DETERMINATION OF THE RARE EARTHS, YTTRIUM AND SCANDIUM IN SILICATE ROCKS AND FOUR NEW GEOLOGICAL REFERENCE MATERIALS BY ELECTROTHERMAL ATOMIZATION FROM GRAPHITE AND TANTALUM SURFACES

J. G. SEN GUPTA
Geological Survey of Canada, Ottawa, Ontario, Canada

(*Received* 11 *April* 1984. *Revised* 15 *June* 1984. *Accepted* 1 *August* 1984)

Summary—An improved graphite furnace atomic-absorption method has been developed for the determination of Sc, Y and the rare-earth elements in silicate rocks and related materials. The method, which involves the separation of the lanthanides by ion-exchange followed by their determination by electrothermal atomization, with use of an automatic sampling device, is more rapid than a previous method based on separation by co-precipitation with calcium oxalate and hydrous ferric oxide followed by normal injection of the solution into the furnace. Greater sensitivity (~ 10–40-fold) for La, Ce, Pr, Gd, Tb and Lu is also achieved by using a tantalum foil-lined graphite furnace instead of a pyrolytically-coated furnace. Results obtained for five international reference rock samples, NIM-G, SCo-1, MAG-1, SDC-1 and BHVO-1, are compared with those obtained previously by the oxalate–hydrous oxide co-precipitation method and with other published values. Results are given for four new Canadian iron-formation reference materials, FeR-1 to FeR-4.

In previous work,[1–3] scandium, yttrium and the lanthanides in rocks were determined by graphite-furnace AAS involving manual injection of the sample solution after separation of the rare earths by double calcium oxalate and single hydrous ferric oxide co-precipitations. Because petrogenetic modelling requires the determination of traces of the rare-earth elements in various ultramafic and common rocks and rock-forming minerals, more rapid and sensitive methods are required for their determination, particularly the lighter lanthanide elements. Following the acquisition of a more modern graphite furnace coupled with an automatic sampling device, an attempt was made to expedite the determination of the rare earths by using this equipment and a faster separation procedure. Separation by extraction of the salicylate complexes into methyl isobutyl ketone[4] was tested but abandoned because of interferences in the separation of the phases. The ion-exchange procedure used earlier[5] was therefore investigated, but had to be modified. This paper describes the results and shows that greater sensitivity can be achieved for lanthanum, praseodymium, gadolinium, terbium and lutetium, as well as for cerium, by using a pyrolytically-coated graphite tube lined with tantalum foil.[6] Results obtained by this method for five international reference rock samples are compared with those obtained earlier[1–3] and with other published values. Results are also given for four new Canadian iron-formation reference materials, FeR-1, FeR-2, FeR-3 and FeR-4.

EXPERIMENTAL

Apparatus

The AAS equipment and ancillary apparatus was the same as that used for the cerium determination described earlier,[6] including the tantalum-lined furnace. The ion-exchange column was that used in the earlier work on lanthanides.[7] The AAS operating conditions are given in Tables 1–3.

Reagents

Stock 1000-ppm solutions of scandium, yttrium and the lanthanides were prepared and standardized as described earlier,[6,7] and diluted further with 0.1*M* nitric acid as required, to give working standards.

Standard mixtures, approximating the compositions of two international reference rocks GA (granite)[8,9] and SY-2 (syenite),[9,10] were prepared as described previously.[7] All reagents were of analytical reagent grade and demineralized water was used for the preparation of all solutions.

Procedures

Calibration solutions. Prepare three calibration solutions with concentrations corresponding to 0.05, 0.1 and 0.2 g of sample per ml by diluting appropriate volumes of the "GA" or "SY-2" standard mixtures (depending on the type of sample being analysed) to a known volume with 0.1*M* nitric acid.[7]

Preparation of solution for analysis. Depending on the rock type, decompose a 1–2 g sample and separate the lanthanides, yttrium and scandium by ion-exchange as described earlier,[7] to obtain "Solution A".

AAS determination. Transfer the calibration and sample solutions (Note 1) to plastic vials in the sample dispenser, then, using 20-μl portions of the sample solutions, measure

*R = restricted 0.5 nm slit-width.

the absorbances of scandium, yttrium and the lanthanides (Note 2), with the appropriate graphite tubes and the instrumental conditions shown in Tables 1–3 (Notes 3–7). For calibration use 5, 10, 15 and 20 μl of a standard "GA" or "SY-2" solution, depending on the sample taken, plus sufficient 0.1*M* nitric acid to give a total volume of 20 μl. For interpretation use either the concentration read-out of the AAS instrument or individual calibration curves (Note 8).

Notes

1. Depending on the sensitivity, it is preferable to use sample solutions containing ~0.1 g of sample per ml, using a scale expansion of up to 10× (see under *Interferences* for details).

2. Because minor to trace amounts of some common elements retained on the resin and co-eluted with the rare earths by 6*M* hydrochloric acid (see under Discussion) interfere seriously with the determination of cerium by electrothermal atomization, this element should be determined by either of the following procedures.

(*a*) Using a 3-ml aliquot of Solution A, precipitate the rare-earth elements as described previously[12] as the hydrous oxides in the presence of SiO_2 (added as tetraethyl silicate),

†2000°C for Gd, 2200°C for Tb and Lu.

Al^{3+} and Fe^{3+}, ignite the precipitate to constant weight at 1200° and determine cerium by emission spectrography.

(*b*) Using a 6-ml aliquot of Solution A, co-precipitate the rare-earth elements once with calcium oxalate and once with hydrous ferric oxide as described previously.[1,2] Decompose the organic material by heating with concentrated nitric acid and 30% hydrogen peroxide and evaporating to dryness on a steam-bath, then dissolve the salts in 0.1*M* nitric acid, transfer the solution to a 5-ml standard flask and dilute to volume with the same acid solution. Use the resulting solution, or a diluted solution, for the determination of cerium by electrothermal atomization, with the operating parameters shown in Tables 1 and 3.

3. The sample dispenser capillary tip should be cleaned periodically with a tissue to prevent formation of a bubble and permit uninterrupted flow of liquid into the furnace during injection.

4. After about 50 firings of a new pyrolytically-coated graphite tube at the recommended temperatures (Table 2) the absorbances decrease because of the destruction or loss of some of the pyrolytic coating. The absorbances of the standards should therefore be checked at this stage and a correction factor applied if necessary.

5. After several firings, the tantalum foil may shift inside the graphite tube and block the hole because of expansion and contraction, so the alignment of the holes should be checked periodically to ensure the correct delivery of solution into the cavity.

6. The condition of the tantalum foil should be monitored by firing a standard after every 5 or 10 samples, and the foil changed when the performance begins to deteriorate (usually after about 40 firings). After about 80 firings the graphite tube and tantalum lining should be discarded.

7. The drying time recommended for the tantalum-lined furnace (Table 3) is suitable for up to 20 μl of solution. For >20 μl, use either a longer drying time at 120°, or multiple injections of 20-μl portions, each being dried before addition of the next.

8. It is recommended that two international reference rocks for which "usable values" for the rare-earth elements have been reported[9] should be run with every batch to check the recovery.

RESULTS AND DISCUSSION

Sensitivity

The manual for the GTA-95 gives sensitivities for dysprosium, erbium, europium and terbium but not for scandium, yttrium and the other lanthanides. Tests with a pyrolytically-coated graphite tube fired at 2700° showed that though the sensitivities for neodymium, yttrium, samarium, erbium, holmium, dysprosium, scandium, europium, thulium and ytterbium ranged from moderate to good, in that

order, the sensitivities for lanthanum, cerium, praseodymium, gadolinium, terbium and lutetium were very poor. L'vov and Pelieva[11] had earlier reported increased sensitivities for 13 lanthanides without any marked memory effects when a tantalum foil liner was used inside an ordinary graphite tube, and a 40-fold increase in sensitivity had been obtained for cerium in the same way.[6] A tantalum foil-lined graphite furnace was therefore used in the present work for determination of lanthanum, cerium, praseodymium, gadolinium, terbium and lutetium. Scandium, yttrium and the other lanthanides were determinable with the pyrolytically-coated graphite furnace.

Interferences

Although there are no interelement interferences in determination of lanthanides by electrothermal atomization in the graphite furnace,[1] some common elements that are retained on the ion-exchange column and co-eluted with the rare earths cause positive errors. To ascertain the nature of these associated common elements (other than iron since it does not interfere[1,6]), an aliquot of Solution A was mixed with 5 mg of Fe^{3+} (to act as a carrier), the elements were precipitated as hydroxides and carbonates with ammonia and ammonium carbonate in presence of some filter pulp, and the precipitate was filtered off, washed and ignited to the oxides. A qualitative emission spectrographic analysis of this material for common elements (iron excepted) showed the presence of major amounts of calcium and traces of aluminium, magnesium, barium and strontium.

Tests showed that interferences from associated common elements could be eliminated by heating the sample at about 1800–2000° before atomization of the lanthanides (except cerium) at 2700° in a pyrolytically-coated graphite furnace or at 2600° in a tantalum foil-lined furnace. Tables 2 and 3 show the temperatures suitable for the elimination of these interferences, for each rare-earth element. To minimize these interference effects, it is also recommended that the sample taken should be such that the apparent sample concentration in the final solution is equivalent to not more than 0.1–0.2 g of sample per ml.

A temperature of about 1800° was found to be adequate for removal of the interferences after separation by double calcium oxalate and single hydrous ferric oxide co-precipitations[1,2] because, except for the small amount of iron added during the co-precipitation step, the final solution is relatively free of other elements. In the case of cerium, the elements retained on the ion-exchange column and co-eluted with the cerium cause severe interference at 567.0 nm, the most sensitive line. Consequently, it is necessary to separate cerium from these elements. This can be done after the ion-exchange separation, by co-precipitating cerium once with calcium oxalate and once with hydrous ferric oxide.[1,2]

Table 4 shows the sensitivities obtained for scandium and the lanthanides. At 2600° the tantalum-

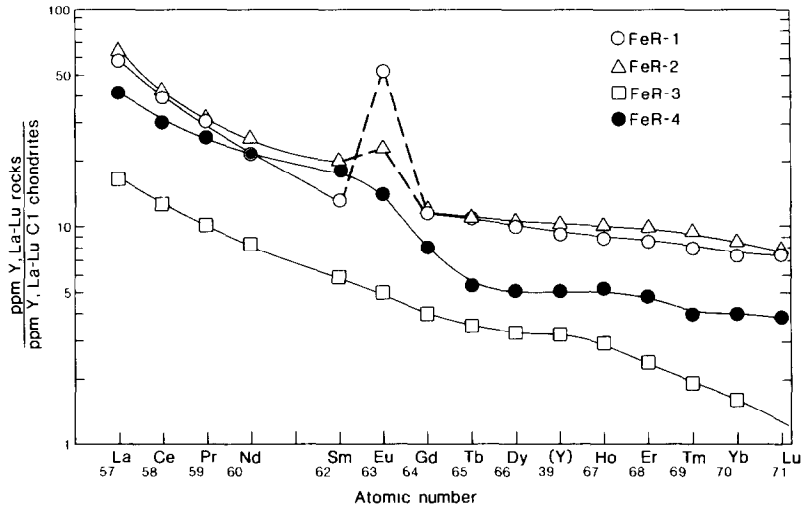

Fig. 1. Chondrite-normalized Y and REE patterns for Canadian iron-formation reference materials.

lined furnace gives considerably higher sensitivity than the pyrolytically-coated graphite furnace, particularly for lanthanum, cerium, neodymium, gadolinium, terbium, erbium and lutetium. Heating of the tantalum-lined furnace at 2700° is not recommended, because the lining deteriorates very rapidly under these conditions.

The method was tested with one South African and four U.S.G.S. reference rocks for which other values were available for comparison purposes, and applied to four new Canadian iron-formation reference materials. The results are given in Tables 5 and 6. Results for praseodymium, erbium and thulium in FeR-1 to FeR-4, for terbium in FeR-3 and for neodymium in FeR-1, FeR-3 and FeR-4 have not been reported previously.

The rare-earth element abundances of FeR-1 to FeR-4 are plotted (normalized to the values for Cl-chondrites of Evensen *et al.*[19]) in Fig. 1 against the atomic numbers. The yttrium abundance data were normalized to the chondritic abundance data of Haskin *et al.*[20] and the data points are plotted between those for dysprosium and holmium because of the similarity in properties and ionic radius for the three elements. From these plots, it is apparent that the lighter rare-earth elements are more fractionated than the heavier ones and, with the exception of the positive europium anomalies for FeR-1 and FeR-2, the shapes of the curves are generally smooth, which supports the accuracy of the data.

Acknowledgements—The author is indebted to Ryan A. Meeds for qualitative emission spectrographic examination of the impurities in the rare-earth concentrates of rocks obtained after ion-exchange separation, and to Elsie M. Donaldson of Canada Centre for Mineral and Energy Technology for critical reading of the manuscript.

(*Received* 13 *July* 1984. *Accepted* 27 *July* 1984)

Summary—Manganese(IV) oxide electrodes formed with a graphite/PTFE substrate are shown to have near-theoretical response to manganese(II) ions in pH-4 acetate medium and a sub-Nernstian response in 0.1*M* nitric acid medium. Lead and iron(III) ions interfere, and iron(II) ions even more so, but other bivalent transition metal ions have little effect. The main drawback of this type of electrode is its long response time (~20 min). Some attempts to use manganese(IV) oxide electrodes as the basis for phosphate electrodes by use of $MnHPO_4.3H_2O$ and $MnNH_4PO_4.H_2O$ are also described.

No manganese(II)-selective electrodes are commercially available and very few experimental electrodes have been reported[1–5]. Electrodes with heterogeneous membranes of either manganese(II) carbonate or manganese(II) hydrogen phosphate respond to manganese(II) ions, but unselectively.[6] An electrode with a sintered manganese(II) telluride–silver sulphide membrane[7] is reported to respond to manganese(II) ions with a sensitivity of 25 mV/pMn, and is selective relative to alkali-metal and alkaline-earth metal cations, but no other performance characteristics were described. More recently[8], a membrane consisting of an ion-exchange resin embedded in an epoxy resin matrix has been proposed for manganese(II) determinations.

Solid-state electrodes based on manganese(II) sulphide, analogous to those for copper, lead and cadmium, are not practicable, mainly because manganese(II) sulphide is soluble in acid solutions. Even in alkaline solutions, however, the useful range would be very small. From the solubility products[9] of manganese(II) sulphide ($pK_s = 12.6$) and manganese(II) hydroxide ($pK_s = 12.72$) and the protonation constants[9] of the sulphide ion, we calculate that hydroxide would displace sulphide from the precipitate at pH > 10. In the pH range 7–10, the range of free manganese concentrations available between dissolution of the manganese(II) sulphide and manganese(II) hydroxide precipitation is fairly small (Table 1) and the range of Nernstian response would be smaller still. These calculations neglect the further complication that in air-saturated solutions oxidation leading to the formation of manganese(IV) oxide, MnO_2, would occur.[10]

In view of this, it was decided to try an electrode based on manganese(IV) oxide. This material has been extensively studied[11–13] because of its use in dry storage batteries, but in many cases the mass ratio of manganese(IV) oxide to solution was high enough for the composition of the solution to be affected. The electrode in these studies usually consisted of a platinum electrode in a paste or suspension of manganese(IV) oxide particles: this is inconvenient for analytical applications since it involves either preparing a fresh electrode for each solution or prolonged washing if carry-over of one solution to the next is to be avoided. We have, therefore, applied manganese(IV) oxide to the surface of a Růžička "Selectrode",[14,15] since this arrangement enables a relatively small surface area to be repeatedly and conveniently presented to successive solutions and has already worked successfully with a lead(IV) oxide coating.[16] The most notable of the previous studies of the manganese(IV) oxide electrode in manganese(II) solutions are those by Covington and co-workers[17,18] and by Caudle *et al.*[19] We have also tested electrodes impregnated with mixtures of manganese(IV) oxide and sparingly soluble phosphate salts, as phosphate sensors.

Table 1. Calculated range of manganese(II) sulphide electrodes

pH	pMn_{max} (MnS saturation)	pMn_{min} [$Mn(OH)_2$ precipitation]
7	3.1	−1.3
7.5	3.5	−0.3
8	3.8	0.7
8.5	4.0	1.7
9	4.3	2.7
9.5	4.5	3.7
10	4.8	4.7

THEORY

Manganese(IV) oxide gives a redox reaction according to equation (1)

$$MnO_{2(s)} + 4H^+ + 2e^- \rightleftharpoons Mn^{2+}_{aq} + 4H_2O \quad (1)$$

for which the electrode potential is

$$E = E^\circ - 2k\,pH - k/2 \log\{Mn^{2+}\} \quad (2)$$

where $k(=2.303\ RT/F)$ is the Nernst slope factor for a one-electron change. It follows from equation (2) that the electrode is sensitive both to pH and to manganese(II) ions. Use of the electrode as a manganese sensor demands, therefore, that the pH of the solution should be rigorously controlled, especially as the electrode is four times as sensitive to pH as to $\log\{Mn^{2+}\}$.

The pH should be controlled by an acidic medium [to avoid the formation of manganese(II) hydroxide or hydroxo-complexes] which does not interact strongly with manganese ions. The media tested were 0.05*M* nitric acid and pH-4 acetate buffer. The stability constant of the manganese acetate complex[20] is $10^{1.4}$.

EXPERIMENTAL

Apparatus

The e.m.f. values were measured with a digital pH-meter reading to 0.1 mV and were displayed on a chart-recorder. A Techne C-100 thermocirculator was used to maintain the temperature of the solution and the electrodes at 25° in a water-jacketed glass vessel. Solutions were stirred by a magnetic stirrer bar.

Manganese(IV) oxide electrodes were prepared by impregnation of the PTFE-graphite substrate of a Radiometer F3012 "Selectrode".[14] The reference electrode was a Radiometer K701 double-junction calomel electrode, the outer sleeve of which was filled with whichever buffer solution was being used at the time, diluted to the same concentration as that in the test solution.

Reagents

The manganese(IV) oxide was Ventron "puratronic" grade (99.999% as metal).

A stock 0.01*M* manganese(II) solution was prepared from manganese(II) sulphate. Other standard manganese solutions were prepared from it by successive dilution.

Solutions for pH adjustment (added in 1:20 v/v ratio) were as follows: 1*M* nitric acid was prepared from a B.D.H. "Con-Vol" ampoule, and acetic acid–acetate buffer, pH 4.0, was prepared by dissolving 243 g of sodium acetate trihydrate in 400 ml of water, adding 480 g of glacial acetic acid and diluting to 1 litre.

Interference tests were made with solutions of sulphate [iron(II), copper(II), cobalt(II)] or nitrate [zinc, lead, nickel, mercury(II), iron(III)] salts.

For the phosphate tests, standard solutions were prepared from stock solutions of 0.1*M* potassium dihydrogen phosphate or 0.2*M* disodium hydrogen phosphate, the former being used in acidic media, the latter in alkaline media.

For solutions in the pH region 4–6, the acetate buffer solution was used, adjusted to the appropriate pH. For pH > 7 the alkaline phosphate solutions were adjusted to the desired pH by addition of 1*M* nitric acid.

Reagents were B.D.H. AnalaR grade unless otherwise specified. Water was distilled and then demineralized on a mixed-bed ion-exchange resin.

RESULTS

Calibration slope

The response in 0.05*M* nitric acid medium was non-linear and the slope in the 10^{-4}–10^{-3}*M* region was about −18 mV/pMn. In the pH-4 acetate medium, the response was almost Nernstian (between −28 and −29 mV/pMn at 25°) at concentrations above 10^{-4}*M*. Deviations from the Nernstian response were obvious below the 5×10^{-5}*M* level. Figure 1 shows the calibration graphs for both media.

Standard potential

The standard potential was calculated from equation (3)

$$E^\circ = E + \frac{k}{2}\log[Mn^{2+}] + \frac{k}{2}\log\alpha + \frac{k}{2}\log f_{Mn} + 2k\ pH + E_{ref} - E_j \quad (3)$$

where E_{ref} is the half-cell potential of the saturated calomel reference electrode, E_j is the liquid-junction potential calculated by means of the Henderson equation, f_{Mn} is the activity coefficient of the manganese(II) ion calculated by the Davies equation,[21] α is a term allowing for complexation with the acetate in the buffer medium and $[Mn^{2+}]$ is the total manganese concentration. The standard potential obtained from measurements in the pH-4 acetate medium was 1224 mV (the standard deviation for the mean of 12 results was 0.4 mV). This figure was obtained with electrodes less than 8 hr old. As the electrodes aged the apparent standard potential decreased by 1–2 mV/day. In these calculations, $k \log \alpha$ had the value −3.0 mV and E_j −0.02 mV. Literature values[17,18] for the standard potential are in the

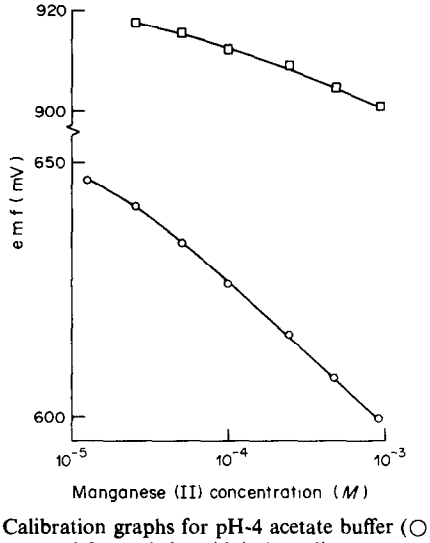

Fig. 1. Calibration graphs for pH-4 acetate buffer (○) and 0.01*M* nitric acid (□) media.

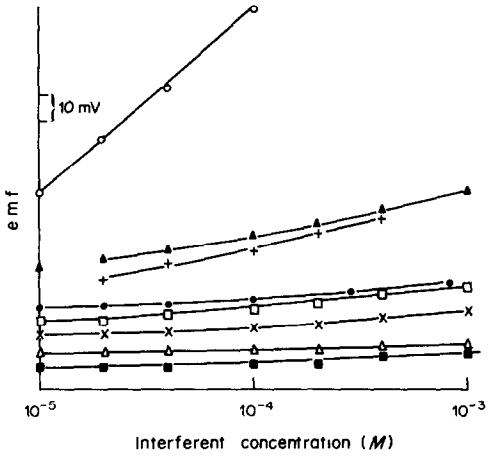

Fig. 2. Interferences in pH-4 acetate buffer medium, Fe^{2+}(○), Pb^{2+}(▲), Fe^{3+}(+), Hg^{2+}(×), Co^{2+}(□), Cu^{2+}(●), Zn^{2+}(△), Ni^{2+}(■).

range 1230–1240 mV with which our measurements are, therefore, in fairly good agreement.

Response time

The response of the manganese(IV) oxide electrode to an approximately twofold increase in concentration was complete within about 10 min in 0.05*M* nitric acid medium, but took 20–30 min in pH-4 acetate buffer, these times being obtained for gently stirred solutions in a beaker. When the electrode was placed in a flow-cell which also provided vigorous stirring at the electrode surface, shorter response times were observed, *e.g.*, equilibrium was reached in 15–20 min (including 3 min dead-time) for tenfold upward and downward changes in concentration.

Interferences

Figure 2 shows the response curves for various metal ions in the pH-4 acetate medium, where the manganese response was most nearly Nernstian; the e.m.f. values are displaced arbitrarily on the ordinate for the sake of clarity. Zinc, nickel, mercury(II) and copper(II) ions had little or no interfering effect at concentrations up to about 10^{-4} but at higher levels gave approximately linear responses of, respectively, −2.7, −4.1, −6.5 and −8.5 mV/decade. Cobalt(II) below $10^{-4}M$ had a more discernible effect and an almost linear response of about −8.5 mV/pCo over the range 10^{-4}–$10^{-3}M$. Iron(III) produced a significant effect: the curve in Fig. 2 represents an almost Nernstian response of about −25 mV/pFe(III), but this graph was constructed from readings taken arbitrarily about 1 hr after the change of concentration, since the potentials were still drifting slowly at that time. The response to lead ions was sub-Nernstian, at −18 mV/pPb. Iron(II) produced the largest effect: the sensitivity was about −115 mV/pFe(II) up to $10^{-4}M$, but this figure was also obtained from potentials recorded arbitrarily after 60 min because equilibrium potentials were not attained within that time.

Selectivity coefficients were determined by the separate solutions method for those ions giving an approximately Nernstian response, with the results shown in Table 2.

Compared with sulphide-based electrodes for transition metal ions, the manganese(IV) oxide electrode is notably tolerant of copper(II) and mercury(II) ions. Comparison with the lead(IV) oxide electrode for lead ions[16] shows very similar interference by zinc, nickel, copper and mercury and cobalt ions and the selectivity coefficient for lead ion with respect to the manganese(IV) oxide electrode is approximately the inverse of that for manganese(II) ion with respect to the lead(IV) oxide electrode. The likeliest explanation for these interferences is an ion-exchange mechanism. The much larger iron(II) interference is presumably brought about by reduction of manganese(IV) oxide, with a consequent release of manganese(II) ions.

DISCUSSION

Manganese (II) response

The results show that the manganese(IV) oxide electrode could be a useful manganese(II)-selective electrode, with a Nernstian response down to $5 \times 10^{-5}M$. The main practical problem is the slow response. The need for precise control of pH is a disadvantage, but this control differs little from the ionic strength adjustment procedures usually applied in measurements with ion-selective electrodes. The durability of the electrode was not specifically tested, but one application of manganese(IV) oxide lasted for at least 2 weeks, during which the standard potential decreased as described above.

The slow response is probably related to the mechanism elucidated by Caudle *et al.*,[19] in which the manganese(IV) oxide electrode does not respond directly to manganese(II) ions but only to hydrogen ions, with sensitivity of 59 mV/pH. Reactions (4) and (5) relate the manganese(II) ion concentration to the pH and hence to the electrode potential with respect to H^+, which, at equilibrium, conforms to that given by equation (1):

$$MnO_{2(s)} + Mn^{2+} + 2H_2O \rightleftharpoons 2MnOOH_{(s)} + 2H^+ \quad (4)$$

$$MnO_{2(s)} + H^+ + e^- \rightleftharpoons MnOOH_{(s)} \quad (5)$$

The formation of MnOOH implies changes in the (solid) membrane phase greater than expected with

Table 2. Selectivity coefficients for manganese(IV) oxide electrodes

Ion	Concentration range, M	Selectivity coefficient
Fe^{3+}	10^{-4}–4×10^{-4}	0.02
Pb^{2+}	10^{-4}–10^{-3}	~0.5

most ion-selective electrodes, unless these are subject to a major interference effect. In the light of the mechanism proposed above, the slow response is less surprising.

Since MnOOH would be expected to be formed first at the surface, changes in the composition of the solid phase would be expected to be slow and gradual, which is in accord with the observed slow changes in standard potential (1–2 mV/day).

Investigation of possible phosphate-selective electrodes

The grey modification of manganese hydrogen phosphate trihydrate[22] has a solubility product[23] of 1.4×10^{-13} and manganese ammonium phosphate[24] has a solubility of the order of $10^{-5}M$ in weakly acidic solutions of ammonium salts.[25] The manganese(IV) oxide electrode, in conjunction with one or other of these salts, was tested for response to phosphate. The tests were performed in two ways: electrodes impregnated with manganese(IV) oxide/phosphate salt mixtures were immersed in phosphate solutions, and electrodes impregnated with only manganese(IV) oxide were immersed in solutions saturated with a sparingly soluble phosphate. Solutions for use with manganese ammonium phosphate contained ammonium nitrate at $1M$ concentration. In no case was a response to phosphate obtained. At pH 8 the pink manganese ammonium phosphate turned white, presumably indicating hydroxide formation. At pH 4–6 (acetate buffer) the e.m.f. changed in the opposite direction to that expected from depression of the manganese concentration in equation (2) by the common ion effect of phosphate. Such e.m.f. changes were traced to small shifts in pH resulting from inadequate buffer capacity at the higher phosphate levels (up to $0.035M$). The manganese(IV) oxide electrode, therefore, appears not to be a suitable basis for a phosphate-selective electrode.

GRAVIMETRIC AND SPECTROPHOTOMETRIC DETERMINATION OF PALLADIUM WITH 2,3,4-PENTANETRIONE TRIOXIME

J. CACHO, M. A. LACOMA and C. NERÍN*
Department of Analytical Chemistry, Faculty of Sciences, University of Zaragoza, Zaragoza, Spain

(*Received* 6 *October* 1982. *Revised* 12 *July* 1984. *Accepted* 27 *July* 1984)

Summary—A study of the use of 2,3,4-pentanetrione trioxime (PTT) in the gravimetric and spectrophotometric determination of palladium is reported. PTT has been applied to the determination of palladium in various synthetic and standard samples. The reagent has some advantages over dimethylglyoxime.

Vicinal α-dioximes have been used as analytical reagents for transition metals,[1] especially nickel and palladium, since Tschugaeff[2] discovered and outlined the selective properties of the dioximes at the beginning of the 20th century. Dimethylglyoxime (DMG) has been the most studied and most often used, but has the drawback of low solubility in water and hence a risk of precipitation in gravimetric procedures.

With the aim of eliminating this problem and studying the effect of an additional oxime group, the reagent 2,3,4-pentanetrione trioxime (PTT) has been prepared and applied to spectrophotometric determination of iron(II), and its analytical characteristics have been studied.[3] The presence of the third oxime group greatly increases the solubility in water, while leaving the analytical properties the same as those of DMG. The use of the reagent for determination of palladium has therefore been examined. It can be used both gravimetrically and spectrophotometrically.

EXPERIMENTAL

Reagents

All chemicals were of analytical-reagent grade. Stock solutions (0.1 and 7.5%) of PTT in water were prepared. The palladium solutions were prepared from palladium chloride and standardized with DMG. An acetic acid/sodium acetate buffer (pH 4.5–6.0) was prepared.

Synthesis of PTT

To 36 g of isonitrosoacetylacetone, add 50 g of hydroxylamine hydrochloride and 100 g of sodium acetate and dilute to 400 ml with distilled water. Heat at 70–80° for 2 hr. Cool, adjust to pH 7 with sodium hydroxide and extract with ether. Evaporate the extract.

Gravimetric procedures

Place a sample containing 25–50 mg of Pd in a beaker, adjust to pH 0.5–2 with hydrochloric acid and dilute to about 150 ml with distilled water, then heat on a water-bath at 80°. Add 50 ml of 7.5% PTT solution with continuous stirring, then digest on the water-bath for at least 30 min. Cool, then filter off the yellow precipitate and wash it with 100 ml of hydrochloric acid (1 + 100). Dry at 110–120°, cool and weigh. The conversion factor from $Pd(C_5H_8N_3O_3)_2$ to Pd is 0.2519.

Determination of Pd in palladinized active carbon. Ignite 250–500 mg of sample at 800°. Dissolve the residue in 10 ml of *aqua regia.* Evaporate almost to dryness and dilute with distilled water. Filter off and wash any residue, and transfer the filtrate to a 400-ml beaker, then determine the palladium as above.

Determination of Pd in Pd–$CaCO_3$ catalyst. Dissolve 250–500 mg of sample in 10 ml of concentrated hydrochloric acid and 1 ml of concentrated nitric acid. Evaporate almost to dryness and dilute with distilled water to 200 ml. Precipitate according to the method above.

Spectrophotometric procedure

Place an aliquot of sample, containing 10–50 μg of palladium, in a 100-ml separatory funnel, add 15 ml of 0.2*M* EDTA, 5 ml of 0.1% PTT solution, and 20 ml of acetate buffer (pH 4.5–6) and dilute to 50 ml with distilled water. Then add 10 ml of chloroform–butan-1-ol mixture (5:1 v/v) and shake the mixture vigorously for 1 min. Separate the layers, filter the organic layer through a Whatman No. 1 PS paper and measure its absorbance at 270 nm against a reagent blank prepared along with the sample.

If molybdenum is present, after the EDTA add sodium fluoride in at least 10-fold molar ratio to the molybdenum. If gold is present, after the EDTA add potassium thiocyanate solution (tolerance limit 500 mg of KSCN).

Determination of Pd in palladinized active carbon. Calcine a 60-mg sample at 800°, and treat the residue as described for the gravimetric method, but finally dilute to volume in a 1000-ml standard flask. Use a 5-ml aliquot for the spectrophotometric determination.

Determination of Pd in palladinized calcium carbonate. Treat a 120-mg sample as described for the gravimetric method, but finally dilute the solution and complete the determination as for the spectrophotometric analysis of palladinized active carbon.

RESULTS AND DISCUSSION

PTT is easily soluble in water, and the solution is stable at room temperature for at least a month. Its first dissociation constant is $pK_1 = 13.7$.[3] The order in which the protons are dissociated is not known. It appears to be a bidentate ligand with a convenient

steric arrangement of its donor groups, and a conjugate system of π-electrons connected with the donor groups.

The Pd–PTT complex

Elemental analysis confirms the formula $Pd(PTT)_2$. The structure has been studied and compared with that of $Pd(DMG)_2$.[4]

The infrared spectrum of the complex shows three bands, at 1533, 1280 and 1140 cm^{-1}, which do not appear in the reagent spectrum. The band at 1533 cm^{-1} is attributed to the asymmetric C = N stretching vibration and the other two bands to N = O stretching modes.[5] Two other bands, at 820 and 780 cm^{-1}, are associated with the Pd–N stretching mode. The Ni–PTT complex was also prepared and its infrared spectrum obtained. New bands also appeared clearly at 1545, 1280 and 1168^{-1}. These considerations lead us to suppose that the chelation will be similar to that of Pd with DMG, which means that only two of the three oxime groups are involved.

Table 1 shows the data from the NMR spectra of PTT and its palladium complex. The characteristic peaks are displaced owing to formation of the complex.

The X-ray powder diffraction pattern shows a very strong peak at $2\theta = 9.19°$, the others peaks being irrelevant. We conclude that there is a layer-stacked structure similar to that of the $Pd(DMG)_2$ complex. The 2θ values for the characteristic peaks are 9.19°, 11.76°, 13.65°, 15.34°, 18.32°, 19.13°, 21.78°, 23.53°. The structure is still being worked out from the X-ray data, but it can be concluded that it could be that shown in Fig. 1.

The thermogravimetric curve for the complex (Fig. 2) shows that the complex is stable up to 180°. Sharp decreases occur at 230° and 290°. At above 410° a stable species appears, and at 800° palladium metal is obtained.

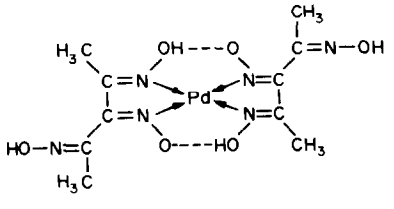

Fig. 1. Structure of the palladium complex.

Optimum precipitation conditions

The precipitate is slightly soluble in water (52 mg/l.), and should be washed with dilute acid. Various acids were examined and dilute hydrochloric acid (1 + 100) was found the most suitable (solubility of the precipitate 3.3 mg/l.). At least a 30-fold molar ratio of PTT to Pd is required for quantitative precipitation (Fig. 3). The precipitation can be done at any temperature from ambient up to 100°, and the optimum pH range is 0.5–2 (Fig. 4).

The most suitable amount of palladium for gravimetric determination is 25–50 mg (Fig. 4). The relative standard deviation for 35–45 mg of palladium is 0.1% (three levels, 10 determinations at each).

Spectrophotometric determination

The yellow Pd–PTT complex is soluble in alkaline medium, but the colour in this medium is unstable and cannot be used for a spectrophotometric determination. The precipitate obtained in acid medium,

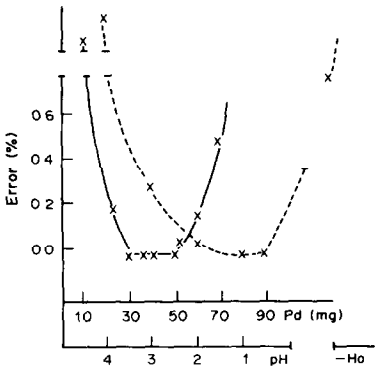

Fig. 4. Influence of pH (- - -) and amount of palladium (——) in the gravimetric determination of Pd.

unlike that obtained with DMG, is insoluble in chloroform, but easily dissolved in slightly more polar liquids, such as a chloroform–butan-1-ol (5:1 v/v) mixture or methyl isobutyl ketone (MIBK). In our study the mixed solvent was preferred, since the more polar solvents such as MIBK are capable of extracting the chloro-complexes of various metals, and these might produce interference in the determination of palladium.

The solvent mixture has minimum absorption at 245 nm. The absorption spectra of the reagent and its palladium-complex in the mixture are shown in Fig. 5. There is a shoulder in the spectrum of the complex at about 270 nm, whereas the absorbance of the reagent is small. At wavelengths longer than 310 nm the absorbance of the reagent is negligible.

The organic solutions of the reagent and its complex are stable for at least 1 month. Beer's law is obeyed up to at least 8 ppm of Pd in the organic phase. The molar absorptivity of the complex is 1.91×10^4 l.mole^{-1}.cm^{-1}.

Influence of pH on extraction of the reagent and its Pd-complex. A wavelength of 320 nm was used for measuring the complex, to avoid the absorbance of excess of the reagent extracted, and the PTT was measured at 230 nm (its wavelength of maximum absorption). The absorbance is practically constant for the complex over the pH range 1–6, and pH 4–5 for the reagent (Fig. 6). As the absorbance of the reagent is low at the wavelength (270 nm) used in the determination, a pH of 4.5–6 is recommended, in order to obtain better results in the removal of possible interferences by means of masking agents.

Extraction of PTT. The distribution coefficient and degree of extraction of the reagent were determined at pH 4.5–6, to establish the maximum amount of reagent permissible for the absorbance blank at 270 nm to be less than 0.2. The distribution coefficient was found by spectrophotometric determination of the PTT concentrations in the two phases after a single extraction, by the procedure given above. The average value of 6 determinations was $D = 0.102 \pm 0.005$ and the degree of extraction was $2.01 \pm 0.005\%$. Consequently, in the proposed method, the aqueous phase can contain a maximum of 6.6 mg of PTT.

In the pH range 4.5–6 the absorbance of the complex is constant if the molar ratio of PTT to Pd is 55:1. A ratio of 100:1 was chosen. It was found that the extraction of the complex was 100.0% complete in a single extraction for 20–50 μg of palladium.

Interferences

The selectivity was investigated by gravimetric determination of 29.44 mg of Pd and spectrophotometric determination of 35.3 μg of Pd in the presence of a number of other ions; the results are summarized in Table 2. Strong oxidants such as chromium(VI) interfere seriously in the gravimetric method. In the spectrophotometric method the interference of Cu, Ni, Fe, Pt, Co, V, Zr, Sn, La and Hg can be eliminated by adding EDTA, and that of Au by adding potassium thiocyanate. The interference of Mo can be eliminated by adding sodium fluoride in at least 10:1 molar ratio to the molybdenum, but only if the molar ratio of Mo to Pd is less than 100.

Fe(II) is oxidized to Fe(III) by dissolving the sample in *aqua regia*, and evaporating almost to dryness.

Applications

Results for the determination of palladium in palladinized calcium carbonate and active carbon, and in synthetic mixtures are shown in Tables 3 and 4. The main advantages of PTT over DMG in the spectrophotometric method are the need for only one extraction, and the much higher sensitivity. In the gravimetric method PTT has the advantages of high solubility in water and a more favourable conversion factor.

HOMOGENEOUS IMMUNOASSAY OF PHENOBARBITAL BY PHASE-RESOLVED FLUORESCENCE SPECTROSCOPY

FRANK V. BRIGHT and LINDA B. MCGOWN*
Department of Chemistry, Oklahoma State University, Stillwater, OK 74078, U.S.A.

(*Received* 11 *June* 1984. *Accepted* 27 *July* 1984)

Summary—A new technique for determination of phenobarbital by homogeneous fluoroimmunoassay is described. Simultaneous determination of free and antibody-bound fluorescein-labelled phenobarbital is accomplished by making phase-resolved fluorescence measurements, in which selectivity is provided by the difference between the fluorescence lifetimes of the two species, as well as by the difference in fluorescence intensities. The technique requires no specialized reagents other than those inherent in immunoassay (antibody, antigen and labelled antigen). Problems due to non-specific binding of labelled antigen to sample matrix components can be alleviated by addition of a relative excess of albumin.

Immunoassays are based on the competitive binding of an antibody (Ab) to its corresponding antigen (Ag) and to an appropriately labelled form of the antigen (Ag*):

$$Ag^* + Ag + Ab \rightleftharpoons Ag^*\text{–}Ab + Ag\text{–}Ab + Ag^* + Ag \quad (1)$$

The original immunoassays used radioactively-labelled antigens. However, in recent years, investigators have sought non-isotopic alternatives to radioimmunoassays (RIA). Fluoroimmunoassay (FIA), in which a fluorescent label is used in lieu of a radioisotope, has offered a promising alternative to RIA. In addition to providing good sensitivity and detection limits, FIA can be either heterogeneous (requiring separation of Ag* and Ag*–Ab) or homogeneous (no separation needed), whereas RIA is inherently heterogeneous.

The use of difference in fluorescence lifetimes for achieving selectivity in heterogeneous FIA, by means of single-photon counting time-resolved fluorescence has been described.[1] Homogeneous FIA based on fluorescence-lifetime selectivity has not, to our knowledge, been previously demonstrated. It has been shown that phase-resolved fluorescence spectroscopy (PRFS) can be used for simultaneous determination of a single species in two different biological microenvironments, on the basis of differences in fluorescence lifetime.[2] In the work described here, PRFS is similarly employed to determine free and antibody-bound labelled antigen simultaneously, thereby providing a homogeneous immunoassay. The phase-resolved fluoroimmunoassay (PRFIA) does not require any specialized reagents beyond those basic to immunoassay (Ab, Ag and Ag*).

Phenobarbital was chosen as a representative hapten analyte to demonstrate PRFIA. Clinical determinations of phenobarbital aid in drug-dosage monitoring and correct patient management as well as in diagnosis of drug abuse. Other homogeneous FIA techniques for phenobarbital have been described, which use fluorescence polarization[3] and a substrate-labelled enzymatic approach.[4]

THEORY

Phase-resolved fluorescence spectroscopy

The theory and instrumentation of PRFS have been described in detail elsewhere.[5–7] The technique is based on the phase-modulation method for the determination of fluorescence lifetimes, in which the sample is excited with sinusoidally modulated light having an angular modulation frequency $\omega = 2\pi f$, where f is the frequency of linear modulation. The time-dependent intensity of the excitation beam $E(t)$ is given by:

$$E(t) = E_0(1 + m_{ex}\sin\omega t) \quad (2)$$

where E_0 is the d.c. intensity contribution and m_{ex} is the degree of beam modulation (*i.e.* the ratio of a.c. amplitude to d.c. intensity). The resulting fluorescence emission, $F(t)$, of a single component with homogeneous exponential decay will be phase-shifted by an angle ϕ and appear as:

$$F(t) = F_0[1 + m_{ex}\cos\phi\,\sin(\omega t + \phi)] \quad (3)$$

where F_0 represents the d.c. component of the fluorescence intensity and $\cos\phi$ is the demodulation factor. For a solution containing two fluorophores, 1 and 2, a similar equation arises:

$$F(t) = F_{01}[1 + m_{ex}\cos\phi_1\sin(\omega t + \phi_1)] + F_{02}[1 + m_{ex}\cos\phi_2\sin(\omega t + \phi_2)] \quad (4)$$

In PRFS, the a.c. component of the fluorescence emission is observed with a phase-sensitive detector in which the fluorescence emission function, equation

(4), is multiplied by a constant function and then integrated. The resulting time-independent signal is proportional to the cosine of the difference between the phase-angles of the detector and the sample. The phase-sensitive fluorescence intensity at detector phase angle ϕ_D for a two-component system will be:

$$F(\phi_D) = F_{01} m_{ex} \cos\phi_1 \cos(\phi_D - \phi_1) + F_{02} m_{ex} \cos\phi_2 \cos(\phi_D - \phi_2) \quad (5)$$

Phase-resolved fluoroimmunoassay

PRFIA involves the use of phase-resolved measurements at a series of non-null ($\phi_D \neq \phi \pm 90°$) detector phase-angles, as has previously been described.[2,8,9] In this multiple phase-angle approach to FIA, a series of linear simultaneous equations is generated. The following equations are used for the determination of free and bound Ag* at n detector phase-angles:

$$\begin{aligned} I_{\phi 1}^{PRF} &= I_{\phi 1}^{F}(\text{free Ag*}) + I_{\phi 1}^{B}(\text{bound Ag*}) \\ &\cdot \\ &\cdot \\ &\cdot \\ I_{\phi n}^{PRF} &= I_{\phi n}^{F}(\text{free Ag*}) + I_{\phi n}^{B}(\text{bound Ag*}) \end{aligned} \quad (6)$$

where $I_{\phi i}^{PRF}$ is the phase-resolved fluorescence intensity (PRFI) of a solution, $I_{\phi i}^{F}$ is the PRFI of the solution containing only free Ag*, and $I_{\phi i}^{B}$ is the PRFI of the solution containing only bound Ag*, for the ith equation generated at $\phi_D = \phi_i$. This set of equations is valid only if the total cuvette concentration of Ag* (free + bound) is constant for all the solutions. The set can be represented in matrix form:

$$\begin{bmatrix} I_{\phi 1}^{F} & I_{\phi 1}^{B} \\ \cdot & \cdot \\ \cdot & \cdot \\ \cdot & \cdot \\ \cdot & \cdot \\ \cdot & \cdot \\ I_{\phi n}^{F} & I_{\phi n}^{B} \end{bmatrix} \begin{bmatrix} (\text{free Ag*}) \\ (\text{bound Ag*}) \end{bmatrix} = \begin{bmatrix} I_{\phi 1}^{PRF} \\ \cdot \\ \cdot \\ \cdot \\ \cdot \\ \cdot \\ I_{\phi n}^{PRF} \end{bmatrix} \quad (7)$$

If $n > 2$ the matrix is "solved" for the fractions of free and bound Ag* by using a Gauss–Newton iterative procedure which includes the constraint:

$$\%\text{free Ag*} + \%\text{bound Ag*} = 100\%\ \text{Ag*} \quad (8)$$

When $n = 1$, *e.g.*, for use of either a single ϕ_D or steady-state conditions, a square matrix is generated, where equation (8) provides the second equation. The matrix can be solved exactly by using Cramer's rule. The PRFIA calibration curve for phenobarbital is constructed by plotting the percentage of free Ag* *vs.* analyte concentration (Ag), followed by third-order polynomial fitting.

EXPERIMENTAL

Materials

Demineralized water was used for all preparations.

Me_2POPOP[1,4-bis(4-methyl-5-phenyloxazol-2-yl)benzene] (Aldrich) was used as a reference fluorophore for the fluorescence lifetime determinations.

Phosphate buffer (0.01M, pH 7.5) was prepared from NaH_2PO_4 and Na_2HPO_4 and contained 1% sodium chloride, and 0.1% sodium azide as a preservative.

The immunoassay reagents, including anti-phenobarbital antibody (Ab), fluorescein-labelled phenobarbital (Ag*), phenobarbital standard and test solutions (Ag), and IgG were purchased as a kit (American Diagnostics Inc., Newport Beach, CA) and used without further purification. Additional phenobarbital standard and test solutions were prepared by weighing the appropriate amount of phenobarbital (Sigma) and diluting with buffered human serum albumin ($10^{-4}M$). The kit standards and test solutions contained 0–80 μg of phenobarbital per ml. These solutions were subsequently diluted 1:101 with buffer before addition to the cuvette solutions.

Human serum albumin (HSA, 30 μM) was prepared by dissolving 201 mg of HSA (Sigma, fatty acid-free, prepared from fraction V, catalogue no. A-1887) in 100 ml of buffer.

Polyethylene disposable cuvettes (Precision Cells Inc.) were used for all fluorescence measurements.

All the cuvette solutions, including the blank, free Ag*, antibody-bound Ag*, standard Ag, and test Ag, are described in Table 1. Fluorescence intensities were all corrected to correspond to 3.000 ml total volume in the cuvette. The addition of a large concentration of HSA to all samples ensured that, if non-specific adsorption of "free" (non-Ab bound) Ag* were to occur, it would be uniform (*i.e.*, all free Ag* would be adsorbed) with all adsorption occurring at a primary site on the HSA. It is important that all non-Ab bound Ag* be in a single type of microenvironment to ensure a homogeneous fluorescence lifetime for the free Ag* component. For simplicity, and to be consistent with immu-

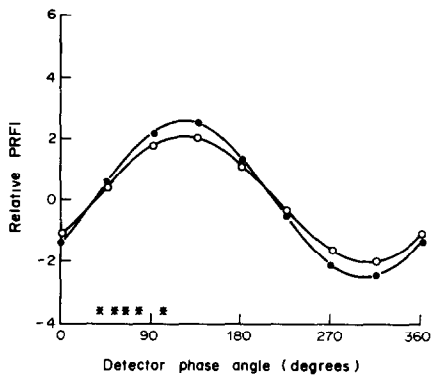

Fig. 1. Relative phase-resolved fluorescence intensity as a function of detector phase angle ϕ_D. Modulation frequency = 30 MHz. ○ Ab-bound Ag*; ● free Ag*. Phase angles used for multiple phase angle determinations are indicated by * (45.0, 58.5, 72.0, 85.5 and 117.0°).

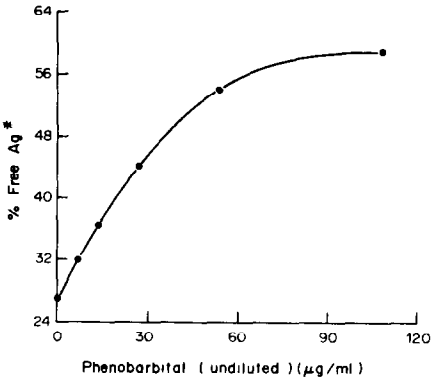

Fig. 2. Phenobarbital calibration curves obtained by using 5 detector phase angles (see Fig. 1).

noassay terminology, the non-Ab bound Ag* will be referred to as "free" Ag*, although it may actually be non-specifically adsorbed on albumin.

As seen in Table 1, the equivalent of ~1 μl of original, undiluted sample is used in 3.000 ml total cuvette volume. This 3000-fold dilution should minimize matrix interferences in the phenobarbital determinations.

Apparatus

All PRFS measurements were made with an SLM 4800S spectrofluorimeter (SLM Instruments, Inc.), with a 450-W xenon source, Hamamatsu R928 photomultiplier-tube detection, and a Glan-Thompson calcite prism polarizer (SLM) in the excitation beam, at 35° to the vertical.

Sample turret temperature was maintained at 20° for all measurements, by means of a Neslab constant-temperature bath (Neslab Instruments).

The excitation and emission monochromators were set at 490 and 520 nm, respectively (the maxima for fluorescein). The slits were set at 16, 0.5, 0.5, 8 and 8 nm resolution for the excitation monochromator entrance and exit, modulation tank exit, and emission monochromator entrance and exit, respectively.

PRFS measurements were all made at 30 MHz modulation frequency, in the delta-phase mode (a ratiometric mode) to minimize the effects of source-output fluctuations and excitation modulation drift. All solutions were measured first at one detector phase-angle (ϕ_D), and then the next, and so on, to eliminate irreproducibility due to resetting the detector phase-angle.

All measurements were made in triplicate, each measurement being the electronic average obtained by integration of 100 samplings during about 30 sec, performed internally by the SLM instrument.

An Apple IIe was used for computation, with programs written in BASIC.

RESULTS AND DISCUSSION

The plots of relative PRFI *vs.* ϕ_D for free and bound Ag* are shown in Fig. 1. The phase-angle difference between the two species corresponds to a fluorescence-lifetime difference of 100 psec. Fluorescence-lifetime (τ_f) determinations were made with Me_2POPOP as the reference fluorophore ($\tau_f = 1.45$ nsec),[10] and yielded 4.04 and 3.94 nsec for the lifetimes of free and bound Ag* respectively.

A typical PRFIA calibration curve generated by using 5 detector phase-angles is shown in Fig. 2.

The effect of the number of detector phase-angles on the accuracy of determinations of phenobarbital in the test solutions was studied. Calibration curves were generated and test solutions analysed for every possible combination of the *n* detector phase-angles, where *n* was varied from 1 to 5. Results for the best combination for each number of detector phase-angles are shown in Table 2. The results indicate that the accuracy is best when 3 detector phase-angles are used, but the magnitude of the errors is relatively large. The combination of 5 detector phase-angles provided good accuracy and the smallest average

Table 2. Error of determination[a]

Test solution	Number of detector phase angles[b] 5	4[c]	3[d]	2[e]	1[f]
1	1.0	5.4	−12.5	−16.9	−5.9

[d]$\phi_D = 45.0°$, 58.5°, and 117.0°.
[e]$\phi_D = 45.0°$ and 58.5°.
[f]$\phi_D = 117.0°$.

error. These 5 detector phase-angles were therefore used for all subsequent studies. The lower accuracy obtained by using 5 angles instead of 3 was probably due to the relative redundancy of the data from the three fairly closely spaced angles 58.5, 72.0 and 85.5° (see Fig. 1), in which case any errors present in the data obtained at these angles outweigh the discriminatory advantage accruing from their use.

A relative standard deviation of 6.7% was found for a set of four calibration curves, normalized as described below, and obtained on a weekly basis (one per week). Each curve was normalized to the percentage of free Ag* found for the highest concentration standard (74.8 μg/ml). Normalization was used to minimize variations due to reagent degradation, which was found to cause a uniform decrease in the apparent values of percentage of free Ag*. Curves were compared by taking values at the 5 standard concentrations from each fitted curve and comparing these values with a "mean" calibration curve obtained by fitting all four sets of data simultaneously. The limit of detection for phenobarbital (defined as 3 times the standard deviation of the blank) was estimated to be 3 μg/ml in the original undiluted sample, corresponding to 1 ng/ml in the cuvette.

Calibration curves (normalized as described above) obtained by using heterogeneous FIA (by the procedure described in the Amerifluor kit) and PRFIA were compared. A correlation coefficient of 0.97 was obtained for the linear ($y = 1.18x - 0.11$) correlation plot.

A homogeneous steady-state quenching approach was also used, based on the difference between the steady-state fluorescence intensities for free and bound Ag*. The steady-state FIA method generated a square 2 × 2 matrix (see section on PRFIA theory, above). The values obtained for free Ag* were poorly correlated ($r = 0.6$) with the standard concentrations. The superior performance of the phase-resolved fluorescence intensity approach indicates the advantage of using fluorescence-lifetime selectivity in addition to selectivity based on fluorescence quenching.

CONCLUSIONS

This phase-resolved approach to homogeneous FIA, as demonstrated by the PRFIA for phenobarbital, offers several advantages. Greater discrimination between free and bound Ag* is achieved than that attainable in a determination based solely on steady-state intensity differences. Homogeneous immunoassay is accomplished without requiring additional specialized reagents (*e.g.*, enzymes, second labels, *etc.*). PRFIA is applicable to determination of antigen species regardless of their molecular weight (provided there is a sufficiently large change in fluorescence lifetime on antibody-binding of the labelled antigen), whereas polarization FIA depends on a large enough change in molecular volume on binding, and is generally best suited to the determination of smaller antigens (molecular weight $< 4 \times 10^4$).[11] In addition, problems due to nonspecific adsorption or binding to sample matrix components such as albumin can be minimized by the addition of an excess of binding reagent (*e.g.*, albumin), provided that there is a sufficient fluorescence-lifetime difference between the reagent-adsorbed and Ab-bound Ag*.

Summary—The inhibition-release titration method has been used to study interference effects in flame atomic-absorption determination of iron. Interferences from anions, cations and complexing agents with the atomic-absorption of iron when a stoichiometric air-acetylene flame is used, can be obviated by a preliminary treatment of the sample solution with sulphosalicylic acid to convert the iron into the same complex before aspiration, thus giving a constant environment for the iron in the flame processes.

Determinations of iron in a wide variety of materials by atomic-absorption spectrophotometry have been collated in the analytical literature.[1-3] Slavin[2] reported that the determination is almost free from interference when a stoichiometric air–acetylene flame is used. Another study by Thompson *et al.*[4] showed that in fuel-rich flames both Fe(II) and Fe(III) give non-linear calibration curves and that a fuel-lean flame is best with respect to linearity, but at sacrifice of sensitivity. However, different cations and anions are reported to affect the iron signal.[5] With measurement in the upper parts of the flame, 8-hydroxyquinoline has been used as a releasing agent to eliminate interference from Co, Ni and Cu in the atomic-absorption determination of iron[6] but is only applicable over a narrow range of interferent concentrations because of precipitation. In addition, the observation height* is a critical parameter. Black *et al.*[7] studied the use of volatile metal-chelate systems for the introduction of iron and other metals into an inductively coupled plasma, and this approach can be used in flame-based systems. Extraction procedures have been used to avoid interferences from a variety of matrices in determination of iron by AAS.[8-10]

EXPERIMENTAL

Reagents

Stock solutions of 3.6 m*M* Fe(III) (chloride), and Na, K, Ca, Ba, Cd, Zn, Co, Ni, Cu and Mn (chloride, nitrate and sulphate) were prepared from reagent-grade chemicals. Pt and Pd solutions were prepared from H_2PtCl_6 and K_2PdCl_4.

Apparatus

The atomic-absorption analysis was done with a Unicam SP 90A Series 2 atomic-absorption spectrophotometer, which incorporated a new HTA photo-tube. Air was supplied from a compressor, and acetylene was obtained from cylinders and passed through concentrated sulphuric acid and glass wool for purification. A continuous titration device[11] was attached to the instrument. Absorbance values were recorded with a single-pen recorder.

The instrumental parameters were: lamp current, 12 mA; wavelength, 248.3 nm; slit-width, 0.1 mm; observation height, 0.8 cm; air flow-rate, 5.0 l./min; fuel flow-rate, 1.4 l./min.

*The distance from the top of the burner to "grazing incidence position".

RESULTS AND DISCUSSION

Effect of anions

A series of almost neutral solutions was prepared, containing iron in 0.36 m*M* concentration and one of the anions in increasing amounts. The anions used were I^-, Br^-, NO_2^-, NO_3^-, Cl^-, ClO_4^-, SO_4^{2-} and PO_4^{3-}, added as the sodium or potassium salt. No interference from these foreign anions was found for up to 7.9, 12.5, 21.7, 16.1, 28.2, 10.1, 10.4 and 10.5 m*M* concentrations respectively.

Interfering effects of cations

The effect of various cations on the atomic-absorption of iron in presence of mineral acids was examined. Figure 1 shows that Na, K, Ca, Ba, Cd, Zn, Co, Ni, Cu and Mn chlorides in hydrochloric acid medium have insignificant effect on the absorption signal of iron up to 43.5, 25.6, 25, 7.3, 8.9, 15.3, 17, 17.5 and 18.2 m*M* for each cation respectively. A relative decrease of 20% in the iron signal was caused by the presence of 0.75m*M* Pt or Pd. A presumable cause for this depressive effect is that the ferric ions are stacked in the crystal lattices of H_2PtCl_6 and K_2PdCl_4 when the solvent has been evaporated in the flame, and are not completely released and atomized

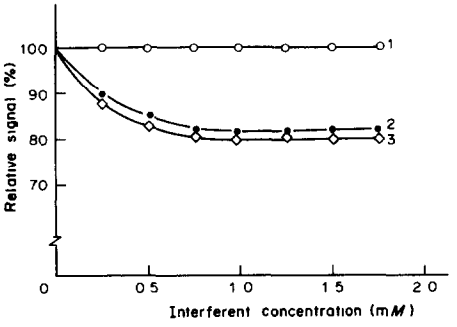

Fig. 1. Interference of some cations as chlorides on the signal from 0.36m*M* iron(III) chloride; (1) Na, K, Ca, Ba, Cd, Zn, Co, Ni, Cu and Mn; (2) Pt as H_2PtCl_6; (3) Pd as K_2PdCl_4.

by the time measurement is made. However, the depressive effect totally disappears if the measurement is done in higher parts of the flame, where release and atomization have become complete.

The effect of the same cations was investigated in solutions containing nitric or sulphuric acid. Figures 2 and 3 show that under these conditions, Ni, Co and Cu are the only cations which cause significant depressive effect on the absorption of iron. This effect also disappears when the measurements are performed in the upper parts of the flame (1.5–2.0 cm burner height). Again, the effect can be attributed to retention of the iron by the matrix as a result of incomplete volatilization.

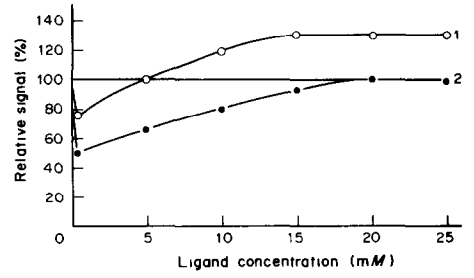

Fig. 4. Changes in the absorption signal from 0.36m*M* iron(III) chloride with increasing ligand concentration; (1) 4-aminosalicylic acid and (2) sulphosalicylic acid.

Effect of complexing agents

Figures 4 and 5 show the effect of some ligands that form iron complexes. The general trend shown by the graphs is to form stable 1:1 complexes with iron (as indicated by the position of the minimum in the iron signal). The stability of the Fe–N, Fe–O or Fe–S bonds left after combustion of the ligands determines the rate of release of iron atoms in the flame. As recently proposed,[12] the effect of ligands on the absorption of metals is principally dependent on the relative stability of the M–N, M–O or M–S bonds in the flame. When these bonds are strong enough, they produce molecular species as the dominant products in the flame and hence there is a depressive effect on the analyte signal. On the other hand, weak bonding

Pd (K_2PdCl_4)	0.94	80	100	100

militates against formation of the molecular compounds and enhances the release of the analyte atoms. Naturally, there should be a sufficient concentration of the ligand to give the desired effect. This is clearly shown by Figs. 4 and 5, which indicate a levelling trend with increase in ligand concentration.

Elimination of interferences

Further investigation revealed that if a large enough excess of 4-aminosalicylic acid or sulphosalicylic acid (60–100 fold relative to iron) is present the absorption signal for iron becomes constant irrespective of the ligand concentration, and also the depressive effect of various complexing agents and metal salts is eliminated (Table 1). The large excess of added ligand presumably leads to essentially complete preferential formation of its iron complex, thus giving a fixed environment for the iron in the flame atomization process.

Since AAS determination of iron in some of its complexes, particularly those containing phenanthroline, bipyridyl and/or amino groups, gives incorrect and variable results,[13,14] an investigation was made of the distribution of iron atoms as a function of the observation height in the flame for different iron complexes. Figure 6 shows that there is a marked difference in the rates of production of free iron atoms in the lower parts of the flame, but the system rapidly reaches the same equilibrium with the flame species (at 2 cm above the burner top). Thus correct results should be obtainable whatever the iron species present in the solution, provided the measurement is made at a high enough position in the flame, but only at the expense of the sensitivity. The treatment of the iron complexes with sulphosalicylic

bipy = bipyridyl; phen = phenanthroline.

acid overcomes the depressive effect in the lower part of the flame, resulting in the iron signal being independent of the nature of the original complex present, though it still varies with the position in the flame (Fig. 7). This indicates that conversion into the iron sulphosalicylate complex takes place in solution, before the aspiration. Table 2 shows the effect of sulphosalicylic acid on the various interferences.

MATRIX MODIFICATION FOR DETERMINATION OF SELENIUM IN GEOLOGICAL SAMPLES BY GRAPHITE-FURNACE ATOMIC-ABSORPTION SPECTROMETRY AFTER PRESEPARATION WITH THIOL COTTON FIBRE

SHAN XIAO-QUAN*
Institute of Environmental Chemistry, Academia Sinica, P.O. Box 934, Beijing, People's Republic of China

HU KAI-JING
Laboratory of Geological Bureau of Hunan Province, People's Republic of China

(*Received* 8 *September* 1983. *Accepted* 16 *July* 1984)

Summary—A graphite-furnace atomic-absorption method has been developed for the determination of selenium in geological samples at or below the μg/g level after decomposition of the sample with a mixture of perchloric, hydrofluoric and nitric acids and separation of selenium from the sample matrix with thiol cotton fibre. A few micrograms of palladium are added as a matrix modifier for the atomic-absorption determination. In the presence of palladium the charring temperature for selenium can be raised to 1100°, and the signal enhancement is greater than with other matrix modifiers reported in the literature.

The determination of selenium in geological materials at or below the μg/g level is important, as selenium is a geochemically interesting indicator for several types of mineral deposit,[1] and also presents a potential public health problem. The methods available for determining selenium in rocks and soils include solution spectrophotometry, flame atomic-absorption spectrometry (AAS) and d.c. arc emission spectrometry. However, these methods are interference-prone, have poor sensitivity and require a multistage process to complete the analysis. Although graphite-furnace atomic-absorption spectrometry offers sufficient sensitivity for the determination of selenium in geological materials at the μg/g level, serious interference problems are encountered, arising from the diverse and complicated nature of the matrices. It seems that preseparation is required. Sanzolone and Chao[2] have developed a method for the determination of selenium in the range 0.05–1000 μg/g. The sample was decomposed with a mixture of nitric, perchloric and hydrofluoric acids and heated with hydrochloric acid to reduce selenium(VI) to selenium(IV), which was then extracted into toluene from hydrochloric acid–hydrobromic acid medium containing iron. The toluene extract was injected into a carbon-rod atomizer, with nickel added as matrix modifier. In a previous paper[3] we reported a method for the determination of selenium in soil, based on digestion of the sample with a mixture of sulphuric and perchloric acids in the presence of ascorbic acid, followed by extraction of the resultant selenium(IV) with 1,2-diamino-4-nitrobenzene, and AAS determination in a zirconium-coated graphite tube. Recently, Kujirai *et al.*[4] have described a method for determining trace selenium in heat-resisting alloys by co-precipitation with arsenic, followed by graphite-furnace AAS with zinc as a matrix modifier to stabilize selenium during the charring step and thus enhance the sensitivity in the atomization step.

The present study describes a method for the determination of selenium in geological samples at or below the μg/g level by graphite-furnace AAS after separation with thiol cotton fibre (TCF). The samples are decomposed with a mixture of nitric, perchloric and hydrofluoric acids. Selenium(VI) in the sample solution is reduced to selenium(IV) by heating on a water-bath with 5*M* hydrochloric acid, and the selenium(IV) quantitatively absorbed on a column packed with TCF, and then desorbed by destruction of the thiol with a mixture of hydrochloric acid and nitric acid. Finally, the selenium(IV) is introduced into a heated graphite-atomizer along with palladium as a matrix modifier which allows the charring temperature for selenium to be raised to 1100° and gives greater enhancement than other matrix modifiers reported in the literature.

EXPERIMENTAL

Apparatus

A Perkin-Elmer model 380 atomic-absorption spectrometer equipped with a model HGA-400 graphite furnace and a Hitachi model 056 chart-recorder was used for the

*To whom correspondence should be addressed.

measurement of the selenium absorbance at 196.0 nm, under "argon stop" conditions. The band-width was set at 0.7 nm. The Perkin-Elmer electrodeless selenium discharge lamp was operated at 6 W. A 20-μl Eppendorf pipette with disposable polypropylene tips was used to introduce sample solutions into the graphite-tube atomizer. A deuterium background-corrector was used throughout.

Reagents

Selenium(IV) stock solution, 1000 μg/ml, was prepared by dissolving 0.1000 g of black elemental selenium in 2 ml of concentrated hydrochloric acid and 1 ml of concentrated nitric acid with gentle heating, and diluting to 100 ml with demineralized water. Other working selenium standard solutions were prepared by serial dilution from this stock solution with 0.1*M* hydrochloric acid.

Palladium and platinum solutions, 1000 μg/ml, were made by dissolving 0.100 g of palladium or platinum metal in a small volume of *aqua regia*, evaporating the solution on a water-bath nearly to dryness, taking up the residue with 10 ml of 0.1*M* hydrochloric acid and diluting to 100 ml with demineralized water.

Procedures

Preparation of thiol cotton fibre (TCF) and package of absorption column. Cotton cellulose (4 g) was soaked in a mixture of 28 g of thioglycollic acid, 15 g of acetic anhydride, 7 g of acetic acid and 0.1 g of sulphuric acid, and left standing for 4 days at 40°. It was then washed with demineralized water and dried under reduced pressure. The fibrous product contained 3–4% of thiol group. A 0.15-g amount of TCF was packed in the neck of a separatory funnel, the inner diameter and length of the neck being 6 mm and 8 cm, respectively. The absorption column was packed in this way to combine filtration of the sample solution with absorption of selenium(IV).

Sample decomposition. A 0.200-g sample was weighed into a 50-ml Teflon crucible, and 0.5 ml of demineralized water was added to moisten the sample thoroughly, followed by 1 ml of concentrated perchloric acid, 15 ml of hydrofluoric acid and 10 ml of nitric acid, in succession. The crucible was placed on a hot-plate, the surface temperature of which was raised from about 160° to 240° in 60 min and kept at the latter temperature until fumes of perchloric acid appeared. The crucible was then removed and cooled to room temperature. Then 30 ml of 5*M* hydrochloric acid were added and the crucible was covered with a watch-glass and heated on a boiling water-bath for 3 min, then cooled to room temperature.

Absorption and desorption of selenium(IV) and determination by graphite-furnace AAS. There was sometimes a precipitate left after the sample decomposition, and this was filtered off on a Millipore filter paper, the filtrate being passed into a TCF column prewashed twice with 5*M* hydrochloric acid; the crucible was rinsed with several 2–3 ml portions of 5*M* hydrochloric acid, the rinsings being passed through the filter paper and TCF column. The paper was washed several times with 5*M* hydrochloric acid and removed, then the TCF was carefully taken out of the column, squeezed dry and transfered to a graduated test-tube containing 1 ml of concentrated hydrochloric acid and *ca.* 0.05 ml of concentrated nitric acid. The tube was loosely stoppered with a glass stopper,[2] heated on a water-bath until the TCF was destroyed, then cooled to room temperature. The solution was diluted to 10 ml with demineralized water and shaken thoroughly, then let stand for a few minutes to allow the cotton fibre to settle out. Finally a 20-μl portion of supernatant solution was introduced into a graphite-tube atomizer, dried at 110° for 30 sec, charred at 1000° for 30 sec and atomized at 2100° for 5 sec at maximum power, and selenium absorbance measured under "argon stop" conditions. The graphite tube was then cleaned by firing at 2600° for 4 sec.

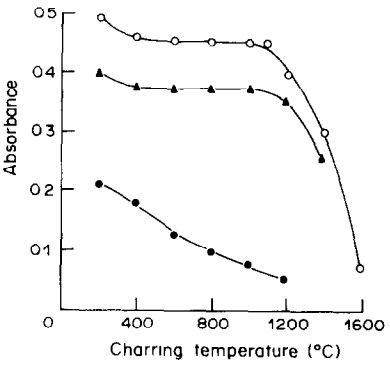

Fig. 1. Effect of charring temperature on the absorbance of selenium in the presence or absence of matrix modifiers: (●) 4 ng of Se in 1*M* HCl; (○) 4 ng of Se + 2 μg of Pd in 0.01*M* HCl; (▲) 4 ng of Se + 20 μg of Zn in 2.5*M* HNO_3.

RESULTS AND DISCUSSION

Stabilizing effect of palladium

It is well known that selenium is relatively volatile, so a certain loss may occur during the pre-atomization stages. To prevent such loss addition of various metal ions, such as nickel,[5] cobalt,[6] molybdenum,[7] lanthanum,[8] copper,[9] chromium[10] and zinc[4] has been recommended, as so-called matrix modifiers. We have found that palladium is the most effective matrix modifier for selenium. When palladium is present the charring temperature for selenium can be raised to 1100°, and the sensitivity is greater by a factor of 1.2 than that obtained by using zinc as matrix modifier (Fig. 1).

The stabilizing effect of palladium depends on the amount present. The absorbance for selenium increases over the range 0–1 μg of palladium and is constant for 1–3 μg (Fig. 2), so addition of 2 μg of palladium was selected as optimal.

Relationship between solution acidity and selenium absorbance

Since a mixture of concentrated hydrochloric and nitric acids is used for desorbing selenium(IV) from

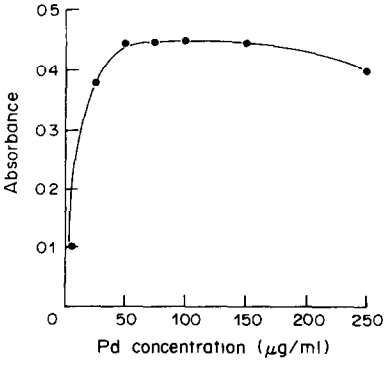

Fig. 2. Dependence of selenium absorbance on amount of palladium: 4 ng of Se + 20 μl of palladium solution of concentration shown (charring temperature 600°).

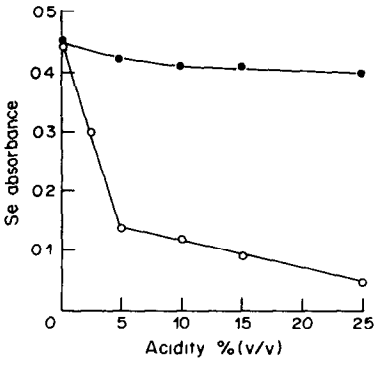

Fig. 3. Effect of acidity (volume percentage of concentrated acid in test solution) of selenium solution on absorbance in the presence of palladium: 4 ng of Se in HCl (●) or HNO_3 (○).

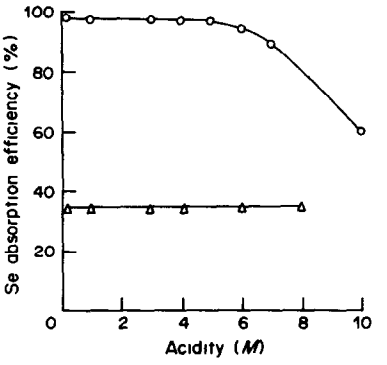

Fig. 4. Relationship between the absorption efficiency of selenium(IV) and selenium(VI) by TCF and the acidity of the sample solution: (○) 1 μg of Se(IV) in 30 ml of HCl; (△) 1 μg of Se(VI) in 30 ml of HCl.

the TCF, as described later, the sample solution which is introduced into the atomizer is highly acidic, so the relationship between solution acidity and selenium absorbance was examined. The results are shown in Fig. 3. The selenium absorbance is fairly constant with 10–25% v/v hydrochloric acid but strongly suppressed by nitric acid. A mixture of 10% v/v hydrochloric acid and 0.5% v/v nitric acid was therefore chosen as optimal for the measurement.

Sorption of selenium on thiol cotton fibre and desorption

Selenium is widely distributed in small amounts in geological materials, with an estimated crustal abundance of 0.05–0.075 μg/g.[11] Besides this problem of low concentration, there is that of the severe interferences encountered in the determination of selenium by graphite-furnace atomic-absorption spectrometry. Hence preseparation and/or concentration of selenium is a prerequisite for its accurate determination in ores and minerals. In the present study a TCF column was used for this purpose. The most important parameters affecting the sorption of selenium are its oxidation state, the acidity of the sample solution, and the amount of TCF used. To find the optimum conditions, an absorption column was packed as described in the procedure and used at a flow-rate of 0.05 ml/sec. Selenium(IV) solutions (30 ml) of various acidities were passed through the column and the selenium concentrations in the filtrate determined, and hence the absorption efficiency. The results are shown in Figs. 4 and 5. The absorption efficiency was found to be >95% over the range 0.5–6*M* hydrochloric acid. Selenium(VI) is not sorbed, but some of it can be reduced to selenium(IV) by the thiol group and sorbed when a selenium(VI) solution is passed through a TCF column, giving an apparent absorption efficiency of 35% for selenium(VI). Hence reduction of selenium(VI) to selenium(IV) is required, and can be obtained by boiling the sample solution with 5*M* hydrochloric acid for 3–5 min. The optimum amount of TCF is 0.15–0.20 g for sorption of 1 μg of selenium(IV) in 30 ml of aqueous solution. Less than 0.15 g is not sufficient, but if more than 0.20 g is used it is difficult to desorb all the selenium(IV). The absorption efficiency increases with volume of aqueous sample solution up to 20 ml and then levels off. The optimum conditions are therefore considered to be the use of 30 ml of 5*M* hydrochloric acid sample solution, and 0.15 g of TCF.

Various acid mixtures were tried for the desorption and a mixture of 1 ml of concentrated hydrochloric acid and 0.05 ml of nitric acid was found the most effective. The eluate was diluted to 10 ml to give the optimum acidity for measurement.

Permissible amounts of diverse ions

Because of the severe interferences encountered in the determination of selenium by graphite-furnace atomic-absorption spectrometry, a very selective extraction procedure was employed in our earlier method.[3] From the general composition of ore and mineral materials and the sample weights taken for analysis in this work, a realistic set of matrix com-

GSD = Geochemical Standard Reference Drainage Sediment.
DPP = differential pulse polarography.

ponent levels was established for study, and it was found that for the determination of 1 μg of selenium in 30 ml of aqueous solution no interference was observed from 0.15 g of Ca, 0.1 g of Pb, Zn, K, Na and Mn, 45 mg of Mg, 40 mg of Fe, Al, Sb, Cu, 30 mg of W, 20 mg of Si, P, 10 mg of Ba, La, 6 mg of Hg, 4 mg of Ni, Mo and Th, 1 mg of Ag, Bi, Cd and Yb, 0.25 mg of As, 0.2 mg of F and 0.1 mg of Au.

Recovery

Various samples were spiked with known quantities of selenium before decomposition of the sample and the total selenium contents were determined and compared with the selenium content of the samples. Table 1 shows that good recovery was obtained.

Determination of selenium in ores and minerals

Although no pronounced interference effects occur and good recoveries are obtained by the recommended method, the standard-additions method was used. The results for some ore and mineral samples are summarized in Table 2, and a good agreement was achieved with the certified values. The relative standard deviation was found to be 7.4% for 9 replicate determinations of selenium in GSD-3 Geochemical Standard Reference Drainage Sediment, for which the certified selenium value is 1.07 ± 0.14 μg/g. It should be pointed out that this method can be employed for the determination of selenium in geological samples at or below the μg/g level.

PHOTOMETRIC COMPLEX-FORMATION TITRATION OF SUBMICROMOLE AMOUNTS OF URANIUM

J. KRAGTEN and W. OZINGA
Laboratory for Analytical Chemistry, University of Amsterdam, Nieuwe Achtergracht 166, 1018 WV Amsterdam, The Netherlands

(*Received* 28 *March* 1984. *Accepted* 30*th June* 1984)

Summary—With DTPA present in excess, small amounts of uranium (100–200 μg) can be reduced quantitatively to the quadrivalent state in a Jones reductor (5% amalgamated Zn powder, 50 mesh). The excess of DTPA is back-titrated photometrically with thorium, with Semi-Xylenol Orange as the indicator. The accuracy is ± 0.2 μg at the 200-μg level. Metals forming complexes with DTPA at pH 2 interfere.

In the determination of uranium, complexometry has so far found little use for a number of reasons. Uranyl ions form complexes with many reagents, such as acetate, sulphate, nitrate, ascorbic acid, *etc.*,[1] but those with the complexing agents DCTA, DTPA and EDTA are remarkably weak.[2] Low concentrations therefore cannot be determined and interference by other elements is rather strong. Moreover, weak 2:1 complexes are also formed, so the stoichiometry is variable.[2] The sexivalent state is hence regarded as rather unsuitable for complexometric determinations.[3]

Uranium(IV) forms stable complexes[4] in strict 1:1 stoichiometry with EDTA, DCTA and DTPA, but its complexometric determination has been of little importance so far, first because of a lack of accuracy and secondly because oxidimetric determination is the obvious choice if the uranium has been reduced to the quadrivalent state, since the oxidative titrations give the same or even greater accuracy and can be done in the presence of a much larger number of metals. Only at low uranium concentrations (10^{-5}–$10^{-4}M$) do the advantages of oxidimetry disappear. The potential jump becomes less pronounced and the reduction may partially proceed to the tervalent state,[5] which is unstable towards water and air. Aeration, recommended in most procedures,[1,5] does not always stop at the quadrivalent state. For macrodeterminations the procedure functions well, but generally the free U^{4+} ions are less easy to keep from decay at low concentrations.[6–8] We have therefore re-examined the possibilities for the complexometric determination of uranium(IV) at low concentrations (10^{-5}–$10^{-4}M$) with accurate analysis as our aim.

A crucial point is the reduction to the quadrivalent state and its preservation. Reducing agents, added in excess, theoretically have the advantage of keeping the element in the reduced state. Hydrazine and sodium tetrahydroborate were examined but did not give quantitative reduction; zinc, ascorbic acid and bisulphite[6–8] were rejected for the same reason. Sodium dithionite ($Na_2S_2O_4$) has been used by various authors.[8–10] Although it gives quantitative reduction it is less suitable because colloidal sulphur is formed at low pH and hydrolysis of U^{4+} occurs at low acidity. At the recommended pH of 3 an accuracy of 7 μg is claimed[9] in a direct photometric titration with EDTA. We tried to improve this by performing the reduction in the presence of EDTA in order to stabilize the U(IV) state and to protect it from hydrolysis, but the accuracy was hardly improved.

Use of reductor columns was tried as an alternative. A silver reductor[5] does not introduce impurities and was therefore considered first. The reduction potential of the silver reductor is

$$E = 0.22 + 0.059\text{pCl} \qquad (1)$$

Combining this with the redox reaction

$$UO_2^{2+} + 4H^+ + 2e \rightleftharpoons U^{4+} + H_2O \ (E^0 = 0.33\ \text{V}) \qquad (2)$$

and taking into account possible side-reactions of both UO_2^{2+} and U^{4+}, we can derive for the conditional equilibrium ratio

$$\log \frac{[UO_2']}{[U(IV)']} = -3.8 + 2\text{pCl} + 4\text{pH} - \log \alpha_{U(IV)} + \log \alpha_{UO_2} \qquad (3)$$

where the primes indicate conditional values.

It will be obvious that in the absence of complexing agents, the hydrochloric acid concentration should theoretically be higher than 1M. This agrees with practical experience that 4M acid must be used (at 60°).[11] We found incomplete reduction with 1M acid, presumably because of low reactivity at the silver surface covered with silver chloride. As high acidity leads to a high ionic strength, causing interference in the titrations or needing time-consuming evaporation to remove the excess of acid (with consequent risk of oxidation), this method is also less suitable. In the presence of EDTA and DTPA (we selected the latter for our experiments because of its much higher solubility in acid media[12]) reduction remains incomplete; at pH 1 the contribution of $\log \alpha_{U(IV)}$, is not

able to compensate for the effect of the term 4pH (Table 1). Neither EDTA nor DTPA is reduced by the silver reductor; nevertheless the reductor is unsuitable for quantitative reduction of uranium(VI) at moderate acidity.

The Jones reductor,[5,15,16] filled with amalgamated zinc, is more powerful and so can be applied at lower acid concentrations (0.01–0.1*M* hydrochloric acid). Both zinc and mercury can participate in the reduction process,[5] but which metal reacts preferentially depends on the substance to be reduced. Uranium(VI) is reduced only by zinc,[16] which leads to an increase of Zn^{2+} in solution and a decrease of metallic zinc at the amalgam surface. Moreover, although the mercury suppresses the evolution of hydrogen because of the large overpotential, gas formation is not negligible. All these processes together make the reduction potential approximately 0.70 V.[5] Combining this value with equation (2) we get

$$\log \frac{[UO_2^+]}{[U(IV)']} = -35 + 4\,pH - \log \alpha_{U(IV)} + \log \alpha_{UO_2} \quad (4)$$

Hence under all experimental conditions of interest, the reduction will theoretically be complete.

