)

The effects of heating temperature, heating time and sample size during wet digestion in the determination of Ca, Fe, Cu and Na in some processed meats: S. A. THOMAS and A. O. FADIRAN. (20 August 1984)

Some factors in the determination of calcium, iron, copper and sodium from plant and soil samples by mixed-acid digestion: S. A. THOMAS and A. JOB. (20 August 1984)

Determination of trace amounts of copper, lead and zinc in cements by X-ray fluorescence spectrometry after precipitation-separation with hexamethylene ammonium hexamethylenedithiocarbamate: YOSHIKAZU YAMAMOTO, YASUHIRO NISHINO and KAZUMASA UEDA. (22 August 1984)

Further developments in the high-precision coulometric titration of uranium: TATSUHIKO TANAKA, GEORGE MARINENKO and WILLIAM F. KOCH. (2 August 1984)

Studies with an inorganic ion-exchange membrane exhibiting selectivity to Pb(II) ions: SURESH K. SRIVASTAVA, SATISH KUMAR, CHAKRESH K. JAIN and SURENDER KUMAR. (22 August 1984)

Determination of carbonate alkalinity and apparent dissociation constants in a multipyrolytic system: ZVI-HAI BURBEA, CIDIO HAIMOVITZ and SAM BEN-YAAKOV. (22 August 1984)

Ruthenium determination in synthetic Purex waste solutions by AAS: W. HEINIG and K. MAUERSBERGER. (24 August 1984)

Differential-pulse stripping voltammetry for the determination of nickel and cobalt in simulated PWR coolant: K. TORRANCE and C. GATFORD. (24 August 1984)

Spectrophotometric methods for the determination of thiobarbiturates: C. S. P. SASTRY, P. SATYANARAYANA and M. K. TUMMURU. (24 August 1984)

MICMAC—un programme général et rigoureux d'affinement multiparamétrique pour la détermination de constantes d'équilibre à partir de méthodes physiques variées: ANDRÉ LAOUENAN and ELISABETH SUET. (9 August 1984)

Dosage thermométrique et potentiométrique de l'aluminium par l'hydroxyde de sodium en présence de divers cations et anions: PHILIPPE BOUDEVILLE. (9 August 1984)

Caractérisation des jus pyrolytiques en provenance de différents procédés de conversion du bois: H. MÉNARD, D. BÉLANGER, G. CHAUVETTE, A. GABOURY, J. KHORAMI, M. GRISÉ, A. MARTEL, E. POTBIN, C. ROY and R. LANGLOIS. (9 August 1984)

N-Acetylmuramoyl-L-alanyl-D-isoglutamine determination in liposomes by HPLC: E. POSTAIRE, M. HAMON, E. SPONTON, D. PRADEAU and R. LARCHEE. (9 August 1984)

Backplane bus structures and systems: V. KARANASSIOS and G. HORLICK. (27 August 1984)

Smart backplanes—I: The Apple II: V. KARANASSIOS and G. HORLICK. (27 August 1984)

Smart backplanes—II: The IBM PC: V. KARANASSIOS and G. HORLICK. (27 August 1984)

Investigation of the effect of dilution and number of points in the performance of a linear method of potentiometric titration of weak bases: L. M. ALEIXO, O. E. S. GODINHO and W. F. DA COSTA. (29 August 1984)

Sorption and permeation behaviour of metal thiocyanate complexes on cellulose acetate polymers: TAKASHI HAYASHITA and MAKOTO TAKAGI. (28 August 1984)

Extraction-spectrophotometric determination of boron and antimony in carbon steel and low alloys with mandelic acid and Malachite Green: SHIGEYA SATO. (31 August 1984)

Spectrophotometric determination of cyanide in biological samples with a new reagent: S. SUNITA and V. K. GUPTA. (31 August 1984)

A kinetic study of the 1,3,5-triphenyl-Δ^2-pyrazoline–Tc(VII) system, and its usefulness for measurement of technetium: F. GRASES, J. G. MARCH, F. MATA and A. PENAFIEL. (4 September 1984)

Injection analysis in flow-gradient systems: A new approach to unsegmented flow techniques: ANGEL RIOS, MARIA DOLORES LUQUE DE CASTRO and MIGUEL VALCARCEL. (4 September 1984)

Mathematical optimization in the determination of the dissociation constants of a tribasic organic acid with ^{13}C NMR spectroscopy: ANNE-MARIE SALONEN. (6 September 1984)

Studies of the solubilized metal–dithizone–surfactants system—I: Spectrophotometric determination of zinc in food and water samples: WEN-BIN QI and WEI-QIANG GUO. (6 September 1984)

Extraction of manganese(II), iron(II), cobalt(II), nickel(II), copper(II), zinc(II) and cadmium(II) into 1,2-dichloroethane with 4,7-diphenyl-1,10-phenanthroline and perchlorate ion: TAKAHARU HONJO, AKIKO OKAZAKI, KIKUO TERADA and TOSHIYASU KIBA. (6 September 1984)

Analytical investigations of cephalosporins—I: Two spectrophotometric methods for the determination of ceftriaxone in pharmaceutical formulations: FATMA INCI SENGÜN and KÖKSAL ULAS. (7 September 1984)

Preparation and properties of a chelating polymer containing the dithiocarboxylate group: C. O. GIWA. (7 September 1984)

A study on the polarography of the alkaline-earth metals—II: The polarographic adsorptive wave of magnesium–Eriochrome Black T and its application: JINGRU AN, JINKUI ZHOU and XIAODAN WEN. (11 September 1984)

Effect of acidity on the extraction and kinetic stability of the copper(II)/APCD/IBMK system in strongly acidic media: MASAHIKO MURAKAMI and TAKEO TAKADA. (11 September 1984)

Discussion on the possibility of reducing systematic error in trace analysis of metals by the SSMS methods: WOJCIECH VIETH. (13 September 1984)

Characterization of sediment reference materials by X-ray photoelectron spectroscopy: M. SOMA, H. SEYAMA and K. OKAMOTO. (17 September 1984)

Spectrophotometric assay of some tranquillizers in pure and dosage forms: P. G. RAMAPPA and K- BASAVAIAH. (18 September 1984)

Electrolytic preconcentration: Preliminary step in instrumental analysis: ROMAN E. SIODA, GRAEME E. BATLEY, WALTER LUND, JOSEPH WANG and STEVEN C. LEACH. (18 September 1984)

Influence of acetate medium on the extraction of Co(II) by di-2-ethylhexylphosphoric acid: P. BENEITEZ, S. J. ORTIZ and J. ORTEGA. (18 September 1984)

Study on the glycopyrronium selective electrodes: SHOU-ZHUO YAO and GIANG-HUA LIU. (18 September 1984)

Methods of preconcentration of organic pollutants: Determination of sorption capacity of solids: JACEK NAMIEŚNIK. (19 September 1984)

Determination of neodymium and boron in iron-neodymium-boron alloys by direct-current plasma atomic-emission spectrometry: NOEL M. POTTER and HARRY E. VERGOSEN, III. (20 September 1984)

Stability constants of the ternary complexes of CuDTPA, NiDCTA, CrEDTA, CoHEEDTA, NiHEEDTA and CuHEEDTA with OH⁻: J. KORSSE, G. A. J. LEURS and P. W. F. LOUWRIER. (20 September 1984)

PAPERS RECEIVED

Spectrophotometric determination of paracetamol with iodylbenzene: KRISHNA K. VERMA and ARCHANA JAIN. (29 May 1984)

Determination of copper in blood serum with *o*-hydroxyphenylthiourea by a kinetic method: S. JAGADEESWARA RAO, G. SIVA REDDY, J. KRISHNAKUMARI and J. KRISHNA REDDY. (30 May 1984)

Multiparametric curve fitting—VII: Determination of a number of complex species by factor analysis of potentiometric data: JOSEF HAVEL and MILAN MELOUN. (30 May 1984)

Platinum–graphite biamperometry in non-aqueous medium: Determination of iron (II), thioglycollic acid and ascorbic acid in *N,N*,-dimethylformamide with copper(II) chloride as the oxidant: D. GHOSH and B. B. PRASAD. (31 May 1984)

Aquametric microdetermination of hydration of ion-exchange resins: Measurement of the water content in anion-exchanges, derivation of hydration isotherms, relationship to hydration and the amount of pre-adsorbed moisture: F. B. SHERMAN, B. M. KATZ and G. N. EVENKO. (31 May 1984)

The use of certified reference materials in the verification of analytical data and methods: R. SUTARNO and H. F. STEGER. (1 June 1984)

Analytical chemistry of uranium in the phosphoric acid wet process: SRBOBRAN RAJIĆ. (1 June 1984)

Polarographic study of mixed ligand (glycoldimercaptopropionate–oxalate/citrate/tartrate/glutamate) complexes of cadmium(II) and lead(II): K. C. GUPTA and KALPANA K. SHARMA. (4 June 1984)

Studies on fluorescein—III: The acid strengths of fluorescein as shown by potentiometric titration: HARVEY DIEHL, NAOMI HORCHAK, ALTA J. HEFLEY, LINDA ANN FREYTAG MUNSON and RICHARD MARKUSZEWSKI. (4 June 1984)

Beiträge zur Frage der Existenz eines Tautomerengleichgewichtes in Lösungen von Dithizon in organischen Solventien: H. WAGLER, H. KOCH and J. FLACHOWSKY. (26 April 1984)

Differential determination of antimony(III) and antimony(V) by solvent extraction–spectrophotometric determination with mandelic acid and Malachite Green, based on the difference in reaction rates: SHIGEYA SATO. (6 June 1984)

Indirect determination of thallium by differential pulse polarography: ALI H. BAZZI and BRIAN R. KERSTEN. (6 June 1984)

Studies on extraction of manganese(II) with 1-phenyl-3-methyl-4-acyl-5-pyrazolone: Y. AKAMA, H. YOKOTA, K. SATO and T. NAKAI. (7 June 1984)

Calculation of equilibrium constants from multiwavelength spectroscopic data—I: Mathematical considerations: HARALD GAMPP, MARCEL MAEDER, CHARLES J. MEYER and ANDREAS D. ZUBERBÜHLER. (7 June 1984)

Studies on determination of fluoride in zinc and lead concentrates by using a fluoride ion electrode: S. C. S. RAJAN, L. M. BHANDARI and B. R. L. ROW. (8 June 1984)

Potentiometric determination of stability constants of Cu(II), Ni(II), Co(II) and Zn(II) complexes with SPADNS: M. L. MARINA, V. GONZALEZ and A. R. RODRIGUEZ. (11 June 1984)

Thermodynamic parameters and stability constants of binary complexes of the lanthanons with acenaphthenequinone monothiosemicarbazone (AQTS): S. K. SINGH, R. K. SHARMA and S. K. SINDHWANI. (11 June 1984)