Uranium can also be reduced to the tervalent state according to

$$U^{4+} + e \rightleftharpoons U^{3+} \quad E^0 = -0.61\ V \quad (5)$$

With the Jones reductor we get

$$\log \frac{[U(IV)']}{[U(III)']} \approx -1.5 + \log \alpha_{U(IV)} - \log \alpha_{U(III)} \quad (6)$$

From Table 1 it will be obvious that in the region of interest (pH > 1) tervalent uranium will not be formed when DTPA is present in excess, and so aeration can be omitted.

In the presence of atmospheric oxygen (redox potential $E = 1.23–0.059\,pH$) uranium(VI) is the stable form ($\log [UO_2^+]/[U(IV)'] > 25$), but it is known that, even in the absence of ligands, oxidation of U(IV) by atmospheric oxygen proceeds so slowly that working under nitrogen is not necessary in macrodeterminations.[6–8,11,16] At low concentration levels, however, irregular results were observed, which is remarkable as a still lower reactivity should have been expected. The cause is indirectly oxygen, which is reduced to hydrogen peroxide in the column:[17]

$$Hg + O_2 + 2H^+ + 2Cl^- \rightarrow Hg_2Cl_2\downarrow + H_2O_2 \quad (7)$$

Although further reduction by the half-reaction $H_2O_2 + 2H^+ + 2e \rightleftharpoons 2H_2O$ has a standard potential of +1.77 V, this reaction is very slow in the reductor because the overpotential for reduction of H_2O_2 at a mercury surface is extremely high ($\simeq 2.5$ V).[17] Hence a steady-state peroxide concentration is built up. Prior deaeration reduces the production of peroxide insufficiently for accurate analysis.

The interference seems not to be simply due to the reoxidation of U^{4+} ions to uranyl ions. It is known that uranyl ions form complexes with hydrogen peroxide. Tridot[18] showed that at pH 0.5–3.5 uranyl ions can be quantitatively precipitated as uranyl peruranate. He states that any U(IV) is first oxidized and then precipitated as peruranate. This is important, because if H_2O_2 is formed in the column first, peruranate may pass in colloidal state through the column before its reduction occurs. It turns out that if DTPA is present in excess during the reduction, U(IV)—once formed—is transformed into its DTPA complex, which is not oxidized by any H_2O_2 formed in the column; no interference by hydrogen peroxide could be observed in our experiments.

It has been found experimentally, that aerial oxidation of the U(IV) in the effluent from the reductor is negligible; 20% oxidation to uranyl ions took place during exposure for a weekend.

It has been reported that oxidation of U(IV) is accelerated appreciably by ultraviolet radiation and direct sunlight.[1] On the other hand, methods have been proposed for the photochemical reduction of U(VI) to U(IV) in the presence of lactic acid, ethanol and other reducing agents.[19,29] Standing for 4 hr in moderate light conditions was found to lead to an

Table 1.

		pH					
	[DTPA] in excess, M	0	0.5	1.0	1.5	2.0	2.5
$\log \alpha_{U(IV)}$	10^{-4}	0	0.3	2.8	5.5	8.0	10.1
	10^{-5}	0	0	1.8	4.5	7.0	9 1
$\log \alpha_{U(III)}$	10^{-4}	0	0	0	0.7	3.0	5.1
	10^{-5}	0	0	0	0.1	2.0	4.1

From the stability constants[2] of the uranyl–DTPA complex and the small tendency for hydrolysis[13] it can be concluded that at moderate uranyl ion concentrations $\log \alpha_{UO_2} = 0$ below pH 3.5. For U(III) no reliable hydrolysis constants are known,[1] but if U(III) is regarded as comparable to lanthanides it can be assumed that hydrolysis is negligible below pH 4.[1] Hence $\log \alpha_{U(III)} = \log \alpha_{U(III)DTPA}$, which has been calculated from the data for protonation of DTPA: $\log \beta_1 = 10.46$, $\log \beta_2 = 18.87$, $\log \beta_3 = 23.01$, $\log \beta_4 = 25.71$, $\log \beta_5 = 27.79$, $\log \beta_6 = 29.01$ and $\log \beta_7 = 29.76$, and $\log K_{U(III)DTPA} = 25.1$.[14] For U(IV) $\log \alpha_{U(IV)}$ is given by $\log \alpha_{U(IV)} = \log \alpha_{U(IV)XDTPA)}$. The literature value[4] $\log K_{U(IV)DTPA} = 28.8$ has been corrected for the neglect of the DTPA protonation constants determined recently,[12] $\log \beta_6$ and β_7, the corrected value being $\log K = 30.1$.

error smaller than -0.1%. Within the experimental error ($\pm 0.1\%$) of the photometric back-titration with thorium [Semi-Xylenol Orange (SXO) as indicator] at pH 2, there was complete recovery of EDTA and DTPA passed through the Jones reductor. This implies first that no Hg^{2+} ions are released in the reduction, and secondly that zinc ions do not interfere in the titration. For each 10 ml of the eluent (0.1*M* hydrochloric acid) 10 μmoles of Zn^{2+} are found to be produced. It is important to use >99.9% pure zinc, as otherwise some of the impurities may interfere.

The procedure developed allows reduction of 150–260 μg of uranium in the presence of excess of DTPA, the surplus being back-titrated with thorium (SXO as indicator).

EXPERIMENTAL

The Jones reductor

Zinc powder (<99.9% pure, Merck) is sieved and the 0.18–0.60 mm fraction collected; a 15-g portion is etched in a 100-ml beaker by short exposure to 1*M* hydrochloric acid, then washed twice with water of "sub-boiling" quality. The wet powder is amalgamated by vigorous stirring with 25 ml of 0.1*M* hydrochloric acid in which 800 mg of mercury chloride have been dissolved. After 15 min the solution is decanted and the zinc washed thrice with sub-boiled water. This produces so-called 5% amalgamated zinc.

As mercury is not consumed during the reduction of U(VI) we thought that 1% amalgamated zinc (made by using 200 mg of mercuric chloride instead of 800 mg) might react faster because of the smaller diffusion distances through the mercury film. However, the reduction is less efficient, as evolution of hydrogen increases and tends to reduce the available mercury surface area by forming a protective gas film.

The amalgamated zinc is transferred into the column (0.8 × 6 cm) with 0.1*M* hydrochloric acid, Merck, Suprapur). The column should not be allowed to become dry. Before use it is filled with 0.1*M* hydrochloric acid and inverted to remove the hydrogen bubbles from between the grains. It is then washed with 0.1*M* hydrochloric acid to remove zinc ions and hydrogen peroxide. This pretreatment should be performed at least daily. The size of the amalgamated particles increases by coagulation, but the large internal surface of the zinc in each grain is increased sufficiently by the use of fine powder for exhaustion of the zinc atoms at the mercury surface not to occur, and the reduction is complete.

Reduction procedure

After pretreatment of the column about 1 ml of the acid is left above the amalgam and 0.005*M* DTPA (250 μl) is added to it from a microburette with a U-shaped tip which is immersed in the solution. On removal, the tip is washed with a few hundred μl of 0.1*M* hydrochloric acid. Then a 200-μl sample containing about 1 μmole of uranium (in 0.1*M* hydrochloric acid) is similarly introduced. Nitrogen gas is introduced through a Teflon microtube to mix the solution and expel atmospheric oxygen. The solution is then let flow through the column until its surface is just above the amalgam. The column is then rinsed with three 0.5-ml portions of 0.1*M* hydrochloric acid, and then with 15 ml of the acid in 3-ml portions. The flow-rate should not exceed about 2 ml/min.

Titration procedure

The eluent is caught directly in a 20-ml titration cell containing hexamine solution (at pH 7). The pH is adjusted to 2.0 with either hydrochloric acid or additional hexamine solution.

The pH-meter electrodes are rinsed with 0.01*M* hydrochloric acid. Then 250 μl of 0.06% SXO solution in acetone are added. The cell is placed in the spectrophotometer and the excess of DTPA is back-titrated with 0.005*M* thorium (adjusted to pH 2) at 530 nm. For accurate analysis, glassware calibration corrections have to be applied.

RESULTS AND DISCUSSION

At pH > 7.5 U(IV)–DTPA dissociates, forming either a precipitate or a soluble hydroxide[21] (Fig. 1). Once formed—for instance locally during neutralization with a strong base—these products will cause irregular results; some uranium will escape from analysis as DTPA will react only slowly with the $U(OH)_5^-$ ions, and precipitated $U(OH)_4$ is easily oxidized by air.[13,22] That is why the eluent is caught directly in the cell and neutralized with a hexamine buffer adjusted to pH 7.

Use of 0.01*M* hydrochloric acid medium in the reduction procedure causes large errors, presumably because it leads to local pH values far above 2 because of the reduction of protons to hydrogen.

SXO[23] has to be preferred to Xylenol Orange (XO) as the indicator. With XO systematic deviations occur at low concentrations because of the predominant formation of Th_2XO.[24] Thorium and SXO form only the ThSXO and $Th(SXO)_2$ complexes, with conditional constants $\log \beta_{11} = 6.85$ and $\log \beta_{12} = 11.4$ (pH = 2.00, I = 0.1, perchlorate medium).[25]

The conditions for photometric back-titrations[26] are amply fulfilled. The curvature of the L-shaped titration curve near the equivalence point agrees very well with the values for $\log \beta_{ThSXO}$, $\log K_{U(IV)DTPA}$ and the difference in stability constants of U(IV)DTPA and ThDTPA as mentioned by Piskunov *et al.*[4]

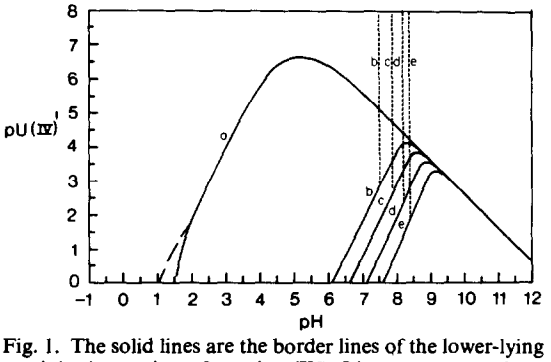

Fig. 1. The solid lines are the border lines of the lower-lying precipitation region of uranium(IV). Line a corresponds to uranium(IV) in the absence of complexing agents; lines b–e hold for the presence of DTPA in excess concentrations of 10^{-4}, 10^{-3}, 10^{-2} and $10^{-1}M$, respectively. The vertical dotted lines mark the region at high pH in which more than 1% of the original U(IV)DTPA is converted into the soluble hydroxide complex. The hydrolysis data for U(IV) used in constructing the diagram are $\log {}^*\beta_1 = -1.5$, $\log {}^*\beta_2 = -3.0$, $\log {}^*\beta_3 = -7.3$, $\log {}^*\beta_4 = -11.80$, $\log {}^*\beta_5 = -17.6$, $\log {}^*\beta^{15}{}_6 = -17.20$ and $\log {}^*K_{s0} = 5.0$.[21,22] The dashed line indicates the 1% border of polycomplex formation, but plays no role in our analysis.

($\Delta \log K = 2.1$). The procedure has been applied to several intermetallic compounds such as UCo_2, UFe_2 and UAl_2 with excellent results. Nickel interferes, as do all metals forming DTPA complexes at pH 2. Perchlorate does not interfere. Nitrate interferes strongly; nitric acid used for sample dissolution should be expelled with perchloric acid. For metallic uranium samples an error of 0.1% can be achieved if all the volumetric apparatus is calibrated. The DTPA can be standardized against high-purity metallic copper by photometric titration with TAR as the indicator. The thorium solution can be standardized against the DTPA solution and its titre need not be known quite so accurately.

A SIMPLE SPECTROPHOTOMETRIC METHOD FOR THE DETERMINATION OF NYLIDRIN HYDROCHLORIDE, ISOXSUPRINE HYDROCHLORIDE AND SALBUTAMOL SULPHATE IN PHARMACEUTICAL PREPARATIONS

R. T. SANE*, V. G. NAYAK and V. B. MALKAR
Department of Chemistry, Ramnarain Ruia College, Matunga, Bombay 400019, India

(*Received* 5 *April* 1982. *Revised* 20 *July* 1984. *Accepted* 14 *September* 1984)

Summary—A simple spectrophotometric method for the determination of nylidrin hydrochloride, isoxsuprine hydrochloride and salbutamol sulphate is described, based on measurement of the orange-yellow species produced when the drugs are coupled with diazotized benzocaine (*p*-aminoethyl benzoate) in trimethylamine medium. The method is applicable over the range 1–12 μg/ml for isoxsuprine hydrochloride and nylidrin hydrochloride and 1–8 μg/ml for salbutamol sulphate. The method is a modification of the Bratton–Marshall reaction and is simple, reproducible, accurate and more sensitive than those cited in the literature.

Nylidrin (buphenine) is a peripheral vasodilator and is incorporated in various pharmaceutical products. No colorimetric method for its determination has been reported but methods such as non-aqueous titration, gas chromatography and HPLC have been used.[1-3]

Isoxsuprine hydrochloride is an orally and parenterally active peripheral and cerebral vasodilator. In addition to adrenolytic action it has a direct relaxant effect on the smooth muscular tissue of the blood vessels and of the uterus. Several methods such as ultraviolet spectrophotometry, gas chromatography and HPLC coupled with colorimetry are cited in the literature for its determination.[1,3-6]

Salbutamol sulphate is a bronchodilator. Non-aqueous titration, ultraviolet spectrophotometry, colorimetry, stable-isotope dilution, fragmentation mass spectrometry, gas chromatography and NMR have been used for its determination.[4,7-14]

We have now developed a rapid, sensitive and general method for the determination of nylidrin hydrochloride, isoxsuprine hydrochloride and salbutamol sulphate, based on our observation that when coupled with diazotized benzocaine in trimethylamine solution these drugs yield an orange-yellow compound, the absorbance of which can be measured at 460 nm. The method is a modification of the Bratton–Marshall reaction, since the diazotization is done in a mixture of trichloroacetic acid and sulphuric acid. This method has wide applicability in the determination of nylidrin hydrochloride, isoxsuprine hydrochloride and salbutamol sulphate in pharmaceutical preparations.

*Author for correspondence.

EXPERIMENTAL

Reagents

Analytical grade chemicals were used throughout.

Benzocaine. A 2 mg/ml solution in 95% alcohol.

Acid mixture. A mixture of 86 ml of 15% trichloroacetic acid solution, 20 ml of 2*M* sulphuric acid and 94 ml of distilled water.

Sodium nitrite solution, 0.1%.

Trimethylamine solution, 40%.

Standard drug solutions

Standard isoxsuprine hydrochloride and nylidrine hydrochloride were checked for purity and strength according to the U.S.P. specifications, which they met. Standard salbutamol sulphate was checked for purity and strength according to the B.P. 1980 specifications and was found to meet those requirements.

Standard solutions were prepared by dissolving 25 mg of the drug (accurately weighed) and diluting to volume in a 250-ml standard flask to give a 100 μg/ml working standard solution.

Optimum reaction conditions

The optimum experimental conditions for the determination were established by systematic variation of reagent volumes. The results are summarized in Fig. 1.

General procedure

Into each of a series of 25-ml standard flasks pipette 1 ml of benzocaine solution, and add 1 ml of acid mixture and 2 ml of sodium nitrite solution. Let the flasks stand for 15 min, then add 2.5 ml of 95% ethanol to each. Next add portions of standard drug solutions ranging from 0.25 to 3 ml for nylidrin hydrochloride or isoxsuprine hydrochloride and from 0.25 to 2.00 ml for salbutamol sulphate, to

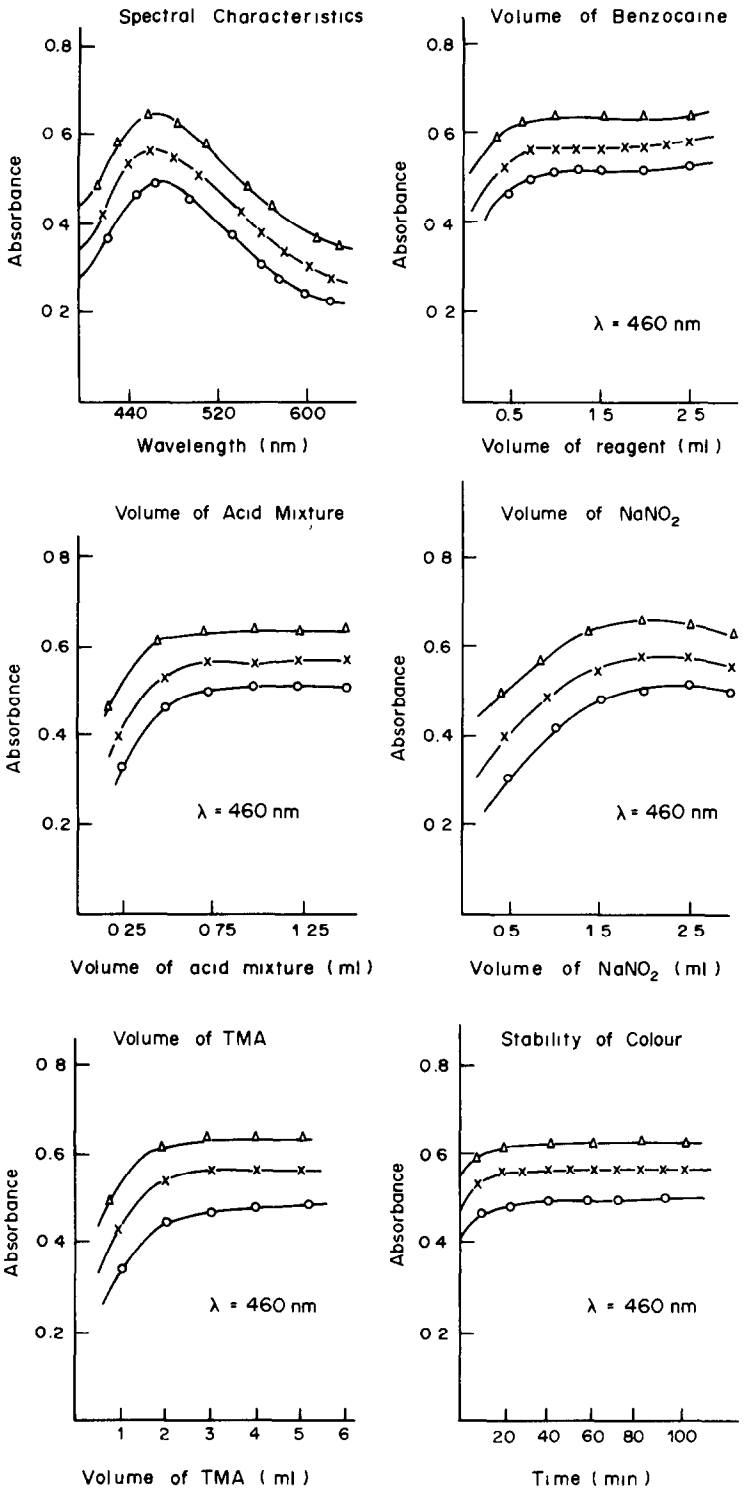

Fig. 1. Absorption spectra and optimization of conditions. × Nylidrin hydrochloride; ○ isoxsuprine hydrochloride; △ salputamol sulphate.

Table 1.

Drug	Product	Nominal content	Coefficient of variation, %	Nominal recovery, %	Molar absorptivity, 10^4 $l.mole^{-1}.cm^{-1}$
Nylidrin hydrochloride	Tablets	6 mg	1.5	100.2	3.36
	Injection	5 mg/ml	1.6	100.4	
Isoxsuprine hydrochloride	Tablets	10 mg	1.9	100.6	2.17
	Injections	5 mg/ml	1.5	99.0	
Salbutamol sulphate	Tablets	2 mg	1.8	100.1	2.30
	Tablets	4 mg	1.7	100.1	
	Syrup	2 mg/5 ml	2.3	100.1	

construct a calibration graph. Let the flasks stand for 5 min and finally add 3 ml of trimethylamine solution and dilute to the mark with distilled water. Measure the absorbances at 460 nm against a reagent blank prepared along with the standards. Analyse the test samples in the same way.

The calibration graphs are linear over the range 1–12 μg/ml for nylidrin hydrochloride and isoxsuprine hydrochloride and 1–8 μg/ml for salbutamol sulphate, in the final solution measured.

Application to pharmaceutical preparations

Tablets. Powder 20 tablets containing one or the other of nylidrin hydrochloride, isoxsuprine hydrochloride and salbutamol sulphate and mix. Weigh an amount of the powder equivalent to about 25 mg of drug and dissolve it and dilute the solution accurately to 250 ml with distilled water. Analyse the solution as detailed above.

Injections or syrups. Thoroughly mix the sample, pipette out a quantity corresponding to about 25 mg of drug and accurately dilute to 250 ml. Analyse the solution as described above.

Recovery experiments

To study the precision and accuracy of the method, a statistical study was undertaken. A fixed volume of sample solution was taken and standard drug solution was added at three different levels and the total amount of drug was determined. Each level was tested 7 times. The recovery was calculated by regression analysis. A standard additions graph gave the drug content of the sample. Results are given in Table 1.

RESULTS AND DISCUSSION

The pharmacopoeial methods described in the U.S.P. and B.P. for the determination of the three drugs require larger quantities of sample, whereas the present method needs less than 200–300 μg of the drugs (in the final solution).

The method is simple and rapid. The diazotization can be done at room temperature, and the excess of nitrite need not be removed. The colour development is complete within 30 min and the product is stable for at least 2 hr. There is no interference from the common excipients such as starch, talc *etc.* used as binding materials in tablet formulation. In the determination of salbutamol sulphate in syrups, the Tartrazine Yellow present does not interfere in the reaction. The recoveries range between 99 and 101% and the coefficients of variations are low. The method can be used for routine quality-control analysis of the drugs.

APPLICATION OF ION-EXCHANGE REACTIONS BETWEEN MEMBRANES AND RESINS

JAMES A. COX* and NOBUYUKI TANAKA
Department of Chemistry and Biochemistry, Southern Illinois University, Carbondale, IL 62901, U.S.A.

(*Received* 13 *June* 1984. *Accepted* 2 *August* 1984)

Summary—The separation of a solution of an electrolyte from an ion-exchange resin by an ion-exchange membrane, where the charge sign of the fixed sites is the same, results in a process that is comparable to Donnan dialysis in its overall effect. That is, the counter-ions from the resin can be exchanged for ions of the same charge sign in the electrolyte. The reaction is demonstrated and the efficiency of the process evaluated by monitoring the metathesis of carbonic acid from sodium carbonate. An application of the metathesis of a non-electrolyte to a preconcentration method for ion chromatography is demonstrated.

Ion-exchange reactions are typically performed between solute ions and those held on a resin with fixed sites of the appropriate charge sign. In the present report we describe what is seemingly a direct exchange reaction between ions on a pair of ion-exchange materials. To our knowledge, such a reaction has not been previously described.

The process, dual ion-exchange, has potential application to both analytical and synthetic chemistry. In the format used, the separation of a resin slurry bath from an electrolyte solution by an ion-exchange membrane, the process is similar to Donnan dialysis; however, incursion of the counter-ion of the electrolyte, which is a limitation of Donnan dialysis because of the non-zero transport numbers for cations (anions) in anion (cation)-exchange membranes,[1-3] cannot occur. In many experimental procedures the ability of dual ion-exchange to introduce a prescribed ion into the sample without even trace level incursion of the counter-ion is desired. Dual ion-exchange has other merits. The change of concentration of an analyte ion in solution because of adsorption losses or sample volume change, which commonly occurs in conventional ion-exchange, is minimized. Only a small sample volume is therefore required. There is virtually no dead volume with this method.

EXPERIMENTAL

Apparatus

The dual ion-exchange apparatus consisted of the following: a Nafion 811 cation-exchange tubular membrane (DuPont Polymer Products, Wilmington, Delaware), 0.64 mm bore, 0.89 mm outer diameter, coiled on a holder made of glass rods; a slurry of 55 g of Dowex 50WX4 100/200 mesh cation-exchange resin, proton form, and 24 g of water, in a 100-ml beaker; a Model 375A tubing pump (Sage Instruments, Cambridge, Massachusetts) and a Nuova II hotplate/magnetic stirrer (Thermolyne Corp., Dubuque, Iowa). The system was assembled as shown in Fig. 1.

The cation-exchange resin was regenerated with 4*M* hydrochloric acid (3 volumes per volume of resin). It was subsequently rinsed with about 150 resin-volumes of water.

The initial clean-up step for a new portion of Nafion tubing consisted of passing 1*M* hydrochloric acid through the tubing for 1 hr, while the tubing was also immersed in 1*M* hydrochloric acid. A specific pretreatment of the Nafion tubing to set the initial ionic form was not necessary. Instead, the holder with the tubing was placed in the resin slurry; the ionic form of the membrane became the same as that of the resin slurry. Between samples, water was pumped through the tubing for at least 2 min. A plug of air was always injected before a sample was introduced, in order to eliminate dilution. In the experiments where the slurry was heated, some water was occasionally added to the slurry in order to compensate for evaporation loss.

The carbonate was determined by flow-injection analysis with conductimetric detection. A model 2010i ion-chromatograph (Dionex Corp., Sunnyvale, California) was used with the columns by-passed (*i.e.*, the injector was coupled directly to the detector with a length of tubing). Water was used as the carrier at a flow-rate of 0.3 ml/min. The conductivity was monitored and displayed on a Speed Servo II strip-chart recorder (Esterline Angus Instrument Co., Indianapolis, Indiana). Solutions of sodium carbonate were used as the sample. In the course of the dual ion-exchange process, the sodium carbonate is converted into carbonic acid, which rapidly decomposes into CO_2 and water.

The efficiency of the process was reported as "% metathesized" based on the change of carbonate concentration as the sample passed through the system. The concentration of carbonate after metathesis was determined by fitting the conductivity of the sample to a calibration curve prepared with standard solutions. The "% metathesized" was calculated as the percentage decrease in carbonate concentration.

In one experiment, nitrate was determined after Donnan dialysis into a mixed sodium bicarbonate/carbonate receiver and dual ion-exchange of the dialysate. Measurement was done by ion-chromatography performed in the conventional manner. The Donnan dialysis of nitrate was performed in a cylindrical cell with an R-1035 anion-exchange membrane 11.3 cm^2 in area (RAI Research Corporation, Hauppauge, New York), 5 ml of receiver electrolyte, 100 ml of sample and dialysis for 30 min. Details of the procedure are available elsewhere.[4]

All chemicals used were ACS reagent grade. Distilled water doubly-demineralized with Cole-Parmer research grade cartridges, was used

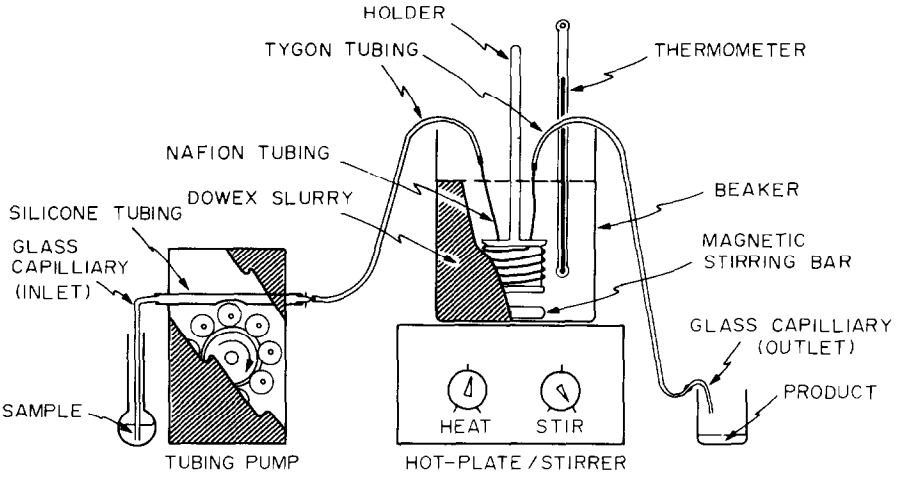

Fig. 1. Apparatus for dual ion-exchange metathesis.

RESULTS AND DISCUSSION

The general characteristics of the dual ion-exchange system were established in experiments performed under the following conditions: sample, 0.20*M* sodium carbonate; Nafion 811 cation-exchange tubing length, 2 m; resin slurry temperature, 75°; sample flow-rate, 0.29 ml/min. The sample was pumped through the Nafion tubing, which was immersed in the stirred, heated slurry. With 0.20*M* sodium carbonate as sample, there was 99.96% conversion into carbonic acid.

The flow-rate does not need to be carefully controlled to give reproducible results; at 0.58 ml/min the final carbonate concentration was $7.2 \times 10^{-5}M$ and $7.7 \times 10^{-5}M$ at a flow-rate of 0.29 ml/min. With shorter lengths of the cation-exchange tubing, the flow-rate is more critical; with a 0.20*M* carbonate sample, a slurry at 75° and 1 m of Nafion tubing, flow-rates of 0.17 and 0.29 ml/min yielded final carbonate concentrations of $1.3 \times 10^{-4}M$ and $6.5 \times 10^{-4}M$, respectively.

In other applications of tubular cation-exchange membranes, the use of either beads[5] or a filament[3,6] as packing material to decrease the dead volume was reported to improve the efficiency. With the dual ion-exchange system, the results shown in Table 1 were obtained. The volumes of the open tube, bead-packed tube and filament-packed tube were 0.46, 0.27 and 0.25 ml, respectively. The efficiency was not related to dead volume, and turbulence within the tubing apparently caused the increased efficiency. With the open tube the turbulence resulted from the decomposition of carbonic acid into CO_2 and water. The bead-packed Nafion tube was generally employed in subsequent experiments.

To establish the optimum operating parameters of the system, it is important to consider the electrolyte concentration of the sample. Table 2 summarizes the effects of temperature, flow-rate and concentration on the efficiency when 1 m of bead-packed tubing is used. The system can be operated at room temperature when the electrolyte concentration is below 0.1*M* and/or slow flow-rates are employed. Alternatively, a longer tube can be used.

The precision was determined by performing eight consecutive experiments at 76°. With 2 m of open Nafion tubing, a 0.1*M* sodium carbonate sample and a 0.29 ml/min flow-rate, the average residual carbonate was $7.5 \times 10^{-5}M$, with a relative standard deviation of 7.7%.

The lifetime of the slurry depends on its volume and the capacity of the ion-exchange resin. Under the reported conditions, the slurry produced carbonic

acid from 0.08 mole of sodium carbonate of exchange capacity (160 ml of 0.5*M* solution). This corresponded to utilization of 2.9 meq per gram of the wet resin; the stated capacity of the dry resin was 5.2 meq/g. Since the specific capacity of the wet resin must be lower than that of the dry, it was evident that a very high percentage of the available proton population was used before regeneration was necessary. Further, the residual carbonate peak was constant until this point was reached, so it was obvious when regeneration was necessary.

The dual ion-exchange process is not limited to carbonate samples. Comparable results are obtained for the conversion of sodium hydroxide into water, trisodium phosphate into phosphoric acid H_3PO_4 and sodium sulphite into sulphurous acid.

The analytical utility of the process is demonstrated by using Donnan dialysis as a preconcentration and matrix normalization technique[4,7–9] prior to ion-chromatography. Such a method has potential advantages over the use of a preconcentrator column,[10] but the Donnan dialysis receiver electrolyte, which must have at least 100 times the ionic strength of the sample, is not suitable for injection into an ion-chromatograph employing a conductivity detector.

A 0.50-mg/l. nitrate sample was Donnan-dialysed into a 0.04*M* sodium carbonate/0.16*M* sodium bicarbonate receiver electrolyte. The dialysate was subsequently passed through the dual ion-exchange system and diluted to 10 ml. The nitrate in the diluted sample was determined by ion-chromatography. The concentration found was 2.5 mg/l. corresponding to an enrichment factor of 5.0. The enrichment factor was independent of nitrate concentration and did not change when chloride, sulphate and/or phosphate were included in the initial sample. Other analytical applications of the dual ion-exchange system, such as a procedure to determine trace level impurities in selected electrolytes, are being investigated in our laboratory.

COMPUTER CONTROL OF MICROPROCESSOR-BASED INSTRUMENTS BY KEYPAD EMULATION

P. M. WIEGAND and S. R. CROUCH
Department of Chemistry, Michigan State University, East Lansing, Michigan 48824-1322, U.S.A.

(*Received* 11 *June* 1984. *Accepted* 31 *July* 1984)

Summary—A keypad emulation method for controlling microprocessor-based instruments by laboratory microcomputers is presented. It is applicable to instruments that use "polled" keypad arrays; the instrument can be controlled by the laboratory computer or operated independently by manual keypad entry. To illustrate the approach, a microprocessor-based HPLC solvent-delivery system was controlled by a laboratory microcomputer which synchronized and sequenced the entire HPLC experiment, including solvent delivery, valve control for column switching and back-flushing, data-acquisition, and data-processing.

Almost all scientific instruments on the market today are equipped with microprocessor control. The incorporation of microprocessors in modern instruments has greatly increased their versatility by making many of the instrument functions user-programmable, often by means of a simple keypad entry system. Despite this increased versatility, it is often desirable to control such instruments externally with a laboratory microcomputer for permanent program storage, for display purposes and for synchronization with other system components. Instrument manufacturers are beginning to recognize this need, and some newer instruments include ports for communicating with general-pupose laboratory computers. Often, however, communication ports are lacking or do not provide the same degree of flexibility as manual keypad entry.

In this paper we describe a general method for controlling microprocessor-based instruments with "polled" keypad arrays from an external laboratory computer. The method uses an integrated circuit (IC) multiplexer and an IC demultiplexer to simulate a keystroke by connecting the desired column of the array to the desired row under computer control. Keypad emulation utilizes fully the existing instrument circuitry, and allows the internal microprocessor to perform its built-in logic and error-checking functions. Manual keypad entry remains undisturbed. Additional advantages of the keypad emulation method are described below.

DESIGN CONSIDERATIONS

There are many approaches to interfacing laboratory microcomputers to microprocessor-based instruments. These range from the hardware interface (the laboratory computer has complete control over the hardware and blocks all control by the instrument) to the keypad emulator, which operates identically to manual keypad entry, except that the laboratory computer assumes control over the key closures.

The hardware interface has several disadvantages when an entire instrument must be controlled. First, the circuitry needed to drive the hardware is usually complex, and is likely to be redundant, since driver circuits should already be present in the instrument. Even if the existing driver circuitry is used, the interface still has the complex tasks of synchronization and inter-circuit signal transfer; interface construction requires detailed knowledge of the instrument design. A hardware interface is also difficult to implement without altering the original functions of the instrument. Simulation of the manual keypad entry system eliminates many of these disadvantages and provides several benefits, as discussed later.

The design of a keypad emulator for an instrument with discrete switches could be very complicated. However, the advent of TTL-based, microprocessor-controlled instrumentation has spawned the keypad array as a convenient, efficient means of entering parameters. These arrays have been used for some time in computer terminals as a simple way to encode a large number of keys with only 8 bits of code.[1–3] Design of a keypad emulator to simulate a keystroke in keypad array-based entry systems is relatively straightforward.

For use in a microprocessor-based instrument, a keypad array must have driver and receiver circuits as shown in Fig. 1. The driver circuit scans across the columns of the array, activating each column in turn by sending it a logic-level pulse. If a key is depressed, the pulse is transmitted along the proper row to the receiving circuit, where it is sensed and acted upon. By knowing the column that was activated and the row from which the pulse was received, the microprocessor can deduce which key was depressed. The keypad driver and receiver are often contained in a single IC as in the National Semiconductor MM5740.[4] The activating pulses are active-high in some implementations, but active-low in others. Whatever the specific logic of the driver circuitry, the general strategy for keypad emulation is the same.

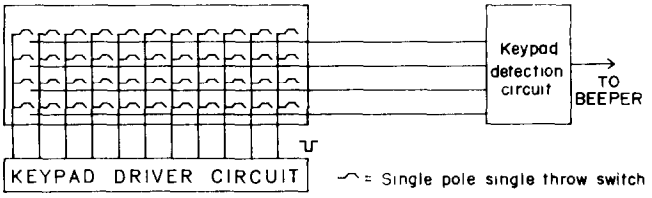

Fig. 1. Schematic of typical 11 × 4 keypad array.

The column selection is made by an IC multiplexer, and the row selection by an IC demultiplexer. Eight lines are sufficient to control a 16 × 8 array of keys: seven of the lines for coding purposes and one to gate the interface on and off. A simple 8-bit parallel input/output (PIO) port is thus sufficient for this size of array.

EXPERIMENTAL

Figure 2 shows the multidimensional chromatography system in which the keypad emulator was employed to allow a laboratory microcomputer[5] to control a Spectra-Physics SP8700 solvent-delivery system. The SP8700 contains a Z80 microprocessor and controls a proportioning valve and dual-piston reciprocating pump to produce HPLC mobile phases of the proper solvent mix and flow-rate. The laboratory microcomputer is based on the 8085 microprocessor; it sequences and controls the entire HPLC experiment. Software for the 8085 processor is loaded from an LSI 11/23 minicomputer (Digital Equipment Corporation), and raw data are sent back for high-level processing and graphics display.

The 11 × 4 keypad array used in the SP8700[6] is shown in Fig. 1. Although the array-driver and receiver circuits are not contained in a single IC, the basic operation is identical to that described above. The characteristics of the signals entering the array were obtained with an oscilloscope. The driver circuit was found to supply active-low pulses 85 μsec in duration. An entire scan cycle was completed in 2.420 msec.

Figure 3 shows the complete interface scheme. The multiplexer is a one-of-sixteen data selector (74150). The input line is chosen by the logic levels established at control inputs A–D. In this way, four PIO lines are used to select which keypad column is the input to the multiplexer. A fifth PIO line is used to gate the interface on and off by using the multiplexer "chip enable" input (E, active-low). When the multiplexer is enabled, the inverted column pulse is transmitted through a logic gate to the demultiplexer, which is a dual 2-line to 4-line decoder (74155). The chip can be used in several ways, but the implementation shown uses an inverting input to obtain the original pulse logic at the output. The A and B inputs are control lines. These are attached to two PIO lines which select the proper row to which the pulse is transmitted. The E input on the demultiplexer is an active-low enable input, tied to a single-pole, double-throw toggle switch which can be used to disable microcomputer control completely. Thus, only 7 of the 8 PIO lines are needed to control an array of this size.

The AND gates shown on the inputs to the receiving circuit allow for simultaneous manual keypad entry. The exclusive-OR gate shown between the multiplexer and demultiplexer acts as a selective inverter to ensure that all outputs of the demultiplexer are high when the multiplexer is disabled. Thus, low pulses arriving by either path are transmitted through the AND gates to the receiving circuit.

Although this implementation was designed for driver circuits that produce active-low pulses, the strategy for active-high pulses is similar. The scheme in Fig. 3 can be modified for active-high pulses by replacing the AND gates with OR gates and putting inverters on the demultiplexer outputs. A non-inverting input is then used on the demultiplexer to restore the original pulse logic after the inverters.

Although not essential to the operation of the interface, a method to verify entries was desired. Many microprocessor-based instruments provide an acknowledgement signal to inform the operator that an entry was valid. The SP8700 uses a beeper which is triggered by a short active-low TTL pulse. A monostable multivibrator (74121)

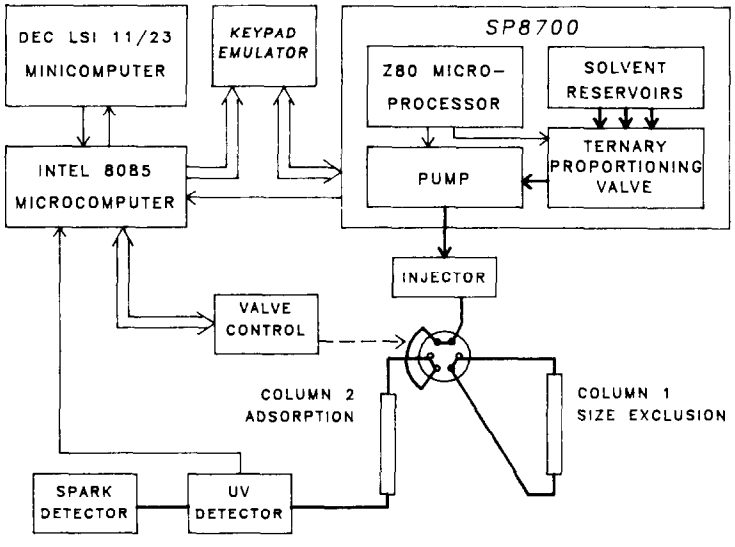

Fig. 2. Block diagram of experimental set-up.

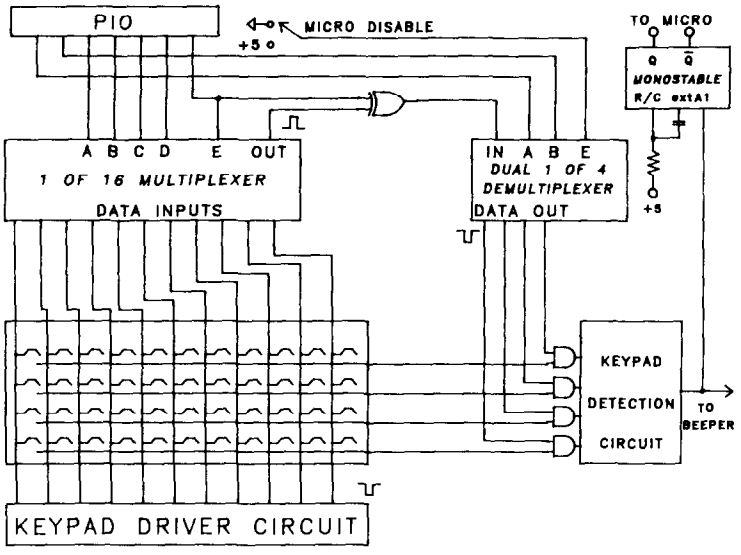

Fig. 3. Keypad array schematic including keypad emulator modification: multiplexer = 74150, demultiplexer = 74155, monostable multivibrator = 74121.

was added to convert the trigger pulse into a 13-msec active-high pulse appropriate for our laboratory microcomputer.

DISCUSSION

Figure 4 shows a simple flow-chart for operation of the keypad emulator. To simulate one keystroke, the microcomputer sends the control code for that key to the PIO port, with the control line to the multiplexer held low. For example, if the multiplexer code for the column is 0110 and the demultiplexer code for the row is 01, the binary word 0101100, or decimal 44, would be sent to the PIO port. This code is maintained at the PIO port for at least one complete array-scan cycle. If an acknowledgement is not being utilized, the emulator is disabled by sending a 1 to the port. The status of the other lines of the PIO is unimportant during the disable period. The microcomputer is then free to send the next control word, or to return to the calling routine.

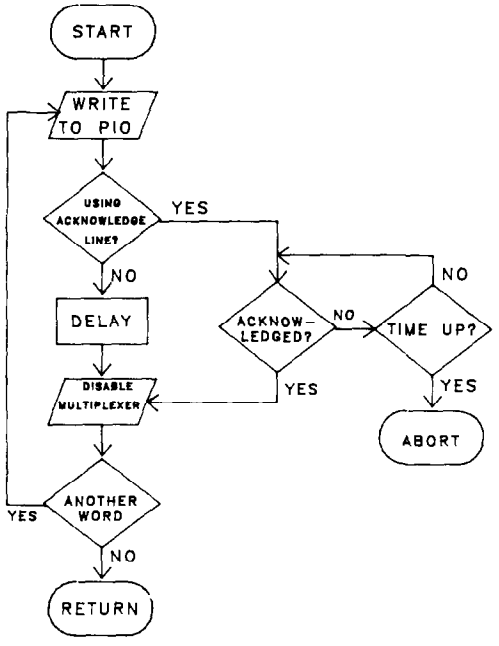

Fig. 4. Flow-chart for operation of keypad emulation system.

If an acknowledgement signal is being used, and the keystroke is not acknowledged within one scan period, the laboratory microcomputer can perform some other action. This lack of acknowledgement usually happens when invalid parameters are entered and discovered by the logic and error-checking routines of the instrument. The emulator itself has been 100% successful in simulating the proper keystroke.

CONCLUSIONS

The keypad emulation system described has been an invaluable addition to our laboratory. It has increased the capabilities of our HPLC system in three ways. (1) The system now has the ability to store a large number of experimental parameters permanently, on hard disk, floppy disk, or as hard copy; disk-stored parameters can be retrieved and re-entered at will. (2) The instrument clock and the laboratory microcomputer clock are synchronized. (3) A feedback loop can be established so that the parameters of the HPLC experiment can be altered on the basis of the chromatogram itself.

Since only simple PIO is required for operation, there are no restrictions on the choice of laboratory microcomputer or programming language. As already said, simultaneous manual operation is also possible, and no modifications are needed to convert from manual to computer operation. Some other advantages are the low cost and the need for only a few chips. By far the best feature, however, is that the

emulator operates independently of the rest of the instrument, so only a minimal knowledge of the instrument circuitry is necessary for implementation.

POSITIVE FEEDBACK COMPENSATION OF *iR*-DROP IN MODIFIED NORMAL PULSE POLAROGRAPHY OF SODIUM ION IN ACID SOLUTION

MINORU HARA
Faculty of Education, Toyama University, 3190 Gofuku Toyama-shi, Toyama 930, Japan

(*Received* 19 *March* 1984. *Accepted* 31 *July* 1984)

Summary—The well-defined polarographic wave for sodium, obtained by modified normal pulse polarography in which the polarographic current is sampled after the fall of each pulse, shifts to more negative potentials with decrease in the pH of the solution. The shift is attributed to the effect of the uncompensated resistance of the sample solution, and can be compensated by a positive feedback circuit.

It has been reported that well-defined polarograms for the five alkali metals and barium in acid solutions can be obtained by modified normal pulse polarography (MNPP),[1,2] the principle of which is represented schematically in Fig. 1. The negative-going potential pulses of duration T_2 are added to the fixed initial potential E_1 to give a pulse potential E_2 after a delay time of T_1 from the growth of a new drop from a dropping mercury electrode (DME). The pulses increase regularly in amplitude and are applied once per drop in the same manner as in normal pulse polarography. The polarographic current is integrated for 16.7 msec after a delay time of T_3 from the fall of the pulse. The average of the polarographic current over the integration period is plotted as ordinate and the pulse potential E_2 as abscissa. When E_1 is set at the potential where hydrogen ion is not reduced, as shown in Fig. 1, the anodic current measured during T_4 does not contain a hydrogen-wave component, because of its irreversibility. Therefore, even in 0.01*M* hydrochloric acid, the MNPP does not give a hydrogen wave but does give well-defined waves for the alkali metals and for barium. The half-wave potentials, however shift to more negative values with decrease in the pH of the sample solution.

Since it was presumed that the shift resulted from the uncompensated resistance between the working and reference electrodes, *iR*-drop compensation by use of a positive feedback circuit was investigated.

EXPERIMENTAL

Apparatus

A positive feedback circuit and a current-averaging circuit were added to the polarograph reported previously.[1] The block diagram of the system is shown in Fig. 2. An *iR*-drop compensation unit, Model 923 (Fuso Manufacturing), was employed as an *iR*-drop compensator. As shown in Fig. 2 (section within the broken line), the unit consists of a current follower with positive feedback and a differential amplifier similar to the one reported by Ohsaka and de Levie.[3] A 1-kΩ resistor was used as the negative feedback resistor to avoid saturation of the output of the current follower, because compensation is made impossible by saturation. The magnitude of positive feedback, α, was adjusted with a 5-kΩ potentiometer. With a fraction α of its output voltage fed back, the output voltage V_1 of the current follower is given by $V_1 = -iR_f/(1-\alpha)$, where i is the cathodic cell current and R_f is the resistance of negative feedback. The voltage of the working electrode is $V_1\alpha$ with respect to ground:

$$V_1\alpha = -iR_f\left(\frac{\alpha}{1-\alpha}\right)$$

If the quantity $R_f\{\alpha/(1-\alpha)\}$ is chosen equal to the uncompensated resistance R_u, the iR_u-drop is compensated. Since V_1 depends on the value of α, the current sensitivity also depends on the value of α. A differential amplifier, with gain of -1, is employed to make the current sensitivity independent of α, and the output voltage V_2 of the differential amplifier is given by

$$\begin{aligned} V_2 &= V_1\alpha - V_1 \\ &= -iR_f\left(\frac{\alpha}{1-\alpha} - \frac{1}{1-\alpha}\right) \\ &= iR_f. \end{aligned}$$

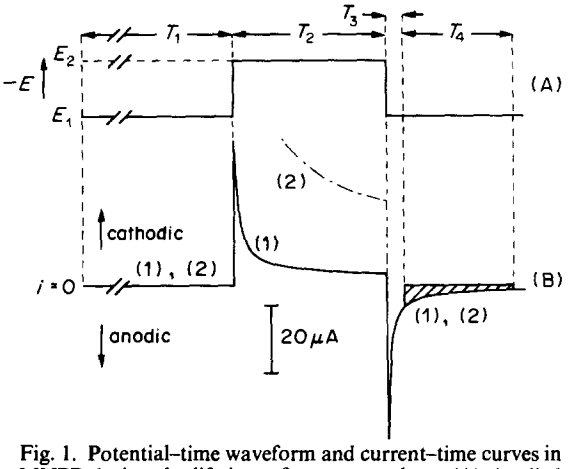

Fig. 1. Potential–time waveform and current–time curves in MNPP during the lifetime of a mercury drop. (A) Applied potential–time curve. (B) Current–time curves. $T_1 = 1.111$ sec, $T_2 = 23.2$ msec, $T_3 = 2.3$ msec, $T_4 = 16.7$ msec, $E_1 = -1.00$ V, $E_2 = -2.30$ V. (1) $4.33 \times 10^{-4}M$ NaCl, 0.1*M* Me_4NBr. (2) $4.33 \times 10^{-4}M$ NaCl, 0.001*M* HCl, 0.1*M* Me_4NBr.

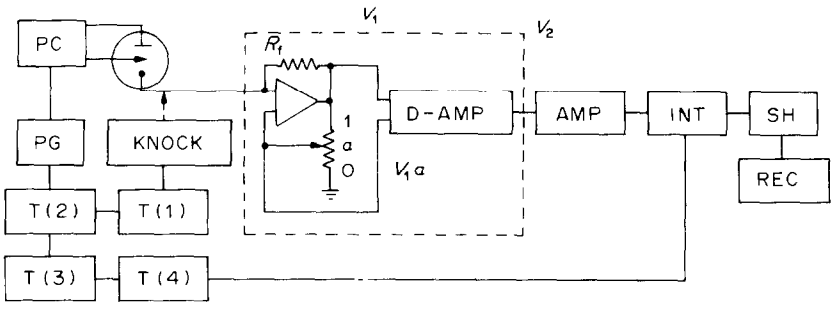

Fig. 2. Block diagram of the modified normal pulse polarograph. PC, potential controller; PG, pulse generator; KNOCK, DME knocker; D-AMP, differential amplifier; AMP, inverting voltage amplifier; INT, integrator; SH, sample-hold; REC, pen recorder. T(1), T(2), T(3) and T(4), timers which generate T_1, T_2, T_3 and 16.7 msec, respectively.

In order to record the average current, the anodic current was integrated for 16.7 msec, the period of one cycle of the a.c. mains, by an integrator circuit consisting of a MOSFET input type operational amplifier, μPC252 (Nihon Electric), and two MOSFETs, 3SK38A (Toshiba Electric). A DME containing an air-bubble[1] was used to suppress a.c. noise on the current–time curves. The mercury flow-rate was 0.422 mg/sec and the dropping period, τ, was controlled to 2.00 sec by a mechanical knocker. The remainder of the apparatus was identical with that reported previously.[1] The sample solutions were deaerated by passage of nitrogen through them for 15 min.

RESULTS AND DISCUSSION

Polarograms of $4.33 \times 10^{-4}M$ sodium in $0.01M$ hydrochloric acid/$0.1M$ tetramethylammonium bromide were measured with different values of α. Figure 3 shows two examples, for α-values of zero and 0.27. Their wave heights and slopes are equal, but the half-wave potential of curve 1 is 0.05 V more positive than that of curve 2 and is identical with that for a neutral solution. It is likely that the shift in the half-wave potential results from an iR-drop in the solution, associated with the large reduction current of the hydrogen ions.

In order to study the cause of the shift, the reduction current was measured throughout the duration of the pulse for various pulse potentials, and the results are shown in Fig. 4, in which the initial potential was −1.00 V in every case and the pulse potentials of curves 1, 2 and 3 were −2.00, −2.20 and −2.40 V respectively. In the uncompensated cases, the current plateaus appeared at the beginning of the curves. Under those conditions where a plateau appears in the reduction current–time curve, the normal pulse polarographic wave for hydrogen ion had a maximum wave. The potentiostat without iR-drop compensator can control only the potential differences between the working and the reference electrodes, and not the potential drop across the working electrode/solution interface.[4] When the cell current and/or the resistance of the solution becomes larger, the iR-drop between the working and reference electrodes cannot be neglected. The actual electrode potential deviates from the applied potential in proportion to the current.

On the other hand, the current–time curves with iR-drop compensation are simple, as can be seen in Fig. 4. Curve 4 in Fig. 4 represents three identical current–time curves for which the compensated pulse potentials are −2.00, −2.20 and −2.40 V. The log i *vs.* log t plot for curve 4 gives a straight line with slope

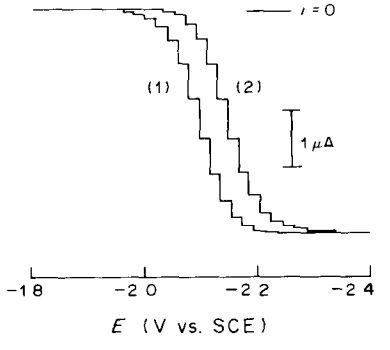

Fig. 3. Modified normal pulse polarograms for sodium. $4.33 \times 10^{-4}M$ NaCl, $0.01M$ HCl, $0.1M$ Me_4NBr. $E_1 = -1.00$ V; $T_1 = 1.111$ sec; $T_2 = 117.6$ msec; $T_3 = 2.3$ msec; α-value, (1) 0.27; (2) 0.00.

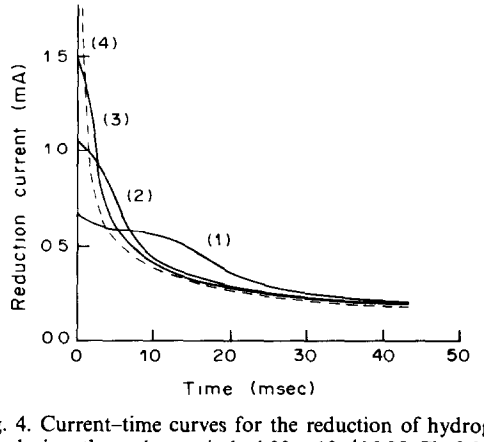

Fig. 4. Current–time curves for the reduction of hydrogen ion during the pulse period. $4.33 \times 10^{-4}M$ NaCl, $0.01M$ HCl, $0.1M$ Me_4NBr. $T_1 = 1.111$ sec; $E_1 = -1.00$ V; E_2, (1) −2.00 V (α = 0); (2) −2.20 V (α = 0); (3) −2.40 V (α = 0); (4) −2.00, −2.20, −2.40 V (α = 0.27).

Table 1. Effect of pulse duration T_2, concentrations of the supporting electrolyte and hydrochloric acid, and α-value on the half-wave potential of sodium; $4.33 \times 10^{-4}M$ NaCl, $E_1 = -1.00$ V, $T_1 = 1.111$ sec, $T_3 = 2.3$ msec

T_2 msec	Wave height at pH 5.6, μA	$E_{1/2}$, V vs. SCE					
		pH 5.6 (0.1M Me_4NBr)		pH 1.9 (0.1M Me_4NBr)		pH 1.9 (0.2M Me_4NBr)	
		α = 0.00	α = 0.30	α = 0.00	α = 0.27	α = 0.00	α = 0.18

57.3	3.07	−2.09	−2.09	−2.17	−2.10	−2.14	−2.10
117.6	3.71	−2.09	−2.09	−2.14	−2.09	−2.12	−2.09
240.0	4.45	−2.09	−2.09	−2.13	−2.09	−2.11	−2.09

equal to −0.53. Since this slope is approximately equal to −0.50, the theoretical slope for use of a stationary spherical electrode, it is supposed that the *iR*-drop is satisfactorily compensated in this system. If the α-value exceeded 0.27 then the potentiostat became unstable, and could not control the electrode potential because of oscillation of the amplifier. The optimum α-value in a particular cell system is selected as the maximum value which does not cause oscillation of the potentiostat.

The effects of pulse duration, concentrations of supporting electrolyte and hydrochloric acid, and α-value on the half-wave potential of sodium are summarized in Table 1. In the case of solutions at pH 5.6, the half-wave potential is constant regardless of pulse duration and α-value, but the wave height increases with pulse duration. Since the cell current decreases with time for any given potential, the difference between the applied and the actual potentials is largest at the beginning of the pulse, then decreases gradually with time. Therefore, the shorter the pulse duration T_2, the more significant is the effect of the *iR*-drop. In the solution at pH 1.9, the half-wave potential shifts to more negative values with decrease of pulse duration, even when α is 0.27. These shifts result from insufficient compensation. When the concentration of the supporting electrolyte is doubled, the shift in the uncompensated half-wave potential is less, since the increase of conductivity decreases the *iR*-drop, and adequate compensation can be achieved with a smaller α-value.

We conclude that the shift in the half-wave potential for sodium in acid solution is due to the *iR*-drop between the working electrode and the reference electrode. The *iR*-drop can be compensated satisfactorily by a positive feedback circuit.

REVERSED-PHASE PARTITION HIGH-PRESSURE LIQUID CHROMATOGRAPHY OF TRACE AMOUNTS OF INORGANIC AND ORGANIC MERCURY WITH SILVER DIETHYLDITHIOCARBAMATE

SADANOBU INOUE*, SUWARU HOSHI and MUTSUYA MATHUBARA
Department of Environmental Engineering, Kitami Institute of Technology, Kitami-shi, 090, Japan

(*Received* 24 *March* 1984. *Accepted* 27 *July* 1984)

Summary—Inorganic and organic mercury diethyldithiocarbamates have been separated by reversed-phase partition high-pressure liquid chromatography. The mercury chelates were formed by an exchange reaction with silver diethyldithiocarbamate in chloroform, in the presence of acetate buffer (pH 5.0). The inorganic and organic mercury chelates in the extract were separated within 30 min on a 3.9 × 300 mm μ-Bondapak C_{18} column. EDTA ($10^{-4}M$) in methanol–water mixture (78:22 v/v) was used as eluent at a flow-rate of 0.5 ml/min.

Recently, considerable attention has been paid to rapid and sensitive determination of trace amounts of inorganic and organic mercury in the environment. Trace amounts of inorganic mercury have been determined by flameless atomic-absorption spectrophotometry, and of organic mercury by gas chromatography. In the past ten years a few reports on the application of high-pressure liquid chromatography (HPLC) to determination of organic mercury have appeared.[1-3] MacCrehan *et al.* reported the use of liquid chromatography with differential pulse electrochemical detection,[1] and the separation of organic mercury compounds by reversed-phase chromatography of their 2-mercaptoethanol complexes.[2] Funasaka *et al.*[3] reported the high-speed liquid chromatographic separation of organic mercury compounds. In a previous paper,[4] the determination of inorganic and organic mercury by HPLC after extraction of diethyldithiocarbamate (DDTC) chelates was described, but many metal ions were extractable as their DDTC chelates and copper(II), nickel(II) and cobalt(II) interfered in the HPLC determination.

In the present paper, separations and simultaneous micro determinations of inorganic and organic mercury–DDTC chelates extracted by the following exchange reactions with silver–DDTC in chloroform from aqueous media by HPLC are described:

$$Hg^{2+} + 2Ag(DDTC) \rightarrow Hg(DDTC)_2 + 2Ag^+$$
$$RHg^+ + Ag(DDTC) \rightarrow RHg(DDTC) + Ag^+$$

where R = $-CH_3$, $-C_2H_5$ and $-C_6H_5$.

EXPERIMENTAL

Reagents

All chemicals used were of analytical-reagent grade.

Standard mercury(II) solution. Dissolve mercuric chloride in 0.01*M* hydrochloric acid to give a $3.75 \times 10^{-2}M$ stock solution, and standardize it by titration with EDTA.

Standard methylmercury solution. Dissolve methylmercuric chloride (purified by recrystallization from methanol) in distilled water to give a $3.75 \times 10^{-4}M$ stock solution.

Standard ethylmercury solution. Dissolve ethylmercuric chloride (purified by recrystallization from ethanol) in a small quantity of ethanol, and dilute with distilled water to give a $3.75 \times 10^{-4}M$ stock solution.

Standard phenylmercury solution. Dissolve phenylmercuric chloride in 0.1*M* sodium hydroxide to give a $3.75 \times 10^{-4}M$ stock solution. Dilute these stock solutions accurately before use.

Silver diethyldithiocarbamate solution. Dissolve silver diethyldithiocarbamate in chloroform to give a $7.5 \times 10^{-4}M$ solution.

Acetate buffer solution. Mix 0.1*M* acetic acid and 0.1*M* sodium acetate to obtain a buffer of pH 5.0.

Apparatus

A Hitachi model 635A HPLC instrument with a wavelength-tunable effluent-monitor set at 254 nm was used. A μ-Bondapak C_{18} column (3.9 × 300 mm, Waters Associates) was used. Inorganic and organic mercury compounds were extracted in 50-ml cylindrical glass vials fitted with polyethylene stoppers and plastic caps.

Procedure

Pipette aliquots of sample solutions containing up to 60, 65, 69 and 83 μg for inorganic mercury(II), methylmercury, ethylmercury and phenylmercury, respectively, into 25-ml standard flasks. Add 2.5 ml of acetate buffer (pH 5.0), dilute to 25 ml with distilled water and transfer to cylindrical glass vials. Shake with 10.0 ml of silver–DDTC solution in chloroform for 3 min. Separate the phases by centrifugation (1000 rpm, 10 min). Inject 25 μl of the chloroform layer by microsyringe into the HPLC column. Use $10^{-4}M$ EDTA in methanol–water mixture (78:22 v/v) as eluent, at a flow-rate of 0.5 ml/min.

RESULTS AND DISCUSSION

Extraction of inorganic and organic mercury with silver–DDTC

The effect of pH on the extraction was investigated

*To whom correspondence should be addressed.

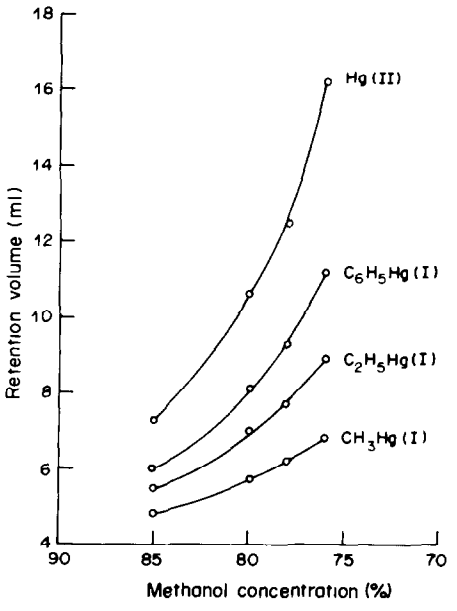

Fig. 1. Variation of retention volume with methanol concentration in the eluent. Column μ-Bondapak C_{18}; flow-rate 0.5 ml/min; wavelength 254 nm; injection volume 25 μl.

and the pH ranges for extraction were found to be from 5.1 to −0.3 for inorganic mercury(II), 5.2–0 for methylmercury, 5.2–2 for ethylmercury and 5.5–2.4 for phenylmercury. Lowering the silver–DDTC concentration to $3.0 \times 10^{-4} M$ had no effect. A pH of 5.0 (acetate buffer) was selected for the simultaneous extraction of inorganic and organic mercury. The DDTC chelates are $Hg(DDTC)_2$,[5] $RHg(DDTC)$[6] and Ag(DDTC),[5] and the wavelengths of the maximum absorbance in chloroform are 275 nm for the inorganic mercury(II) complex, 254 nm and 297 nm for the organomercurials and 273 nm for silver(I). Inorganic and organic mercury chelates in the eluent were detected at 254 nm.

Separation of inorganic and organic mercury–DDTC

Inorganic and organic mercury–DDTC chelates can be separated by HPLC, on a μ-Bondapak C_{18} column. The effect of methanol content and flow-rate of the eluent on the separation of the chelates was studied. The retention volumes of the chelates were found to increase with increasing concentration of water in the eluent but although good separations were achieved (Fig. 1), the peaks were broad. The most suitable eluent for the separation of the chelates was a 78:22 v/v methanol–water mixture. To avoid contamination with metal ions through contact between the eluent and the metal parts of the HPLC apparatus, $10^{-4} M$ EDTA was added to the eluent.[7] A flow-rate of 0.5 ml/min was most suitable for the separation. A typical separation is shown in Fig. 2. All four peaks are well resolved. The retention volumes are 6.2 ml for methylmercury, 7.7 ml for ethylmercury, 9.3 ml for phenylmercury and 12.5 ml for inorganic mercury(II). The elution order is the same as that observed by McCrehan *et al.*[2] for 2-mercaptoethanol chelates. The degree of interaction of the stationary phase with these chelates probably increases in the order

$$Hg(II) > C_6H_5Hg > C_2H_5Hg > CH_3Hg.$$

Calibration graph

The amounts of inorganic and organic mercury could be determined from the peak areas under the recorded elution curve (full-scale deflection = 0.04 absorbance). Calibration graphs were linear in the ranges 0–6.02 μg for inorganic mercury(II), 0–6.47 μg for methylmercury, 0–6.89 μg for ethylmercury and 0–8.33 μg for phenylmercury, per ml of chloroform solution. The detection limits were 8.8 ng for inorganic mercury(II), 9.5 ng for methylmercury, 13.8 ng for ethylmercury and 10.8 ng for phenylmercury. The coefficients of variation were 3.2% for inorganic mercury(II), 2.8% for methylmercury, 1.6% for ethylmercury and 3.6% for phenyl mercury for 10 measurements with 3.01 μg of inorganic mercury(II), 3.23 μg of methylmercury, 3.44 μg of ethylmercury and 4.16 μg of phenylmercury per ml of chloroform solution.

Interferences

The interference of several metal ions was studied. Mn(II), As(III), Sn(II), Ni(II), Cr(III), Fe(II), Fe(III),

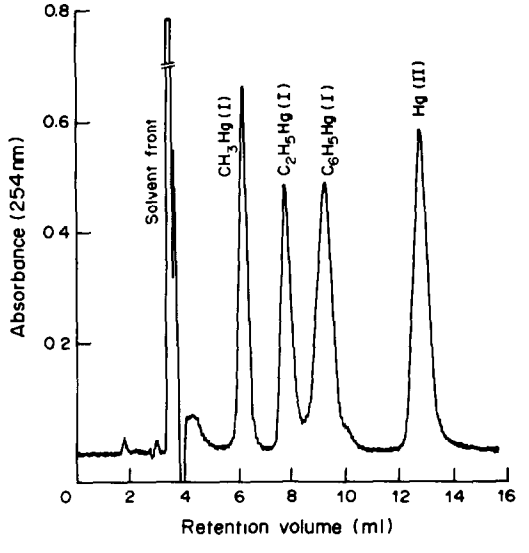

Fig. 2. Chromatogram of CH_3Hg, C_2H_5Hg, D_6H_5Hg and Hg(II) chelates of DDTC. Chelate concentration in chloroform (μg/ml): CH_3Hg 6.47, C_2H_5Hg 6.89, C_6H_5Hg 8.33, Hg(II) 6.02, Column μ-Bondapak C_{18} (3.9 mm × 300 mm); eluent methanol–water (78:22 v/v) containing $10^{-4} M$ EDTA; flow-rate 0.5 ml/min; injection volume 25 μl.

Co(II), Cd(II) and Zn(II) (1000 μg), Bi(III) (100 μg) and Pb(II) (20 μg) were not extracted under the experimental conditions described above. However, Pb(II) (100 μg) and Cu(II) (10 μg) were partially extracted, although the DDTC chelates of Cu(II), Pb(II) and Ag(I) were not eluted in the range of retention volumes of the mercury–DDTC chelates under the chromatographic conditions specified. From these results, this method is found to be free from interference from other metal ions and can be used for the simultaneous determination of trace amounts of inorganic and organic mercury.

THIN-LAYER CHROMATOGRAPHY OF THE MBTH DERIVATIVES OF SOME ALIPHATIC ALDEHYDES

V. CARUNCHIO, G. DE ANGELIS, A. M. GIRELLI and A. MESSINA
Department of Chemistry, University of Rome, 00185 Rome, Italy

(*Received* 12 *March* 1984. *Accepted* 18 *July* 1984)

Summary—A rapid, simple method for resolution and detection of mixtures of aliphatic aldehyde by thin-layer chromatography of their MBTH derivatives is proposed. Less than 1 mg/l. levels of each aldehyde in the original aqueous solution can be detected.

Techniques used for the separation and/or determination of various aldehydes (as such or as their derivatives) include thin-layer chromatography,[1–6] gas chromatography,[7–13] high-pressure liquid chromatography[14–21] and chemical-ionization mass spectrometry.[22] The aldehydes are usually separated and determined as the 2,4-dinitrophenylhydrazone (DNPH) derivatives, together with ketones, but the 3-methyl-2-benzothiazolinone hydrazone (MBTH) derivatives (which do not suffer from interference by ketones) have been proposed for thin-layer chromatography of aliphatic aldehydes on silica gel plates,[1,6] and for their spectrophotometric determination for routine environmental analysis.[23–27] However, the MBTH spectrophotometric method expresses the total aldehyde content empirically in terms of formaldehyde, because the products have almost identical wavelength of maximum absorption, but different molar absorptivities and rates of formation (Table 1).

We have therefore developed a thin-layer chromatographic method for separation of the MBTH derivatives formed in the presence of an oxidizing agent, with subsequent spectrophotometric determination.

EXPERIMENTAL

Reagents

All reagents were analytical grade. The aldehydes were Merck products.

3-Methyl-2-benzothiazolinone hydrazone hydrochloride (MBTH) solution, 0.050%. Stored at 5° (stable for one week), and filtered before use; the solution must not be coloured.

Oxidizing solution. An aqueous solution containing 1.0% $FeCl_3 \cdot 6H_2O$ and 1.6% sulphamic acid; it is stable for one month.

Procedure

Aldehyde–MBTH derivatives were prepared by addition of 10 ml of MBTH solution to 5 ml of aqueous aldehyde sample: 60 min later, 5 ml of oxidizing solution and 5 ml of water were added. After another 30 min 7.3 g of solid sodium chloride were added and the solution was shaken with 25 ml of chloroform in three portions (10, 10, 5 ml) and the combined extract was evaporated to 1 ml under reduced pressure at room temperature.

Silica gel TLC or HPTLC plates (Merck 60 F_{254}) were employed; 0.50-μl of the portions of the concentrated extracts were applied as streaks 1 cm apart, and 1 cm from the lower edge of the plate. Before the elution the chromatographic tank was equilibrated for 30 min with the eluent (benzene-ethanol 7:6 v/v) at room temperature. Ascending elution was run over a distance of about 3 cm.

After the chromatographic separation, accomplished in about 15 min, the spots were located by means of their

n-Valeraldehyde	0.37	0.65

colour or, better, by scanning at 628 nm with a densitometer.

RESULTS

Table 2 gives the R_f values for the TLC and HPTLC separation of the derivatives of some aliphatic aldehydes. Figure 1 shows the HPTLC chromatogram measured by densitometry.

The extraction with chloroform eliminates the background colour of iron from the chromatogram (since the iron is not extracted) and increases the sensitivity, as seen in Fig. 1, which refers to a concentration of 1 mg/l. of each aldehyde in the original aqueous sample (5 ml) and hence to about 2.5 ng of each aldehyde on the TLC plate.

This very small amount and the small volume (0.5 μl) of the organic solution spotted on the plate allow, especially in the HPTLC method, a very good separation, not previously achieved. The detection limit in the aqueous sample can be altered by changing the volumes of the sample taken and of the final organic solution. The resolution can be modified by changing the benzene/ethanol ratio. Complete separation has been achieved by a run of 3 cm, in 15 min: a longer elution does not increase the resolution. The proposed method is therefore more advantageous than the one based on chromatographic separation of the azine derivatives followed by spraying with the oxidizing-MBTH solution to form the coloured compounds, and those which involve precipitation of the derivatives (*e.g.*, the DNPH derivatives). The recovery of the aldehydes is complete: the aqueous solution does not absorb at 628 nm after the extraction. Hence the proposed chromatographic method, initially intended for the identification of the aldehydes present in order to improve the quantitative spectrophotometric analysis, could also be suitable for quantitative denitometic HPTLC determination provided proper standardizations are performed.

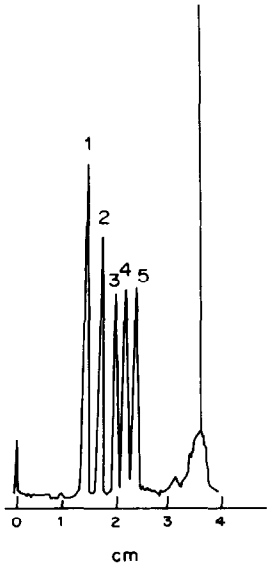

Fig. 1. Chromatogram of C_1—C_5 aliphatic aldehyde–MBTH derivatives on silica gel HPTLC plates: (1) formaldehyde, (2) acetaldehyde, (3) propionaldehyde, (4) n-butyraldehyde, (5) n-valeraldehyde. Eluent benzene–ethanol 7:6 v/v; λ = 628 nm; scan-rate 10 mm/min; chart-speed 10 mm/min. The initial weight of each aldehyde was 2.5 ng (see results).

DETERMINATION OF IRON AND CYANIDE IN CYANOFERRATE COMPLEXES

NICOLETTA BURGER
Department of Chemistry and Biochemistry, Faculty of Medicine, University of Zagreb, 41000 Zagreb, Šalata 3, Yugoslavia

(*Received* 16 *May* 1984. *Accepted* 17 *July* 1984)

Summary—A simple method of destroying cyano-complexes and of analysing for both iron and cyanide in a single sample of a cyanoferrate complex is proposed.

It is well known that it is not possible to detect iron and cyanide in freshly prepared aqueous solutions of potassium hexacyanoferrate(II) at room temperature, because of stabilization of the complex anion by π-donor back-bonding between the metal ion and the ligands. Substitution of one or more of the cyanide ions by other ligands will result in changes in bonding and reactivity, but determination of iron and cyanide is still not possible without cleavage of the Fe–CN bonds.

Cleavage can be achieved by refluxing the complex with *aqua regia* or by Kjehldahl decomposition, and the iron determined by any convenient method, but the cyanide is destroyed and cannot be determined. Treatment with perchloric acid is often suggested, but for the iron determination the cyanide must be expelled as hydrocyanic acid by heating to fuming.[1] Ignition of the complex and determination of the iron as Fe_2O_3 is simple and useful, but again only if the cyanide is not to be determined. Distillation from phosphoric acid medium at reduced pressure gives low recovery of the cyanide, and so does a tartaric acid distillation method.[2] Refluxing with dilute sulphuric acid, in the presence of magnesium and mercuric chlorides, with passage of a current of air to transfer hydrogen cyanide into an absorption tube, seems to be satisfactory when applied to silver, zinc and nickel complex cyanides but not if applied to analysis of more stable cyano-complexes such as those of cobalt and iron.[2] Fusing finely ground complex cyano-compounds with sulphur at 300° permits determination of the cyanides but not of iron,[3] and decomposition of cyanoferrates with concentrated nitric acid produces ammonium salts, which can be determined by the Kjehldahl and Parnas methods.[4]

The methods of organic elemental analysis usually yield low results for the carbon and nitrogen contents (probably owing to the formation of stable carbides and nitrides with the central metal ion of the complex). However, during our investigations on oximatocyanoferrate(II) complexes,[5–7] we have found a simple possibility for cleaving cyanoferrates and determining both iron and cyanide in a single sample.

EXPERIMENTAL

Reagents

All reagents used were of analytical-reagent grade. Redistilled water was used throughout. The 0.4*M* acetate buffer, pH 3.5, was prepared by mixing 12.8 ml of 2*M* sodium acetate with 187.2 ml of 2*M* acetic acid and diluting with water to 1000 ml. A 0.0125*M* phenanthroline solution was prepared by dissolving 0.5406 g of 1,10-phenanthroline in 250 ml of 0.4*M* acetate buffer of pH 3.5. The 1% ascorbic acid solution used was always freshly prepared. A solution containing 100 μg of Hg^{2+} per ml was prepared by dissolving 0.0136 g of mercury(II) chloride in 100 ml of water.

$Na_2[Fe(CN)_5NO]\cdot 2H_2O$ (Kemika), $Na_3[Fe(CN)_5NH_3]\cdot 3H_2O$ (Touzart-Matignon), $K_3[Fe(CN)_6]$ and $K_4[Fe(CN)_6]\cdot 3H_2O$ (Merck) were obtained commercially.

Cleavage and analysis

Weigh 5–10 mg of sample into a three-necked round-bottomed flask and add 25 ml of a mixture of 10 ml of 0.0125*M* phenanthroline, 7 ml of acetate buffer, 7 ml of 1% ascorbic acid solution and 1 ml of mercury(II) chloride solution. Boil the mixture for 15–20 min under a nitrogen atmosphere. Use two Drechsel bottles, the first containing 100 ml of 2% sodium hydroxide and the second 100 ml of water, to collect the hydrogen cyanide produced. Mix the contents of the two bottles and titrate with 0.01*M* silver nitrate with potassium iodide as indicator. Transfer the contents of the reaction flask quantitatively into a 100-ml standard flask, dilute to volume and measure the absorbance of the ferroin at 510 nm against a reagent blank.

RESULTS AND DISCUSSION

The proposed method is based on earlier knowledge of the conditions under which potassium hexacyanoferrate(II) is totally decomposed into Fe^{2+} and CN^-,[8] namely an acidic medium, elevated temperature, and the presence of small amounts of Au^{3+}, Ag^+, Pt^{4+}, Pd^{2+}, Hg_2^{2+} or especially Hg^{2+}. Because the decomposition depends on successive displacement of cyanide ions to yield pentacyanoferrate(II), tetracyanoferrate(II) and so on, the same conditions can be applied for the cleavage of substituted cyanoferrate complexes. Ascorbic acid is added as

*Values of 13.8 and 14.2% had been obtained earlier by complexometry.

reductant to ensure that Fe^{2+} is the only oxidation state of iron present and to prevent already liberated iron(II) from bonding with the undestroyed hexacyanoferrate to form Prussian Blue. It also makes the method applicable to analysis of cyanoferrate(III) complexes. The colorimetric reagent is already present in the reaction mixture and immediately binds the liberated iron, the buffer ensures the correct acidity for both the displacement reaction and the ferroin formation (pH 3.5), and the Hg^{2+} acts as a catalyst. Results of analyses of some commercial samples of cyano-complexes are present in Table 1, and have good reproducibility. The potassium hexacyanoferrate(II) trihydrate was an old sample, and appears to have lost some of the water of crystallization. Sparingly soluble compounds cannot be analysed in this way, however.

A NOVEL AND SENSITIVE SPOT-TEST FOR *m*-DINITROAROMATICS AND THEIR DERIVATIVES WITH SODIUM SULPHITE AND DIMETHYLSULPHOXIDE

SAEEDUZZAFAR QURESHI, PUSHKIN M. QURESHI* and SEEMA HAQUE
Department of Chemistry, Aligarh Muslim University, Aligarh 202001, India

(*Received* 27 *April* 1984. *Accepted* 17 *July* 1984)

Summary—Sodium sulphite has been used for a very sensitive characterization of *m*-dinitroaromatics and their derivatives, with dimethylsulphoxide as solvent.

The interaction of bases with polynitroaromatics is a fascinating field.[1–5] For quite some time we have been exploring the analytical potential of such reactions.[6–8] A significant and possible use of these reactions is for detection and determination of 2,4-dinitrophenyl (DNP) derivatives of amino-acids. Virtually all published tests for *m*-dinitroaromatics can, after suitable modification, be used for the determination of DNP derivatives.

However, because of the variation in the colours given by different *m*-dinitroaromatics, the tests cannot be used as general tests for the group identification of *m*-dinitroaromatics and the corresponding DNP derivatives. For example, we have re-investigated the reaction of sodium hydroxide with *m*-dinitroaromatics and their derivatives[8] and found that by a novel "alkali pellet spot-test", they can be detected at the nanogram level, and though the test is highly sensitive and useful for these compounds it is unlikely to be useful for DNP derivatives, because the colour produced depends on the substituents in the 1-position and hence the test is unlikely to be very characteristic of the 2,4-DNP group. It is therefore difficult to predict the effect of the substituent at the 1-position on the colour produced in this and related methods.

Though the reaction with sodium sulphite has been studied for a few polynitroaromatics, there has been no detailed investigation and as far as we are aware these reactions have not been used in organic analytical chemistry. An alternative test with sodium cyanide[8] is unattractive because of the poisonous nature of the reagent, and here again the colour produced is dependent on the substituent at the 1-position.

The analytical potential of sulphite has therefore been investigated. The test is more sensitive than all others except our recent method[8] but has the distinct advantage of appearing to be specific for the 2,4-DNP moiety and therefore usable as a characteristic and specific test for the detection of 2,4-DNP derivatives of amino-acids.

EXPERIMENTAL

Materials

Most nitroaromatics tested were Merck guaranteed reagents and used as received. Some were BDH laboratory-reagents grade and were recrystallized by standard procedures until the melting points were in agreement with literature values. The dimethylsulphoxide (DMSO) was a Baker "Analyzed" reagent. Merck acetone, BDH Analar dimethylformamide (DMF) and BDH sodium sulphite were used.

Procedures

(*a*) Transfer 1 μl of the test substance onto a white spot-plate, followed by 1 μl of a saturated sodium sulphite solution in conductivity water. Note the colour. Repeat with the addition of 1 μl of DMSO, acetone or DMF respectively. The colour of the product is deep or light violet in each case.

(*b*) Place a few resin beads (Amberlite IRA 400, Cl^- form) in the depression of a white spot-plate. Add 1 μl of the test substance, followed by the other reagents as described in method (*a*).

RESULTS

A number of other types of organic compounds were found not to interfere with the test. They included carbohydrates (xylose, starch, galactose, maltose, fructose, L(+)-arabinose, lactose, glucose, rhamnose, sucrose), acids (acetic, formic, tartaric, phthalic, pyrogallic, oxalic), alcohols (isopropyl, ethyl, methyl, 2-methylisopropyl, amyl, isoamyl), heterocyclic bases (pyridine, piperidine), aldehydes (formaldehyde, acetaldehyde, benzaldehyde, paraldehyde, *p*-chlorobenzaldehyde), ketones (acetophenone, cyclopentanone, cyclohexanone, propiophenone, benzophenone), hydrocarbons and their derivatives (benzene, xylene, *o*-dichlorobenzene, bromobenzene, toluene), ethers (diethyl anisole,

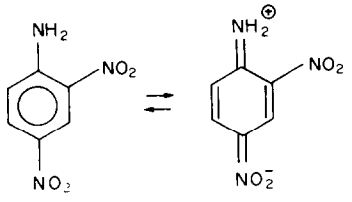
1,4-dioxan), amino-acids (DL-tryptophan, L-lysine, DL-phenylalamine, L-histidine), anilides (acetanilide, benzanilide), nitriles (aceto-, benzo-), amides (acetamide, benzamide), amines (trimethyl, triethyl, methyl, diethyl, aniline, diphenyl), phenols (phenol, *m*-cresol, resorcinol), chloroform, carbon tetrachloride, urea and thiourea.

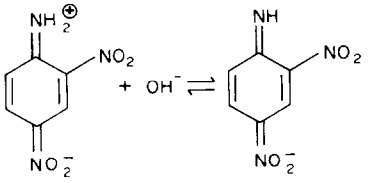
The limit of detection for a number of nitrocompounds was determined and the results are summarized in Table 1.

DISCUSSION

Table 1 shows the resin spot-test to be much more sensitive than the conventional spot-test and DMSO seems to be the solvent of choice, in agreement with the solvent effect on anionic σ-complexes. An interesting feature was that compounds containing an electron-donor group, such as 2,4-dinitrotoluene, 2,4-dinitroaniline and 2,4-dinitrophenylhydrazine do not give a colour in the conventional spot-test but do on the resin. This is because the electron-donor group enhances the electron density within the ring, which is otherwise depleted by the two nitro-groups. In these cases the resin seems to play a specific role. With 2,4-dinitroaniline for example, the zwitterion canonical form in the tautomerism:

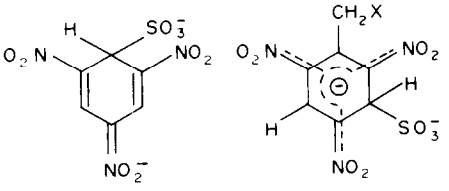


can react with hydroxide ion to give an anion:



In the reaction with sulphite, however, addition seems more likely than proton loss, but because of the increased electron density within the ring (caused by the electron-donating amino group) anion addition can take place only with difficulty. However on the large positively charged matrix of the anion-exchanger the aniline loses much of its excess negative charge to the matrix, thereby facilitating anion addition and giving a positive test response on the resin surface.

Work reported by others[2,12] points to sulphite addition:



Since all the polynitroaromatics tested give a blue violet colour, the test seems to be independent of the substituent at the 1-position, and the colour seems specific for detection of the *m*-dinitroaromatic moiety.

2-[2-(5-CHLOROPYRIDYL)AZO]-5-DIMETHYLAMINOPHENOL AS INDICATOR FOR THE COMPLEXOMETRIC DETERMINATION OF ZINC

E. MARCHEVSKY, R. OLSINA and C. MARONE
Universidad Nacional de San Luis, Chacabuco y Pedernera, 5700-San Luis, Argentina

(*Received* 13 *October* 1983. *Revised* 4 *June* 1984. *Accepted* 16 *July* 1984)

Summary—2-[2-(5-Chloropyridyl)azo]-5-dimethylaminophenol (ClDMPAP) is proposed as a metallochromic indicator for zinc. The end-point colour change is from the violet-red of the zinc complex to the brownish-yellow of the indicator. The colour contrast is markedly greater than that for Erio-T.

Eriochrome Black T (Erio-T) is often used as a metallochromic indicator for complexometric determination of zinc,[1–3] but has some important deficiencies. Its solutions are unstable, and copper(II), cobalt(II), nickel(II) and aluminium(III) can interfere by blocking the indicator. Iron(III) and titanium(IV) also interfere. Cadmium(II) is co-titrated.

Use of PAN[4–6] and PAR[7] has therefore been recommended. Other pyridylazo reagents used in zinc titrations include 5-(2-pyridylazo)-2-monoethylamino-*p*-cresol,[8] 2-(2-pyridylazo)-4-methylphenol,[9] 5-(2-pyridylazo)-*p*-cresol,[10] and 2-[2-(5-bromo-2-pyridylazo)]-5-diethylamino-*m*-phenol.[9] All have in common a high colour contrast between the zinc complex and the free reagent, from violet-red to brownish-yellow, with a change of about 100 nm in the wavelength of the absorption maximum. The molar absorptivities (ε) are also high, *ca.* 1×10^{-5} $l.mole^{-1}.cm^{-1}$.

2-[2-(5-Chloropyridyl)azo]-5-dimethylaminophenol (ClDMPAP) is known[11] to react instantly with zinc in aqueous solutions buffered at pH 8.2–10.4, producing an intensely violet-red complex (ε is much greater than that for the zinc complexes listed above). The complex is stable for at least 5 days. The reagent is readily displaced from its zinc complex by EDTA and thus should be suitable as an indicator for EDTA titration of zinc.

EXPERIMENTAL

Reagents

Standard zinc solution (0.1000*M*). Prepared by dissolving the pure metal (6.537 g) with *ca.* 20 ml of hydrochloric acid (1 + 1) by gentle warming, cooling and dilution to volume in a standard flask with water.

EDTA solution, ca. *0.1*M. Standardized potentiometrically with the standard zinc solution[12] and further diluted as required.

5ClDMPAP. The reagent was synthesized according to Johnson and Florence.[13] A 0.05% solution in 95% ethanol was used as indicator. For spectrometric studies, solutions of the required molarity were prepared with 95% ethanol as solvent.

Ammonia–ammonium chloride buffer, ca. *0.1*M, *pH 8.5.* Ammonium chloride (4.55 g) was dissolved in a small volume of water and concentrated ammonia solution was added dropwise until pH 8.5 was reached. Final pH adjustment was made after dilution to nearly 1000 ml.

Aqueous Eriochrome Black T solution, ca. *0.05%*. Prepared immediately before use.

All other reagents, chemicals and standards were of analytical grade.

Apparatus

Spectrophotometric titrations were done in a cell constructed according to Sweetser and Bricker,[14] and the titrant was added from a Metrohm piston-burette.

Procedure

Take a 50-ml sample, make it slightly alkaline and finally adjust to pH 8.5 by adding 5 ml of ammonia–ammonium chloride buffer (the buffer capacity of the NH_4^+–NH_3 solution was enough to maintain this pH in the titration of 50 ml of zinc solution of concentration up to about 800 ppm). Add 60 ml of alcohol and 2 or 3 drops of indicator. Titrate with EDTA added at *ca.* 0.1 ml/min near the end-point. Typical results are summarized in Table 1.

Analysis of zinc insulin

In a 25–30 ml centrifuge tube, take 10.0 ml of the liquid sample. Add dilute hydrochloric acid (1 + 50) until a clear solution is obtained, and 6 ml of 10% trichloroacetic acid solution. Shake, then centrifuge for 5 min. Transfer the supernatant liquid to a 25-ml standard flask and dilute to the mark with water. Transfer 20 ml of the solution to the photometric titration cell and add 5 ml of ammonium chloride–ammonia buffer (pH 8.6), enough ethanol to give a final content of about 50% v/v, and 3 drops of 5ClDMPAP indicator, and titrate with EDTA.

Table 1. Changes in absorbance during the EDTA titration of zinc, with Erio-T and 5ClDMPAP as indicators

	Error, %	
Zn taken, *mg*	5ClDMPAP	Erio-T
0.813	1.0	1.5
3.250	0.06	0.1
8.14	0.03	0.1
16.28	0.02	0.08
40.69	0.006	0.09

RESULTS AND DISCUSSION

The spectral differences between Erio-T and 5ClDMPAP and their zinc complexes are shown in Fig. 1. 5ClDMPAP is clearly a very much more sensitive reagent, and the shift in the wavelength of maximum absorption on complexation is twice as great for 5ClDMPAP as for Erio-T, and gives a much bigger contrast in the colour change. The human eye is also more sensitive to the colour change for the 5ClDMPAP system. Graphical methods[15–17] were used to choose the optimum pH for the titration. The equilibrium constants required for construction of the graphs were obtained from the literature[18] or determined by us.[19] Results obtained by the method of Reilley and Schmid[15] are shown in Fig. 2. It can be seen that the pH range 5.5–9 is the most suitable; this was experimentally verified (Fig. 3). The curves in Fig. 4 correspond to spectrometric titrations with 5ClDMPAP. Curves for Erio-T are included for comparison.

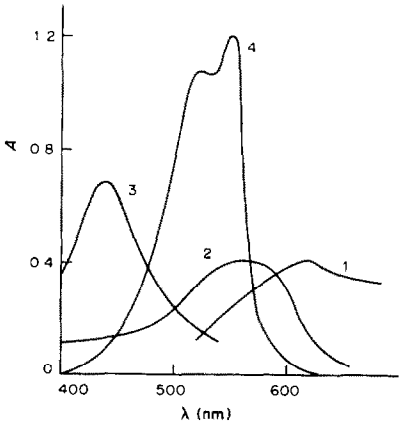

Fig. 1. Spectral curves of 5ClDMPAP and Erio-T and their zinc complexes, $C_{reag} = 2.0 \times 10^{-5} M$; $C_{Zn} = 6.2 \times 10^{-4} M$; (1) Erio-T; (2) Erio T–Zn complex; (3) 5ClDMPAP; (4) 5ClDMPAP–Zn complex.

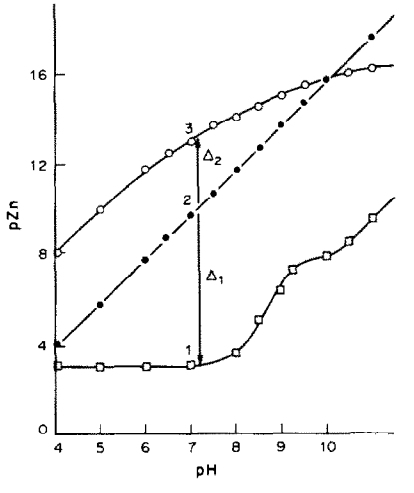

Fig. 2. The pZn data required for the method of Reilley and Schmid:[15]
(1) for the system Zn plus NH_4^+–NH_3 buffer;
(2) for 50% transformation of the indicator;
(3) for the system with EDTA added in 100% excess.

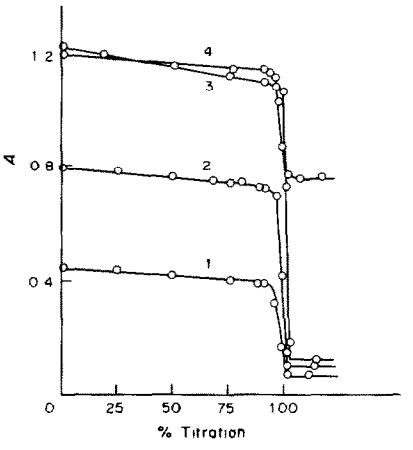

Fig. 3. Photometric titration: Effect of pH on the end-point. pH: (1) 4.5; (2) 5.6; (3) 7.2; (4) 8.5; (5) 9.0; (6) 10.8; (7) 12.

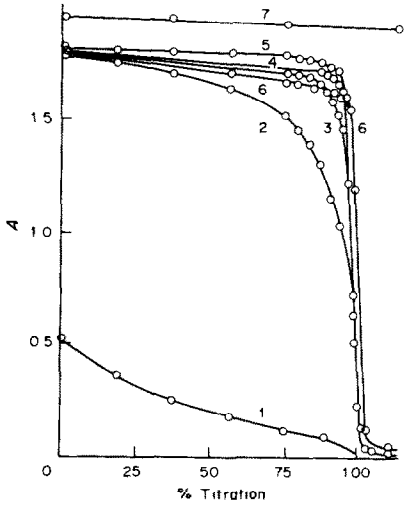

Fig. 4. Absorbances at λ_{max} of the zinc complex, in photometric, titration of zinc. [5ClDMPAP] = (1) $5 \times 10^{-6} M$; (2) $1 \times 10^{-5} M$; (3) $2 \times 10^{-5} M$; [Erio-T] = (4). $6 \times 10^{-5} M$.

Both indicators give the same location of the end-point, but the colour change is much sharper with 5ClDMPAP than with Erio-T. This is clearly shown by the change in absorbance (ΔA) on addition of 0.05-ml increments of EDTA in the vicinity of the end-point (Table 2).

	5ClDMPAP		Erio-T	
Titration, %	A_{550}	ΔA	A_{560}	ΔA
97.2	0.686	0.031	0.961	0.026
98.5	0.655	0.081	0.935	0.066
99.7	0.574	0.484	0.869	0.116
101.1	0.090	0.002	0.753	0.103
102.3	0.088	0.001	0.650	0.003
103.5	0.087		0.647	

Effect of ethanol content and ionic strength

Erio-T has the advantage that it can be used in purely aqueous solution, whereas 5ClDMPAP (which is insoluble in water) must be used in aqueous ethanolic medium. Hence the effect of the ethanol concentration was tested over the range 20–60% v/v. With <40% ethanol the reaction is slow, more time is required to stabilize the absorbance, and the end-point is sluggish. These effects are basically due to the low solubility of the zinc–5ClDMPAP complex. With 40–60% ethanol present these difficulties are overcome, but the relatively high ethanol content required limits the concentration of inorganic salts in the solution. The effect of ionic strength was tested on zinc solutions in 50% v/v ethanol–water medium by addition of sodium perchlorate, nitrate, chloride, sulphate and acetate. The most serious limitation is imposed by sulphate. At concentrations >0.2*M* sodium sulphate is not completely soluble in this medium and the dispersed solid makes it difficult to see the colour change at the end-point. For the other sodium salts tested this effect does not arise. With Erio-T in purely aqueous medium, the only effect was a slight diminution in ΔA at the end-point.

Effect of foreign ions

The ions which interfere were known from previous work,[11] the most serious being cadmium, copper, nickel, iron and cobalt, which also interfere in the complexometric titration. Nickel, copper and iron may be effectively dealt with by the cyanide–formaldehyde method (Table 3) but cadmium and cobalt cannot. Sodium, potassium, magnesium, barium, and strontium do not interfere in at least 100:1 w/w ratio to zinc. Calcium is tolerated at 25:1 ratio but iron and mercury are tolerated only in 5:1 ratio to zinc. Tolerance limits for most common anions were determined when the effect of ionic strength was studied, and found to be dictated by the solubility of the sodium salts in the alcoholic media used. Lead interferes but can be dealt with by the method used to eliminate its interference when Erio-T is used as indicator.[20]

Xylenol Orange shows an advantage over 5ClDMPAP in selectivity, mainly in the case of bismuth, thorium, scandium, lanthanum, lead, zinc and cadmium,[21] because it is used at pH < 6 (5ClDMPAP can be used in the pH range 5.5–9, with an appropriate buffer).

Table 3. Determination of zinc in binary samples; interferents were masked by the cyanide–formaldehyde method

Interferent	Zinc, *mg*		Ratio (w/w) of interferent to Zn
	Taken	Found	
Nickel	1.63	1.64	12.5
Copper	1.63	1.64	24.5
Iron	1.63	1.65	1.22

Applications

Analysis of a zinc insulin preparation (Lilly) gave a mean of 0.156 mg/ml by the present method (standard deviation 0.002 mg/ml), 0.157 (s.d. 0.0013) by a reference method,[22] and 0.154 (s.d. 0.0010) by AAS, for six replicates.

Synthetic brass samples corresponding to British Standards BCS 385 and BCS 344 were analysed by a modification of the recommended procedure (immediately after the pH was adjusted, 2 ml of 5% potassium cyanide solution followed by 4 ml of 5% formaldehyde solution were added). The zinc results were 38.4% (s.d. 0.02%) for BCS 385 (certified value 38.5%) and 30.8% (s.d. 0.02%) for BCS 344 (certified value 31.0%) for six replicates in each case.

THERMODESORPTIVE ANALYSIS OF GaAs AND ZnSe SURFACES

I. A. KIROVSKAYA*, G. M. ZELYEVA and A. V. YURYEVA
Omsk Polytechnical Institute, Omsk, USSR

(*Received* 12 *March* 1984. *Accepted* 16 *July* 1984)

Summary—This paper concerns thermodesorption analysis of the interaction of ammonia, hydrogen, carbon dioxide and a mixture of $H_2 + CO_2$ with GaAs and ZnSe surfaces, to determine the strength and concentration of acid surface centres. The mechanism of interaction of the gases and surfaces has been examined. This work was aimed at differentiating between the strengths of acid centres on GaAs and ZnSe semiconductor surfaces to obtain more information about the quantity of hydrogen and carbon dioxide adsorbed, their energy characteristics, the presence or absence of dissociation, and the nature of the CO_2 hydration.[1]

EXPERIMENTAL

For analysing surface acid–base properties, ammonia was used as the adsorbent probe. Thermodesorptive measurements were done with an apparatus similar to that described by Yakerson and Rozanov.[2] The desorption products were determined by gas chromatography and mass spectrometry, with programmed linear heating from 298 to 653 K at 10 K/min. The powdered samples were pressed into tablets at a pressure of 35 kg/m^2 and then conditioned at 673 K and 0.1 Pa pressure. The conditioned samples were then saturated with the gas under study (NH_3, H_2, CO_2, $H_2 + CO_2$) for 2 hr at the temperature of the experiment. The free gas was pumped out, and programmed heating of the reactor started, with simultaneous analysis of the desorption products. Helium was used as carrier gas. An MCh-1301, RMS-1 mass-spectrograph was used, with Pimonova's method.[3] The gases were obtained as described by Kirovskaya *et al.*[4]

RESULTS AND DISCUSSION

The thermochromatograms for ammonia desorption (Fig. 1) contain three peaks, one at 301–305 K, for both samples, the other two at 463 and 563 K for GaAs, and 433 and 533 K for ZnSe. These data indicate that ammonia is adsorbed on the semiconductor surfaces at three kinds of site, which differ in their activity. This is corroborated by the results of the thermodesorption curves, and the mass-spectrometric and infrared-spectrometric determination of the kinetics. By means of the approximately integrated Polani-Vigner equation[5] the desorption activation energy was calculated to be 12–21 kJ/mole for the low-temperature peak and 59–63 and 67–71 kJ/mole for the high-temperature peaks. At 301–305 K, the thermodesorption follows first-order kinetics, whereas at 353–503 K for GaAs and 363–573 K for ZnSe it follows second-order kinetics. These kinetic characteristics, combined with the results of the infrared spectroscopy, make it possible to state that at low temperature the ammonia is rapidly but feebly bound by residually adsorbed H_2O and OH-groups whereas at high temperatures the ammonia is co-ordinately bound to surface atoms,[7,8] with dissociation accompanying adsorption at the highest temperature. This is confirmed indirectly by the kinetic data and directly by the mass-spectral data (Fig. 2). The presence of small quantities of a species of mass number 18 seems to be due to water vapour in the gaseous ammonia used.

The difference in strength of the acid centres of the surfaces corresponds to the degree and temperature

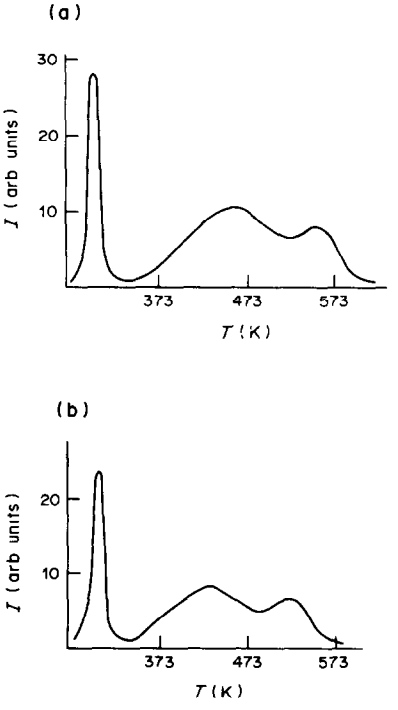

Fig. 1. Chromatograms of ammonia thermodesorption from GaAs (*a*) and ZnSe (*b*) surfaces.

*Author for correspondence.

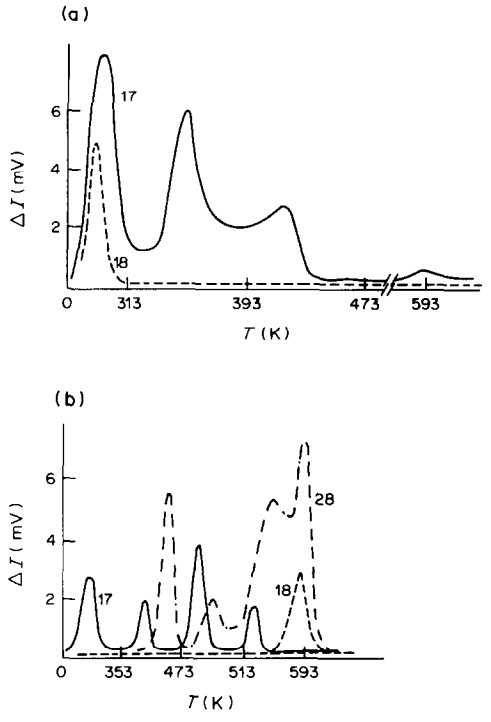

Fig. 2. Mass spectra of NH_3 desorption from GaAs (*a*) and ZnSe (*b*) surfaces.

of adsorption, the acid centres of ZnSe being weaker than those of GaAs.

Analysis of the adsorption characteristics of H_2 and CO_2 on ZnSe showed the following. The thermodesorptive chromatogram for H_2 (Fig. 3) has two distinct peaks at $T_{max_1} = 310$ K, $T_{max_2} = 338$ K, and a very broad and shallow one with $T_{max_3} = 523$ K. The three peaks correspond to three types of adsorption sites, differing in their bond strength. The first two types of site have activation energies of 19 and 25 kJ/mole respectively. That for the third type could not be identified because of the low intensity of the desorptive peak. At T_{max} desorption occurs by first-order kinetics, so at $T \leqslant 310$ K molecular adsorption prevails and at $T > 643$ K dissociative adsorption predominates. The comparatively low heat of chemical adsorption,[9] together with the secondary-ion mass spectra,[10] indicates that dissociation occurs on ZnSe and analogous surfaces at higher temperatures.

The thermodesorptive chromatogram of CO_2 has a very sharp peak at T_{max} about 336 K (Fig. 4), with 3 kJ/mole activation energy and first-order kinetics, *i.e.*, under these conditions weak non-dissociative adsorption of CO_2 takes place. The mass spectra[11] also indicate the absence of dissociation of adsorbed CO_2 on the ZnSe surface in the temperature interval examined. According to infrared spectroscopic

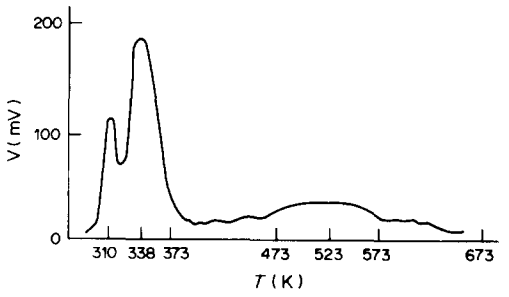

Fig. 3. Thermodesorption of H_2 from ZnSe surface.

examination[12] and the nature of the surface acid centres discussed above, CO_2 adsorption of this type should be due to formation of a linear donor–acceptor complex, without free molecular rotation, on the adsorbent surface ($\nu_{max} = 2380\ cm^{-1}$):

The mass-spectral examination of desorption of the $CO_2 + H_2$ mixture showed decreasing desorption at high temperatures and increasing yield of species with mass numbers 18 and 28 at $T > 423$ K. Taking the non-dissociative character of the CO_2 adsorption into account, the presence of CO_2 as well as H_2O in the desorbed phase is evidently due to interaction of the adsorbed CO_2 and H_2. As mentioned before,[1] such an interaction is accompanied by intermediate complex formation analogous to formation of adsorbed formic acid. The formic acid is relatively stable and is not decomposed at lower temperatures, but at higher temperatures (473–573 K) dissociates into CO and H_2O in the desorption process:

$$[HCOOH]^{+\delta} \rightarrow CO_{(gas)} + H_2O_{(gas)} + \delta^{\oplus *}$$

The lower desorption of water when the mixture is used, compared with that for hydrogen alone, also confirms that the carbon dioxide suppresses the hydrogen adsorption, as mentioned by us earlier.[4]

Thus the thermodesorptive examination of these semiconductor surfaces makes it possible to obtain some additional information about the surface acidity characteristics and some media interacting with

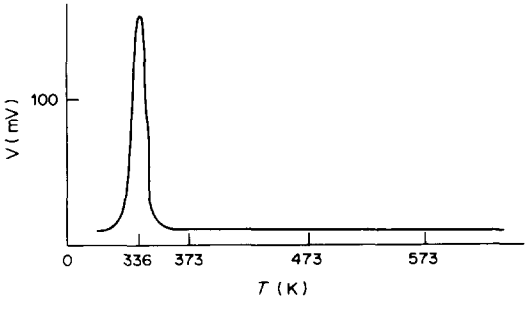

Fig. 4. Thermodesorption of CO_2 from ZnSe surface.

*$\delta^{\oplus}$ is an extra (effective) charge remaining on the surface.

them (H_2, CO_2, $H_2 + CO_2$). The latter information is most important in research into the physical chemistry of real diamond-like semiconductor surfaces.

DIFFERENTIAL PULSE POLAROGRAPHY IN THE ALTERNATING PULSE MODE

CSABA URBANICZKY
Department of Analytical Chemistry, University of Uppsala, P.O. Box 531, S-751 21 Uppsala, Sweden

(*Received* 11 *June* 1984. *Accepted* 10 *July* 1984)

Summary—A polarographic two-drop pulse technique for trace analysis is described. By using a second pulse, in the opposite direction to the first one, on the second drop, a high current sensitivity is obtained, with a very flat background. The theoretical response for a reversible electrode process is presented together with experimental results for the reduction of Pb^{2+} in hydrochloric acid medium. It is shown that without enrichment determination of lead at concentrations as low as 71n*M* is possible with this technique.

Differential pulse polarography (DPP)[1,2] is a very useful electroanalytical technique, but it has the following disadvantages. At the dropping mercury electrode (DME) there is a charging current due to the continuous drop expansion, since the current is sampled at two different times during the life of a drop. Further, there is a contribution due to the potential-dependence of the differential capacity, since the current is measured at two different potentials. There is also a d.c. faradaic current contribution which leads to a positive distortion.[3] At the static mercury drop electrode (SMDE), on the other hand, there is a negative d.c. faradaic distortion.[4] Alternate-drop differential pulse polarography (ADDPP) compensates for these effects but the sensitivity is diminished.[5] In both DPP and ADDPP the potential at which the current peak appears is dependent on the magnitude of the applied potential pulses.

In this report a two-drop method is described, called differential pulse polarography in the alternating pulse mode (DPPAPM). This is a hybrid between ADDPP and differential normal-pulse voltammetry in the alternating pulse mode (DNPVAPM).[6] By using a second pulse in the opposite direction on the second drop, the following advantages are obtained: (1) higher current sensitivity than for ADDPP; (2) the potential at which the current peak appears is independent of the pulse amplitude; (3) the d.c. faradaic distortion current is absent: (4) the charging current is lower than it is in DPP and DNPVAPM.

EXPERIMENTAL

Apparatus

A Z-80 based personal computer, the Luxor ABC-80, was used to control the voltammetric instrumentation.[7-9] The potentiostat is of conventional addition design and employs National LF 356 Bi-FET operational amplifiers.

In this study the following settings were used throughout. The potential increments between the two drops were 2 mV and the step height of the applied potential pulses was 20 mV. The drop-time was 0.5 sec and pulses were applied during the last 40 msec. The current was sampled during the last 20 msec of each pulse. The time constants in the sample and hold circuits were 20 msec.

The polarograms were recorded on a Hewlett-Packard 9044A X–Y recorder.

Potential and time calibrations were performed with a Fluke 8050 A $4\frac{1}{2}$-digit digital multimeter and a Ballantine model 5500B timer/counter respectively.

Reagents

All chemicals were of analytical-reagent grade except the hydrochloric acid, which was of "Suprapur" grade. The hydrochloric acid concentration of the solutions was 10m*M*. Aliquots of a 4 m*M* stock solution of lead nitrate were diluted on the day of use to obtain working solutions. Distilled water was purified prior to use, with a Millipore Milli-Q filtration system. The mercury was purified before use.[10] Solutions were purged with water-saturated nitrogen before each scan.

Cell and electrodes

The cell, the SCE reference electrode (with a salt bridge) and the auxiliary electrode (a platinum wire) were conventional. The capillary used for the DME had a mercury flow-rate of 1.57 mg/sec and a drop-time of 5.36 sec on open circuit. Triton X-100 was added to give a final concentration of 10 ppm.

The temperature was kept at $25 \pm 0.5°$.

RESULTS AND DISCUSSION

In Fig. 1 the DPPAPM waveform is shown and the potential variables are defined. The potential on the first drop (α) is held at E_1^α and at the end of the drop-life, at time τ, a small potential pulse, ΔE, is added to obtain potential E_2^α during a time δ. The potential on the next drop (β) is held at E_1^β which has numerical value of $E_1^\alpha + 2\Delta E$, and at the end of the drop-life a small potential pulse is subtracted to obtain E_2^β with numerical value identical to E_2^α. Each consecutive pair of double pulses is similar, except that the scanned potential is incremented. The sampled currents are I_2^α and I_2^β and the differential current is monitored as a function of E_2.

For a reversible system, the current response for the DPPAPM waveform can be derived in a similar way as for ADDPP[5]. The current for a "pulsed drop"

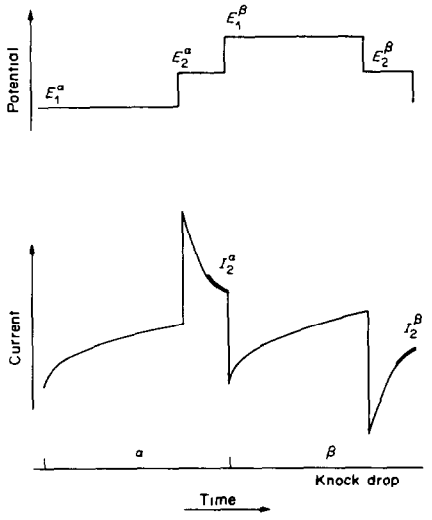

Fig. 1. Definitions of the potentials and the currents in differential pulse polarography in the alternate pulse mode. See the text for further information.

is [equation (16) in reference 5]:

$$I_2 = I_{F,DPP} + I_{Po}(E_1, \tau + \delta) + I_C(E_2, \tau + \delta) \quad (1)$$

where

$$I_{F,DPP} = nFkm^{2/3}C(\tau + \delta)^{2/3}(D/\pi\delta)^{1/2} \times \left[\frac{1}{1+\xi\Theta_2} - \frac{1}{1+\xi\Theta_1}\right] \quad (2)$$

$$\Theta = \exp[nF(E - E'_{1/2})/RT] \quad (3)$$

$E'_{1/2}$ is the reversible half-wave potential and the constant k has a numerical value of 0.8515 $cm^2/g^{2/3}$,

$$I_{Po} = (7D/3\pi)^{1/2}nFkm^{2/3}C(\tau + \delta)^{1/6}\left[\frac{1}{1+\xi\Theta_1}\right] \quad (4)$$

and

$$I_C = -(2/3)km^{2/3}Q(E_2)/(\tau + \delta)^{1/3} \quad (5)$$

Equation (4) is the Heyrovský–Ilkovič equation, and I_C is the charging current due to the drop growth. $Q(E)$ is the potential-dependent charge density on the electrode surface. All the other symbols are according to Bard and Faulkner.[11]

According to equation (1) the currents I_2^α and I_2^β are then

$$I_2^\alpha = I_{2,F,DPP}^\alpha + I_{2,Po}^\alpha(E_1^\alpha, \tau + \delta) + I_{2,C}^\alpha(E_2^\alpha, \tau + \delta) \quad (6)$$

$$I_2^\beta = I_{2,F,DPP}^\beta + I_{2,Po}^\beta(E_1^\beta, \tau + \delta) + I_{2,C}^\beta(E_2^\beta, \tau + \delta) \quad (7)$$

and the differential current sought is then

$$\Delta I = I_2^\alpha - I_2^\beta \quad (8)$$

The charging current, I_C, equation (5), is a function of only the potential and time. This component is absent at the SMDE, because the drop area is constant when the currents are sampled. At the DME the charging currents will be equal and can be cancelled. Since the currents are sampled at the same point of time in a drop-life, there is no d.c. faradaic distortion. After some algebraic manipulation

$$\Delta I = nFkm^{2/3}(\tau + \delta)^{2/3}(D/\pi\delta)^{1/2}C\{1 - [7\delta/3(\tau + \delta)]^{1/2}\}\left[\frac{1}{1+\xi\Theta_1^\alpha} - \frac{1}{1+\xi\Theta_1^\beta}\right] \quad (9)$$

is obtained. The same diminution factor as in ADDPP, $1 - [7\delta/3(\tau + \delta)]^{1/2}$, appears in this equation, but the last potential term is also a function of the applied second pulse and thus an improved current sensitivity is obtained. Equation (9) can be rewritten as

$$\Delta I = nFkm^{2/3}(\tau + \delta)^{2/3}(D/\pi\delta)^{1/2}C \times \{1 - [7\delta/3(\tau + \delta)]^{1/2}\} \times \frac{-\sinh(nF\Delta E/RT)}{\cosh(\ln\xi\Theta_2) + \cosh(nF\Delta E/RT)} \quad (10)$$

As in DNPVAPM, ΔI is symmetrical with respect to the peak potential in DPPAPM. The peak current, ΔI_S, is then

$$\Delta I_S = nFkm^{2/3}(\tau + \delta)^{2/3}D/\pi\delta)^{1/2}C \times \{1 - [7\delta/3(\tau + \delta)]^{1/2}\} \times \tanh(nF\Delta E/2RT) \quad (11)$$

Compared with DNPVAPM, the peak current for DPPAPM has a diminution factor in the same way as ADDPP has compared with DPP. From equation

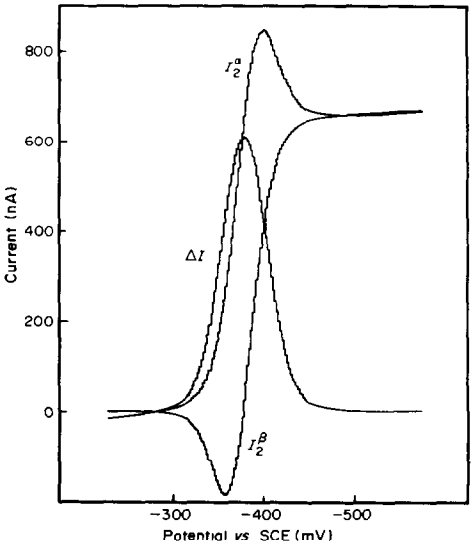

Fig. 2. The forward (I_2^α), the reverse (I_2^β) and the difference (ΔI) polarograms of 123 μM Pb^{2+} in acetate buffer.

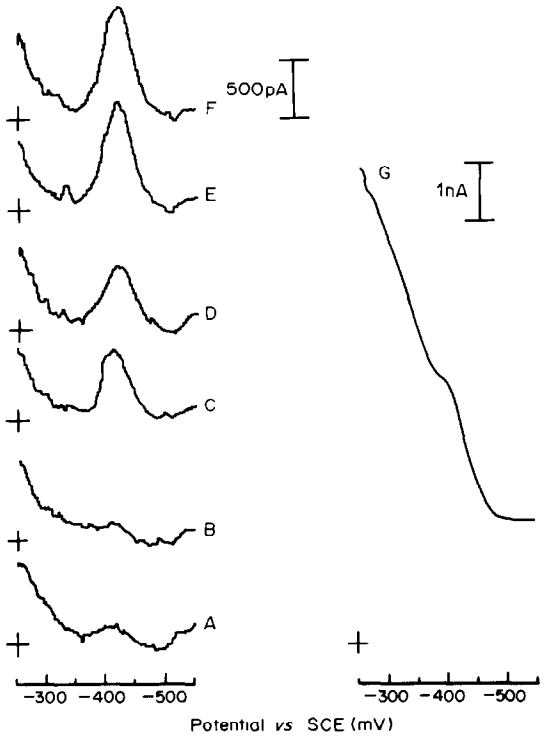

Fig. 3. DPPAPM (A–F) and DPP (G) polarograms of (A, B) 0, (C, D) 71 and (E–G) 142nM Pb^{2+}. The cross indicates zero current.

(10) the peak-width at half-height, $W_{1/2}$, is given by

$$W_{1/2} = \frac{2RT}{nF} \cosh^{-1}[2 + \cosh(nF\Delta E/RT)] \qquad (12)$$

The experimental behaviour of a reversible system is illustrated by reduction of Pb^{2+}. Figure 2 shows the experimental current responses from the forward (I_2^a) and reverse (I_2^β) potential pulses and that the difference polarogram (ΔI) gives a symmetrical peak. The current sensitivity, $\Delta I_C/C$, is 4.75, 2.78 and 5.00 mA.l.mole^{-1} for DPP, ADDPP and DPPAPM respectively. According to theory the quotients DPP/DPPAPM and ADDPP/DPPAPM are 1.00 and 0.57, which agree well with the experimental values of 0.95 and 0.56.

Curves A and B in Fig. 3 show that the charging current is considerably diminished when DPPAPM is used instead of DPP. Efforts to smooth the background further, included experiments with different ultraviolet-irradiated solutions. No improvement in background was obtained. In Fig. 3 it is also shown that determination of lead at concentrations down to $10^{-7}M$ is possible with DPPAPM at the DME when a drop-time of 0.5 sec is used. In the DPP voltamperogram the peak is hardly discernible.

EXTRACTIVE-SPECTROPHOTOMETRIC DETERMINATION OF MOLYBDENUM AS AN ION-ASSOCIATION COMPLEX WITH THIOCYANATE AND ADOGEN

F. SALINAS, J. J. BERZAS NEVADO and M. I. ACEDO VALENZUELA
Department of Analytical Chemistry, Faculty of Sciences, University of Extremadura, Badajoz, Spain

(*Received* 12 *March* 1984. *Accepted* 30 *June* 1984)

Summary—A selective and sensitive method is described for the determination of trace amounts of molybdenum, based on its reaction with thiocyanate and its extraction (into toluene) as an ion-association complex formed with adogen (methyltrioctylammonium chloride). The molar absorptivity is 2.13×10^4 l.mole^{-1}.cm^{-1} at λ_{max} 467 nm. The method has been applied to molybdenum determination in steels.

The use of thiocyanate for the determination of molybdenum has been widely studied and a number of methods have been reported. The fundamental differences between these methods are the reducing agents and solvents used, and in recent years the use of mixed-ligand complexes or ion-association complexes. Stannous chloride is the reducing agent most commonly used,[1–8] but ascorbic acid is recommended[9–13] because it gives a high absorbance for the complex and its concentration is not critical. It has also been found that extraction of the molybdenum–thiocyanate complex is complete even in the absence of a reducing agent if the reaction mixture is shaken for at least 30 min.[12,13] However, the presence of a reducing agent is necessary to eliminate interference, such as that of Fe(III).

In this paper, we report a selective, sensitive and reproducible method for determination of molybdenum, based on reduction of Mo(VI) to Mo(V) with stannous chloride [in presence of Fe(II)] and then reaction with thiocyanate in hydrochloric acid media, formation of the Mo(V)–thiocyanate complex and its subsequent extraction into toluene with adogen.

EXPERIMENTAL

Reagents

Molybdenum(VI) solution. Prepared from sodium molybdate dihydrate and standardized gravimetrically. The working solution (Mo 11.6 μg/ml) was prepared by appropriate dilution.

Tin(II) solution. A 0.25*M* solution in 2*M* hydrochloric acid.

Adogen solution. A 0.5 g/l. solution in toluene.

Iron(II) solution. Freshly prepared by dissolving 1 g of $(NH_4)_2Fe(SO_4)_2.6H_2O$ in 100 ml of water.

Thiocyanate solution, 1M.

All solvents and reagents were of analytical grade.

Procedure

The sample solution, containing 2.5–50 μg of Mo, was placed in a 100-ml separatory funnel, then 6 ml of thiocyanate solution, 9.5 ml of 2*M* hydrochloric acid, 1 ml of iron(II) solution, and 0.5 ml of stannous chloride solution were added, followed by dilution to 50 ml with demineralized water. The mixture was then shaken with 10 ml of the toluene solution of adogen for 2 min. The toluene layer was collected 30 min later and dried over anhydrous sodium sulphate in a 50-ml beaker, and its absorbance was measured at 467 nm against adogen solution.

Determination of Mo in steel

A 0.1-g sample was dissolved in 5–7 ml of 70% perchloric acid and the solution evaporated to dryness. The residue was heated with 5 ml of concentrated hydrochloric acid and evaporated almost to dryness, then the mass was cooled, dissolved in 15–20 ml of 2*M* hydrochloric acid, and diluted to 100 ml with demineralized water. When perchloric acid was not satisfactory as the solvent, 10 ml of *aqua regia* were added and the mixture was heated to fumes of oxides of nitrogen. After the solution was cooled, 3–5 ml of sulphuric acid were added, the solution was evaporated to dryness and the dried mass was cooled and dissolved in 15–20 ml of 2*M* hydrochloric acid and diluted to 100 ml with demineralized water. An aliquot (containing not more than 5 mg of Fe) was taken in a 100-ml separatory funnel and molybdenum was then determined as described in the procedure above.

When the Mo content (in steel) is <0.1%, the standard-addition method is recommended.

RESULTS AND DISCUSSION

Spectral characteristics

The absorption spectrum of the ion-association complex in toluene is shown in Fig. 1. Adogen has negligible absorption at the wavelength of maximum absorption. The absorption peak of the complex (at 467 nm) corresponds to an Mo(V)–thiocyanate complex.[2]

Influence of reducing agents

Ascorbic acid and stannous chloride were tried as reducing agents. Ascorbic acid gives a high absorbance for the complex and the amount to be added is not critical when $[SCN^-] = 0.4M$ and $[HCl] = 2M$. Under these conditions the extraction (shaking for 2 min) is complete even in the absence of ascorbic acid. Stannous chloride [in the absence of Fe(II)]

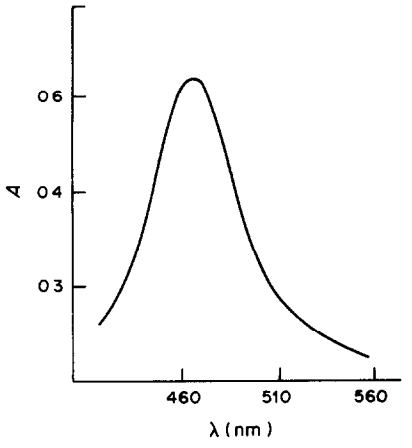

Fig. 1. Absorption spectrum of molybdenum–thiocyanate–adogen complex in toluene.

gives a lower absorbance and its concentration must be between 1×10^{-3} and $3.5 \times 10^{-3}M$ when $[SCN^-] = 0.1M$ and $[HCl] = 0.3M$. However, if iron(II) is present, stannous chloride gives a similar absorbance to that obtained with ascorbic acid. When stannous chloride is used, the absorbance can be measured against adogen solution, whereas when ascorbic acid is used, the absorbance must be measured against a reagent blank. Hence the stannous chloride/iron(II) system is preferred. The effect of the tin(II) concentration is shown in Fig. 2. The presence of iron(II) increases the extraction efficiency and makes the tin(II) concentration range less critical.

Effect of other variables

The extraction was found to be maximal at $[HCl] \geqslant 0.25M$ and 0.05–0.15M thiocyanate (Fig. 3); the adogen must have a concentration of at least 0.03%.

The presence of iron(II) increased the extraction of molybdenum. The absorbance was maximal and constant at $[Fe(II)] \geqslant 5$ ppm. A similar effect was observed when copper(II) was added, and the effect is not inhibited by the presence of EDTA or tartrate.

The absorbance was practically constant for aqueous/organic phase-volume ratios from 5:1 to 1:1. A shaking time of 2 min was sufficient for complete extraction. For low concentrations of molybdenum (1–2 ppm), the absorbance was constant for at least 6 hr, but for higher concentration (5 ppm) it was constant only for 15–60 min.

The order of addition of the reagents affects the absorbance (decreasing it), only when stannous chloride and molybdenum are mixed in the absence of thiocyanate.

Spectrophotometric characteristics

In the absence of iron(II), Beer's law is obeyed in the range 5–50 μg of Mo in the aqueous phase, and the molar absorptivity is 1.29×10^4 l.mole^{-1}.cm^{-1}. The relative error (95% confidence level) for 23 μg of Mo was $\pm 1.5\%$ (11 replicates). In presence of iron(II), Beer's law is obeyed in the range 2.5–50 μg of Mo in the aqueous phase, and the molar absorptivity is 2.13×10^4 l.mole^{-1}.cm^{-1}. The optimum range on the basis of a Ringbom plot is 10–40 μg of Mo. The relative error (95% confidence level) for 23 μg of Mo was $\pm 0.6\%$.

Composition of the complex

Different stoichiometries for Mo–thiocyanate complexes are given in the literature. We used the Job[14] and Yoe and Jones methods[15] and found the most probable composition of the ion-association complex to be 1:4:3, Mo–SCN–adogen, so the species extracted into toluene is probably $MoO_2(SCN)_4(ADG)_3$ where ADG is the trioctylmethylammonium ion. This stoichiometry agrees with that reported for the molybdenum–thiocyanate–tetrabutylammonium system.[16]

Interferences

The effect of other ions on the determination of 23 μg of Mo was examined. The tolerance limit was taken as the concentration that did not cause more than $\pm 2\%$ change in the absorbance. The results are summarized in Table 1.

TITRIMETRIC DETERMINATION OF AMINOBENZOIC ACIDS

D. AMIN, F. M. EL-SAMMAN and H. ABDULAHED-MALALLA
Department of Chemistry, College of Science, University of Mosul, Mosul, Iraq

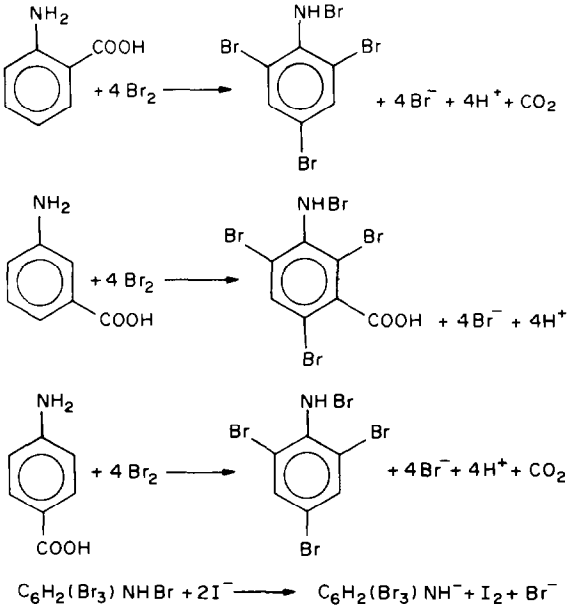
(*Received* 7 *November* 1983. *Revised* 14 *May* 1984. *Accepted* 19 *June* 1984)

Summary—A novel titrimetric method for determination of aminobenzoic acids is based on their reaction with excess of bromine to form *N*-bromo-2,4,6-tribromoaniline, which liberates an equivalent amount of iodine when treated with iodide. The method is applicable to the aminobenzoic acids in the range 0.1–5.0 mg, with a recovery ranging from 96 to 99.7% and a coefficient of variation of 0.2–2.0%, depending on the concentration level.

A method[1] based on bromine substitution has been used for determination of aminobenzoic acids, excess of bromine being back-titrated. A titrimetric[2] determination of as little as 2–30 mg has been reported for determination of aminobenzoic acids. The development of a sensitive, rapid and accurate titrimetric procedure based on the quantitative reaction of *o*-, *m*- and *p*-aminobenzoic acids with bromine was therefore undertaken.

The bromination of aromatic amines proceeds only at the unoccupied *ortho* and *para* positions on the ring. However, in the presence of a large excess of bromine the substitution goes further, to form *N*-bromo-2,4,6-tribromoaniline, which can be reacted with excess of iodide to liberate equivalent amounts of iodine which can be titrated with thiosulphate.

The suggested reactions are:



Scheme 1.

EXPERIMENTAL

Reagents

All chemicals used were of analytical grade, and distilled water was always used.

Aminobenzoic acid solutions. Aqueous solutions of each acid, with concentrations 0.1 and 1.0 mg/ml, were prepared in 0.04*M* sodium hydroxide.

Sodium thiosulphate solutions, 0.001 *and* 0.01*N*. Standardized against potassium iodate solutions of similar normality.

Solutions of bromine water (saturated) and formic acid (80%) were used.

Procedure

In a 50-ml conical flask, place a suitable volume (1–5 ml) of sample solution containing 0.1–5.0 mg of *o*-, *m*- or *p*-aminobenzoic acid, dilute with water to about 15 ml, then add about 3 ml of bromine water. Stopper the flask and shake it for 5 min. Remove the stopper, add about 1 ml of formic acid solution, shake for 1 min, then add 1 ml of concentrated phosphoric acid and about 0.5 g of potassium iodide. Let the flask stand for 10 min, with occasional shaking, then titrate the liberated iodine with 0.01*N* thiosulphate, with starch as indicator (for less than 2 mg of aminobenzoic acid, use 0.001*N* thiosulphate). Run a blank determination.

1 ml of 0.01*N* thiosulphate ≡ 0.6857 mg of aminobenzoic acid.

RESULTS AND DISCUSSION

The bromination of aminobenzoic acids normally proceeds at the unoccupied *ortho* and *para* positions, but preliminary studies confirmed that with a large excess of bromine the bromination goes further, to the amino group reacting to give the *N*-bromo derivative. Decarboxylation of the *o*- and *p*-isomers was confirmed by disappearance of the carboxylate band in the infrared spectrum.

The bromination is complete within 5 min; longer reaction time has no effect on the results. The complete bromination requires 2–3 ml of saturated bromine water, the excess of which is destroyed by addition of 1 ml of formic acid.

Reduction of the *N*-bromo-2,4,6-tribromoanilines requires about 0.5 g of potassium iodide and takes

Table 1. Determination of aminobenzoic acids (5 replicates)

Isomer	Weight, *mg*		Recovery, %	Coefficient of variation, %
	Taken	Mean found

ANALYTICAL DATA

ARSENIC SPECIATION IN SOIL-PORE WATERS FROM MINERALIZED AND UNMINERALIZED AREAS OF SOUTH-WEST ENGLAND

STEPHEN J. HASWELL
Thames Polytechnic, Wellington Street, Woolwich, London SE18, England

PETER O'NEILL and KEITH C. C. BANCROFT
Plymouth Polytechnic, Drake Circus, Plymouth, Devon, England

(*Received* 1 *May* 1984. *Accepted* 27 *July* 1984)

Summary—Arsenate, arsenite and monomethylarsonic acid (MMAA) have been characterized in soil-pore waters extracted from soils in mineralized and unmineralized areas. Special attention has been paid to collection and storage of the samples. The dominant arsenic species in aerobic soils was arsenate, with small quantities of arsenite and MMAA in mineralized areas. In anaerobic soils arsenite was found to be the major soluble species. The analysis was done with an HPLC anion-exchange column combined with continuous-flow hydride-generation and atomic-absorption spectrometry. A preconcentration column was incorporated to increase the sensitivity.

Mineralization and past mining activities in South-West England have resulted in areas with above-average naturally occurring arsenic levels in the soil.[1] The high rainfall in the region results in waterlogging in many of these soils. The region thus lends itself to an investigation of the effects of mineralization and waterlogging on the soluble arsenic species found in these soils.

The chemical species of arsenic present in soil-pore waters will depend on the physical and chemical characteristics of the soil and the soil-pore water.[2] In aerobic soils, on which no arsenical herbicides have been used, arsenate is found to be the predominant species.[3,4] In waterlogged soils where reducing conditions occur the major species is reported to be arsenite.[5] The biomethylation of inorganic arsenic compounds[6,7] results in trace amounts of monomethylarsonic acid (MMAA) and dimethylarsinic acid (DMAA).[8,9] Takanatsu *et al.*[10] have also reported two unidentified organoarsenic compounds to be present in soil extracts.

In speciation studies a rapid reliable separative technique coupled with a suitable detection system is required. The samples should be analysed as soon as possible after collection, without use of sample-preservation techniques such as acidification which will modify the natural equilibria of the species present. The four arsenic species commonly reported to be present in soils, arsenate, arsenite, MMAA and DMAA, are all weak acids, the dissociation constants of which are quite different, and anion-exchange chromatography has been demonstrated to be a simple and efficient technique for their separation, with gravity column systems[11,12] and HPLC systems.[13] The greater control of eluent flow-rates, smaller sample and eluent volumes, and high resolving power of HPLC make it the separation technique of choice, and it is readily directly coupled to a detection system.

A popular method for determining low levels of reducible arsenic species involves the generation of arsine, followed by atomic-absorption detection.[8,14] The separation of arsenate, arsenite, MMAA and DMAA on a low-capacity anion-exchange HPLC column coupled to a graphite-furnace atomic-absorption spectrometer for arsenic detection has been demonstrated.[13] This method, however, does not give complete analysis of the eluate and has a sample analysis time of more than 30 min. Ricci *et al.*[8] have described an ion-chromatographic system, based on Dionex columns, which was coupled directly to a continuous arsine-generation system followed by atomization in a heated quartz-furnace and atomic-absorption determination (FAAS). The method used in the work reported here is based on HPLC anion-exchange chromatography with post-column continuous hydride-generation, followed by atomic-absorption measurement. The method takes 4 min for a single analysis and gives enhanced detection limits by the use of a preconcentration column.[15] The concentrations of arsenic species in soil-pore waters from mineralized and unmineralized soils are re-

ported in this paper. Special attention was paid to the collection and storage of the samples collected from reducing anaerobic waterlogged soils.

EXPERIMENTAL

Apparatus

A schematic diagram of the HPLC/FAAS continuous flow system for the determination of reducible arsenic is shown in Fig. 1. A Waters 6000A solvent-delivery system, and a Water U6K injection valve fitted with a 1-ml sample loop were attached to two anion-exchange columns in series. A peristaltic pump flow-rate of 1.6 ml/min and two borosilicate glass Auto-Analyser Y-pieces were used to entrain the hydrochloric acid (6*M*) and borohydride solution (4% solution in 0.1*M* sodium hydroxide) into the column eluate, flowing at 4 ml/min. Reduction took place in a short mixing coil and the arsine liberated was separated in a glass gas–liquid separator and subsequently flushed with nitrogen into a heated quartz tube mounted in the optical path of a Pye-Unicam SP9 spectrometer, with the detection wavelength adjusted to 193.6 nm. Samples (1 ml) were loaded onto the columns through the HPLC injector, with 10^{-4}% sulphuric acid as the eluent at a flow-rate of 4.0 ml/min. After loading, the eluent was switched from sulphuric acid to 0.01*M* ammonium carbonate (at the same flow-rate).

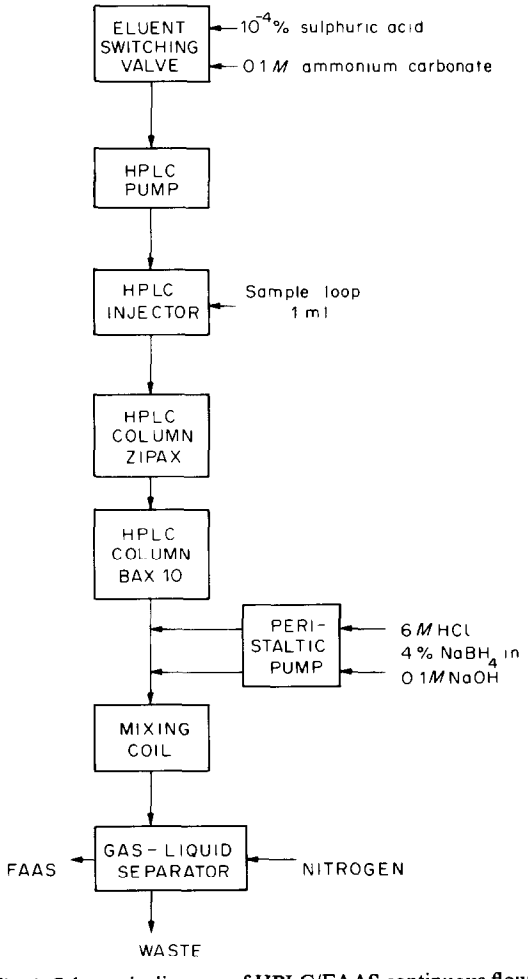

Fig. 1. Schematic diagram of HPLC/FAAS continuous flow system for the determination of arsenic.

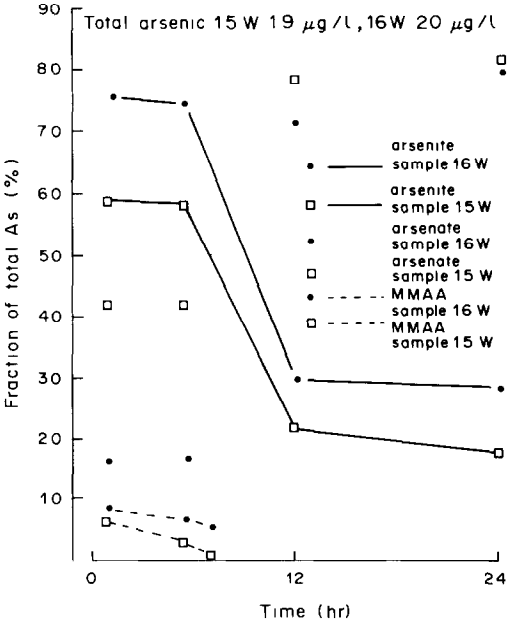

Fig. 2. Changes in arsenic species for samples filtered on site at time of collection and stored at room temperature in the light.

Chromatographic columns

A Zipax ion-exchange resin of mean particle size 40 μm, supplied by Dupont, was slurried into a stainless-steel Shandon 100 × 5 mm column. This column was attached in series to a second column containing a strong-base anion-exchange BAX10 resin, mean particle size 5 μm, supplied by Benson Co., which was slurried into a stainless-steel Shandon 250 × 5 mm column. The Zipax precolumn acted as a guard column and enabled a preconcentration step to be incorporated in the analysis; full details are given elsewhere.[15]

Reagents

Sulphuric acid, hydrochloric acid, ammonium carbonate, sodium borohydride, sodium hydroxide and the arsenic standards were all of analytical-reagent grade; the water used was demineralized and distilled.

Procedures

Aerobic soil-pore water extraction. Surface soil samples (0–10 cm depth) from the Dartington and Trusham series[16] were placed in 100-ml plastic centrifuge tubes and centrifuged on site (3000 rpm, 1000 *g* for 1 min) to extract a suitable volume of pore water (~0.5 ml). The pore water was drawn up into a plastic syringe and immediately filtered with a Whatman WCN filter (pore size 0.45 μm) in a Millipore Swinex apparatus, into an acid-washed vial, and the pH was taken. Arsenic determinations were made within 5 hr.

Anaerobic soil-pore water collection and sample storage. Soil-pore waters were collected from waterlogged soils of the Conway and Yeolland Park series[16] not directly affected by arsenic mineralization. These samples were treated in two ways: (*i*) filtered (0.45 μm filter) on site, and (*ii*) sealed unfiltered in an air-tight container and filtered (0.45 μm filter) just before analysis; both types of sample were stored in the light at room temperature. Figure 2 indicates that samples filtered on site may be stored for up to 5 hr with no apparent compositional changes, whereas losses of about 20% are observed for arsenite in unfiltered stored samples (Fig. 3) within the same time period. For samples treated by either method it was found that within 12 hr 90% of the arsenite was oxidized to arsenate, and both dimethylarsinic

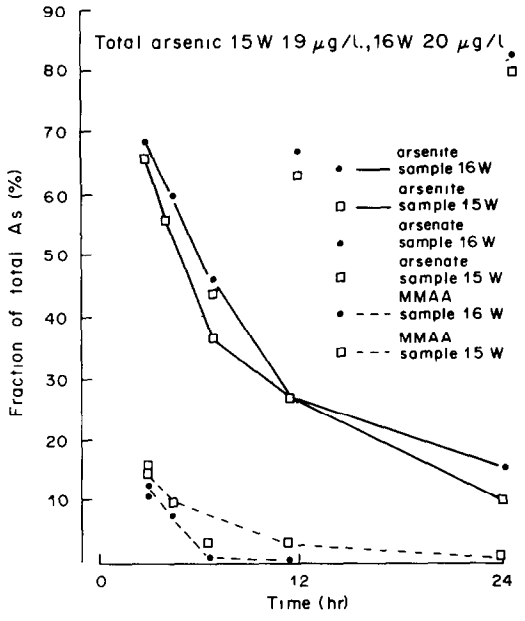

Fig. 3. Changes in arsenic species for samples not filtered on site, stored at room temperature in the light and filtered prior to analysis

acid and monomethylarsonic acid were partly lost from the system.

RESULTS AND DISCUSSION

Arsenic speciation in soil-pore waters from mineralized and unmineralized areas

Soil-pore waters were collected from mineralized, unmineralized, and unmineralized but waterlogged sites; the concentrations of arsenic species found are shown in Table 1.

In all the aerobic soils the predominant species (~90%) present in the soil-pore waters was found to be arsenate, in agreement with other published work.[3,4] From the *Eh*–pH diagram for arsenic,[2] the probability of finding arsenite in aerobic soils is greater at pH < 4.5 and in anaerobic soils at pH < 7. The pH of the soil-pore waters in this study was typically 4.1–5.3. Where mineralization had enhanced the soil arsenic-levels (samples 1M–8M) the presence of monomethylarsonic acid was observed. However, the range of arsenite in these samples was not noticeably different from that obtained for the unmineralized areas (samples 9U–14U). This suggests that there may be a threshold concentration of arsenite at which monomethylarsonic acid is microbially produced.[7] Samples 5M–8M, from a different mineralized area, have a range of arsenate levels similar to that of samples 1M–4M. Comparison of the samples containing the highest total levels of arsenic (samples 1M, 2M, 5M and 6M) indicates that samples 5M and 6M contain less monomethylarsonic acid than the other two do. This lower level of monomethylarsonic acid in samples 5M and 6M is accompanied by higher levels of arsenite; this relationship is also apparent in samples with intermediate total arsenic levels, namely 4M, 7M and 8M. Thus in samples with high arsenic levels the arsenite concentration may either be similar to those in samples with low arsenic levels, in which case monomethylarsonic acid will be present, or it may be 2–5 times the levels normally observed, in which case very little or no monomethylarsonic acid will be present.

The typical total levels of arsenic found in unmineralized aerobic soils (samples 9U–14U) are 16–56 μg/l., compared to 80–215 μg/l. for the mineralized soils discussed above. No monomethylarsonic acid was found in the samples from unmineralized areas except for one sample (10U), which was unusual in that the arsenite level was low.

Samples 15W and 16W were collected from anaerobic soils in an unmineralized area. The arsenite level

which represents 59 and 77% respectively of the total arsenic present, in contrast to the ~10% for aerobic soils, is in agreement with previously published results, which suggests that up to 80% of the total arsenic in anaerobic soils may be present as arsenite.[5] The chemical conditions in the aerobic and anaerobic environments suggest that the arsenite levels will be increased in the latter, owing to the chemical reducing conditions. Although microbial reduction of arsenate to arsenite has been reported,[7] at the negative redox potential found in anaerobic soils chemical reduction will override the microbial conversion of arsenate into arsenite. Though reduction of arsenate to arsenite is predominantly a chemically controlled reaction in both anaerobic and aerobic soils, methylation of arsenite to MMAA may be considered to be controlled by micro-organisms. No clear relationship between the arsenate, arsenite and MMAA levels is apparent from the results. As the MMAA levels increase, the levels of arsenite decrease, which may suggest that production of MMAA affects the residual arsenite levels in the soil. As indicated above the chemical conversion of arsenate into arsenite may preclude microbial activity, thus reducing the production of MMAA.

The complicated processes in the interconversion of arsenic species in soil systems depend primarily upon the *E*h–pH and the physicochemical factors affecting microbial activity. These processes pose a great problem to the analyst in the interpretation of experimental data.

CONCLUSIONS

This system of HPLC coupled with continuous-flow hydride generation and atomic-absorption measurement allows the rapid detection of reducible arsenic species at low concentrations in soil-pore waters. In aerobic soils the pore-water the main arsenic species is arsenate. Where mineralization and past mining activities have elevated the total soluble arsenic levels, arsenite and monomethylarsonic acid are also present. The arsenic species in anaerobic waterlogged soils are markedly different from those in aerobic soils, with arsenite predominant. Such samples should be filtered on site and analysed for arsenic species within 5 hr of collection.

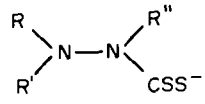
(*Received* 22 *February* 1984. *Revised* 17 *April* 1984. *Accepted* 27 *July* 1984)

Summary—The protonation constants of 2-methyldithiocarbazate, 3,3-dimethyldithiocarbazate and 3-methyl-3-phenyldithiocarbazate, have been determined potentiometrically ($I = 1.00M$) and spectrophotometrically ($I = 0.01M$) at 25° in aqueous solution. The analytical properties of the reagents have been studied, and also the compositions of some of their insoluble metallic chelates.

Dithiocarbazates have been widely studied as potential substitutes for dithiocarbamates, which have found considerable application as surfactants, pharmaceuticals and very active fungicides, and in vulcanization processes. This has given rise to a number of papers dealing with their synthesis[1–4] and the study of their structural properties.[5–11] In contrast, their analytical properties have received little attention. 3-Phenyldithiocarbazate was proposed by Musil and Haas[12] for the gravimetric determination of Ag(I), Cu(II) and Pb(II) and by T'ien and Wang[13] for the colorimetric determination of Cu(II). Hydrazinium dithiocarbazate has been used in the photometric determination of V(V), Fe(II) and Fe(III) by Byr'ko *et al.*[14] and of Fe(II), Fe(III) and Co(II) by Haas *et al.*[15,16]

Because the substances containing the dithiocarbazate group are of interest as multidentate ligands, a systematic study of these compounds as analytical reagents has been undertaken in this laboratory. In this paper, the analytical properties of 2-methyldithiocarbazate (**I**), 3,3-dimethyldithiocarbazate (**II**) and 3-methyl-3-phenyldithiocarbazate (**III**) are described.



(I) $R = R' = H$; $R'' = CH_3$
(II) $R = R' = CH_3$; $R'' = H$
(III) $R = CH_3$; $R' = C_6H_5$; $R'' = H$

EXPERIMENTAL

Instruments

A Beckman 5260 spectrophotometer (1-cm cells) was used for spectrophotometric measurements. A Beckman 4260 infrared spectrophotometer (KBr discs) and a Perkin-Elmer R-24B NMR spectrophotometer were used. A Radiometer PHM-64 pH-meter along with a G-202B Radiometer glass electrode, an Ag/AgCl reference electrode prepared according to Brown[17] and a Wilhelm-type salt bridge[18] were used to measure pH values.

Reagents

Reagents (I) and (II) were obtained by the method of Anthoni *et al.*[4] by addition of CS_2 to the corresponding hydrazines in alkaline medium. Reagent (**III**) was synthesized by a modification of the method of Henriksen and Jensen.[3] A solution of 0.04 mole of CS_2 in 5 ml of dimethyl sulphoxide was added dropwise during 1 hr, at room temperature, to a suspension of 0.04 mole of sodium hydride (with 20% paraffin) in 15 ml of dry dimethyl sulphoxide containing 0.04 mole of 1-methyl-1-phenylhydrazine. The resulting solution was added to a mixture of 300 ml of acetone and diethyl ether (2:3) and allowed to stand for 24 hr at 4°. The white crystals obtained were filtered off by suction, washed with diethyl ether and recrystallized from chloroform (yield 24–30%). Melting points: (I) 178–179°, (II)128–129° and (III) 121–123°. Elemental analysis: (I) $H_2NN(CH_3)$ CSSK.$2H_2O$ requires 12.2% C, 4.6% H, 14.3% N, 32.7% S, 19.9% K; found 12.1% C, 4.3% H, 14.6% N, 31.8% S, 19.7% K. (II) $(CH_3)_2NNHCSSK.2H_2O$ requires 17.1% C, 5.3% H, 13.3% N, 30.5% S, 18.6% K; found 17.6% C, 4.9% H, 13.4% N, 29.9% S, 18.7% K. (III) (CH_3) (C_6H_5) NNHCSSNa.$2H_2O$ requires 37.5% C, 5.1% H, 10.9% N, 25.0% S, 9.0% Na; found 37.7% C, 5.0% H, 10.6% N, 25.8% S, 8.8% Na.

Because of the low stability of the solid dithiocarbazates in air (3–14% decomposition per day) they must be stored under nitrogen at 4°. They are then stable for at least 1 yr. Their purity was tested by the method of Clarke *et al.*,[19] originally devised for the analysis of dithiocarbamates. The substance is decomposed in strongly acidic medium and the

CS_2 evolved is collected in methanolic potassium hydroxide solution. Iodine titration of the xanthate thus formed showed, in all cases, the purity of the dithiocarbazates to be higher than 99%.

Protonation constants

The protonation constants were determined at $25 \pm 0.1°$ and $I = 0.01M$ by using the spectrophotometric method of Stenström and Goldsmith,[20] which makes use of the relationship between absorbance and pH; 1 ml of the aqueous $10^{-3}M$ dithiocarbazate solution was diluted to 50 ml with $0.01M$ buffer prepared as described by Perrin and Dempsey.[21] The pH and the absorbance at 273 nm (I), 267 nm (II) and 285 nm (III) were measured.

The potentiometric determination involved titration of alkaline solutions of the test substances (1.3×10^{-3}–$3.5 \times 10^{-3}M$) with $0.100M$ nitric acid at $I = 1.00M$, with potassium nitrate as ionic medium, at $25 \pm 0.1°$. Before and during the titration, a stream of pure nitrogen was continuously bubbled through the solutions. The potential of the following cell was measured:

Glass electrode (−)	Test solution: xM reagent, yM KOH, $(1-x-y)M$ KNO_3	$1.00M$ KNO_3	$0.01M$ KCl, $0.99M$ KNO_3, $AgCl_{(s)}$	Ag(+)

Beforehand, $0.10M$ nitric acid was titrated with $0.10M$ potassium hydroxide in the same cell. The Gran method[22] was used to determine $E^{\circ\prime}$ and E_j which relate the measured potential E to the hydrogen-ion concentration $[H^+]$ by means of the equation:

$$E(\text{mV}) = E^{\circ\prime} - 59.157 \log[H^+] + E_j$$

A known amount of reagent was added to the alkaline solution, then the mixture was titrated with nitric acid.

Chelation studies

The pH range over which complexation occurred, as indicated by colour and colour formation, was determined for each combination of metal ion and test substance by the technique established by Benedetti-Pichler.[23] The solubilities of the complexes in benzene, diethyl ether, chloroform, isoamyl alcohol and methyl isobutyl ketone were tested and absorption data (λ_{max}, ϵ) for buffered solutions of complexes were measured.

The insoluble metal chelates were prepared by reacting aqueous solutions of the metal ions with aqueous solutions of the dithiocarbazates in 1:4 mole ratio. The precipitates were filtered off, washed with water, ethanol and acetone and dried under reduced pressure over calcium chloride.

RESULTS AND DISCUSSION

The solubility values and the most significant infrared and NMR spectrophotometric data for the ligands are given in Table 1. The IR absorption peaks are assigned in accordance with earlier works.[1,3,4,6–9] These bands confirm the structure of the dithiocarbazates; thus, the addition of CS_2 to methylhydrazine takes place through the substituted nitrogen atom, giving rise to the appearance of the $-NH_2$ bending peak (1580–1645 cm^{-1}) in the spectrum of (I). This band does not appear in the spectra of (II) and (III) since the CS_2 is added to the primary nitrogen atom of 1,1-dimethylhydrazine and 1-methyl-1-phenylhydrazine. The NMR spectra recorded for D_2O solutions of the reagents with DSS as internal reference, give peaks similar to those reported previously.[10,11] The large shift corresponding to the methyl group of (II) ($\delta = 2.55$ ppm) relative to (III) ($\delta = 3.66$ ppm) is consistent with the presence of the neighbouring $-CSS^-$ group in the 2-methyldithiocarbazate.

The ultraviolet spectra of the reagents in some common solvents were measured (Table 2). A bathochromic shift of λ_{max} is observed for (I) and (II) as the polarity of the solvent decreases. This can be attributed to n–π^* transitions. The spectrum of (III) is more complicated, with the presence of overlapping bands corresponding to π–π^* aromatic ring transitions.

The stability of the reagents in aqueous solutions is pH-dependent. In neutral or alkaline media, the absorbance at λ_{max} decreases by about 15% in 24 hr, the sequence of stability being (II) > (III) > (I). In fairly acidic medium (pH < 2.5) all decompose rapidly with evolution of CS_2. This breakdown hinders the experimental determination of the absorbance of the protonated species in acidic media, as is required for the calculation of the equilibrium constants by the Stenström and Goldsmith method. Therefore, the Sommer method[25] was used, since it allows graphical determination of the values by solution of the equation:

$$A_R - A = A_R - A_{HR} - \frac{(A_R - A)}{[H^+]\,K_1^H}$$

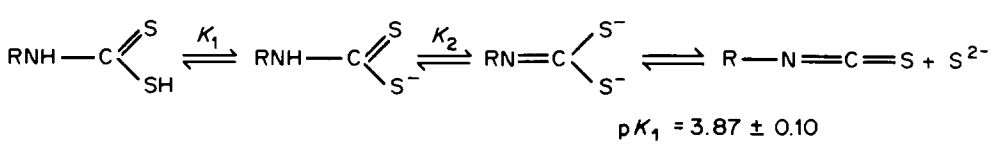
where A_R and A_{HR} are the absorbances of the fully deprotonated and protonated reagents respectively, and K_1^H is the protonation constant. The resulting data have been optimized by the graphical method described by Rossotti and Rossotti[26] and McBryde.[27]

The values of the protonation constants determined fully coincide with those obtained by means of the least-squares program MINISPEF[28] (PDP 11/60 computer). Table 3 lists the values of the protonation constants of (I) and (II). Log K_1^H for (III) could not be determined because of interference from the absorbance of the 1-methyl-1-phenylhydrazine released on decomposition of (III) in acid. However, this constant, along with those for (I) and (II), was determined potentiometrically. The $E^{\circ\prime}$ and E_j values found in the Gran titration allowed determination of the protonation constant by use of the Bjerrum function,[29] $\bar{n}$,

$$\bar{n} = \frac{H_T - [H^+] + K_w/[H^+]}{R_T} = \frac{K_1^H[H^+]}{1 + K_1^H[H^+]}$$

which can be calculated experimentally from the pH of the solution, the total concentration of titratable hydrogen ion H_T and the total reagent concentration R_T. The constants were determined by use of the least-squares program MINIPOT.[30] The protonation constants are given in Table 3. The discrepancy between the spectrophotometric and potentiometric values is attributed to the difference in ionic strength.

The results obtained in the present work are not in accord with the overall ionization mechanism proposed for the hydrazinium dithiocarbazate by Byr'ko *et al.*,[14] who suggested



$pK_1 = 3.87 \pm 0.10$

$pK_2 = 8.90 \pm 0.10$

The fact that, in the present study, both potentiometrically and spectrophotometrically only a single protonation constant was observed, along with the absence of ionizable cations such the hydrazinium ion, provides strong evidence for a single acid–base equilibrium. This equilibrium, in a similar way to that proposed by Hulanicki[31] for the dithiocarbamates, could be represented by

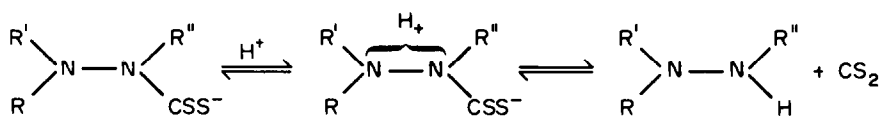


Table 3. Protonation constants of the reagents at 25 ± 0.1°C

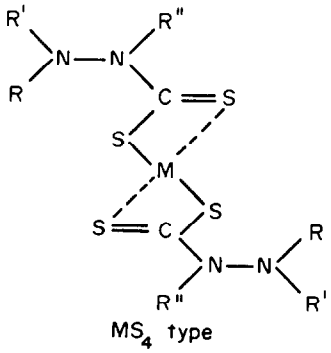
Reagent	Spectrophotometrically ($I = 0.01M$) log K_1^H	Potentiometrically ($I = 1.00M$) log K_1^H
(I)	4.90 ± 0.07	5.42 ± 0.05
(II)	4.56 ± 0.02	4.73 ± 0.02
(III)	—	6.18 ± 0.03

This mechanism is consistent with the reported zwitterion structure of dithiocarbazic acid[1,7] and the indirect titration of the dithiocarbazates with iodine, where the presence of the CS_2 evolved in strongly acidic medium is required. On the other hand, the differences between constants for the different compounds show the influence of the substituents bound to the protonated N–N skeleton (the protonation of the CSS^- group would give rise to very similar values of the protonation constants, as occurs with xanthates and carboxydithioates[32]).

Table 4 gives the spectral characteristics of the soluble metal–reagent complexes, which have high absorptivities. The pH does not greatly influence the complex formation; this confirms that it is the N–N group rather than the CSS^- group that is protonated.

All three substances react very similarly with metal ions, although it is interesting to note the closer resemblance between (II) and (III). This behaviour can be attributed to the difference in structure of the complexes (Table 5). Reagents (II) and (III) give MS_4 type complexes, as previously reported by Battistoni *et al.*[7] Chelation occurs through both sulphur atoms, according to the structure:



MS_4 type

The infrared spectra of the complexes studied show that the C–N stretching absorption (1525–1490 cm^{-1}) has been shifted to higher frequencies than for the

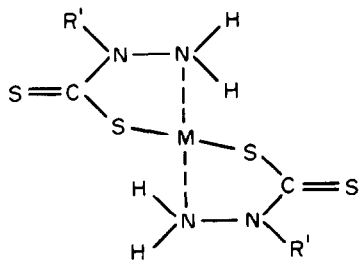
§Shoulders in brackets.

alkali-metal dithiocarbazates [1494 cm^{-1} (**II**) and 1498 cm^{-1} (**III**)] because of the important double bond C=N contribution in this type of chelate.[7,8] The antisymmetric and symmetric CSS^- stretching modes, absorbing at around 975 cm^{-1} and 685 cm^{-1} respectively, also confirm this kind of chelation as reported earlier for MS_4 chelates of nickel with 2-methyldithiocarbazate,[2,7] 3,3-dimethyldithiocarbazate[1,7] and 3-methyl-3-phenyldithiocarbazate.[7] In contrast reagent (**I**) forms MN_2S_2 type metal complexes, through the nitrogen and sulphur atoms:



MN_2S_2 type

The C–N stretching vibration, with a smaller double bond contribution, overlaps in this case with neighbouring lower-frequency bands such as C–H (around 1440 cm^{-1}).[8] The chelates formed with reagent (**I**) all display NH_2 bonding peaks at lower frequencies (1605–1583 cm^{-1}), supporting the postulate of MN_2S_2 co-ordination.[7,8] Finally, the presence of a shoulder in the absorption peak assigned to the asymmetric CSS^- mode also confirms[7,8] the chelation through only one nitrogen and one sulphur atom.

IONIC STRENGTH DEPENDENCE OF FORMATION CONSTANTS—V

PROTONATION CONSTANTS OF SOME NITROGEN-CONTAINING LIGANDS AT DIFFERENT TEMPERATURES AND IONIC STRENGTHS

(*Received* 9 *May* 1984. *Accepted* 17 *July* 1984)

Summary—The protonation constants of 2,2′-bipyridyl, 1,10-phenanthroline, 1,3-diaminopropane, L-histidine and histamine have been determined potentiometrically, in the temperature range 10–40° and at ionic strengths ranging from 0.04 to 1 (potassium chloride). The dependence of the protonation constants on ionic strength is described by a simple general equation. The enthalpy changes for the protonation of the ligands have been calculated from the temperature dependence of the protonation constants.

In a series of papers[1-3] on the ionic strength dependence of formation constants we reported some interesting features of the function $\log K = f(I)$. In particular, (*a*) all the formation constants seem to follow the same trend as a function of ionic strength, if allowance is made for the different types of reaction stoichiometry and for the different charges of reagents and products and (*b*) there is a term in the equation $\log K = f(I)$ that is independent of the charges and accounts for the variations of the protonation constants of species that form cationic acids on protonation.

In order to elucidate the latter point we decided to investigate systematically cationic acids formed by protonation. Here we report a potentiometric study of the protonation of 2,2′-bipyridyl, 1,10-phenanthroline, 1,3-diaminopropane, L-histidine and histamine, at three temperatures (10°, 25°, 40°) and five ionic strengths (0.04, 0.1, 0.3, 0.6 and 1.0; KCl).

EXPERIMENTAL

Apparatus and procedures

The measurements were performed by potentiometric measurement of hydrogen-ion concentration with a model E600 Metrohm potentiometer equipped with Metrohm glass and silver/silver chloride electrodes. The glass electrode was calibrated (in $-\log[H^+]$ units) in the acid and alkaline region by titrating nitric acid (3–8 m*M*) with standard 1.000*M* carbonate-free potassium hydroxide, at the same ionic strength (adjusted with potassium chloride) as the solution under examination. The E° and pK_w values were calculated as reported elsewhere.[4] The ionic strength was adjusted by adding potassium chloride. This ionic medium was employed since interaction between potassium ions and the ligands concerned can be considered negligible.[2] The temperature (T°C) was kept constant by circulation of liquid from a model D1-G Haake thermocryostat. The titrant was delivered from a microsyringe (5000 divisions/ml). For each ligand five titrations were performed; the ligand concentration ranged from 3 to 6 m*M*; for each protonation step fifteen experimental points were used in the calculation.

Chemicals

2,2′-Bipyridyl, 1,10-phenanthroline, 1,3-diaminopropane, L-histidine monohydrochloride, histamine dihydrochloride and potassium chloride, all Fluka purissimum products, were used without further purification. The purity of the ligands, checked by acid–base titrations, was always >99% and was taken into account in the calculations. Nitric acid and potassium hydroxide stock solutions were prepared by diluting concentrated solutions (Merck ampoules).

Calculations

The protonation constants, expressed as

$$K_j^H = [H_jL]/([H][H_{j-1}L])$$

were calculated separately for each ionic strength by the program MINIQUAD 76A, modified in order to take into account the variation of ionic strength during the titrations;[5] the parameters defining the dependence on ionic strength were obtained from these values.

RESULTS AND DISCUSSION

The protonation constants of the ligands under study are collected in Table 1. The dependence of these values on ionic strength can be described by the general equation[1-3]

$$\log K^H(I) = \log K^H(I') - Az^*\left(\frac{\sqrt{I}}{1+B\sqrt{I}} - \frac{\sqrt{I'}}{1+B\sqrt{I'}}\right) + C(I-I') + D(I^{3/2} - I'^{3/2}) \quad (1)$$

where

$$A = 0.5115 + 8.885 \times 10^{-4}\,(T-25) + 2.953 \times 10^{-6}\,(T-25)^2$$

$$B = 1.489 + 8.772 \times 10^{-4}\,(T-25) + 4.693 \times 10^{-6}\,(T-25)^2;$$

*The 95% confidence interval of the mean (C.I) is given in parentheses [*e.g.*, 4.52(3) = 4.52 ± 0.03], and was estimated by using the equation C.I. = $st/\sqrt{n}$, where s is the standard deviation of the mean value of log K_j^H (log K_j^H values were calculated separately for each titration), t is the Student-t value for $p = 0.95$, and n is the number of titration curves.