Differential pulse polarography in the alternating pulse mode: CSABA URBANICZKY. (11 June 1984)

Preparation of a new complexing resin modified by SPADNS: Application to separation of metal ions: M. L. MARINA, V. GONZALEZ and A. R. RODRIGUEZ. (13 June 1984)

Kinetic determination of cysteine traces by their inhibitory effect on the silver-catalysed phloxin–persulphate reaction: M. HERNANDEZ CORDOBA, P. VINAS and C. SANCHEZ-PEDRENO. (13 June 1984)

Application of ion-exchange reactions between membranes and resins: JAMES A. COX and NOBUYUKI TANAKA. (13 June 1984)

Copper(I) electrode function of two types of ion-selective electrodes for copper(II): M. NESHKOVA and H. SHEYTANOV. (13 June 1984)

The behaviour of two types of copper ion-selective electrodes in different copper(II)–ligand systems: M. NESHKOVA and H. SHEYTANOV. (13 June 1984)

Quality control in clinical chemistry: Characterization of reference materials: ROBERT REJ, RICHARD W. JENNY and JEAN-PIERRE BRETAUDIERE. (24 May 1984)

Solid-phase chemistry: Its principles and applications in clinical analysis: ADAM ZIPP and W. E. HORNBY. (5 May 1984)

Formation constants for the complexes of orthophosphate with magnesium(II) and hydrogen ions: PETER W. LINDER and JOHN C. LITTLE. (14 June 1984)

Anionic interferences with copper ion-selective electrodes: The chloride and bromide interferences: A. LEWENSTAM, T. SOKALSKI and A. HULANICKI. (14 June 1984)

An inexpensive and robust conductance electrode: J. P. LORIMER, K. JAGIT and TIMOTHY J. MASON. (18 June 1984)

Determination of manganese in steels by atomic-absorption spectrophotometry: L. P. PANDEY, P. DASGUPTA, N. N. CHATTERJEE and S. N. JHA. (22 June 1984)

A chemical amplification method for the sequential estimation of phosphorus, arsenic and silicon at ng/ml levels by dc polarography: R. KANNAN, T. V. RAMAKRISHNA and S. R. RAJAGOPALAN. (22 June 1984)

Extractive spectrophotometric determination of zirconium as zirconium(IV) ferronate: S. P. ARYA and VEENA SLATHIA. (26 June 1984)

Spectrophotometric determination of saccharin in different materials by a solvent extraction method using Nile Blue as reagent: M. HERNANDEZ CORDOBA, I. LOPEZ GARCIA and C. SÁNCHEZ-PEDRENO. (26 June 1984)

Separation of iron-52 from chromium cyclotron targets on the 2% cross-linked anion-exchange resin AG1-X2 in hydrochloric acid: TJAART N. VAN DER WALT, FRANZ W. E. STRELOW and FLORIS J. HAASBROEK. (26 June 1984)

Asymmetric derivatives of carbohydrazide and thiocarbohydrazide as analytical reagents: DANIEL ROSALES, GUSTAVO GONZALEZ and JOSE L. GOMEZ ARIZA. (26 June 1984)

Presence of unreacted alcohol in n-alkyl ethoxylates used in spin finish lubricant formulations: H. A. ANDERSON, D. L. BRYDON and C. D. TAYLOR. (27 June 1984)

Consistent sub-micromolar traces of phosphate in doubly demineralized and demineralized–distilled water: VINCENT P. GUTSCHICK. (12 May 1984)

A sensitive method for the fluorometric determination of lithium with a "crowned" benzothiazolylphenol: KENICHIRO NAKASHIMA, SHIN'ICHI NAKATSUJI, SHUZO AKIYAMA, ISAMU TANIGAWA, TAKAHIRO KANEDA and SOICHI MISUMI. (25 June 1984)

Contributions to the theory of catalytic titrations—II: Precipitation catalytic titrations: BILJANA F. ABRAMOVIĆ and FERENC F. GAÁL. (3 July 1984)

Contributions to the theory of catalytic titrations—III: Redox catalytic titrations: BILJANA F. ABRAMOVIĆ, FERENC F. GAÁL and DJURA Ž. PAUNIĆ. (3 July 1984)

Influence of some metal ions on NADH oxidation and on the formation of the superoxide anion O_2^- radical during the enzymatic catalysis of E.C. 1.2.3.2. xanthine oxidase: ANNA MARIA GHE, CLAUDIO STEFANELLI, PAGONA TSINTIKI and GABRIELE VESCHI. (3 July 1984)

Use of enzymatic catalysis with E.C. 1.2.3.2 xanthine oxidase for the kinetic determination of V(V) at low concentrations: ANNA MARIA GHE, CLAUDIO STEFANELLI, GIUSEPPE CHIAVARI and PAGONA TSINTIKI. (3 July 1984)

Determination of trace amounts of molybdenum in plant tissue by solvent extraction—atomic-absorption and direct-current plasma emission spectrometry: LAURI H. J. LAJUNEN and AARO KUBIN. (3 July 1984)

Extractive spectrophotometric determination of trace amounts of cobalt with benzyltriethylammonium chloride: K. C. BAYAN and H. K. DAS. (3 July 1984)

Precipitation of cobalt and iron with alkali metal hydroxide and oxides: C.O. GIWA. (3 July 1984)

Homogeneous immunoassay of phenobarbital by phase-resolved fluorescence spectroscopy: FRANK V. BRIGHT and LINDA B. McGOWN. (11 June 1984)

Computer interfacing of intelligent instrumentation by means of keyboard emulation: P. M. WIEGAND and S. R. CROUCH. (11 June 1984)

Determination of polyethylene glycols by precipitation with I_2: M. FRANCOIS and R. DE NEVE. (5 July 1984)

Effect of container material, storage time and temperature on determination of cadmium levels in human urine: KUNNATH S. SUBRAMANIAN, JEAN-CHARLES MÉRANGER and JOHN CONNOR. (6 July 1984)

Polarographic determination of the stability constants of cadmium and lead ternary complexes with thiosemicarbazide and thiosulphate: MAHMOUD A. GHANDOUR, AHMAD A. EL SAMAHY and ZANATI KOMY. (10 July 1984)

Phosphorus-31 nuclear magnetic resonance chemical shifts of phosphoric acid derivatives: ZS. WITTMAN and ZS. KOVÁCS. (11 July 1984)

Fluorimetric determination of dissociation constants and pH-controlled fluorescence analysis of purines and pyrimidines: DIARIATOU GNINGUE and JEAN JACQUES AARON. (11 July 1984)

Spectrophotometric determination of some ketosteroid drugs: MAGDA M. AYAD, SAIED F. BELAL, SOBHI M. EL ADL and AFAF A. EL KHEIR. (11 July 1984)

PAPERS RECEIVED

Spectrophotometric determination of zinc(II) with phenylfluorone in the presence of hexadecylpyridinium bromide and pyridine: SATORU SAKURABA. (9 January 1984)

Pyrimidinethiol, a new reagent for extraction spectrophotometric determination of gold(III): M. A. ANUSE, S. R. KUCHEKAR, N. A. MOTE and M. B. CHAVAN. (9 January 1984)

Kinetic fluorimetric determination of cyanide by its catalytic effect on the aerial oxidation of pyridoxal 5-phosphate oxalyldihydrazone: S. RUBIO, A. GOMEZ-HENS and M. VALCARCEL. (9 January 1984)

Interferences in the determination of total nitrogen in natural waters by photo-oxidation to nitrate and nitrite: LILLY GUSTAFSSON. (9 January 1984)

Analytical applications of copper(II) and copper(I) in acetonitrile: Potentiometric and spectrophotometric determination of dithiocarbamates: BALBIR CHAND VERMA, SAROJ CHAUHAN, ANITA SOOD, D. K. SHARMA and H. S. SIDHU. (9 January 1984)

Determination of sulpha-drugs with ion-selective membrane electrodes—II: G. E. BAIULESCU, GÖNÜL KANDEMIR, M. S. IONESCU and C. CRISTESCU. (10 January 1984)

Gel speciation studies—II: An extension of earlier studies of the protonation equilibria of cross-linked carboxymethyldextran: SALVADOR ALEGRET, MARIA-TERESA ESCALAS and JACOB A. MARINSKY. (10 January 1984)

Simultaneous determination of dextropropoxyphene napsylate, caffeine, aspirin and salicylic acid in pharmaceutical preparations by reversed-phase HPLC: I. M. JALAL and S. I. SA'SA'. (10 January 1984)

Untersuchungen zur Anwendung ternärer Komplexe in der Photometrie—III: Die Bestimmung des Titanium(IV) mit Brompyrogallolrot in Gegenwart von Nitrilotriessigsäure bzw. Ethylendiamintetraessigsäure: S. KOCH, G. ACKERMANN and H. MOSLER. (10 January 1984)

Testing the adequacy of equilibrium models for complex formation: Complexation between molybdate and oxalate revisited: ERIK SYLVEST JOHANSEN and OLE JØNS. (11 January 1984)

Colorimetric determination of some phenothiazine derivatives and chlorprothexine with different oxidizing agents: EL-SEBAI A. IBRAHIM, A. S. ISSA, M. A. ABDEL SALAM and M. S. MAHROUS. (11 January 1984)

The macrocyclic crown ether and cryptand mediated extraction of potassium *p*-nitrophenoxide from aqueous medium into diverse organic solvents: A systematic evaluation: E. BUNCEL, H. S. SHIN, R. A. B. BANNARD, J. G. PURDON and B. G. COX. (13 December 1983)

Determination of poly(oxyethylene) non-ionic surfactants by two-phase titration: MASAHIRO TSUBOUCHI and YOSHIKO TANAKA. (11 January 1984)

The polarographic determination of malononitrile: D. PH. ZOLLINGER, M. BOS, A. M. W. VAN VEEN-BLAAUW and W. E. VAN DER LINDEN. (11 January 1984)

Synthesis and analytical properties of monobutyl esters of α(*N*-benzylamino)salicylphosphonic acid and α(*N-p*-chlorobenzylamino)salicylphosphonic acid: JERZY SIEPAK. (13 January 1984)

Dual-wavelength spectrophotometric determination of trace sulphide in domestic water through its ligand-exchange reaction with silver–Cadion 2B–Triton X-100: FU-SHENG WEI, EN-JIANG TENG and KUI-SHENG RUI. (13 January 1984)

Orthophosphoric acid dissolution of geological material and flame atomic-absorption spectroscopy and inductively-coupled plasma atomic-emission spectroscopy for major element determinations: PHILIP HANNAKER and HOU QING-LIE. (16 January 1984)

Determination of uranium in phosphogypsum: HELENA GÓRECKA and HENRYK GÓRECKI. (16 January 1984)

Simultaneous kinetic determination of copper, cobalt and nickel by means of interchange of >C=N– groups: A. RIOS and M. VALCARCEL. (16 January 1984)