I and I' represent the actual and reference ionic strengths, respectively; $z^* = 2(1 - z - j)$ for the reaction $[H_{j-1}L]^{z+j-1} + H^+ = [H_jL]^{z+j}$ (z is the charge on L); C and D are parameters experimentally determined.

Considering that $A \simeq 0.5$ and $B \simeq 1.5$, equation (1) can be simplified, since small errors in A and B are absorbed in the linear term:[6]

$$\log K^H(I) = \log K^H(I') - z^*\left(\frac{\sqrt{I}}{2+3\sqrt{I}} - \frac{\sqrt{I'}}{2+3\sqrt{I'}}\right) + C(I - I') + D(I^{3/2} - I'^{3/2}) \quad (2)$$

The experimental values of C and D [equation (2)] are in general[1-3] a simple function of z^*:

$$C = c_0 + c_1 z^*, \quad D = dz^* \quad (3)$$

If $z^* = 0$ (for reactions involving uncharged ligands, such as $L + H^+ = [HL]^+$ or $[HL] + H^+ = [H_2L]^+$), substituting the values of C and D from equation (3) into equation (2) yields

$$\log K^H(I) = \log K^H(I') + c_0(I - I') \quad (4)$$

Over the temperature range used, for all the ligands considered the coefficient c_0 can be expressed as a function of temperature by

Table 2. Thermodynamic parameters for the protonation of the ligands under study, calculated for 25°C and $I = 0.25$; the 95% confidence interval is indicated by the figure in parentheses [*e.g.*, 6.10(3) = 6.10 ± 0.03]

Ligand	j	log K_j^H	$-\Delta G$, kcal/mole	$-\Delta H$, kcal/mole	ΔS, cal.mole^{-1}.deg^{-1}
2,2'-Bipyridyl	1	4.47(2)	6.10(3)	3.8(2)	8(1)
1,10-Phenanthroline	1	5.00(2)	6.82(3)	4.3(3)	9(2)
1,3-Diaminopropane	1	10.67(3)	14.55(4)	14.8(4)	−1(2)
	2	8.88(2)	12.11(3)	13.0(5)	−3(2)
L-Histidine	1	9.07(2)	12.37(3)	11.1(2)	4(1)
	2	6.07(1)	8.28(2)	7.2(2)	4(1)
Histamine	1	9.85(2)	13.44(3)	13.6(3)	−1(2)
	2	6.15(2)	8.39(3)	8.2(3)	1(2)

$$c_0 = 0.23 - 0.0013\ (T - 25) \qquad (5)$$

With the c_0 value calculated from equation (5), analysis of the data in Table 1 for reactions with $z^* \neq 0$ leads to the following values for c_1 and d [see equation (3)]:

T, °C	c_1	d
10	0.26	-0.18_5
25	0.23	-0.16_5
40	0.19	-0.13

(6)

If $\log K^{H}_{calcd}$ is the protonation constant ($z^* = 0$) calculated from equations (4) and (5), the mean deviation $\varepsilon = \log K^{H}_{exp} - \log K^{H}_{calcd}$ is:

$$\varepsilon = 0.05\,|\,I - 0.25\,| \qquad (7)$$

For the other protonation constants ($z^* \neq 0$) the mean deviation and the values of parameters c_1 and d, which define the dependence on ionic strength, are in agreement with our previous findings,[1] if allowance is made for the higher c_0 values found here.

The thermodynamic parameters ΔH and ΔS are collected in Table 2. These values can be considered to be in agreement with the literature values,[7] especially if it is taken into account that the protonation constants were determined at only three different temperatures.

CALCULATION OF THE Cu(II)–THIOSEMICARBAZONE COMPLEX FORMATION CONSTANTS BY A MODIFICATION OF THE DEFORD AND HUME METHOD APPLICABLE TO QUASI-REVERSIBLE AND IRREVERSIBLE PROCESSES

MANUEL ARGÜESO, M. DOLORES LUQUE DE CASTRO
and MIGUEL VALCÁRCEL
Department of Analytical Chemistry, Faculty of Sciences, University of Córdoba, Córdoba, Spain

(*Received* 27 *March* 1984. *Accepted* 16 *July* 1984)

Summary—Six cupric thiosemicarbazonates have been studied by differential pulse polarography and their formation constants calculated by the DeFord and Hume method and by a modification of this method applicable to quasi-reversible and irreversible processes. Comparison of the values found by both procedures shows the validity of the suggested modification.

Of the polarographic methods for calculation of complex formation constants, the one by DeFord and Hume[1] is undoubtedly the most widely used. In an earlier paper[2] we used this method, not in its original form but as the modification suggested by Heath and Hefter for differential pulse polarography (dpp)[3] with all its implicit approximations. An additional modification suggested by us involved taking into account not the theoretical number of electrons transferred but the product of the number of electrons and the transfer coefficient; the product was taken into account for each particular experiment and calculated in addition to I_p (peak intensity) and E_p (peak potential) by a computer program [F0(I)] based on applying a weighted least-squares method to the equation of the Tomes lines for a.c. polarography and dpp.[4] In the same paper[2] three computer programs for the calculation of the formation constants of chelates were suggested, and their applicability demonstrated for the cadmium–chloride,[3] cadmium–thiocyanate[5] and zinc–pyridine[4] systems. The suggested modification and programs have more recently been applied to the Bi(III)–azomethine 2-benzoylpyridine derivative systems,[6] which give irreversible reduction processes.

We now apply the modification and two of the programs to six Cu(II)–thiosemicarbazone systems.

EXPERIMENTAL

Apparatus

A Metrohm E-505 polarograph and E-506 recording system, with Ag/AgCl electrodes as reference and auxiliary electrodes, in conjunction with conventional dropping mercury and hanging drop electrodes. A Beckman 3500 pH-meter with combined calomel–glass electrode. An HP-85 microcomputer (32 kbyte).

Reagents

Acetone solutions ($5 \times 10^{-3} M$) of the thiosemicarbazones of the following carbonyl compounds: benzaldehyde (BAT), picolinaldehyde (PAT), 6-methylpicolinaldehyde (6-Me-PAT), biacetyl monoxime (BAMT), salicylaldehyde (SAT) and *p*-hydroxybenzaldehyde (pHBT). Aqueous solutions ($1.0 M$) of sodium perchlorate, potassium chlorate and potassium chloride, and $0.1 M$ tetramethylammonium bromide. Britton and Robinson buffers (pH 1–12). Gelatine solution (1%). Aqueous standardized copper(II) solution ($0.167 M$). More dilute solutions were prepared as required. All solvents were of analytical grade.

RESULTS AND DISCUSSION

The behaviour of the six systems is simultaneously discussed. Unless otherwise specified, the working conditions were as follows: initial potential, −0.2 V; scan-rate, 5 mV/sec; drop-time, 0.6 sec; pulse-amplitude, 50 mV; rate of mercury flow, 0.8083 mg/sec; height of the mercury head, 60 cm; temperature, 25°; [Cu(II)], $2 \times 10^{-4} M$; [ligand], $1.5 \times 10^{-3} M$.

The effect of type of supporting electrolyte was examined with sodium perchlorate, potassium chlorate, potassium chloride and tetramethylammonium bromide solutions. The concentration of organic solvent (acetone in all cases[7–9]) was below 4% for all the systems, since higher concentrations make the reduction processes more irreversible. Study of the effects of pH, temperature, drop-time and pulse amplitude showed that the processes were diffusion-controlled; the optimal values of these variables are summarized in Table 1.

The ligand concentration was changed between 50 and 100 times the cupric ion concentration for each thiosemicarbazone. The application of the F0(I) program allowed calculation of the $n\alpha$, I_p and E_p data

Table 1. Optimal values of variables

Ligand	Supporting electrolyte	pH
BAT	$NaClO_4$	11.0
PAT	KCl	9.7
6MePAT	KCl	10.6
BAMT	$NaClO_4$	11.5
SAT	KCl	11.5
pHBT	KCl	11.7

Temperature 25°, pulse amplitude 50 mV, drop-line 0.6 sec (except for 6 MePAT, for which it was 0.8 sec).

from each polarogram. The formation constants for each Cu(II)–thiosemicarbazone system were calculated by programs GIP II and FOW,[2] taking into account the theoretical number of electrons exchanged in the process ($n = 2$), that is, the Heath and Hefter modification,[3] (Table 2) and also taking into account[2] the product $n\alpha$ (Table 3).

The values of the formation constants obtained by our modification (Table 3) are all smaller than those found by the Heath and Hefter method because α was always < 1. The divergence between the values found by the two methods is a measurement of the irreversibility of the process.

The values of the formation constants for all the systems were very similar, except for the Cu(II)–PAT system. The great divergence in β values as well as in the number of formation constants obtained by both methods for the Cu–SAT and Cu–pHBT systems may be attributed to the marked degree of adsorption of the hydroxylic ligands on the electrode surface,[10] which dramatically disturbs their electrode behaviour.

In the Cu(II)–SAT system the occurrence of a ligand reduction which overlaps that of the complexed Cu(II) prevents the peak-width measurements necessary for calculating the $n\alpha$ values.

Once again the suitability of this modification for quasi and irreversible processes is emphasized.

Summary—The system of orthophosphate, magnesium and hydrogen ions in aqueous solution at 25° and $I = 0.2M$ chloride has been characterized by means of glass-electrode potentiometry. Protonation constants for orthophosphate species and formation constants for the complexes $MgH_2PO_4^+$, $MgHPO_4$, $MgPO_4^-$ and $MgOH^+$ are reported.

We are currently developing a metal speciation model for urine along similar lines to our blood plasma model[1] and for this we require formation and protonation constants applicable to an ionic strength of $0.2M$ and a temperature of 37° for all the metal–ligand–proton complexes that can potentially be formed. The latter include complexes between magnesium, orthophosphate and hydrogen ions but the literature data[2–10] for this system cover ionic strengths sufficiently far removed from our requirements for us to be concerned about the reliability of applying theoretical corrections to the relevant constants. Furthermore, there is a variation in the range of magnesium complexes postulated, some authors[5–10] giving $MgHPO_4$ as the only one whereas others[3,4] include $MgPO_4^-$ and/or $MgH_2PO_4^+$. For these reasons, we decided to investigate the magnesium–phosphate–proton system further, at an ionic strength of $0.2M$ but at a temperature of 25°. This temperature was chosen in preference to 37° to avoid condensation problems inside the titration assembly and because it was considered that correction over as small a temperature range as 12° by using the van't Hoff equation and assuming constant enthalpies of reaction would not introduce errors of unacceptable magnitude for our urine model.

EXPERIMENTAL

Sodium hydroxide solutions ($0.1M$) were freshly prepared at frequent intervals, by dilution of the contents of Merck ampoules, under nitrogen, and standardized against potassium hydrogen phthalate (Merck). The $0.1M$ hydrochloric acid used was also prepared by use of Merck ampoules, and standardized with the sodium hydroxide solutions. Orthophosphoric acid solutions (0.01–$0.1M$) were prepared from the Merck concentrated acid and standardized with the sodium hydroxide solutions. Magnesium chloride solutions ($0.04M$) were prepared by dissolving high-purity magnesium ribbon (BDH) in hydrochloric acid after initial cleaning with the acid, washing with glass-distilled water and drying in a vacuum oven at 40°. The acid content of the magnesium chloride solutions was determined by titration with standardized sodium hydroxide. Sodium chloride solutions ($0.200M$) were prepared from Merck ampoules. All the solutions mentioned were prepared with boiled-out glass-distilled water. The sodium hydroxide, hydrochloric acid and orthophosphoric acid solutions were prepared with a total chloride concentration of $0.200M$, by addition of sodium chloride from Merck ampoules.

Equilibrium constants for the protonation of orthophosphate and the complexation of orthophosphate by magnesium were determined by potentiometric titrations in a Metrohm EA876-20 titration vessel maintained at 25°. The electrodes were Metrohm EA109 glass electrodes, and Metrohm EA404 calomel electrodes containing $5M$ sodium chloride as electrolyte. During the titrations, a purified nitrogen atmosphere was maintained in the titration vessel.

In the determination of the protonation constants, solutions containing orthophosphoric acid and sodium chloride were titrated with sodium hydroxide/chloride solution added from a Metrohm Dosimat E635 piston-burette controlled by a Metrohm Titroprocessor E636, which also measured and recorded the emf of the cell. The data obtained were used to calibrate the electrodes and determine the protonation constants simultaneously.

Three types of titration procedure were followed to investigate the complexation equilibria. Solutions containing orthophosphoric acid, magnesium chloride and sodium chloride were titrated with sodium hydroxide/chloride solution or a solution containing sodium hydroxide, orthophosphate and chloride. In the latter type of titration, the solutions were prepared in such a way that the orthophosphate concentration in the titration solution remained constant. In the third type of titration, the magnesium concentration was maintained at a constant level by titrating with solutions containing hydrochloric acid, magnesium chloride and sodium chloride. Concentration adjustments could be made before or during each titration by adding sodium chloride solution from a calibrated Metrohm E274-50 piston-burette.

The orthophosphate protonation constants and the electrode calibration parameters were determined by applying the MAGEC[11] and MINIQUAD[12] programs alternately to the relevant titration data, following the procedure described in reference 11. The complexation-titration data were processed initially by ZPLOT[13] in order to obtain formation curves and subsequently by MINIQUAD in order to obtain best-fitting chemical models and refined formation constants. The validity of the finally chosen chemical model and "best" formation constants was checked by supplying the latter as input to PSEUDOPLOT,[14] which generated theoretical formation curves. The degree of matching between the experimental and

theoretical formation curves gave a sound measure of the validity or accuracy of the chemical model.

As a further check, attempts were made to determine the formation constants by processing the constant-ligand and constant-metal titration data according to the method of Österberg,[15,16] but the conditions were found to be unsuitable

RESULTS AND DISCUSSION

Two protonation titrations were done with an initial orthophosphoric acid concentration of about 0.01*M* and two with an initial concentration of about 0.1*M*. Converging values were obtained for the electrode parameters and the protonation constants over a pH range of about 2–12. Satisfactory statistical fits between the parameters and the data were indicated by reasonable values obtained for the MAGEC objective function (0.016 cm^6), the MINIQUAD *R*-factor (0.0007) and χ^2 (23.7). Values found for the protonation constants, together with corresponding literature data, are presented in Table 1. Allowing for the variation in background medium and temperature, the agreement between our protonation constants and the literature data is acceptable. The value we find for the ionic product of water also appears to be acceptable.

Ten complexation titrations were done with initial conditions covering wide ranges of component concentration, namely 0.003–0.022*M* for orthophosphate and 0.002–0.008*M* for magnesium. Ligand to metal ratios ranged from 0.5:1 to 10:1. The pH ranged from 3 to 10. When MINIQUAD was applied in order to obtain consistent chemical models to explain the entire set of titrations, the data were divided into two groups, namely those for pH > 8 and for pH < 8. The first group was used to refine the constants for the species $MgPO_4^-$ and $MgOH^+$, and the second for $MgHPO_4$ and $MgH_2PO_4^+$. The equilibrium constants obtained, together with standard

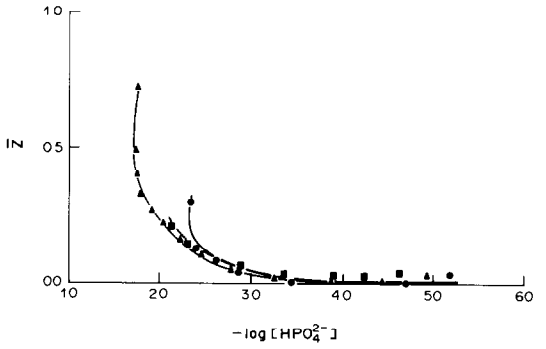

Fig. 1. PSEUDOPLOT curve calculated from the orthophosphate–proton and orthophosphate–magnesium formation constants in Table 1, plotted on a selection of the experimental formation values. Initial concentrations (m*M*) of orthophosphate and magnesium respectively were: 22.5 and 7.6 (▲); 11.3 and 2.1 (■); and 6.4 and 3.0 (●). ▲ = constant [orthophosphate] titration; ■ = constant [magnesium] titration.

deviations, the MINIQUAD *R*-factors, χ^2 values and corresponding literature data, are presented in Table 1. The *R* and χ^2 values indicate satisfactory fits of the data to the chemical model proposed and the corresponding formation constants. In Fig. 1, the individual points represent a selection of the formation function values (obtained from ZPLOT) plotted against the negative logarithm of the free HPO_4^{2-} concentration. Superimposed are theoretical formation curves generated by PSEUDOPLOT from the refined constants listed in Table 1. The good match between the curves and the points confirms the validity of the chemical model and the constants in Table 1. Figure 2 shows the species distribution for the magnesium–orthophosphate–proton system, computed from the constants in Table 1, for total concentrations of orthophosphate and magnesium both equal to 0.01*M*.

Table 1. Logarithms of formation constants (*K*) for proton and magnesium complexes of orthophosphate at 25° and $I = 0.2M$ [Cl^-]

Reaction	log *K*	*d*	*n*	*R*	χ^2	Literature data: log *K* (temp., *I*, [medium])[ref]

$Mg^{2+} + H_2PO_4^- \rightleftharpoons MgH_2PO_4^+$	1.51	0.05	387	0.0012	392	0.60 (37°, 0.15 [KNO_3]),[4] 0.16 (25°, 3 [$NaClO_4$]).[3]
$Mg^{2+} + OH^- \rightleftharpoons MgOH^+$	3.07	0.04	47	0.0004	19	2.58 (25°, 0).[18]

H^+ represents the sum of all forms of hydrated protons; *d* = standard deviation of log *K*; *n* = number of observations; *R* = Hamilton *R*-factor, from MINIQUAD output; χ^2 indicates deviation (from normal distribution) of residuals in total concentrations from MINIQUAD output.

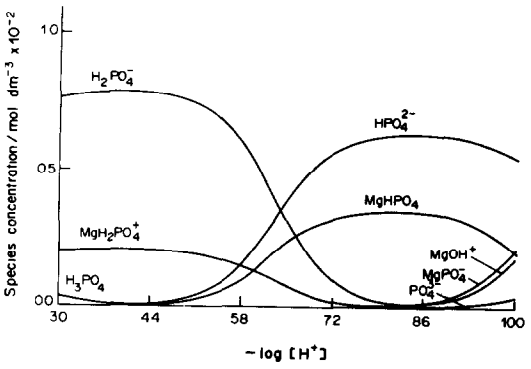

Fig. 2. Concentrations of the complexes present, as a function of $-\log[H^+]$ for the orthophosphate–magnesium–proton system when the total concentrations of orthophosphate and magnesium are both 10 m*M*.

The agreement between our constants for the magnesium complexes and the corresponding literature values is generally satisfactory, taking into consideration the differences in temperature and ionic background medium. The most commonly reported constant in the literature is for the species $MgHPO_4$.[5–10] Several of the authors concerned give this as the only magnesium complex, possibly because of the limited pH-range examined by these authors, and also because of the predominance of $MgHPO_4$, as illustrated in Fig. 2. In contrast, the reliability of our proposed model and constants is given weight by the good match, shown in Fig. 1, between the theoretical formation curves and the formation function points, even though the system is only weakly complexing and hence difficult to characterize quantitatively.

Attempts made to apply the method of Österberg[15,16] to the titrations with constant ligand but varying metal concentration and with constant metal but varying ligand concentration were not fruitful. This evidently stems from our inability to achieve, experimentally, the appropriate ranges of conditions required for application of the Österberg method.

CHARACTERISTICS OF INDUSTRIAL DI(ALKYLPHENYL)DITHIOPHOSPHORIC ACIDS

Zs. WITTMANN, Z. DÉCSY and E. PUDMER
Hungarian Oil and Gas Research Institute, József Attila u. 34, H-8200 Veszprém, Hungary

(*Received* 26 *March* 1984. *Accepted* 30 *June* 1984)

Summary—Instrumental and classical methods have been used to characterize some industrial di(alkylphenyl)dithiophosphoric acids. The ^{31}P-NMR chemical shifts of di(nonylphenyl)dithiophosphoric acid and its derivatives are summarized.

Various dialkyldithiophosphoric acids and their derivatives have been investigated by several authors, and the NMR (^{31}P and ^{1}H), and infrared spectral data, pK values, methods of separation, *etc.*, have been given in the literature. Almost all the acids examined were dialkyldithiophosphoric acids with at most four carbon atoms in the alkyl chains. There are only a few data for di(alkylphenyl)dithiophosphoric acids.

In this paper, the identification and determination of the compounds formed during the production of industrial di(nonylphenyl)dithiophosphoric acid are described. All industrial di(nonylphenyl) dithiophosphoric acids contain similar compounds as impurities, sometimes only in traces. Products from a pilot plant were monitored to find several especially irregular samples containing various components in sufficient quantity for study.

EXPERIMENTAL

Mass spectrometry of di(nonylphenyl)dithiophosphoric acid samples

A high-resolution double-focusing mass spectrometer with Herzog–Mattauch geometry and equipped with a direct sample-inlet system was used at an ionization potential of 15 eV. The mass spectra of the various di(nonylphenyl)dithiophosphoric acids examined show the presence of several compounds characterized by molecular ions. Table 1 gives the data for the compounds identified.

Three main groups of compounds can be identified: alkylphenols, and various acids and neutral molecules containing phosphorus.

To find suitable analytical methods for determining the different groups of compounds, infrared and NMR (^{31}P and ^{1}H) spectrometry, potentiometric titration and classical methods were tried.

Infrared spectrometry

Infrared spectrometry is often used to examine dialkyldithiophosphoric acids, their derivatives and their metal salts. Nyquist,[1] Zimina,[2] and Mark and Van Wazer[3] have established the characteristic bands for the pure compounds.

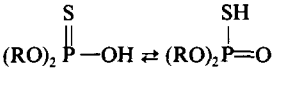
The same groups in the different kinds of di(alkylphenyl)dithiophosphoric acids and their derivatives give similar infrared spectra. Therefore infrared spectrometry is not suitable for differentiating the individual compounds present in industrial di(nonylphenyl)dithiophosphoric acid samples. However, any alkylphenols present can be determined by infrared spectrometry, by means of the intensity of the ν_{O-H} band at 3620 cm^{-1} in carbon tetrachloride solution. Table 3 (see later) shows the alkylphenol content of some of the acids examined.

^{1}H-NMR spectrometry

The diazomethane derivatives of the acid compounds in industrial di(nonylphenyl)dithiophosphoric acid samples give characteristic NMR signals for S–CH_3 and O–CH_3, but as Kabachnik *et al.*[4] have pointed out, the products from dithiophosphoric acids are mixtures of isomers, and the thione–thiol equilibrium of the derivative is different from that for the parent acid. Hence use of ^{1}H-NMR spectrometry with these derivatives is not suitable for examining the composition of di(nonylphenyl)dithiophosphoric acid samples.

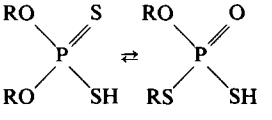
Potentiometric titration

Dialkylthiophosphoric acids exhibit a tautomeric equilibrium[5–7] as follows:



thione thiol

Kabachnik and co-workers[4,8] used potentiometric titration to study the tautomeric equilibrium of dialkyldithiophosphoric acids. Brazier and Elliott[9] titrated di(4-methylpentyl-2)dithiophosphoric acid. The titration curve showed two distinct inflections which could be attributed to the thione–thiol tautomerism



Di(nonylphenyl)dithiophosphoric acid samples were titrated in methanol with methanolic potassium hydroxide solution in our laboratory, and also gave two distinct inflections, from which the amount of the acids can be calculated (Table 3).

Kabachnik and co-workers[4,5] established that the tautomeric equilibrium of dialkyldithiophosphoric acids depends on the solvent used. In water the thiol form is dominant, and the thione in ethanol.

We have found that different industrial di(nonylphenyl)-dithiophosphoric acid samples of similar composition show

*For convenience of identification, the suffix a denotes the sodium salt of the correspondingly numbered acid.

different tautomeric equilibria under the same conditions. This seems to show that the tautomerism can be affected by the preparation conditions.

Iodometric titration

Bode and Arnswald[10] determined the concentration of diethyldithiophosphoric acid by iodometric titration. This method is convenient for determining the acids containing a thiol group (Table 3).

Extraction method for determination of neutral molecules

The sample (about 1 g) was dissolved in 30 ml of petroleum ether (b.p. 40–70°). An equivalent amount of 2*M* sodium hydroxide in methanol was added and the sodium salt was extracted with 30 ml of water (methanol prevents foaming of the aqueous phase). The petroleum ether phase was washed three times with water and the ether was distilled off. The residue contained the neutral molecules. The purity of the ether phase and the absence of neutral molecules in the aqueous phase were checked by mass spectrometry. Table 3 shows the neutral-molecule content of some of the samples examined.

Dyrssen[11,12] established that the dimerization of di-n-butyl phosphate depends on the solvent used. In hydroxyl-containing solvents the dimerization is almost negligible. Potentiometric titration in methanol and extraction of the neutral molecules into petroleum ether does not result in dimerization of the acids (Table 3).

^{31}P-NMR spectrometry

The ^{31}P-NMR results are interesting and suitable for identifying several components of the di(nonylphenyl)-dithiophosphoric acids samples examined. The ^{31}P-NMR spectra were recorded at 8000 Hz on a commercial NMR spectrometer operating in the pulse–Fourier transform mode. The samples were diluted with deuterochloroform. All ^{31}P-NMR chemical shifts were referred to Merck reagent-grade 85% orthophosphoric acid as internal standard.

Figure 1 shows the ^{31}P-NMR spectra of one of the di(nonylphenyl)dithiophosphoric acid samples examined. Identification of the chemical shifts of the compounds was facilitated by separating the components of the acid sample by gel-permeation chromatography and using some general considerations.

Harris *et al.*[13] confirm that the magnitudes of the chemical shifts for $(RO)_2P(O)O^- \rightarrow (RO)_2P(O)S^-$ and $(RO)_2P(S)O^- \rightarrow (RO)_2P(S)S^-$ are similar for compounds containing these groups.

Most of the chemical shift data available refer only to diethyldithiophosphoric acid and its derivatives. These data were compared with the data for the compounds examined here. Table 2 shows the chemical shifts for diethyl-dithiophosphoric acid and di(nonylphenyl)dithiophosphoric acid and their derivatives. The data given without a literature reference were determined in our laboratory. As can be seen, structures that are similar but have different hydrocarbon moieties have chemical shifts of similar magnitude in their ^{31}P-NMR spectra.

The chemical shifts of the sodium salts of the acids and their derivatives were selected on the basis of the results of the chemical shifts measured on the aqueous phase containing the neutral molecules extracted as described above. The neutral molecules were identified by mass spectrometry. There are no chemical shift data in the literature for structure $(C_9H_{19}-C_6H_4-O)_2P(O)SP(O)(C_9H_{19}-C_6H_4-O)_2$ (VIII). The mass spectra showed a large amount of a compound with the same empirical formula as VIII in the extracted phase of some acid samples. The ^{31}P-NMR spectra contained only one unidentified peak of high intensity, which could therefore be assigned to this structure.

Gel-permeation chromatography (GPC)

The alkylphenols, acids and neutral molecules in industrial di(nonylphenyl)dithiophosphoric acids can be determined by GPC. The functional groups of the acids are destroyed on the surface of the gel, so GPC is not directly usable, but the methyl derivatives obtained by reaction with diazomethane are suitable for separation. Although the derivatives are mixtures of isomers,[4] the molecular weights of the isomers are unchanged.

All separations were done on a 20-cm column (14 mm diameter) of 25–100 μm Sephadex LH-20. Dichloromethane–methanol mixture (9:1 v/v) was used as eluent at a flow-rate of 1.0 ml/min and a temperature of 25.0 ± 0.2°. A 3-mg sample reacted with diazomethane in dichloromethane was loaded on the column. The absorbance of the eluate was measured at 278 nm.

The neutral molecules were eluted first, followed by diazomethane derivatives of the acids and finally the diazomethane derivatives of the alkylphenols.

The elution volume is approximately a linear function of the logarithm of the molecular weight. Figure 2 shows the elution curve from an acid sample.

CONCLUSIONS

Table 3 shows the amounts of the components of some di(nonylphenyl)dithiophosphoric acid samples, found by different methods. The most information was given by ^{31}P-NMR spectrometry for the compounds containing phosphorus.

The phenols were determined by infrared spectrometry. The acid content of the samples was titrated potentiometrically and also measured on the basis of the peak intensities of the ^{31}P-NMR spectra.

Acids with an SH group were titrated iodometrically after formation of the sodium salts, and also determined directly from the ^{31}P-NMR spectra. These results are not in agreement, however, because the tautomeric equilibrium in alkaline solution is different from the equilibrium in the original acid sample. However, the amounts determined by ^{31}P-NMR spectrometry of the sodium salts show good agreement with the results of the iodometric titration.

The amounts of the neutral molecules determined by the extraction method are in agreement with the total amount of these molecules calculated from the ^{31}P-NMR spectra.

The total amounts of the groups of compounds in

industrial di(nonylphenyl)dithiophosphoric acids were determined by GPC; Table 3 shows the results.

Different industrial di(nonylphenyl)dithiophosphoric acid samples contain the detected components in different quantity. The methods described here are convenient for determining the components of any industrial di(nonylphenyl)dithiophosphoric acid sample.

The reproducibility of the analytical methods was tested by making 10 determinations of the components of an industrial di(nonylphenyl)dithiophosphoric acid; Table 4 shows the results.

ANNOTATION

OCCURRENCE OF CONSISTENT n*M* LEVELS OF PHOSPHATE IN DOUBLY DEMINERALIZED AND DEMINERALIZED-DISTILLED WATER*

VINCENT P. GUTSCHICK
Environmental Science Group, LS-6, Los Alamos National Laboratory, Los Alamos, NM 87545, U.S.A.

(*Received* 12 *May* 1984. *Accepted* 17 *July* 1984)

Summary—A double demineralization system and a demineralization-distillation system operated over several months consistently delivered water that was approximately 30 n*M* in phosphate, as determined by a molybdenum blue spectrophotometric method. Silicate and hydrolysed polyphosphate in the water, and contaminants in the analytical reagents, were eliminated as sources of error in the determination. Caution is suggested in preparing blanks and dilutions in analyses of samples of natural waters or plant nutrient solutions, when either of these types of purification system is used.

Recent studies of plant nutrition[1,2] and of dissolved nutrients in both fresh water[3] and sea-water[4] have established that the most frequently occurring and important range of phosphate concentration is below 1 μM (P < 31 μg/l.), and often below 0.1 μM. Various extractive spectrophotometric analytical methods[5,6] are in use for these water samples, as are double demineralization and demineralization–distillation systems to provide water for blanks, standards, and sample dilutions.

In the course of a current Los Alamos study of plant nutritional stress, it was found that phosphate blanks of either type of purified water routinely lay in the region of 50n*M* (P $\simeq$ 1.5 μg/l.). Such high blank values complicated the nutrient-level control and the uptake analyses in the plant nutrition experiment, which extended over several months. Contamination by trace phosphate in the analytical reagents was ruled out as the source of the error, when samples of plant nutrient solution inadvertently contaminated by a modest algal growth showed results equivalent to only 5n*M* phosphate. Several other possible sources for the high phosphate content of the other samples were eliminated, including desorption of phosphate from analytical equipment or storage containers, and photometric interference by silicate incompletely removed by the water purification systems. Phosphate appears to pass through the water purifiers in fairly consistent and significant traces, in monomeric form.

EXPERIMENTAL

Water purification

The double demineralization system consisted of a single Calgon mixed-bed resin in a 9-in. (23-cm) diameter steel vessel, followed by a Vaponics four-cartridge purifier (organic removal cartridge, two mixed-bed demineralizers, and a particulate filter). The specific resistance of the outflow from the Calgon resin and of the final outflow attained the theoretically limiting value of 18 MΩ (automatically corrected to 20°), within the resolution of the monitor. The demineralization–distillation system consisted of a similar Calgon mixed-bed resin, followed by a low flow-rate mixed-bed resin (Ion X Changer Research) and a Corning AG-3 all-glass still. The systems are thus typical of high-quality reagent-grade water supply systems.

Analytical methods

For sub-μM concentrations, a modification of the molybdenum blue method of Gibson *et al.*[5] (to be discussed in a future publication) was used. To a 1-litre sample were added 30 ml of concentrated hydrochloric acid, then 20 ml of molybdate reagent [50 g of $(NH_4)_6Mo7O_{24}\cdot 4H_2O$ per litre in 3.4 *N* hydrochloric acid], 2 ml of 1% potassium antimonyl tartrate solution, and 5 ml of 10% ascorbic acid solution, in that order. The solution was extracted successively with 30, 20 and 20 ml of methyl isobutyl ketone, with shaking for 10 min each time. The volumes of extract and the absorbances at 882 nm in a 1-cm cell were recorded and the sum of the three absorbance–volume (AV) products was calculated.

For higher concentrations of phosphate and silicate, as used during tests of silicate cross-reactivity, a scaled-down version of the method was used, with a 50-ml sample and a single extraction with 10 ml of the ketone.

All reagents were ACS analytical reagent grade, or better.

Samples

Samples of the water purifier outputs were taken directly in the analytical glassware used or stored for up to several weeks in bottles of either high- or low-density polyethylene. The bottles had been washed with phosphate-free detergent and hydrochloric acid and then rinsed seven or more times with the purified water. The plant nutrient solution samples were also taken in polyethylene bottles and then kept refrigerated for up to several months; most were acidified to pH 2 with sulphuric acid within 1 hr of collection in order to prevent loss of nitrate, which was also determined in the plant nutritional studies.

Calibration graphs for the analysis were constructed by sequential dilution of a weighed potassium dihydrogen

*Work performed under the auspices of the U.S. Department of Energy.

phosphate standard. The graphs were linear from 1μM down to 0.1μM phosphate or lower, with a standard deviation equivalent to 5nM.

RESULTS AND DISCUSSION

Fifteen blank samples from the two water purifiers obtained over a four-month period gave analytical readings in the range $\Sigma A_i V_i = 0.64$–1.69 ml, corresponding to phosphate concentrations of 47–125nM if it is assumed that the true blank value is zero. One other blank gave a reading corresponding to 15nM. The higher blank readings were attributed to residual phosphate on the molybdate reagent dispenser bottle; after a second filling of the bottle, no blank corresponded to a concentration above 75nM.

Three non-acidified but refrigerated samples of plant nutrient solution that showed algal contamination gave readings of $\Sigma A_i V_i = 0.07$–0.09 ml, corresponding to phosphate concentrations of 5–7nM. All properly preserved nutrient solution samples corresponded to 67nM concentration or above, with a single exception of 33nM.

It is known that properly adapted plants and algae can deplete phosphate down to a "compensation concentration" at least as low as 10nM.[1] This was taken to indicate that the algal-contaminated samples were close to a true blank, with the finite spectrophotometric reading attributable primarily to reagent contamination, and that measurable phosphate (or silicate) existed in both types of purified water. Phosphate contamination of the analytical glassware was eliminated as a possibility because the algal-contaminated low-reading samples were analysed in the same glassware. Similarly, phosphate contamination of the sample storage bottle was eliminated; also, direct delivery of purified water into the analytical apparatus gave very similar results to those from use of bottle-stored water for blanks.

Interference of silicate contaminants in the samples in the molybdenum blue analysis was a possible source of the blank reading, because at least one of the water purification systems used a glass holding tank, and because the Los Alamos County water input to the purifiers contains the equivalent of approximately 80 μg/ml SiO_2.[7] The performance of the Calgon demineralizers may reduce this to perhaps 20 ng/ml SiO_2 (300 nM). Extraction with ketones that are selective for phosphomolybdate relative to silicomolybdate[8] might decrease the spectrophotometric signal from this amount of silicate to that of the observed blank readings. In any case, polymeric silica, the form dominant in all the blanks and samples, is a much less significant interference than is monomeric silica. Indeed, both tap water and silica standards up to 30μM in concentration reacted negligibly. Even a 1-hr hydrolytic pretreatment with ammonia at pH 12 gave spectrophotometric results equivalent to a phosphate concentration only 2% of that of the silicate concentration. Furthermore, use of 1-butanol as extractant in order to favour extraction of silicomolybdate[8] gave results not significantly different from those obtained with methyl isobutyl ketone. Thus, the silica content of the blanks and samples could not explain the high blank readings obtained under the analytical conditions used.

It might be expected on chemical grounds that phosphate should be removed more efficiently than was observed. Polyphosphates are more likely than simple phosphates to penetrate the demineralizer resin beds. However, polyphosphates are unstable to hydrolysis and attain significant concentrations only when added intentionally and recently. The Los Alamos County water supply has no added polyphosphates for inhibiting pipe corrosion.

CONCLUSIONS

Double demineralization and demineralization–distillation water purification systems of two common types appear to pass phosphate at trace levels that can be significant in preparing and analysing plant nutrient solutions or in analysing natural water samples. For concentrations much below 1μM, corrections may often be necessary for dilution of samples below the standard volume of analysis and for calibrations and blanks, when these operations are done with such purified water. The use of separate anion- and cation-exchangers and the use of nuclear-grade resins may lower the phosphate contamination level, though probably not very near to a true zero (personal communication from resin manufacturers). The use of polyphosphates for pipe-corrosion inhibition in municipal water supplied to the purifiers may exacerbate the problem.

CALCULATION OF EQUILIBRIUM CONSTANTS FROM MULTIWAVELENGTH SPECTROSCOPIC DATA—I

MATHEMATICAL CONSIDERATIONS

HARALD GAMPP, MARCEL MAEDER, CHARLES J. MEYER and ANDREAS D. ZUBERBÜHLER
Institute of Inorganic Chemistry, University of Basel, CH-4056 Basel, Switzerland

(*Received* 19 *June* 1984. *Accepted* 20 *September* 1984)

Summary—Multiwavelength spectrophotometric and spectroscopic data in general contain considerably more information about complexation equilibria than potentiometric data do. With the construction of a fully automatic titration set-up built into a high-precision spectrophotometer, the problems related to the wider use of this method have shifted from the quality of the primary data to the complexity of their numerical treatment. Matrix algebra is used to show how these problems can be overcome. An algorithm is described for calculation of stability constants and absorption spectra, together with the associated standard errors, at a reasonable expense of computer time. Problems in finding the minimum in a multidimensional parameter space are reduced by elimination of the molar absorptivities from the algorithm for the iterative refinement. Numerical safety and speed of calculation are improved by use of analytical instead of numerical derivatives. The number of data to be fitted is decreased by principal-component analysis.

It is still a widespread belief that spectrophotometric data are inherently less precise than potentiometric, with standard errors of ± 0.003 units at best for single absorbance values.[1] Consequently most equilibrium constants are determined by means of potentiometric titrations, and only a few general programs are available at present for processing spectrophotometric data[2–4] (*cf.*[5–8] for reviews of the older literature).

Some time ago we developed a fully automatic titration set-up[9] which gives data with standard errors as low as $2–5 \times 10^{-4}$ absorbance units.[9,10] The spectrophotometric data from this unit have been shown to have a reproducibility similar to that of potentiometric titrations. In addition, spectrophotometric titrations have been found to be superior in discriminating between different models for a complexation equilibrium,[11,12] even for rather complicated systems.

Because of the availability of large quantities of high-quality data, a fast, reliable and user-friendly program for the numerical treatment was needed. Here we wish to describe the mathematical features which have been used to achieve this in our new program SPECFIT.[13]

In theory, any general non-linear least-squares program can be used for calculation of stability constants from spectrophotometric data obtained at a single wavelength. However, for all but the most simple equilibrium systems this straightforward approach does not really work and several problems have to be overcome.

(*i*) Even for data obtained at a single wavelength there are two adjustable parameters for each unknown species, *viz.* the stability constant and the molar absorptivity. Convergence properties tend to deteriorate rapidly with the number of parameters. This problem is overcome by the elimination of the molar absorptivities from the process of iterative refinement, effectively reducing the number of parameters to the number of unknown stability constants, as is the case with data from potentiometric titrations.

(*ii*) Because of the correlations between stability constants and molar absorptivities, and also between stability constants themselves, numerical difficulties can arise in the algorithm for the refinement of the stability constants (non-linear parameters). This can be eased by the use of analytical derivatives in the calculation of the Jacobian matrix, increasing not only numerical safety but also the speed of calculation.

(*iii*) In systems with more than two or three absorbing species it is unlikely that a single wavelength will be sufficient to differentiate between all the species. This is especially true for the electronic absorption spectra of transition metal complexes, which are often broad, rather unstructured, and strongly overlapping. Data from a large number of wavelengths should then be used, and factor analysis leads to a considerable reduction of the number of data points required to be subjected to the least-squares treatment.

In SPECFIT, the features described in (*i*)–(*iii*) are combined with the efficient Marquardt algorithm[14,15] to ensure convergence. Points (*i*)–(*iii*) will now be considered in turn. Matrix notation is used and schematic illustration is added whenever this is felt to be helpful. Most of the algorithms used in this paper have been described before in one form or another. Normally this was done in a highly abstract mathe-

matical way, out of the chemical context, and the different features have never been combined to give the complete picture. Here, we wish to describe the problems specifically for chemical equilibrium systems and in terms which should be understandable to the chemist with an elementary knowledge of matrix algebra and having some familiarity with equilibrium calculations.

SYMBOLS

Bold-face lower-case letters **v** represent column vectors $[v(1), \ldots, v(i), \ldots, v(I)]^t$ and upper case letters **M** general matrices with elements $M(i,j)$ consisting of J columns and I rows. $\mathbf{M}^t$ and $\mathbf{v}^t$ are transposes of **M** and **v**, respectively. Differentiation of vectors and matrices with respect to parameters **p** or a single variable p will be denoted by $D\mathbf{v}$ and $D\mathbf{M}$. The trace of a matrix will be indicated by tr(**M**). Appropriate subscripts, *e.g.*, $\mathbf{a}_{calc}$ or $D\mathbf{M}_p$ are added in cases of ambiguity. Dimensions of vectors and matrices are given in brackets.

a [K]	Analytical (total) concentrations, experimental values
$\mathbf{a}_{calc}$ [K]	Analytical (total) concentrations, calculated values
A [K, K]	Partial derivatives of $\mathbf{a}_{calc}$ with respect to **c**
α [K, J]	Stoichiometric coefficients
β [J]	Equilibrium constants, fixed or adjustable
c [K]	Actual concentrations of components
C [M, S]	Concentrations of absorbing species, identical with partial derivatives of **r** with respect to **e**
$\mathbf{C}_f$ [M, F]	Concentrations of absorbing species with fixed spectra
$\mathbf{C}_u$ [M, U]	Concentrations of absorbing species with unknown spectra
$\delta_{i,j}$	Kronecker delta, $\delta_{i,i} = 1$; $\delta_{i,j} = 0$ for $i \neq j$
e, $\hat{\mathbf{e}}$ [S]	Molar absorptivities at a single wavelength
$\hat{\mathbf{e}}_f$ [F]	Molar absorptivities of species with fixed spectra
$\hat{\mathbf{e}}_u$ [U]	Molar absorptivities of species with unknown spectra
f [M]	Elements of fitting (model) function
F	Number of species with fixed spectra
I	Identity matrix of appropriate dimensions
I	Number of significant eigenvectors in factor analysis
J [M, N]	Jacobian matrix, partial derivatives of **f** with respect to **p**
J	Number of species in solution
K	Number of components in equilibrium mixture
$\mathbf{L}_I$ [M, I]	Significant linear coefficients used in refinement
λ [I]	Significant eigenvalues
M [W, W]	$\mathbf{Y}^t\mathbf{Y}$, second-moment matrix of absorbances
M	Number of measurements (equilibrium mixtures)
N	Number of non-linear parameters (equilibrium constants)
p, $\Delta\mathbf{p}$ [N]	Non-linear parameters (equilibrium constants) with shifts
P [M, M]	Projector matrix
Q var	Hessian matrix of variable dimensions, *e.g.*, $\mathbf{C}^t\mathbf{C}$
r [M]	residuals, $\mathbf{f} - \mathbf{y}$
s [J]	Concentrations of species in a given mixture
S	Number of absorbing species
SQ	Sum of squares of residuals
T [U, U]	Upper triangular matrix
U [M, U]	Matrix with orthogonal columns, $\mathbf{U}^t\mathbf{U} = \mathbf{I}$
U	Number of species with unknown spectra
$\mathbf{V}_I$ [I, W]	Eigenvectors corresponding to significant eigenvalues λ
W	Number of wavelengths
y [M]	Experimental absorbances
$\mathbf{y}_u$ [M]	Absorbances due to species with unknown spectra

Note: **F**, **R**, **Y** and **E** are the multiwavelength analogues of **f**, **r**, **y** and **e**, dimensions [M,W] and [S, W], respectively. **L** and **V** are the hypothetical analogues of $\mathbf{L}_I$ and $\mathbf{V}_I$, assuming full rank of **Y**.

Standard non-linear least-squares method

Given a set of M measurements $\mathbf{y} = [y(1), \ldots, y(m), \ldots, y(M)]^t$, it is the goal of any least-squares calculation to find the elements of a fitting function, **f**, such that the length of the vector of residuals **r** (weighted if necessary) is minimized.

$$SQ = \mathbf{r}^t\,\mathbf{r} = (\mathbf{f} - \mathbf{y})^t(\mathbf{f} - \mathbf{y}) = \text{minimum} \qquad (1)$$

In the case of determination of stability constants from spectrophotometric data, the elements $\mathbf{f}(m)$ for a chemical model with a total of S absorbing species are obtained from Beer's law:

$$f(m) = \sum_{s=1}^{S} e(s)C(m,s) \quad \text{or} \quad \mathbf{f} = \mathbf{C}\,\mathbf{e} \qquad (2)$$

Here **e** contains the molar absorptivities of the S absorbing species and **C** is the matrix of concentrations of only the absorbing species. **C** can be calculated from the analytical concentrations of the components [ligand(s) and metal ion(s)], $\mathbf{a} = [a(1), \ldots, a(k), \ldots, a(K)]^t$, and the known or estimated set of stability constants β, see below. The molar absorptivities, **e**, are also, in general, unknowns and thus the minimum of SQ would have to be found in a parameter space of N (equilibrium constants) plus S (absorptivities) dimensions.

Elimination of linear parameters

The molar absorptivities (linear parameters) can, however, be replaced non-iteratively by their least-squares estimates $\hat{\mathbf{e}}$ for a given concentration matrix **C**:

$$\hat{\mathbf{e}} = (\mathbf{C}^t\,\mathbf{C})^{-1}\,\mathbf{C}^t\,\mathbf{y} \tag{3}$$

This possibility has been described for the numerical treatment of kinetic data, *e.g.*, the resolution of a sum of exponentials.[16] It is also used in SQUAD[2] and in ELORMA,[4] where a detailed description may be found. The main points are briefly summarized here. By making use of equation (3), the fitting function **f** and the vector of residuals **r** can be described as a function of the concentration matrix **C** or, indirectly, of the set of stability constants (non-linear parameters) β alone [equation (4)]. The dimensionality of the parameter space is thus reduced to the number of unknown equilibrium constants, N, as would be the case if data from potentiometric titrations were used.

$$\mathbf{r} = \mathbf{f} - \mathbf{y} = \mathbf{C}\,\hat{\mathbf{e}} - \mathbf{y} = \mathbf{C}\,(\mathbf{C}^t\,\mathbf{C})^{-1}\,\mathbf{C}^t\,\mathbf{y} - \mathbf{y} \tag{4}$$

As also discussed previously,[4] numerical safety can be significantly increased by decomposition of **C** into a matrix **U** with orthogonal columns, ($\mathbf{U}^t\,\mathbf{U} = \mathbf{I}$, **I** = identity matrix), and an upper triangular matrix **T**.

$$\mathbf{C} = \mathbf{U}\,\mathbf{T} \tag{5}$$

Then equation (4) can be transformed to give

$$\begin{aligned}\mathbf{r} &= \{\mathbf{U}\,\mathbf{T}\,[(\mathbf{U}\,\mathbf{T})^t\,\mathbf{U}\,\mathbf{T}]^{-1}\,(\mathbf{U}\,\mathbf{T})^t - \mathbf{I}\}\mathbf{y}\\ &= \{\mathbf{U}\,\mathbf{T}\,\mathbf{T}^{-1}\,(\mathbf{U}^t\,\mathbf{U})^{-1}\,(\mathbf{T}^t)^{-1}\,\mathbf{T}^t\,\mathbf{U}^t - \mathbf{I}\}\mathbf{y}\\ &= (\mathbf{U}\,\mathbf{U}^t - \mathbf{I})\mathbf{y}\end{aligned} \tag{6}$$

The use of equation (6) instead of equation (4) proved essential in ELORMA[4] when this program was implemented on a single-precision hobby computer, but equation (4) may be sufficient in SQUAD, which is written for a mainframe machine and makes use of the double precision facility. In fact, about half as many significant digits are lost by using equation (6) instead of equation (4),[17] so that single precision and (6) give similar performance to double precision and (4).

Parameter refinement with use of analytical derivatives

When the effective number of parameters $\mathbf{p} = [p(1), \ldots, p(n), \ldots, p(N)]^t$ has been reduced to that of the unknown equilibrium constants β, the next step in parameter refinement is compilation of the Jacobian matrix **J**, *i.e.* the partial derivatives of the elements of the fitting function with respect to the non-linear parameters, $J(m,n) = \partial f(m)/\partial p(n) = \partial r(m)/\partial p(n)$. Based on either equation (4) or (6) this is straightforward when numerical derivatives are used, as has also been discussed in the description of ELORMA.[4] Any of the standard procedures of least-squares refinement can be applied to the approximate Jacobian matrix **J** thus obtained, calculation of a shift vector $\Delta\mathbf{p}$ by solving the Gaussian normal equations (7) being the simplest possibility.

$$\Delta\mathbf{p} = -(\mathbf{J}^t\,\mathbf{J})^{-1}\,\mathbf{J}^t\,\mathbf{r} \tag{7}$$

However, whenever feasible, the use of analytical instead of numerical derivatives greatly increases numerical safety and in general decreases computation time. Analytical expressions for the Jacobian matrix **J** based on partial derivatives have been derived[18,19] in a highly sophisticated mathematical approach, on the assumption that **C** is a general matrix, with the only condition being the differentiability of its elements. Here, we describe the problem specifically for chemical equilibrium systems and in terms which should be understandable to the chemist. In addition, the description is as close as feasible to the algorithm used in SPECFIT.[13]

The differentiation of a product of matrices **A B** follows the normal rules of differentiation.

$$D(\mathbf{A}\,\mathbf{B}) = (D\mathbf{A})\mathbf{B} + \mathbf{A}(D\mathbf{B}) \tag{8}$$

We therefore obtain the nth column of the Jacobian matrix **J** by differentiation of the vector of residuals [equation (4)] with respect to the nth unknown non-linear parameter, $p(n)$ [equation (9)]:

$$D\mathbf{r}_n = D(\mathbf{C}\,\hat{\mathbf{e}}) = (D\mathbf{C})\hat{\mathbf{e}} + \mathbf{C}(D\hat{\mathbf{e}}) \tag{9}$$

For the calculation of $D\hat{\mathbf{e}}$ we need an algorithm for $D(\mathbf{C}^t\,\mathbf{C})^{-1}$. By abbreviating $\mathbf{C}^t\,\mathbf{C}$ to **Q** and again making use of equation (8) we obtain equations (10)–(12). Substitution into equation (3) gives equation (13) and then the final expression for $D\mathbf{r}_n$, equation (14).

$$\begin{aligned}D\mathbf{Q} = D(\mathbf{C}^t\,\mathbf{C}) &= D\mathbf{C}^t\,\mathbf{C} + \mathbf{C}^t\,D\mathbf{C}\\ &= D\mathbf{C}^t\,\mathbf{C} + (D\mathbf{C}^t\,\mathbf{C})^t\end{aligned} \tag{10}$$

$$D(\mathbf{Q}^{-1}\,\mathbf{Q}) = D(\mathbf{I}) = 0 = D\mathbf{Q}^{-1}\,\mathbf{Q} + \mathbf{Q}^{-1}\,D\mathbf{Q} \tag{11}$$

$$D\mathbf{Q}^{-1} = -\mathbf{Q}^{-1}\,D\mathbf{Q}\,\mathbf{Q}^{-1} \tag{12}$$

$$\begin{aligned}D\hat{\mathbf{e}} = D[(\mathbf{C}^t\,\mathbf{C})^{-1}\,\mathbf{C}^t\,\mathbf{y}] &= D\mathbf{Q}^{-1}\,\mathbf{C}^t\,\mathbf{y}\\ &\quad + \mathbf{Q}^{-1}\,D\mathbf{C}^t\,\mathbf{y}\\ &= -\mathbf{Q}^{-1}\,D\mathbf{Q}\,\mathbf{Q}^{-1}\,\mathbf{C}^t\,\mathbf{y}\\ &\quad + \mathbf{Q}^{-1}\,D\mathbf{C}^t\,\mathbf{y}\\ &= -\mathbf{Q}^{-1}\,D\mathbf{Q}\,\hat{\mathbf{e}} + \mathbf{Q}^{-1}\,D\mathbf{C}^t\,\mathbf{y}\end{aligned} \tag{13}$$

$$\begin{aligned}D\mathbf{r}_n &= D\mathbf{C}\,\hat{\mathbf{e}} - \mathbf{C}\,\mathbf{Q}^{-1}\,D\mathbf{Q}\,\hat{\mathbf{e}}\\ &\quad + \mathbf{C}\,\mathbf{Q}^{-1}\,D\mathbf{C}^t\,\mathbf{y} = D\mathbf{C}\,\hat{\mathbf{e}}\\ &\quad + \mathbf{C}\,\mathbf{Q}^{-1}\,(D\mathbf{C}^t\,\mathbf{y} - D\mathbf{Q}\,\hat{\mathbf{e}})\end{aligned} \tag{14}$$

The result [equation (14)] obtained so far is rather general and can be applied to any least-squares problem with a combination of linear and non-linear parameters, *i.e.*, a problem which can be described by an equation of type (4). Since $\mathbf{Q}^{-1}$, $D\mathbf{Q}$, and $\hat{\mathbf{e}}$ are simply functions of **C** (and **y**), all we need for the calculation of the vector of residuals, **r**, and the

Jacobian matrix **J**, is the knowledge of **C** and its derivative $D\mathbf{C}$ with elements $\partial C(m,s)/\partial p(n)$ (see below). For further reference we also note that **C** is identical with the partial derivative of **r** with respect to **e** and thus part of the total Jacobian matrix $\mathbf{J}_t$ which is obtained without elimination. Equally, **Q** would be part of the total Hessian $\mathbf{Q}_t = \mathbf{J}_t^t\,\mathbf{J}_t$ (see calculation of standard errors, below).

Inclusion of species with known spectra

Occasionally, the molar absorptivities of some of the complexes are already known from independent measurements and refinement is not desired. In this case, expressions analogous to equations (4) and (14) can be obtained for the residuals and the Jacobian matrix by subdividing **C** and $\hat{\mathbf{e}}$ into $\mathbf{C}_f$ and $\mathbf{C}_u$ for species with fixed or unknown absorptivities $\hat{\mathbf{e}}_f$ or $\hat{\mathbf{e}}_u$, respectively, followed by subtracting the contributions of $\mathbf{C}_f$ from **y**.

$$\mathbf{y}_u = \mathbf{y} - \mathbf{C}_f\,\hat{\mathbf{e}}_f \tag{15}$$

Equations (3) and (4) can then be transformed into (3a) and (4a), but for the calculation of the Jacobian matrix, we have to take into account that now $\mathbf{y}_u$ itself also is a function of the stability constants, $D\mathbf{y}_u = -D\mathbf{C}_f\,\hat{\mathbf{e}}_f$ [equation (14a)].

$$\hat{\mathbf{e}}_u = (\mathbf{C}_u^t\,\mathbf{C}_u)^{-1}\,\mathbf{C}_u^t\,\mathbf{y}_u = \mathbf{Q}_u^{-1}\,\mathbf{C}_u^t\,\mathbf{y}_u \tag{3a}$$

$$\begin{aligned}\mathbf{r}_u &= \mathbf{C}_u\,(\mathbf{C}_u^t\,\mathbf{C}_u)^{-1}\,\mathbf{C}_u^t\,\mathbf{y}_u - \mathbf{y}_u\\ &= \mathbf{C}_u\,\mathbf{Q}_u^{-1}\,\mathbf{C}_u^t\,\mathbf{y}_u - \mathbf{y}_u\\ &= \mathbf{C}_u\,\hat{\mathbf{e}}_u - \mathbf{y}_u\end{aligned} \tag{4a}$$

$$\begin{aligned}D\mathbf{r}_{u,n} &= D\mathbf{C}_u\,\hat{\mathbf{e}}_u + \mathbf{C}_u\,D\hat{\mathbf{e}}_u - D\mathbf{y}_u\\ &= D\mathbf{C}_u\,\hat{\mathbf{e}}_u + \mathbf{C}_u\,(D\mathbf{Q}_u^{-1}\,\mathbf{C}_u^t\,\mathbf{y}_u\\ &\quad + \mathbf{Q}_u^{-1}\,D\mathbf{C}_u^t\,\mathbf{y}_u + \mathbf{Q}_u^{-1}\,\mathbf{C}_u^t\,D\mathbf{y}_u)\\ &\quad + D\mathbf{C}_f\,\hat{\mathbf{e}}_f\\ &= D\mathbf{C}\,\hat{\mathbf{e}} + \mathbf{C}_u\,\mathbf{Q}_u^{-1}\,(D\mathbf{C}_u^t\,\mathbf{y}_u\\ &\quad - D\mathbf{Q}_u\,\hat{\mathbf{e}}_u - \mathbf{C}_u^t\,D\mathbf{C}_f\,\hat{\mathbf{e}}_f)\end{aligned} \tag{14a}$$

Obviously, $\mathbf{y}_u$ [equation (15)] has to be recalculated in each iterative cycle of parameter refinement, since $\mathbf{C}_f$ is also a function of the equilibrium constants.

Analytical derivatives of the species concentrations

For the calculation of stability constants from spectrophotometric data, $D\mathbf{C}$ consists of the partial derivatives of the concentrations of the absorbing species with respect to the equilibrium constants or, preferably,[20] their logarithms.

The use of analytical derivatives in the numerical treatment of solution equilibria was introduced by Bugaevsky *et al.*[21] More recently, this has been discussed for the treatment of potentiometric data[22] and incorporated into TITFIT[20] for the calculation of $\partial \mathrm{ml}_{calc}/\partial \ln \beta_{mlh}$, the partial derivatives of the amount of base consumed with respect to the logarithms of the equilibrium constants. In a somewhat analogous way $D\mathbf{C}$ can be obtained after calculation of all the species concentrations $\mathbf{s} = [s(1), \ldots, s(j), \ldots, s(J)]^t$ by the usual Newton–Raphson method.[23]

$$\begin{aligned}0 &= \mathbf{A}\,\Delta\mathbf{c} + \mathbf{a}_{calc} - \mathbf{a}\\ \Delta\mathbf{c} &= \mathbf{A}^{-1}(\mathbf{a} - \mathbf{a}_{calc});\ \mathbf{c}_{n+1} = \mathbf{c}_n + \Delta\mathbf{c}\end{aligned} \tag{16}$$

In equation (16), **a** contains the set of analytical (total) concentrations describing the chemical composition, **c** gives the actual free concentrations of the components, and $\Delta\mathbf{c}$ the corrections in the nth iterative cycle of refinement. The values in $\mathbf{a}_{calc} = [a(1)_{calc}, \ldots, a(k)_{calc}, \ldots, a(K)_{calc}]^t$ are the total concentrations calculated for a given set of equilibrium constants and component concentrations **c** [equation (17)] with the aid of the stoichiometric coefficients $\alpha(k,j)$, indicating the number of entities of component k contained in species j.

$$\begin{aligned}a(k)_{calc} &= \sum_{j=1}^{J} \alpha(k,j)\,s(j)\\ &= \sum_{j=1}^{J} \left\{\alpha(k,j)\,\beta(j)\,\prod_{i=1}^{K} c(i)^{\alpha(i,j)}\right\}\end{aligned} \tag{17}$$

The array **A** is made up finally from the partial derivatives of $\mathbf{a}_{calc}$ with respect to the component concentrations, $A(k,i) = \partial a(k)_{calc}/\partial c(i)$ and can readily be calculated from equation (17). Since the construction of **r** and **J** is actually done point by point, the subscript m is dropped for the present. It may be noted that one row of the concentrations of the absorbing species, **C**, and the concentrations of the components, **c**, are both subsets of **s**, and also that the non-linear parameters **p** are a subset of $\ln \boldsymbol{\beta}$.

After calculation of **s**, **c**, and **A** from equations (16) and (17), the elements of $D\mathbf{C} = \partial C(m,j)/\partial \delta p(n) = \partial s(j)/\partial \ln \beta(n)$ are obtained at little extra cost from equation (18):

$$\begin{aligned}\frac{\partial s(j)}{\partial \ln \beta(n)} &= \frac{\partial s(j)}{\partial \beta(n)}\,\beta(n) = s(j)\delta_{j,n}\\ &\quad + \sum_{k=1}^{K} \frac{\partial s(j)}{\partial c(k)}\,\frac{\partial c(k)}{\partial \ln \beta(n)}\end{aligned} \tag{18}$$

$$\partial s(j)/\partial c(k) = \alpha(k,j)s(j)/c(k) \tag{19}$$

In equation (18), $\delta_{j,n}$ is the Kronecker delta and the partial derivatives of the species concentrations with respect to the concentrations of the components [equation (19)] are already known from the Newton–Raphson procedure. The derivatives of the components with respect to $\ln \beta(n)$ are finally obtained by a simple matrix manipulation:

$$\begin{aligned}\frac{\partial a(k)_{calc}}{\partial \ln \beta(n)} &= 0 = \alpha(k,n)\,s(n)\\ &\quad + \sum_{i=1}^{K} \frac{\partial a(k)_{calc}}{\partial c(i)}\,\frac{\partial c(i)}{\partial \ln \beta(n)}\end{aligned}$$

or

$$\begin{aligned}D\mathbf{a}_{calc,n} &= 0 = \mathbf{s}_{\alpha,n} + \mathbf{A}\,D\mathbf{c}_n\\ D\mathbf{c}_n &= -\mathbf{A}^{-1}\,\mathbf{s}_{\alpha,n}\end{aligned} \tag{20}$$

The elements of $D\mathbf{C}$ are now obtained by simple substitution of the results from equations (19) and (20) into equation (18). It should be noted that the complete derivative of **C** with respect to the unknown parameters **p** is in fact a tensor with dimensions $M \times S \times N$ and that the derivatives with respect to all N parameters are obtained by making repetitive use of equations (18)–(20). With the knowledge of both **C** and $D\mathbf{C}$ we now obtain **r** and **J** from equations (4) and (14), so we are back to the standard situation of non-linear least-squares refinement. The elements of **J** can also be obtained by starting from equation (6), *i.e.*, after orthogonalization of **C**. However, this increases computing time and proved to be unnecessary when analytical instead of numerical derivatives were used. This possibility was therefore not included in the final version of SPECFIT.

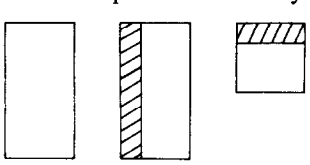
Multiwavelength data—factor analysis

Data obtained at W different wavelengths are conveniently written as a matrix **Y** and the expression for the calculation of the residuals [equation (4)] is transformed into equation (21):

$$\mathbf{R} = \mathbf{F} - \mathbf{Y} = \mathbf{C}\,(\mathbf{C}^t\,\mathbf{C})^{-1}\,\mathbf{C}^t\,\mathbf{Y} - \mathbf{Y} = \mathbf{P}\,\mathbf{Y} \quad (21)$$

F, **R**, and **Y** are all matrices with M columns and W rows. The data can, however, be treated exactly as described by applying equations (4) and (14) [or (4a) and (14a)], by using successively the individual columns of **Y** in the place of **y**. For a given wavelength w, the residuals $\mathbf{r}_w$ and the Jacobian matrix $\mathbf{J}_w$ do not depend on corresponding elements from other wave lengths. Therefore, SQ as well as $\mathbf{J}^t\,\mathbf{J}$ and $\mathbf{J}^t\,\mathbf{r}$, which are needed for the iterative refinement, are all simply the sums of the corresponding elements obtained at the individual wavelengths, *cf.* equations (1), (4) and (14), respectively.

If, however, the number of wavelengths, W, is large compared to the number of absorbing species, S, the repetitive application of equations (1), (4) and (14) can become unnecessarily cumbersome. The demand on computer time can then be significantly reduced by applying the technique of factor analysis to **Y**.[24,25]

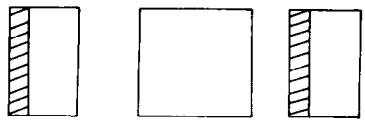


$$\mathbf{Y} \quad = \quad \mathbf{L} \qquad \mathbf{V} \qquad (22)$$

Since **V** is made up by the eigenvectors of **Y**, its rows are orthonormal, $\mathbf{V}\,\mathbf{V}^t = \mathbf{I}$. When equations (21) and (22) are combined, the sum of squares, SQ, can be written as:

$$SQ = \sum_{m=1}^{M}\sum_{w=1}^{W} R(m,w)^2 = \mathrm{tr}(\mathbf{R}^t\,\mathbf{R})$$
$$= \mathrm{tr}(\mathbf{R}\,\mathbf{R}^t) = \mathrm{tr}(\mathbf{P}\,\mathbf{Y}\,\mathbf{Y}^t\,\mathbf{P}^t)$$
$$= \mathrm{tr}(\mathbf{P}\,\mathbf{L}\,\mathbf{V}\,\mathbf{V}^t\,\mathbf{L}^t\,\mathbf{P}^t) = \mathrm{tr}(\mathbf{P}\,\mathbf{L}\,\mathbf{L}^t\,\mathbf{P}^t) \quad (23)$$

In other words, instead of calculating **R** from equation (21), we obtain the same SQ for a given **C** (and thus **P**) by using the linear coefficients **L** in place of the original data **Y**:



$$\mathbf{R} \quad = \quad \mathbf{P} \qquad \mathbf{L} \qquad (24)$$

Now, all the essential information concerning the data is contained in the first I (shaded) columns of **L**, that is, in $\mathbf{L}_I$. In fact, in the absence of experimental error, the rank of **Y** could not exceed the number of absorbing species, S, and at most S non-vanishing columns of **L** would be obtained. The right (unshaded) part of **L** thus contains only noise and does not have to be considered in the calculation. Therefore, the dimensions of **L** and **R** are reduced from $M \times W$ (typically $M \times 30$) to $M \times I$ (typically $M \times 5$) and the effect increases with the number of wavelengths included. The complete iterative refinement is now done on the reduced matrix $\mathbf{L}_I$ instead of on **Y**.

It may be noted that the number of columns I in $\mathbf{L}_I$ is neither uniquely defined nor very critical. As mentioned, experimental noise will increase the number of non-vanishing columns. On the other hand, spectra of some of the absorbing species may be essentially linear combinations of others, thus reducing the effective rank of **Y** to $I \leqslant S$.

Decomposition of **Y** into **L** and **V** can be accomplished in many ways. Practically all of them make use of the second-moment matrix **M**.

$$\mathbf{M} = \frac{1}{M}\,(\mathbf{Y}^t\,\mathbf{Y}) \quad (25)$$

In the present case, only a few eigenvectors with the largest I eigenvalues are needed, and the simple method of vector iteration[17] proves to be faster than general library routines which calculate all the eigenvectors of **M**. This technique yields the rows of **V** in decreasing order of the eigenvalues $\boldsymbol{\lambda} = [\lambda(1), \ldots, \lambda(i), \ldots, \lambda(I)]^t$.

Factor analysis also gives an indication of the number of relevant eigenvectors, I, or components in a given set of data, which is actually the most common application of factor analysis to chemical problems,[26–29] which can be made by comparing the estimated instrumental standard deviations of the absorbance measurements, SA with the residual errors of the decomposition, SD,[24] [equation (26)].

$$SD = \sqrt{\left[\mathrm{tr}(\mathbf{M}) - \sum_{i=1}^{I}\lambda(i)\right]/(W - I)} \quad (26)$$

We may assume that all relevant factors have been found if $SD \leqslant SA$.

The linear coefficients $\mathbf{L}_I$ which are needed in the iterative refinement are finally obtained from

$$\mathbf{L}_I = \mathbf{Y}\,\mathbf{V}_I^t \quad (27)$$

where $\mathbf{V}_I$ is the $I \times W$ matrix of I relevant eigenvectors. While the exact determination of I for the model-free deduction of the number of absorbing species[26–29] is by no means trivial and in many cases ambiguous, its choice for the present purpose of data reduction is uncritical. If I is made too small, some information may be lost, but the effect on the final values of the equilibrium constants is normally almost negligible. Too large values of I increase the computing time with little effect on the results. In addition, we note that the large $(M \times M)$ matrix $\mathbf{P}$ is never actually calculated. The residuals $\mathbf{R}_I$ and thus SQ are in fact obtained from

$$\mathbf{R}_I = \mathbf{C}\,(\mathbf{C}^t\,\mathbf{C})^{-1}\,\mathbf{C}^t\,\mathbf{L}_I - \mathbf{L}_I;\; SQ = \mathrm{tr}(\mathbf{R}_I^t\,\mathbf{R}_I) \quad (28)$$

which needs less computer space and time if done in the proper order.

In the case of strongly structured (*e.g.*, EPR[30]) spectra, it may be useful to obtain data at a rather large number of wavelengths, $W \gg M$. Then the second moment matrix $\mathbf{M}$ [equation (25)] with dimensions $W \times W$ may be unduly large and an alternative route for the calculation of $\mathbf{L}_I$ is preferable:

$$\mathbf{M}^* = \frac{1}{W}\,\mathbf{Y}\,\mathbf{Y}^t \quad (29)$$

$$\mathbf{L}_I = (\mathbf{V}_I^*)^t\,\mathbf{F};\; F(i,j) = \delta_{i,j}\,\sqrt{\lambda(i) \times W} \quad (30)$$

This method for calculation of $\mathbf{L}_I$ is somewhat simpler than the use of equations (25) and (27), and is therefore preferred whenever $W \geqslant M$.

Since equation (28) is identical in structure with equations (21) and (4), the calculations of SQ (1) and the Jacobian matrix (14), as well as the refinement of the equilibrium constants [equation (7)] proceeds exactly as with the original data. Fixed spectra $\hat{\mathbf{E}}_f$ are easily included, if they are first represented in the vector space spanned by the eigenvectors $\mathbf{V}$:

$$\hat{\mathbf{E}}_{f,V} = \hat{\mathbf{E}}^f\,\mathbf{V}^t \quad (31)$$

$\hat{\mathbf{E}}_f$ and $\hat{\mathbf{E}}_{f,V}$ are matrices with W and I columns, respectively. After this transformation, the columns of the Jacobian matrix may again be obtained from equation (14a) instead of (14), if some species with known spectra are present. In equation (28), the molar absorptivities $\hat{\mathbf{E}}^u$ of the absorbing species are not immediately available at the end of the iterative refinement. By analogy with equation (3a) they are, however, readily obtained from the original data and the previously calculated arrays $\mathbf{Q}_u^{-1}$ and $\mathbf{C}_u^t$ [equation (32)].

$$\hat{\mathbf{E}}_u = \mathbf{Q}_u^{-1}\,\mathbf{C}_u^t\,\mathbf{Y}_u \quad (32)$$

Estimation of standard errors

The standard errors of the refined parameters (and if desired the complete covariance matrix[15]) are obtained through equations (33) and (34), where $\mathbf{J}_t$ is the total Jacobian matrix with respect to both non-linear and linear parameters.

$$\mathbf{Q}_t = \mathbf{J}_t^t\,\mathbf{J}_t;\quad \mathbf{Q}_{I,t} = \mathbf{Q}_t^{-1} \quad (33)$$

$$\sigma(i) = \sqrt{Q_{I,t}\,(i,i)}\;\sigma(y) \quad (34)$$

The elements of $\mathbf{Q}_{I,t}$ can be obtained without first constructing $\mathbf{J}_t$ and $\mathbf{Q}_t$, however. Following ideas developed earlier,[31] we can subdivide $\mathbf{Q}_t$ and $\mathbf{Q}_{I,t}$ according to equation (35).

$$\mathbf{Q}_t = \begin{array}{|c|c|}\hline \mathbf{Q}_1 & \mathbf{Q}_3 \\ \hline \mathbf{Q}_3^t & \mathbf{Q}_2 \\ \hline \end{array}\;;\quad \mathbf{Q}_{I,t} = \begin{array}{|c|c|}\hline \mathbf{Q}_{I,1} & \mathbf{Q}_{I,3} \\ \hline \mathbf{Q}_{I,3}^t & \mathbf{Q}_{I,2} \\ \hline \end{array} \quad (35)$$

In equation (35), $\mathbf{Q}_1$ and $\mathbf{Q}_{I,1}$ refer only to the equilibrium constants, $\mathbf{Q}_2$ and $\mathbf{Q}_{I,2}$ belong only to the molar absorptivities, and $\mathbf{Q}_3$ and $\mathbf{Q}_{I,3}$ contain mixed terms. By applying the least-squares condition to both linear and non-linear parameters, the expressions (36)–(38) can be derived.[31]

$$\mathbf{Q}_{I,1} = (\mathbf{J}^t\,\mathbf{J})^{-1} \quad (36)$$

$$\mathbf{Q}_{I,3}^t = D\hat{\mathbf{e}}_p\,\mathbf{Q}_{I,1} \quad (37)$$

$$\mathbf{Q}_{I,2} = \mathbf{Q}_u^{-1} + \mathbf{Q}_{I,3}^t\,D\hat{\mathbf{e}}_p^t \quad (38)$$

In equation (36), $\mathbf{J}$ is the Jacobian matrix associated with the non-linear parameters after elimination of the linear ones. Thus $\mathbf{Q}_{I,1}$ is already known [equation (7)]. Equally, $\mathbf{Q}_u^{-1} = \mathbf{Q}_2^{-1} = (\mathbf{C}_u^t\,\mathbf{C}_u)^{-1}$ has been calculated before [equation (3a)]. Finally $D\hat{\mathbf{e}}_p$ is the matrix of partial derivatives of the molar absorptivities with respect to the N unknown equilibrium constants and thus consists of N columns of $D\hat{\mathbf{e}}$, [*cf.* equation (13)]. Therefore, all elements of $\mathbf{Q}_{I,t}$ are obtained at very little cost and the information available at the end of the refinement is identical to that obtained without elimination and without factor analysis.

CONCLUSIONS

By a combination of appropriate elementary matrix manipulations, the calculation of equilibrium constants from multiwavelength spectrophotometric data is greatly simplified. Equations (3) and (4) reduce the number of parameters in the iterative refinement to the number of unknown stability constants. The use of analytical derivatives [(14) and (18)] increases the numerical safety and speed of the calculation. Computer time and memory are saved by doing the iterative refinement in an orthogonal vector space spanned by the eigenvectors of the original absorbance matrix [equation (28)]. The standard errors of all parameters are readily obtained without ever calculating the full Jacobian matrix [equations (36)–(38)]. For the iterative refinement of the non-linear parameters, any modification to the solution of the Gaussian normal equations [equation (7)] may be applied, as in standard non-linear least-squares data reduction. A comprehensive computer program

SPECFIT which combines the ideas above with the efficient Marquardt algorithm[3,14,15,20] and is written in standard FORTRAN 77, will be described in a later paper.

Summary—A procedure is described for simultaneous determination of arsenic, selenium, tin and mercury in aqueous solution by non-dispersive atomic-fluorescence spectrometry. Radiofrequency-excited EDLs, 100% modulated in the kHz region, were used for atom excitation. Sodium tetrahydroborate was used as reductant and a hydrogen–argon miniflame as atomizer. In the optimized procedure, which uses 1 ml of sample, the limits of detection (three times the standard deviation of the blank) were 0.04, 0.08, 0.1 and 0.1 ng/ml for arsenic, selenium, tin and mercury respectively. The linear dynamic range was greater than three decades for all analytes and the precision was better than 7% (typically 3%) for concentrations ≥ 1 ng/ml. Results for mutual interference effects are reported. Copper, nickel, lead and cobalt interfered only with selenium (5 ng/ml), when present in at least 200-fold weight ratio to it. Using 5 ml of sample improved the limits of detection for selenium and arsenic (0.01 and 0.02 ng/ml respectively), but at the expense of greater interference. Recovery from spiked natural water samples was better than 95% at the ng/ml level, except for selenium in sea-water, when the recovery was only 85%. Determination of the four elements, including standard-addition and background measurements, requires about 10 min.

Non-dispersive atomic-fluorescence spectrometry (NDAFS) has proved to be superior to dispersive atomic-fluorescence and atomic-absorption spectrometry on account of its potential for simultaneous multielement analysis and its lower detection limit and larger dynamic range.[1–5]

In a previous paper,[6] describing a new instrument for simultaneous determination of elements by NDAFS, attention was mainly focused on the characteristics of the optical and electronic components and optimization of the signal to noise ratio (SNR). The present paper describes use of that instrument for simultaneous determination of arsenic, selenium, tin and mercury at sub-ng/ml levels, with sodium tetrahydroborate as reductant for generation of the volatile species measured.

EXPERIMENTAL

Apparatus

Radiofrequency-excited electrodeless discharge lamps (RFEDL) (Perkin-Elmer) were used in the four-channel excitation system.[6] Individual modulation of the RF power of each channel in the range 6–8 kHz allowed approximately 100% modulation of the light-beam, with a low (d.c.) background level.

An argon–hydrogen entrained air miniflame[7] was preferred because of its optical transparency and low noise as well as its chemical inertia and the absence of memory effects (which often occur with electrothermal atomizers[8]). The flame was supported on a glass tube (4 mm bore) and obtained, unless otherwise specified, with flow-rates of 0.35 l./min for hydrogen and 1.0 l./min for argon, the latter also serving as the carrier gas. Ball flowmeters (Sho-Rate 150, Brooks) were used to measure the flow-rates. The 70-ml reaction vessel was constructed as described by others.[7,9] Disposable micropipettes were used for adding the tetrahydroborate and for sample injection.

Reagents

As(III), Se(IV), Sn(IV) and Hg(II) stock solutions (1000 μg/ml) were prepared from pure As_2O_3, SeO_2, Sn and Hg. Working standards were prepared just before use. The sodium tetrahydroborate solution was stabilized with sodium hydroxide (0.1%) and filtered.[10] Erba RLE sodium tetrahydroborate (powder) was preferred because of its high purity and low cost. Merck "Suprapur" hydrochloric acid and sodium hydroxide were used.

Procedure

One ml of 2% sodium tetrahydroborate solution was placed in the reaction vessel and a disposable micropipette containing the sample (0.2–1.0 ml) was placed in the injector port. Argon was then passed through the reaction vessel until stable base-lines were obtained. The sample was then injected and the signals were recorded. For a sample volume of 5 ml, the procedure was modified. The sample was placed in the reaction vessel and stirred (magnetic stirrer) with argon passing through the vessel, then 1 ml of sodium tetrahydroborate solution was added through the injector port. The connecting tubing and the glass burner were conditioned with 3*M* hydrochloric acid before measurements, whenever determination of selenium was required.

*Presented in part at the "1° Convegno Incontri di Chimica Analitica dell'Ambiente", Genoa, Italy, 23–24 May 1983.

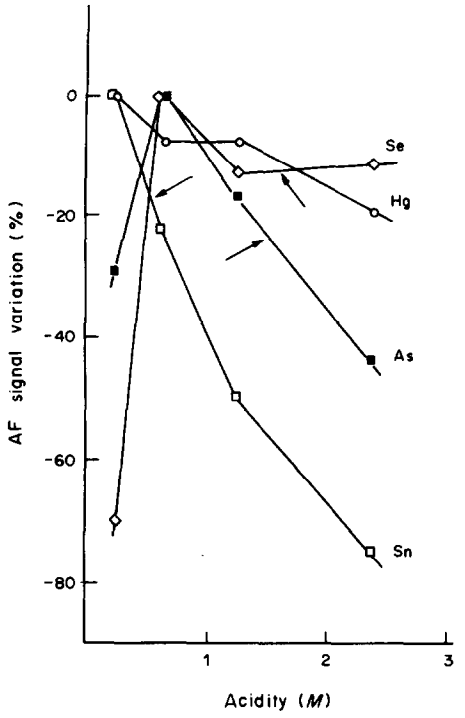

Fig. 1. Effect of sample acidity (HCl) on the atomic-fluorescence signals of arsenic, selenium, tin and mercury, each present at a concentration of 10 ng/ml. The arrows indicate the sample acidity proposed by Thompson and Thomerson.[9] Conditions: 1-ml sample, 1 ml of 2% $NaBH_4$ solution, observation height 15 mm, H_2 0.35 l./min, argon 1.0 l./min.

RESULTS AND DISCUSSION

Effect of gas flow-rates

In agreement with the findings of Tsujii and Kuga,[7] the hydrogen flow-rate was found to affect the SNR, depending on the acidity and volume of the solution injected into the reaction vessel. With 0.6*M* hydrochloric acid sample medium and different sample volumes, the best SNR was obtained with the following hydrogen flow-rates: 0.25 l./min for 0.2 and 0.5 ml samples, and 0.35 and 0.45 l./min for 1 and 5 ml samples respectively.

An argon flow-rate of 1.0 ± 0.2 l./min resulted in relatively large (7–9 sec) reproducible peak widths at half peak-height. It was therefore possible to use a relatively high time-constant (10 sec) at the output low-pass filter, with consequent gain in SNR.

Effect of acidity

Figure 1 shows, for each element, the effect of acidity on the signal peak heights. The arrows show the acid concentration giving maximal response, as obtained by Thompson and Thomerson[9] by AAS with a quartz furnace atomizer, other conditions being the same. For the elements for which the comparison is possible, the highest signals are reached at lower acidities in our procedure. This can be attributed to the fact that when the argon–hydrogen miniflame is used, the enhancement of the signal caused at increasing acidity by the increased rate of hydrogen production and faster stripping of volatile species, is offset by the change in geometry and stoichiometry of the flame, which decreases the degree of atomic excitation.

Anomalous behaviour was observed for selenium. If the glassware and tubing were not preconditioned, strong and reproducible signals were obtained only when the sample acid concentration was 1.2*M* hydrochloric acid. For instance, when successive 1-ml samples in 0.6*M* hydrochloric acid medium were injected, a progressive decrease in signal peak height was observed (Fig. 2). We attribute this to the relatively high acidity of hydrogen selenide ($K_a = 2.2 \times 10^{-4}$), resulting in its reacting along the walls of the transfer line with basic impurities resulting from decomposition of the sodium tetrahydroborate and carried away by the transport gas.