Determination of beryllium in Pt–Be alloy by atomic-absorption spectrometry and preliminary ion-exchange separation: KRYSTYNA BRAJTER and KRZYSZTOF KLEJNY. (17 January 1984)

Beiträge zur Frage der Existenz eines Tautomerengleichgewichtes in Losungen von Dithizon in organischen Solventien—I: Die Korrelation zwischen den lösungsmittelabhängigen Reaktionsunterschieden in den Systemen Palladium/Dithizon und Kupfer/Dithizon und den lösungsmittelabhängigen Unterschieden der VIS-Spektren der Dithizonlösungen: H. WAGLER and H. KOCH. (17 January 1984)

An improved titrimetric method for the determination of oxygen to metal ratio in uranium oxide: FAHMIDA KHATOON and C. SUBBA RAO. (18 January 1984)

Cadmium-113 and carbon-13 nuclear magnetic resonance spectrometry of cadmium peptide complexes: SHUI-MEI WANG and ROGER K. GILPIN. (14 November 1983)

Polarographic determination of amoxacillin in certain pharmaceutical preparations: M. M. AYAD, A. M. A. MORSI and M. YOUSEF. (23 January 1984)

Aerosol collection on a tungsten wire: KEIJO HAAPAKKA and ROGER STEPHENS. (24 January 1984)

Determination of silver in doré metal by weight titration with equivalence point detection by differential electrolytic potentiometry (DEP): PABLO COFRE and GEORGIAN COPIA. (25 January 1984)

Determination of certain quinones by a chemiluminescence reaction in solution: J. L. BURGUERA and M. BURGUERA. (25 January 1984)

A chelate-forming resin prepared from sulphonated dithizone and an anion-exchange resin and its application to collection of heavy metal ions: MASAHIKO CHIKUMA, MORIO NAKAYAMA, KUNICHI KUNIMASA, YUNIKO SUZUKI, YORIKO KURISAKA and HISASHI TANAKA. (26 February 1984)

Detection of uranium in aqueous media by using X-ray photoelectron spectroscopy: DALE L. PERRY and LEON TSAO. (27 January 1984)

Studies on synthetic inorganic ion exchangers—X: Synthesis and physicochemical properties of crystalline zirconium selenite: PRITAM SINGH THIND and HARBANS SINGH. (27 January 1984)

Elucidation of the redox behaviour of ethyl 2,3-dioxobutyrate-2-phenylhydrazono 3-semicarbazone by polarographic and voltammetric techniques: R. N. GOYAL and ASHWANI MINOCHA. (27 January 1984)

Non-extractive spectrophotometric determination of trace amounts of thallium with 7-(4,5-dimethylthiazolyl-2-azo)-8-oxime-5-sulphonic acid: Determination of thallium in metals and ores: GAO JIALONG, GU GANG, LIU XILIN and CHEN TONGYUE. (30 January 1984)

A new experimental technique for validating models of carbon dioxide exchange between the atmosphere and sea-water: SAM BEN-YAAKOV and HUGO GUTERMAN. (1 February 1984)

Spectrophotometric determination of molybdenum in steel alloys after separation by adsorption of its trifluoroethylxanthate on naphthalene: M. F. HUSSAIN, B. K. PURI, R. K. BANSAL and M. SATAKE. (1 February 1984)

A versatile low-cost laboratory computer network: R. L. A. SING and ERIC D. SALIN. (3 February 1984)

The determination of the heavy-metal content of fluvial sediments: STEPHEN B. BRADLEY. (6 February 1984)

Differential pulse polarography as a tool for determining trace levels of nicotinamide adenine dinucleotide (NAD^+) and nicotinamide adenine dinucleotide phosphate ($NADP^+$) in aqueous solution: S. T. SULAIMAN. (6 February 1984)

Basic studies and analytical applications of Nb(V)–Bromopyrogallol Red complexation in micellar media: M. E. DIAZ GARCIA and A. SANZ-MEDEL. (6 February 1984)

Spectrophotometric determination of formation constants of 1:1 complexes of lanthanides with 4-(2-pyridylazo)resorcinol (PAR): EMIKO OHYOSHI. (7 February 1984)

Oxidation of PGR by chromium(VI): Kinetic-spectrophotometric determination: J. MEDINA-ESCRICHE, A. SEVILLANO-CABEZA and M. DE LA GUARDIA-CIRUGEDA. (9 February 1984)

Solvent extraction separation of tantalum from niobium on macro scale with di(2-ethyl hexyl)phosphoric acid as the extractant: S. N. BHATTACHARYYA and B. (NANDI) GANGULY. (10 February 1984)

Application of some colorimetric methods for the spectrophotometric determination of some antipyretic and antirheumatic drugs: A. S. ISSA, Y. A. BELTAGY, M. GABR KASSEM and H. G. DAABEES. (10 February 1984)

1,2 and 1,3-cyclohexandione bis(2-hydroxybenzoylhydrazones)s as analytical reagents: M. GALLEGO, M. SILVA and M. VALCARCEL. (13 February 1984)

Determination of scandium, yttrium and seven lanthanides in silicate rocks and four new Canadian iron-formation reference materials by flame micro-sample injection atomic-absorption spectrometry: J. G. SEN GUPTA. (14 February 1984)

Comparison of two digestion methods used for the determination of selenium in marine biological tissues by gas chromatography with electron capture detection: K. W. MICHAEL SIU and SHIER S. BERMAN. (14 February 1984)

EDITORIAL:
SOFTWARE SURVEY SECTION

In order to encourage the open exchange of information on software for use in analytical chemistry, TALANTA is to introduce a new Software Survey Section. Alongside the rapid penetration of computers into academic and industrial institutions has come a parallel increase in the number of scientists and researchers designing their own software. The existence of much of this software remains unknown to many who could greatly benefit from its use. We believe that it would be extremely useful to our readers to have such information made available, and that a professional journal is the best place for doing it. We therefore invite you to consider making a contribution to the Section.

The two-page questionnaire on the following pages is designed to assist you in reporting on software that you have developed or are in the process of developing. The information you supply will then be published; thus it will reach thousands of your colleagues who may benefit from your work and possibly offer suggestions for enhancement of your software. If you are interested, please complete the form and return it to our Computing Editor:

Dr M R Masson
Dept of Chemistry
University of Aberdeen
Old Aberdeen, Scotland

We do not intend to comment on or review the material submitted, which will be published "as received" (apart from any editing needed for clarity and uniformity) in order to expedite its publication. Any comments or suggestions you may have will be welcome. The Software Description Form will appear in all future issues.

ERRATUM

In the letter to the editor, on pages 233 and 234 in the March 1984 issue of *Talanta*, an error in interpretation led to an error in the letter. The second paragraph should read:

"Linear equations in four terms and three unknowns[3] can be used to evaluate the $p\underline{K}_a$ of a monoprotic acid:

$$\frac{[H]_i\underline{A}_i}{\underline{K}_a} - \frac{[H]_i A_{HR}}{\underline{K}_a} - \underline{A}_R = -\underline{A}_i$$

in which $\underline{A}_i$ is the absorbance of a solution containing a mixture of HR and R, $\underline{A}_{HR}$ and $\underline{A}_R$ are the unknown absorbances for pure HR and R respectively at a concentration equal to $[HR]_i + [R]_i$ for the solution measured, and charges are omitted for simplicity . . . "

In equations (2) and (3) and the line above them, ε_{HR} and ε_R should be replaced by $\underline{A}_{HR}$ and $\underline{A}_R$ respectively. In reference 3, Rossenblatt should be Rosenblatt.

NOTICE

1985 PITTSBURGH CONFERENCE
CALL FOR PAPERS

The Pittsburgh Conference takes great pride in providing a scientific forum for authors from diverse backgrounds—from the Nobel Laureate to the novice. We invite you to join our distinguished array of invited speakers in presenting papers at the 1985 Pittsburgh Conference and Exposition.

Papers may be contributed in all areas of the disciplines of Analytical Chemistry and Applied Spectroscopy.

Those authors wishing to present papers at the 1985 Pittsburgh Conference should submit four (4) copies of a 300-word abstract to:

Mrs. Linda Briggs, Program Secretary
Pittsburgh Conference, Department J-029
437 Donald Road
Pittsburgh, PA 15235, U.S.A.

The abstract should be complete and show:

a. The title of the paper.
b. The name of the author(s), the organization(s) in whose laboratory the work was done, and the address(es). Provide the COMPLETE mailing address of each author, including department and any other mailing code.
c. The name of the author who will present the paper must be underlined..
d. Sign and date the abstract page in verification that the paper and all material therein has not been published or previously presented.

The final data for receipt of abstracts is 15 August 1984. Abstracts received after this date cannot be guaranteed consideration for inclusion in the 1985 Technical Program.

Exposition of modern laboratory equipment

In 1984 the Modern Laboratory Equipment presented at the Conference totalled 636 exhibitors occupying 1607 booths and seminar rooms in which was displayed the latest equipment available in the areas of Analytical Chemistry and Spectroscopy. Anyone desiring to reserve exhibit space or to obtain additional information regarding the 1985 Exposition should contact:

Mr. Peter Castle, Exposition Chairman
Pittsburgh Conference
437 Donald Road
Pittsburgh, PA 15235, U.S.A.

PUBLICATIONS RECEIVED

Atomic Absorption Spectrometry: JOHN E. CANTLE (ed.), Elsevier, Amsterdam, 1982. Pp. xvi + 448 $97.75, Dfl. 210.

It is always interesting, when looking at a new text on atomic-absorption spectroscopy, to see what the author(s) feel they have to offer that makes their particular text different from the many already published. In this instance the book is really a collection of specialized reviews, drawing on the expertise of more than twenty contributors. The price paid is that there are substantial differences in quality and style, and inconsistencies in choice of units, from section to section. This is most noticeable in the figures, which often look distinctly "second hand". Moreover there is little cross-referencing. However these are minor criticisms, and the coverage of the selected topics in the applications section is generally good.

The first chapter in the book, one on basic principles, is disappointing. In several places a novice in the field could acquire ideas which are basically wrong. It might perhaps have been improved by stricter editing. Chapters 2 and 3, on instrumentation and practical techniques, are more helpful, but unfortunately devoid of references to the literature. Chapter 4, the applications chapter, is undoubtedly the most useful. The areas covered include water and effluents, marine samples, airborne particulates, foodstuffs, ferrous and non-ferrous metallurgy, geochemistry, petroleum products, glasses and ceramics, medicine, forensic science and miscellaneous chemicals. These sections contain much useful material, and generally, with two or three exceptions, include extensive references, at least to the pre-1978 literature. The index is, to put it politely, pathetically inadequate, and the reader will find the detailed contents pages far more useful.

If the book happens to cover your particular field of specialization in its applications section, then it is well worth reading. However, its future probably depends on purchase by libraries rather than by individual users.

MALCOLM S. CRESSER

An Introduction to Chemical Equilibrium and Kinetics: LOUIS MEITES, Pergamon Press, Oxford, 1981. Pp. xii + 549. Hard cover $75.00, £31.00; Flexicover $19.95, £8.95.

This book is the first of the Pergamon Series in Analytical Chemistry and is intended for first and second year students. It deals with the equilibria and rates of chemical reactions, along with the various methods for their study. It is beautifully organized and written with great clarity. Each of the fifteen chapters starts with a brief introduction, and every subsection begins with a summary of the material discussed. All chapters contain a number of worked mathematical problems, followed by some for the reader to solve.

The first chapter tells what the book is about, and the next two introduce chemical thermodynamics, equilibrium and kinetics in a simple but comprehensive manner. The next five chapters deal with different types of chemical equilibria and the study of reaction rates. These chapters are well written but could have been further improved by inclusion of more graphical representations. Chapter 9 discusses gravimetric and titrimetric analysis, right from sample preparation to the stoichiometric calculation of the results, and Chapter 10 deals with the mechanism of precipitation and co-precipitation, and also the various factors that affect the physical properties and the rates of formation and growth of precipitates. The next chapter deals with titration curves and contains a number of graphical representations of different chemical equilibria, and this makes the subject easier to understand.

Chapter 12 is on errors in scientific measurements. The author is successful in presenting the basic statistics in a simple way, a task which is often difficult to achieve. The next chapter, on activity and activity coefficients, is the best written in the book. It deals with the effect of ionic strength on activity coefficients and with the Debye-Hückel limiting law and its various extended forms.

The last two chapters deal with the most common techniques for studying chemical equilibria and reaction rates, viz. potentiometry and spectrometry, and convey the essentials necessary for a working knowledge of both techniques. In the chapter on potentiometry, however, the last of a detailed section on use of ion-selective electrodes is a notable omission, since these have become essential tools for the chemist working in the field of potentiometry.

Overall, in spite of a few printing errors, the book is well illustrated and informative. It successfully serves its purpose of introduction of chemical equilibria and kinetics to a beginner in analytical chemistry. The standard of printing and binding is good, and the price of the flexicover edition well within the reach of students.

MAHMOUD I. FAROOQI

Quantitative Analysis of Steroids: S. GÖRÖG, Elsevier, Amsterdam, 1983. Pp. 440. US $86.50 (U.S.A. and Canada); Dfl. 225.00 (Rest of World).

Görög's latest book provides a comprehensive and readable account of the quantitative aspects of the analytical methods currently used in the steroid field. All the major classes of steroids are covered in crisp and critical fashion, from the sex hormones and their metabolites (including conjugates), through corticoids, cholesterol and other sterols, the vitamin D group, bile acids, cardiac glycosides, sapogenins and ecdysones, to steroid alkaloids. Techniques covered range from the spectroscopic methods (ultraviolet, infrared, nmr, *etc.*) through chromatographic methods, particularly gas chromatography and high-pressure thin-layer liquid chromatography, to biochemical methods such as radioimmunoassay and ezyme immunoassay. Only the very recent chemiluminescence methods are omitted. In the discussion of gas chromatography the superior resolving power of capillary columns over packed columns for the profiling of complex mixtures is clear, but clean-cut comparisons for a given sample mixture are lacking. Sample preparation procedures for analysis of steroids from various types of biological fluids are covered in detail.

Thankfully, the book does not follow the recent sinister trend for review books to have only an author index (or at most an author index and a token subject index)—instead there is a most useful index of the substances dealt with.

ALAN B. TURNER

EDITORIAL

"THE EDITOR REGRETS...."

It is always a difficult and unpleasant task to reject a paper submitted for publication, and it is not easy to avoid offending the author(s). Nevertheless, standards must be maintained, for the sake of the author as much as the reader and the reputation of the journal, and papers that fall into the category of "futile" (see the Editorial in the February 1979 issue of *Talanta*) or are incorrect in their chemistry, or unacceptable for other reasons, must be firmly but politely rejected. Judging by the Editorial in the January 1984 issue of *Analytical Chemistry*, rejection can produce rather startling reactions from authors, presumably those most urgently in need of publications to support claims for tenure or promotion. Such authors might well reflect that besides the "publish or perish" situation, there is also "publish *and* perish" if the papers are of inadequate standard. Our policy in *Talanta* has always been to explain to the author exactly why his paper is not being accepted, and often to suggest ways in which the work might be improved. Sometimes we have gone so far as to edit the paper in order to help him if he decides to try his luck elsewhere. Some papers, however, are so poor that *no* journal can be found that will accept them. Very occasionally an author will have had a paper rejected by so many journals that he has forgotten which ones he has tried, and sends it back (unaltered!) to the journal he tried first.

We are glad to say that the problem of writing the rejection letter has now been solved, and by courtesy of *World Medicine* (where we found the solution on p. 45 of the issue for 21 January 1984) we can share the solution with our readers. The letter was said to be written by the editor of a Chinese medical journal, and reads as follows.

"Dear Dr. —,

We have read your manuscript with boundless delight. If we were to publish your paper it would be impossible for us to publish any work of lower standard. And as it is unthinkable that, within the next thousand years, we shall see its equal we are, to our great regret, compelled to return your divine composition, and to beg you a thousand times to overlook our short sight and timidity."

Now who could want a better letter than that (or even write one)?

PUBLICATIONS RECEIVED

Soil Analysis—Instrumental Techniques and Related Procedures: K. A. SMITH (ed.), Marcel Dekker, New York, 1983. Pages 562 + xii. SFr. 198.

This text goes a long way towards filling a conspicuous gap in the literature of analytical chemistry, in providing a useful and comprehensive account of most of the major instrumental techniques that find widespread use in soil science. Eleven chapters from 16 established authorities cover atomic-absorption and flame emission spectroscopy, ion-selective electrodes, automation, XRF, isotope techniques (including ^{15}N determination), neutron-activation analysis, gas chromatography, and high-pressure liquid chromatography.

A consistent style has been maintained throughout the book. Each chapter covers fundamental principles, instrumentation and practical aspects of analysis, with many references to the original literature up to 1978. Unfortunately, in most of the contributions very little more recent work has been included, creating the impression that the book was a long time in the writing, with sometimes reluctance to update contributions.

Nevertheless the end-product has benefited from a wealth of first-hand experience, and provides excellent coverage of the topics selected. The material is presented at a level which makes it useful to the complete newcomer to a technique, or to experienced users who simply require more background information. The book will be useful both to soil scientists needing to use analytical techniques and to analysts whose work includes soil samples.

The title of the book is rather more all-embracing than the contents, which are primarily concerned with elemental analysis. Instrumental methods of mineralogical analysis are therefore excluded. This must have been necessary to keep length and costs at a reasonable level. It would, however, still have been possible to write another volume of the same length covering topics which are omitted, including for example conductivity measurement and other electrochemical techniques, ion analysers, autotitrators, sub-sampling techniques, *etc.* Generally the book can be strongly recommended.

MALCOLM S. CRESSER

Recent Advances in Capillary Gas Chromatography, Volumes 1–3: W. BERTSCH, W. G. JENKINS and R. E. KAISER (eds). Hüthig Verlag, Heidelberg, 1981–2. Vol. 1, pp. XII + 592, DM 75.00, $38.00; Vol. 2, pp. XII + 557, DM 75.00, $38.00; Vol. 3, pp. XII + 590, DM 75.00, $38.00.

These volumes are published as a trilogy reflecting the worldwide growth of the development of modern capillary chromatography and its application to a very wide range of chemical problems. It is a particularly unusual series in that it republishes papers already in print in the *Journal of High Resolution Chromatography and Chromatographic Communications*. However, rather than giving a wasteful proliferation of mediocre information the editors have wisely and carefully selected papers which reflect the major innovations made in capillary gas chromatography during the years when this technique took a quantum step forward. This selection and exclusive focus on capillary chromatography will make this series invaluable to the legion of modern chromatographers. Such a dedicated series is very timely and should do much to dispel any lingering concern, not in academia, but in industrial analytical services, about the reliability and accuracy of analyses by capillary gas chromatography.

The three volumes have a similar format of subject areas, each volume covering the development of the subject chronologically. There are eight chapters in each volume and each begins with a series of reviews. The review subjects covered are: (Vol. 1) Techniques in Two Dimensional High Resolution Gas Chromatography (HRGC); Performance of Gas Chromatograph (GC) Detectors with Glass Capillary Columns; Twenty years of Glass Capillary Columns; Practical Capillary GC—a Systematic Approach; (Vol. II) Evolution and Application of the Fused Silica Column; (Vol. III) Glass Surfaces as Support Phases in GC; Analysis of Drugs and Related Compounds; Surface Modification in Glass Capillary GC.

There are 4 papers on Theoretical Considerations, 39 covering the Preparation, Deactivation and Repair of Columns, and 10 dealing with Testing, Selection and Efficiency of Columns. The section covering Column Installation, Conversion of Apparatus for Capillary GC has 13 papers, Sampling; Special Conditions and Techniques of Sampling has 18, Applications has 48 and the final section on Detection Conditions: Separation and Detection Optimization and Data Handling has 8.

The series spans some 1700 pages and encompasses the work of 240 authors, who collectively cover a number of major themes which encourage the reader to adopt a lateral approach to each subject. There is the continuing search for the utopian column having maximum activity and efficiency for every conceivable sample type. One fruit of this apparently endless search has been the successful emergence of the polyimide-coated fused silica column, which now has cross-linked (chemically bonded) phases to enhance stability and prevent liquid phase from being stripped by the solvent during injection. The development, rigorous testing and applications of these columns have been fully documented and comparisons made with their glass predecessors. Considerable attention has also been given to methods of sample introduction, with a number of designs for on-column injection highlighting the need for a "cold" injection, and expansion of the various hypotheses advanced to explain cold-trapping and solvent effects. There are a number of sophisticated separation procedures, involving column switching, two-dimensional chromatography and multidetection techniques, some of which are no more than an academic exercise, while others have already found some practical everyday use.

Volume 3 contains the cumulative author and subject index for the series, while the first two books have just their own indexes. Such a trilogy will be ideal for scientists new to the field. The set should become well thumbed handbooks for the practising chromatographer and an excellent review source for future authors developing these subjects.

D. E. WELLS

PUBLICATIONS RECEIVED

Computers in Analytical Chemistry: PHILIP BARKER, Pergamon Press, Oxford, 1983. Pages xvi + 472. £37.50, $75.00.