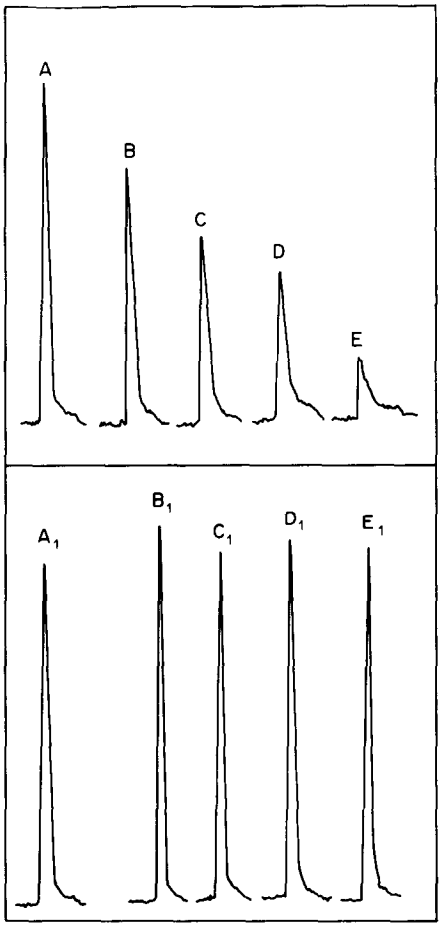

Fig. 2. Effect of acid preconditioning on the signal from 1 ml of 2-ng/ml selenium solution. Signals A–E were obtained with non-preconditioned apparatus, and signals A_1–E_1 with acid-preconditioned apparatus. Signals A and A_1 were obtained with 1.2*M* HCl sample medium. Signals B, C, D, E and B_1, C_1, D_1, E_1 were obtained with 0.6*M* HCl medium, injected straight after A and A_1 respectively. Other conditions: 1 ml of 2% $NaBH_4$ solution, H_2 0.35 l./min, argon 1.0 l./min, observation height 15 mm.

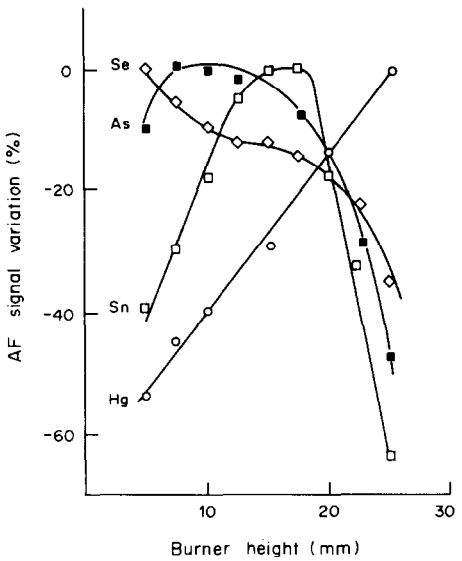

Fig. 3. Effect of observation height on atomic-fluorescence signal of arsenic, selenium, tin and mercury, each present at 10-ng/ml concentration. Conditions: 1 ml of sample in 0.6*M* HCl, 1 ml of 2% $NaBH_4$ solution, H_2 0.35 l./min, argon 1.0 l./min.

Preconditioning with 3*M* acid prevented this effect, and reproducible signals were obtained (Fig. 2) for several successive injections of sample.

For multielement determination, a sample acidity of 0.6*M* hydrochloric acid provides maximal sensitivity for arsenic and selenium and only a 10–20% loss in sensitivity for mercury and tin.

Effect of observation height

The optimum position for the optical path of the EDL light-beams is 15 mm above the burner top, which gives the highest sensitivity for arsenic and tin, and about 70 and 90% of maximum sensitivity for mercury and selenium respectively (Fig. 3).

Effect of amount of sodium tetrahydroborate

Figure 4 shows that the highest fluorescence signals were obtained for arsenic, mercury and selenium with 1 ml of 2% sodium tetrahydroborate solution. The signal for tin was 90% of the maximal value (reached with 1 ml of 4% sodium tetrahydroborate solution).

Effect of sample volume

The influence of sample volume on some of the performance characteristics is summarized in Table 1. Changing the sample volume changes the pH reached by the solution after the addition of tetrahydroborate (the change being biggest for the smallest sample volume), and the procedure must be changed when a 5-ml sample is used. The blank signal, S_B, is assumed to be due to the analyte present in the reagents. The detection limit C_L is taken as three times the standard deviation of the concentration in the blank, C_B. The peak-to-peak noise measured for the background near the signal, which is sometimes used for calculation of C_L in AFS, was practically devoid of meaning in this work, since the nature and size of the noise signal before and during the tetrahydroborate reaction were quite different.

Table 1 shows that the C_B values tended to decrease with increasing sample volume for all four elements, but with different patterns according to whether the impurities were mainly present in the acid or in the tetrahydroborate. In the case of selenium it is evident that the hydrochloric acid in the sample does not contribute to the size of C_B, since the product VC_B is fairly constant. The slope of the calibration graph would be expected to remain constant for constant yield of atomic events per unit volume of sample, *i.e.*, m/V should be constant. This was found to be approximately the case for arsenic over the whole sample volume range and for selenium in the 1–5 ml range, but for tin and mercury the yield decreased consistently with sample volume.

Since the decrease in detection limit when the sample volume is increased from 1.0 to 5 ml is very significant only for selenium, the use of 1 ml of sample is suggested, especially as interferences are higher with 5 ml of sample than with 1 ml, as will appear later.

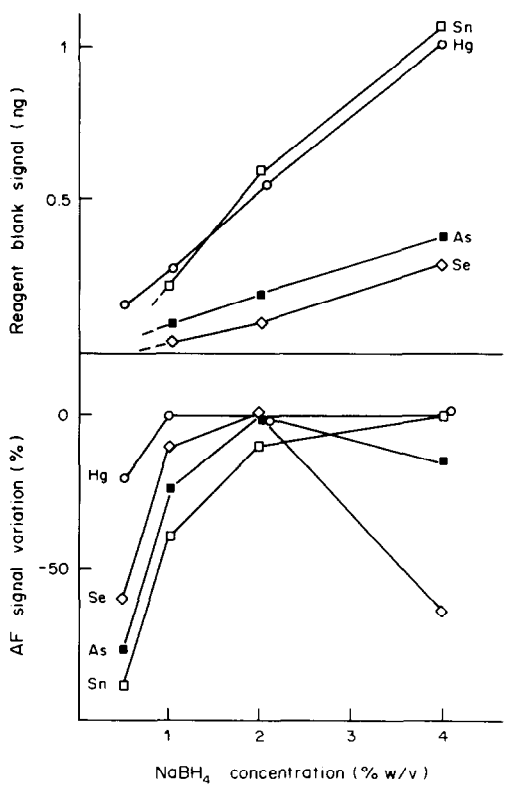

Fig. 4. Effect of concentration of $NaBH_4$ solution on blank signal and on atomic-fluorescence signal of arsenic, selenium, tin and mercury, each present at 10-ng/ml concentration. Conditions: 1 ml of sample in 0.6*M* HCl, 1 ml of $NaBH_4$ solution, H_2 0.35 l./min, argon 1.0 l./min, observation height 15 mm.

*Conditions: as for Table 2.
†Relative standard deviation of ten replicate measurements in absence of interferent.
§Relative standard deviation of ten replicate measurements in presence of a 500 ng/ml concentration of interferent.

Dynamic range and precision

Table 2 shows that the precision was between 2 and 7% for all four elements at the 1-ng/ml level and improved with concentration, except for mercury, for which it was almost constant. The precision was unaffected by the presence of the other three elements in 500-fold w/w ratio to the analyte (Table 3) though there were some effects on signal height (Table 4, see below).

Interferences

In the preceding paper[6] the instrumental cross-talk was measured separately from chemical and optical effects and was calculated to be at least 68 dB.

Mutual interferences. Varying the sample volume but using a constant amount of sodium tetrahydroborate was found to affect the size of the interference effects, except for mercury (Table 4). Mercury is the only one of the four elements which does not form a hydride, so the interference probably arises in the hydride formation.

With 1 ml of sample, mercury interferes with the selenium signal only when present at concentrations higher than 5 μg/ml. Arsenic and tin present a peculiar mutual effect: the arsenic peak is enhanced by tin concentrations ≥ 0.5 μg/ml with maximal increase at tin ≥ 2 μg/ml. Arsenic affects the tin response with a similar but negative effect. The mutual arsenic–tin effect depends mainly on the concentration of the interferent and not on the concentration of analyte or the analyte/interferent concentration ratio (see Fig. 5). With 5 ml of sample, the effect of arsenic on the tin signal was the same as for 1 ml, but the effect of tin on the arsenic signal is evident at tin concentrations above 0.03 μg/ml. Mutual effects, not observed with 1 ml of sample, were found for the selenium–tin pair at interferent concentrations higher than 2 μg/ml and for the arsenic–selenium pair at interferent concentrations higher than 5 μg/ml.

Other interferences. Copper was considered as a typical example of an element which strongly interferes in the hydride generation of many elements.[8,11,12]

§Sample volume 5 ml, 0.6*M* HCl. See text for procedure.

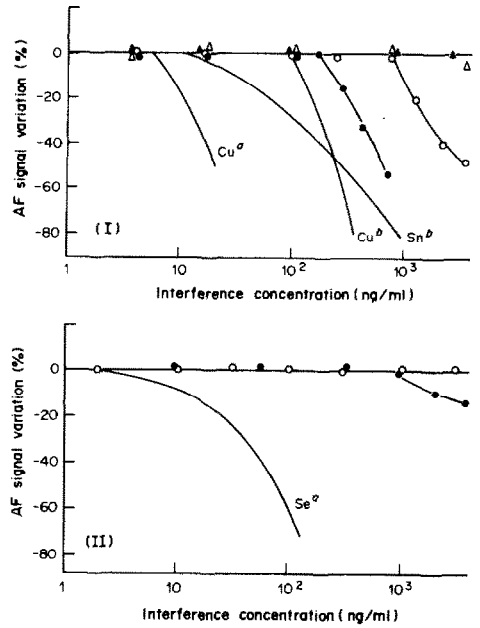

Fig. 6. (I). Interference effects on signal for selenium (5 ng/ml). Effect of copper(II) and tin(IV) as observed in present work: (○) copper, 1 ml of sample; (●) copper, 5 ml of sample; (▲) tin, 1 ml of sample; (△) tin, 5 ml of sample. Curves *a* and *b* refer to the effect of copper and tin on selenium (10 ng/ml) as observed by Welz and Melcher[7] (curve *a*) and Verlinden and Deelstra[12] (curve *b*).

(II). Interference effect of selenium(IV) on signal for arsenic (5 ng/ml) as observed in the present work with 1 ml (○) or 5 ml (●) of sample, and as observed by Welz and Melcher[7] (curve *a*).

With 1 ml of sample, each analyte at the 5-ng/ml level, and the copper concentration varied in the range 0.005–5 μg/ml, no interference with the signals of arsenic, tin and mercury was found. With selenium, copper did not interfere up to 1 μg/ml (Fig. 6). With 5 ml of sample and the same concentration of selenium, copper interfered at concentrations down to 0.2 μg/ml.

The effect of nickel, cobalt and lead (tested in the 0.005–5 μg/ml range) on the selenium signal for 1 ml of sample was then studied. It was found that nickel and cobalt exhibited the same behaviour as copper, whereas lead did not interfere.

Comparison with literature data

The interference effects could be compared with the literature only for arsenic and selenium, for which data obtained under similar experimental conditions were available.[8,11] The difference ih pattern from the literature data was essentially due to differences in the time elapsing between mixing of the reactants and stripping of the volatile hydrides from the cell, and to variation of the sample volume with constant tetrahydroborate volume. The interference threshold shifts towards higher interferent concentrations as the sample volume is decreased. It is the sample volume which is the more likely to play the decisive role. Decreasing the sample volume should increase the

Table 5. Simultaneous determination of As, Se, Sn and Hg in water samples

With 5-ml samples, selenium was found only in the sea-water samples. The relevant concentrations for samples A and B were 0.02 and 0.07 ng/ml respectively.
All samples were filtered through a 0.45-μm filter, acidified to pH 2 with HCl and stored at 4°. Each measurement was repeated five times and the r.s.d. was always less than 10%.
Conditions: as for Table 2.

rapidity of mixing the sample and reagent solutions and give a higher reagent concentration, thus reducing the risk of incomplete analyte hydride formation on account of side-reactions with interferents. In this respect it is interesting that no mutual interference effects between arsenic, selenium and tin were reported in a study of their automatic continuous-flow hydride-generation, even at very high interferent concentrations.[13,14]

Application to water samples

The natural concentration levels[15–21] of mercury and tin in uncontaminated waters being lower than the detection limits, only selenium and arsenic can be determined in such samples without preconcentration. For potable or polluted waters the method can indicate whether the four elements are above or below the allowable limits. Depending on the analyte, the simultaneous determination may give speciation information, or only the total concentration. Under the experimental conditions used, inorganic arsenic and methylarsenic acids are reduced to the corresponding arsines, which give the same analytical response;[17,22] inorganic mercury, methylmercury, ethylmercury and phenylmercury are all reduced to mercury metal;[23] tin(II) and tin(IV) give the same response,[24] but some alkyltins found in natural waters cannot be quantitatively determined, owing to the high boiling point of the alkylstannanes generated by tetrahydroborate reduction.[20,21] Only selenium(IV) reacts with tetrahydroborate to give hydrogen selenide, and is practically the only form present in natural water.[25,26] If the presence of Se(VI) or Se(II) is suspected (as in polluted water) the sample must be chemically pretreated to transform all the selenium species into Se(IV).[27,28] Total selenium and tin must therefore be determined by single-mode procedures.[21,27,28] With the four-channel detector, the determination of arsenic, mercury, selenium and tin (including standard-addition and reagent background correction) requires about 10 min. This significant shortening of operation time allows replicate analysis of the same sample or analysis of a larger number of samples, with a consistent improvement of the statistical meaning of the analytical data. The accuracy of the method was tested by analysis of spiked samples. At the 1–2 ng/ml level the recovery was better than 95% except for selenium in sea-water, for which it was only 85% (Table 5). The relative standard deviation for five replicate measurements was better than 10%.

CONCLUSIONS

Arsenic, selenium, tin and mercury can be determined simultaneously at sub-ng/ml levels by non-dispersive atomic-fluorescence spectrometry combined with the vapour-generation technique with sodium tetrahydroborate as reductant. Sample volumes from 0.2 to 5 ml can be used. The lowest detection limit is obtained with 5 ml of sample for selenium and arsenic and either 1 or 5 ml of sample for mercury and tin. Except for determination of selenium and arsenic at concentrations near the detection limit, 1 ml of sample is to be preferred because the interferences are then minimal. The relative standard deviation is then less than 7% for each of the four analytes within their dynamic ranges and down to 1 ng/ml, regardless of the presence of high concentrations of the other three analytes. The linear dynamic ranges cover more than three orders of magnitude for all four analytes.

SEPARATION AND DETERMINATION OF ARSENIC(V) AND ARSENIC(III) IN SEA-WATER BY SOLVENT EXTRACTION AND ATOMIC-ABSORPTION SPECTROPHOTOMETRY BY THE HYDRIDE-GENERATION TECHNIQUE

SAMUEL A. AMANKWAH and JAMES L. FASCHING*
Department of Chemistry, University of Rhode Island, Kingston, RI 02881, U.S.A.

(*Received* 25 *October* 1983. *Revised* 7 *August* 1984. *Accepted* 14 *September* 1984)

Summary—Arsenic(V) and arsenic(III) in sea-water have been separated by complexing the arsenic(III) with ammonium pyrrolidinedithiocarbamate (APDC) in the range 4.0–4.5 and extracting the complex with chloroform. The organic phase is then wet-ashed with a 1:1 mixture of concentrated nitric acid and perchloric acid to get rid of all organics, and the arsenic(III) is determined by hydride generation and atomic-absorption spectrophotometry. Total arsenic is determined by first reducing arsenic(V) to arsenic(III) with potassium iodide and then applying the method used for arsenic(III). The arsenic(V) content is determined by difference. The low detection limit of 0.031 ng/ml and the high sensitivity and precision make the method suitable for analysis of open ocean waters.

Currently, four basic methods are used for the investigation of arsenic speciation: ion-exchange chromatography,[1–3] differential pulse polarography,[4] selective hydride evolution,[5,6] and solvent extraction followed by flame[7] or graphite-furnace[8] atomic-absorption spectrophotometry or neutron activation.[9]

Although the investigation of arsenic speciation by solvent extraction followed by graphite-furnace/atomic-absorption spectrophotometry gives good sensitivity, interference by trace elements in the sample matrix is a problem and tends to cause unreliable results, as has been observed in our laboratory.

Differential pulse polarography does not give the required detection limit for the determination of arsenic in sea-water.[4] Several attempts by us to repeat the experiments by Aggett and Aspell[5] involving selective hydride evolution did not prove successful.

The problem of interference can be solved by using a method based on solvent extraction, wet-ashing to eliminate organic interferences, and selective determination of arsenic(III) by the hydride-generation technique. Complexation with ammonium pyrrolidinedithiocarbamate (APDC) and extraction into chloroform is the preferred separation step. The optimum pH and reagent concentration, and the accuracy, precision, sensitivity and detection limits of the method have been determined.

EXPERIMENTAL

Apparatus

A Perkin–Elmer Model 403 atomic-absorption spectrophotometer equipped with an electrothermal quartz-cell furnace, a chart-recorder and an arsenic electrodeless discharge lamp powered by an 8-W supply was used for all analyses. The Perkin–Elmer MHS-10 mercury/hydride generation system was connected to the quartz cell through two traps containing calcium chloride to remove water vapour. The carrier gas was argon, and the flow-rate was regulated by a flowmeter. Figure 1 shows the assembly of the system.

The electrothermal quartz cell was 1.7 cm in diameter and 18.8 cm long, with open ends. Graphite sleeves were used for heat dissipation. A sufficient length (about 4 ft) of nichrome wire (diameter 0.0254 in., resistance 1 Ω/ft) was wound round the tube for a temperature of about 900° to be reached by resistance heating. To insulate the tube and maintain uniform temperature distribution round it, the tube was wrapped first with asbestos and then with fibre-glass cloth. Power to the resistance wire was supplied by a variable transformer.

Reagents

All solutions were prepared from analytical grade chemicals. Distilled demineralized water was used for making all solutions.

Standard arsenic(III) solution (1 mg/ml). Prepared by dissolving 1.322 g of primary standard As_2O_3 in 100 ml of alkaline solution.

Standard arsenic(V) solution (1 mg/ml). Prepared by dissolving 4.165 g of $Na_2HAsO_4 \cdot 7H_2O$ and diluting to 1000 ml.

Sodium borohydride solution (5%). Prepared by dissolving 5 g of sodium borohydride powder in 100 ml of demineralized water, followed by addition of 1 pellet of potassium hydroxide. The resulting turbid solution was filtered through a 0.45-μm membrane filter to obtain a clear solution. This solution was prepared once every two weeks, following the procedure of Bye[10] and of Knechtel and Fraser.[11]

Concentrated nitric acid and hydrochloric acid were redistilled in a Pyrex still before use. All cleaned Pyrex glass was assumed to be free from arsenic impurities.[12]

Synthetic sea-water. Prepared by dissolving 254.0 g of NaCl, 105.0 g of $MgCl_2 \cdot 6H_2O$, 39.1 g of Na_2SO_4, 11.0 g of $CaCl_2 \cdot 2H_2O$, 7.2 g of KCl, 2.03 g of $SrCl_2$, 0.27 g of H_3BO_3 and 19.2 g of $NaHCO_3$ in 10 litres of demineralized water.

Ammonium acetate buffer. pH 4.5. Equal volumes of 4*M* sodium acetate and 4*M* acetic acid were mixed.

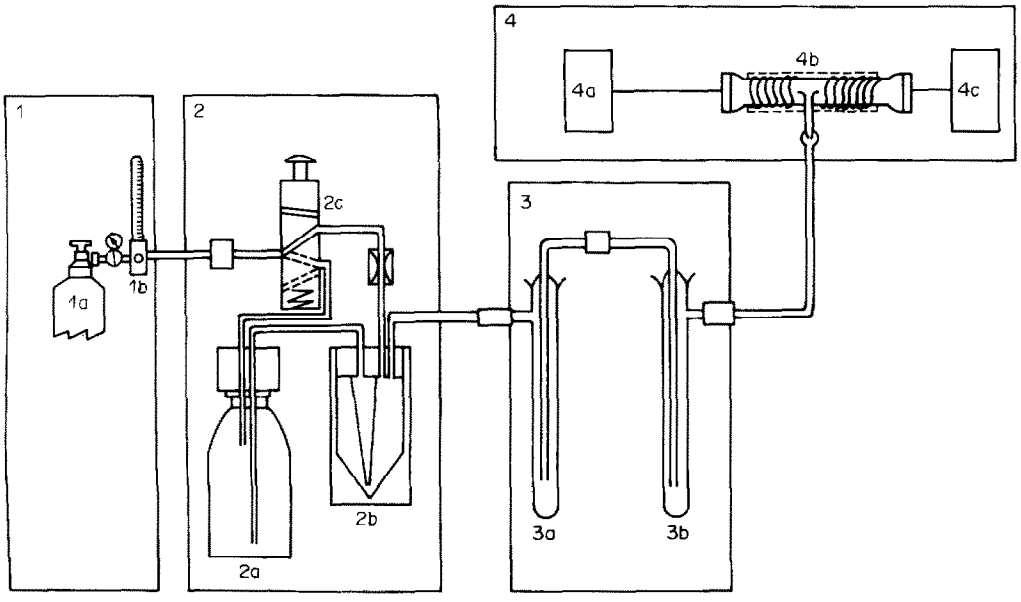

Fig. 1. Perkin–Elmer atomic-absorption spectrophotometric MHS-10 hydride-generation assembly: 1a, argon gas cylinder; 1b, flowmeter; 2, Perkin-Elmer MHS-10, 2a, sodium borohydride container; 2b, reaction vessel; 2c, plunger; 3a & b, contain calcium chloride pellets to remove water vapour; 4, Perkin-Elmer atomic-absorption spectrophotometer 403; 4a, arsenic electrodeless discharge lamp; 4b, electrothermal quartz-cell furnace; 4c, monochromators and detector.

Ammonium acetate buffer, pH 6.1. Concentrated ammonia solution (470 ml) was slowly added to 430 ml of glacial acetic acid, cooled in an ice-bath.

Atomic-absorption standards. Stock standards for lead (996 ppm), iron (1013 ppm), cobalt (998 ppm), zinc (1000 ppm), cadmium (1000 ppm), copper (1000 ppm), mercury (1000 ppm) and nickel (997 ppm) were obtained from Alpha Analytical Laboratories. These solutions were prepared from the chlorides except for the lead, nickel and mercury solutions, which were made from the nitrates. Each stock standard solution was diluted to the desired concentration before use.

Ammonium pyrrolidinedithiocarbamate (APDC) solution (1%). One g of APDC was dissolved in 100 ml of demineralized water, and the solution was filtered through a 0.45-μm membrane filter, then extracted with chloroform to purify it. The purified APDC solution was prepared as needed. The chloroform was used as received.

Procedure

All glassware was cleaned by washing several times with 4*M* nitric acid and then rinsed in demineralized water until the washings were neutral to litmus paper.

The synthetic sea-water was spiked with an appropriate concentration of arsenic(V) and arsenic(III).

Natural sea-water was collected from Narragansett Bay and filtered through a 0.45-μm membrane filter (Millipore) to remove any particulate matter. Analysis of the filter showed no retention of arsenic. The pH was lowered to 2 with hydrochloric acid and the solution stored in a polyethylene bottle (following the recommendation by Robertson[13]). It was assumed that the As(III)/As(V) ratio did not change at the pH value used. To study the two oxidation states of arsenic, a 10-litre sea-water sample (either synthetic or natural) was divided into two equal parts. To one aliquot about 100 g of potassium iodide was added to reduce all arsenic(V) to arsenic(III). The resulting solution was used for the total arsenic determination. The other aliquot was used for arsenic(III) determination.

A 300-ml sea-water (synthetic or natural) sample was placed in a 500-ml separatory funnel and brought to a pH within the range 4.0–4.5 with the ammonium acetate buffers. Ten ml of purified 1% APDC solution were then added, followed by 25 ml of chloroform. The mixture was shaken for 20 min on a horizontal mechanical shaker. After separation of the layers, the chloroform layer was drained into a 150-ml erlenmeyer flask. The aqueous layer was discarded. The chloroform layer was wet-ashed as follows. Ten ml of concentrated nitric acid and 10 ml of 70% perchloric acid were added, with some glass beads to prevent bumping and spattering, and the flask was fitted with a short-stemmed funnel. The mixture was boiled on a hot-plate until dense white fumes of perchloric acid were evolved. The flask was cooled, 10 ml of demineralized water were added, and the evaporation to dense white fumes of perchloric acid was repeated. The solution was then cooled to about 40°, and about 1 g of potassium iodide was added to reduce arsenic(V) to arsenic(III). The solution was made up to volume in a 50-ml standard flask with 1*M* hydrochloric acid. Arsenic(III) was then determined by the hydride-generation technique and atomic-absorption spectrophotometry with 15-ml portions of this solution, and the standard-addition method. The exact experimental procedure followed for the hydride generation procedure was that given in the manual for the Perkin-Elmer MHS-10 Mercury/Hydride system. Synthetic sea-water was used as the blank in all experiments.

RESULTS AND DISCUSSION

Effect of pH

The reaction between arsenic(III) and ammonium pyrrolidinedithiocarbamate is pH-dependent. The complex is extractable into organic solvents. Figure 2 shows the effect of pH on the complexation and extraction in the method developed, and indicates that the optimal pH-range is rather narrow, 4.5–4.6, but the pH range 4.0–4.5 gives adequate precision for the purpose.

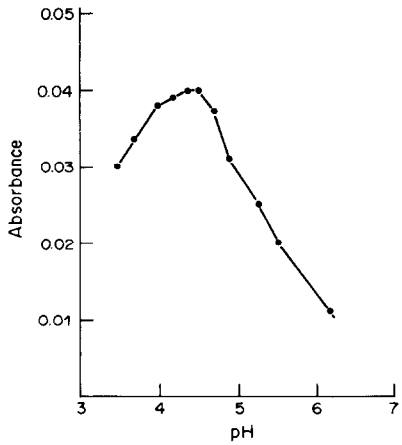

Fig. 2. Absorbance *vs.* pH of sample solution (in APDC preconcentration step).

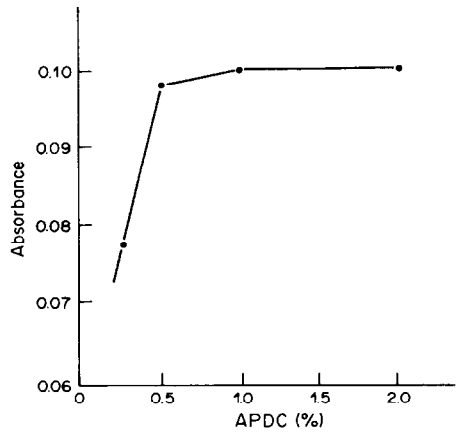

Fig. 3. Absorbance *vs.* APDC concentration.

Dependence of APDC concentration

Figure 3 shows the effect of APDC concentration on the efficiency of extraction of 50 ng of As(III) from 300 ml of synthetic sea-water at the optimum pH of 4.0–4.5. The extraction is constant and maximal when 10 ml of 1–2% APDC solution are used. Use of a 1% solution is recommended.

Sensitivity and detection limit

The sensitivity was obtained from the reciprocal of the mean slope of three graphs (plot of per cent absorption *vs.* concentration in ng/ml). The value of 0.140 ng/ml obtained (s.d. 0.006 ng/ml for triplicate analyses) is comparable to values reported for other methods involving the use of solvent extraction.[14]

The detection limit (D.L.) was determined from the relationship D.L. $= X \pm 3\ \sigma_{bl}$, according to Zief and Mitchell,[15] where X is the average value of ten determinations of the blank and σ_{bl} is the standard deviation.

The detection limit of 0.031 ng/ml (s.d. 0.005 ng/ml, triplicate analyses) is based on use of preconcentration to a volume of 50 ml, from which 10-ml aliquots are taken for the analysis. This value is very low and indicates that the method can be used for sea-water analysis.

Accuracy and precision

Tables 1 and 2 show the results for recovery and precision, obtained by the standard-addition method. Recoveries ranged from 95 to 106%. The precision data were obtained from analyses done on different days and the relative standard deviation of 0.6–0.8% shows the good reproducibility of the method.

Analysis of natural sea-water

The method was applied to the analysis of samples from Narragansett Bay. One sample was analysed on different days to assess the precision, and the results in Table 3 indicate that there was no change in the As(III)/As(V) ratio. The standard deviation for As(III) was the same as that for the synthetic sea-water samples, but that for As(V) was rather higher.

Interferences

Sea-water contains traces of metals such as Cu, Ni, Fe, Pb, Co, Zn, Cd and Hg. APDC forms complexes with all these elements[16] and they are therefore likely to be co-extracted and mineralized along with the arsenic. Severe interference by Cu and Ni in the hydride-generation determination of arsenic has also been reported.[17] The effect of traces of copper and nickel on the arsenic determination was therefore examined, and no interference was found from these species when present at below the 4-μg/ml level (Table 4). Since their concentration in sea-water is normally below 5 μg/ml,[1] they should not interfere in hydride-generation methods for arsenic, though they may be a problem in graphite-furnace analyses. No interference was found from Fe(III), Pb, Co(II), Zn, Cd and Hg(II) at the 1000 μg/ml level.

APDC and pyrrolidine were found to interfere

1000	0.440	0.011

severely at trace levels. Besides being reduced to gaseous products by sodium borohydride, pyrrolidine complexes with arsenic to form an arsenic–amido derivative[18] if the arsenic is stripped from the As–APDC complex with concentrated nitric acid; since this derivative is more soluble in chloroform than in aqueous medium, much of the arsenic would be lost from the aqueous layer before its determination by hydride generation. Wet-ashing was therefore used to eliminate this problem.

CONCLUSIONS

The method has the following advantages. (*a*) The combination of wet–ashing and hydride generation makes the method free from interferences: (*b*) the detection limit of 0.031 ± 0.005 ng/ml is lower than values reported for other methods;[8,19,20] (*c*) twelve samples can be analysed per day, which makes the method economical for routine analysis of sea-water samples.

SPECTROPHOTOMETRIC DETERMINATION OF NITRATE AND NITRITE IN NATURAL WATER AND SEA-WATER

STANLEY J. BAJIC and BRUNO JASELSKIS
Department of Chemistry, Loyola University of Chicago, Chicago, IL 60626, U.S.A.

(*Received* 24 *February* 1984. *Revised* 31 *July* 1984. *Accepted* 14 *September* 1984)

Summary—Nitrate and nitrite in natural waters are determined spectrophotometrically by passage through an amalgamated zinc reductor at pH 3.4 into iron(III)–Ferrozine solution. Interference by high levels of nitrite is eliminated by treatment with azide. Levels as low as 0.2 μg/ml (expressed as nitrogen) can be determined with a precision of $\pm 3\%$.

Because the determination of nitrite and nitrate in natural and waste waters is of ecological importance, numerous analytical methods have been proposed and some are presented as either accepted or tentative methods in the publication of the American Public Health Association.[1] These methods, in general, can be classified as based on use of:

(*i*) direct spectrophotometric measurements in the ultraviolet;[2–6]

(*ii*) specific ion electrodes;[7–9]

(*iii*) spectrophotometric measurement involving use of brucine,[10–12] chromotropic acid,[13] Methylene Blue,[14] 2,4-xylenol,[15–17] or nitron;[1]

(*iv*) reduction of nitrate to nitrite, followed by diazotization and coupling to form a coloured dye;[18–21]

(*v*) reduction of nitrate and nitrite to ammonia.[22–25]

Nitrite in the presence of nitrate is determined spectrophotometrically by a diazotization reaction and formation of an azo dye.[26–28] It can also be determined by electrochemical methods.[29] In a similar manner nitrate can be reduced to nitrite and then determined electrochemically.[30,31] When small amounts of nitrite are accompanied by large amounts of nitrate the nitrite is determined first, then the nitrate is reduced by hydrazine or a cadmium reductor, the total of nitrate plus nitrite is determined, and the nitrate is obtained by difference. However, if there is more nitrite than nitrate, the latter can be determined only after elimination of the nitrite.

In this paper we present a rather simple colorimetric procedure for the determination of nitrate alone and in the presence of nitrite, involving reduction of nitrate and nitrite to hydroxylamine by the zinc amalgam reductor (Jones reductor) at pH 3.4 and reoxidation of the product with iron(III) in the presence of Ferrozine. Large amounts of nitrite are eliminated by a preferential reaction with sodium azide.[32]

EXPERIMENTAL

Apparatus

A Cary 14 spectrophotometer and a Corning Model XII pH-meter were used. The zinc amalgam reductor was prepared by treating analytical grade 20-mesh metallic zinc with acidified mercuric chloride by the procedure described by Kolthoff *et al.*[33] A shortened 50-ml burette was filled with enough amalgamated zinc to produce a 15-cm column. The reductor was copiously washed with water and then with the monochloroacetate–sodium chloride buffer solution. When not in use, the metal in the reductor was always kept covered with water. All glassware was washed with 6*M* hydrochloric acid and demineralized water.

Reagents

All chemicals were analytical or primary standard grade. Ferrozine, 3-(2-pyridyl)-5,6-diphenyl-1,2,4-triazine-*p,p'*-disulphonic acid disodium salt trihydrate (Aldrich), was used as a stock solution prepared by dissolving 2.55 g in 250 ml of demineralized water. An approximately 0.003*M* iron(III) stock solution was prepared by dissolving 0.363 g of reagent-grade ammonium ferric sulphate dodecahydrate in approximately 0.1*M* sulphuric acid and diluting with water to 250 ml. A stock 0.002*M* solution of sodium nitrite was prepared daily by dissolving exactly 69.0 mg of dry sodium nitrite in 500 ml of water; this corresponds to 28 μg/ml as nitrogen. Sodium nitrate solution was prepared by dissolving exactly 85.0 mg of sodium nitrate in 500 ml of water, corresponding to 28 μg/ml as nitrogen. Standard solutions were made by diluting the stock solutions.

A pH-3.2 buffer solution was prepared by dissolving 28.5 g of monochloroacetic acid in 900 ml of demineralized water, adjusting to pH 3.2 with concentrated sodium hydroxide solution, then diluting with water to 1 litre. An eluent solution was prepared by mixing 300 ml of this buffer with 100 ml of 1*M* sodium chloride.

A 0.4% aqueous sodium azide solution was prepared.

Procedures

Determination of nitrate or nitrite alone and in mixtures. Working nitrate and nitrite solutions were prepared by diluting 10 ml of the 0.002*M* stock solutions to 100 ml with demineralized water. Test solutions of nitrate or nitrite, alone or mixed, were prepared by taking from 1.0 to 10 ml of the working solutions and diluting to 100 ml with the eluent solution. The reductor column was prewashed with approximately 35 ml of the solution to be analysed, then filled with the solution, 20 ml of which were passed through

the column at a rate of 24–30 drops/min. Any gas bubbles produced were eliminated by tapping the burette. The eluent was collected in a 25-ml standard flask containing 2 ml of 0.003*M* iron(III) and 1.5 ml of 0.02*M* Ferrozine. The contents were diluted to the mark and the absorbance was measured at 562 nm after 15 min. A blank sample containing neither nitrate nor nitrite was prepared and treated in the same way as the test solution and all absorbance values were corrected for the blank absorbance.

Elimination of nitrite interference by treatment with azide. A sample containing nitrate and nitrite but no eluent buffer was transferred to a 100-ml standard flask. Then approximately 0.5 ml of 0.06*M* sodium azide was added followed by 0.05 ml of 1*M* sulphuric acid. The solution was stirred vigorously for 15 min. Hydrazoic acid was eliminated by passage of nitrogen for approximately 5 min. The solution was then diluted with the eluent buffer solution and analysed as for nitrate alone.

Determination of total nitrate and nitrite in natural waters. Natural or waste-waters were first filtered through a fine filter paper, then a 20-ml portion of the filtrate was transferred into a 25-ml standard flask containing Ferrozine and a small amount of ascorbic acid and buffer solution, to determine the amount of iron present. If the amount was small (commonly the case for Lake Michigan), then this absorbance was used as a blank correction in the nitrate and nitrite determination. Also 80 ml of the filtrate were placed in a 100-ml standard flask and diluted to volume with a buffer containing chloride. However, if the blank absorbance was high, the filtered water was passed through a strong acid cation-exchanger (Dowex 500-10 × 4; sodium form) the first 35 ml being used to precondition the ion-exchanger (and discarded) and the next 80 ml being collected in a 100-ml standard flask and diluted to the mark with the buffer solution containing chloride, and used for analysis. The Jones reductor was preconditioned with approximately 35 ml of the filtered and diluted solution and then a 20-ml portion of the effluent from the reductor was collected in a 25-ml standard flask containing 2 ml of iron(III) solution and 1.50 ml of Ferrozine solution, and diluted to the mark with demineralized water. The absorbance was then measured at 562 nm, and corrected for the reagent and iron blank as described above.

The amount of total nitrate plus nitrite in natural waters was also determined by the standard addition method. Two 80-ml samples of filtered natural water were taken. The first sample was directly diluted with the buffer solution to 100 ml, and 0.500 ml of 0.002*M* sodium nitrate was added to the second sample before the dilution with the buffer solution. Both samples were then passed through the Jones reductor and analysed as described above. The observed absorbances were corrected for the blank values and were used in the calculation of the total amount of nitrate plus nitrite nitrogen present in the original sample.

RESULTS

Synthetic samples containing nitrate and/or nitrite were first analysed for total nitrate plus nitrite and then, after the elimination of nitrite with azide, for nitrate. Results for an average of four determinations are summarized in Table 1. In each case blank absorbance values were determined in the presence and absence of azide.

Natural and synthetic sea-water samples were also analysed for total nitrate plus nitrite: the results are summarized in Table 2.

DISCUSSION

The method is based on hydroxylamine (resulting from initial reduction of nitrate or nitrite) reducing iron(III) to give the intensely coloured iron(II)–Ferrozine complex, the absorbance of which is proportional to the original amount of nitrate (or nitrite). The apparent molar absorptivity in terms of nitrate (or nitrite) is 4.21×10^4 l.mole^{-1}.cm^{-1}.

The reduction of nitrate and nitrite is affected significantly by the pH, as shown in Fig. 1. In the pH range 3.2–3.5 nitrate and nitrite are both reduced primarily to hydroxylamine and to some extent to ammonia. Hydroxylamine, in this determination, is oxidized by iron(III) to nitrous oxide, whereas ammonia is not oxidized. The amount of hydroxylamine produced decreases substantially at pH >4.5 and also at pH <2.7. At high pH, reduction of nitrate in particular is incomplete, and at low pH formation of ammonia is favoured. Thus, the pH must be kept between 3.2 and 3.5 and controlled to within ±0.1. In addition, it is advisable to add sodium chloride. This provides a higher ionic strength and gives more reproducible results.

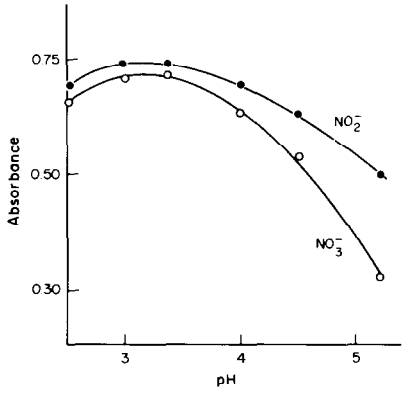

Fig. 1. Absorbance of iron(II)–Ferrozine after the reaction of iron(III) with the reduced products of nitrate and nitrite as a function of pH: nitrate concentration $1.60 \times 10^{-5}M$; nitrite concentration $1.63 \times 10^{-5}M$.

The degree of reduction depends also on the flow-rate through the reductor and on the length of the reductor. More ammonia is produced with a longer column than with a shorter one. Doubling the flow-rate through the reductor decreases the absorbance for nitrate (obtained at pH 3.3) by only approximately 3%. In general, the flow-rate is less critical for the pH range 3.2–3.5 than for higher pH values: between 1 and 1.2 ml/min is satisfactory. At higher pH the flow-rate has a greater effect on the amount of hydroxylamine produced. As shown in Fig. 1, nitrite is reduced somewhat faster than nitrate at pH 4, while in the pH range 3–3.5 nitrate is reduced as readily as nitrite. Also, in the optimum pH-range reduction of nitrate and nitrite is not affected by temperature variations of 20°, indicating that the reduction proceeds exclusively to hydroxylamine.

Nitrate in the presence of large amounts of nitrite is determined after the elimination of the nitrite with azide.[32] This reaction requires the pH to be less than 2.0 and is complete in less than 5 min. The excess of azide is eliminated as hydrazoic acid by passing a stream of nitrogen through the solution. Small amounts of hydrazoic acid remaining in solution do not interfere with the reduction of nitrate. The reduction of nitrite is ensured by adding an approximately 5–10-fold molar excess of azide. It is important, after elimination of hydrazoic acid, to adjust the pH before passing the solution through the reductor. The amount of nitrite is obtained by subtracting the nitrate value from the total amount of nitrate plus nitrite.

Interference by iron can be removed by passing the filtered solution through a cation-exchanger (in sodium form), but small amounts of iron can be tolerated if the sample absorbance is corrected for the absorbance of a blank obtained by running an equal volume of sample solution through the procedure, without reduction with the amalgamated zinc.

This method is particularly suitable for the determination of nitrate in the presence of large amounts of nitrite and of chloride, at levels as low as 0.1 ppm (when 1-cm cells are used) with a relative precision of better than 3%. The synthetic sea-water samples yielded consistently high blank values, which were primarily due to the nitrate impurities in the reagent grade sodium and potassium chlorides used for preparing the samples.

DETERMINATION OF SILVER IN DORE METAL BY WEIGHT TITRATION WITH EQUIVALENCE-POINT DETECTION BY DIFFERENTIAL ELECTROLYTIC POTENTIOMETRY

PABLO COFRE* and GEORGINA COPIA
Facultad de Química, Pontificia Universidad Católica de Chile, Vicuña Mackenna 4860, Santiago, Chile

(*Received* 25 *January* 1984. *Revised* 16 *July* 1984. *Accepted* 14 *September* 1984)

Summary—Use of weight titrimetry, with differential electrolytic potentiometry for detection of the equivalence point, instead of gravimetry, has been critically tested for the determination of silver in doré metal. The electrode response in the presence of possible interferences (Sb, As, Se, Cu, Ni, Fe, Pb and Co) was studied by voltammetry. Titration curves for six different samples were obtained and their differences from those for pure silver were interpreted. Positive errors were found to occur in the presence of 0.1% Fe(III) and Se(IV) but not in the presence of 1% Cu(II). The results obtained by gravimetry and weight titrimetry were compared. The imprecision of the proposed method was between 0.03 and 0.05% (relative standard deviation); that of gravimetry was between 0.05 and 0.08%. The absolute difference from the gravimetric results was between +0.05 and +0.08%. The time for analysis of one sample was between 60 and 80 min.

The doré metal obtained from the anodic sludges produced during the electrolytic refining of copper, obtained from the Chilean copper ore Chuquicamata, has a silver content of about 97–99% plus some other precious metals in small quantities. Its commercial value is mainly determined by its silver content.

The silver is currently determined gravimetrically by precipitation of silver chloride, with a precision of ±0.05%.[1] Although other gravimetric methods[2–4] could be used, all of them are time-consuming. Volumetric titration methods, although faster, do not provide the required precision.

Weight titrimetry[5] appears a possible alternative if a proper method for end-point location is chosen. Photometric, potentiometric and amperometric end-point detection, among others, have been reported,[6–8] but not applied to this system. We have demonstrated recently[9] that the combination of weight titrimetry with end-point location by differential electrolytic potentiometry can be applied successfully to the determination of silver in samples of pure silver and can replace the classical gravimetric method with advantage.

The purpose of the present work was to assess the validity of that method in analysis of doré metal samples, by study of possible interferences and comparison of the results with those of gravimetry.

EXPERIMENTAL

Apparatus

All the equipment used for the voltammetry[10] and weight titrations[9] has been described previously.

Reagents

All chemicals were of analytical reagent grade. Standard solutions were prepared as described by Smith and Parsons.[11] Samples of doré metal (six different batches) were purchased from Codelco-Chile, and spectrographically analysed by Centro de Investigación Minera y Metalurgica (CIMM). The determination of the copper and iron content was done by atomic-absorption spectrophotometry at the Centro de Servicio Externo in our Faculty. The determination of the selenium content was done by neutron-activation analysis at the Comisión Chilena de Energía Nuclear. The composition of the samples is shown in Table 1.

Procedure

Samples of doré metal (1 g for gravimetry and 0.5 g for weight titrimetry) were weighed to ±0.1 mg in 100-ml beakers. They were dissolved by adding 2 ml of nitric acid (1 + 1), covering with a watch-glass and heating on a hot-plate to eliminate nitrogen oxides. The insoluble metallic residue was filtered off with a medium porosity fritted-glass crucible, and washed with distilled water.

For the gravimetric determinations the ASTM E56-63 standard method was then followed.

For the gravimetric titrations, the filtrate and washings were combined in a 100-ml beaker, then concentrated by evaporation on a hot-plate to a final volume of 10–15 ml. Solid barium nitrate (2 g) was added and the solution titrated with standard potassium bromide solution. The concentration of the titrant was adjusted so that about 50 g would be needed for the titration.

The twin silver-electrodes, activated as previously described,[9] were immersed in the sample solution only when the titration was 95–98% complete. The titration was stopped when the first decrease in potential difference was observed.

RESULTS AND DISCUSSION

Voltammetry

The possible interference of the minor elements

§On solutions after sample attack and silver precipitation as AgCl.

present in doré metal, such as Sb, As, Se, Cu, Ni, Fe, Pb, Co, was studied by voltammetry. Results obtained are summarized in Fig. 1. Although all the species tested (except Co^{2+}, Ni^{2+} and Pb^{2+}) showed electrochemical activity, not all of them represent a potential hazard. They give reduction waves at particular electrode potentials, but the question is whether these electrochemical reactions actually occur at the silver electrode during the titration.

In our previous work,[9] we determined the range of electrode potentials of the anode and cathode in the end-point region of the titration. These are shown in Fig. 1 by the vertical dashed lines.

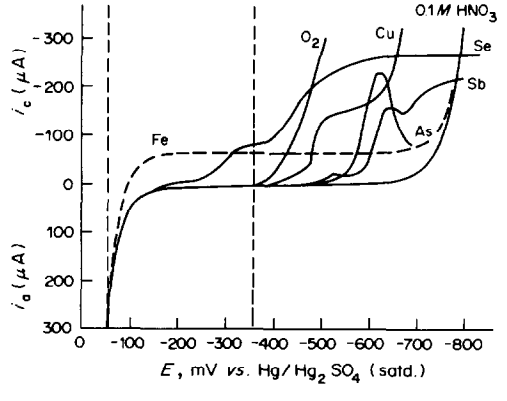

Fig. 1. Voltammetric behaviour of the silver electrode in the presence of different substances. Solution: 50 ml of 0.1*M* HNO_3 + *X* μl of 0.1*M* stock solution, as follows: *X* = 80 for As, Sb, Se; *X* = 100 for Cu, Fe, Ni, Co, Pb. For O_2, the solution was saturated with air.

If the impurities present in the solution are reduced at a potential more negative than −350 mV, there should be no interference with the indicator electrodes. This means there should be no interference by As(III), Sb(III) and Cu(II). Dissolved oxygen does not interfere either.[9]

The presence of Cu(II) has a slight effect on the electrode response well after the end-point, however. Reduction of Cu(II) at the silver cathode is possible, but this is expected to have no effect on the end-point location.

Se(IV) and Fe(III) were found to interfere severely. With both, a clear reduction wave was observed just between the potential limits indicated in Fig. 1. Se(IV) is reduced with consequent depositon of Se on the silver electrode. This is an irreversible reduction which interferes very severely with the electrode response, and the electrode is rapidly fouled.

Fe(III) is easily reduced at the silver cathode, introducing an imbalance between the twin indicator electrodes, which is greater the larger the polarizing current used. Silver ions generated at the anode would not be reduced at the cathode, but Fe(III) would be instead.

Titration curves

The results obtained by voltammetry encouraged us to study the titration curves for six different

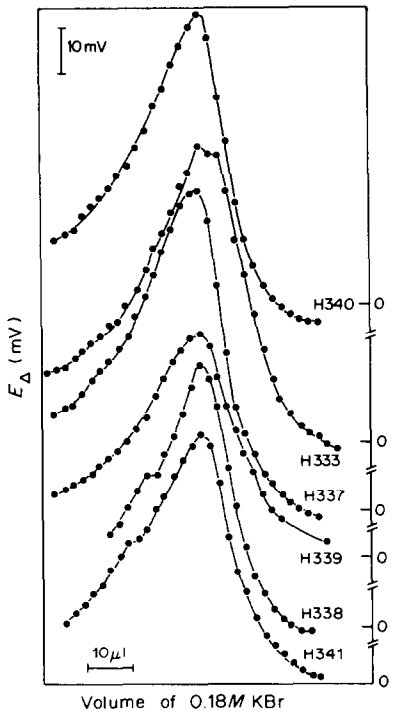

Fig. 2. Titration curves for samples of doré metal. Curves are vertically shifted for convenience. Polarizing current density: 2 μA/cm^2. Electrodes: silver wire, 0.5 cm^2 area.

samples of doré metal. The results obtained are shown in Fig. 2.

Two distinct differences from the curves obtained with pure silver[9] were found. The peaks have a broader base and the potential difference $\Delta E = E_{anode} - E_{cathode}$ becomes negative well after the end-point. Neither effect alters the width at half peak-height, which remains about 25μl, and neither has any influence on the end-point location. The end-point can be determined with the same precision as that for pure silver.[9]

The presence of Cu(II) in the solution was proved to be responsible for ΔE becoming negative after the end-point. Neither effect alters the width at half peak-height, which remains about 25 μl, and neither $Ag + Br^- \rightarrow AgBr + e^-$ would occur at a more negative potential than the cathodic reaction $Cu^{2+} + 2e^- \rightarrow Cu$.

The effect of Fe(III), Se(IV) and Cu(II) on the titration curves was studied separately. Synthetic samples of silver plus 0.1% of iron and selenium and 1% of copper were prepared. A dramatic reduction in peak height with slight positive shift of peak location was observed in the case of Fe(III) and Se(IV). Fortunately these two elements are present only at trace level in doré metal samples (see Table 1), so their effect is not expected to have any real importance. The titration curves shown in Fig. 2 confirm this. Cu(II) in the doré metals tested was always present in amounts large enough for the sample solutions to be pale blue before titration (see Table 1). Fortunately its effect is observed only well after the end-point, as predicted by voltammetry.

Weight titrations

Synthetic samples were first analysed by weight titrimetry in order to determine the effect of interference by Fe(III), Se(IV) and Cu(II). The results obtained, shown in Table 2, are the averages of five determinations (except for pure silver, for which ten determinations were done). It is clear that the presence of Fe and Se introduces only a small positive error when they are present at the 0.1% level (which is high for this type of material: real samples may contain these elements, but only at trace level). Cu(II) is definitely not an interference even at 1% level.

These results encouraged us to analyse real samples. We made ten determinations of silver by gravimetry and ten by weight titrimetry, on each of the six different samples of doré metal, in order to assess the reproducibility and accuracy of the proposed method. From the results, which are summarized in Table 3, we can conclude that the proposed method can be at least as good as gravimetry.

Five determinations were performed on each sample by two analysts, as indicated. There was a clear difference between the titrimetric and gravimetric results obtained by each analyst. Analyst A obtained a closer agreement than analyst B. If an F-test is applied to the sets of results produced by analyst A and B separately, the dispersion of results obtained by analyst B shows no significant difference between the two methods for the six samples analysed. However, the dispersion of the results obtained by analyst A shows a significant difference at the 95% confidence level for three of the six samples analysed (H337, H338, H340). If the whole set of ten determinations is considered, an F-test shows a significant difference between the two methods for three of the six samples analysed (this time H337, H339, H340). Nevertheless, it is clear that the dispersion of results obtained in our laboratory is less for the proposed method than for the classical gravimetry.

*Set of five samples analysed by each analyst.
†Values for the whole set of ten samples.

If results given by gravimetry are accepted as correct and no previous calibration with reference material is used, the error of the proposed method is indicated in Table 3 as $\Delta\bar{X}$. Values are shown for both analysts separately and for the whole set of ten determinations. There is a clear positive error of 0.05–0.08% with the proposed method, because the end-point location requires a certain degree of overtitration. If a drop of titrant typically weighs 5 mg, and 50 g of titrant are needed, overtitration by one drop means an error of +0.01%. The higher results obtained by analyst B suggest a higher degree of overtitration. On the other hand the gravimetric results obtained by analyst B show a trend towards lower results. These two effects result in analyst A getting better agreement between the two methods than analyst B, but an F-test shows that analyst B's results should be more reliable than those of analyst A.

The only difficulty found with the proposed method was the need to introduce the indicator electrodes only when the titration is 95–98% complete. Otherwise they become coated with precipitate, which interferes with the electrode response. This degree of titration is easily judged by an experienced analyst from the amount of precipitate or turbidity observed after each titrant addition (made without stirring).

Another problem was the presence of insoluble metal residues from samples of doré metal. We tried to perform the titration with the residue present, but potential spikes developed each time a metallic particle struck the silver-wire electrodes (contact potentials). Although the titration was still possible if very gentle stirring was used, mixing of the solution was not good when a large quantity of precipitate was present. That is why we decided to filter the solutions and then concentrate them by evaporation, but these additional operations can increase the time for analysis of a single sample by 30–50 min, depending on the degree of dilution caused by washing the filter.

Finally, we mentioned in the previous paper[9] the possibility of automation. We now have to add, that anticipation of the end-point, which is needed for an automatic titration, can easily be achieved with this technique. All we have to do is to increase the polarizing current density by a factor of ten. The titration curves will broaden and fast addition of titrant be possible until the end-point region is reached. The titration can then be completed by decreasing the polarizing current density to the recommended value of 2 μA/cm^2. This implies that the problem of the electrode becoming covered with precipitate has to be solved in a different way, so that the twin silver electrodes can be introduced into the solution from the start.

A SIMPLE THERMOMETRIC TECHNIQUE FOR REACTION-RATE DETERMINATION OF INORGANIC SPECIES, BASED ON THE IODIDE-CATALYSED CERIUM(IV)–ARSENIC(III) REACTION

F. GRASES, R. FORTEZA, J. G. MARCH and V. CERDA
Department of Analytical Chemistry, Faculty of Sciences, University of Palma de Mallorca, Spain

(*Received* 20 *December* 1983. *Revised* 30 *May* 1984. *Accepted* 14 *September* 1984)

Summary—A very simple reaction-rate thermometric technique is used for determination of iodide (5–20 ng/ml), based on its catalytic action on the cerium(IV)–arsenic(III) reaction, and for determination of mercury(II) (1.5–10 ng/ml) and silver(I) (2–10 ng/ml), based on their inhibitory effect on this reaction. The reaction is followed by measuring the rate of temperature increase. The method suffers from very few interferences and is applied to determination of iodide in biological and inorganic samples, and Hg(II) and Ag(I) in pharmaceutical products.

A common method for determination of traces of iodide is based on its catalysis of the redox reaction between cerium(IV) and arsenic(III), first studied in detail by Sandell and Kolthoff.[1,2]

The reaction has been applied to the determination of iodide in waters[3–7] and thyroid hormones,[8–10] and of inhibitors of the reaction, such as mercury and silver.[11,12] Osmium[12,13] and ruthenium[14] also catalyse the reaction and have been similarly determined. The reaction has been used as an indicator reaction in catalytic titrations.[15–19] The end-point can be detected spectrophotometrically, potentiometrically,[16,20] biamperometrically,[21] or thermometrically.[19] A flow enthalpimeter has been used to determine 0.01–10 μM iodide by measurement of the temperature rise in the Ce(IV)–As(III) system.[22,23] In the sense that the heat "pulse" detected by this method is the integral of the heat generated by the catalytic reaction in a specific time (determined by the flow characteristics) these were kinetics determinations, and in principle an initial-rate method was used. So far, however, measurements of the reaction rate do not seem to have been used as the determination technique. Generally, the principal advantages of reaction-rate methods (particularly the initial-rate method) are speed and precision. Very few examples of the use of calorimetry in reaction-rate methods for determination of inorganic species have been reported[24–26] and the method has been mainly used in biochemical analysis.[27,28]

EXPERIMENTAL

Reagents

Stock solutions included 0.1 M ceric ammonium sulphate in 1 M sulphuric acid, 0.1 M sodium arsenite in 1 M sulphuric acid, potassium iodide solution (iodide 0.983 g/l.), mercuric nitrate solution (mercury 0.972 g/l.) and silver nitrate solution (silver 0.960 g/l.).

Apparatus

The temperature-monitoring system consisted of a rapid-response thermistor, a Wheatstone bridge, and a recorder (Goerz, Servogor RE 511) (Fig. 1). The thermistor was sealed in glass and has a resistance of 100 kΩ at 25°. The e.m.f. for the Wheatstone bridge was supplied from a 7.85-V stabilized source. At the sensitivity setting used, the thermistor bridge yielded a temperature response of 60.6 mV/deg and full-scale deflection on the recorder was 2 mV (20 cm). This temperature-monitoring system is part of a thermometric titrator built according to the design of Lumbiarres *et al.*[29] An adiabatic cell (Fig. 1) was used. The solution in the cell was stirred with a magnetic stirrer. Rigid temperature control is essential.

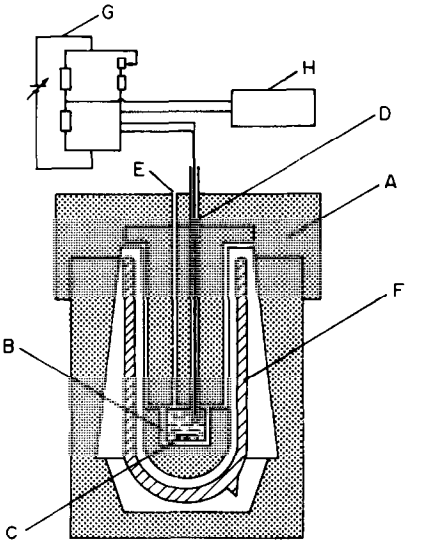

Fig. 1. Diagram of circuitry and apparatus used in reaction-rate thermometric analysis. A, polystyrene insulators; B, plastic beaker; C, magnetic stirrer; D, thermistor; E, Hole for pipette F, Dewar flask; G, Wheatstone bridge; H, recorder.

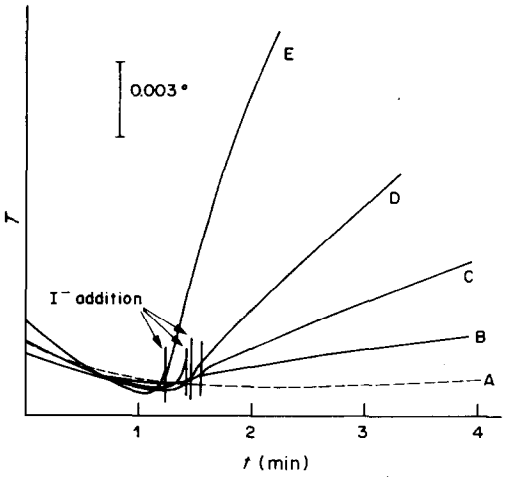

Fig. 2. Temperature–time curves for (A) 0, (B) 5, (C) 10, (D) 14 and (E) 20 ng/ml of iodide The recommended procedure was used.

Procedure

For iodide determination the following were placed in the cell compartment: 10 ml of 0.1*M* ceric sulphate, 10 ml of 0.1*M* sodium arsenite and enough sulphuric acid to give a concentration of 1*M* and a final volume of 50 ml. The recorder (chart speed 3 cm/min) was switched on. When the temperature–time curve was horizontal, the necessary volume of sample to give a final iodide concentration between 5 and 20 ng/ml was added. From the resulting curve, the rate of reaction was calculated by the initial-rate (tangent) method. All solutions were brought to 22° beforehand, in a thermostat.

To determine mercury(II) or silver, the same procedure was used, except that a suitable amount of the cation (75–500 ng for mercury, 100–500 ng for silver) was introduced before the sulphuric acid, and finally 1 μg of iodide was added.

RESULTS AND DISCUSSION

Examples of the temperature–time curves for determination of iodide are shown in Fig. 2. The slope of the curve should correspond to the temperature change due to catalytic reaction. To obtain rapid stabilization (horizontal temperature–time curves) before the addition of the iodide, all solutions must be brought to the same temperature (which must be the room temperature, so it is convenient to keep this as constant as possible). It has been found that the rate of initial thermal stabilization is remarkably favoured by eliminating the free air space above the solution in the inner part of the adiabatic cell (Fig. 1).

Minimal background is attained in the temperature–time curves by efficient stirring, and precise control of this variable is important.

Effect of reaction conditions

To optimize the conditions for determination of iodide, the effect of the sulphuric acid, arsenite and ceric sulphate concentrations on the reaction rate was studied (Figs. 3 and 4). The optimum concentrations are those at which the initial rate is maximal and the relative standard deviation minimal. These will be the concentrations at which the order of reaction with respect to these variables is as near zero as possible, since small variations in the concentrations will not affect the initial reaction rate. For this reason a sulphuric acid concentration of 1*M* and ceric sulphate and arsenite concentrations of 0.02*M* are considered optimum.

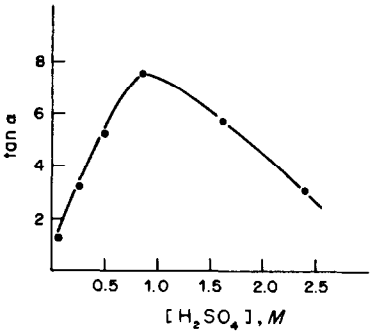

Fig. 3. Effect of sulphuric acid concentration on the initial rate: $[Ce(IV)] = 1 \times 10^{-2}M$, $[As(III)] = 1 \times 10^{-2}M$, $[I^-] = 70$ ng/ml.

Under these conditions, there was a linear relationship between the logarithm of the initial reaction rate and the iodide concentration in the range 5–20 ng/ml in the final solution. The reaction order for iodide, obtained from the corresponding logarithmic plot, was 3 ($v_0 = k[I^-]^3$ for $3.9 \times 10^{-8}M < [I^-] < 1.6 \times 10^{-7}M$).

Characteristics of the iodide determination

Owing to the shape of the temperature–time curves the initial-rate method was the only one applied for preparing the semi-logarithmic calibration graph (Fig. 5). The relative standard deviation was 1.1% ($n = 11, \alpha = 0.05$).

The selectivity has been examined, and the results in Table 1 show there are few interferences.

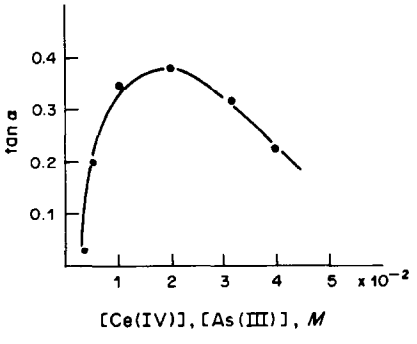

Fig. 4. Effect of As(III)–Ce(IV) concentrations on the initial rate: $[H_2SO_4] = 1M$, $[I^-] = 10$ ng/ml.

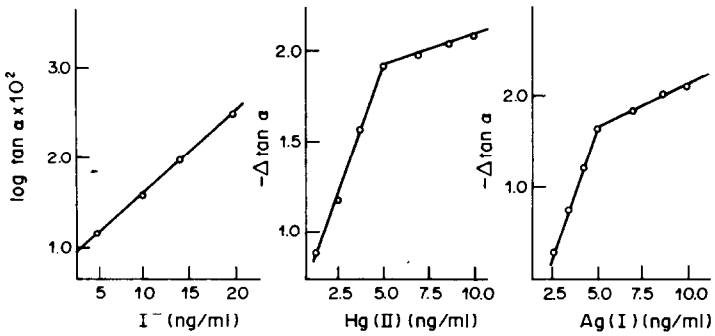

Fig. 5. Calibration graphs for I^-, Hg(II) and Ag(I).

Determination of mercury and silver

The inhibitory effect of mercury(II) and silver on the iodide catalysis of Ce(IV)/As(III) system has been used to develop reaction-rate methods for the determination of these cations. A fixed iodide concentration is used and the decrease in initial reaction-rate, caused by the presence of the inhibitor, is measured. As shown by Fig. 5, with an iodide concentration of 20 ng/ml the calibration graph is steep and linear for 1.5–10 ng/ml mercury and 2–10 ng/ml silver concentrations. The relative standard deviation for the 5-ng/ml level ($n = 11$, $\alpha = 0.05$) was 1.3% for mercury and 1.5% for silver.

Applications

To test the applicability of the proposed methods, they were applied to the determination of iodide in urine, sea-water and analytical-reagent grade sodium chloride, and of mercury(II) and silver in pharmaceutical products. In all instances, the standard-addition method was employed. The recovery was calculated by comparing the results obtained before and after the standard additions.

Iodide in urine was determined both before and after mineralization of the sample. The value obtained without mineralization was 7.0 μg/ml. To destroy organic matter and liberate the organically bound iodine the sample was evaporated to dryness on a hot-plate after addition of sodium carbonate, and then heated for 3 hr at 600° in a muffle furnace.[30] The cooled residue was dissolved in a minimum of 2*M* hydrochloric acid and diluted with water to the original sample volume. The value obtained was 13.6 μg/ml. These results were compared with those obtained by Acland's spectrophotometric method,[31] which uses As(III) and Ce(IV) as reagents and gave a value of 12.1 μg/ml for total iodide.

Iodide in sea-water was determined without previous treatment of the sample. The value obtained was 0.10 μg/ml. That found by the Acland method was 0.12 μg/ml.

The sodium chloride sample was dissolved in distilled water and the iodide determined. The value obtained was 0.0015% (reported maximum value, 0.0020% I^-).

Mercury was determined in a commercial pharmaceutical product (Resorpil, Reig Jofre) after dilution of the product with distilled water. The value obtained was 149 μg/ml (reported value, 150 μg/ml).

Silver was similarly determined in a commercial pharmaceutical product (Argentofenol, Bucca). The value found was 12.6% (reported value 12.7%).

Table 1. Concentrations of foreign ions tolerated (error ≤ 1.1%) for 20 ng/ml iodide

Ion added	Amount tolerated
Ca(II), Mg(II), Sr(II), Ba(II), Cd(II), Sn(II), Mo(VI), Co(II), Cu(II), Bi(III), V(V), Cr(III), Ni(II), Zn(II), Sb(III), Pb(II), Al(III), Cl^-, F^-, Br^-, CN^-, PO_4^{3-}, AcO^-, SCN^-	20* μg/ml
Mn(II)	2† μg/ml
Fe(III)	2§ μg/ml
IO_3^-	0.2† μg/ml
Hg(II)	1§ ng/ml
Ag(I)	1.5§ ng/ml

*Largest amount examined.
†Higher concentrations increase the initial rate.
§Higher concentrations decrease the initial rate.

DETERMINATION OF SIMPLE AND COMPLEX IODIDES WITH FERRIC CHLORIDE—AN ALTERNATIVE TO THE ANDREWS TITRATION

M. CARTWRIGHT and A. A. WOOLF
School of Chemistry, University of Bath, Bath, England

(*Received* 18 *May* 1984. *Accepted* 2 *August* 1984)

Summary—The iodide content of simple and complex iodides can be extracted as iodine after dissolution of the sample with acidified ferric chloride solution. Most iodides can thus be decomposed in 3*M* hydrochloric acid medium. A suitable extraction flask is described. Information on the cation oxidation state can be obtained by titrating the released ferrous ions *in situ*. A precision of 0.2% for 1–5 mmoles of iodide is attainable.

During an investigation into the electrical properties of some simple and complex iodides we needed to confirm their stoichiometry and hence required a reasonably precise and widely applicable analytical method. The Andrews titrimetric method[1] was only partly suitable. The strongly acid conditions help to dissolve water-insoluble iodides, but the method becomes non-specific when the complex contains a cation that is oxidizable with iodate under the conditions used. We have therefore developed an alternative and specific method based on use of acidic ferric chloride solution as oxidant, followed by solvent extraction of the iodine formed. The iron(II) content of the extracted solution can also provide information on any cation oxidation.

EXPERIMENTAL

Apparatus

A standard (250-ml, B24 ground-glass neck) conical flask is modified by attaching a glass stopcock to the bottom (Fig. 1). A PTFE key is not recommended, because it obscures the phase interface during separation. (In effect the tap of a conical separating funnel is being shifted from the apex to the base and the funnel inverted.)

Reagents

$FeCl_3$ (0.1M). Dissolve 27 g of $FeCl_3 \cdot 6H_2O$ in the volume of concentrated hydrochloric acid corresponding to the acid molarity required, and dilute to 1 litre.

$Na_2S_2O_3$ (0.05M). Prepared by weight.[2]

$K_2Cr_2O_7$ (0.02M). Prepared by weight.

Extractants. Benzene–carbon tetrachloride, 60/40 v/v, and 50/50 v/v, or pure carbon tetrachloride.

Samples

Iodides not readily available were prepared from the elements or by precipitation. SnI_4 and AsI_3 were recrystallized from purified chloroform and vacuum-dried. SnI_2 and TiI_4 were purified by vacuum sublimation.

Procedure

By means of a long weighing tube (Fig. 1), place at the bottom of the extraction flask an amount of the solid iodide corresponding to not more than 5 mmoles of iodide. (If other oxidizable species are present, reduce the quantity correspondingly, *e.g.*, for SnI_2 the maximum quantity is 1.25 mmoles of SnI_2). Add 50 ml of 0.1*M* ferric chloride solution, stopper the flask and stir the mixture magnetically until the solid has dissolved and the iodine been liberated. Then add 25 ml of solvent and extract the iodine by moderate stirring. At this stage add a few drops of a dilute detergent solution to detach any solvent floating at the water–air interface and to enable water in the side-tube to be easily displaced. Hold a magnet under the flask to keep the internal magnet in place when the flask is tilted to fill the side-tube with the organic phase. Remove the stopper and run the lower organic layer into another conical flask containing about 50 ml of water. (The organic liquid in the capillary can be almost completely displaced, and the liquid remaining in the capillary runs back into the flask when that is uprighted.) Wash the capillary through with water before closing the tap. Perform three further extractions in the same way with 25-ml portions of solvent. Titrate the combined extracts with thiosulphate (starch as indicator) after adding some potassium iodide to help back-extraction. Titrate the

iron(II) in the original flask with potassium dichromate after diluting to a hydrochloric acid concentration of about 1.5*M*.

RESULTS AND DISCUSSION

Distribution ratios, defined as the ratio of concentration of iodine extracted into the organic phase to concentration of residual iodine in the aqueous phase, were measured after each extraction in a few experiments. The solubility of iodine in hydrochloric acid, and in acidic metal chloride solutions, after equilibration for three days, was determined by taking weight aliquots of the filtrates, diluting with an equal volume of water and titrating with thiosulphate.

Some results are collected in Tables 1 and 2. For those in Table 1 the thiosulphate and dichromate titrations are equivalent since the cation in the salt is not oxidized. A direct comparison with conventional silver iodide gravimetry is possible with these water-soluble iodides.

The iodides in Table 2 are insoluble in water and some of the cations are oxidizable. Thus with a mole of $CuTiI_4$, four moles of Fe(II) arise from I^- oxidation, and two moles from the Cu(I)→Cu(II) and Ti(III)→Ti(IV) oxidations. The silver iodide estimation is included merely to show that even the extremely insoluble iodides can be handled at high acidities.

The relative efficiency of different extractants was examined. One consideration was that the efficiency of mixing of the phases with gentle stirring should be enhanced by minimizing the density difference between the phases. Another consideration was to increase the distribution ratio by changing the solvents. Mixtures of benzene and carbon tetrachloride

which had a density about 0.1 g/ml greater than that of the hydrochloric acid phase were chosen and these were more efficient than carbon tetrachloride alone in the first three partitions. Because four partitions were needed to complete the extraction there was no preference for use of the mixed solvent, except for mercuric iodide, for which more than four extractions were required if carbon tetrachloride was used alone.

Although not all iodides were examined, the scope of the method can be predicted from the general principles of periodicity. The iodides can be divided into three classes for analytical purposes. The water-soluble ionic iodides of Groups I, II and IIIB, which exist as the metal iodide or monomeric complexes such as MI^+, will behave like potassium or cadmium iodide. In these instances there is no advantage over the argentimetric or oxidimetric methods apart from specificity. A second class of more or less covalent iodides (*e.g.*, TiI_4, TiI_3, AsI_3, SnI_4, SnI_2) hydrolyses to give hydriodic acid and for this class, which covers Groups II-IV of the non-transition elements as well as transition elements from d^2 to about d^7, the ferric chloride method has definite advantages. First it can provide additional information on the oxidation states of the elements, and secondly it is possible to keep the iodides in solution with hydrochloric acid but not necessarily with the oxy-acids required in other methods. The water-insoluble iodides formed by some d^8 and d^9 transition metals constitute the third class of iodides. Apart from PdI_2 and AgI, which are the standard weighing forms anyway, these can be estimated conveniently by the ferric chloride method, though the difficulty increases with decrease in the solubility of the iodide. The method could obviously be extended to small quantities of iodides although the extractions would become more difficult as the Cl^-/I_2 ratio increased (see later discussion).

The combination of a suitable redox couple with a selective solvent extraction provides a general method specific for iodide. Previous methods used ferric chloride in sulphuric acid as the oxidant, followed by a steam distillation of the iodine,[3] or a stronger oxidant such as MnO_4^-, $Cr_2O_7^{2-}$, or MnO_2 followed by extraction of the liberated iodine into chloroform.[4] Insufficient details were given for the applications or accuracy of the methods to be assessed.

The basis of the method described is the selective oxidation of iodide by the ferric ion. The small difference in redox potential for the two reactions

$$Fe^{+3} + e \rightarrow Fe^{2+} \quad 0.77\ V$$

$$\tfrac{1}{2}I_2 + e \rightarrow I^- \quad 0.53\ V$$

gives an equilibrium constant of *ca.* 10^4 for the reaction

$$Fe^{3+} + I^- = Fe^{2+} + \tfrac{1}{2}I_2$$

†By direct titration of diluted aqueous solution.
§By extraction into organic solvent before titration.

which means that the reaction is only about 99% complete unless the equilibrium is shifted to the right. When used for determination of ferric ion the reaction is brought to completion by making the iodide to iodine ratio large by use of a large excess of iodide and the removal of the liberated iodine by the titration with thiosulphate. In our method the equilibrium is shifted towards complete reaction by repeated extraction of the iodine into an organic phase. Solvent extraction prevents interference by some other species, such as sulphides, oxidized by the ferric ion. The decrease in redox potential for the iron(III)/iron(II) system by ferric ion complexing agents such as fluoride or EDTA is overcome by increasing the ferric chloride concentration.

Hydrochloric acid plays a key role in the method. It prevents hydrolysis of ferric chloride, increases the rate of dissolution of the less soluble iodides (Tables 2 and 3) and increases the solubility of iodine in aqueous media (Table 4), which prevents separation of solid iodine and loss by sublimation.

The solubility of iodine in 3*M* hydrochloric acid is about 6 times that in water, probably because of the formation of I_2Cl^-. The occurrence of this species can be inferred from previous analytical experience. Thus the solvent extraction of micro-amounts of iodine is inhibited by chlorides but not by sulphates,[5] iodine is retained on anion-exchange resins in the chloride form,[6] and the solubility of iodine in water goes through a maximum on addition of magnesium chloride.[7]

The di-iodochloride anion has been isolated in the salt $N(CH_3)_4^+ \cdot I_2Cl^-$, which slowly loses iodine at room temperature and rapidly disproportionates into the more stable ICl_2^- and I_3^- ions in acetonitrile solution.[8] The structure of I_2Cl^- is not known but is likely to resemble that of the I_2Br^- ion, in which the I–I and I–Br bonds are longer and weaker than in iodine or iodine bromide.

The formation constant for $I_2 + Cl^- \rightleftharpoons I_2Cl^-$ is likely to be of the same order as that of Br_2Cl^- (1.14) and much less than that of I_3^- (740 at 25°).[9] Hence it is understandable that the solubility of iodine increases with hydrochloric acid concentration, as the equilibrium is moved to the right. The decrease in distribution ratio as iodine is extracted also illustrates the effect of mass action as the Cl^-/I_2 ratio increases (Table 3). This would lead to more of the residual iodine being present as the complex ion in solution and to greater difficulty in extracting the whole of the iodine.

The metal ion can also affect the solubility and extractability of iodine and this is particularly noticeable for zinc, cadmium and mercury(II) (Table 4). For these chlorides the effects vary from an appreciable salting-out effect with zinc chloride to the large increase with mercuric chloride, which corresponds to an uptake of one I_2 molecule per 20 Hg^{2+} ions. It is possible that these effects are determined by the ternary metal–iodine–chloride interactions rather than the simple binary metal–halogen ones. Thus mercuric chloride, which in hydrochloric acid is predominantly complexed as $HgCl_3^-$ and $HgCl_4^{2-}$, could produce ions such as $[Cl_3HgCl \ldots I \ldots I]^{2-}$ or $[Cl_3Hg\,I \ldots I \ldots Cl]^{2-}$ in the presence of iodine. It is interesting to note that iodine can be extracted from mercuric chloride solutions in 3*M* hydrochloric acid but not from mercuric iodide solutions at the same acidity. In the latter solution formation of the most stable adduct[10] $[Cl_3Hg \ldots I \ldots I \ldots I]^{2-}$ could prevent oxidation and extraction (in view of the greater stability of I_3^- compared to that of I_2Cl^-).

EFFECT OF ORGANIC COLLOIDS ON ASV SIGNALS OF Cd, Pb AND Cu

T. UGAPO and W. F. PICKERING
Department of Chemistry, University of Newcastle, N.S.W. 2308, Australia

(*Received* 10 *April* 1984. *Accepted* 14 *September* 1984)

Summary—The effect of organic colloids, such as humic and fulvic acids, on the ASV signals of Cd, Pb and Cu in acetate-buffer media has been investigated. Owing to their ability to adsorb metal ions, or form complexes (some sparingly soluble), the presence of the organic acids caused the magnitude of the signal peaks to decrease, the effect increasing with increase in organic acid:metal-ion ratio, and pH (from 5 to 8). Analysis before and after filtration through a 0.45-μm membrane indicated that most of the Cd retained was labile; in the Pb and Cu system less than half of the sorbed metal ion was labile, though a further fraction was displaced in the presence of Chelex 100 resin. The magnitude of the interference effect varied with the molarity of the medium and the presence of diverse anions (*e.g.*, chloride, bromide) in the system. Cu displayed the most anomalous behaviour, with the stripping peak tending to broaden and split, particularly in the presence of humic acids. This behaviour was enhanced when the contact time with the preformed Hg film before the deposition/stripping cycle was increased above 5–10 min. This effect has been attributed to reduction (and subsequent oxidation) of Cu–humate species adsorbed on the mercury film.

Colloidal particles are believed to play an important role in the movement and distribution of metal ions within an ecosystem.[1] Transport in streams is accompanied by redistribution between the aqueous and mobile solid phases, whilst flocculation of particulates (*e.g.*, in estuaries) promotes incorporation of the metals into the base sediments. Clarification of this role has been hindered, however, by the complexity of natural systems and limited understanding of many of the chemical equilibria involved.

Combination of anodic-stripping voltammetry with selective preliminary steps (such as membrane filtration, passage through a Chelex column and destruction of organic complexes) has been used to subdivide the metal-ion content of waters into several different categories, and it has been demonstrated, *inter alia*, that a significant fraction can be associated with colloidal organic matter.[2–7]

There are differing views, however, on the effect of organic compounds on ASV signals. For example, the addition of "fresh water" humic acid concentrate to synthetic sea-water was observed[8] to cause both enhancement and suppression of individual metal ion peaks (depending on the pH of the system) but there were no significant changes in the peak positions. With a different base electrolyte at pH 6.8, addition of humic acid was found to alter both peak height and position.[9] The size, shape and position of Cu, Pb and Cd peaks has been shown[8–13] to be sensitive to the presence of a wide range of organic species (including surfactants), and as with the humic acids, the changes induced tend to be random in nature.

The lability of metal ions associated with organic species has not been clearly resolved. This situation is complicated by the fact that bonding modes (*e.g.*, with humic acids) tend to vary with pH, relative concentrations and type of functional groups involved.[15,16] Extraction studies[17] indicate that a high proportion of the sorbed material is ion-exchangeable, and accordingly may be labile in ASV. The acid-soluble, lower molecular-weight, companion species, fulvic acid, is considered to form soluble metal complexes. The conditional formation constants reported vary with pH and the material used,[18–24] and under some conditions, sparingly soluble species have been isolated.[25,26] The apparent stabilities of the complexes formed when metal ions are added to natural waters are often similar to those quoted for metal fulvate complexes.[1]

In an attempt to provide additional basic information, the effect of both humic and fulvic acids on the ASV signals of Cd, Pb and Cu has been re-examined.

EXPERIMENTAL

Apparatus

An ESA Anodic Stripping Analyzer Model 2014, and a Rikandenki fast-response recorder (Model B-181 H) were used. Each of the four operating cells contained a wax-saturated graphite rod (precoated with a thin mercury film), a platinum counter-electrode and an Ag/AgCl reference electrode (S.R.E.) separated from the 5 ml of test solution by a porous Vicor® sheath. As the cell geometries differed slightly, all comparison studies were based on single-cell operation. A nitrogen flow (monitored by an in-line ball flowmeter) was used to remove dissolved oxygen and stir each test solution.

At the end of each working week, the existing thin mercury film was removed by gently stroking the polished electrode tip with the dampened edge of a tissue towel. A new film was then deposited overnight from a non-stirred solution containing 4 μmoles of mercury(II) chloride, at a cathode potential of -500 mV *vs.* the S.R.E. The electrode tips had geometric surface areas of 4.1 cm^2, hence this procedure yielded films having an average thickness of

around 145 nm. To compensate for mercury lost during the analytical sequences, at the end of each working day the film was augmented by plating out the metal present in 5.0 ml of $3.2 \times 10^{-4}M$ mercury(II) chloride. Control samples, run as part of each analytical sequence for comparison purposes, yielded Cd and Pb peaks which varied only marginally in size (4–5% R.S.D.) over the working week.

For a mixture containing 100 μg/l. each of Cd, Pb and Cu, the precision of five successive ASV scans was normally $<2\%$ R.S.D. for Cd and Pb and $<6\%$ R.S.D. for Cu. The poor reproducibility for Cu arose because the peak increased with each successive analytical cycle, a pattern of behaviour noted in other ASV studies.

Base solutions and particulates

Acidified 100-μg/ml stock solutions of metal ions (Cu, Cd, Pb) were prepared from the analytical grade salts, and diluted as required with demineralized water.

The base electrolyte used in most studies was $1M$ sodium acetate, adjusted to pH 5 by addition of acid. Metal ion impurities in this solution were reduced to a minimum by using an electrolytic reagent-cleaning system (ESA Model 2014P). In other study sequences, the pH of the base electrolyte was adjusted to 6.35 or 8.0, or the concentration was varied between 0.05 and $0.7M$. In other cases, salts (NaCl, NaF, KBr or K_2CO_3) were added at the $0.2M$ level. For comparison purposes, some studies were also made with sodium citrate as the base electrolyte.

The organic acid particles which were added to the test solutions varied in type from pure salicylic acid to technical grade "natural" products. The humic acids marketed by Fluka AG (HAI) and Aldrich (HAII) were widely studied. Both contained traces of Cu and Pb (corrected for by blank subtraction) and required pH > 8 for dissolution. At pH 5, the reported[14] sorptive capacities (mole/kg) are Cd^{2+}, 0.5 (0.25); Cu^{2+}, 0.8 (0.5); Pb^{2+}, 1.0 (0.7), the Aldrich values being given in brackets. Two other humic acids (THA-1 and THA-4), extracted from forest soils, had lower ash contents, and dissolved at pH > 6. The acid-soluble fulvic acid (molecular weight < 1000) was obtained from Contech Ltd., Ottowa.

ASV operating conditions

The ASV analytical cycle was based on a 5-min deaeration period (with a 40 ml/min nitrogen flow) and a 10-min electro-deposition, followed by a stripping scan at 50 mV/sec to cut-off at -50 mV. For simultaneous determination of Cu, Pb and Cd, the deposition potential used was -900 mV (acetate base) or -1.0 V (citrate base). Longer deaeration periods in the presence of the Hg film resulted in distorted Cu peaks.

Procedure

Each test solution (containing 5.0 ml of base solution and 100 μg/l. Cd, Pb and Cu) was subjected to five successive ASV deposition/stripping cycles, and mean values were calculated for peak current (i_p) and peak potential (E_p). Then 2 mg of finely divided solid were added to the cell and the procedure was repeated. Variations subsequently investigated included the effect of different weights of solid (0.5–10 mg), changes in the concentration of metal ion (20–100 μg/l.) or the concentration of electrolyte in the base solution (0.05–$1M$), and the presence of diverse anions ($0.2M$ Cl^-, Br^-, F^-, CO_3^{2-}) or chelating resin (6 mg of Chelex 100) or added $Hg(NO_3)_2$ (0.25–0.8 μmole).

To ascertain the total amount of sorption, one group of samples was filtered through 0.45-μm membranes before analysis of the filtrate by ASV. The Cd and Cu results were confirmed by atomic-absorption spectroscopy (AAS).

Cold vapour AAS was used to determine the mercury present in the acetate base solutions as a result of extended stirring of the solution in contact with the thin film electrode.

RESULTS AND DISCUSSION

Operational parameter effects

Numerous authors[27,28] have emphasised the importance of controlling the pH of the base electrolytes used in ASV studies, and for this investigation an acetate buffer system was selected because of the high lability[27] and relatively low stability[29] of metal acetato-complexes.

In this medium a cut-off potential of -50 mV yielded a clearly defined Cu peak but released only small amounts of Hg(II) into solution on standing (*e.g.*, 5.5 ng of Hg detected after 7 min, 11 μg after 25 min). The presence of 2 mg of humic acid (which strongly sorbs Hg^{2+})[30] increased the Hg found in solution to 10 μg (7 min) and 50 μg (25 min). Redeposition of this mercury in the next analytical cycle tends to provide the equivalent of an "*in situ*" film, a technique modification reported to yield enhanced peak currents.[11] With the conditions used in our investigation, the addition of 0.25, 0.5 and 0.8 μmole of Hg(II) to the test solution increased the Cu peak current by 60, 73 and 87%, respectively, and only part of this change can be attributed to thickening of the preformed (4 μmole) film. These additional amounts of mercury may have increased the metal volume (and hence the current) by 6, 12 and 20% and in fact, with 2 mg of humic acid present, the enhancement was of this order (11–19%).

Variations in film droplet size arising from partial dissolution and redeposition in repeated cycles provide a tenuous explanation for the continual increase in Cu stripping currents (noted by several authors.[11,13,31]) The humic acid result, on the other hand, suggests that sorbed Hg(II) has limited lability.

As the role of the supporting electrolyte is to reduce the solution resistance and vary the chemical form of the reducible species, dilution or composition changes affect both the plating and stripping stages and yield variations in ASV responses, such as those indicated in Fig. 1 and given in Table 1.

Dilution of the $1M$ pH-5 buffer solution (curves a, Fig. 1) led to anodic peak shifts and changes in peak current (particularly at $<0.2M$ CH_3COONa; with $<0.05M$ electrolyte the peaks became very broad and of minimal height). In a second series, varying amounts of sodium acetate were added to $0.2M$ acetic acid, yielding solutions having pH values between 3.8 and 5.5 (curves b). In these base solutions, the changes induced in peak size and position were relatively small (*e.g.*, ~ 30 mV) except with Cu and $<0.2M$ sodium acetate. Adding 2 mg of humic acid to these base solutions resulted in no significant shift in peak positions (curves c), but there were changes in stripping currents, attributable to metal-ion sorption by the solid, an effect which declined at pH < 4 as protons competed for the sorption sites.

It has been reported previously that Cu, Pb and Cd peak currents are almost independent of pH changes (between 4 and 7) when acetate base solutions are

used,[28,32] but several other studies[31,33-36] have indicated distinct pH effects, particularly at pH < 7. In our investigation, increasing the pH from 5 to 6.35 resulted in slight peak enhancement (< 10%) and small cathodic peak shifts (~8 mV, Cd, Pb; ~30 mV Cu). At pH 8, the extent of peak shifting doubled and current flows were suppressed (*ca.* 10% for Cd; 25% for Pb; 40% for Cu). With Cu, the plot indicated two partially resolved peaks, an effect which has been attributed[31,36,34] to adsorption of Cu(II) hydroxy compounds or the formation of some Cu(I) species. In the presence of humic acid (Table 1) this double peak became very low and broad, with almost complete loss of the larger peak (*i.e.*, E_p was similar to that for the more cathodic component). With Cd and Pb, the addition of organic acids at pH 8 resulted in little change in E_p, but significant depression of peak currents (~33% for Cd, ~66% for Pb). Adsorption of metal ions by humic acids increases with pH,[14] up to the point where dissolution begins, and this explains most of the observed peak changes.

Diverse anion effects

Cu signals are known[31,32,37] to be depressed by the presence of even low levels of chloride (*e.g.*, <0.05*M*), but the effect levels off at <0.1*M*, and inclusion of sodium chloride at the 0.2*M* level in acetate base solutions has been recommended. This

excess of chloride swamps trace effects arising from chloride diffusing from the reference half-cell or introduced with the reagents, and it has been found to sharpen Cd and Pb peaks. All the previously described chloride effects were confirmed in our studies, *e.g.*, when the influence of diluted acetate/chloride base solutions was investigated. The effect of chloride on Cu behaviour has been attributed[32] to the existence of two poorly resolved dissolution processes, namely, $Cu + 2Cl^- \rightleftharpoons CuCl_2^- + e^-$, plus some oxidation to Cu(II) at a more positive potential, *i.e.*, $Cu + 3Cl^- \rightleftharpoons CuCl_3^- + 2e$. The stability of the chloro-complexes shifts the peak by ~100 mV; formation of the more stable bromo-species results in a greater shift (~170 mV). Discernible shoulders appear in the presence of both anions, but only in the case of Cl^- does the addition of some humic acid result in further cathodic shift (~65 mV) (Table 1).

The introduction of fluoride or carbonate ions had little effect on Cd, Pb or Cu peak positions, which confirmed the greater stability of the acetato–metal complexes in these mixtures. The addition of 2 mg of HAII resulted in no significant change in Cd or Pb peak positions, and with Cu the change was small (10–20 mV).

The major cathodic shifts observed for citrate base electrolyte solution are consistent with the citrate complexes of the three metal ions being more stable but less labile (smaller peaks) than other complexes examined in this study. The limited lability hindered uptake by humic acid particles (as shown by the small +HA effect). The peaks in citrate base solutions were reasonably broad, reflecting the ability of this ligand to form a sequence of complexes of varied stability,[29]

Sorption of organic compounds on the electrode can also result in peak broadening and lower i_p values, but this interpretation has been rejected since sorption is usually accompanied by anodic peak-shifts. In addition, i_p increased when the deposition potential was successively raised from −0.9 to −0.95, −1.0 and −1.1 V.

Sorption by suspended particles

The removal of metal ions from solution on the addition of fulvic or humic acids was clearly demonstrated when the cloudy test solutions were analysed before and after filtration through a 0.45-μm membrane (Table 2). The ASV readings were lower after filtration, which implies that part or all of the sorbed material was labile. With Cd and Pb there were only small shifts in E_p after the filtration, but with copper, both peaks shifted anodically (~20 and 30 mV). Carbon cup AAS analysis for Cd confirmed the filtrate analysis value (*i.e.*, no non-labile soluble complexes were identified). The acetate base interfered with Cu and Pb determinations by the carbon cup method, but confirmatory Cu solution levels were obtained by flame AAS (with maximum scale expansion).

The splitting of the Cu peak complicated calculation of the labile fraction, but the approximate values reported are consistent with the data derived from electrolyte displacement[17] and adsorption studies. Both Cu and Pb form sparingly soluble fulvates at around pH 5,[25] and the humic acids have a much greater affinity for Cu and Pb than for Cd.[14] The apparent high mobility of Cd associated with organic species present in natural waters has been noted previously.[6,38,39]

The loss on filtration of suspensions with a pH of 8 was greater than that for suspensions at pH 5, a change attributable to partial precipitation of metal hydroxy species, in addition to a higher degree of metal chelation with the organic acids.

When test solutions were equilibrated overnight with a mixture of 2 mg of organic acid and 6 mg of Chelex 100 resin, Cu was totally removed from solution, and the Cd and Pb values were halved. In the absence of humic acid, addition of Chelex removed 50% of the Cd, 60% of the Pb and 80% of the Cu present, and these values were used to calculate the fractions retained by the organic acid, from which were derived the apparent non-labile fractions, Chelex method ([] in Table 2). Comparison of these results with the ASV data indicates that about 20% of the Cu and Pb may be classified as moderately labile.

ASV studies provide only an indication of the lability of complexed or sorbed metal ions, since the peak currents recorded reflect both the experimental conditions chosen (*e.g.*, applied potential, system pH) and the type of bonding involved.

Another approach to stability studies involves adding increasing concentrations of metal ion to a fixed amount of ligand, or increasing amounts of ligand to a fixed amount of metal ion.

Figure 2(A) summarizes the ASV peak heights observed for test solutions of varied concentration, on addition of 2 mg of humic acid. It can be observed that the degree of current suppression varied with the metal ion involved and the organic acid used, and was in the order Cu > Pb > Cd.

This sequence was again evident when the weight of solid acid added was increased [Fig. 2(B)]. The addition of >3 mg of solid acid reduced the Cu ASV signals to near zero, with a small (5–10 mV) cathodic shift in peak position and the appearance of a more prominent shoulder. The change in E_p is attributed to a higher proportion of the copper being bound in non-labile complexes. If formation of a stable soluble complex were involved, a response similar to that obtained with salicylic acid would be expected.

The ability of humic acids to sorb metal ions strongly from their aqueous solutions at mg/l., concentration was demonstrated in an earlier study[14] which utilized AAS as the monitoring technique. The amount sorbed was found to vary with pH and the humic acid sample studied, with maximum removal of metal ion occurring within distinct pH regions (*e.g.*, pH 5.5–7 for Cu, Pb). The relative affinity order was Cu, Pb > Zn, Cd. Pb, and to a lesser extent Cu, Cd and Zn, have been found to form sparingly soluble metal fulvates[25] within narrow pH regions (*e.g.*, Pb, pH 5–7; Zn, pH 6.5–8).

In qualitative terms, these studies indicate that the three metal ions belong to different "lability" categories:

(*i*) strongly sorbed or bound, low lability—Cu;
(*ii*) firmly sorbed, intermediate lability—Pb;
(*iii*) weakly sorbed, high degree of lability—Cd.

Less predictable is the observation that adding <1 mg of organic acid leads to enhanced Cd and Pb peaks. Some surfactants also promote peak enhancement,[13] and it has been suggested[40] that in such systems electrostatic attraction between metal ions and adsorbed dipolar surfactant molecules may lead to acceleration of the discharge reaction at the electrode. Alternatively, the positive effects of dissolution of the mercury film in the presence of solids (discussed earlier) may exceed the sorption losses.

Mercury film effects

Enhancement of Cu and Pb peaks and formation of dual Cu peaks were also observed when the colloidal suspensions were left in contact with the MTFE for longer periods, prior to deposition and stripping analysis (*cf.* Figs. 3 and 4). These changes did not occur when the colloid–metal ion mixtures were retained in vials for various periods prior to transfer to the ASV cell, so the peak changes cannot be attributed to slow achievement of sorption equilibria, and must involve the mercury film.

With Cd and Pb, there were no changes in peak position but the peak height increased more or less linearly with the square root of the contact time (5–45 min). This time relationship implies that the slow step is probably a diffusion process. For example, gradual build up of an adsorbed organic layer could bring with it sorbed metal ions, leading to an elevated surface concentration and proportionately greater metal ion deposition. Alternatively, the film build-up may promote oxidation of the mercury, with redeposition in a more active form at the start of the deposition cycle. Disturbing the system, *e.g.*, by introducing a fresh base solution between the deposition and stripping cycles, led to much smaller current flows, which suggests that the film may consist of fine droplets of mercury, loosely attached to a more coherent base layer.

Peak sizes were also smaller when a pH of 6.35 was used (*cf.* Fig. 3), reflecting some change in bonding mode, but the contact time effect persisted. At both pH 5 and 6.35 the magnitude of the change varied with the type of organic material added (*cf.* Figs. 3 and 4) and the element being examined.

The behaviour of copper was far more anomalous. When a deposition potential of −800 mV was used, peak changes were relatively small, but when a voltage of −900 mV was applied (to ensure deposition of Cd) the peak characteristics became a definite function of film contact time (*cf.* Fig. 4).

A d.c. polarogram for an acetate base solution (pH 5) of copper (2 mg/l.) containing 10 mg of acid exhibited two distinct reduction steps. The first ($E_{1/2} \sim -60$ mV) matched the wave obtained in the absence of the organic solid. The slope of the second wave was more gradual, indicating an irreversible or kinetically controlled reduction process ($E_{1/2} \sim -900$ mV), most probably direct reduction of a copper–humate complex. The anodic shift of the $Cu(Hg) \rightarrow Cu^{2+}$ stripping peak with increased contact time thus probably indicates adsorption of organic matter on the electrode, whereas the cathodic

component of the dual peak possibly represents oxidation of Cu(I), present as a stable, poorly labile complex. Increasing the pH appears to increase the fraction of adsorbed copper present as a less labile chelate and so reduces the amount retained by electrostatic forces only, *i.e.*, the main contributor to i_p. Further investigations of the electrode phenomena are planned.

ANALYTICAL AND ENVIRONMENTAL ASPECTS

It has now been clearly established that both dissolved organic compounds and colloidal particles influence the size of the Cd, Pb and Cu ASV peaks and accordingly experimental conditions need to be carefully controlled if accurate data are to be recorded. Some of the inherent problems (*e.g.*, anion effects) can be minimized by proper selection of the base electrolyte, but others (*e.g.*, film contact-time effects, peak enhancements) require standardization of operating parameters and calibration by standard-additions. Separate determination of copper, at a much lower deposition potential, may be regarded as another wise precaution.

The study also emphasises the desirability of having an appreciation of the limitations of the technique and some knowledge of the system chemistry, before embarking on speciation studies. For example, it is standard practice to filter waters through a 0.45-μm membrane before analysing both filtrate and solid for total metal content, but omission of a third test, *viz.* analysing the water as collected (and thus determining the labile fraction attached to the isolated solids) may result in loss of evaluation of an important biologically active fraction. Similarly, analysing the filtrate by two techniques (*e.g.*, AAS and ASV) should readily allow the contribution of stable non-labile complexes to be assessed. The case for more detailed subdivision can then be based on this preliminary information.

The results of this ASV study also indicate that some of the published data on metal–organic acid complex stability may be in error because due allowance has not been made for the presence of sparingly soluble reaction products or sorption by colloidal particles.

An important environmental consideration is the high proportion of sorbed metal ion which is ASV-labile, and displaceable by electrolytes. The values determined by different approaches are not directly comparable, but each confirms that a portion of each colloidal particle load is destined to be conveyed directly to the sediments, while another fraction can be repeatedly cycled between phases. Preliminary studies have shown that a significant fraction of the metal ions sorbed by clays is also ASV-labile and that electrolytes displace ions from hydrous oxides (*e.g.*, MnOOH),[40] so ASV studies on unfiltered and filtered natural waters should provide interesting information on average overall lability or availability.

ANALYTICAL APPLICATIONS OF COPPER(II) AND COPPER(I) IN ACETONITRILE: POTENTIOMETRIC AND SPECTROPHOTOMETRIC DETERMINATION OF DITHIOCARBAMATES

B. C. VERMA*, SAROJ CHAUHAN, ANITA SOOD, D. K. SHARMA and H. S. SIDHU
Chemistry Department, Himachal Pradesh University, Shimla-171005, India

(*Received* 9 *January* 1984. *Accepted* 14 *September* 1984)

Summary—The use of copper(II) perchlorate and tetra-acetonitrilocopper(I) perchlorate (in acetonitrile) for the potentiometric and spectrophotometric determination of dithiocarbamates in acetonitrile medium is described. The proposed methods are simple, accurate and reliable and show promise of wide applicability. They are recommended for routine determination of dithiocarbamates. Their advantages over the carbon disulphide evolution method, commonly employed for the determination of these compounds, are discussed.

Dithiocarbamates find extensive use as agricultural fungicides and as vulcanization accelerators in the rubber industry. Because of the wide commercial importance of these compounds, their determination has received much attention. A variety of techniques has been used for the determination of these materials but the usual approach[1–6] involves hydrolysing them with hot mineral acids to the corresponding amines and carbon disulphide, either of which may be determined.

$$R_2N{-}\underset{\underset{S}{\|}}{C}{-}S^- + H^+ \rightarrow R_2NH + CS_2$$

Usually carbon disulphide is selected and measured either by the xanthate method (for macro/semimicro determination) or colorimetrically (for micro determination). The method in either case is tedious, and requires both special apparatus and careful control of experimental conditions if evolution of carbon disulphide is to be quantitative. There is, therefore, a need for a method which, besides being accurate and precise, should also be rapid. We have developed potentiometric and spectrophotometric methods that obviate the time-consuming degradation of the sample and the distillation step. These methods are based on oxidation of the dithiocarbamate with copper(II) perchlorate in acetonitrile. This system was chosen for the following reasons.

(*i*) Dithiocarbamates are easily oxidized to the corresponding thiuram disulphides **(I)**, but this is best done in non-aqueous medium, first because of the tendency of these compounds to undergo decomposition with acids[7,8] (which serve as the media for most conventional redox titrations) and secondly because of the interference[9,10] of the water-insoluble oxidation products **(I)** in neutral aqueous medium.

$$2RR'N{-}\underset{\underset{S}{\|}}{C}{-}S^- \rightarrow RR'N{-}\underset{\underset{S}{\|}}{C}{-}S{-}S{-}\underset{\underset{S}{\|}}{C}{-}NR'R + 2E^-$$

(I)

(R = alkyl group; R′ = hydrogen atom or alkyl group)

(*ii*) Acetonitrile, because of its high dielectric constant and resistance to oxidation and reduction, is a promising solvent for non-aqueous redox titrations.[11]

(*iii*) Copper(II) in acetonitrile is a powerful and stable oxidizing agent.[11,12]

The following observations were made.

(*i*) The potentiometric titrations show two well-defined breaks at copper(II):dithiocarbamate ratios of 0.5 and 1.0, corresponding to the oxidation mechanism:

$$4RR'N{-}\underset{\underset{S}{\|}}{C}{-}S^- + 2Cu^{2+} \rightarrow RR'N{-}\underset{\underset{S}{\|}}{C}{-}S{-}S{-}\underset{\underset{S}{\|}}{C}{-}NR'R + 2RR'N{-}\underset{\underset{S}{\|}}{C}{-}SCu$$

(I) **(II)**

$$2RR'N{-}\underset{\underset{S}{\|}}{C}{-}SCu + 2Cu^{2+} + 16CH_3CN \rightarrow RR'N{-}\underset{\underset{S}{\|}}{C}{-}S{-}S{-}\underset{\underset{S}{\|}}{C}{-}NR'R + 4[Cu(CH_3CN)_4^+]$$

(I)

(*ii*) The solution is initially colourless but becomes increasingly yellow [owing to the formation of cop-

*Author for correspondence.

per(I) dithiocarbamate] as the reagent is added, until a maximum is reached at a molar ratio of 0.5, then the colour starts decreasing again (thiuram disulphides are colourless) and finally becomes colourless, which substantiates the mechanism shown above.

These observations reveal that in acetonitrile medium, copper(II) and copper(I) salts could serve as useful reagents for the determination of dithiocarbamates. Consequently, we have been able to evolve simple, accurate and reliable methods, potentiometric and spectrophotometric, of wide applicability for the determination of dithiocarbamates with acetonitrile solutions of copper(II) perchlorate and tetraacetonitrilocopper(I) perchlorate as reagents. The most attractive feature of these reagents is their excellent stability. Copper(II) has a higher redox potential in acetonitrile than in aqueous medium because the copper(I) produced is stabilized by solvation[11-14] and is resistant to aerial oxidation and does not disproportionate. The conditional potential of the couple in acetonitrile is slightly higher than that of the hexanitratocerate couple in the same solvent.[13] The potentiometric titrations with tetraacetonitrilocopper(I) perchlorate as titrant are based on stoichiometric formation of the copper(I) dithiocarbamates.

$$RR'N-\underset{\underset{S}{\|}}{C}-S^- + Cu^+ \rightarrow RR'N-\underset{\underset{S}{\|}}{C}-SCu$$

To make the platinum electrode responsive to dithiocarbamate concentration, a drop of dilute iodine solution in acetonitrile is added to generate a trace of the corresponding thiuram disulphide.

$$2RR'N-\underset{\underset{S}{\|}}{C}-S^- + I_2 \rightarrow RR'N-\underset{\underset{S}{\|}}{C}-S-S-\underset{\underset{S}{\|}}{C}-NR'R + 2I^-$$

A sharp jump in potential is observed at the equivalence point at a 1:1 copper(I):dithiocarbamate ratio.

Photometric titration procedures have also been developed for the micro-determination of dithiocarbamates with either the copper(II) or copper(I) reagent. The titrations are monitored at 430 nm, the wavelength of maximum absorbance of copper(I) dithiocarbamates. With either reagent, the absorbance increases up to the end-point, then decreases in titrations with copper(II) and remains constant in those with copper(I).

For determination of traces of dithiocarbamates, the yellow colour resulting from their reaction with copper(I) perchlorate in acetonitrile can be measured; the colour develops immediately and is stable for at least 24 hr.

EXPERIMENTAL

Apparatus

Potentiometric titrations were performed with a bright platinum wire as indicator electrode and a modified calomel electrode (saturated methanolic potassium chloride used instead of aqueous solution) as reference.

Reagents

Acetonitrile. Distilled twice from phosphorus pentoxide (5 g/l.).

Dithiocarbamates. Sodium diethyldithiocarbamate was recrystallized before use. Sodium salts of n-propyl, n-butyl, sec-butyl, n-pentyl, dimethyl, di-n-propyl, di-n-butyl, di-n-pentyl and di-n-hexyl dithiocarbamic acids were prepared and purified by known methods.[15-18] Alkylammonium alkyl dithiocarbamates were prepared by the method of Anchutz[19] by mixing primary or secondary amines with carbon disulphide in dry ether. Monoalkylammonium monoalkyl dithiocarbamates ($RHN.CS.SNH_3R$ with R as methyl, n-propyl, n-butyl and n-pentyl) and dialkylammonium dialkyldithiocarbamates ($R_2N.CS.SNH_2R_2$ with R as methyl, n-propyl and n-butyl) were prepared and kept in a vacuum desiccator. The purity of each dithiocarbamate was checked by non-aqueous titration with iodine monobromide.[20]

†Amount taken, 10 mg.

Hydrated copper(II) perchlorate solution in acetonitrile (0.02 M). Prepared and standardized as described earlier.[21]

Tetra-acetonitrilocopper(I) perchlorate solution in acetonitrile (0.02 M). Solid $CuClO_4.4CH_3CN$ was prepared by a method similar to that reported by Hathaway *et al.*[22] To a solution of copper(II) perchlorate in acetonitrile, an excess of copper powder (99.9% pure) was added and the solution stirred vigorously. Complete reduction was indicated by the solution becoming colourless. The solution was then quickly filtered while hot. White crystals separated as the solution cooled and were recrystallized from anhydrous acetonitrile and dried under vacuum. Standard solutions were prepared by dissolving a little more than the calculated amount of the compound in acetonitrile and standardized by titration with ammonium hexanitratocerate(IV) in aqueous sulphuric acid with ferroin as indicator.

Procedures

Potentiometric titrations with copper(II) perchlorate. Aliquots of acetonitrile solutions of each dithiocarbamate are diluted to 30 ml with acetonitrile and titrated potentiometrically at room temperature (~25°) with the standard (0.02*M*) copper(II) perchlorate solution. The results as calculated on the basis of the first break for dialkyldithiocarbamates and the second break for monoalkyldithiocarbamates are given in Table 1. The potentiometric titration curves a and b (Fig. 1) are typical of the listed monoalkyldithiocarbamates and dialkyldithiocarbamates respectively.

Potentiometric titrations with tetra-acetonitrilocopper(I) perchlorate. The procedure is the same as that above except that a drop of 0.001*N* iodine solution in acetonitrile is added before the titration. The results are given in Table 2. Titration curve c (Fig. 1) is typical of the listed dithiocarbamates.

Photometric titrations. Aliquots of acetonitrile solutions of each dithiocarbamate are diluted to 8 ml with acetonitrile and titrated photometrically at 430 nm with copper(II) perchlorate solution in acetonitrile, with magnetic stirring. Dilution correction is applied and the titration curve plotted in the usual way. The results are recorded in Table 3 and a typical titration is represented by curve a in Fig. 2.

Alternatively, similar titrations are performed with copper(I) perchlorate in acetonitrile. The results are given in Table 4 and a typical titration is represented by curve b in Fig. 2.

Spectrophotometric determination. A suitable aliquot (0.1–2.0 ml) of dithiocarbamate solution in acetonitrile or chloroform is transferred to a 10-ml standard flask and diluted to between 8 and 9 ml with acetonitrile. Copper(I) perchlorate in acetonitrile (1 ml, 0.01*M*) is added and the solution diluted to the mark with acetonitrile. The absorbance at 430 nm is measured against a reagent blank. A calibration curve is constructed by taking standards through the same procedure. Working ranges and molar absorptivities are given in Tables 5 and 6 respectively.

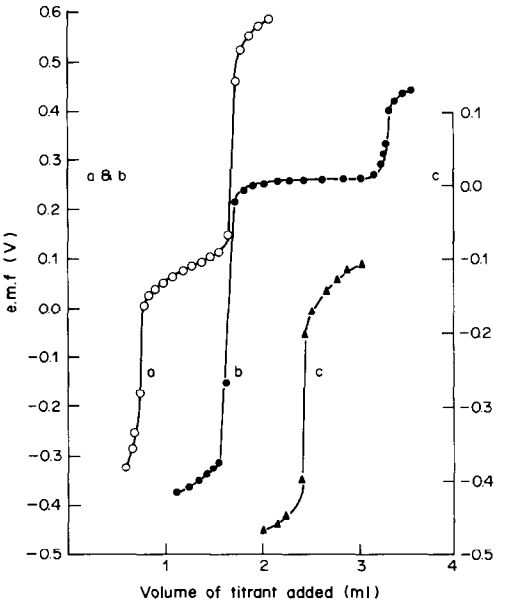

Fig. 1.

RESULTS AND DISCUSSION

Dithiocarbamates readily undergo decomposition with acids,[7,8] so oxidative determinations are notably lacking in the literature. The iodimetric method used in neutral aqueous medium suffers from difficulty in detection of the starch–iodine end-point in the presence of the thiuram disulphides which precipitate during the titration. Use of extraction of thiuram

RUTHENIUM DETERMINATION IN SYNTHETIC PUREX WASTE SOLUTIONS BY AAS

W. HEINIG and K. MAUERSBERGER
Zentralinstitut für Isotopen- und Strahlenforschung der AdW der DDR, Permoserstr. 15, 7050 Leipzig, DDR

(*Received* 5 *September* 1984. *Accepted* 29 *September* 1984)

Summary—A method for the determination of ruthenium in synthetic Purex waste solutions by flame AAS is described. With the usual flames and a lanthanum buffer, only cerium interference in the air–acetylene flame need be considered under the conditions applied. Ruthenium nitrosyl nitrate, ruthenium(IV) hydroxychloride and alkaline ruthenate samples gave identical results, showing that the extraordinarily stable Ru–NO bond does not hinder atomization. The preparation and standardization of the ruthenium nitrosyl solutions, and the alkaline fusion, are briefly described.

Besides technetium, neptunium, and zirconium/niobium, ruthenium is one of the troublesome elements in the reprocessing of irradiated fuels. During the extraction of fuel solutions in nitric acid with TBP (Purex process) it is particularly the nitrate complexes of ruthenium nitrosyl that enter the organic phase and accompany uranium and plutonium. Problems arise from the diversity of existing ruthenium nitrosyl compounds, their different extraction coefficients and the sensitive equilibria between all the compounds.[1,2]

The elucidation of the extraction behaviour of all these species in nuclear fuel reprocessing, including ruthenium recovery from fission product solutions, requires efficient analytical methods for this element. Ruthenium in nuclear fuel solutions is usually determined radiometrically, by measurement of the gamma radiation of the nuclides ^{103}Ru and ^{106}Ru. However, depending on the intermediate storage time, much of the ruthenium activity may be lost[3] (Table 1). Therefore, conventional methods are also useful for low-activity samples, particularly for model experiments.

EXPERIMENTAL

Apparatus

All atomic-absorption measurements were done with a Carl Zeiss (Jena) AA spectrometer, type AAS 1N, equipped with a Beckman ruthenium hollow-cathode lamp. The lamp current was 10 mA, and the slits were set to give 0.12 nm spectral bandwidth. The air–acetylene flame (5-cm triple-slot burner) was used as well as a nitrous oxide–acetylene flame (5-cm single-slot burner). The instrument allows single and triple beam-passage through the flame, and it was shown that for ruthenium both modes are suitable, with either flame. The spectrophotometric determinations were done in 1-cm cells with a Carl Zeiss Specord.

Reagents

The powdery ruthenium metal used was 97.65% pure according to mass spectrometric analysis, and contained also 1.38% Pt and 0.66% Ir. All other reagents were of analytical grade. For AAS a lanthanum buffer was prepared by dissolution of 56.4 g of $La(NO_3)_3 . 6H_2O$ in 670 ml of 12*M* hydrochloric acid and dilution to 1000 ml.

Preparation and standardization of Ru solutions

The ruthenium nitrosyl nitrate solutions were prepared as described by Gorski and Foersterling.[4] Ruthenium metal was oxidized in three stages to RuO_2, K_2RuO_4, and RuO_4, respectively, and the last was absorbed in NO-saturated nitric acid. The ruthenium nitrosyl nitrate stock solutions were adjusted to 8*M* nitric acid concentration and kept under nitrogen in the dark. Their Ru content was determined gravimetrically according to Heinig and Foersterling.[5] Aliquots were evaporated to dryness and the residue reduced to the metal with hydrogen at 300° or, in a double determination, transformed into RuO_2 at 350°, weighed, and then reduced to the metal.

Ruthenium(IV) hydroxychloride solution was prepared by distilling ruthenium tetroxide into 6*M* hydrochloric acid. The ruthenium content was determined after Banks and O'Laughlin[6] by pipetting 4-ml aliquots into porcelain boats, carefully evaporating to dryness in an oven at 110° and reducing the residue to the metal with hydrogen at 300°. The

Fe^{3+}	0.20	Y^{3+}	
Pd^{2+}	0.32		

ruthenium content of the stock solution was 2.80 ± 0.08 mg/ml.

Potassium ruthenate solution was prepared by heating 10 mg of Ru metal, 150 mg of potassium hydroxide and 50 mg of sodium peroxide at 550–570° in a nickel crucible for 1 hr, with further addition of another 100 mg of sodium peroxide, then dissolving the cooled melt in warm water and diluting accurately to 100 ml. The completeness of reaction was tested by measuring the absorbance of the orange-red K_2RuO_4 at the 465-nm absorption maximum.

The synthetic Purex waste solution was prepared according to Suess.[7] Its composition (Table 2) corresponded to a burn-up of 35,000 MWd/t and a 5-year intermediate storage time.

RESULTS AND DISCUSSION

All publications on ruthenium determination by flame AAS show that it is characterized by serious interferences and instabilities in all types of flames. In an air–acetylene flame most interferences can be controlled by using a copper/cadmium buffer according to Rowston and Ottaway.[8] Scarborough[9] eliminated strong disturbances caused by Mo, Pd, and Rh, by means of a massive addition of uranium. Montford and Cribbs[10] were also successful with uranium addition (except for interference by Ti), and so were Mallett *et al.*,[11] who also proposed use of vanadyl chloride. Heinemann[12] gave optimum analytical conditions for AAS determination of noble metals with maximum precision, but did not consider matrix phenomena. El-Defrawy *et al.*[13] successfully used cyanide solutions, and Harrington and Bramstedt[14] used a titanium buffer. Schwab and Hembree[15] examined ruthenium determination in nitric acid solutions of nuclear fuels and controlled instabilities by mixing samples with an equal volume of a buffer consisting of 0.13*M* lanthanum nitrate in 8*M* hydrochloric acid.

*Triple beam-passage.
†Single beam-passage.

Lanthanum offers considerable enhancement in sensitivity, compensating for the dilution effect. Kolonina *et al.*[16] used lanthanum at lower concentrations.

Interference study

Each of the fission elements in the Purex waste solution was tested for interference in the ruthenium determination. The ruthenium absorbance was measured with and without the addition of each element listed in Table 2, at a concentration three times that in an average Purex solution. An additional comparison was made between a synthetic Purex solution and a pure ruthenium solution with precisely the same Ru concentration. To bring them into the linear range of the ruthenium calibration curve, samples were fivefold diluted with 4*M* nitric acid and then mixed with an equal volume of the lanthanum buffer.

Under these conditions, with the nitrous oxide–acetylene flame, none of the fission products caused an effect exceeding the experimental error of ±2%. The same was true for the air–acetylene flame except for cerium, which caused a significant depression, the magnitude of which depended on the flame stoichiometry and number of beam-passages, and increased with cerium/ruthenium ratio (Table 3). Furthermore, at a fixed Ce/Ru ratio, the relative depression depended on the absolute concentrations (Table 4), and on the oxidation state of the cerium.

Ruthenium determination

The air–acetylene flame gives good sensitivity but there is interference from cerium; however, this effect, which in practice amounts to −1%, can be easily compensated by adding cerium to the calibration solutions. Use of the nitrous oxide–acetylene flame is free from interferences but gives lower sensitivity (by a factor of 2.5) and a poorer signal to noise ratio; there is also a tendency for the single-slot burner to become blocked, owing to the high salt content.

	492	495	—
	492	497	—
	492	488	—

All the ruthenium nitrosyl nitrate test samples were 4*M* in nitric acid, with a ruthenium concentration of 30–70 μg/ml, and were mixed with the lanthanum buffer. For the triple beam-passage in the air–acetylene flame a characteristic concentration of 1.7 μg/ml (for 1% absorption) and a detection limit of 0.1 μg/ml were found; for the nitrous oxide–acetylene flame the values were 4.4 and 0.35 μg/ml, respectively. The air–acetylene flame should also be preferred because of the better precision (r.s.d. 1.5%). Some results are shown in Table 5.

The ruthenium calibration standards (4*M* nitric acid) stored in borosilicate glass were found to be stable for months even without protection by a nitrogen atmosphere. The analysis of ruthenium(IV) hydroxychloride in 6*M* hydrochloric acid gave excellent agreement with the theoretical values. Furthermore, the determination is also possible, starting from alkaline ruthenate instead of nitrosyl nitrate solutions. To avoid systematic errors, the samples must be made 4*M* in nitric acid before the lanthanum addition. The analyte should be pipetted into nitric acid to avoid precipitation of ruthenium dioxide by local neutralization, and then the buffer is added.

The identical results from ruthenium nitrosyl, ruthenium chloride and ruthenate compounds prove that the atomization process in the flame is not influenced by the unusually strong Ru–NO bond.

AN EXTRACTIVE SPECTROPHOTOMETRIC METHOD FOR THE DETERMINATION OF TETRAMISOLE HYDROCHLORIDE IN PHARMACEUTICAL PREPARATIONS

R. T. SANE, D. S. SAPRE and V. G. NAYAK
Department of Chemistry, Ramnarain Ruia College, Matunga, Bombay 400019, India

(*Received* 5 *April* 1982. *Revised* 20 *July* 1984. *Accepted* 14 *September* 1984)

Summary—A simple extractive photometric method for the determination of tetramisole hydrochloride in pharmaceutical preparations is described. The method uses the formation of coloured complexes of the drug with reagents such as Solochrome Dark Blue, Solochrome Black T, Bromocresol Purple, Bromothymol Blue, Bromophenol Blue and Bromocresol Green in an acidic buffer. The ion-pair complexes formed are quantitatively extracted into chloroform under the experimental conditions.

Tetramisole hydrochloride is an anthelmintic drug with antidepressant activity. Holbrook and Scales[1] have determined it in animal tissue extract polarographically. Mourot *et al.*[2] have determined it by HPLC in the routine analysis of veterinary anthelmintics. In the present communication an extractive spectrophotometric method for its determination is described. The method is rapid and sensitive. It is based on our observation that tetramisole hydrochloride forms ion-pair complexes in acidic buffer with dyestuffs such as Solochrome Dark Blue (SDB), Solochrome Black T (SBT), Bromocresol Purple (BCP), Bromothymol Blue (BTB), Bromophenol Blue (BPB) and Bromocresol Green (BCG) and these complexes are quantitatively extracted into chloroform under the reaction conditions used.

EXPERIMENTAL

Reagents

The dyestuffs were used as 0.08% solutions of BCP, BTB, BPB and BCG, a 0.2% solution of SDB and a 0.1% solution of SBT, all in distilled water; 1 ml of 0.1*M* sodium hydroxide was added to the SBT solution before its final dilution.

Buffer solutions were prepared by dissolving 10–20 g of potassium hydrogen phthalate (accurately weighed) in 1000 ml of distilled water, to give a solution of pH 4.01, portions of which were then adjusted with dilute hydrochloric acid or sodium hydroxide solution to pH 2.0, 2.5, 2.8, 3.5, 4.0 and 6.0.

The purity of the tetramisole hydrochloride used was checked by non-aqueous titration and found to meet the normal criteria for purity. Standard tetramisole hydrochloride solution (100 μg/ml) was prepared by accurately weighing 25 mg of the drug, dissolving it in distilled water and diluting to volume in a 250-ml standard flask.

Analytical grade chloroform was used.

Determination of optimum reaction conditions

The optimum conditions were established by a series of preliminary experiments, the results of which are summarized in Fig. 1.

General procedure

In each of a series of 125-ml separating funnels place 5 ml of buffer solution (pH as indicated in Table 1) and 5 ml of dye solution. To each funnel add an appropriate volume of working standard solution for construction of a calibration graph. Add 10 ml of chloroform when the dye is BCP, BTB, BPB or BCG and 25 ml when it is SDB or SBT. Shake the funnels vigorously for 2 min, then let them stand for clear separation of the phases. Measure the absorbance of the organic phase at 420 nm when BCP, BTB, BPB and BCG are used and 520 nm for SDB and SBT, against a reagent blank similarly prepared. The calibration graphs are linear over the concentration ranges given in Table 1. The colour is stable for at least 2 hr.

Application to pharmaceutical preparations

Weigh ten tablets accurately and grind them. Weigh a portion of the thoroughly mixed powder equivalent to 25 mg of the drug, dissolve it in distilled water and dilute the solution to volume in a 250-ml standard flask after filtration.

Table 1. Results of analysis for tetramisole hydrochloride

Reagent	pH	λ_{max}, *nm*	Beer's law range, *μg/ml*	Molar absorptivity, $10^3 l.mole^{-1}.cm^{-1}$	Recovery, %	Coefficient of variation, %

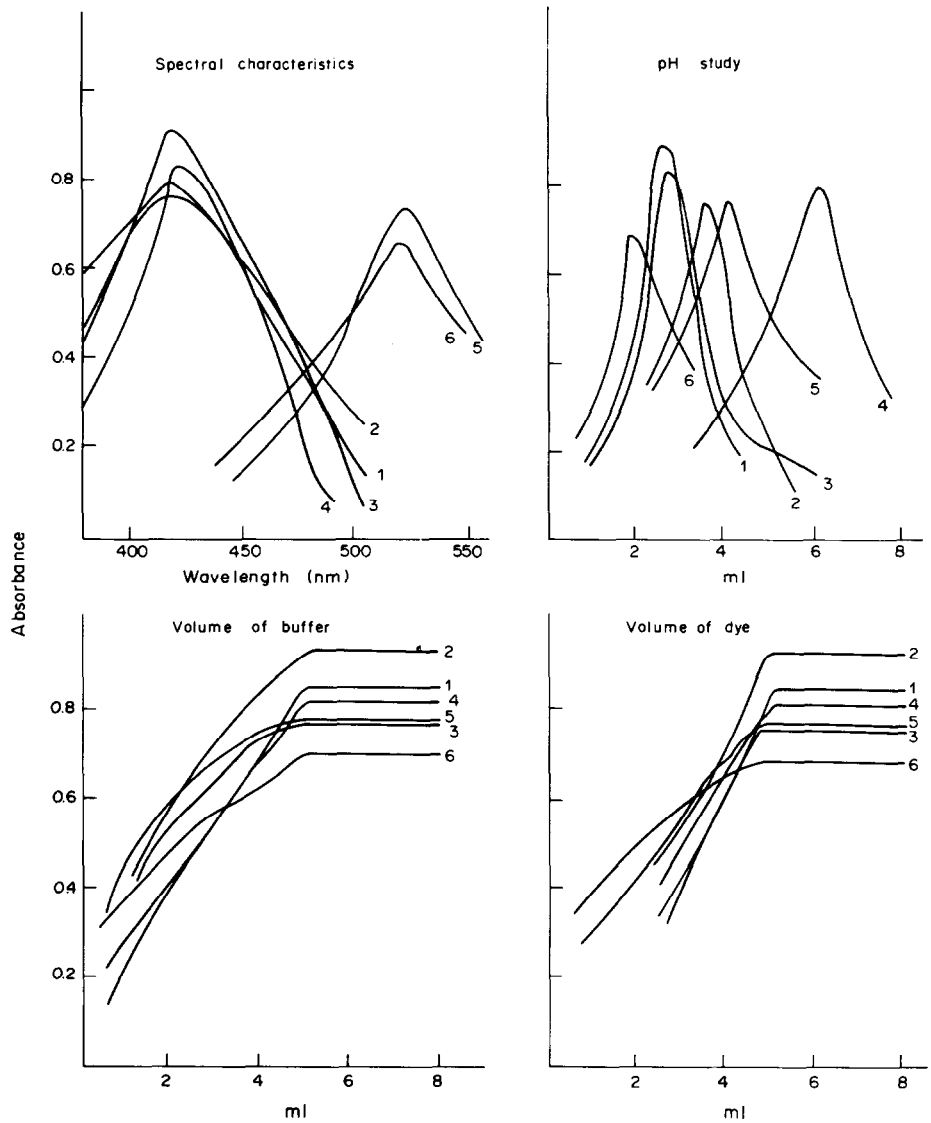

Fig. 1. Absorption spectra and optimization of conditions 1, BTB; 2 BPB; 3, BCG; 4, BCP; 5, SDB; 6, SBT.

Analyse the solution by the general procedure with an appropriate volume of sample solution.

Recovery

To study the precision and accuracy of the proposed method, a statistical study was made. Three series of fixed volumes of sample solution were taken and three different levels of standard drug solution were added, each level being repeated seven times. The total amount of the drug was determined by the proposed method. The recovery was calculated by regression analysis of the results.

A plot of the concentration of drug found against the concentration of drug added has an intercept which represents the concentration of the drug in the sample. Any deviation of the slope of the plot from unity indicates interference by a component of the pharmaceutical sample.

DISCUSSION

This is the first colorimetric method for the determination of tetramisole hydrochloride. It is simple, fast and sensitive and does not suffer interference from common excipients such as starch, talc, *etc.* There is no pharmacopoeial method described by the B.P., U.S.P. and I.P. for the determination of tetramisole hydrochloride in pharmaceutical formulations. The methods given in the literature[1,2] require mg quantities of the drug but the proposed method can be applied to a few hundred μg. The recoveries are between 98 and 100% and the coefficient of variation is 1–2% (Table 1). The proposed method can be successfully employed for the routine determination of tetramisole hydrochloride in pharmaceutical preparations.

DETERMINATION OF NITRIC OXIDE BY BROMATE OXIDATION OF THE NITROSYL ETHYLENEDIAMINETETRA-ACETATOIRON(II) COMPLEX

SHUNICHI UCHIYAMA and GIICHI MUTO
Department of Environmental Engineering, Saitama Institute of Technology, 1690 Fusaiji, Okabe, Saitama, Japan

(*Received* 25 *August* 1982. *Revised* 16 *July* 1984. *Accepted* 14 *September* 1984)

Summary—A new spectrophotometric method for nitric oxide is proposed, based on formation of the nitrosyl-ethylenediaminetetra-acetatoiron(II) complex [Fe(II)NO–edta] by absorption of NO in Fe(II)edta solution and spectrophotometric determination of the NO_2^- produced by oxidation of the Fe(II)NO–edta complex by potassium bromate. The oxidation is easily performed completely and the absorption efficiency for 10.1–102.0 ppm NO (flow-rate, 100 ml/min) is nearly 100%. The detection limit is about 3 ppm for a sampling absorption time of 30 min.

Since the German patent was published in 1967,[1] it has been known that nitric oxide is effectively absorbed by a solution of the ethylenediaminetetra-acetatoiron(II) complex [Fe(II)edta] to form a nitrosyl-ethylenediaminetetra-acetatoiron(II) complex [Fe(II)NO–edta]. We have already proposed an indirect analytical method for NO in which the Fe(II)NO–edta complex is determined directly by spectrophotometry[2] and controlled potential coulometry[3] but the sensitivity is rather low and the absorption efficiency for low concentrations of NO was not examined.

We now report that the Fe(II)NO–edta complex can be oxidized by bromate to the Fe(III)edta complex and NO_2^-. This could form the basis for a more sensitive determination of the Fe(II)NO–edta complex and hence of NO by spectrophotometric determination of the NO_2^- produced by the oxidation. In the customary method,[4,5] nitric oxide has to be oxidized to NO_2 by oxidizing agents such as permanganate or ozone in a liquid–gas or a gas system, and the complete oxidation is rather difficult and time-consuming. Moreover, the "Saltzman factor" has to be used in calculating the amount of NO.

In contrast, in the method described here, the chemical conversion of the co-ordinated NO into NO_2^- is easily done in a liquid phase, and the Saltzman factor is not needed.

EXPERIMENTAL

Apparatus

A double-beam spectrophotometer (Hitachi Model 100-50) was used with 1-cm glass cells. The absorption system was made from two 200-ml Erlenmeyer flasks connected in series with Teflon tubing. A sintered-glass filter (porosity 3) and a gas flowmeter with needle valve were used to bubble NO through the absorbent at constant rate.

Reagents

Standard nitric oxide mixtures with nitrogen (10.1, 30.4, 70.2 and 102.0 ppm concentration) were obtained from Nihon Sanso.

The Saltzman colour-forming solution was that described by Fisher and Becknell.[5] All chemicals used were reagent grade.

Procedure

The appropriate weights of ferrous ammonium sulphate and ethylenediaminetetra-acetic acid needed to give 200 ml of a 0.01*M* solution of the complex were dissolved in 1*M* acetic acid–sodium acetate buffer (pH 4.0) purged with nitrogen. Then 1.00 ml of 2×10^{-3}–$2 \times 10^{-2}M$ sodium nitrite was added to this solution to give an Fe(II)NO–edta solution of concentration 1×10^{-5}–$1 \times 10^{-4}M$ by means of the reactions.

$$NO_2^- + \text{Fe(II)edta} + 2H^+ \rightarrow \text{Fe(III)edta} + NO + H_2O$$

$$NO + \text{Fe(II)edta} \rightarrow \text{Fe(II)NO–edta}$$

A 10-ml portion of this solution was treated with 4 ml of 0.01*M* potassium bromate for 5 min, the Fe(III)edta complex and NO_2^- being produced. Finally, 1 ml of this oxidized solution was reacted with 6 ml of Saltzman solution for 15 min, and the absorption spectrum was measured with a double-beam spectrophotometer. A calibration graph relating absorbance to amount of Fe(II)NO–edta complex, and hence of NO, was prepared.

To determine the absorption efficiency for NO, a standard gas mixture containing NO was bubbled into Fe(II)edta solution in the absorption system. The NO complex formed was oxidized, the colour reaction applied and the absorption efficiency calculated.

To investigate analysis of an NO and NO_2 mixture, a Teflon three-way stopcock was used to mix a gas containing 100 ppm of NO_2 (flowing at 40 ml/min) with the standard NO mixtures (flowing at 100 ml/min) to give a total flow-rate of 140 ml/min. The mixture of gases was bubbled first through Saltzman solution and then through Fe(II)edta solution, contained in absorption flasks connected in series. After the absorption, the Saltzman solution was diluted tenfold with additional Saltzman solution and the absorbance of this diluted solution was measured. The NO complex formed in the second flask was measured by the oxidation procedure already described.

RESULTS AND DISCUSSION

Oxidation and colour formation of the NO complex

The absorption spectra of $1 \times 10^{-3}M$ Fe(II)NO–edta complex (——) and of the solution

oxidized by bromate (---) are shown in Fig. 1. This result shows that the NO complex has two absorption peaks, at about 440 and 620 nm; a similar result has been reported by Ogura and Ozeki.[6] The oxidation destroys the NO complex completely, and only the spectrum of the Fe(III)edta complex is observed.

The absorption spectra of $5 \times 10^{-5}M$ NO complex solution and of the solution obtained by oxidation and reaction with Saltzman solution are shown in Fig. 2. The two peaks in the NO-complex spectrum could not be detected in this concentration range. The absorption spectrum of the coloured product has a maximum at 545 nm, in fair agreement with that obtained in the conventional Saltzman method. The molar absorptivity of this peak is about 100 times that of the NO complex at 620 nm, so the oxidative method is much more sensitive than direct spectrophotometric determination of the NO complex.

The effect of the volume of Saltzman solution added is shown in Fig. 3. Initially, the absorbance increases with amount of Saltzman solution, but then decreases with larger volumes because of dilution. The largest absorbance was obtained when 2 ml of Saltzman solution were added to 1 ml of oxidized solution, but the azo-dye was unstable if the total volume was less than 5 ml, so we chose to add 6 ml of Saltzman solution.

The stability of the absorbance (at 545 nm) as a function of bromate concentration used is shown in Fig. 4, for $0.01M$ Fe(II)edta concentration. When $0.01M$ bromate was used, the absorbance became constant within about 12 min, and was stable for a further 30 min, so this concentration was selected for use.

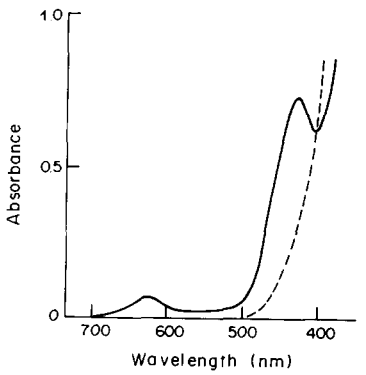

Fig. 1. Absorption spectra of $1 \times 10^{-3}M$ Fe(II)NO–edta complex solution (——) and the oxidized solution (---).

NO absorption

The calibration graph for the NO complex was linear over the Fe(II)NO–edta concentration range from 1×10^{-5} to $1 \times 10^{-4}M$, and was used to calculate the absorption efficiency for NO. The slope of this calibration curve was 35% lower than that in the conventional Saltzman method,[7] which suggests that the NO co-ordinated in the complex is oxidized to some other species besides NO_2^-, so the anion species obtained were determined by ion chromatography.[8] It was found that there was 65% conversion of NO into NO_2^- and 35% into NO_3^-, which accounts for the lower slope.

The effect of the concentration of Fe(II)edta complex is shown in Fig. 5. The absorbance becomes maximal and constant with an Fe(II)edta concentration above about $0.005M$.

Table 1 shows that NO was absorbed in the first absorption flask with 100% efficiency. The solution in the second absorption flask gave zero absorbance,

Table 1. Efficiency of absorption of NO by 0.01*M* Fe(II)edta during passage of 3 litres of sample gas at 100 ml/min

Concentration of NO gas, *ppm*	Absorbance	Absorption efficiency*, %	Coeff. of variation, %
10.1	0.024	100	4.3
30.4	0.073	100	4.0
70.2	0.166	99.4	1.3
102.0	0.243	99.6	3.1

*Mean of five results

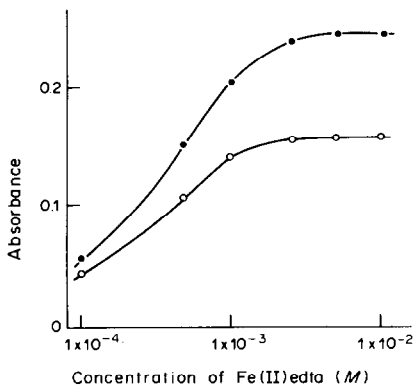

Fig. 5. Effect of the Fe(II)edta concentration in the absorbent, on the absorbance obtained: [NO] ●—102.0 ppm, ○—70.2 ppm; flow-rate, 100 ml/min.

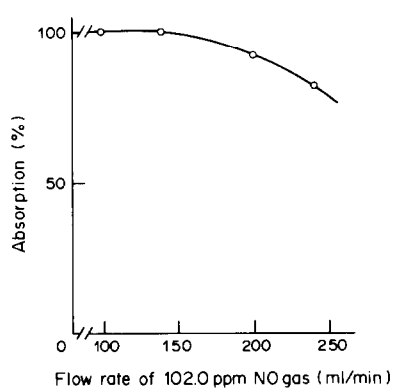

Fig. 6. Effect of sample flow-rate (102.0 ppm NO) on absorption efficiency.

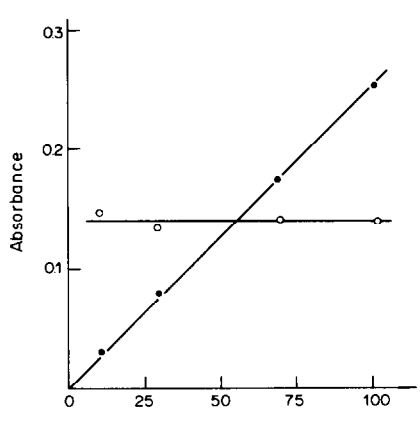

Fig. 7. Separative determination of NO and NO_2 in a mixture. ● NO (flow-rate 100 ml/min); ○ NO_2 (100 ppm, flow-rate 40 ml/min).

the second absorption flask gave zero absorbance, confirming complete absorption of NO in the first flask.

The effect of flow-rate on the absorption efficiency at the 102-ppm NO level is shown in Fig. 6. Absorption is complete if the flow-rate does not exceed about 130 ml/min.

From these results, it is seen that the method has the merits that NO can be completely absorbed and reproducibly (though not completely) oxidized to NO_2^-. The detection limit of the method is about 3 ppm for a sample size of about 3 litres of air; the analysis takes about an hour, half of this time being needed for sampling. No "Saltzman" type conversion factor is needed, since the fractional conversion of NO into NO_2^- is compensated for in the calibration procedure.

Nitrogen dioxide is also absorbed by the Fe(II)edta solution to form the Fe(II)NO–edta complex and NO_3^- in weakly acidic media,[9,10] so NO_2 might be expected to interfere in the determination of NO. However, NO_2 can be removed from its mixture with NO by selective absorption with Saltzman solution, and the NO then absorbed in Fe(II)edta solution. A series of mixtures of a fixed level of NO_2 and various concentrations of NO was analysed in this way, and gave the results shown in Fig. 7. The NO_2 gave practically constant absorbance on reaction with the Saltzman solution in the first flask, and the correct values were found for the NO collected in the second flask. Thus both oxides can be determined in the same sample.

COMPLEXOMETRIC DETERMINATION OF CITRIC ACID WITH COPPER

E. SZEKELY
Institute for Chemistry & Chemical Technology, The Institutes for Applied Research, Ben-Gurion University of the Negev, P.O. Box 1025, Beer-Sheva 84110, Israel

(*Received* 13 *April* 1984. *Revised* 14 *June* 1984. *Accepted* 14 *September* 1984)

Summary—A method is presented in which citrate is determined by complexation with excess of copper(II), followed by back-titration with EDTA. Small amounts of citrate can be determined by this method in the presence of large amounts of most organic acids present in natural products. Interfering reductants are removed by treatment with permanganate, amino-acids with nitrous acid, and metal ions with a cation-exchange resin. The indicator used for end-point detection is Szechromotrope, 4,4′-sulphonyl-bis(azobenzene) dichromotropic acid.

The use of 4,4′-sulphonyl-bis(azobenzene) dichromotropic acid as a metallochromic indicator for colorimetric and complexometric determination of small amounts of copper(II) was reported earlier.[1] This paper presents a method in which this indicator is used in the determination of citrate by addition of excess of copper(II) and back-titration with EDTA. Citric acid can be determined by this method with high precision in the presence of other acids if interfering amino-acids are removed by treatment with nitrous acid, reductants by treatment with permanganate, and metal ions by treatment with a cation-exchange resin.

The use of copper(II) for complexation and determination of citric acid has been reported before,[2–8] but our method has advantages of simplicity and reliability, can be performed without expensive instruments, and can also be used for micro-amounts of citrate.

The indicator was synthesized in our laboratory by diazotizing 4,4′-sulphonyldianiline and coupling it with chromotropic acid. It has been recommended as a reagent for the colorimetric determination of boron.[9] The indicator ($C_{32}H_{18}N_4O_{18}Na_4$) is a brownish-red powder, easily soluble in water to give a pink solution with molar absorptivity 5.8×10^4 $l.mole^{-1}.cm^{-1}$ at $\lambda_{max} = 538$ nm. A blue copper complex forms instantly at pH 6.8–7.6 (molar absorptivity 4.2×10^4 $l.mole^{-1}.cm^{-1}$ at $\lambda_{max} = 384$ nm). Aqueous solutions of the reagent and its complexes are stable. No blue colour develops with other uni-, bi- or tervalent metal ions. The reagent is commercially available under the trade name Szechromotrope, from Gammatest Ltd, Ben-Gurion University of the Negev, Beer-Sheva 84110, Israel.

EXPERIMENTAL

Reagents

Aqueous indicator solution, 0.1%.

Copper sulphate solution, 0.01M, *standardized by EDTA titration.*

Standard 0.01*M and* 0.001*M EDTA.*

Buffer solution. Ammonium chloride (1*M*)/sodium acetate (1*M*), adjusted to pH 7.5 with dilute ammonia solution or hydrochloric acid.

Tetra-amminocuprate(II) solution. Prepared by mixing 10 ml of 0.01*M* copper sulphate with 40 ml of the buffer.

Procedures

Detection and estimation. Transfer about 5 ml of water into a small flask or large test-tube, add 0.25 ml (5 drops) of amminocuprate solution and 1 drop of indicator solution and mix. Add nearly neutral sample solution slowly from a graduated pipette, continuously shaking the vessel until the colour changes from blue to violet, which corresponds to the presence of about 0.1 mg of citric acid in the volume of sample solution added. A colour change to pink indicates the presence of larger amounts of citric acid. Repeat the estimation with a more dilute sample solution if a colour change is observed after addition of only a few drops of sample. Interfering substances must be removed beforehand.

Determinations. (A) Transfer an amount of sample solution containing 1–8 mg of citric acid into an Erlenmeyer flask and dilute it to about 100 ml. Add exactly 5 ml of 0.01*M* copper sulphate, 2 drops of indicator solution, and if necessary 0.1*M* ammonia or hydrochloric acid until the colour turns blue (pH 6.8–7.6). Add 5 ml of buffer solution and titrate the excess of copper with 0.01*M* EDTA until the colour changes to pink.

(B) Transfer an aliquot of sample solution containing 0.2–3 mg of citric acid into an Erlenmeyer flask and dilute it to about 50 ml. Add exactly 2 ml of 0.01*M* copper sulphate, 1 drop of indicator solution, and if necessary 0.1*M* ammonia or hydrochloric acid until the colour becomes blue (pH 6.7–7.6). Add 2 ml of buffer solution and titrate the excess of copper with 0.001*M* EDTA until the colour changes to violet, then slowly until it becomes pink.

RESULTS AND DISCUSSION

Interferences

Only a few of the organic acids present in natural products interfere in the detection, estimation and determination of citrate ions by the procedures above. Up to 1000 ppm of tartaric, succinic, malic, hydroxyacetic, lactic, salicylic and quinic acids have no influence on the precision, nor do phosphoric or

nitric acids or univalent metal ions. Determinations performed in the presence of up to 5 g of glucose and up to 20 ml of ethanol in 100 ml of sample solution showed no bias. Interference by reducing acids such as ascorbic, oxalic, fumaric and sulphurous was prevented by the addition of 0.1*N* permanganate. Metal ions were removed by treatment with a cation-exchange resin. Interference from amino-acids was eliminated by addition of sodium or potassium nitrite to acidified solutions.

The reliability and precision were determined by repeated analysis. An accurately prepared 20-mg/ml citric acid stock solution was prepared with anhydrous citric acid dried at 110° to constant weight; a 10-ml aliquot of this solution was diluted, neutralized and made up to 200 ml: 1 ml ≡ 1 mg of citric acid. Various mixtures were also analysed.

Sample I. A 5-ml aliquot of the 1-mg/ml solution was diluted to about 100 ml and analysed by procedure (A). In 5 determinations an average of 2.40 ml of EDTA solution was used for titration of the excess of copper, with a maximum deviation of ±0.02 ml (0.8%). The amount of citric acid was calculated from citric acid = $(5 - a) \times 1.92$ mg where a = ml of 0.01*M* EDTA used (found: 4.99 mg).

A 5-ml aliquot of the 1-mg/ml solution was diluted accurately to 100 ml and a 10-ml portion of this solution was titrated with 0.001*M* EDTA by procedure (B). In 5 determinations an average of 17.40 ml of EDTA was used, with a maximal deviation of ±0.1 ml (0.6%). The amount of citric acid was calculated from citric acid = $(20 - a) \times 0.192$ mg = 0.499 mg.

Sample II. Citric acid, 0.02 g; malic acid, 0.50 g; tartaric acid, 1.00 g; glucose 10.0 g; ethanol, 20 ml; water to 100 ml. Samples of 10, 25, and 50 ml were taken. The 10-ml sample was diluted to about 50 ml, treated by procedure B, and titrated with 0.001*M* EDTA (14.9 ml). Citric acid found = 0.98 mg. The 25- and 50-ml samples were diluted to about 100 ml and titrated with 0.01*M* EDTA. Citric acid found = 2.53 mg (25-ml sample) and 4.90 mg (50 ml).

Sample III. Citric acid, 0.05 g; calcium chloride, 1.0 g; magnesium chloride, 0.50 g; urea, 5.0 g; water to 100 ml. A 50-ml portion was treated with Amberlite IR 120 cation-exchange resin, neutralized, and diluted to 100 ml. Three aliquots (25 ml each) were diluted to about 100 ml, treated by procedure A and titrated with 0.01*M* EDTA (1.76, 1.80 and 1.78 ml). Citric acid found = 6.18 mg, corresponding to 49.4 mg in 100 ml of sample III.

Sample IV. Citric acid, 0.50 g; ascorbic acid, 0.25 g; oxalic acid, 0.05 g; water to 100 ml. Ten ml were diluted to about 50 ml and 1 ml of 0.1*N* hydrochloric acid was added, and then 0.1*N* permanganate (dropwise). The excess of permanganate was removed by adding 1 drop of 0.1*N* thiosulphate. The solution was then treated with the cation-exchange resin, neutralized, and diluted to about 100 ml, treated by procedure A, and titrated with 0.01*M* EDTA (2.40, 2.42 and 2.42 ml). Citric acid found = 4.79 mg, corresponding to 0.479 g in sample IV.

Sample V. Citric acid, 0.50 g; lactic acid, 5.0 g; glutamic acid, 1.0 g; water to 100 m. To 25 ml of this solution 5 ml of concentrated hydrochloric acid and 0.5 g of sodium nitrite were added. The solution was mixed and heated to about 70° until no more gas was evolved. The neutralized solution was diluted to 100 ml. Three 5-ml aliquots of the sample solution were diluted to about 100 ml, treated by procedure A, and titrated with 0.01*M* EDTA (1.74, 1.72 and 1.74 ml). Citric acid found = 6.28 mg, corresponding to 0.502 g in sample V.

Though there are several indicators for complexometric determination of copper(II)[10] which can also be used in our method, the indicator recommended has several advantages. Murexide, though widely used, is less stable, the colour change from yellow to violet is less sensitive, and it is more difficult to maintain the desired pH. The nitrosochromotropic acid indicator[11,12] gives a colour change comparable to that of our indicator, but its solution, which has to be freshly prepared for each assay, is less stable. Also, two different pH ranges were recommended by the authors (pH 7.25–8.80 and 5.8–6.5), without explanation.

REVERSED-PHASE EXTRACTION CHROMATOGRAPHY OF GERMANIUM(IV) WITH TRIBUTYL PHOSPHATE ON SILICA GEL

S. N. BHOSALE and S. M. KHOPKAR
Department of Chemistry, Indian Institute of Technology, Powai, Bombay 400076, India

(*Received* 25 *April* 1984. *Accepted* 14 *September* 1984)

Summary—Germanium(IV) can be separated by reversed-phase extraction chromatography with TBP as stationary phase on a column of silica gel, with 6*M* hydrochloric acid as the mobile phase, and stripped with various eluents. Germanium can thus be separated (by selective extraction) from those elements which are not extractable with TBP, and (by selective stripping) from elements that *are* extractable.

Reversed-phase extraction chromatography offers a promising separation of germanium at tracer concentration from associated elements. Trioctylamine has been used as the stationary phase ("Corvic" as support) for separation of germanium from arsenic, indium, manganese, cobalt, copper and zinc.[1] Here we describe the use of tributyl phosphate as the stationary phase (on silica gel) for separation of germanium from iron, gallium, antimony and lead.

EXPERIMENTAL

Reagents

Stock germanium solution was prepared by fusing 1.27 g of pure germanium dioxide with an equal amount of sodium hydroxide in a platinum crucible, cooling, extracting with water, neutralizing, and diluting to 250 ml with water, standardized gravimetrically,[2] and diluted appropriately as required.

Gum arabic solution was prepared by dissolving 0.5 g of the powder in 50 ml of hot water.

Phenylfluorone solution was prepared by dissolving 0.03 g in 50 ml of ethanol and 5 ml of sulphuric acid (1 + 6).

Silica gel was rendered hydrophobic and coated with tributyl phosphate (TBP) as described earlier,[3] and a 2–3 g portion of the coated gel was slurried with 25 ml of distilled water and used to make a 6 × 0.8 cm column. The column was washed with 6*M* hydrochloric acid, pre-equilibrated with TBP.

RESULTS AND DISCUSSION

Germanium can be quantitatively extracted with 25% TBP in toluene from 3*M* hydrochloric acid containing 2*M* magnesium chloride as salting-out agent[4] and with pure TBP from 1.5*M* hydrochloric acid only in the presence of salting-out agent, but for the present extraction chromatographic study salting-out agents were not used. The retention of germanium on the column was measured for various concentrations of hydrochloric acid (1–6*M*) in the eluent. The retention increased with acid concentration, maximum extraction occurring from 5–6*M* hydrochloric acid. The degree of extraction was found to depend on the flow-rate of the mobile phase. Experiments with 4, 5 and 6*M* hydrochloric acid and flow-rates of 0.5, 1.0 and 2.0 ml/min showed that germanium was quantitatively retained from the 6*M* acid at a flow-rate of 0.5 ml/min (Fig. 1). The maximum uptake of germanium was also found to depend on the flow-rate (Table 1).

A portion of solution containing 64 μg of germanium was made 6*M* in hydrochloric acid and passed through the column at a flow-rate of 0.5 ml/min, then the germanium was stripped with an eluent, ten 2-ml fractions being collected and analysed spectrophotometrically with phenylfluorone,[5] with measurement at 510 nm. Hydrochloric acid

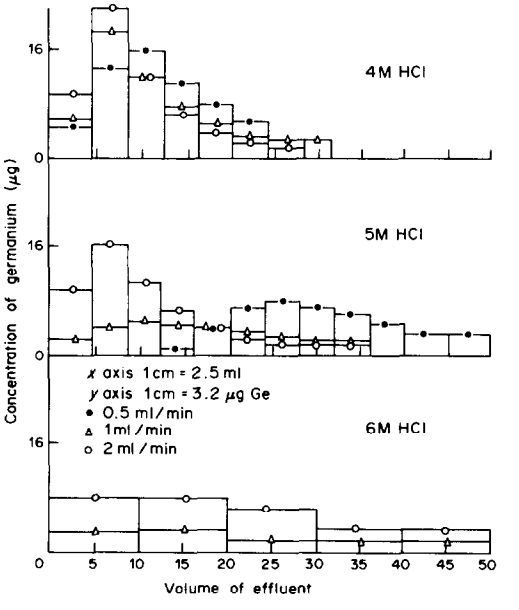

Fig. 1. Effect of flow-rate and eluent concentration on retention of Ge.

Table 1. Effect of flow-rate on column capacity (mobile phase 6*M* HCl)

Flow-rate, *ml/min*	Column capacity, *mg/g*
0.2	2.41
0.5	1.25
0.7	0.71
1.0	0.30

(0.001–3*M*), nitric acid (0.5–2*M*), sulphuric acid (0.5–2*M*), lithium chloride (0.2–1*M*) and water all gave quantitative elution (Table 2).

Separation of germanium from mixtures

Ions which are not extracted from 6*M* hydrochloric acid by TBP will pass through the column unsorbed, and germanium can be separated from them by retention on the column and then elution with 0.001*M* hydrochloric acid. Germanium can thus be separated from alkali and alkaline-earth metals, aluminium, yttrium, zirconium, vanadium(IV), chromium(III), manganese(II), cobalt, nickel, copper(II), zinc, bismuth and lead, by this technique, with 99.4–100% recovery.

Germanium can be separated from elements extractable by TBP from 6*M* hydrochloric acid by exploiting the differences in distribution coefficient at various concentrations of hydrochloric acid. Thus germanium can be separated from a mixture with thallium(III), chromium(VI) or mercury(II), by making the mixture 1*M* in hydrochloric acid before passing it through the column, where germanium is unextracted whereas the other species are retained and can subsequently be eluted with 0.1*M* hydrochloric acid containing 4% thiourea. Similarly germanium can be separated from gallium, iron(III), indium or antimony(III) by using 4*M* hydrochloric acid medium, the germanium again passing through.

Table 2. Elution of Ge(IV) (64 μg)

Eluent	Concentration, M	Peak elution volume, *ml*	Total volume, *ml*	Recovery, %

Ge(IV)	64.3	64			2
Fe(III)	510.3	511			0.5
Al	70.3	70	5	0.5	6
Ge(IV)	64.3	64			3
Fe(III)	100.1	100			1
Cr(VI)	200.3	201			0.001

Separation from multicomponent mixtures

When a mixture of germanium, iron(III) and chromium(VI) in 3*M* hydrochloric acid is passed through the column, germanium comes out first, with no extraction. Iron(III) can then be eluted with 1*M* hydrochloric acid and finally chromium(VI) with 0.001*M* hydrochloric acid.

When a mixture of germanium with cobalt, chromium(III) and iron(III) in 6*M* hydrochloric acid is passed through the column, the cobalt or chromium(III) will pass through. Germanium can then be eluted with 3*M* hydrochloric acid, followed by elution of iron(III) with 0.5 or 1*M* hydrochloric acid.

These separation schemes can obviously be extended to cover mixtures of germanium with both the extractable and non-extractable groups of ions. Some results for analysis of some typical mixtures are shown in Table 3. The elements were determined either titrimetrically[6] or spectrophotometrically[5].

The separation of germanium from copper, zinc, gallium, lead and antimony is important as they are associated with it in various minerals. The proposed method is simple, rapid and selective. The total time required for separation and determination is just 3 hr. The results are reproducible within $\pm 1.1\%$. However, it was found impossible to separate germanium from cadmium (which is also associated with it in minerals).

ANALYTICAL DATA

STUDIES ON FLUORESCEIN—II*

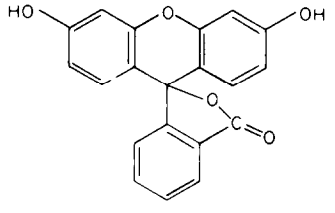
THE SOLUBILITY AND ACID DISSOCIATION CONSTANTS OF FLUORESCEIN IN WATER SOLUTION

HARVEY DIEHL and RICHARD MARKUSZEWSKI†
Department of Chemistry, Iowa State University, Ames, Iowa, 50011, U.S.A.

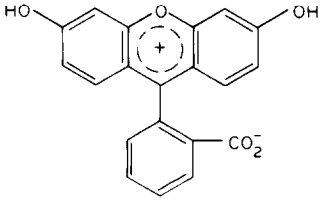
(*Received* 4 *April* 1984. *Accepted* 14 *September* 1984)

Summary—The solubility of yellow fluorescein and of red fluorescein as a function of pH has been measured in water at ionic strength 0.10. The pH of minimum solubility is the same for both, 3.28. The intrinsic solubility, defined as the solubility of the undissociated species, H_2Fl, and assumed to be constant and independent of pH, was calculated from the observed solubilities on the low-pH side of the minimum: $S_{i,yellow} = 3.80 \times 10^{-4} M$: $S_{i,red} = 1.45 \times 10^{-4} M$. The first dissociation constants were evaluated from the intrinsic solubilities and the observed solubilities on the low-pH side: both fluoresceins yielded the same value, $pK_{H_3Fl} = 2.13$. In using the observed solubilities on the high-pH side of the minimum to evaluate the intrinsic solubility and the second dissociation constant it was necessary to modify the existing theoretical approach by taking into account the presence of the fully dissociated anion. Appropriate mathematical treatments were devised to handle the more complex equations. Both fluoresceins yielded the same value for the second dissociation constant, $pK_{H_2Fl} = 4.44$. Both fluoresceins give the same yellow colour in saturated solution and the results just reported for the pH of minimum solubility and for the dissociation constants also indicate that for each of the three prototropic forms of fluorescein present in solution, H_3Fl^+, H_2Fl, and HFl^-, only one structure exists.

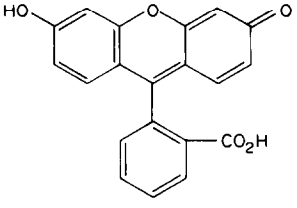
During 1980 we advanced structures for the three solid forms of fluorescein,[1] *viz.* for the colourless solid the lactone structure (**I**), for the red solid the *p*-quinonoid structure (**III**), and for the yellow solid a zwitterion structure with a positive charge distributed over the oxygen-bearing ring (**II**). We have now measured the solubilities of the yellow and red solids



I Lactone structure, colourless form



II Zwitterion structure, yellow form



III *p*-Quinonoid structure, red form

as functions of pH. As pointed out in the earlier paper, the colourless lactone solid exists in solution only in dry organic non-polar solvents such as dioxan and, on contact with water, changes quickly to the yellow zwitterion form; it therefore plays no part in the present discussion.

Fluorescein is characterized by three acid dissociation constants. For clarity, and to emphasize the amphoteric nature of fluorescein, we have adopted the designation H_2Fl for fluorescein (the "free acid") and for the respective dissociation constants the symbols:

Reaction	*Constant*	
$H_3Fl^+ = H^+ + H_2Fl$	$K_{H_3Fl} = [H^+][H_2Fl]/[H_3Fl^+]$	(1)
$H_2Fl = H^+ + HFl^-$	$K_{H_2Fl} = [H^+][HFl^-]/[H_2Fl]$	(2)
$HFl^- = H^+ + Fl^{2-}$	$K_{HFl} = [H^+][Fl^{2-}]/[HFl^-]$	(3)

We have determined the first two of the three acid dissociation constants from data on the solubilities as a function of pH, for both the yellow and red solids, by a modification of the procedure of Krebs and Speakman.[2] The concentration of fluorescein in the various saturated solutions was determined by mea-

†Present address: Ames Laboratory, Iowa State University, Ames, Iowa 50011, U.S.A.

suring the fluorescence of an aliquot brought to pH 11.

As in the earlier paper, we worked with fluorescein prepared from diacetylfluorescein and verified the purity of the materials by titration with alkali; we thus avoided certain faults which adversely affected certain earlier studies.

EXPERIMENTAL

Materials

Diacetylfluorescein, yellow fluorescein and red fluorescein were prepared as described earlier.[1]

Buffers with pH-values in the range 1–6 were prepared from 0.10*M* hydrochloric acid, potassium hydrogen phthalate and potassium hydroxide. Dilutions were made with 0.10*M* potassium chloride to maintain the ionic strength. The pH of the buffer solutions was measured before and after saturation with the fluorescein, with a Corning Model 10 pH-meter, with a Beckman glass electrode and a saturated calomel electrode as reference electrode. The pH-meter was standardized with a standard buffer solution of pH 4.01, prepared from potassium hydrogen phthalate according to the NBS specification.

Preparation of calibration graphs

Highly purified yellow and red fluorescein were dried at 100–110° for 3 hr, and 100.0 mg of each were dissolved in, and diluted to exactly 1 litre with, 0.10*M* potassium hydroxide. Stock solutions containing 1.0 ppm of fluorescein were prepared by diluting 1.00 ml of these solutions to 100.0 ml with 0.10*M* potassium hydroxide. Volumes of 1, 3, 6, 10, 15 and 20 ml of these solutions were taken and diluted to 100.0 ml with 0.10*M* potassium hydroxide for fluorimetric measurement. The calibration curves for the yellow and red fluoresceins were identical.

Measurement of fluorescence

Relative fluorescence was measured with a Turner Model 110 Fluorometer. A Corning No. 5850 filter was used as a primary filter to isolate the blue portion of the excitation radiation. A combination of a Corning Yellow 2A-15 filter and a Wratten N. D. Filter 10 per cent 1.00 was used as the secondary filter. The calibration graphs were measured at three different sensitivity settings of the fluorometer. This, in combination with variations in the size of aliquots and final volumes, provided maximum accuracy.

Solubility measurements

Approximately 25 ml of each buffer solution was placed in a 600-ml plastic bottle provided with a screw cap. Into each bottle sufficient red or yellow fluorescein was added to ensure saturation of the resulting solution. Bottles and suspensions were then shaken mechanically for 72 hr at room temperature, 23.0 ± 0.5°. Each solution was subsequently filtered through a sintered-glass crucible, and the final pH was measured. A 5.00-ml aliquot of each solution was diluted to 100.0 ml with potassium hydroxide and the relative fluorescence of the solution was measured. The results are given in Table 1.

EVALUATION OF THE INTRINSIC SOLUBILITY OF THE YELLOW AND RED FLUORESCEINS

As will be seen on examination of Table 1 and Fig. 1, the solubilities of both the yellow and red forms of fluorescein exhibit a minimum at pH 3.28. The solubility increases on the low-pH side owing to protonation to form H_3Fl^+ [equation (1)] and on the high-pH side owing to dissociation to form HFl^- [equation (2)]. Such amphoteric behaviour is typical of zwitterions, and the dissociation constants can be evaluated from the solubility data by a method originated by Krebs and Speakman.[2]

The solubility of the free acid, the *intrinsic solubility*, S_i, is assumed to be constant and independent of pH:

$$S_i = [H_2Fl] \quad (4)$$

The solubility at any pH below the minimum is given by

$$S_j = [H_3Fl^+] + [H_2Fl] \quad (5)$$

and that at pH values above the minimum, S_h, is given by

$$S_h = [H_2Fl] + [HFl^-] \quad (6)$$

It is also assumed that over the pH range immediately above the minimum the concentration of Fl^{2-} is

5.55	5.53	4.72×10^{-3}	5.55	1.90×10^{-3}
6.04	6.03	1.80×10^{-2}	6.06	6.95×10^{-3}

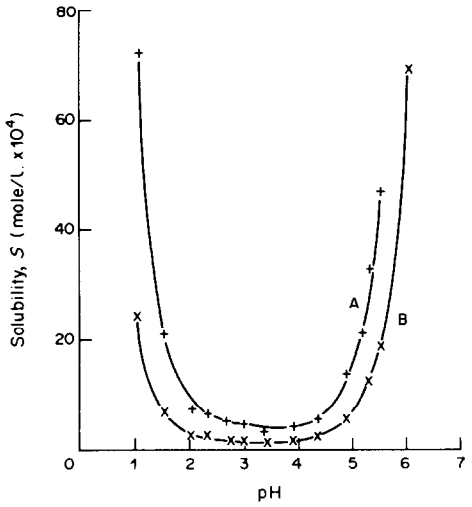

Fig. 1. Solubility of yellow fluorescein (curve A) and of red fluorescein (curve B) as a function of pH at 23°.

negligible (the validity of this assumption is examined below).

Combination of equations (1) and (4) yields

$$K_{H_3Fl} = [H^+]S_i/(S_j - S_i) \quad (7)$$

Rearrangement of equation (7) gives

$$S_j = S_i + [H^+]S_i/K_{H_3Fl} \quad (8)$$

and

$$-\log[(S_j/S_i) - 1] = -pK_{H_3Fl} + pH \quad (9)$$

According to equation (8) a plot of S_j *vs.* $[H^+]$ yields a straight line, the intercept of which at $[H^+] = 0$ is S_i. According to equation (9) the plot of $-\log[S_j/S_i) - 1]$ *vs.* pH yields a straight line of unit slope, the intercept of which is pK_{H_3Fl}.

Similarly, combination of equations (2) and (4) yields

$$K_{H_2Fl} = [H^+](S_h - S_i)/S_i \quad (10)$$

Rearrangement of equation (10) gives

$$S_h = S_i + K_{H_2Fl}S_i/[H^+] \quad (11)$$

or

$$\log[(S_h/S_i) - 1] = -pK_{H_2Fl} + pH \quad (12)$$

According to equation (11) a plot of S_h *vs.* $1/[H^+]$ yields a straight line, the intercept of which at $1/[H^+] = 0$ is S_i. According to equation (12) a plot of $\log[(S_h/S_i) - 1]$ *vs.* pH gives a straight line of unit slope, the intercept of which is $-pK_{H_2Fl}$.

Thus, the intrinsic solubility can be evaluated from two sets of data, on the low-pH side of the minimum, equation (8), and on the high-pH side, equation (11). For yellow fluorescein, the two approaches yielded somewhat different values, as shown in Table 2. Least-squares treatment of the 6 data points on the low-pH side yielded $S_j = 3.795 \times 10^{-4} + 0.0579[H^+]$ with R (correlation coefficient) = 0.997 (Fig. 2 curve A); hence $S_{i,yellow} = 3.80 \times 10^{-4}M$, and $K_{H_3Fl(yellow)} = 6.55 \times 10^{-3}$. For red fluorescein, the corresponding values were $S_j = 1.45 \times 10^{-4} + 0.0175[H^+]$, $R = 0.994$ (Fig. 1, curve B), $S_{i,red} = 1.45 \times 10^{-4}M$, and $K_{H_3Fl(red)} = 8.30 \times 10^{-3}$.