Although some of its chapters contain well-presented useful information, I feel that this book as an entity is not totally satisfactory, and that a more appropriate title might have been chosen, since most of the emphasis of the book is on the use of computers in association with analytical instrumentation. The long-established use of computers for calculations and predictions of classical analytical equilibria is scarcely mentioned: the review by Childs *et al.* (*Talanta*, 1969, **16**, 629, 1119), the program HALTAFALL (*Talanta*, 1967, **14**, 1261) and the book by Dyrssen, Jagner and Wenglein (*Computer Calculation of Ionic Equilibria and Titration Procedures*, Almqvist and Wiksell, Stockholm, 1968) are not referred to at all. It is rather unusual to make this criticism, but I think that the author has placed far too much emphasis on very recent literature, to the detriment of earlier material.

As an analytical chemist, I found the first three chapters, What is Analysis?, Analytical techniques, and Instrumentation, almost totally superfluous. They made me wonder just who the author wrote the book for. Chapter 4 gives a good brief description of computers and their function, but I felt that it was rather too brief for the real novice. I also felt that the author had been rather selective in his choice of microprocessors and microcomputers for detailed consideration. For example, he does not mention the Apple II computer, which has found very wide application.

Chapters 5–8, on Data Collection, Interfaces and Principles of Interfacing, Communication Channels, and Automation in the Laboratory, I found much more satisfactory—the real meat of the book. The chapter on interfacing gives a great deal of detailed information, and is likely to be the most useful one to an analytical chemist who is actually trying to hitch up his instruments to computers.

Of the remaining chapters, Chapter 9 gives a rather superficial picture of Data-Processing Methods, and Chapter 10 gives a useful introduction to Data Bases and Data Centres. Chapter 11, Information Services, could well have been omitted, since the topic has been discussed in detail elsewhere (*e.g.*, by Ash and Hyde, *Chemical Information Systems*, Horwood, Chichester, 1974) and is one with which all chemists should be concerned, not just analytical chemists. The final chapter, on Computer Networks, is probably timely, but much of the detailed information would be of more use to computer experts than to the average working analytical chemist.

MARY MASSON

Metal Vapours in Flames: C. TH. J. ALKEMADE, TJ. HOLLANDER, W. SNELLEMAN and P. J. TH. ZEEGERS. Pergamon Press, Oxford, 1982. Pages xxii + 1033. £50.00, $95.00.

The book is devoted to all aspects of metal-vapour behaviour in combustion flames. It contains a great deal of material of interest for those who work in spectrochemical analysis, plasma physics and high-temperature chemistry of metal compounds. The volume is very helpful as a summary of the multitude of works scattered throughout the literature on emission, absorption and fluorescence spectroscopy. It was a titanic work for the authors to systematize so huge and so varied an amount of material. The tremendous merit of Professor Alkemade is that he managed to organize for the task a group of experts who actively research in this field.

It must be mentioned that the professional interests of the authors in emission and fluorescence spectroscopy manifest themselves in the scope of the topics covered. As a result the authors pay relatively small attention to the chemistry of the carbon-rich flames, which are of little interest for emission and fluorescence, and the two-line atomic-absorption method of temperature measurement is altogether out of the scope of the book. At the same time, the authors' own rich experience has made it possible to select the most reliable and proved data for the book.

This has resulted in a volume of more than 1000 pages. The literature cited comprises about 2000 works. Chapters II and II deal with fundamentals of the structure and interaction of atoms and molecules, and general experimental methods which give rapid information about the material in question. The authors have avoided excessive use of mathematical expressions, which is why the book is of great value for both the expert and the beginner in the field. The topics are covered very thoroughly and the practical experience of the authors is evident throughout the volume. The system of cross-references throughout the text and the detailed subject index (including about 3500 items) make the book the real encyclopaedia on laboratory flames.

Undoubtedly, the book should be a part of the personal libraries of theoreticians and experimentalists interested in the fundamentals and the analytical application of flame spectroscopy.

B. V. L'VOV

TALANTA ADVISORY BOARD

The Editorial Board and the Publisher of *Talanta* take pleasure in welcoming the following new member of the Advisory Board of the journal.

KAREL ŠTULÍK

They also wish to record their sincere thanks for the help given by

R. PŘIBIL   H. SANKE GOWDA

who retire from the Advisory Board. They are particularly grateful to Dr. Přibil, who has been associated with *Talanta* from its inception.
Dr. Štulík was born in Kolín, Czechoslovakia in 1941, and graduated in chemistry in 1963 from the Faculty of Technical and Nuclear Physics, at the Czech Technical University in Prague. His postgraduate studies in electroanalytical chemistry at the J. Heyrovský Polarographic Institute, Czechoslovak Academy of Sciences, Prague, from 1964 to 1968 led to his Ph.D. degree in 1967. Since then he has been a research worker and lecturer at the Department of Analytical Chemistry, Charles University, Prague, except for the year 1968–1969, which he spent as assistant lecturer in the Department of Pure and Applied Chemistry, University of Strathclyde, Glasgow, Scotland. His research interests include polarography, electrochemical stripping analysis, ion-selective electrodes, and combination of electrochemistry with separation techniques, chiefly HPLC. He has published about 80 research and review papers and several university texts. He is co-author of "Electrochemical Stripping Analysis" and "Analysis with Ion-Selective Electrodes", published by Ellis Horwood in 1968 and 1969; the former has been translated into Russian and published by Mir, Moscow (in 1980). He is co-author with Professor J. Koryta, of "Ion-Selective Electrodes", to be published by Cambridge University Press. He is a member of the Czechoslovak Chemical Society.

ERRATA

In the paper by P. A. Michalik and R. Stephens, *Talanta*, 1983, **30**, 819, the symbol $\triangledown$ should be replaced by $\triangle$ in the captions of Figs 2, 3 and 5.

In the paper by D. F. Grant and D. Eastwood, *Talanta*, 1983, **30**, 825, the following corrections should be made.

In Fig. 6 the y-axis should be labelled "Absorbance".

In Fig. 7 the labels "1.0–2.0(O.D.)" and "0–1.0(O.D.)" in the middle of the scales on the left- and right-hand y-axes should be deleted, and so should the second sentence in the caption.

PUBLICATIONS RECEIVED

Liquid Chromatography in Environmental Analysis: Edited by JAMES F. LAWRENCE. Humana Press, Clifton, New Jersey, 1984. Pages xiv + 382. $55 ($65 outside USA).

Success in chromatography comes with experience: acquiring the instrument and learning the theory are just the first steps. It can help to work alongside an old hand and be guided round some of the pitfalls, but not every beginner is so fortunate. So if you are thinking of setting up for HPLC this book might be the next best thing. Individual chapters are written by specialists, *e.g.*, on Polycyclic aromatics, Pesticide residues, and Surfactants. Probably fewer people will intend to determine trace metals by HPLC, but the review here is certainly welcome. The chapter on ion chromatography should please many readers, and remind them that there *is* a choice of columns for difficult combinations of anions, as in sea-water or acid extracts. Other chapters balance the picture by covering Quality assurance programmes, Injection and switching, and HPLC as a clean-up technique, but basic theory and instrumentation are not discussed. I was surprised to find so little attention given to HPLC/MS considering that this combination is now commercially available. However, what is covered is done in a readable text with many references from the literature up to 1981, and frequent inclusion of experimental details: recommended.

IAIN L. MARR

Reversed Phase High-Performance Liquid Chromatography: ANTE M. KRSTULOVIĆ and PHYLLIS R. BROWN. Wiley, New York, 1982. Pages xi + 296. $27.00.

The choice of title for this book—and therefore the bias of the subject matter—strikes me as slightly odd. But then, just as Molière's character was surprised to find he had been speaking prose all his life, we may need to be reminded that most HPLC users are actually using RPLC. Would it not have been better to include an additional section on columns and another on applications of normal HPLC to complete the picture? But let us look at what is included. I find this a very lucid account of HPLC—a combination of theoretical and practical aspects with much useful information for the newcomer intending to set up for HPLC. On the other hand I wonder why the tabular comparison of detection systems covers only polarographic, conductimetric and fluorimetric devices, so that they are not so easily seen in relation to the very widely used UV and RI systems. And should not there be some mention of element-selective detection by, *e.g.*, plasma spectroscopy, and of diode-array "instant-scan" spectrometers which are now available from several manufacturers? Attention is, however, given to columns, solvents, and the difficulties of characterizing unknown peaks, and a final chapter summarizes a wide range of biochemical applications of RPLC, serving to illustrate the scope and power of the technique. There is much to commend in this book: possibly the omissions are compensated by the smooth continuity of the text resulting from close co-operation between the authors, which has resulted in a readable and useful book.

IAIN L. MARR

Solvation, Ionic and Complex Formation Reactions in Non-Aqueous Solvents: K. BURGER, Elsevier, Amsterdam, 1983. Pages 286. DFR 145; $61.75

This rather specialized monograph is concerned with properties of solvents and with the various interactions of solvents with various kinds of solutes. Thus, solvent–solute interactions, donor–acceptor interactions, effects of solvents on metal complexes in solution, effects of solvents on kinetics and mechanism of co-ordination reactions, and interactions in solvent mixtures are some of the topics included. A survey of the various theories of such systems is given, but the main emphasis of the book is on experimental methods for study of complex systems and for the characterization of solvents. (Sixteen possible techniques for study of complex systems are discussed.) There is an extensive wide-ranging bibliography.

MARY MASSON

The Practice of Ion Chromatography: F. C. SMITH, JR. and R. C. CHANG, Wiley, New York, 1983. Pages xxiv + 218. £43.95.

This is an outstanding "how-to-do-it" book, written by two very experienced workers in the field. It traces the history of Ion Chromatography from the original Dow patents in 1975, which led to the exploitation by Dionex of suppressor IC, and also the later development of non-suppressor systems. The merits of suppressor and non-suppressor IC are discussed without bias, and the various sorts of instrumention that can be used are described. The rest of the book deals with practical IC, giving first of all standard conditions for the various variants of the technique, then offering suggestions as to the procedure for finding conditions for some particular problem. There is a useful discussion of chromatogram anomalies, such as the so-called "water dip". The chapter on applications gives some idea of very wide range of applications of IC that have been developed, and should be of considerable use to the potential IC user (331 references are included).

MARY MASSON

Wilson and Wilson's Comprehensive Analytical Chemistry, Vol. XV: G. SVEHLA (ed.). **Methods of Organic Analysis:** L. MAZOR, Elsevier, Amsterdam, 1983. Pages xxii + 529. DFl 325, $138.25.

As befits a title in "Wilson and Wilson", this book might well have been entitled "Comprehensive Organic Analysis", because of the wide scope of the contents. The main chapters cover the topics "Preliminary Tests", "Qualitative Elemental Analysis", "Determination of Physical Constants", "Qualitative Functional Group Analysis", "Micro Reactions for the

Detection of Certain Important Organic Compounds", "Instrumental Methods in Organic Chemical Analysis", "Quantitative Elemental Analysis", "Quantitative Functional Group Analysis", and finally "Automatiac Analysis". The chapter on "Instrumental Methods" is short and gives only a general introduction to the use of these methods. Thus, most of the book is devoted to review, discussion, and detailed descriptions of chemical methods of qualitative and quantitative analysis. Is is difficult to say much more about a book so packed-full of useful information, except perhaps to recommend that a copy should be available for use in every organic analytical laboratory. The one disappointing feature is that the only reference I could find after 1976 was a 1979 one to the author's own work.