Least-squares treatment of the data on the high-pH side of the minimum, equation (11), yielded intercepts which varied with the number of data points used: $3.23 \times 10^{-4}M$ ($n = 4$), $3.49 \times 10^{-4}M$ ($n = 5$), $3.12 \times 10^{-4}M$ ($n = 6$), $3.22 \times 10^{-7}M$ ($n = 7$), $-0.347 \times 10^{-4}M$ ($n = 8$); although the successive plots (as n increased) were linear with high correlation coefficients (Fig. 3 curve A, for $n = 7$, for which least-squares gave $S_h = 3.22 \times 10^{-4} + 1.309 \times 10^{-9}/[H^+]$; $R = 0.9962$), only a likely average (disregarding

§Correction made for the presence of Fl^{2-}.

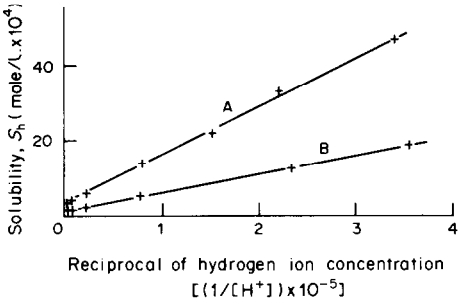

Fig. 3. Determination of the intrinsic solubility, S_i, of yellow fluorescein (curve A) and of red fluorescein (curve B) from solubility data on the high-pH side of the minimum solubility [equation (11)].

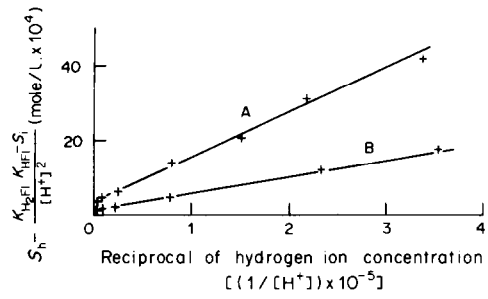

Fig. 4. Determination of the intrinsic solubility, S_i, of yellow fluorescein (curve A) and of red fluorescein (curve B) from solubility data on the high-pH side of the minimum solubility, with correction applied for the presence of Fl^{2-}; [equation (16), second approximation treatment].

$n = 8$) could be chosen: $S_{i,yellow} = 3.27 \times 10^{-4} M$ (Table 2). In general, the inclusion of the data at pH 6 (6.03 for yellow and 6.06 for red fluorescein) seriously distorted the results; it was suspected that at this pH (well above the pH, 5.5, at which the neutral form is completely dissociated) the systems did not conform to the assumptions made, so these data were not used in obtaining results by the unmodified Krebs and Speakman procedure.

For red fluorescein, corresponding treatment again yielded a value for the intercept which varied with the number of data included: $1.24 \times 10^{-4} M$ (4), $1.23 \times 10^{-4} M$ (5), $1.16 \times 10^{-4} M$ (6), $0.018 \times 10^{-14} M$ (7), *e.g.*, Fig. 2, curve B (for $n = 6$, for which least-squares gave $S_h = 1.16 \times 10^{-4} + 4.97 \times 10^{-9}/[H^+]$, $R = 0.99965$); again only a likely average (omitting the data for pH 6.06) could be chosen: $S_{i,red} = 1.21 \times 10^{-4} M$ (Table 2).

The variability and the drift in the values for the intrinsic solubilities obtained on the high-pH side of the minimum indicated that some additional factor was involved.

Since we knew from other work that the difference between the second and third dissociation constants is small (about 1.5–1.8 pK units) we realized that a significant amount of the doubly-charged anion must be present and of course increases with rising pH. The solubility on the high-pH side is then given by

$$S_h = [H_2Fl] + [HFl^-] + [Fl^{2-}] \qquad (13)$$

Introduction of equations (1)–(3) into (13) and assuming the solubility of the undissociated species to be constant and independent of pH, so that $[H_2Fl] = S_i$, gives

$$S_h = S_i\{1 + K_{H_2Fl}/[H^+] + K_{H_2Fl}K_{HFl}/[H^+]^2\} \qquad (14)$$

This is an awkward form for evaluation of S_i, and we adopted an approximation approach. The values best known at the time for the three constants in the third term within the braces were used to calculate the value of this term at each experimental pH, and this was applied as a correction to the solubility observed:

$$S_h - K_{H_2Fl}K_{HFl}S_i/[H^+]^2 = S_i + K_{H_2Fl}S_i/[H^+] \qquad (15)$$

For yellow fluorescein, the constants used in this treatment were p$K_{H_2Fl} = 4.73$, p$K_{HFl} = 6.36$, $S_{i,yellow} = 3.80 \times 10^{-4} M$. The correction was zero at the data points near the minimum but became significant at higher pH-values. The plots of $S_h - K_{H_2Fl}K_{HFl}S_i/[H^+]^2$ *vs.* $1/[H^+]$ were linear and led to an essentially constant value for the intrinsic solubility as the number of sets of data included was increased. The value obtained was $S_{i,yellow} = 3.42 \times 10^{-4} M$, Table 2. This value was then used in equation (12), as described in the next section, to obtain a new value for the second dissociation constant; this new value (p$K_{H_2Fl} = 4.52$) and the corrected S_i value were then used in a second approximation. The plot was linear (Fig. 3, curve A) and least-squares treatment yielded $S_h - K_{H_2Fl}K_{HFl}S_i/[H^+]^2 = 3.48 \times 10^{-4} + 1.198 \times 10^{-8}/[H^+]$, giving $S_{i,yellow} = 3.48 \times 10^{-4} M$, practically the same as that from the first approximation.

For red fluorescein, the constants used in the first approximation treatment were p$K_{H_2Fl} = 4.73$, p$K_{HFl} = 6.36$, $S_{i,red} = 1.16 \times 10^{-4} M$, and gave $S_{i,red} = 1.24 \times 10^{-4} M$ (Table 2). This value was used in equation (12) to obtain p$K_{H_2Fl} = 4.52$, and the second approximation treatment gave a linear plot (Fig. 4, curve

Table 3. Values for the dissociation constants, K_{H_3Fl} and K_{H_2Fl}, of yellow and of red fluorescein as determined from solubility data (ionic strength 0.10)

Constant	Yellow fluorescein	Red fluorescein
pK_{H_3Fl} low-pH side of minimum equation (9)[a]	2.15	2.11
pK_{H_2Fl} high-pH side of minimum equation (12)[b]	4.44[c,d]	4.42[e,d]
equation (18)	4.45[f]	4.43[f]

[a] By least-squares with slope forced to be equal to 1.000.
[b] From intercept on pH-axis.
[c] Including the data at pH 6.03.
[d] By least-squares; same value obtained by forcing slope to be 1.000.
[e] Including data point at pH 6.06.
[f] Slope of least-squares line was zero; direct averaging of the value on the ordinate of the plot gave: yellow fluorescein, pK 4.43, red fluorescein, pK 4.42.

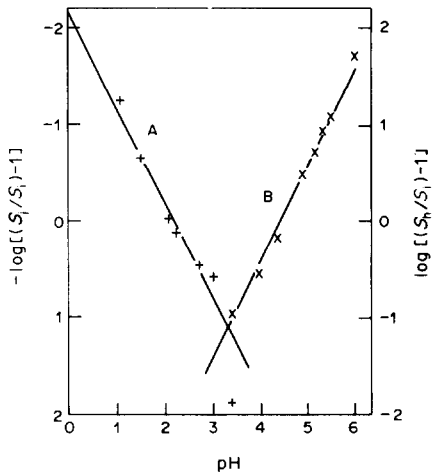

Fig. 5. Evaluation of the dissociation constants, K_{H_3Fl} and K_{H_2Fl}, of yellow fluorescein. Curve A, from solubility data on the low-pH side; $-\log[(S_j/S_i) - 1]$ *vs.* pH [equation (9)]; curve B, from solubility data on the high-pH side; $\log[(S_h/S_i) - 1]$ *vs.* pH [equation (12)]. For both straight lines the slope has been forced to be 1.000 in the least-squares treatment. The intersection point, pH 3.29, is the pH of minimum solubility.

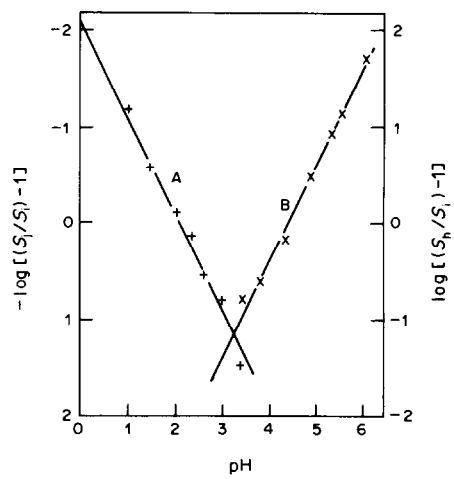

Fig. 6. Evaluation of the dissociation constants, K_{H_3Fl} and K_{H_2Fl}, of red fluorescein. Symbols and method as for Fig. 5. The point of intersection, pH 3.27, is the pH of minimum solubility.

B): $S_h - K_{H_2Fl}K_{HFl}\ S_i/[H^+]^2 = 1.30 \times 10^{-4} + 4.42 \times 10^{-9}/[H^+]$. Thus $S_{i,red} = 1.30 \times 10^{-4}M$ (Table 2) was again little changed from the first approximation.

EVALUATION OF THE FIRST AND SECOND DISSOCIATION CONSTANTS OF YELLOW AND RED FLUORESCEIN

To obtain values for the dissociation constants, it is convenient to place the two plots, $-\log[(S_j/S_i) - 1]$ *vs.* pH [equation (9)] and $\log[(S_h/S_i) - 1]$ *vs.* pH [equation (12)] on the same graph, as in Fig. 3 for yellow fluorescein and Fig. 4 for red fluorescein. The values obtained are given in Table 3.

For both fluoresceins, the values for the intrinsic solubility used in equation (9) were those found by evaluating the data on the low-pH side as described above: $S_{i,yellow} = 3.80 \times 10^{-4}M$; $S_{i,red} = 1.45 \times 10^{-4}M$. Least-squares treatment of data from equation (9) gave for both yellow fluorescein (Fig. 5, curve A) and red fluorescein (Fig. 6, curve A) straight lines of slope close to the theoretical value of one, and intercepts on the pH-axis which were not greatly changed by the number of sets of data included. We also used a least-squares treatment in which the slope was forced to be 1.000, and consider the values so obtained to be the best:

Number of sets of data included	5	6	7	Forced slope
Yellow fluorescein				
Intercept on pH-axis	2.212	2.231	2.155	2.152
Slope	1.048	1.019	1.2416	1.000
R	0.9900	0.99049	0.975	
Red fluorescein				
Intercept on pH-axis	2.090	2.090	2.212	2.113
Slope	0.9961	0.9955	1.0429	1.000
R	0.9713	0.9853	0.9910	

The astonishing feature is that yellow fluorescein and red fluorescein yield practically the same value for the first dissociation constant. We believe that the various protonated species in water exist in only one structural form and accordingly average the values 2.152 and 2.113, and propose

$$K_{H_3Fl} = 7.41 \times 10^{-3};\ pK_{H_3Fl} = 2.13 \qquad (16)$$

To evaluate the second dissociation constant from the data on the high-pH side of the minimum, both equations (12) and (17) were used; for both equations a value must be selected for the intrinsic solubility (Table 2). When the S_i value was that obtained by equation (11), the values for K_{H_2Fl} [the intercept of equation (12)] varied with the number of data points included, for both fluoresceins. On the other hand, when the S_i value was that obtained by equation (15), second approximation, concordant values were obtained, with little variation with the number of sets of data included, and incorporated the high-pH data smoothly.

Thus application of equation (12) to yellow fluorescein, with use of $S_{i,yellow} = 3.48 \times 10^{-4}M$ and least-squares treatment forcing the slope to be 1.000 for all 8 sets of data in Fig. 5 curve B, gave $pK_{H_2Fl} = 4.43$. Similarly for red fluorescein, with $S_{i,red} = 1.30 \times 10^{-4}M$ and all 7 sets of data from Fig. 6 curve B, and a forced slope of 1.000, $pK_{H_2Fl} = 4.42$.

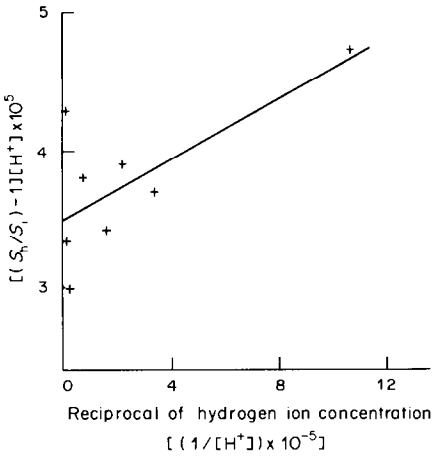

Fig. 7. Evaluation of the second dissociation constant, K_{H_2Fl}, of yellow fluorescein from solubility data on the high-pH side of the minimum solubility, with correction for the presence of the doubly-charged anion [equation (17)].

Equation (12) is based on the assumption that only the neutral species and the singly-charged anion are present, although a correction for the presence of the double-charged anion was made in arriving at the value of the intrinsic solubility used. A more rigorous treatment followed next, starting with the assumptions in equations (13)–(15). Equation (15), on rearrangement, yields

$$[(S_h/S_i) - 1][H^+] = K_{H_2Fl} + K_{H_2Fl}K_{HFl}/[H^+] \quad (17)$$

A plot of $[(S_h/S_i) - 1][H^+]$ *vs.* the reciprocal of the hydrogen-ion concentration for yellow fluorescein, again using $S_{i,yellow} = 3.48 \times 10^{-4}M$, is shown in Fig. 7; least-squares treatment gave $[(S_h/S_i) - 1][H^+] = 3.496 \times 10^{-5} + 1.103 \times 10^{-11}/[H^+]$, for all 8 sets of data ($R = 0.68511$), *i.e.*, $K_{H_2Fl} = 3.496 \times 10^{-5}$. The slope of almost zero makes equation (17) an interesting function, since the left-hand side is essentially independent of pH. A consequence of this is a low correlation coefficient of the least-squares line [for yellow fluorescein, $R = 0.01739$ for 4 sets of data, increasing to $R = 0.1492$ (6 sets), and to $R = 0.68511$ (8 sets, including the set at pH 6)]; thus, not surprisingly, the eight values for $[(S_h/S_i) - 1][H^+]$ yielded, on simple averaging, an intercept of 3.757×10^{-5}, and thus $pK_{H_2Fl} = 4.43$. Note that equations (12) and (17) yielded the same value for the second dissociation constant from the data for yellow fluorescein. Basically, then, the approach in equations (13)–(15) and (17) appears correct.

Application of equation (17) to red fluorescein, using $S_{i,red} = 1.30 \times 10^{-4}M$, yielded a linear plot (Fig. 8); least-squares treatment gave $[(S_h/S_i) - 1][H^+] = 3.690 \times 10^{-5} + 5.73 \times 10^{-12}/[H^+]$, so $pK_{H_2Fl} = 4.33$. As with yellow fluorescein, the slope was close to zero; a simple averaging of the seven values for $[(S_h/S_i) - 1][H^+]$ yielded 3.841×10^{-5}, *i.e.*, $pK_{H_2Fl} = 4.42$.

As reported above and in Table 3, equations (12) and (17) yielded the same values for the second dissociation constant for both the yellow and red fluoresceins. We therefore reiterate our belief that only one structure is present in the various prototropic forms of fluorescein existing in water solution and accordingly we average the results for both fluoresceins and propose $K_{H_2Fl} = 3.63 \times 10^{-5}$ ($pK_{H_2Fl} = 4.44$).

Comment on the pH of minimum solubility

Addition of equations (9) and (12) gives

$$\log[(S_h - S_i)/(S_j - S_i)] = 2pH - pK_{H_3Fl} - pK_{H_2Fl} \quad (18)$$

At the point of minimum solubility, the disproportionation of the undissociated species, the only species theoretically present, would produce equal amounts of the cation and the singly-charged anion:

$$2H_2Fl = H_3Fl^+ + HFl^- \quad (19)$$

and

$$S_j = S_h \quad (20)$$

At this pH, the left-hand side of equation (18) becomes zero, and

$$pH_{min.soly} = \tfrac{1}{2}(pK_{H_3Fl} + pK_{H_2Fl} \quad (21)$$

For the values presented in equations (16) and (18), $pH_{min.soly} = \frac{1}{2}(2.13 + 4.44) = 3.28$.

RESULTS AND DISCUSSION

The U-shaped curves of solubility as a function of pH, Fig. 1, for the yellow and red fluoresceins, are not expected to be symmetrical about the pH of min-

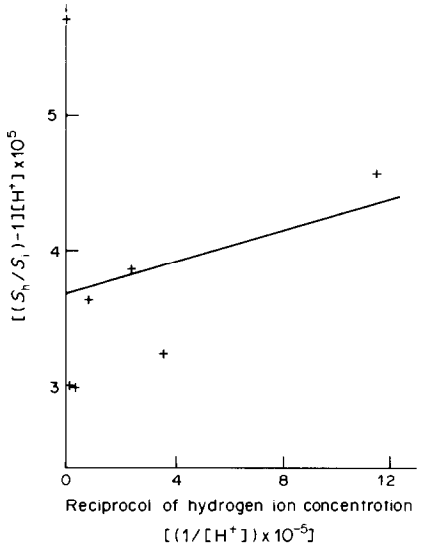

Fig. 8. Evaluation of the second dissociation constant, K_{H_2Fl}, of red fluorescein from solubility data on the high-pH side of the minimum solubility, with correction for the presence of the doubly-charged anion [equation (17)].

imum solubility, inasmuch as the branches are defined by different equations [(8) and (11)] and constants. The intrinsic solubility, however, is given the same definition, equation (4), in both equations and is assumed to be a constant independent of pH. Thus, the evaluation of the intrinsic solubility by equations (8) and (11), the first phase of the Krebs and Speakman treatment, would be expected to yield the same values, but failed to do so for the solubilities of the two fluoresceins. The treatment on the low-pH side of the minimum was straightforward, the linear least-squares treatment of the plots, Fig. 2, curves A and B, having high correlation coefficients, and the intercepts and slope showing essentially no variation with the number of sets of data used. The values found were: $S_{i,yellow} = 3.80 \times 10^{-4}M$; $S_{i,red} = 1.45 \times 10^{-4}M$ (Table 2). These values, when used in conjunction with the observed solubilities of the yellow and the red fluoresceins in the second phase of the Krebs and Speakman treatment [equation (9)] gave an identical value for the first dissociation constant $K_{H_3Fl} = 7.41 \times 10^{-3}$ ($pK_{H_3Fl} = 2.13$) (Table 3).

For both fluoresceins the data on the high-pH side of the minimum, however, gave by equation (11) significantly lower values for the intrinsic solubilities than those obtained from the data on the low-pH side, and moreover, gave values which shifted with the number of data points used. A similar effect was observed for the values of the second dissociation constants [equation (12), Krebs and Speakman second phase]. The supposition that the results were being distorted by the presence of appreciable amounts of the doubly-charged anion, Fl^{2-}, proved to be correct. The values for pK_{H_2Fl} and pK_{HFl} differ by only 1.5–1.8 and the dissociation of HFl^- is significant even at pH 4.5; at pH 5.5 it is completely dissociated and it is not surprising that the system does not conform to the assumption of the Krebs and Speakman approach.

The new theory, in which all three species (H_2Fl, HFl^- and Fl^{2-}) are assumed to be present [equations (13)–(17)], proved to be successful. Because of the nature of the equations involved, it was necessary to evaluate the intrinsic solubility by an approximation procedure. In practice, the second approximation was all that was necessary and the results from use of equation (15) conformed nicely to the theory and smoothly incorporated the data at high pH (pH > 6, data discarded in the simpler approach). The values found were $S_{i,yellow} = 3.48 \times 10^{-4}M$; $S_{i,red} = 1.30 \times 10^{-4}M$ (Table 2).

The second phase, the evaluation of the second dissociation constant, proved interesting. From the value for the intrinsic solubility obtained by use of equation (15) with the presence of Fl^{2-} taken into account, the same value for the second dissociation constant was obtained by both equation (12) (Krebs and Speakman) and equation (17) (new approach), for both yellow fluorescein and red fluorescein (Table 3); $pK_{H_2Fl} = 4.44$.

That sets of data on the solubility of two solid forms of the same chemical material should yield identical values for the pH of minimum solubility and for the two sets of dissociation constants is remarkable. The conclusion is that only one *structure* exists for fluorescein in water solution, for all three (and probably four) prototropic forms. Because the solutions at all pH values are yellow, the structure is probably the zwitterion structure **II**, with a positive charge located on the central oxygen-bearing ring and with protons and negative charges distributed about the periphery as determined by the prevailing pH.

PRELIMINARY COMMUNICATION

A NEW FLUOROGENIC THIOL-SELECTIVE REAGENT: N-{p-[2-(6-DIMETHYLAMINO)BENZOFURANYL]PHENYL}MALEIMIDE[1)]

Kenichiro Nakashima, Hiroyuki Akimoto, Ken'ichi Nishida, Shin'ichi Nakatsuji and Shuzo Akiyama*

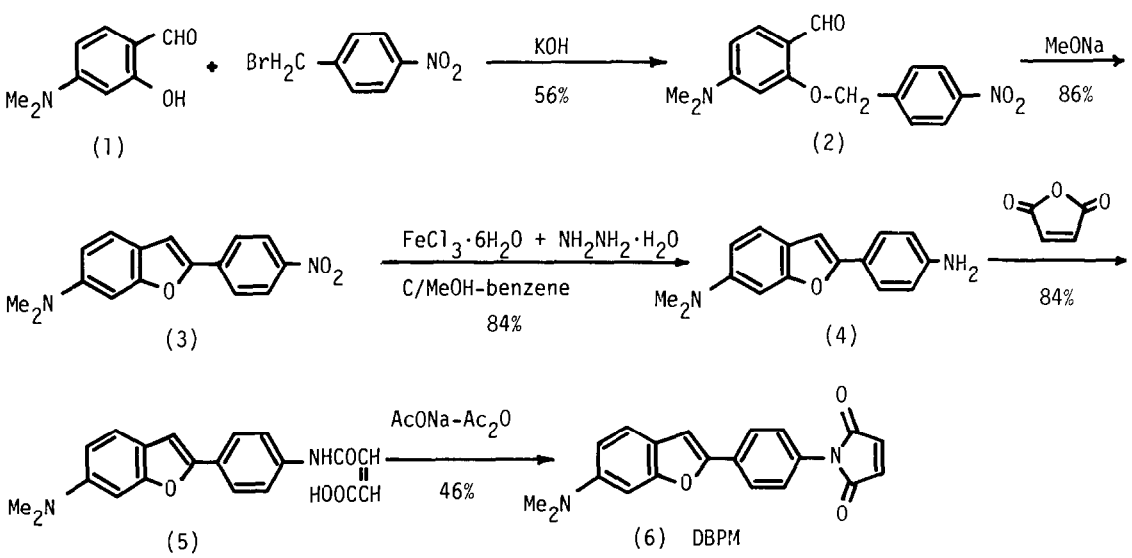
(Received 3 October 1984. Accepted 4 December 1984)

Summary - N-{p-[2-(6-Dimethylamino)benzofuranyl]phenyl}maleimide (DBPM), has been synthesized and found to give fluorescent products when reacted with certain thiols. The reaction is very sensitive, and concentrations as low as 10^{-9}M can be detected.

Recently, several examples of thiol-selective reagents bearing the maleimide ring have been reported.[2-7] For the development of sensitive and useful fluorogenic thiol reagents, our attention has been directed to the synthesis of 2-phenylbenzofuran derivatives, which might be expected to be strongly fluorescent owing to the presence of a latent trans-stilbene skeleton.

In the work described here, a new fluorogenic reagent for thiols, DBPM (N-{p-[2-(6-dimethylamino)benzofuranyl]phenyl}maleimide), has been synthesized, and its application to the determination of glutathione (GSH), as a representative thiol, investigated.

The synthesis of DBPM (6) is shown. Treatment of the benzyl ether (2) obtained by the reaction of the aldehyde (1) with p-nitrobenzylbromide, with sodium methoxide, gave the nitro compound (3).



Reduction of (3) to (4), followed by treatment with maleic anhydride, and cyclization yielded DBPM. DBPM when combined with thiols shows strong fluorescence, with the emission maximum at 457 nm, and excitation at 355 nm, whereas the reagent itself is practically non-fluorescent. The large difference (ca. 100 nm) between the excitation and emission maxima makes the reagent advantageous for practical use. N-Acetyl-L-cysteine (taken as a representative thiol) reacts with DBPM to give a 1:1 adduct (m.p. 119 - 121°), the structure of which is under further investigation.

We have examined the application of DBPM to the determination of thiols, especially GSH, and have established the following procedure. To a standard solution (0.5 ml) of GSH ($\leq 2 \times 10^{-5}$M) in 0.02M EDTA, is added a buffer solution (pH 8.5, 0.1M borate-carbonate, 2.0 ml) and a solution of DBPM in CH_3CN (8×10^{-6}M, 2.5 ml). The well-mixed solution is heated for 30 min at 60°, cooled to room temperature, and then the relative fluorescence intensity (RFI) is measured at 457 nm with excitation at 355 nm. The RFI remains constant for 24 hr. The conditions given were chosen after examination of the effect of varying the DBPM and CH_3CN concentrations, pH, and reaction time. Maximal RFI is obtained with a final concentration of 4μM DBPM and 50 - 60% v/v CH_3CN over the pH range 8 - 10.5. The reaction of DBPM with thiols goes essentially to completion within 20 - 30 min at 60°.

The relationship between GSH concentration and RFI was linear over the range 2 - 2000nM (relative standard deviation 2.4% for 200nM GSH, 10 replicates). Oxidized glutathione (GSSG) can be quite easily reduced to GSH by means of KBH_4 within 5 min at 40° and determined by the proposed method. The excess of KBH_4 is easily removed with HPO_3. The calibration curve is linear over the GSSG concentration range 5 - 1000nM (r.s.d. 2.4% at the 200 nM level).

DBPM reacts with various thiol compounds, as shown in Table 1, which also gives the relative fluorescence yields. Cystine can be determined (after reduction to cysteine with KBH_4) 1 - 1000nM (r.s.d. 2.4% at the 200nM level).

Table 1. The reaction of thiol compounds with DBPM*

Compound	RFI
GSH	100
GSSG	13.2
Cysteine	109.4
Cystine	0
N-Acetyl-L-cysteine	83.8
Methionine	0
Coenzyme A	74.2

* The reaction and the measurement of the fluorescence intensity were performed according to the procedure described above. The final concentrations of the reaction products were 2 μM.

DBPM is easily prepared from commercially available materials and both its reactivity with thiols (reaction time 20 - 30 min at 60°) and the fluorescence stability of the reaction products (stable up to 24 hr) are rather superior to those of the known maleimide reagents.

Unfortunately, selective determination is not possible, because the fluorescence wavelengths of the reaction products from the thiols tested are almost identical. However, the proposed method has been successfully applied to the determination of total thiol group in rat tissue. The detailed results will be reported elsewhere. Use of DBPM after HPLC is being explored for determination of thiols in biological samples.

(*Received* 30 *May* 1984. *Accepted* 7 *November* 1984)

Summary—The number of complex species in solution may be determined by a computer-assisted factor analysis of a set of potentiometric titration curves, by finding the rank of the normalized data matrix. An application of the program SPECIES is demonstrated for some examples of titration data. The method is limited in that it can discriminate only between species with differing degrees of polymerization.

In the study of solution equilibria, it is not only necessary to determine the stoichiometry and stability constant of each complex species, but also to find out how many such species are present. This number can emerge from a careful least-squares treatment which seeks to find the best chemical model. One method is to use a species selector[1] in which the various complexes are tested and the best combination of them is determined. Such a treatment was first used for potentiometric data analysis by Sillén in the program LETAGROP,[1,2] and a new species selector was included recently in the program PSEQUAD.[3] The problem of species selection and determination is also discussed in a forthcoming publication.[4] With spectrophotometric data, the number of species in solution can be determined as the rank of the second moment of the absorbance matrix. This can be found by matrix-algebra operations[5] or by factor analysis.[6–8] Principal-component analysis[9,10] has been used to find the number of components from mass spectra,[11,12] fluorescence data,[13] *etc.* The use of the method in spectrophotometry is reviewed in a forthcoming monograph.[14]

This paper describes a factor-analysis method for finding the number of species present in a system studied by potentiometric titration. As with spectrophotometric data, the rank of the matrix constructed from normalized potentiometric data is shown to be less than or equal to the number of species in solution.

THEORY

Matrix analysis of normalized potentiometric data

Consider the complex-forming equilibria of components A, B and C; the general reaction equation and the corresponding overall stability constant are given by

$$pA + qB + rC \rightleftharpoons A_pB_qC_r \quad (1)$$

$$\beta_{pqr} = [A_pB_qC_r]/([A]^p[B]^q[C]^r) \quad (2)$$

The equation for the potentiometric titration curve must be transformed into the form of normalized variables $Z = f(\mathrm{pA})$ where the free equilibrium concentration of component A is usually measured potentiometrically as $\mathrm{pA} = -\log[A]$ (*e.g.*, pH) and Z represents the average number of one component (for example A) bound per B or C.

$$Z = (c_A - [A])/c_B = \left(\sum_{i=1}^{n_c} p_i[A_{p_i}B_{q_i}C_{r_i}]\right)\Big/ c_B = \left(\sum_{i=1}^{n_c} p_i c_i\right)\Big/ c_B \quad (3)$$

where c_A, c_B and c_C, are the total analytical concentrations of A, B and C, [A] is the free equilibrium concentration of A, and n_c is the number of complex species in solution.

Each curve $Z = F(\mathrm{pA})$ has n_s points, and curves may be measured for n_B total concentrations of either B or C (or both), to give finally an $n_s \times n_B$ matrix **Z** $[(Z_{k,j},\ k = 1,\ n_s),\ j = 1,\ n_B]$. Equation (3) may be written as

$$Z = \sum_{i=1}^{n_c} e_i\, c_i \quad (4)$$

where $e_i = p_i/c_B$, or in matrix notation

$$\mathbf{Z} = \mathbf{E}\,\mathbf{C} \quad (5)$$

where matrix **Z** is $(n_s \times n_B)$, **E** is $(n_B \times n_c)$ and the concentration matrix **C** is $(n_c \times n_s)$.

Equation (5) is analogous to the generalized form of the Beer–Lambert law for unit path-length, and element e_i of **E** is analogous to the molar absorptivity.

*Part VI: *Talanta* 1984, **31**, 1083.
†Author for correspondence.

The rank of matrix **Z** may be obtained from the equation

$$\text{rank}(\mathbf{Z}) = \min[\text{rank}(\mathbf{E}), \text{rank}(\mathbf{C})] \leqq \min(n_B, n_c, n_s) \quad (6)$$

If we now arrange experimentally that $n_B > n_c$ and $n_s > n_c$ we obtain

$$\text{rank}(\mathbf{E}) \leqq n_c \; [\text{rank}(\mathbf{E}) = \min(n_B, n_c)] \quad (7)$$

$$\text{rank}(\mathbf{C}) \leqq n_c \; [\text{rank}(\mathbf{C}) = \min(n_c, n_s)] \quad (8)$$

so

$$\text{rank}(\mathbf{Z}) \leqq n_c \quad (9)$$

Thus, the rank of **Z** gives directly the number of complex species in solution. The treatment is analogous to the factor analysis of absorbance matrices by Kankare[6] and Wernimont.[15] The "spectra" of the solutions in this case are replaced by the functions $Z = f(c_B)$ or $Z = f(c_c)$.

In continuance of the analogy with absorbance matrix analysis,[6] the matrix **Z** may be subjected to factor analysis. Thus, the second moment matrix **M** is defined by

$$\mathbf{M} = (1/n_s) \cdot \mathbf{Z}\,\mathbf{Z}^T \quad (10)$$

where $\mathbf{Z}^T$ denotes the transpose of **Z**. From equation (9),

$$\text{rank}(\mathbf{M}) \leqq n_c \quad (11)$$

This implies that matrix **M** has at most n_c non-zero eigenvalues. Because of experimental errors, the actual number of non-zero eigenvalues is $\min(n_B, n_s)$. Let the eigenvalues of **M** be r_i and suppose that there are k independent components in the equilibrium system. Then the residual standard deviation of Z is given by

$$s_k(Z) = \left[\left(\text{tr}(\mathbf{M}) - \sum_{i=1}^{k} r_i\right) \Big/ (n_B - k)\right]^{1/2} \quad (12)$$

where tr(**M**) is the trace of **M**. Let the precision of estimation of Z be $s_{inst}(Z)$; then it may be concluded that if $s_k(Z) < s_{inst}(Z)$ it is probable that $n_c < k$. Values for the eigenvalues r_i, and the standard deviation of Z, $s_k(Z)$, and also for the relative variance (expressed as a percentage), RV, the cumulative percentage relative variance, CRV, and the Malinowski factor indicator function,[16] IND, are calculated and printed by the program SPECIES.

$$\text{RV}\,(\%) = [r_i/\text{tr}(\mathbf{M})] \times 100 \quad (13)$$

$$\text{CRV}\,(\%) = \sum_{i=1}^{k} r_i \times 100/\text{tr}(\mathbf{M}) \quad (14)$$

$$\text{IND} = s_k(Z)/(n_B - k)^2 \quad (15)$$

The higher the value of the variance RV, the higher the contribution of the corresponding eigenvalue to the trace, and thus the more significant the eigenvalue. Eigenvalues with variance < 0.01% are regarded as negligible. Similarly, consideration of the CRV shows how 100% variance is approached as more eigenvalues are included. If inclusion of a certain eigenvalue brings the CRV to 99.99%, the remaining eigenvalues should be assumed to be of negligible significance. The Malinowski factor indicator function IND should reach a minimum when the correct number of factors (*i.e.*, species) has been chosen.[16]

PROPOSED PROCEDURE

For various possible integer values of the rank of **Z** the standard deviation, $s_k(Z)$, is calculated from equation (12). The graph of $s_k(Z) = f(k)$ where k is an actual value of the rank, consists of two nearly linear parts which intersect on extrapolation. The point of intersection should lie near to the experimental standard deviation value, $s_{inst}(Z)$. The coordinate k on the rank-axis for this intersection is the value sought for the rank of the matrix, and is equal to the number of complex species in solution (Fig. 1). At the same value of k, $s_k(Z)$ should be $\leqq s_{inst}(Z)$, the CRV should reach almost 99.99%, the variance of any remaining eigenvalues should be negligible (< 0.1%) and IND should reach a minimum. However, these criteria may *not* all be met at the same value of k.

Limitation of the method

The situation for potentiometric data is not strictly analogous to that for spectrophotometric data, in that the method is applicable *only* when a change in the total analytical concentration of component B or C, c_B or c_c, leads to a set of different curves for $Z_B = f(\text{pA})$ or $Z_C = f(\text{pA})$. That is, the complexes that can be detected must not be mononuclear (in B or C). For mononuclear complexes the curves of $Z_B = f(\text{pA})$ are identical; thus there is just one curve, and the rank of **Z** is one. The method cannot be used, therefore, to find the number of differently protonated species of a weak acid H_nL. [In such cases the number of species may be indicated by the number of inflection points on the $Z = f(\text{pH})$ curve.]

In the case of metal–ligand equilibria, curves for varied metal or varied ligand concentrations should be measured. The matrix **Z** is then obtained by taking vertical sections at constant pH values, or by taking horizontal sections at constant Z values. Only species with differing p_i indices can be distinguished.

Computation

Computations were done with use of a mainframe computer EC 1033. The program SPECIES is available, with specimen data, on request.

DISCUSSION

The program SPECIES was validated by use of literature titration data and simulated data sets.

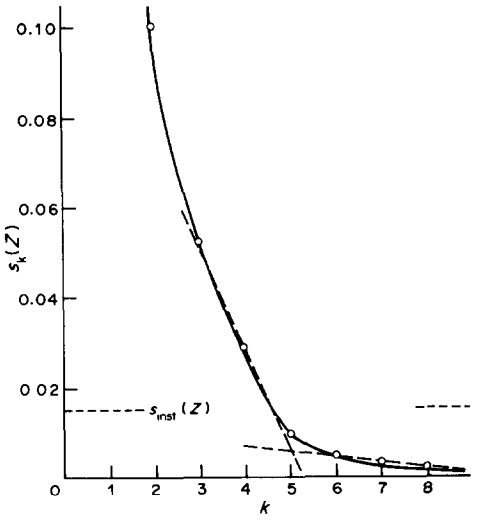

Fig. 1. Graphical determination of the number of complexes. The k-co-ordinate of the point of intersection of the two linear parts of $s_k(Z) = f(k)$ gives a good estimate of the matrix rank, and the $s_k(Z)$-co-ordinate should be close to the value of $s_{inst}(Z)$ (data from Table 2.).

Baldwin and Wiese[17] studied polymolybdate equilibria in $1M$ magnesium perchlorate solution and found three $H_p(MoO_4)_q$ species with (p, q) values (2, 1), (8, 6) and (9, 8). The normalized Z values for various pH values at different total concentrations of molybdate were taken from Fig. 1 in that paper and the matrix **Z** was constructed (Table 1). On the assumption that the precision of reading Z-values from this graph is $s_{inst}(Z) \approx 0.02$, the rank of the matrix should be three. It may be concluded that there are 3 polynuclear complexes in solution.

Sasaki and Sillén[18] studied the hydrolysis of molybdate in $3M$ sodium perchlorate and found eight $H_p(MoO_4)_q$ species with indices (1, 1), (2, 1), (8, 7), (9, 7), (10, 7) and (11,7). The Z values were read from Fig. 1 in that paper with precision $s_{inst}(Z) \approx 0.02$ for various pH values in the range 1.50–7.50. The resulting matrix **Z** was treated by program SPECIES (Table 2). The rank of the matrix is 5, in agreement with the five polynuclear species (with differing p_i indices) among those found in solution by the authors.

Biedermann and Ciavatta[19] found three complexes, $Y(OH)^{2+}$, $Y_2(OH)_2^{4+}$, and $Y_3(OH)_5^{4+}$ in hydrolysed solutions of Y(III) in $3M$ perchlorate. The matrix **Z** was constructed from the data of their Fig. 2 with precision $s_{inst}(Z) \approx 0.02$ (Table 3). The matrix rank is found to be 2, in accordance with the two polynuclear hydrolytic products formed in solution.

A data set was simulated for a metal-ion hydrolysis based on a study by Ahlberg[20] of Hg(II) in $3M$ perchlorate. Five species, $HgOH^+$, $Hg(OH)_2$, $Hg_2(OH)^{3+}$, $Hg_2(OH)_2^{2+}$ and $Hg_4(OH)_3^{5+}$ were found. The $Z = f(\text{pH})$ curves were simulated by the program POLET,[21] then the Z values were loaded with a random error so that $s_{inst}(Z) = 0.001$. Program SPECIES showed the rank of **Z** to be 2, which

CONCLUSIONS

The graphical procedure for examination of $s_k(Z) = f(k)$ appears to yield results in agreement with the literature,[17–19] as shown in Tables 1–4. The commonly used methods for estimation of matrix rank in factor analysis, *viz.* IND, the Malinowski factor indicator function, and CRV, the cumulative relative variance, do not appear to be so reliable as criteria, at least for this particular application of factor analysis.

CHARACTERIZATION OF SEDIMENT REFERENCE MATERIALS BY X-RAY PHOTOELECTRON SPECTROSCOPY

M. SOMA, H. SEYAMA and K. OKAMOTO
National Institute for Environmental Studies, Tsukuba, Ibaraki 305, Japan

(*Received* 17 *September* 1984. *Accepted* 5 *November* 1984)

Summary—The chemical composition of surface layers of three sediment reference materials, Pond Sediment (Japan NIES CRM No. 2), River Sediment (US NBS SRM 1645) and Estuarine Sediment (US NBS SRM 1646), has been studied comparatively by X-ray photoelectron spectroscopy (XPS). The composition of River Sediment as determined by XPS is peculiar in that the concentration of Cr is much higher but that of Si is much lower than that expected from the bulk composition of the sample. This can be attributed to the structure of the sediment particles, which consist of silica-rich cores covered by surface layers rich in Cr(III). Organic substances are predominant in the surface layers of all three materials, as indicated by the C 1*s* and N 1*s* lines. The elemental composition of the surface layers can be reasonably related to the origin of the sediments. The bonding states of some elements in the sediment samples, deduced from the photoelectron binding energies, are briefly discussed.

It is well established that X-ray photoelectron spectroscopy (XPS), as a tool for analysing the elemental composition as well as the chemical state of surface layers of solids,[1] is applicable to a wide variety of solid materials, including those of geochemical and mineralogical interest.[2] However, in spite of its excellent capability for analysing solids of widely varied compositions, which may play important roles in environmental problems,[3] its application to environmental samples has been practically confined to the study of the surface chemical composition of aerosol[4] and fly-ash particles.[5]

In this report, an attempt has been made to characterize three reference sediment materials by XPS. It will be shown that, although there are difficulties in the quantification of XPS measurements made on such complex heterogeneous materials, the average elemental compositions of the surface layers of those materials, as determined by XPS, can deviate significantly from those given by total analysis (bulk composition), and reflect the origin and/or the history of the samples. Information obtained from the chemical shifts for certain elements will also be discussed. A brief account of the XPS of Pond Sediment has already been published.[6]

EXPERIMENTAL

Materials

The three reference materials studied are U.S. National Bureau of Standards (NBS) standard reference material (SRM) 1645 "River Sediment",[7,8] NBS SRM 1646 "Estuarine Sediment",[9] and Japan National Institute for Environmental Studies (NIES) certified reference material (CRM) No. 2 "Pond Sediment".[6,10,11] They were chosen because their properties and elemental compositions are well characterized, and they are in a form suitable for XPS measurements.

XPS measurement

The electron spectra were recorded on a Vacuum Generators ESCALAB 5 apparatus. The powdered sediment sample, as received, was fixed by double-sided adhesive tape on a stainless-steel sample holder 10 mm in diameter. The sample was irradiated by Al $K\alpha$ or Mg $K\alpha$ radiation from a twin anode. The typical measuring conditions were: X-ray power, 13 kV and 10 mA; electron pass-energy through the analyser, 50 eV; width of the analyser entrance slit, 4 mm. The instrumental resolution determined by the pass-energy and the slit-width was 1.25 eV. To determine the intensities of weak transitions, signals for narrow range scans were accumulated on a Nicolet 1070 signal averager until an acceptable signal-to-noise ratio was attained. For most elements measured, the electron emission intensity was stable enough for long exposure to the X-rays. However, the carbon and nitrogen lines of organic origin sometimes changed their intensities considerably during prolonged measurement (several hours) at room temperature. This instability was made negligible by cooling the sample with a continuous flow of liquid nitrogen through the specimen manipulator.

The electron binding energies were standardized against the Au $4f_{7/2}$ line (83.8 eV) of a gold film evaporated onto the sample. The uncertainty in the determination of binding energy for most of the emission lines was ± 0.2 eV.

The quantitative analysis was based on the relative atomic sensitivity factors for the photoelectron and Auger electron emissions tabulated in Table 1. These were determined either by integrating the experimental line intensities for the compounds of known stoichiometry or by theoretical estimation. The theoretical estimation was done by the procedure described by Seah,[12] with use of the theoretical ionization cross-section[13] and the asymmetry factor[14] given by Scofield and by Reilman *et al.*, respectively.

The reproducibilities in the determination of the relative area intensities for sediment samples, as examplified by Pond Sediment, have been shown to be within 10%.[6] The uncertainty in determining the elemental composition by XPS largely arises from the application of the atomic sensitivity factor to samples with different matrices, as has often been pointed out.[12] Our empirical estimation is that the error may be as large as 20%, but would rarely exceed this figure.

Table 1. Relative atomic sensitivity of the elements (Si $2s = 1$)

Element	Line	X-ray source: Al $K\alpha$	X-ray source: Mg $K\alpha$	Note
Al	$2p$	0.520	0.74	*a*
Fe	$2p$	10.2	11.0	*b*
Mg	$KL_{23}L_{23}$Auger	8.0	—	*c*
Ca	$2p$	4.64	5.75	*c*
Na	$KL_{23}L_{23}$Auger	5.08	6.69	*c*
K	$2p$	3.94	4.98	*c*
Ti	$2p$	4.81	5.95	*d*
Cr	$2p$	7.19	8.73	*c*
O	$1s$	1.83	2.19	*d*
C	$1s$	0.70	0.87	*d*
N	$1s$	1.24	1.51	*d*
P	$2p$	1.15	1.50	*d*

a Based on the measurement of halloysite, molecular sieve 4A and 13X. The given sensitivity was proved to reproduce the Al/Si ratio in NBS standard reference materials 97a (flint clay) and 98a (plastic clay) within 10%.
b Based on the measurement of $K_3[Fe(CN)_6]$ and $K_4[Fe(CN)_6]$.
c Based on the measurement of fluoride, sulphate and chloride.
d Theoretical estimation (see text), but also substantiated by the experimental measurement of reference materials.

RESULTS AND DISCUSSION

Elemental composition

Figure 1 shows the XPS spectra of the three sediment reference materials, excited by Al $K\alpha$ radiation. Since all the materials contain at least about 20% of silicon, the spectrum of River Sediment is evidently anomalous. Its silicon peaks ($2p$ and $2s$) are very weak, whereas the C $1s$ and Cr $2p$ lines are prominent. At first glance it would be presumed that the sample is a mixture of carbonaceous material and oxides of chromium and iron. Such survey spectra, obtained by scanning a wide energy range within a short time (~60 eV/min in the present case), give a rough idea of the relative abundance of the major elements (>1% w/w) and reveal the existence of the minor elements (~0.1% w/w). For environmental samples, in our experience, most of the useful information can be provided at this stage of the measurement if preliminary knowledge of the bulk composition is available. In addition to the inorganic components, the elements of organic origin, such as carbon and nitrogen (see below), can be easily seen, although care must be taken with the carbon lines, because carbon contamination layers accumulated on the surface of the samples during the experimental procedures (especially from pump oil) always contribute carbon lines.

From the integrated intensities of the relevant emission lines and the atomic sensitivity factors listed in Table 1, the relative atomic compositions for the sediment samples were determined. Table 2 gives the atomic abundances of selected elements relative to Si, and Fig. 2 depicts the compositions in weight per cent

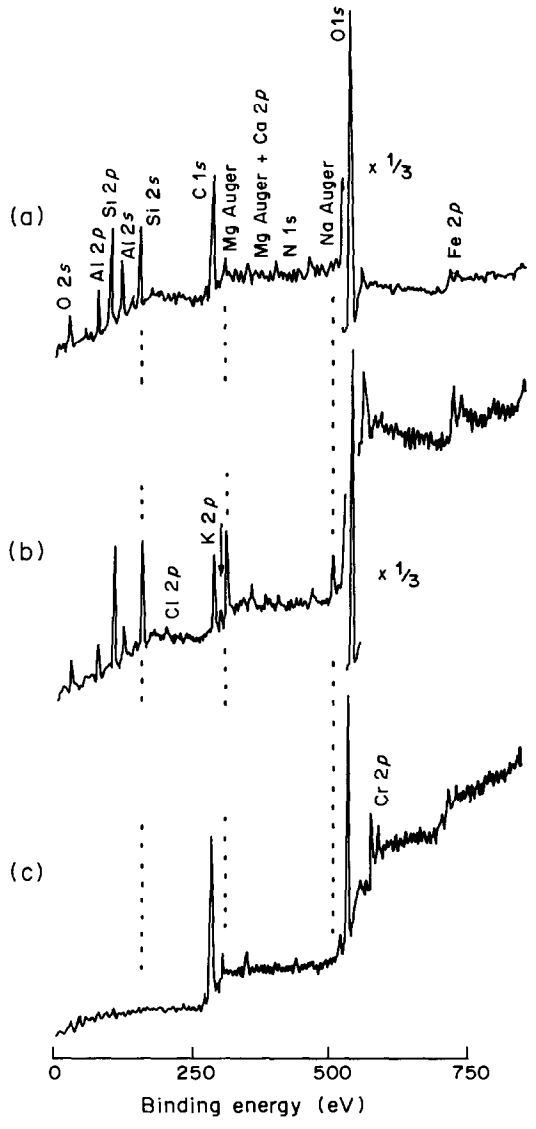

Fig. 1. X-Ray photoelectron spectra of (a) Pond Sediment, (b) Estuarine Sediment and (c) River Sediment.

and compares them with the corresponding analytical values for the bulk composition.[6-9] In representing the XPS results in weight per cent, the contribution of hydrogen is not considered, since it is not determined by XPS. The amount of carbon includes the contribution from contamination. However, for Pond Sediment as an example, the C/N ratio (16.4) determined by XPS is comparable to that (14.8) for the bulk composition, and therefore the contribution of the carbon contamination is not significant. Though various factors (*e.g.*, the probe depth in XPS, which depends both on the kinetic energy of the photoelectron and on the composition of the individual particles,[12,15] and the structure of the surface in an actual sample[16-19]) complicate evaluation of the relation of elemental composition determined by XPS to the true average surface composition, the result

Table 2. Atomic composition of the sediment reference materials, determined by XPS (Si = 1)*

Element	Line	Source target	NIES No. 2	NBS 1645	NBS 1646

Cr	2*p*	Al	—	3.1 (46)	—
P	2*p*	Al	0.01 (1.7)	—	0.041 (2.6)

*Relative to Si. For Si, the 2*s* line was used. The numbers in parentheses are the ratios to the corresponding value for the bulk composition.[6-9]

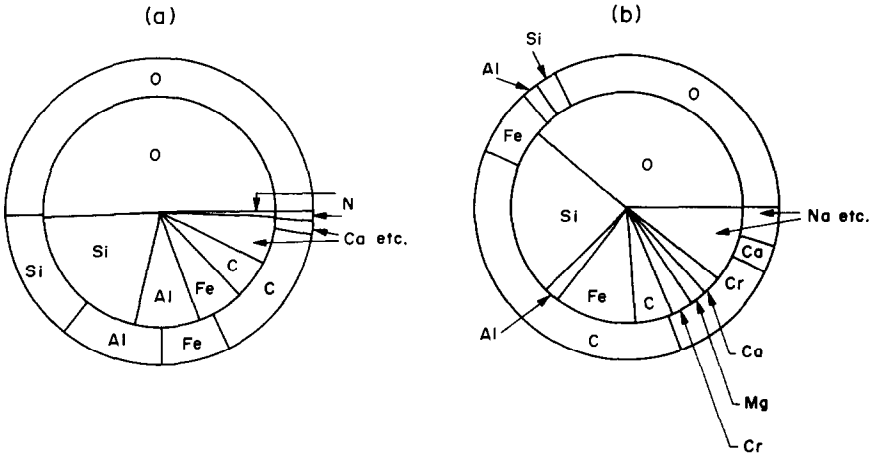

Fig. 2. Elemental composition of (a) Pond Sediment and (b) River Sediment in weight per cent. The inner circle represents bulk composition and the outer circle represents the composition determined by XPS.

may be regarded as representing the apparent surface composition "seen" by the X-ray flux. The peculiar features in the composition of River Sediment, as determined by XPS, are more clearly seen. As shown in Table 2, the atomic abundances of the major elements relative to Si, determined by XPS, are higher than those for the bulk composition, and the Cr/Si ratio is exceptionally large.

Since the finer particles are expected to contribute relatively more to the surface area seen by the X-ray flux (the contribution should be inversely proportional to the particle diameter if the particles are randomly arranged in the sample layer for the XPS measurement), we examined how the Cr/Si ratio determined by XPS depended on the particle size. Sieving of River Sediment powder revealed that it consisted of a 105–180 μm (particle diameter) fraction (80% in weight), a 44–105 μm fraction (20%) and a small amount of a finer portion. Table 3 shows the Cr/Si ratio of the coarser fraction is small but still more than an order of magnitude larger than the bulk ratio. Fine particles may be attached to coarse particles to form composite particles, and may not be separated by sieving. When the coarsest portion (105–180 μm) was subjected to ultrasonification in water, fine particles were dispersed. The coarse precipitate was separated and washed repeatedly (with ultrasonification) until no turbidity was visible in the supernatant liquid. The Cr/Si ratio (XPS) of the precipitate (Table 3) is significantly smaller than that for the sample before washing, but still far exceeds the bulk value. It can be concluded from these observations that in the River Sediment particles,

Table 3. Particle-size dependence of Cr/Si ratio for NBS 1645 River Sediment

	Cr/Si
(1) XPS	
44–105 μm	3.6
105–180 μm	2.1
105–180 μm washed with ultrasonification	0.86
(2) Bulk total	0.067*

*From refs. 7 and 8.

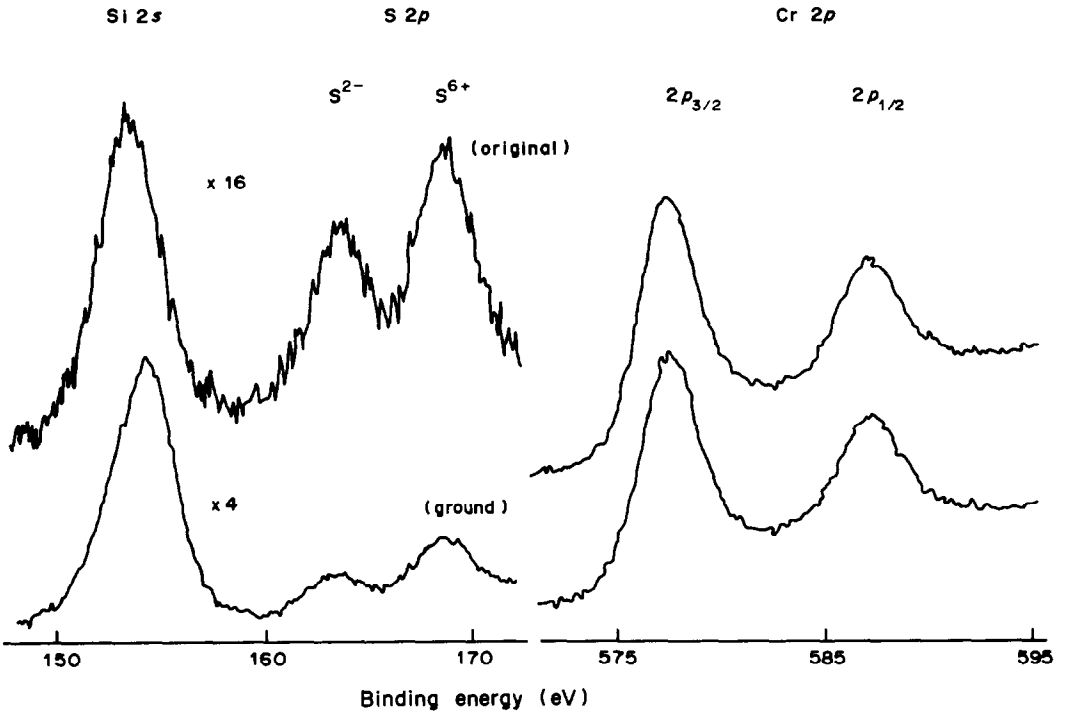

Fig. 3. Changes in the XPS spectra of River Sediment in the Si 2*s*, S 2*p* and Cr 2*p* regions after the powder has been ground in an agate mortar.

Si-rich particle cores are covered with Cr-rich surface layers, which include attached fine particles, and that Si is depleted in the surface layers. At least a part of the surface layers cannot be removed by physical methods such as ultrasonification.

Such a distribution of Cr and Si suggests that Cr was introduced into the river as a pollutant and deposited on the surface of the originally silica-rich sediment particles. The reported ease of acid extraction of Cr from River Sediment[20] is consistent with such a composition of the sediment particles. As Fig. 2b shows, carbon (and nitrogen) is most enriched in the surface layers, *i.e.*, the surface is rich in organic substances. Sulphur is also more abundant in the surface layers (1.8% w/w) compared to the bulk composition (*ca.* 0.5% as determined with a Carlo Erba 1108 Elemental Analyzer).

For other elements (Al, Fe, Mg, Ca, Na) in River Sediment, the amounts relative to Si are significantly larger in the surface than those in the bulk composition, because of the depletion of Si in the surface, but the amounts in terms of weight per cent are only slightly less than those in the bulk, owing to the diluting effect of organic substances in the surface. That is to say, unlike Si, they are mixed in the organic and chromium-rich surface layers.

Figure 3 shows the changes in the spectra when the sample of River Sediment was ground in a mortar (agate or alumina). The intensity of the Si 2*s* line relative to the lines of other elements increased remarkably after the grinding. This demonstrates that Si is exposed in the surface by grinding and that the Si-rich particles are covered by the surface overlayers in the original preparation.

In contrast to River Sediment, the deviation of the composition determined by XPS from that of the bulk for Pond Sediment (NIES No. 2) is much less pronounced (Fig. 2a). However, organic components (C, N) are again rich in the surface layers, as is also the case for Estuarine Sediment. Thus XPS offers direct evidence for the surface predominance of organic substances in soil or sediment particles.[21] The weight content of Si in the surface of Pond Sediment is about two-thirds of the bulk content, whereas the contents of Al and Fe in the surface are comparable to those in the bulk. As shown in Table 2, Na is depleted in the surface (one-fifth of the bulk content). K is also depleted in the surface, although the quantification is difficult because the energy-loss satellite of the C 1*s* line interferes with the weak K 2*p* lines. The depletion of alkali elements in the XPS analysis is also observed for a sample from the sedimentation pond of a water purification plant. Thus, it is probable that leaching causes the depletion of the alkali-metal elements from the surface. On the other hand, Al, Fe and P had the same concentration levels in the surface as in the bulk. There must be certain mechanisms, such as deposition from the aqueous phase, keeping the surface concentrations of those elements at a comparable level to the bulk

concentration, in spite of the diluting effect of organic substance.

The deviation of the surface elemental composition from the bulk composition for Estuarine Sediment is not as large as that for River Sediment but larger than that for Pond Sediment. The latter fact can be attributed to the mixing of river and sea-water causing more extensive reorganization of the surface composition for estuarine sediments.[21] The surface enrichment of Al and Fe relative to Si may thus be attributable to the deposition of these elements in the estuarine region.[21] The surface enrichment of Mg and depletion of Ca are also notable, but whether this is general behaviour for estuarine or coastal sediment is uncertain at the present stage.

Characterization of the bonding states of elements

We summarize here the information obtained from the photoelectron binding energies for the three reference materials. The peak positions of C 1*s* (284.7 ± 0.2 eV) and N 1*s* (399.8 ± 0.2 eV) indicate that the carbon and nitrogen are of organic origin, the latter being mainly due to the amino-group. The binding energies of Si 2*s* (153.6, 153.7 and 153.1 eV for Pond Sediment, Estuarine Sediment and River Sediment, respectively) are compatible with a range of silicate minerals.[22] They depend on the O/Si ratio and on the negative charge in the silicate skeleton. As can be seen in Fig. 3, the peak position of Si 2*s* for River Sediment shifted to 153.9 eV when the sample powder was ground. The binding energy after grinding was close to that for quartz (SiO_2, 154.2 eV).[22] This fact supports the preceding argument that the chemical composition of the surface layer of River Sediment is significantly different from that of the average (bulk) composition. Figure 3 also demonstrates that S^{6+} (168.5 eV; SO_4^{2-} should be the main species) and S^{2-} (163.5 eV) can be distinguished. As the latter energy is slightly higher than those observed for metal sulphides, we attribute it to organic sulphide(s). A comparison of the Cr $2p_{3/2}$ binding energy found in River Sediment (577.2 eV) with those of chromium compounds (Cr_2O_3, 576.6; $CrCl_3$, 577.0; $K_2Cr_2O_7$, 579.6 eV) shows that the chromium in the surface layers of River Sediment particles is tervalent. Since its binding energy is slightly higher than that for the oxide, the species is considered to be probably the hydrous oxide or Cr(III) adsorbed on minerals.[23] Similarly, the Fe $2p_{3/2}$ binding energies for Pond Sediment (711.2 eV) and River Sediment (711.4 eV) are slightly higher than that of ferric oxide (α-Fe_2O_3, 710.8 eV) and are consistent with hydrous oxides such as goethite[24] or Fe(III) adsorbed on minerals.[23] The Fe $2p_{3/2}$ binding energy for Estuarine Sediment (712.4 eV) is significantly higher and can be attributed to Fe(III) incorporated into clay minerals[23] or to amorphous ferric hydroxide.[23,24]

Acknowledgement—The authors are grateful to Mr. Masataka Nishikawa for the determination of sulphur in the River Sediment.

FLUORIMETRIC DETERMINATION OF DISSOCIATION CONSTANTS AND pH-CONTROLLED FLUORESCENCE ANALYSIS OF PURINES AND PYRIMIDINES

DIARIATOU GNINGUE and JEAN-JACQUES AARON*
Laboratoire de Chimie Physique Organique et d'Analyse Instrumentale, Département de Chimie, Faculté des Sciences, Université de Dakar, Dakar-Fann, Sénégal

(*Received* 11 *July* 1984. *Accepted* 28 *October* 1984)

Summary—Fluorimetrically determined pH-titration curves have been obtained for twelve purines and pyrimidines at room temperature, in aqueous solution. The pK_a values for these compounds have been determined fluorimetrically and potentiometrically. Except for 6-mercaptopurine and uric acid, there is close agreement between the two sets of pK_a values, but a large difference for the corresponding excited singlet-state values, $pK_a^{S_1}$, which were calculated previously. This indicates that the excited singlet-state proton-transfer rate is much slower than the fluorescence-decay rate of purines and pyrimidines in our experimental conditions. A direct, simple, pH-controlled fluorimetric method is proposed for the determination of purines and pyrimidines. The limits of detection vary between 60 ng/ml and 5.4 μg/ml.

In recent years, fluorimetry has been demonstrated to be a simple and relatively accurate method for the determination of dissociation constants of organic acids and bases.[1–5] For those cases in which excited-state proton-transfer takes place during the fluorescence lifetimes of acids and conjugate bases,[6–8] instrumental and chemical means have been proposed to overcome its interference with the fluorimetric measurement of the ground-state pK_a values.[1–9] However, for most nitrogen- and oxygen-containing heterocyclic compounds, with pK_a values in the range 3–10, the rate of deactivation of the excited singlet-state was found to be much larger than that of excited-state proton-exchange, resulting in fluorimetrically determined pK_a values that were in good agreement with absorptiometrically or potentiometrically measured ground-state pK_a values.[1,3–5,10,11] The effect of pH also has important consequences for the sensitivity and selectivity of the fluorimetric determination of acids and bases, owing to the large differences in fluorescence spectra and quantum yields between the various dissociated and undissociated species. For this reason, pH-dependent fluorimetry has recently aroused considerable interest.[4,7,8]

However, there have been relatively few reports concerning the pH effects on the fluorescence of purines and pyrimidines.[12–15] Börresen[12] found that the fluorimetrically determined dissociation constants of purine and guanine were significantly higher than the ground-state values obtained by potentiometric titration, whereas for adenine there was no difference between the pK_a values measured fluorimetrically and potentiometrically. The existence of a highly fluorescent tautomer was postulated by Börresen[13] to explain the broadening and red-shift in the fluorescence of protonated adenine derivatives relative to that of the corresponding neutral species, and confirmed recently by Knighton *et al.*[14] Finally, dissociation constants of purines and pyrimidines in the excited singlet-state were determined very recently by Parkanyi *et al.*,[15] using the Förster cycle method. These authors found that in the excited singlet-state the basicity of most of the purines and pyrimidines is increased for the equilibria between the cationic and neutral species, but for the equilibria between the neutral and anionic species, all purines and pyrimidines are more acidic.[15]

In the present work, we wish to report on the fluorimetric measurement of the dissociation constants of some purines and pyrimidines, and to evaluate the performance of a pH-controlled method of fluorescence analysis for the determination of these compounds.

EXPERIMENTAL

Reagents

Purine and guanine were purchased from CDC Chemicals, adenine, 6-chloropurine, 6-mercaptopurine, hypoxanthine, cytosine, and 5-fluorouracil from US Biochemical Co., theobromine and uric acid from Eastman Kodak, and thymine and uracil from Aldrich Chemical Co. Distilled water, hydrochloric acid and sodium hydroxide were used for preparing solutions in the pH range 1–10.

Instrumentation

A Turner model 111 fluorometer, an ultraviolet lamp model 110-855 (which gives an excitation band between 270 and 340 nm), 7-54 excitation and 2-A emission filters, and 10% and 1% neutral density filters. A Metrohm model E520 pH-meter.

Procedure

The pK_a values were determined from the inflection points of the fluorimetric-titration plots of relative fluorescence intensity (I_F) *vs.* acidity (pH or Hammett function H_0). The

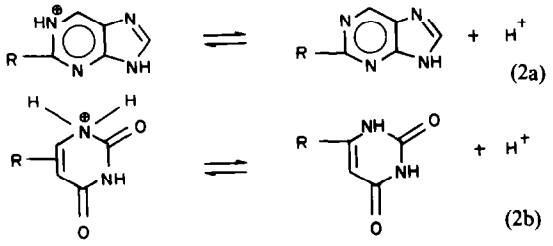
*Author to whom all correspondence should be addressed.

excitation wavelength used was an isobestic wavelength of the pH-dependent absorption spectrum to ensure that the same amount of radiation was absorbed at all points of the titration curve. For some compounds, the pK_a values were also calculated from the equation:[1,3]

$$pK_a = pH - \log \frac{(I_F - I_F^{BH^+})}{I_F^B - I_F} \quad (1)$$

where I_F^B and $I_F^{BH^+}$ are the relative fluorescent intensities of the free base and the conjugate acid respectively.

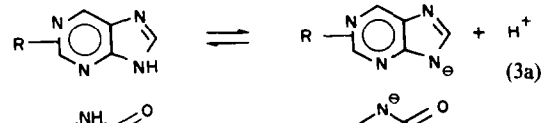
The pK_a^{CN} values are those for the equilibria (2a) and (2b) between the cationic and neutral species of purines and pyrimidines:



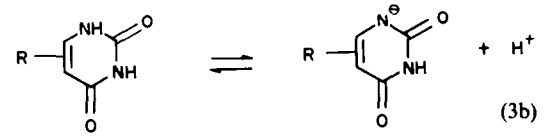
(2a)

(2b)

The pK_a^{NA} values refer to the equilibria (3a) and (3b) between the neutral and anionic species:



(3a)



(3b)

Note that B is the neutral species in equilibria (2a) and (2b) but the anionic species in equilibria (3a) and (3b), and BH^+ is the cationic species in (2a) and (2b) but the neutral species in (3a) and (3b).

RESULTS AND DISCUSSION

Effect of pH on fluorescence intensity

The fluorescence intensity of purines and pyrimidines changes drastically with pH, as can be seen in Figs. 1–4, which give some examples of fluorimetric titration curves. In the case of purine (Fig. 1), 6-chloropurine, thymine (Fig. 3, curve b), and 5-fluorouracil (Fig. 4), the fluorescence intensity increases strongly between pH 6 and 11, because of the formation of the anionic species, which generally have a larger fluorescence quantum yield than neutral molecules.[15] At higher sodium hydroxide concentrations (pH > 12), the fluorescence of the anions of purine and thymine is partially quenched (Fig. 1 and Fig. 3, curve b).

In the case of adenine, cytosine (Fig. 3, curve a), and uric acid (Fig. 2, curve b), the fluorescence signal increases at around pH 4, which corresponds to the dissociation of the cationic species into the neutral molecule. Between pH 7 and pH 11, the titration curves level off, and the fluorescence is partially quenched in more alkaline solution (pH > 12). In the case of cytosine, there is a second inflection point at about pH 12, which corresponds to the neutral molecule–anion equilibrium (3b), (Fig. 3, curve a).

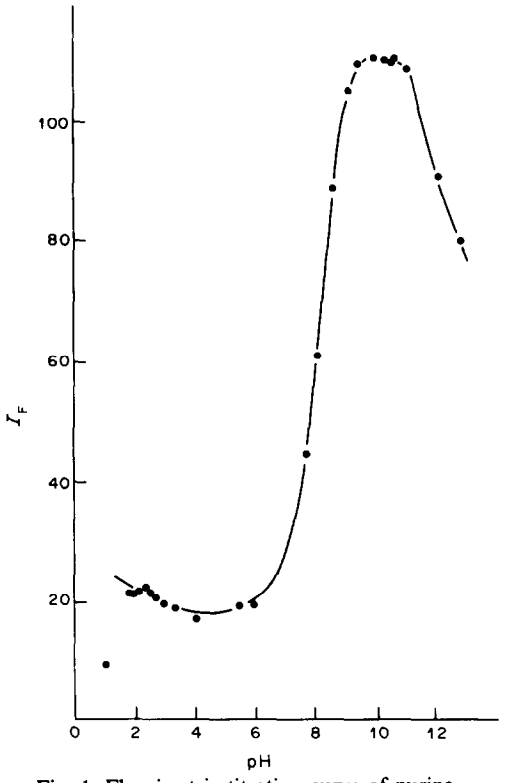


Fig. 1. Fluorimetric titration curve of purine.

A fluorimetric titration curve with two inflection points at around pH 3.9 and pH 8.9 is also found for guanine (Fig. 2, curve a). The first inflection point, characterized by a decrease in fluorescence intensity

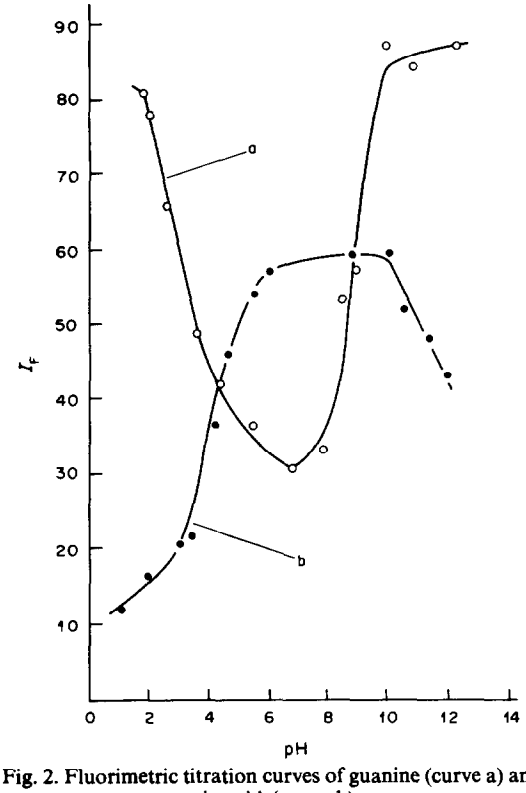

Fig. 2. Fluorimetric titration curves of guanine (curve a) and uric acid (curve b).

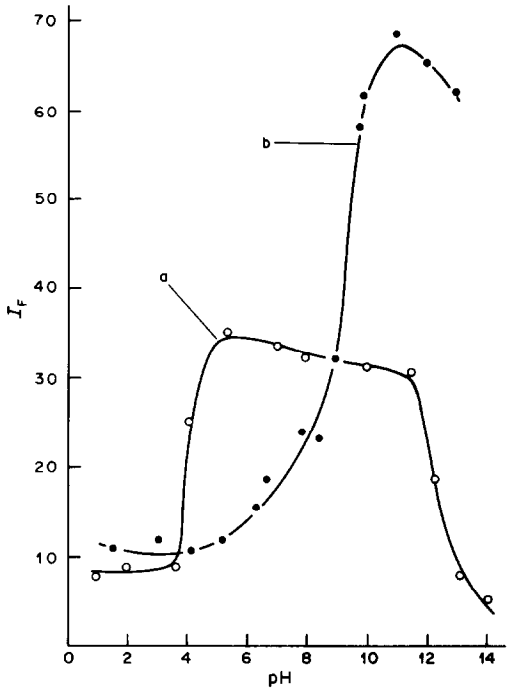

Fig. 3. Fluorimetric titration curves of cytosine (curve a) and thymine (curve b).

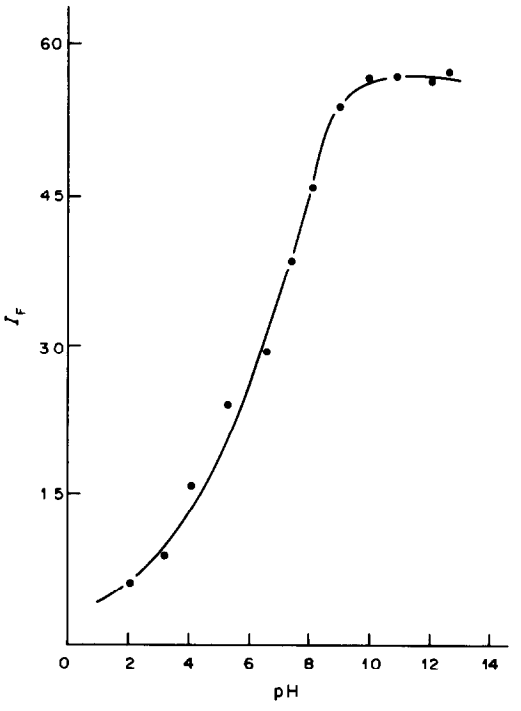

Fig. 4. Fluorimetric titration curve of 5-fluorouracil.

between pH 2 and pH 5, is due to the deprotonation of the cation, while the second, showing a strong increase in the fluorescence signal between pH 8 and pH 10.5, results from the formation of the more fluorescent anionic species of guanine.

Fluorimetric determination of pK_a

Table 1 summarizes the pK_a values of the purines and pyrimidines, calculated from the fluorescence titration curves, and also the ground-state dissociation constants determined potentiometrically and absorptiometrically. Our findings show that, for most of the compounds, the values of pK_a obtained fluorimetrically agree very well, within experimental error, with the ground-state pK_a value; the difference between the fluorimetric and the ground-state pK_a values is generally less than 0.2. There is also a good agreement between the pK_a values calculated from

*LDR = linear dynamic range, defined by the concentrations between which the log–log analytical curve is linear.

†Values calculated by the statistical treatment of 9–12 measurements for each analytical curve.

§LOD = limit of detection, defined as the concentration (in μg/ml) of compound giving a fluorescence signal equal to three times the fluctuations of the background fluroescence signal.

the inflection point of the fluorescence titration curve and from equation (1).

In contrast, the pK_a values obtained fluorimetrically present large differences from the corresponding excited singlet-state dissociation constants ($pK_a^{S_1}$), calculated earlier[15] by the Förster cycle method. For example, for adenine a pK_a^{CN,S_1} value of 10.03 was found,[15] which is much higher than the fluorimetric pK_a^{CN} value of 4.10; for thymine the pK_a^{NA,S_1} value[15] was 3.85, whereas the pK_a^{NA} value determined fluorimetrically is 9.50. This results from the fact that the rate of excited singlet-state proton-transfer is much slower than the rate of fluorescence decay of the purine and pyrimidine cations, anions and neutral species; therefore, the prototropic equilibrium is not attained during the lifetime of the S_1 state, and the inflection points of the fluorimetric titration curves correspond to the ground-state pK_a values. Similar behaviour has been observed for other nitrogen- and oxygen-containing heterocycles, with $pK_a^{S_1}$ values in the range 3–10.[1,3,7,10,11]

Two exceptions are 6-mercaptopurine and uric acid, for which the fluorimetric pK_a^{NA} values (7.0 and 4.2 respectively) differ by more than 0.7 from the ground-state pK_a^{NA} values (Table 1). For 6-mercaptopurine, the fluorimetric value is closer to the excited-state pK_a^{NA,S_1} value[15] of 7.29, while for uric acid the fluorimetric value is between the excited-state pK_a^{NA,S_1} value[15] of 0.05 and the ground-state pK_a^{NA} value of 5.3. This may be due to partial establishment of the prototropic equilibrium in the lowest excited singlet-state of both compounds.

Quantitative analytical applications

The fluorimetric titration curves also have important consequences for the determination of purines and pyrimidines. They have allowed us to select, for each compound, the optimal pH region corresponding to the maximum sensitivity of fluorimetry. We found that, except for cytosine, the anionic species gave larger relative fluorescence intensities than the neutral molecules, the fluorescence signal generally being maximal at around pH 10, which corresponds to the predominant presence of the anionic species. This is in agreement with our previous results for the relative fluorescence quantum yields of neutral and anionic species of some purines.[15] Pyrimidines have also been found to be much more phosphorescent in basic than in neutral media.[18]

Although purines and pyrimidines are generally considered to be relatively weak fluorophores,[19] most of the compounds studied here were shown to have analytically useful fluorescence signals when our pH-controlled fluorimetric technique is used. Table 2 gives the pH values used, the statistical characteristics of the fluorimetric calibration curves, and the limits of detection (LOD). The linear dynamic ranges (LDR) are relatively large since they cover 2–3 orders of magnitude. However, the slopes of the log–log curves are much smaller than unity, indicating non-linearity for non-logarithmic calibration plots. This is thought to be due to concentration-independent secondary Rayleigh scattering intensity at wavelengths longer than 500 nm for most purines and pyrimidines,[15] which results in interference in the fluorescence measurements under the instrumental conditions used.

The limits of detection, defined here as the concentration giving a signal-to-noise ratio equal to 3, ranged between 60 ng/ml and 5.4 μg/ml, depending on the particular compound. Specially low LOD values (all lower than 90 ng/ml) were obtained for 6-chloropurine, guanine, cytosine, thymine, and 5-fluorouracil. It was only for adenine and uric acid that the LOD values were larger than 1 μg/ml (Table 2).

Purine and pyrimidine bases and nucleotides have been detected and separated, often in biological media, by chromatographic methods such as

TLC,[20,21] GC[22,23] and HPLC.[24–26] The use of low-temperature phosphorimetry (LTP)[18,27,28] and fluorimetry of derivatives[29–33] has also been reported for the determination of these compounds, with LOD values in the low ng/ml range. In spite of their high sensitivity, both techniques suffer from some limitations. LTP needs cryogenic equipment,[34,35] and preparation of highly fluorescent derivatives of purines and pyrimidines is time-consuming and often complicated.[31] Therefore, pH-controlled fluorimetry offers a convenient alternative method which, though sometimes less sensitive than the other technqiues, presents the great advantage of permitting direct, simple, and rapid determiantion of purines and pyrimidines.

ANALYTICAL APPLICATION OF THE COMPLEXATION OF Nb(V) WITH BROMOPYROGALLOL RED IN MICELLAR MEDIA

M. E. DIAZ GARCIA and A. SANZ-MEDEL
Department of Analytical Chemistry, Faculty of Chemistry, University of Oviedo, Oviedo, Spain

(*Received* 6 *February* 1984. *Revised* 10 *September* 1984. *Accepted* 29 *September* 1984)

Summary—A spectrophotometric method for the determination of trace amounts of Nb(V) based on the formation of a ternary complex with Bromopyrogallol Red (L) and cetylpyridinium bromide (CPB) in 1*M* hydrochloric acid/15% dimethylformamide medium has been developed. The ternary 1:2:2 Nb–L–CPB complex is formed. The absorbance maximum is at 645 nm, the molar absorptivity being $(4.00 \pm 0.04) \times 10^4$ l.mole^{-1}.cm^{-1}. The relative standard deviation is 1.9% and Beer's law is obeyed up to 1.4 μg of Nb(V) per ml. The application of the method to the determination of Nb in pyrochlore-bearing rocks is described. A possible mechanism of interaction of the surfactant with the Nb–L complex is discussed.

The characteristics of analytically useful anionic metal complexes are known to be modified by the addition of cationic surfactants. The charged micelles (through their large superficial electrostatic potential and hydrophobic forces) are able to promote formation of "new" complexes which exhibit markedly improved spectrophotometric properties, *viz.* higher molar absorptivities, stability over a wider pH range, larger bathochromic shifts in comparison with the binary complex, and so on.[1]

These unique properties of micellar systems have been extensively exploited,[1,2] mainly for improving the sensitivity of analytical methods ("surfactant-sensitized reactions"). Less attention has been paid, however, to the solution chemistry involved in this kind of reaction.

It is well known that surfactant molecules in aqueous solution associate upon reaching the so-called "critical micelle concentration" (c.m.c.) to form micelles capable of solubilizing a great variety of organic-like solutes (which otherwise would be insoluble in water). In this context, a binary chelate complex solubilized (or incorporated) in a micelle is exposed to a microenvironment quite different from that in bulk water. In fact, a micellar medium is best characterized as a mixed aqueous–organic solvent,[3] where reaction rates, spectral characteristics, redox processes, *etc.* of a given complex may change drastically.

The principles which are operative in the effects of micelles in analytical reactions are poorly known. No satisfactory theory exists so far to explain the possible mechanism(s) associated with sensitized reactions. Therefore, a better understanding of the nature of surfactant sensitization is a major goal of research in our laboratory.[4–6]

The ternary system Nb(V)–BPR–EDTA has been used to determine niobium in steels in a cetyltrimethylammonium medium of pH 4.5.[7] The object of the present paper is a detailed study of the niobium–Bromopyrogallol Red complex in micellar media. Some special features of using mixed solvents are discussed and attempts are made to extend some physico-chemical observations of micellar systems to surfactant-sensitized analytical reactions.

As a result, a mechanism for the reaction of Nb(V) with Bromopyrogallol Red and cetylpyridinium bromide is proposed, and the analytical characteristics of a new "sensitized" spectrophotometric method for Nb(V) determination are given. The method has been successfully applied to the determination of the metal in pyrochlore-bearing rocks.

EXPERIMENTAL

Reagents

Nb(V) stock solution (200 μg/ml). Prepared as described elsewhere.[4] Diluted further with 2% tartaric acid solution as required, immediately before use.

Cetylpyridinium bromide (CPB) solution, 0.2%. Prepared by dissolving the solid in water by warming, and standardized by titration.[8]

Bromopyrogallol Red solution, 0.1%. Prepared by dissolving 0.1 g of BPR in water containing 0.5 ml of 0.1*M* sodium hydroxide and diluting accurately to 100 ml with water.

All reagents were analytical-reagent grade and distilled demineralized water was used to prepare all solutions.

Spectrophotometric procedure

Pipette standard Nb(V) solution (up to 12 μg of the metal) into a series of 10-ml volumetric flasks already containing the following, added in the order shown and mixed after each addition: 0.5 ml of the reagent solution, 1.5 ml of dimethylformamide (DMF), 1.7 ml of 6*M* hydrochloric acid and 0.5 ml of CPB solution. Mix thoroughly and dilute to the mark with distilled demineralized water. After about 60 min measure the absorbance at 645 nm against a reagent blank.