MARY R. MASSON

PUBLICATIONS RECEIVED

Computer Applications in Chemistry: S. R. HELLER and R. POTENZONE, JR., (eds.), Analytical Chemistry Symposia Series, Vol. 15, Elsevier, Amsterdam, 1983. Pages xii + 394. US$89.25. Dfl.210.

It is very difficult to give a general review of a book like this, covering as it does such a wide range of topics as Macromolecular Structure Representation, Computer Networks, Computerized Standard Reference Data, Chemical Information Systems, Structure Elucidation, and Computer-Aided Drug Design. The seventeen full papers included were presented at the 6th International Conference on Computers in Chemical Research and Education (ICCCRE), held in Washington, DC, July 1982. Also included are the abstracts of 63 poster papers, and a list of those attending the meeting. The most novel paper included is the one on "The Chemistry in Future Molecular Computers", by F. L. Carter, and this paper is also the one that contains the most "meat". Many of the other papers are very general in content. I was impressed, however, by the introductory paper, on "The Neglected Ingredient in Chemical Computer Systems". In this the author, E. Hyde, discusses the problems met by non-chemists seeking chemical information from chemical computer databases. He suggests that chemists use a sign language and unpronounceable words to maintain a mystique that non-chemists cannot penetrate. He criticizes the *Chemical Abstracts* computer files, in that they are convenient for the indexer but not for the user, be he a chemist or non-chemist, who is interested in relationships between compounds. He points out the futility of the CA Registry Numbers, but then goes on to suggest how improvements might be made. I cannot recommend this volume for purchase by individuals (other than conference participants), but it probably does deserve a place in most chemical libraries.

MARY MASSON

Environmental Chemical Analysis: L. L. MARR and M. S. CRESSER, International Textbook Company, Glasgow, 1983. pp. xii + 258. £21.00.

This book is an effort to compile and present the complex of knowledge on a variety of analytical methods in such a form that it will be useful to students, teachers, analysts and even experts in other fields. It demonstrates a new approach to teaching analytical chemistry and shows how chemical analysis can yield reliable data which are valuable to other scientists. The authors underline the difficulties facing the analyst who deals with environmental chemical analysis and show how he chooses methods and techniques appropriate to the situation. They gave some insight not just into the working tools of the environmental analyst, but also into the types of problems he may be called upon to help in solving. The authors have also tried to indicate why a certain line of approach or choice of methods may be needed for attacking the problem in hand.

The methods developed and the results obtained by analytical chemists are used by many other scientists. This book will give them some background knowledge and appreciation of the subject to avoid possible pitfalls or errors. It will help all readers, both practitioners and customers, to get most out of their analysis by taking time to think, to check and then to analyse.

A. KHALONIN

Practical Absorption Spectrometry: A. KNOWLES and C. BURGESS (eds.), Chapman and Hall, London, 1984. Pp. xxii + 234. £18.00.

The Ultraviolet Spectrometry Group have produced another invaluable volume in their series on Techniques in Visible and Ultraviolet Spectrometry. The book is both a guide to the practice of absorption spectrometry, and a succinct account of the relevant theory. Much of the information provided is not found in standard texts nor in the manufacturers' handbooks, yet it is vital for the user, in order that instruments can be used correctly and to their best advantage. A copy of this book should be in every laboratory that uses absorption spectrometers.

MARY MASSON

Electrochemistry: Principles, Methods and Applications: ALLEN J. BARD, LARRY R. FAULKNER; R. ROSSET and D. BAUER (eds.), Masson, Paris, 1983. pp. XXX + 791. FFr. 350.

At the present time the importance of electrochemistry in solving various scientific problems and for characteristic chemical systems in research areas is rapidly increasing. The present book, now in French translation, will prove to be very useful for modern education in the field of electroanalytical chemistry. There is a full systematic treatment of both the fundamental theory of electrochemistry and the basic aspects and techniques of up-to-date electroanalytical methods, complete with mathematical interpretations and equations.

The book contains 14 chapters and 3 appendixes. Chapters 1–4 cover the general thermodynamic and kinetic properties of electrode processes. The main attention is focused on the theoretical grounds of electrochemistry, which are useful for mastering various electrochemical methods, in particular the problems of mass transfer at the electrode–electrolyte interfaces and the kinetics of electrochemical reactions at electrode surfaces.

Chapters 6–10 deal with the theory of modern electrochemical methods, including micro- and macro-electrolyses, hydrodynamic and impedance methods, methods with voltage- and current-control *etc.*

Chapters 11 and 12 give details of electrochemical reactions coupled with chemical reactions in a homogeneous phase. It gives the treatment of the double electrical layer structure and adsorption processes on the electrodes.

Chapters 13 and 14 describe in detail various electrochemical techniques developed or widely used during recent years.

Unlike other books on electroanalytical chemistry it devotes special attention to the interpretation of all electrochemical processes with the help of exact mathematical descriptions. Complete references and also special exercises and chemical tasks are given for each chapter, helping successful assimilation of the contents.

This book is highly recommended to students and teachers at universities and institutes. It contains much useful information and should be of interest to all chemists who use electroanalytical methods in research and would like to explore the practical possibilities of electrochemistry.

L. K. SHPIGUN

PUBLICATIONS RECEIVED

Treatise on Analytical Chemistry, 2nd Ed., Part I, Vols. 3, 10, 12: I. M. KOLTHOFF and PHILIP L. ELVING (editors), Wiley/Interscience, New York, 1983–1984. Volume 3: pp. xxi + 592; £66.50. Volume 10: pp. xxvii + 533; £61.75. Volume 12: pp. xxvii + 603; £71.25.

These three volumes continue the second edition of "Kolthoff and Elving", and maintain the standards now expected of the series as a matter of course. There are certain surprises, however. For instance, the reader of Volume 3 may wonder whether some of the authors had read Volume 2, since they discuss certain aspects of solution of equilibria without cross-reference to Högfeldt's chapter there, on graphical representation of equilibria, and do not seem to have heard of Ringbom's classic work on complexation effects and use of conditional constants *etc.*, or at any rate do not choose to mention it. Nevertheless, the volume contains authoritative and useful accounts of redox equilibria, the application of surface chemistry in analysis, precipitation methods, solubility (although some comment on the effect of pressure on the solubility of solids in liquids would have been a welcome addition), and the role of reactive groups in reagents.

Volume 10 (with Dr. M. M. Bursey as associate editor) covers proton and carbon-13 nuclear magnetic resonance, electron spin resonance and nuclear quadrupole resonance and their applications, Mössbauer spectroscopy and secondary ion mass spectrometry (SIMS). Volume 12 (with C. B. Murphy as associate editor) deals with some thermal techniques used in analysis, ranging from temperature measurement, constant-temperature baths, calorimetry, thermochemistry, and thermal analytical methods, to evolved gas analysis, measurement of thermal expansion, electrothermal analysis (based on the effect of temperature on conductivity) and thermoacoustic methods (based on the effect of temperature changes on sound waves transmitted by the sample).

As with the other volumes in the second edition, it at once becomes evident that the last two decades have seen an extraordinarily rapid and fruitful development of physical and instrumental methods of analysis, many of which owe their existence as routine methods to the introduction of reliable and sensitive transducers systems. As Professor Pimentel observed at the 1984 Pittsburgh Conference, we now have the tools available for exploring systems that were hitherto completely inaccessible to experimentation, and the resulting greater understanding of the fundamental processes of physics and chemistry should allow us to make greater progress in industry and technology. Such progress is urgently needed in view of the ever more rapid depletion of natural resources by that most rapacious of animals—man.

These volumes, together with the others in the series, will undoubtedly play an important role in these future researches.

R. A. CHALMERS

Aquametry, 2nd Ed., Part II: DONALD MILTON SMITH and JOHN MITCHELL, JR., Wiley/Interscience, New York, 1984. Pages xii + 1352. $165.00

The long-awaited final volume of this monumental treatise on the determination of water has at last appeared, though unhappily after the death of one of its authors (to whom it is dedicated). This volume alone is more than twice the size of the first edition of the whole work, which shows the great strides made in advancement of the subject. It deals with the measurement of water by means of capacitance determination (259 pages), conductivity measurements (255 pages), coulometry (601 pages) and micrcoulometry (218 pages). The book is full of practical hints and tips, critical and informed comment on the extraordinarily widespread and varied literature, and is written in a most lucid and and refreshing style. It should be made required reading for all authors of papers submitted to the scientific journals—they could learn so much from it about conciseness achieved without loss of information. Together with Parts I and III it is an essential part of any chemical library worthy of the name, and well worth the price.

R. A. CHALMERS

Mass Spectrometry Advances 1982, Parts A,B and C,D in two volumes: E. R. SCHMIDT, K. VARMUZA and I. FOGY (editors) Elsevier, Amsterdam, 1983. Part A XLI + 379, Part B XVII + 544, Part C XVII + 544, Part D XVI + 461; $361.75.

This is a record of the 9th Triennial International Mass Spectrometry Conference held in Vienna 30 August–3 September 1982. The great values of such published accounts of scientific conferences is that they provide an accurate picture of the state of the discipline under review at the time of the meeting. At the most elementary level, the size of the conference is a reasonable indication of the well-being of the scientific enterprise. By this criterion the technique of mass spectrometry is still expanding and attracting interest, the accounts of its three-yearly conferences having grown from the modest books of the fifties to the substantial two-volume work reviewed here.

All the familiar aspects of the subject are covered in a series of plenary lectures collected together in Part A. The analytical possibilities of the technique, both qualitative and quantitative, and its use in the determination of molecular structure are included, together with the applications to environmental and geological studies. Other aspects under discussion range from isotopic analysis to data processing. Part B deals with instrumentation and reveals the success which has been achieved in devising methods of ionizing large molecules and of recording their mass spectra. Another preoccupation has been with the coupling of mass spectrometry with chromatographic techniques such as HPLC to provide ever more versatile and sensitive analytical systems. Advances in the construction of "tandem" mass spectrometers and triple quadrupoles and their application to specific problems are also discussed. Theoretical aspects of ionization and dissociation are given some attention and there are a large number of papers concerned with the newer methods of producing both positive and negative ions from a wide variety of samples. In particular, the analytical potentialities of fast-atom bombardment ion sources, laser desorption, pyrolysis and secondary-ion mass spectrometry are well illustrated in many contributions. Some authors have devoted their attention to the physical chemistry of ion fragmentation and kinetic energy release and to the interactions

of ions and molecules. In contrast to previous meetings, the interest in the analysis of solid samples by spark-source mass spectrometry has waned and there are comparatively few papers describing specific investigations.

The subject of the mechanism of the fragmentation of positive ions which has proved so fascinating to organic chemists is represented in Section C by the largest number of papers and in addition there are many contributions detailing the processing of such information by computers.

Part D is exclusively confined to applications of the technique and it is an indication of the ever widening uses of mass spectrometry that this part contains no less than 100 papers covering the fields of gas analysis, biochemical problems, environmental studies, geological specimens and nuclear chemistry. This is an excellent production and is recommended to the libraries of all scientific institutes, particularly those where analysis by physical methods is a prime concern.

J. R. MAJER

The Analysis of Gases by Chromatography: C. J. COWPER and A. J. DEROSE. Pergamon Press, Oxford, 1983. Pages xii + 147. £14.00

From time to time a book comes along which is so much needed that it finds a space empty on the reader's bookshelf waiting for it. This is such a book, though to be fair, the space has not been totally vacant since Jeffery and Kipping's monograph has been the gas analyst's pocket chromatography book for many years and will remain alongside this newcomer. The marvel is that two people who have spent so much time doing gas analyses have found the time to write about their subject, because only experienced practitioners can make the contribution which Cowper and DeRose are offering us.

The gas analyst is accustomed to solving each new problem from scratch: how to sample, how to match the plumbing, how to condition the column (after deciding which stationary phase), how to prepare the reference standards how to quantify the results. This volume combines all this blended with recent applications from the literature and spiced with those invaluable tips which are learned only by long experience. The gas analyst is of course also accustomed to using other than chromatographic techniques, and this book frequently points out that gas chromatography may not be the best approach for some particular problems.

I must confess to having been surprised by the statement that "measurement of a major component by difference is considerably more precise and usually more accurate (than direct measurement)" since I have been accustomed to quoting a value by difference only when the customer likes the results to add up to exactly 100%. Perhaps the authors might have stressed that the difference method works when it is known what all the impurities are likely to be. But this is after all a small quibble and the authors have the results to prove their point.

Do you know what might give rise to a small peak between nitrogen and methane for a sample of contaminated air run on a 5A molecular sieve column? The cost of this book will be a cheap price to pay for at least one colleague of mine who has this problem, and for anyone concerned with gas analysis the purchase of this book must get high priority.

IAIN L. MARR

Sample Preparation for Gas Chromatographic Analysis: W. G. JENNINGS and A. RAPP, Hüthig Verlag, Heidelberg, 1983. Pages 104. DM 46.00.

This small monograph sets out to describe sample preparation for gas chromatography, but in only 90 pages or so, it can hardly be expected to cover such a wide subject completely. What it does do, and that very well, is to give a lucid and useful account of direct injection procedures, and some isolation and concentration techniques. The chapter on direct injection I found very good, covering split, splitless, on-column and various headspace techniques. The isolation and concentration chapter I found less satisfactory, largely because the authors give very little practical detail of the more novel and hence interesting techniques. The final short chapter on specific application I felt did not match the standard of the rest of this small book, and is extremely sketchy in its treatment. For me, the most useful 7 pages in the 22 of this section was the reproduction of the NIOSH/OSHA air sampling standards. The book is well produced and bound, and is pleasant to handle and to read. It is marred by a few proof-reading errors; I noted one point where μl is used where ng is meant and another where an equation as written would be acceptable as a statement in BASIC but is a nonsense as a statement in simple mathematics. There is a consistent misuse of "analyte" to mean the solution being analysed, and a description of detection limits as lower when poorer is meant, but these are minor flaws in an otherwise nice little book.

R. C. ROONEY

PUBLICATIONS RECEIVED

Ion-Selective Electrode Reviews, Volume 3: J. D. R. Thomas (editor), Pergamon Press, Oxford, 1982. 257 pages. $62.00

Volume 3 continues this now well-established series of reviews on ion-selective electrodes, edited by one of the most prolific authors in the field. The volume under scrutiny contains five chapters, a compilation of recent literature, a couple of book reviews by the editor, and indexes. The five chapters are primarily concerned with analytical applications of electrodes and will be most appreciated by professional analysts responsible for developing and improving the use of electrodes in their own special areas.

In the first chapter Birch and Cockcroft open with some general comments on surfactant analysis with a view to introducing immobilized liquid membranes, mostly supported in inactive poly(vinyl chloride), containing a surfactant complex as sensor. Details are given for the preparation of several types and the effects of different constituents are described. Dip, flow and coated-wire electrodes are dealt with. The discussion principally concerns their use as titration end-point indicators and it is clearly proved that the results obtained are the same as those given by the conventional two-phase dye-indicator method. Finally, a number of practical cases are dealt with in which surfactants at high and at trace concentrations have to be determined. The reviewer is not aware of any more complete or recent review of this topic.

The second and fifth chapters are closely related. Midgley deals with the detection limits of ion-selective electrodes and Moody and Thomas consider ways of extending the linear range. Both chapters make it evident that there is no substitute for painstaking care in seeking ideal responses from electrodes. Midgley includes a scholarly account of the definition and determination of the lower detection limit. He gives a theoretical analysis of the factors that affect the limit and this shows how to work reliably close to the limit and how to improve matters in the future. Moody and Thomas describe in a practical way what can be done to extend the linear range of the main types of electrodes currently in use. Both chapters contain a great deal of information on how to get the best out of particular electrodes and so will be welcomed by users.

A chapter on the use of inorganic ion-exchangers in electrodes, by Coetzee, shows that, despite a good deal of hard work, rather few have been found useful. These are mostly heterogeneous membrane electrodes in which the inorganic ion-exchanger is embedded in a polymeric binder. Their main value is as end-point indicators in titrations.

Kakabadse has reviewed his own work and that of others on ion-selective electrodes used in non-aqueous and mixed aqueous and non-aqueous solvents. It appears that, given some precautions, inorganic and glass electrodes will function well in such solvents although liquid and polymeric membrane electrodes usually will not. There are, however, many incompletely understood changes in the response characteristics with changes of solvent composition, and these limit the range of uses in non-aqueous media. This is a long chapter with 242 references and covers many individual electrodes as well as discussing wider issues.

Finally, Moody and Thomas have listed systematically 40 pages of new titles in the literature on ion-selective electrodes but this must surely overlap with similar compilations in *Anal. Chem.*

This is not really a book for reading but it is a necessary addition to the analyst's library.

P. MEARES

Analytical Techniques for Heavy Metals in Biological Fluids: S. FACCHETTI (editor), Elsevier, for the Commission of the European Communities, Amsterdam, 1983.

Analytical Techniques for Heavy Metals in Biological Fluids contains a series of lectures given during a source held at the Ispra Establishment of the Joint Research Centre of the European Communities in June 1981, and updated in 1982. It is a most useful textbook both for people involved in research on the biomedical aspects of toxic (and/or essential) substances, especially the heavy metals, and for those concerned with the preservation of human health in industrial areas, where exposure of workers to toxic metals poses a real threat to their physical and mental well-being.

This volume gives an *instructive introduction* to the epidemiological, biological and medical aspects of human exposure to heavy metals, while also summarizing the analytical chemistry that underlies the results by means of which these are studied. It can be divided into two main sections, dealing with the biomedical and the analytical aspects of the subject, respectively. The first five chapters cover the biomedical aspects. A review of the objectives of and requirements for biological monitoring, as well as of the currently available monitoring possibilities, is incorporated in the description of WHO and CEC projects on biological monitoring in environmental and occupational health. Although the main focus is on biomedical features, attention is also paid to preanalytical quality assurance (sampling conditions. sampling materials, quality control, sample composition, spiking procedures, storage and transport guidelines), statistical analyses and laboratory performance. The most illustrative examples of biological indicators of metals in occupational health are presented in Chapter 3. Alessio and Bertelli elucidatively review a number of important concepts in the field of biological monitoring. Lead, cadmium and arsenic serve as examples to illustrate the indicators of *internal dose* (dose, exposure, accumulation) and of *effect* (indicators of critical effect, dose–effect relationship). The periodic surveillance of workers who are exposed to a noxious agent requires the use of biological indicators *in the field*. The pros and cons of screening tests are discussed.

The rationale for biological monitoring as based on the identification and quantification of toxic agents and the prevention of their impact on man requires the availability of accurate and precise analytical techniques, and knowledge of the pharmacokinetic and metabolic behaviour of the toxic agents, as illustrated by lead (Chapter 4) and arsenic (Chapter 5).

Two-thirds of the book deal with analytical aspects of biological monitoring of heavy metals. An excellent, comprehensive and critical update of mineralization procedures that can be used in the pretreatment of biological samples for biological monitoring, is given by Sansoni and Panday. It may be rather detailed for the biomedical profession, but to the analyst in charge of the quantification of metals and their metabolites, in general, it undoubtedly represents one of the most useful,

practical, complete and guiding parts of the book. It links the first part of the book to the second in a logical way. Analytical methods suitable for determinations on biological materials are selected on the basis of a number of criteria such as accuracy, precision, sensitivity, single or multielement analysis, cost, *etc.* Requirements for these will differ according to the specific purpose of a trace element analysis, as illustrated in Chapter 6 by lead, cadmium and nickel analysis. Spectrochemical techniques are used in the majority of cases in analytical practice. A very general introduction on spectrochemical techniques, their indicators of analytical performance (limit of detection, noise, analytical range) and the newer methodologies such as Zeeman correction, wavelength modulation and inductively coupled emission spectrosopy precedes a detailed evaluation of atomic absorption and emission spectrometric techniques for heavy-metal determinations. Voltammetry techniques, however, have a number of advantages over the latter. The best known example may well be the determination of lead in blood by inverse voltammetry or anodic stripping voltammetry (Chapter 11). Mass spectrometric isotope dilution analysis is dealt with in the Ispra course as a technique capable of determining absolute quantities of heavy metals.

The combination of a review on the state-of-the-art of sample pretreatment procedures with accounts of the fundamental aspects of different analytical techniques uncoveres the potentialities of specific methods that are currently available to both physician and analyst, and that are capable of guaranteeing the technical reliability, accuracy and precision that render biological monitoring of metals sensible. A number of errors leading to bias need to be excluded or accounted for. This necessitates a regular assessment of quality-control performance. In the last chapter of the book, the methods by which the latter is established are introduced to the reader.

MARLEEN VERLINDEN

NOTICE

FLOW ANALYSIS III—AN INTERNATIONAL CONFERENCE ON FLOW ANALYSIS

Birmingham, Great Britain, 5–8 September, 1985

The Third International Conference on Flow Analysis will be held in Birmingham, Great Britain, from 5 to 8 September, 1985. It will be organized by the Midlands Region of the Analytical Division of the Royal Society of Chemistry. The scope of the Conference will be similar to that of the Flow Analysis Conferences held in Amsterdam, 1979, and Lund, 1982, and will cover research on all aspects of continuous flow analysis. The scientific programme will consist of plenary and invited lectures, submitted research papers and posters, and working demonstrations. An exhibition of commercial equipment will be organized. As with the earlier conferences, proceedings will be published in a special issue of *Analytica Chimica Acta*.

The Conference will be held in the Department of Chemistry, University of Birmingham; accommodation will be available in the University Halls of Residence.

For further information, contact: Flow Analysis III, Dr. A. M. G. Macdonald, Department of Chemistry, The University, P.O. Box 363, Birmingham B15 2TT, England.

NOTICE

INTERNATIONAL SYMPOSIUM ON QUANTITATIVE LUMINESCENCE SPECTROMETRY IN BIOMEDICAL SCIENCES

An international symposium on quantitative luminescence spectrometry in biomedical sciences, sponsored by the Faculty of Pharmaceutical Sciences of the State University of Ghent, the National Foundation of Scientific Research (N.F.W.O.—F.N.R.S.), and the Ministry of Education, will be held in Ghent, Belgium, 3–6 September 1984, at the Farmaceutisch Instituut.

Contributed papers (20-minute lectures or poster communications) will cover the following topics: drug and bioanalysis by fluorescence and phosphorescence (LTP, RTP, micellar); fluorescence and chemiluminescence immunoassays; detection techniques in chromatography (fluorescence, RTPL, . . .); solid surface luminescence methods; chemical derivatization methods; luminescence applications and drug metabolism, clinical chemistry, biochemistry, pharmacokinetics, toxicology, ecology, protein tagging. The Conference will be conducted in English and no simultaneous translation will be provided. Facilities for technical exhibitions will be arranged.

Five plenary lectures will be presented by outstanding specialists in the field of quantitative luminescence spectrometry: R. P. Ekins (fluoroimmunoassays, Institute of Nuclear Medicine, The Middlesex Hospital Medical School, London, U.K.); R. W. Frei (detection techniques, Vrije Universiteit Amsterdam, The Netherlands); G. G. Guilbault (fluorescence techniques, University of New Orleans, Louisiana, U.S.A.); J. N. Miller (solid surface methods, University of Technology, Loughborough, U.K.); J. S. Woodhead (chemiluminescence immunoassays, University of Wales, Cardiff, U.K.).

Before and after the Symposium all correspondence should be sent to: Dr. W. Baeyens, Symposium Chairman, Laboratoria voor Farmaceutische Chemie en voor Ontleding van Geneesmiddelen, Rijksuniversiteit Gent, Harelbekestraat 72, B-9000-Gent, Belgium, from whom full details can be obtained.

FOREWORD

This "Paper Symposium" deals with selected analytical aspects of modern day clinical chemistry. Clinical chemistry is concerned with the analysis of biological specimens as an aid to the detection, diagnosis and management of disease. The precision and accuracy of analytical results is of vital importance and considerable attention is paid to quality control of analytical procedures (p. 851) and also to detecting possible inteferences, *e.g.*, by drugs (p. 937). Many different analytical methods have been utilized by the clinical chemist, and these include flow-injection analysis (p. 879), turbidimetry (p. 923), methods based on reagent strips (p. 863), and immunoassays employing labelled reagents. This last method, because of its great sensitivity, has assumed particular importance, and a range of labels have been used, *e.g.*, radioisotopes (p. 917), enzymes (p. 889), fluorophores (p. 909), and chemiluminescent molecules (p. 901). In the quest for new tests with improved sensitivity and specificity, clinical chemists have investigated many analytical methods. The penultimate paper in this symposium reviews a new development, the application of tandem mass spectrometry to clinical analysis.

L. J. KRICKA

NOTICE

FACSS 11
ELEVENTH ANNUAL MEETING
FEDERATION OF ANALYTICAL CHEMISTRY
AND SPECTROSCOPY SOCIETIES
SEPTEMBER 16–21, 1984
PHILADELPHIA MARRIOTT HOTEL
CITY LINE AVENUE AND MONUMENT ROAD
PHILADELPHIA, U.S.A

The Eleventh Annual FACSS meeting will once again be held in Philadelphia—this year at the Philadelphia Marriott Hotel. The Philadelphia Marriott Hotel is conveniently located on City Line Avenue at the edge of Philadelphia's Main Line. There is direct public limousine service from Philadelphia International Airport and express bus service from downtown Philadelphia. The Marriott has fine conference facilities with up to twelve meeting rooms, 705 accommodation rooms, seven restaurants and lounges, indoor/outdoor pools, platform tennis, and a games room. There is ample parking with no charge for any parking. The Marriott is within easy walking distance of the Bala Cynwyd Shopping Centre and several fine area restaurants.

SYMPOSIUM ON ANALYTICAL METHODS IN FORENSIC CHEMISTRY AND TOXICOLOGY

MIAMI, FLORIDA
29 April–2 May 1985

CALL FOR PAPERS

This symposium is sponsored by the American Chemical Society Division of Analytical Chemistry and will be held in conjunction with the 189th ACS National Meeting in Miami, Florida (28 April–3 May 1985). The scientific programme will comprise invited lectures and contributed papers dealing with the state-of-the-art of analytical methodology in forensic chemistry and toxicology. Topics such as the following will be covered: novel optical and spectroscopic methods, analytical separation and chromatographic methods; electro-analytical methods; biological and immunological methods; automated systems; computer-aided methods; luminescence methods; electrophoresis; drug analysis; explosives analysis; gunshot residue, arson and bloodstain investigations; trace-evidence detection; other recent advances in forensic analytical chemistry and analytical toxicology.

You are invited to submit abstracts for presentation. Papers submitted for consideration may be reviews or original research papers. Abstracts (150 words on ACS standard abstract forms) should be sent to Dr. M. H. Ho, Department of Chemistry, University of Alabama in Birmingham, Birmingham, Alabama 35294, phone 205-934-4747, by *November 30, 1985*. Publication of the proceedings as a hard-cover book in the ACS Symposium Series is planned.

ISM-10
10th INTERNATIONAL SYMPOSIUM ON MICROCHEMICAL TECHNIQUES

ANTWERP, BELGIUM
25–29 August 1986

This Symposium is the next in the series of triennial conferences, the last three of which were held in Amsterdam (1983), Graz (1980) and Davos (1977). As with the preceding Symposia, ISM-10 will cover both pure and applied micro- and trace-analysis. Special attention will be paid to the application of modern techniques such as microbeam analysis methods. A special workshop on laser microprobe mass analysis is planned, and a special session in co-operation with the Association of Official Analytical Chemists will deal with trace-analysis of food. The Symposium language will be English, and no simultaneous translation will be provided. Contributions for presentation in either oral or poster sessions are invited. A second announcement will appear early in 1985, and can be obtained by writing to

CHROMATOGRAPHIC COURSE AT KENT STATE UNIVERSITY

KENT, OHIO 44242, U.S.A.
3–7 December 1984

The course, entitled "Fundamentals of Chromatographic Analysis", is co-sponsored by the KSU Chemistry Department, IBM Instruments and the University Conference Bureau. It will provide a coherent overview of chemical separations by chromatographic methods, and will be directed towards beginning and intermediate chromatographers, with material on gas, liquid and thin-layer methods. The course will treat the three techniques as complementary rather than competing processes, and will be a blend of fundamental information on theory and instrumentation, with applications. In addition to lecture sessions, accompanying laboratory sessions will provide intensive "hands-on" training in the various techniques discussed.

The lecturers will be Dr. Roger K. Gilpin (Kent State University), Dr. Neil D. Danielson (Miami University) and Mr. Ronald L. Lewis of IBM Instruments.

Information and registration through Carl J. Knauss, Chromatographic Course Coordinator, Chemistry Department, Kent State University, Kent, Ohio 44242, U.S.A. (telephone 216/672-2327).

THIRD INTERNATIONAL CONGRESS ON
ANALYTICAL TECHNIQUES IN ENVIRONMENTAL CHEMISTRY

21–23 November 1984

This International Congress, to be held in conjunction with the 14th Annual Symposium on the Analytical Chemistry of Pollutants, will take place at the Congress Centre, Barcelona, Spain, 21–23 November 1984. The Congress will be devoted to invited plenary lectures, invited and submitted research lectures, and poster presentations, covering the whole field of environmental analytical chemistry.

   Further details, together with registration form and preliminary programme, may be obtained from: Dr. J. Albaiges, Expoquimia, Avenida Reina Ma, Cristina, Barcelona 4, Spain.

First International World Congress

NEW COMPOUNDS IN BIOLOGICAL AND CHEMICAL WARFARE:
TOXICOLOGICAL EVALUATION

21–23 May 1984

State University of Ghent—Belgium
Department of Toxicology
Chairman: Professor A. Heyndrickx

Scientific Programme

Human and medical factors

   New evidence; effects of chemicals, the methods of detection, mortality and morbidity rates, environmental problems, defensive needs, protection.

Diagnosis, treatment, influence

   Methods of diagnosis, assignment to treatment modalities.

Action Programme

International legislation and rules, enforcement, sanctioning strategies, interaction between public information and enforcement. Evidence of chemical warfare in SE Asia and Afghanistan.

All information can be obtained from:

Professor A. Heyndrickx
Head of the Department of Toxicology
State University of Ghent
Hospitaalstraat 13
B-9000 Ghent
Belgium

THE EASTERN ANALYTICAL SYMPOSIUM

NEW YORK PENTA HOTEL, NEW YORK CITY, 13–16 NOVEMBER 1984

A limited number of oral and poster presentations on new developments in analytical chemistry will be accepted for the 1984 Eastern Analytical Symposium. These presentations will be grouped into several sessions to complement the Symposium's invited technical sessions. Prospective authors should submit a 50–100 word abstract before the deadline, 1 April 1984, indicating preference for oral or poster format, to: Mr. Thomas Kometani, EAS Program Chairman, Bell Laboratories RM1A-378, 600 Mountain Avenue, Murray Hill, NJ 07974, telephone (201) 582-6559. Care should be exercised in considering the title and authors of the proposed presentation; if the presentation is accepted, both title and authors will be considered final. Authors of accepted presentations will receive forms for submission of a 200–300 word abstract which will appear in the final programme.

For details contact:

Dr. S. David Klein

P.O. Box 2000/R80L-106
Rahway, NJ 07065, U.S.A.

ERRATA

In the paper by A. C. Mehta, *Talanta*, 1984, 31, 1, the following corrections are needed:
Page 3, right-hand column, paragraph 2, line 23, for "chlodiazepoxide" read "chlordiazepoxide"
Page 5, Table 2, below "Fluazepam" in column 1, for "††" read "‡‡"