Determination of Nb in pyrochlore-bearing rocks

Decompose the rock samples as described elsewhere,[9] and prepare a known volume of stock solution. Transfer a suitable aliquot (< 2 ml) containing 2–14 μg of Nb(V) into

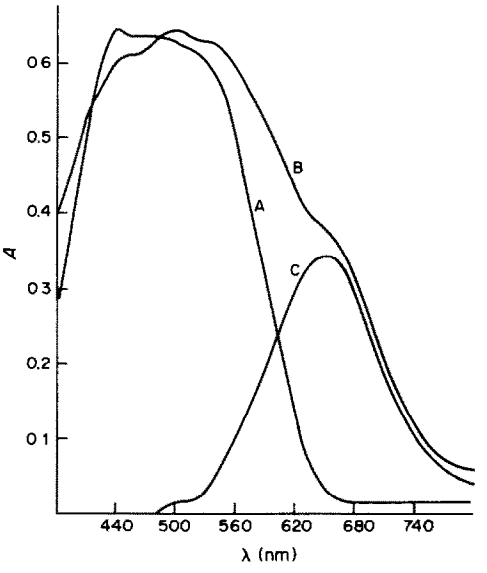

Fig. 1. Absorption spectra of: A, reagent blank against water as reference; B, Nb(V)–Bromopyrogallol Red–CPB complex measured against water as reference; C, Nb(V)–Bromopyrogallol Red–CPB complex against reagent blank. [Nb(V)] = $1.07 \times 10^{-5}M$; [BPR] = $5.37 \times 10^{-5}M$; [CPB] = $2.53 \times 10^{-4}M$. Medium, $1M$ HCl–15% DMF.

a 100-ml separatory funnel and dilute with 11 ml of concentrated hydrochloric acid. Add 10 ml of isopentyl acetate and shake the mixture vigorously for 10 min. Allow the layers to separate and discard the aqueous lower layer. Then add 3 ml of 2% tartaric acid solution, shaking the funnel for 10 min. Transfer the aqueous layer to a 10-ml standard flask which already contains the reagents (0.5 ml of 0.1% BPR solution, 1.5 ml of DMF, 0.2 ml of concentrated hydrochloric acid and 0.5 ml of 0.2% surfactant solution). Wash the remaining organic layer with 2 ml of $1M$ hydrochloric acid to collect any suspended water droplets; add this aqueous portion to the 10-ml standard flask. Dilute to the mark with distilled water and mix thoroughly. After 60 min measure the absorbance of the solution at 645 nm against a reagent blank prepared in the same way (2 ml of "blank ore" solution).

Prepare the calibration curve by treating independent portions of dilute standard niobium solution according to the method above.

RESULTS AND DISCUSSION

Spectral characteristics

The nature of the complex species formed in the presence of CPB depends on the acidity of the medium: in more acidic media (0.3–1.6M hydrochloric acid) a complex predominates which has its absorption maximum in the region 645–650 nm; as the pH increases a second complex with λ_{max} at 620–625 nm starts to appear and predominates between pH 2 and 6.

As $1M$ hydrochloric acid medium provides similar sensitivity to that observed at higher pH values, but higher selectivity, this medium was used in subsequent studies.

In Fig. 1, curves A and B show the absorption spectra of Bromopyrogallol Red and its Nb(V) complex in the presence of CPB in $1M$ hydrochloric acid. The maximum absorbance difference (curve C) for the Nb(V) complex is observed at 645 nm. Figure 2 shows that the spectrum of the ternary complex is very different from that of the binary Nb–Bromopyrogallol Red complex. The spectrum of the binary complex shows peaks corresponding to the 1:1 and 1:3 (Nb:BPR) complexes (see below).

Influence of experimental variables

Water-miscible solvent effect. Increasing turbidity and fading of the colour takes place on standing. A large surfactant concentration eliminates the precipitation, but also undesirably reduces the absorbance. Therefore, several water-soluble solvents were tested for stabilization: methanol, acetone, dimethylsulphoxide and *N,N'*-dimethylformamide (DMF). A final DMF concentration of 15% proved to be most suitable.

Mixing order and standing time. The absorbance was independent of the order in which the components of the reaction mixture were mixed, but in practice the order dye, DMF, acid, surfactant and Nb(V) solution was followed. Maximal constant absorbance was obtained in 60 min and remained unchanged for at least 12 hr.

Ionic strength effects. Callahan and Cook[10] have reported the effects of added electrolytes on the Be–Chrome Azurol S complex sensitized by cetyltrimethylammonium bromide: the molar absorptivity increases with addition of salt and the wavelength of maximum absorbance is shifted to a wavelength 12–14 nm longer.

The influence of the ionic strength (I) on the complex formation of Nb(V) and BPR in presence of CPB micelles was studied in the range 1.4–3M by adding increasing amounts of $4M$ sodium chloride. The results show that the shape of the spectrum remains practically unchanged but the turbidity (as

absorbance measured at 800 nm) increases with I (Fig. 3). No turbidity was observed in the reagent blanks.

In the light of our observations it seems that a high electrolyte level may have a profound effect on the properties of the micellar medium. It is known that at high salt concentrations the shape of the micelles changes,[11] and that when the micelles change from spherical to rod-like, the viscosity increases markedly.[12]

Changes in viscosity, due not only to changes of the micellar structure but also to a higher salt content, could affect the solubility of the solutes. In this context, the turbidity observed in the Nb system could be attributed to the Nb–BPR–CPB complex becoming more insoluble as the salt concentration increases, but it is hard to draw any general conclusion, since it would be difficult to disentangle the effects due to changes in the medium viscosity from those due to influence of the micellar structure on the solubilizing capacity.

Surfactant concentration. The c.m.c. of CPB in a 1M hydrochloric acid medium was found to be $4.96 \times 10^{-4}M$, as determined by surface-tension measurement; the presence of 15% DMF lowered the c.m.c. to $2.39 \times 10^{-4}M$. This trend seems to be related to the solubility of the DMF in the micelles, which affects the hydrophobic forces in the micellar surface.[13]

During the study of the influence of surfactant concentration (in the presence of 15% DMF) we observed no precipitation of the ternary ion-association complex at surfactant concentrations below the c.m.c., whereas precipitation in such conditions is usually observed in many sensitized systems.[6] The formation of premicelles (mixed micelles) between DMF and surfactant monomers seems to play an important role; these mixed-micelles should be responsible for solubilization of the chelate–surfactant ion-association complex to give a clear and stable solution, even at low surfactant concentrations (DMF acts as a co-surfactant).

As shown in Fig. 4, the absorbance of the ternary system increases linearly with increasing CPB concentration up to a sharp break [at about 11-fold molar excess of surfactant relative to Nb(V)], after which,

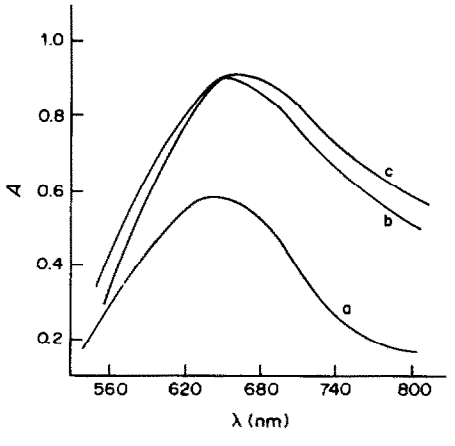

Fig. 3. Spectra of Nb(V)–BPR–CPB complex in 1M HCl–15% DMF medium with (a) no salt (b) 0.8M NaCl and (c) 2M NaCl. [Nb(V)] = $1.07 \times 10^{-5}M$; [BPR] = $8.95 \times 10^{-5}M$; [CPB] = $2.73 \times 10^{-4}M$.

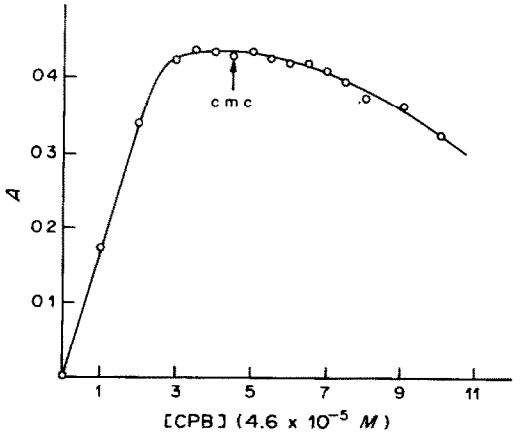

Fig. 4. Effect of cetylpyridinium bromide concentration on the Nb–BPR complex in 1M HCl–15% DMF medium. Wavelength, 645 nm. [Nb(V)] = $1.07 \times 10^{-5}M$; [BPR] = $8.95 \times 10^{-5}M$.

the absorbance remains virtually constant. For CPB concentrations above the c.m.c. a further increase in surfactant concentration produces a progressive decrease in absorbance.

Analytical characteristics

Beer's law, sensitivity and precision. The calibration graph was found to obey Beer's law in the Nb(V) range 0.1–1.4 μg/ml. At 645 nm the molar absorptivity was $(4.00 \pm 0.04) \times 10^4$ $l.mole^{-1}.cm^{-1}$. Absorbance measurements on ten independent 0.6 μg/ml solutions gave a relative standard deviation of 1.9%.

Interferences. The selectivity was investigated by determination of 0.8 μg/ml Nb(V) in the presence of a series of other ions. An ion was considered to interfere only if it produced a change of at least 2% in the absorbance obtained for niobium alone.

The following ions did not interfere: 400 μg/ml B; 80 μg/ml Si(IV), Ni, Co(II), Mn (II), Ca, Pb, Ce(III), U(VI); 40 μg/ml Cu(II), Al, Cr(III) and Sb(III); 0.8 μg/ml Fe(III), V(V) and Hg(II). The interference of 0.8 μg/ml Zr was eliminated by the addition of EDTA. The other interferences are dealt with by preliminary extraction of the Nb(V), see below.

Large amounts of common masking agents for Nb(V), *viz.* phosphate (up to 2.37*M*), EDTA (0.003*M*), citrate (0.085*M*), ascorbate (0.23*M*), fluoride (0.42*M*), oxalate (0.009*M*) and tartrate (0.053*M*) did not interfere.

Although the proposed method has lower sensitivity than that of the method reported by Jadhav and Venkateswarlu,[7] it is rather more selective; of 22 cations and 7 anions only Ta(V), Mo(VI), W(VI), Sn(IV) and Ti(IV) interfered. These interferences can be easily overcome by selectively separating Nb(V) before its determination, as in the surfactant-free method of Ramakrishna *et al.*[14] (see procedure for determination of Nb in pyrochlore-bearing rocks).

Nature of the sensitized reaction

Composition of the species formed. The continuous-variation method indicated that in the absence of surfactant two binary complexes were formed between Nb(V) and BPR in 1*M* hydrochloric acid medium, with Nb/L ratios of 1:1 ($\lambda_{max} = 524$ nm) and 1:3 ($\lambda_{max} = 645$ nm). In the presence of excess of CPB two complexes were again found, but of composition 1:1 and 1:2 (Nb/L).

Figure 4 shows that sensitization starts at well below the c.m.c. of CPB, indicating that a true ternary complex Nb:BPR:CPB of the type 1:1:*a* or 1:2:*b* might be responsible for the observed spectral changes on addition of surfactant. If this is so, a fixed stoichiometric ratio of chelate to surfactant is to be expected.[5]

To establish the values of *a* and *b*, equimolar solutions of surfactant and chelate (NbL or NbL_2) were prepared. Continuous-variation plots indicated a 1:1 chelate:surfactant ratio for the NbL system and a 1:2 ratio for NbL_2. In other words, at the relatively high dye concentrations used in the analytical procedure a 1:2:2 ternary complex seems to be formed. Complete formation of this complex, however, apparently necessitates an excess of surfactant (Fig. 3).

Reaction mechanism. The sensitization by the cationic surfactant appears to be the result of concurrently electrostatic and hydrophobic interactions.

Formation of the ion-association ternary complex NbL_2^{2-} $(CP^+)_2$ is attributable to *electrostatic interactions* through the sulphonate group of the dye. This kind of interaction alone, however, is not sufficient to explain the spectral changes observed on addition of CPB, because non-micelle-forming counter-ions, *viz.* diphenylguanidinium or tetraethylammonium, did not change the spectral characteristics of the binary complexes at all. In fact, simple ion-pairing between the sulphonate group of the dye and a quaternary ammonium counter-ion does not perturb the chromophore.[15] Therefore, surface-active agents do not simply act as counter-ions but clearly change the microenvironment of the chromophore (*hydrophobic interactions*), bringing about remarkable spectral changes.

Hydrophobic interactions, then, have to be considered: even at stoichiometric concentrations of the CPB, sensitization is observed and such hydrophobic interactions must then occur. As shown previously[5] the cationic surfactant electrostatically bound to the chelate would originate, probably by twisting of its long hydrocarbon chains towards the inner complex, a special microenvironment in which the physical properties (dielectric constant, viscosity, solubility, *etc.*) must be different from those of bulk water. This is more probable in our case where the ion-association complex is solubilized by surfactant–DMF premicelles. The more this microenvironment approaches that existing in the micelles of CPB the bigger is the sensitization observed (which would explain that maximum sensitization is observed around the c.m.c., see Fig. 3).

In any case, the overall effect of the cationic surfactant is quite involved and it cannot be attributed only to the addition of the electrostatic and hydrophobic contributions. Adding to the NbL_2 complex a mixture formed of a bulky non-micelle-forming cation (to provide the electrostatic contribution) and a non-ionic surfactant (Triton X-100, which would provide the hydrophobic effect) does not sensitize the binary complex.

Now, let us consider what happens if we secure maximum sensitization as in the analytical procedure (at CPB concentration around the c.m.c.): in this case the binary complex is incorporated into the Stern layer through the sulphonate groups.[12] This incorporation facilitates the reorientation of water molecules around the metal ion, and owing to the lower di-

electric constant near the micellar surface[16] the weakening of the hydration forces would make it possible for the central ion to co-ordinate more dye molecules (there would be an increase in the co-ordination number). This is a general trend observed in micellar systems.[17] In our systems, an $NbOL_3$ binary complex was detected: the presence of micelles should favour formation of this complex instead of the 1:1 or 1:2 complexes. Experiments showed, however, that the 1:2 complex was favoured by the presence of CPB micelles. This proves that exceptions to the rule above are quite common.[18] In our case, the CPB micelles seem to shift the equilibria towards the formation of the more stable complex, as it is known[19] that the $NbOL_3$ binary complex is very weak even at pH 6. The low stability of these binary complexes could be due to the effect of stereochemical factors.

Determination of niobium in pyrochlore-bearing rocks

The proposed method has been applied to the determination of Nb(V) in certified and synthetic rocks (synthetic samples were prepared from calcite-based Canadian pyrochlores by mixing them with pure Nb_2O_5 powder).

Table 1 summarizes the results obtained by the present method and by an independent solvent-extraction method using dichloro-oxine.[9]

Summary—Etching procedures for separation of thin layers of InAs (up to 1.4 μm thick) have been developed and optimized. A solid-state microtome has been used for cutting layers thicker than 1 μm. AAS/ETA methods for determination of traces of Ag, Au, Bi, Cd, Sn, and Tl have been developed. The matrix interferences of nitric acid, hydrobromic acid, and As^{3+} or In^{3+} in nitric or hydrobromic acid have been studied. The main causes of the matrix interference are the formation of diatomic molecules between the trace and matrix components, and the effect of the evaporation processes. By use of the platform technique with special platforms some matrix interferences could be minimized. For the determination of traces of Sn, matrix modification with $Ni(NO_3)_2$ as additive gave the best analytical values. For the trace determination of Au, separation of In from Au by evaporation of $InBr_3$ from 0.6*M* HBR medium in the AAS ashing phase was developed. The detection limits are in the 10^{16} atoms/cm^3 region for layers of 1 μm thickness and surface area 1 cm^2.

For thin-layer and layer-by-layer analysis of semiconductor materials reproducible methods of layer separation and very sensitive methods for trace analysis of microsamples are needed. So far we have investigated the possibility of determining doping elements in thin layers of GaAs,[1] and InSb,[2] separating the layers by anodic oxidation followed by chemical etching, by chemical etching alone, and by mechanical separation with a diamond knife in a solid-state microtome. The anodic oxidation procedure gave the best depth resolution. For the determinations we used atomic-absorption spectrometry with electrothermal atomization (AAS/ETA).

The purpose of the present work was to extend these researches to thin layers of InAs. We have proved that chemical etching and mechanical separation are both useful for the purpose and have developed sensitive determination methods for trace amounts of Ag, Au, Bi, Cd, Sn, and Tl by AAS/ETA. The influence of the matrix substances was investigated.

*Part VI, *Talanta*, 1982, **29**, 577.

EXPERIMENTAL

Materials

InAs monocrystals with 111B surface; "suprapur" In, As, hydrobromic acid and nitric acid; acetone (quartz-distilled), purified paraffin, and doubly quartz-distilled water. Stock 0.1-mg/ml solutions of Ag, Au, Cd, Bi, Sn, Tl in nitric acid or a mixture of nitric and hydrochloric acids were used, and for the analytical investigations were diluted with 0.1*M* nitric acid (Ag, Bi, Cd, Sn, Tl) or 0.6*M* hydrobromic acid (Au). Purified $Ni(NO_3)_2$ solution (1*M*) was used as matrix modifier.

Apparatus

A Jarrell–Ash 811 atomic-absorption spectrometer, and Beckmann 1268 graphite cuvette, with background compensation by the two-line method, and a Perkin-Elmer 303 atomic-absorption spectrometer and HGA 74 graphite tube atomizer, with background correction by continuous light-source, were used.

Chemical etching and mechanical separation

InAs with an appropriate plane-polished surface was washed with distilled acetone to remove traces of grease. The non-planar surface was coated with paraffin to avoid any etching effects. Then 0.15 ml of etching reagent was placed on 1 cm^2 of the InAs surface. After an etching time of about 3 min this solution was removed with a Teflon capillary and used for the analytical determinations.

Table 1. Experimental conditions for the determination of trace elements by AAS/ETA

§Sensitivity of AA with Sn EDL twice as good.

For separation of layers >2 μm thick chemical etching is very time-consuming, but such layers can be separated in 1-μm steps by use of a diamond knife in a solid-state microtome. The powder separated was collected, weighed, and dissolved in dilute nitric acid.

Determination of added traces

The etching solutions or nitric acid solutions were evaporated to dryness under infrared radiation at a temperature not exceeding 60°. For determination of Ag, Bi, Cd, Sn, and Tl, 0.1 ml of 1*M* nitric acid was added to the dry residue and evaporated to dryness to remove residues of hydrobromic acid. This step was repeated, then the residue was dissolved in 0.1*M* nitric acid (0.1–1.0 ml, accurately measured, depending on the amount of residue). For the determination of Au the dry residues were dissolved in 0.1–1.0 ml of 0.6*M* hydrobromic acid (accurately measured). Finally a 20-μl portion of the solution was placed in the graphite tube. The optimal working conditions for the AAS/ETA determination are shown in Table 1.

For the investigations using the L'vov platform technique we made special 10 × 6 mm platforms from normal graphite tubes. These platforms are chamfered to fit snugly on the inner surface of the graphite tube (*cf.* L'vov *et al.*[3]).

RESULTS AND DISCUSSION

Optimization of the separation method

First we tested some polishing reagents[4–6] for etching properties, but none was suitable for etching purposes. The polishing reagent proposed by Luft *et al.*[6] was based on sulphuric acid, which is a very bad reagent for use in AAS/ETA. We therefore tried other mixtures of acids and finally found the combination of hydrobromic and nitric acid to be the best. The etching properties of this reagent are due to the elemental bromine formed by oxidation. For etching of layers between 0.1 and 1.4 μm thick the reagents used were mixtures of concentrated hydrobromic acid, nitric acid and water in the ratios 20:1:40, 20:1:60 and 20:1:80 v/v. Before use the mixtures must stand for at least 2 hr, during which a brown colour due to bromine develops. The solutions are usable for 14 days.

The results of etching the 111B surface of InAs are shown in Fig. 1. The etching rate and depth depend on the water content of the etching solutions. In all cases a constant etch depth is achieved in 2–3 min, and increases with decreasing water content. Figure 1 shows that the etch depth can be varied by adjusting the acid concentration or the etching time. The first is recommended.

Ellipsometric measurement of the roughness of the etched surfaces showed a relative standard deviation of 10% for the depth. The mean depths of replicate etches had a relative standard deviation of 6%.

Effect matrix substances on the AAS/ETA results

Hydrobromic acid. Figure 2 shows the effect of hydrobromic acid concentration on the determination of Ag, Au, Bi, Cd, Sn, and Tl traces by AAS/ETA, at a fixed 0.1*M* nitric acid concentration. Use of the special platforms decreases this matrix effect (cf. Table 2), especially for Cd. The determination of Bi, Sn and Tl in 1.2*M* hydrobromic acid medium is practically impossible, even with use of the special platforms. There is no matrix effect on the signal for Ag when the platform is used, but the signal for Au is doubled at hydrobromic acid concentrations >0.6*M*.

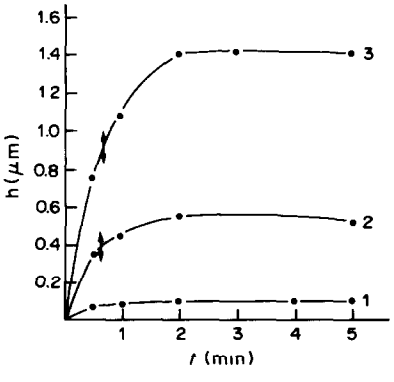

Fig. 1. Quantitative characteristics of the etching of InAs (111)B with 1, $HBr:HNO_3:H_2O = 20:1:80$; 2. $HBr:HNO_3:H_2O = 20:1:60$; 3. $Hbr:HNO_3:H_2O = 20:1:40$. The double arrow shows the uncertainty for $P = 95\%$.

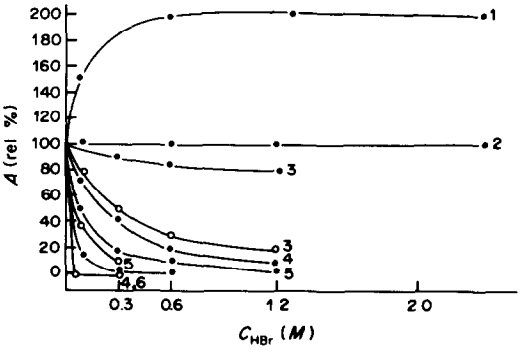

Fig. 2. Influence of the concentration of hydrobromic acid on trace element determinations by AAS/ETA, normalized to the signal for 0.1*M* HNO_3 medium: ● with platform; ○ without platform; 1-Au, 2—Ag, 3—Cd, 4—Sn, 5—Bi, 6—Tl.

Table 2 gives the improvement factors achieved by using the platform technique for both nitric and hydrobromic acid media. Except for the tin determination the improvement factors are small for nitric acid medium. With hydrobromic acid medium the signal improvement is significant for Ag and Cd trace determinations. The improvement in the determination of tin and thallium is very great, because there is zero signal if no platform is used (Fig. 2). The depression of the signals can be explained in terms of the thermal properties of the compounds which are probably formed in the hot tubes. Some of these are shown in Table 3.

The strong depression of the Bi and Sn signals by hydrobromic acid is due to the formation of the low-boiling bromides $BiBr_3$ (b.p. 461°) and $SnBr_4$ (b.p. 208°), which volatilize in the ashing phase. The signal for Tl is also strongly depressed, because of formation of sparingly soluble and easily volatilized TlBr. Katzkov[7] showed that in the AAS determination of Tl in nitric acid solution the Tl volatilizes as the metal in the temperature range 1200–1500°. The metal is formed from the salts by reaction with the hot graphite tube surface. This process is theoretically possible at high temperatures in presence of bromide but the TlBr will already have been lost by volatilization in the ashing phase and the beginning of the atomization phase. In earlier work on molecular absorption[8] we showed that in the vapour phase TlBr is a stable diatomic molecule (dissociation energy 3.4 eV) and exists at high temperatures in the gas phase inside the graphite tube. Its molecular absorption can be used for determination of traces of bromide, and the existence of TlBr molecules in the gas phase under the conditions used in this work was established by light-absorption measurements at 342.9 nm[9].

In principle, bromide should also influence the AAS determination of silver. In acid media the sparingly soluble AgBr is formed, which volatilizes at comparatively low temperature, with incomplete dissociation. We could detect the AgBr molecule by its light-absorption at 318.4 nm in hot graphite tubes.[9] The dissociation energy of this molecule is smaller than that of TlBr (3.2 eV). This fact and the incomplete dissociation on volatilization lead to the situation that all the silver species dissociate in the high-temperature gas phase before the AgBr has disappeared by diffusion.

The explanation for the depression of the Cd signal by hydrobromic acid is less well defined. Sturgeon *et al.*[10] showed that the atomization of Cd takes place by dissociation of gaseous CdO if nitric acid medium is used and by dissociation of gaseous CdCl if hydrochloric acid medium is used. The appearance temperature for Cd atoms in hydrochloric acid medium is 50° lower than that in nitric acid medium.

In presence of hydrobromic acid the appearance temperature is still lower than in hydrochloric acid medium because the b.p. of $CdBr_2$ is about 100° lower than that of $CdCl_2$. As we have shown,[11] hydrochloric acid has much less influence than nitric acid on the Cd AAS signals. From these facts we can conclude that the depressive effect of hydrobromic acid arises from the high volatility of $CdBr_2$ and diffusion of undissociated CdBr particles. This opinion is confirmed by the marked change when the platform technique is used, since the CdBr molecules are more extensively dissociated in a given atomization time by the higher temperature of the gas phase in the tube/platform system.

The improvement of the Au signals by hydrobromic acid can be explained as due to better and faster volatilization, with increased dissociation of AuBr particles.

Table 2. Influence of the platform technique on the AA determinations

Element and concentration,			Ratio of improvement*	
	μg/ml	*pg/20 μl*	0.1*M* HNO_3	0.2*M* HBr
Ag	0.004	80	1	1.6

Effect of As(III) on AAS determination of Ag, Bi, Cd, Sn and Tl

The influence of the matrix As(III) formed from the InAs by oxidation with nitric acid and partly by the etching process, was investigated, for traces of Bi, Sn and Tl in only the nitric acid medium and for traces of Ag, Au and Cd in both nitric and hydrobromic acid media. It was found that As concentrations between 0.05 and 4 mg/ml have no influence on the AAS signals of these elements. Considering that up to 85–95% of the arsenic is lost during the evaporation of the etching solution (mixture of hydrobromic and nitric acids), this means that the residual arsenic does not influence the AAS determinations of Ag, Bi, Cd, Sn, Tl and Au. In the case of Au the evaporation of the arsenic is complete during drying of its solution in hydrobromic acid in the graphite tube.

Influence of In^{3+} on the AAS determination of Ag, Au, Bi, Cd, Sn and Tl

In nitric acid medium the presence of In^{3+} in concentrations up to 5 mg/ml does not affect the height of the signals for Ag, Bi, Cd, Sn and Tl, but the non-specific background for the determination of Bi, Cd and Tl is very high and cannot be compensated by use of a deuterium lamp. Use of the platform technique improves the background by fractional volatilization. The effect of the matrix substances is stronger in hydrobromic acid medium than nitric acid medium.

The AAS signals of Bi, Sn and Tl are completely depressed, and those of Ag and Cd are up to 50–90% depressed, even when the platform technique is used (Fig. 3). Comparison of Figs. 2 and 3 shows that the influence of the combination of In^{3+} and hydrobromic acid is much stronger than that of the acid alone.

The influence of the In^{3+}/HBr combination is due to $InBr_3$ being formed in the drying and ashing processes in the graphite tube, and only incompletely thermally decomposed at high temperatures. There are some losses of volatile InBr species in the ashing phase (Table 3), but the bulk of the indium bromide volatilizes only in the atomization phase. At the high temperatures of the atomization phase the indium bromide is partly dissociated (dissociation energy 4.2 eV)[8] into In and Br atoms. This leads to a high Br concentration in the graphite cuvette, which affects the complete (Bi, Sn, Tl) or incomplete but strong (Ag, Cd) formation of the diatomic metal bromides in the graphite tube, *cf.* Layson and Holcombe.[12] The strong influence of In^{3+} in hydrochloric acid medium is caused in the same way and was described by us earlier.[11]

The signal enhancement by the platform technique is caused first by the fractionated volatilizations and secondly by the increased dissociation at the higher temperatures achieved.

When the mixed matrix In^{3+}/As(III)/HBr is present in the determinations, there is a small improvement in the AAS determinations, caused by volatilization of part of the bromide as $AsBr_3$ and by the fact that the weak but volatile arsenious acid forms $InAsO_3$ at higher temperatures. The extent of

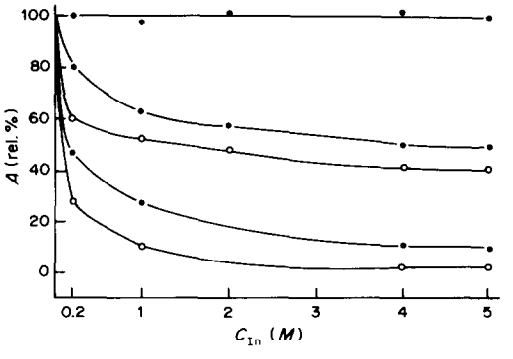

Fig. 3. Influence of the In^{3+} concentration in 0.2*M* hydrobromic acid on trace element determinations by AAS/ETA, normalized to the signal for 0.2*M* HBr medium: ● with platform; ○ without platform; 1—Au, 2—Ag, 3—Cd.

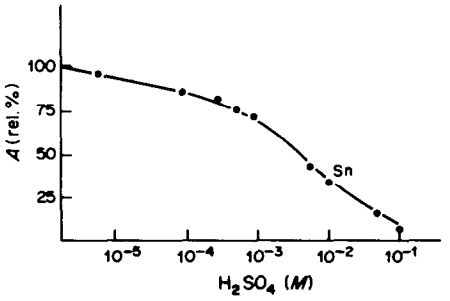

Fig. 4. Influence of sulphuric acid concentration on determination of Sn by AAS/ETA: signal for 0.1*M* HNO_3 medium = 100%.

these reactions also depends on the nitric acid concentration in the medium (cf. Dittrich *et al.*[11]).

Optimization of the Sn determination by matrix modification

The determination of Sn traces by AAS/ETA in hydrobromic acid medium is impossible, and in nitric acid medium is not very sensitive. The improvement of the sensitivity in both media by use of the platform technique shows the strong influence of the vaporization and dissociation processes on the determination.[12] To improve the sensitivity of the Sn determination we first tried sulphuric acid medium. The results are shown in Fig. 4. Low concentrations of sulphuric acid strongly depress the Sn signal by formation of the stable diatomic molecule SnS (dissociation energy 4.8 eV). We tried to detect this molecule in the gas phase in the graphite cuvette. The result is shown in Fig. 5, which shows characteristic differences in the molecular absorbance of Sn species in presence and absence of sodium sulphide, *cf.* Dittrich and Vorberg.[13] We therefore investigated some marix modifiers.[14] The results shown in Fig. 6 indicate that some metal nitrates improve the Sn signals significantly. It could also be shown that the parent acid and base, *e.g.*, nitric acid or barium hydroxide, also improve the analytical results when present at higher concentrations.

The salts are more effective however, stabilizing the easily volatilized and easily decomposed SnO by formation of the metal stannites and stannates, which

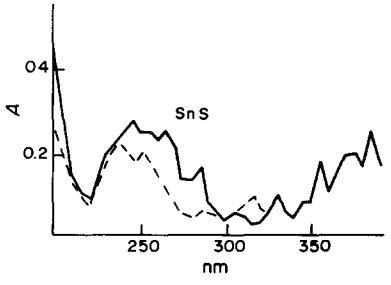

Fig. 5. Molecular absorption spectra of Sn species volatilized in the graphite tube in presence and absence of S: ——with S (as Na_2S); ---without S.

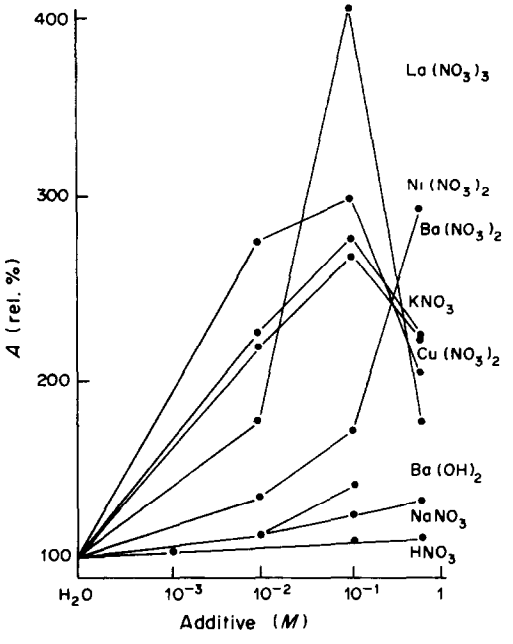

Fig. 6. Influence of various substances on AAS/ETA Sn signals.

are thermally stable and non-volatile. The metal stannites can also be formed in the presence of only the metal ion, but in presence of nitric acid only SnO_2 can be formed. The stannates are more stable than SnO_2 and the stannites, so the analytical results are best in the presence of metal nitrates. We also suppose that a high concentration of the metal nitrate influences the surface of the graphite. The direct contact of reducible substances with graphite at high temperatures leads to reduction processes. It is possible that active carbon centres on the surface are removed by oxidation by nitrates.

The truth of our hypothesis was demonstrated by the fact that the appearance temperatures for Sn are much higher in presence of metal nitrates: 800–1000° in the absence and 1500–1700° in the presence of metal nitrates such as $Ni(NO_3)_2$ or $Ba(NO_3)_2$, irrespective of whether nitric or hydrochloric acid me-

	5	2×10^{15}
Tl	1.4	2×10^{16}
	5	6×10^{15}

dium is used. In the absence of metal nitrates the Sn signal is lower for hydrochloric acid medium than for nitric acid medium. In presence of metal nitrates the Sn signals are the same for both media. Hence the improvement of the signals by metal nitrates is relatively greater for hydrochloric acid medium.

Use of the platform technique as well, brings no further improvement. The best results were achieved by using $Ni(NO_3)_2$ as matrix modifier, but $Ba(NO_3)_2$ and $La(NO_3)_3$ also gave good results. For the Sn determination by AAS/ETA we used 0.2–0.5*M* $Ni(NO_3)_2$. The analytical signals were then greater by a factor of 4 than these in the absence of $Ni(NO_3)_2$.

Interference of In^{3+} in the Au determination, and optimization of the determination

As shown in Fig. 2 the AAS signal for Au in 0.6 *M* hydrobromic acid was twice that for Au in 0.1*M* nitric acid. We found that in presence of In^{3+}, irrespective of the medium (nitric, hydrochloric or hydrobromic acid), there was a high background at both 242.8 and 267.6 nm. The background absorption was directly proportional to the In^{3+} concentration. Background compensation by use of a continuous light-source, *e.g.*, a deuterium lamp, improves the situation, but accurate measurement of the Au atomic absorption is impossible. For example, at low concentrations of Au we found "negative" AA signals. Höhn and Jackwerth[15] investigated the reason for this interference in hydrochloric acid medium. In the vaporization phase most of the indium[13] volatilized as InCl (or InBr or InO, depending on the medium, cf. earlier results[8,9,16]. These molecular species absorb light in this 240–270 nm range very strongly. Because the absorption bands are strongly structured (pseudo line spectra), accurate compensation of the background is not possible. The Au absorption line at 267.6 nm lies between two rotational lines for the InCl molecule. The reason for the "negative" results is the inaccurate compensation.

Because it was necessary to determine traces of Au in InAs we tried to avoid the interference of In compounds. Table 3 shows that the b.p. of $InBr_3$ is very low, and we hoped to separate the matrix and the trace element by optimization of the chemical and thermal conditions. Therefore we studied the vaporization of 80 μg of In^{3+} from different acid media by use of the platform technique. After the appropriate thermal treatment the platforms were treated with nitric acid to dissolve any residual In^{3+}, and the In^{3+} content of these solutions was determined by flame AAS.

Figure 7 shows the results. It can be seen that indium volatilizes completely from hydrobromic acid medium at temperatures >750°, but in nitric acid medium the vaporization of indium is low and incomplete up to 1000°.

We also investigated whether the combined presence of hydrobromic acid and In^{3+} depresses the Au signal. Figure 8 shows that up to ashing temperatures

Table 5. Accuracy of trace determination in thin layers of InAs by AAS/ETA

Trace	Amount added in the etching step, *ng*	Amount found, *ng*	Absolute standard deviation, *ng* (P = 95%)
Ag	1.5	1.4	0.15
Au	5	4.9	0.5
Bi	5	5.2	0.4
Cd	0.2	0.2	0.02
Sn	20	22	3
Tl	10	10.5	0.5

of 750° there is no loss of Au. Therefore it is possible to separate In in hydrobromic acid medium (0.6*M*) from Au traces by using the optimal ashing temperature of 750°. The analytical results could be improved by this procedure.

Analytical results

The thin-layer or layer-by-layer analysis of InAs can be done in the following way. Etching with $HBr/HNO_3/H_2O$ mixtures is used for removal of layers up to a thickness of 1.4 μm, and for thicker layers a solid state microtome is used, in steps of 1 μm, to obtain the desired thickness. The residue from evaporation of the etching solution, or the product from the microtome sectioning, is dissolved in 0.1*M* nitric acid for the determination of Ag, Bi, Cd, Tl, in 0.1*M* HNO_3/0.2–0.5*M* $Ni(NO_3)_2$ medium for determination of Sn, and in 0.6*M* hydrobromic acid for Au determination by AAS/ETA, with 20-μl samples. Table 4 gives the analytical results. The accuracy of the results was established by the standard-addition method. Table 5 shows that the analytical results are accurate within the limits of the reproducibility.

FLUORIMETRIC DETERMINATION OF SULPHATE BY TERNARY COMPLEX FORMATION WITH ZIRCONIUM AND BIACETYLMONOXIME NICOTINYLHYDRAZONE

S. RUBIO, A. GOMEZ-HENS and M. VALCARCEL
Department of Analytical Chemistry, Faculty of Sciences, University of Córdoba, Córdoba, Spain

(*Received* 30 *April* 1984. *Accepted* 14 *September* 1984)

Summary—A fluorimetric procedure for the determination of sulphate (0.5–6 μg/ml) based on the formation of a ternary complex with biacetylmonoxime nicotinylhydrazone and zirconium(IV) is described. The excitation and fluorescence maxima are at 415 and 505 nm, respectively. The method is rapid and the procedure reproducible. The precision is ±2% near to the middle range of the calibration curves. There is no interference from most common ions. Phosphate and fluoride are tolerated at 100-fold molar ratio to sulphate. The method has been applied to the determination of sulphate in a variety of water samples.

Fluorimetric methods for determining sulphate are mainly based on the ability of this anion to liberate an organic reagent (*e.g.*, salicylfluorone,[1] flavonol[2] or morin[3]) from its complex with thorium. The salicylfluorone method is the most sensitive. Only one fluorimetric method based on a complex *formation* reaction has been proposed.[4] Although it was necessary to use a considerable (100–1000 molar ratio) amount of the sulphate ion to obtain a linear calibration graph, the authors suggest the probable existence of a 1:1:1 ternary complex, but this cannot be proved.

Several applications of these fluorimetric methods have been described. Vlasov *et al.*[5,6] used the thorium–morin method to determine sulphate in weakly mineralized waters and Nasu[7] used it to analyse snow and river waters. Nasu *et al.*[2] have also used the thorium–flavonol system to determine sulphate in lake, river and mine waters and snow. The thorium–salicylfluorone system has been proposed for determining sulphate in germanium dioxide[1] and distilled water.[8] These methods are subject to serious interference from ions such as phosphate and fluoride and also several other ions, and it is generally impossible to determine sulphate in the presence of phosphate ions.[2,5–7]

In this paper, a direct fluorimetric determination of sulphate, based on the formation of a 1:2:1 ternary complex between zirconium(IV), biacetylmonoxime nicotinylhydrazone (BMNH) and sulphate, is described. BMNH has been used previously as a fluorimetric reagent for the determination of titanium, zirconium and hafnium.[9] It was found that the addition of sulphate to the zirconium–BMNH and hafnium–BMNH complexes resulted in an enhancement of the fluorescence intensity and the stoichiometry of the ternary complexes found to be formed was evaluated by the continuous-variation and molar-ratio methods. We now describe an investigation of this effect, and its use for the determination of sulphate. Although the methods based on substitution reactions[1–3] are more sensitive, they are also less selective. Interference by phosphate and fluoride is eliminated by addition of tartrate and aluminium respectively. Sulphate can be determined in the presence of 100-fold amounts of these ions. The method has been applied to water analysis.

EXPERIMENTAL

Reagents

All experiments were performed with reagent-grade chemicals and pure solvents.

Biacetylmonoxime nicotinylhydrazone (BMNH)[9], 5.5×10^{-4}M *solution in ethanol.*

Zirconium solution, 0.01M. Prepared by dissolving 3.22 g of $ZrOCl_2 \cdot 8H_2O$ in 1 litre of 3*M* hydrochloric acid. This solution should not polymerize on storage.[10] Lower concentrations were obtained by dilution with 3*M* hydrochloric acid.

Standard sulphate solution, ~0.01M. Anhydrous sodium sulphate (1.40 g) was dissolved in 1 litre of distilled water and the solution was standardized gravimetrically by precipitation with barium chloride.

Apparatus

A Perkin-Elmer fluorescence spectrophotometer, model MPF-43A, fitted with 1-cm quartz cells and a xenon arc source was used. Because of day-to-day variations in lamp intensity, it is necessary to run two or three standards with each batch of unknowns, as in all single-beam fluorimetric procedures, to establish the position and slope of the calibration curve. The slit-widths were adjusted to give a 6-nm band-width, both in the excitation and the emission monochromators.

Procedure

To a sample solution containing 12.5–150 μg of sulphate, in a 25-ml standard flask, add 0.25 ml of $2 \times 10^{-4}M$ zirconium, 6 ml of $5.5 \times 10^{-4}M$ BMNH and enough 1*M* hydrochloric acid to make the pH of the final solution between 1.75 and 2. Mix, dilute to volume, and measure the fluorescence intensity (λ_{ex} 415 nm, λ_{em} 505 nm) at 20 ± 0.1°.

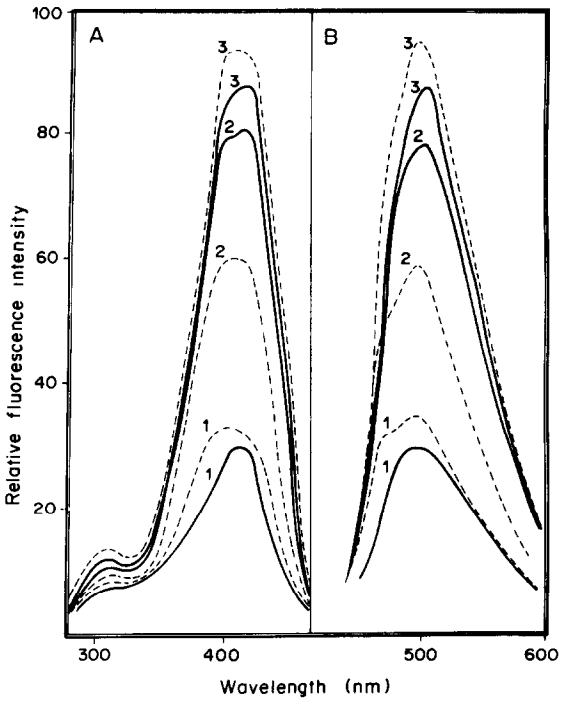

Fig. 1. Uncorrected excitation (A) and emission (B) spectra, showing the effect of the sulphate ion on the 1:2 Zr(IV)–BMNH and Hf(IV)–BMNH complexes. Broken lines: Hf(IV), complexes, bold lines: Zr(IV) complexes. Sulphate concentration: curves 1: 0, curves 2: 10 μg/ml, curves 3: 100 μg/ml. [Zr(IV)] = [Hf(IV)] = 50 ng/ml, [BMNH] = $10^{-4}M$.

Apply a correction for a reagent blank. Prepare a calibration graph in the same way.

RESULTS AND DISCUSSION

Spectral characteristics

BMNH reacts with zirconium(IV) and hafnium(IV) in mineral acid medium to produce fluorescent 2:1 BMNH–metal complexes. Sulphate enhances the fluorescence of these complexes but causes no changes in the wavelengths of the excitation or emission maxima and 2:1:1 BMNH–metal–sulphate ternary complexes have been formulated.[9] A comparative study has been made to decide which system is the more sensitive for sulphate determination. Figure 1 shows the uncorrected excitation and emission spectra of solutions containing BMNH, zirconium or hafnium, and sulphate at three levels (0, 10 and 100 μg/ml). The zirconium system gives a much greater sensitivity of response for sulphate levels < 10 μg/ml, and is therefore preferred. Maximum fluorescence intensity is reached in 10 min and remains constant for at least 3 hr.

Influence of variables

The effect of acidity was studied with use of sodium hydroxide and hydrochloric acid for adjustment. The fluorescence intensity was maximal and independent of pH in the range 1.7–2 (Fig. 2a). The effect of the type of buffer was examined. Phthalate and monochloroacetate buffers gave a fluorescence intensity for the ternary complex that was about half that obtained with hydrochloric acid (although there was no effect on the fluorescence intensity of the binary complex). Therefore, hydrochloric acid medium is preferred.

Increasing the zirconium concentration raised the fluorescence intensity of the ternary complex (Fig. 2b), the effect being maximal over the range 0.17–0.22 μg/ml. A level of 0.2 μg/ml was chosen.

As BMNH is insoluble in water, various solvents were tested. Ethanolic media gave the highest fluorescence intensity, which was independent of the ethanol content over a wide range. The fluorescence intensity was found to increase linearly with BMNH concentration in the range $1–5 \times 10^{-5}M$ and then remain constant from $5 \times 10^{-5}M$ up to at least $2.2 \times 10^{-4}M$ (Fig. 2c).

Variation in the ionic strength or in the order of mixing of the solutions had no influence on the fluorescence.

A temperature coefficient of about $-1\%/°C$ was found over the range of 15–35°, so the temperature should be controlled to within 1–2°. Under the recommended conditions, the system is stable for at least 2 hr.

*Plus aluminium nitrate (Al^{3+}/F^- molar ratio = 1).
†Plus tartrate (tartrate/PO_4^{3-} molar ratio = 2).

Characteristics of the method

The calibration graph was linear over the sulphate concentration range 0.5–6 μg/ml. The relative standard deviation for 3 μg/ml ($P = 0.05$, $n = 11$) was ±2%.

Interferences

The influence of various ions likely to interfere by forming complexes or precipitates with zirconium, BMNH or sulphate was examined. The results are summarized in Table 1. The most serious cationic interference found was that of iron(III), caused by strong absorption of both the excitation and the emission radiation by the Fe(III)–BMNH complex. Reduction to iron(II) permitted the direct determination of sulphate in the presence of a 5-fold molar ratio of iron. Oxalate interferes at the same level as sulphate, probably owing to the formation of a fluorescent ternary complex with zirconium and BMNH. The positive interference caused by sulphite can be attributed to its oxidation to sulphate in dilute solutions. It is not regarded as a reaction of the sulphite ion itself, since addition of sulphite to a deoxygenated sulphate-free medium did not cause any effect.

It is important to emphasize the effect of fluoride and phosphate, since they are serious interferences in all fluorimetric methods proposed for the determination of sulphate. Fluoride does not interfere at 50-fold molar ratio to sulphate. Higher ratios yield low recoveries but Al(III) can be used as a masking agent. Phosphate causes very serious negative error

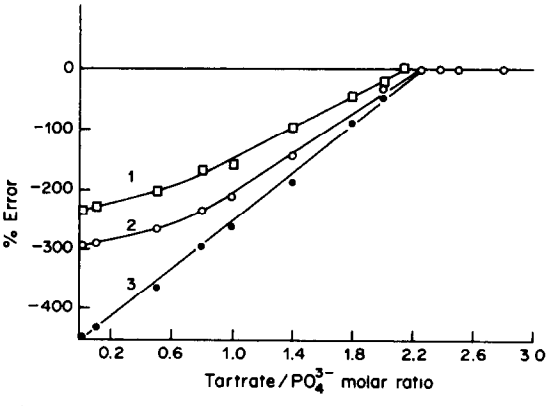

Fig. 3. Effect of the tartrate ion on the phosphate interference in the determination of sulphate. All the samples have $10^{-3}M$ phosphate, and the PO_4^{3-}/SO_4^{2-} molar ratios are: curve 1:20, curve 2:33, curve 3:100.

*Mean of six determinations.

by reducing the zirconium concentration. Common methods for the elimination of this error are precipitation of this ion with magnesium or lanthanum, its retention on a weak-base anion-exchange resin *etc.*, but these procedures are time-consuming. In our method, tartrate is used to eliminate the phosphate interference. The use of tartrate as masking agent for phosphate is mentioned in Table 3.3 of Perrin's monograph.[11] Initially a zirconium–phosphate complex is formed, but the tartrate ions destroy this complex. The fluorescence intensity is measured when it has reached a maximum. Figure 3 shows the error obtained for different PO_4^{3-}/SO_4^{2-} molar ratios, as the tartrate/PO_4^{3-} molar ratio changes. From this graph it can be inferred that: (*a*) the interference increases with PO_4^{3-}/SO_4^{2-} molar ratio for a fixed tartrate/PO_4^{3-} molar ratio; (*b*) as the tartrate/PO_4^{3-} ratio increases, the error is reduced, reaching zero when this ratio is about 2. In this way, sulphate can be determined in the presence of a 100-fold molar ratio of phosphate.

Applications

To test the applicability of the procedure to the determination of sulphate in water samples, various amounts of sulphate were added to each sample. The results obtained are shown in Table 2. The recoveries were calculated by comparing the results obtained before and after the addition of standard sulphate solutions. The data obtained show the precision of the method over a wide range.

Chemistry Department, Université de Moncton, Moncton, Canada

(*Received* 2 *November* 1984. *Accepted* 8 *November* 1984)

Summary—Trace amounts of bismuth have been determined by atomic-absorption spectrophotometry after adsorption of the 2-mercaptobenzothiazole complex on naphthalene. The method has been applied to the determination of bismuth in aluminium alloys.

2-Mercaptobenzothiazole forms water-insoluble complexes with various metals. The bismuth complex is not extractable into the usual organic solvents such as chloroform, benzene, nitrobenzene and methyl isobutyl ketone. Several metals have been separated by adsorption of their complexes on microcrystalline naphthalene,[1–5] and this technique can be applied to the 2-mercaptobenzothiazole of bismuth.

EXPERIMENTAL

Reagents

Standard bismuth solution, 20 ppm.
2-Mercaptobenzothiazole solution in ethanol, 2%.
Acetic acid/ammonium acetate buffer, 1*M*, pH 4.5.
Naphthalene solution in acetone, 20%.

Procedure

Pipette a volume of sample containing 20–200 μg of bismuth into an 80-ml stoppered Erlenmeyer flask and dilute with water to about 35 ml. Add 4.0 ml of 2% 2-mercaptobenzothiazole solution and 2.0 ml of buffer. Mix and let stand for a few minutes. Add 2.0 ml of 20% naphthalene solution and shake the mixture vigorously for 30 sec. Filter through a paper (*e.g.*, No. 5C, Toyo Roshi Co., Japan) placed flat on a perforated Teflon disc (3 cm in diameter) in an ordinary filter funnel, or a sintered glass filter (porosity 2). Wash with water, then add dimethylformamide to the filter to dissolve the naphthalene and bismuth complex, and collect the solution in a 10-ml standard flask. Aspirate the solution into an air–acetylene flame and measure the absorbance at 223.1 nm, using a bismuth hollow-cathode lamp as light-source.

RESULTS AND DISCUSSION

The optimum pH range for the adsorption step is 2.2–6.4 (Fig. 1). Adsorption of the bismuth complex is quantitative when 1.0–6.0 ml of 2-mercaptobenzothiazole solution and 1–5 ml of buffer are used. Formation of the complex is complete in a few minutes. For complete adsorption of the complex 0.5–4.0 ml of the naphthalene solution is enough. The adsorption is very fast. Varying the aqueous phase volume from 30 to 100 ml has no effect on the bismuth absorbance measured but the absorbance decreases with larger volumes of aqueous phase. Beer's law is obeyed for bismuth concentrations up to 20 μg/ml in the final dimethylformamide solution. For ten replicate determinations of 100 μg of bismuth, the relative standard deviation found was 1.1%. The concentration giving 1% absorption was 0.34 μg/ml. The mixture of complex and naphthalene is soluble in dioxan, dimethylformamide, propylene carbonate and dimethyl sulphoxide, but dimethyl-

formamide is the most suitable for the atomic-absorption measurements.

Effect of diverse ions

The procedure was applied to solutions containing 100 μg of bismuth and various amounts of other ions, adjusted to pH 1.5–1.8 to prevent precipitation of bismuth hydroxide. The results are shown in Table 1. EDTA interferes seriously. Bismuth can be determined in aluminium alloys without prior removal of other metal ions. Table 2 gives results obtained for analysis of some standards; they are in reasonable agreement with the certified values of those obtained by direct AAS determination.

SOME SPECTROPHOTOMETRIC METHODS FOR DETERMINATION OF CERTAIN ANTIPYRETIC AND ANTIRHEUMATIC DRUGS

A. S. ISSA, Y. A. BELTAGY, M. GABR KASSEM and H. G. DAABEES
Pharmaceutical Chemistry Department, Faculty of Pharmacy, Alexandria University, Alexandria, Egypt

(*Received* 10 *February* 1984. *Revised* 10 *July* 1984. *Accepted* 5 *November* 1984)

Summary—Heating paracetamol in strongly alkaline medium with 4-nitrosoantipyrine gives a red colour with maximum absorption at 515 nm. Mefenamic and flufenamic acids can be determined colorimetrically after extraction as ion-pairs with Methylene Blue.

Paracetamol can be determined spectrophotometrically by reaction with sodium nitrite[1,2] or sodium cobaltinitrite,[3] or can be hydrolysed to *p*-aminophenol which is then either condensed with aldehydes[4–9] or diazotized and coupled with phenols.[10,11] Titration with sodium nitrite[12–14] or ceric sulphate[15–17] has also been reported. Fluorimetric and HPLC techniques are also used.[18–22] 4-Nitrosoantipyrine gives coloured products with α-naphthylamine, naphthalene-1,5-di-isocyanate and 8-amino-1-naphtholdisulphonic acid.[23] Mefenamic and flufenamic acids are determined alkalimetrically,[24,25] fluorimetrically[26] or by atomic-absorption,[27] and also with Fast Red Salt B.[28] Methylene Blue was first used by Jones[29] for determination of surfactants and has been used for the determination of probencid, saccharin, penicillins, some organic acids and sodium lauryl sulphate.[30–33]

Here we describe the use of 4-nitrosoantipyrine and Methylene Blue for the determination of some antipyretic and antirheumatic drugs.

EXPERIMENTAL

Reagents

4-Nitrosoantipyrine reagent.[23] Dissolve 1 g of antipyrine in 20 ml of acetic acid (1 + 1), add 0.6 g of sodium nitrite and let stand for 10 min. Then add 0.75 g of sulphamic acid and dilute to 150 ml with acetic acid (1 + 1).

Sodium hydroxide solution, 40%.

Methylene Blue solution, 0.5%.

Buffer, pH 6.8.[34] Mix 50.8 ml of 0.0667*M* potassium dihydrogen phosphate with 49.2 ml of 0.0667*M* disodium hydrogen phosphate.

Procedure for paracetamol

Dissolve 10–50 mg of paracetamol (accurately weighed) in 25 ml of 0.1*M* sodium hydroxide and dilute accurately to 1000 ml with water. Transfer 5 ml of this solution to a 25-ml standard flask, add 3 ml of 40% sodium hydroxide solution and 0.3 ml of 4-nitrosoantipyrine reagent, heat in a boiling water-bath for 15 min, cool, dilute to volume with ethanol, then allow to stand for 100 min. Measure the absorbance at 515 nm against a reagent blank treated in the same way.

Procedure for tablets. Weigh and powder 20 tablets. Weigh out a quantity of powder equivalent to 30–40 mg of the drug, into a 100-ml standard flask, and shake it for 15 min with 25 ml of 0.1*M* sodium hydroxide, then dilute to volume with water and filter. Dilute 10 ml of the filtrate to 100 ml with water, then analyse 5 ml of this solution as described above.

Procedure for liquid preparations. Dilute a known volume of syrup or drops with water to a volume large enough to give a final paracetamol concentration of 0.03–0.04 mg/ml. Transfer 5 ml of this solution to a 25-ml standard flask and analyse as above.

Procedure for mefenamic and flufenamic acids

Dissolve 1–3 mg of the drug in 5 ml of chloroform, and dilute accurately to 100 ml with methylene chloride. Transfer a known volume containing 0.05–0.15 mg of the drug to a 100-ml separatory funnel, add 20 ml of buffer (pH 6.8) and 1 ml of Methylene Blue solution, and extract with three 10-ml portions of methylene chloride, shaking for 5 min each time. Dry the combined extracts with anhydrous sodium sulphate and transfer to a 50-ml standard flask. Wash the sodium sulphate with 10 ml of methylene chloride, transferring the washings to the flask, and dilute to volume with the same solvent. Measure the absorbance at 658 nm against a blank prepared by the procedure.

Procedure for capsules. Empty 20 capsules, mix the contents and weigh. Transfer a weighed quantity equivalent to about 20 mg of mefenamic or flufenamic acid to a 50-ml standard flask, add 30 ml of chloroform, shake the flask for 15 min, then dilute to volume with chloroform. Transfer 5 ml of the clear solution to a 100-ml standard flask and dilute to volume with methylene chloride. Transfer 5 ml of the solution to a 100-ml separatory funnel and analyse as described above.

RESULTS AND DISCUSSION

The 4-nitrosoantipyrine procedure involves the use of a high alkali concentration to hydrolyse the drug to *p*-aminophenol, which is then condensed with 4-nitrosoantipyrine to give a red colour. Heating the reaction mixture and the addition of an alcohol are essential for colour formation. Methanol gives an unstable colour and isopropyl or n-butyl alcohol gives only a faint colour and is immiscible with the alkaline solution. Ethanol gives a stable colour and is completely miscible. Absolute ethanol gives the best colour development and stability. The common tablet fillers such as lactose, talc, starch and magnesium stearate do not interfere, nor do the other drugs present in paracetamol compound tablets (salicylamide, caffeine, aspirin, codeine phosphate and

Table 1. Results of determination of paracetamol by the 4-nitrosoantipyrine and B.P. 1980 methods

Drug form	4-Nitrosoanti-pyrine	B.P. 1980

Pyral syrup[K] (120 mg/5 ml)	100.5 ± 1.0	—	—

*Mean and standard deviation (6 results) calculated with respect to nominal content in sample.

M = Misr company; C = Cid company; A = Alexandria company; K = Kahira company.

Asco contains 200 mg of paracetamol, 250 mg of salicylamide, 60 mg of caffeine, 7 mg of codeine phosphate and 15 mg of phenyltoloxamine dihydrogen citrate per tablet.

Vegaskin contains 200 mg of paracetamol, 300 mg of aspirin and 10 mg of codeine phosphate per tablet.

phenyltoloxamine dihydrogen citrate). Beer's law is valid over the concentration range 0.2–1.0 mg/100 ml. Results are shown in Table 1. The applicability of the method to some commercial preparations was compared with the B.P. 1980 method (Table 1). Efficient extraction of Methylene Blue ion-pairs into methylene chloride was achieved with Sørensen's pH-6.8 phosphate buffer. The use of methylene chloride gives higher sensitivity and better stability than use of chloroform does. The reacting ratio was found to be 1:1 by the mole-ratio method, indicating that the carboxylic group of the drug and not the imino group is involved in the reaction. Beer's law is valid over a concentration range of 0.12–0.28/100 ml; results are shown in Table 2. The method is applicable to some preparations (Table 2).

AN INEXPENSIVE AND ROBUST CONDUCTANCE ELECTRODE

J. P. LORIMER, K. JAGIT and TIMOTHY J. MASON
Department of Applied Chemistry, Coventry (Lanchester) Polytechnic, Priory Street, Coventry, England

(*Received* 18 *June* 1984. *Revised* 5 *October* 1984. *Accepted* 29 *October* 1984)

Summary—A conductance electrode consisting of carbon "pultrusion" rod embedded in PTFE has been shown to have similar characteristics to those of the traditional platinum-on-glass type. The new electrode has the advantages of being both robust and inexpensive and could prove particularly useful in Karl Fischer analyses of biological material where maceration of the sample is required.

In our recent conductometric studies[1] into the effect of ultrasonic irradiation on chemical reactivity, the traditional platinum-on-glass electrodes were found to suffer occasional irreversible mechanical breakdown (*i.e.*, foil chipping) owing to the hostile ultrasound environment. This difficulty was overcome by using an electrode system in which disks of carbon fibre composite (5 mm diameter "pultrusion" rod[2]) were embedded in Perspex.[3] The design proved a suitable replacement for the traditional electrode in a number of routine conductance measurements[4] with the exception of water determination by the Karl Fischer method. In this instance, although the electrode responded adequately, its repeated use led to physical breakdown due to attack by the Karl Fischer reagent on the adhesive used in fabrication.

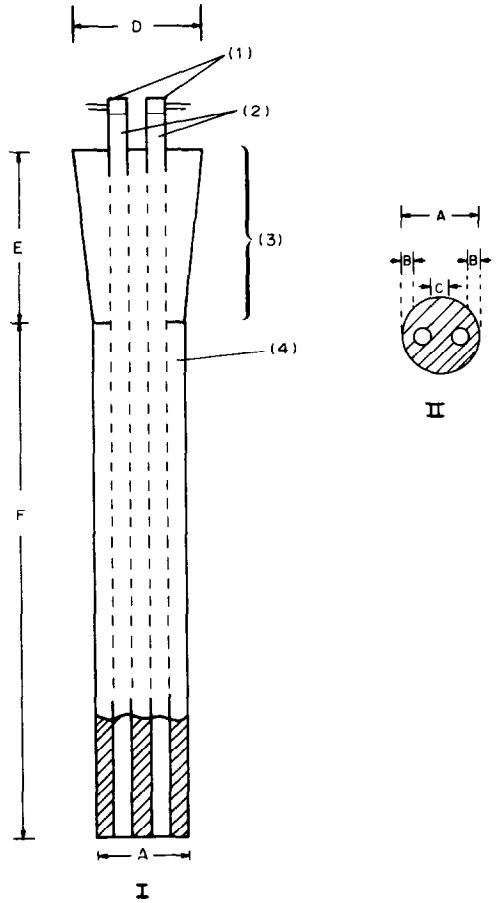

Fig. 1. Electrode assembly. I, longitudinal section; II, lower end view. (1) Electrical connections, (2) carbon "pultrusion" rod (3 mm section), (3) standard taper (1 in 10), (4) Teflon body. Dimensions (mm): A, 12; B, 1.5; C, 3; D, 14; E, 20; F, 75 (not critical).

We report here a new and simpler design (Fig. 1) which has proved to have both improved solvent resistance and better performance than the previous model.[5] In addition it has been found that neither the response nor the reproducibility of the system was affected by the application of ultrasound either during, or prior to, the Karl Fischer determination. This suggests a potential application to Karl Fischer analyses of biological material where the hostile environment of high-speed maceration or ultrasonic disruption may cause damage to traditional electrode systems.

The general performance of the electrode in a number of conductometric experiments has also been assessed and compared with that of platinum. Since the techniques used are all well known, experimental details have been kept to a minimum.

EXPERIMENTAL

Reagents

The following reagents were used as received: sodium lauryl sulphate and magnesium sulphate from BDH, barium chloride (analytical grade) from Fisons. Solutions of these salts (approximately 0.1*M*, 0.01*M* and 0.02*M* respectively) were prepared with demineralized water.

Stock solutions (0.5*M*) of all acids and bases were prepared by dilution of the appropriate concentrated solutions (BDH ampoules). Further dilution provided approximately 0.1*M* solutions for analysis.

Karl Fischer reagent (1 ml ≡ 5 mg of water) and standard methanol (1 ml ≡ 5 mg of water) were used as supplied by BDH.

Cells and measuring devices

The new assembly (Fig. 1) consists of two lengths of 3 mm diameter "pultrusion" rod (supplied by Carbon Fibres

Division, Courtaulds Ltd), push-fitted through a drilled PTFE plug machined from a 14 mm diameter rod.

The dimensions were such as to give a cell constant of approximately 2.5. A conventional (dip-type) platinum-on-glass conductance cell, of cell constant 1.0, was used for comparison.

A Portland conductance meter (P335) was used to monitor the conductance changes in the acid–base and precipitation titrations, and in the determination of critical micelle concentration (CMC). A Corning 109 mV/pH-meter was employed for the Karl Fischer determination.

General procedures

Conductometric titrations. In all cases 20 ml of the reagent under investigation, together with 50 ml of demineralized water to minimize dilution effects, were added to the titration vessel. Titrant was delivered in 0.2-ml aliquots from a 10-ml microburette. The solutions were stirred magnetically.

CMC. Sodium lauryl sulphate (0.1*M*) was added in 0.5-ml aliquots from a 25-ml burette to continually stirred demineralized water (100 ml) at 25 ± 0.1°.

Karl Fischer. The dead-stop method was employed. The stability of the assembly was assessed by subjecting the system to ultrasonic irradiation (4 min) prior to a determination, and also by continuous irradiation during the course of a determination. A Heat Systems Inc. W-225R Sonicator, operating at 60% power and 20 kHz, with a $\frac{1}{4}$-in. probe, was used as the ultrasonic source.

Speed of response and reproducibility of the electrode systems. Two methods were employed for comparing the response times of the systems to rapid changes in conductance. In the first, the electrodes, after drying, were rapidly dipped into an aqueous solution of hydrochloric acid. The conductance change was monitored on a chart recorder (Rikadenki, DBEI) and the response time taken to be the difference between the time of electrode insertion and the attainment of a constant conductance value. In the second, each electrode, after being washed and dried, was inserted into 50 ml of demineralized water, then 1 ml of 0.1*M* hydrochloric acid was rapidly injected with a syringe and the response recorded as previously.

Table 1. Comparison of platinum (Pt) and carbon rod (C) electrodes in conductometric titrations

System*	End-point, *ml*		Rel. std. devn., %	
	Pt	C	Pt	C
HCl/NaOH	4.54	4.48	0.8	0.5

†With ultrasound.

RESULTS AND DISCUSSION

Titrations

The results in Tables 1 and 2 are the means of 6 determinations and demonstrate that the carbon rod assembly is a good inexpensive replacement for the traditional platinum model. The reproducibility of the results, even in the presence of ultrasonic irradiation, suggests that leakage around the joints (even after repeated usage) is not significant under the reaction conditions used.

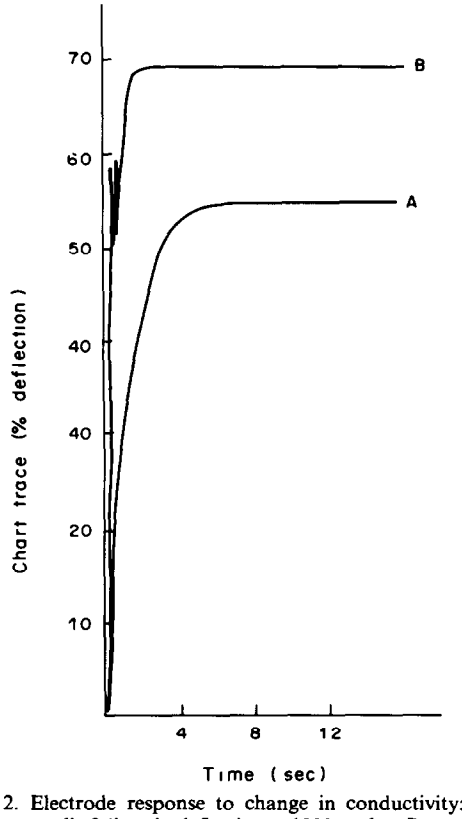

Fig. 2. Electrode response to change in conductivity: A, platinum cell, full-scale deflection = 1000 μmho; B, carbon rod cell, full-scale deflection = 300 μmho.

Table 3. Response and reproducibility of the electrode systems (8 replicates)

Method	Response time, *sec*		Rel. std. devn., %		Constant conductance value, *μmho*		Rel. std. devn., %	
	Pt	C	Pt	C	Pt	C	Pt	C
Electrode immersion	0.5	0.7	31	40	530	200	0.1	0.6
Solution addition	8.0	3.6	7	3	548	210	0.5	1.0

Response and reproducibility

Table 3 demonstrates that the speeds of response of both systems to changes in conductance are similar. The slightly longer response time of the traditional model to addition of a conducting solution is due mainly to its design, which is not conducive to efficient mixing. Typical response curves are given in Fig. 2.

Surface adsorption

At the reagent concentrations examined, no evidence was seen for the adsorption of species from solution. Both electrode systems gave constant conductance values ($\pm 0.5\%$) over periods of 2 hr.

INDIRECT DETERMINATION OF TRACE PHENOL IN WATER BY ATOMIC-ABSORPTION SPECTROPHOTOMETRY

XU BO-XING, XU TONG-MING, SHEN MING-NENG and FANG YU-ZHI
Department of Chemistry, East China Normal University, 3663 Chung Shan Road (N.), Shanghai, People's Republic of China

(*Received* 30 *March* 1984. *Revised* 11 *August* 1984. *Accepted* 24 *October* 1984)

Summary—An indirect method for determination of trace phenol in water by atomic-absorption spectrophotometry (AAS) is described. The phenol is brominated in acidic solution with $KBrO_3$–KBr solution at room temperature. The excess of bromine is reacted with KI and the I_2 produced is extracted into cyclohexane and then reduced back to I^- with ascorbic acid. The I^- is then complexed with Cd^{2+} in sulphuric acid medium and the complex extracted into MIBK. The extract is analysed by flame AAS for Cd (and hence indirectly for phenol). The linear concentration range for determination of phenol is 6×10^{-7}–$0.9 \times 10^{-5}M$ in aqueous solution. Several foreign ions and organic substances do not interfere.

The determination of trace phenol is difficult but important in monitoring water quality. The methods usually used include bromination,[1] colorimetry[2] and gas chromatography.[3] The recommended method is colorimetry, but it is time-consuming because of the distillation step needed to remove interferences. Bromination is the traditional titrimetric method, but it cannot be used for phenol concentration < 10 mg/l. We have made an attempt to determine trace phenol in water samples by AAS, as part of a programme of indirect determination of organic compounds by AAS.

Indirect determinations of phenol by AAS have already been reported. Yamamoto *et al.*[4] determined pentachlorophenol by AAS determination of iron after extraction of the iron(III)–pentachlorophenol ion-pair complex into nitrobenzene. Mitsui and Fujimura[5] reacted nitrosated phenol with sodium cobaltinitrite to form nitrosophenol which further reacts with cobalt (III) to form a cobalt–phenol complex, which can be extracted into methyl isobutyl ketone (MIBK) and determined by AAS.

The present method is based on the bromination of phenol to form tribromophenol. The excess of bromine is then reacted with iodide, and the iodine formed is extracted into cyclohexane and reduced back to iodide, which is then reacted with cadmium in sulphuric acid solution to form H_2CdI_4, which in turn is extracted into MIBK. This extract is aspirated into an air–acetylene flame to be analysed for Cd.

Bromine can react with several other classes of organic compounds, such as unsaturated organic acids, aniline, *etc.* Therefore, it is first necessary to remove these interferences by solvent extraction of the phenol with 1:1 v/v chloroform/ether mixture at pH 8–9, which can be done with nearly 100% efficiency.[6] At this pH the organic acids are not extracted. The extracted phenol is then stripped with $0.1M$ potassium hydroxide, and the aniline remains behind in the organic solvent. In this way the phenol can not only be preconcentrated but also freed from interferences. This paper shows that the method is highly sensitive and can be used to analyse for relatively low concentrations of trace phenol in water.

EXPERIMENTAL

Reagents

Use demineralized water and analytical grade reagents throughout.

Phenol stock solution (*1 g/l.*). Dissolve 0.1 g of freshly distilled phenol in 100 ml of water, and standardize the solution by iodometry. Prepare a working solution ($1 \times 10^{-5}M$), just before use, by diluting 1 ml of the phenol stock solution to 100 ml and then diluting 10 ml of this solution to 100 ml with water.

Bromate–bromide solution (5×10^{-4}M Br_2). Dissolve 2.78 g of dried potassium bromate and 10 g of potassium bromide in 1000 ml of water, then before use, dilute 1 ml of this solution to 100 ml with water.

Potassium iodide solution (1.0×10^{-3}M). Dissolve 1.66 g of potassium iodide in 100 ml of water and dilute 1 ml of this solution to 100 ml with water.

Cadmium working solution (1.37×10^{-3}M). Dissolve 38.5 mg of $CdSO_4 \cdot 4H_2O$ in 100 ml of water.

Ascorbic acid solution, *0.01*M.

Mixed solvent. Mix equal volumes of chloroform and diethyl ether.

Procedure

In a 60-ml separatory funnel place 10 ml (or more) of the water sample (depending on the phenol concentration), adjust the pH to 8–9 with $0.1M$ potassium hydroxide, and add 2 ml of mixed solvent (the amount of solvent should be increased in proportion to the volume of the sample. Shake the funnel for 2 min. Transfer the organic phase to a 25-ml separatory funnel, add 2 ml of $0.1M$ potassium hydroxide, shake the funnel for 1 min, separate the organic phase and add the following solutions to the aqueous phase in the order given: 0.3 ml of bromate–bromide solution, 0.5 ml of cyclohexane and 2 ml of $2M$ hydrochloric acid, mix well and leave to stand for 20 min, then add 0.5 ml of $10^{-3}M$

Table 1. Effect of foreign ions on determination of 1.13 μg of phenol in 10 ml of water

†After addition of 1000 μg of EDTA.

postassium iodide and shake the funnel for 1 min. Separate the aqueous phase and add to the cyclohexane layer 0.1 ml of 0.01*M* ascorbic acid and 0.2 ml of $1.37 \times 10^{-3}M$ cadmium solution, shake, then add 1 ml of 10*M* sulphuric acid and 1 ml of MIBK. Shake the funnel for 1 min, then run off the aqueous phase. Aspirate the mixed cyclohexane/MIBK phase directly into the air–acetylene flame for determination of cadmium under the following conditions:

Wavelength	228.8 nm
Cd lamp current	10 mA
Band-width	1.3 nm
Air flow	9.4 l./min
Acetylene flow	2.3 l./min

RESULTS AND DISCUSSION

Bromination

The initial reaction between bromine and phenol is rapid in acid solution, but the trisubstitution is slower and so a waiting period is needed to avoid negative errors; on the other hand, if this period is too long, side-reactions can take place and cause positive errors. From the data presented in Fig. 1 it can be seen that 10–20 min is a suitable period.

The hydrochloric acid concentration is fairly critical—it affects both the generation of bromine and the rate of bromination of phenol. The results shown in Fig. 2 indicate that the optimum acid concentration is 1*M*.

Extraction

Cadmium reacts with iodide in acid solution to form the iodide complex, which can be extracted into certain organic solvents, such as the MIBK/cyclohexane mixture used here, with high efficiency. The data plotted in Fig. 3 suggest that the 1:4 complex is extracted, presumably as H_2CdI_4; Fig. 4 shows that the sulphuric acid concentration must be at least 7*M* for extraction to be complete.

Interferences

The effect of various ionic species on the complete procedure was investigated. The results are summarized in Table 1. Some metal ions can cause problems by hydrolysing and precipitating when the pH is raised to 8–9 for the clean-up extraction of the phenol, and some phenol may then be lost by adsorption on the surface of the precipitate. The effect may be minimized by adding EDTA to keep the metal ions in solution.

Calibration and performance

The calibration graph is linear up to 2.3 μg of phenol in the original sample, and with a 100-ml

sample, the limit of detection is 1.2 μg/l. For 7 determinations of 1.13 μg of phenol the relative standard deviation was 3.3% and the recovery 98–112%. The result for the determination of phenol in three water samples are shown in Table 2. They indicate that method is sensitive and useful for low levels of phenol, though of course other phenolic compounds would interfere and to different extents, depending on the nature of their bromination reactions. Some apparent efficiencies of bromination of various phenols (at the $10^{-5}M$ level) under the conditions given in the procedure are listed in Table 3, and indicate which substituted phenols would interfere.

CATALYTIC TITRATION OF IODIDE, BROMIDE AND THIOCYANATE BY USE OF THE SILVER CATALYSED PHLOXIN–PERSULPHATE REACTION

C. SANCHEZ-PEDREÑO,* M. HERNANDEZ CORDOBA and P. VIÑAS
Department of Analytical Chemistry, University of Murcia, Murcia, Spain

(*Received* 12 *March* 1984. *Revised* 19 *September* 1984. *Accepted* 5 *October* 1984)

Summary—A method for the catalytic titrimetric determination of iodide, bromide and thiocyanate is described, based on the inhibitory effect of these anions on the silver-catalysed oxidation of phloxin by persulphate in the presence of 2,2′-bipyridyl. The end-point is determined photometrically by measuring the absorbance at 537 nm. Amounts of iodide, bromide and thiocyanate in the 0.01–7.94, 0.11–4.73 and 0.12–3.59 mg ranges, respectively, are titrated with a relative error of about 1%.

The oxidation of phloxin by persulphate, catalysed by silver in the presence of 2,2′-bipyridyl as an activator, has recently been described.[1] Iodide, bromide and thiocyanate have an inhibitory effect on the catalytic reaction and the phloxin–persulphate system can be used for indication of the end-point in their titration with silver nitrate. When the inhibitor has been titrated, the first excess of the titrant will immediately accelerate the indicator reaction, and this effect can be used to locate the end-point.

Catalytic reactions were first applied for end-point determination in titrimetric analysis by Weisz *et al.*[2–5] and later studied in depth by Mottola.[6] Titrimetric procedures with visual,[7] spectrophotometric,[2,3,7–15] potentiometric,[4,9–11] biamperometric[7,10,16] and thermometric[5,7,9,17–21] catalytic indication of the end-point have been used for the determination of several inorganic and organic compounds.

Although some titrations of iodide with silver, based on use of different catalytic indicator systems, have been described,[2,22–25] we have found only two references to similar determination of bromide and thiocyanate.[2,7]

This paper describes a semi-automatic method for the determination of iodide, bromide and thiocyanate, based on their inhibitory effect on the silver-catalysed phloxin–persulphate reaction.

EXPERIMENTAL

Reagents

All inorganic chemicals used were of analytical reagent grade and the solutions were prepared with doubly distilled water.

Phloxin solution. An aqueous $5 \times 10^{-4}M$ solution was prepared from the commercial product (Geigy) without further purification.

Bromide, iodide and thiocyanate solutions, 0.02M. These were prepared from the potassium salts and standardized with standard silver nitrate solution. Dilute solutions were prepared just before the measurements.

Other reagent stock solutions were $1M$ acetate buffer (pH 5) and $0.003M$ 2,2′-bipyridyl. A $0.15M$ potassium persulphate solution was prepared daily.

Apparatus

A Metrohm 616 photometric titrator was coupled to an Omniscribe recorder and an ABU 12 Radiometer automatic constant-rate burette.

Procedure

Fill the automatic burette with standard silver nitrate solution of concentration appropriate to that of the titrand in the sample. Set the wavelength of the photometric titrator at 537 nm, the rate of titrant addition at about 0.3 ml/min and the chart-speed at 0.5 in./min. To the titration vessel, add the reactants in the following order: 1 ml of $5 \times 10^{-4}M$ phloxin, 10 ml of $1M$ acetate buffer (pH 5), 10 ml of $0.003M$ 2,2′-bipyridyl, the sample containing the inhibitor ion, and 10 ml of $0.15M$ potassium persulphate. Dilute to 50 ml with doubly distilled water. Stir the solution with the magnetic stirrer. Switch on the recorder and the autoburette simultaneously and record the absorbance–volume curve.

Obtain the end-point by extrapolation of the linear segments of the curve and calculate the titrand concentration by simple proportion from the results for the sample and a standard titrand solution.

RESULTS AND DISCUSSION

The reaction is followed by monitoring the decrease in absorbance at 537 nm. During the precipitation process, the photometric signal decreases slowly. When the equivalence point is reached, the first excess of silver catalyses the indicator reaction and a sharp decrease in absorbance is recorded. There is always a blank because a small excess of silver is needed to start the indicator reaction. There is also a contribution to the absorbance from the scattering of incident radiation by the precipitate produced. The

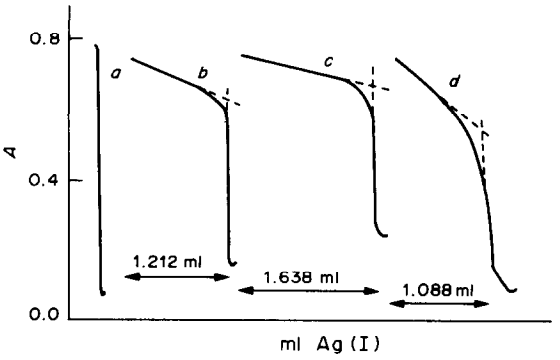

Fig. 1. Catalytic spectrophotometric titration of iodide, thiocyanate and bromide with 0.01*M* silver nitrate. Curve *a*, without inhibitory ion; *b*, 1.589 mg of I^-; *c*, 0.957 mg of SCN^-; *d*, 0.898 *mg of* Br^-.

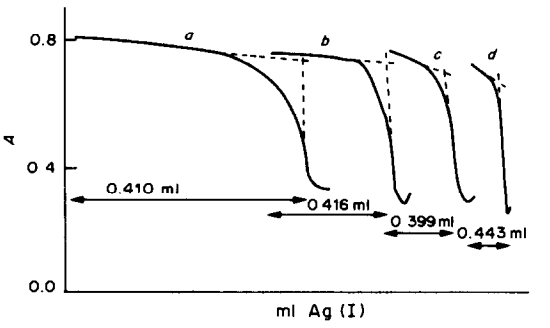

Fig. 2. Influence of the rate of addition of titrant for the determination of 2.641 mg of iodide with 0.05*M* silver nitrate. Chart-speed 1 in./min. Rate of addition, ml/min; *a*, 0.0712; *b* 0.1425; *c*, 0.285; *d* 0.570.

blank value and the sharpness of the end-point depend on the concentration of the reagents, and the concentration of the titrant and its rate of addition. When all these variables are kept constant, the blank is highly reproducible.

The effect of varying the reagent concentrations was studied, and the optimum values (indicated in the procedure) were found to be the same as those[1] for maximum rate of the catalysed reaction in the absence of inhibitor. The catalytic reaction starts before the equivalence point, but because of the dynamic nature of the titration system, does not become fast enough to give a large signal until the equivalence point is reached.

Titration curves obtained for iodide, thiocyanate and bromide are shown in Fig. 1.

The end-point indication is obviously sharper for iodide because the solubility of silver iodide is lower than that of silver thiocyanate or bromide, and the indicator reaction does not begin until nearer the end-point. Chloride cannot be titrated by this procedure because the indicator reaction is completed before the equivalence point is reached.

The influence of the rate of titrant addition on the determination of iodide is shown in Fig. 2. The addition rates ranged from 0.071 to 0.570 ml/min and the recorder was run at 1 in./min. To obtain optimal results, an addition rate of 0.285 ml/min was selected.

Since phloxin is a fluorescein derivative which has been used as an adsorption indicator,[26] several titrations were performed in the absence of persulphate to decide whether an adsorption mechanism is involved. The results indicate that the catalytic process is responsible for the sharp decrease in absorbance at 537 nm.

Results and performance characteristics for the catalytic titration of iodide, bromide and thiocyanate with silver nitrate are shown in Tables 1–3.

Table 1 shows that iodide can be titrated over a wide range of concentrations. The average error was 1%, with an average coefficient of variation of 0.7%. The best results were obtained with 10^{-3} and $10^{-2}M$

silver nitrate as titrant. The concentration of iodide in the reaction vessel must be kept below $10^{-3}M$. More concentrated solutions produce abundant precipitates and location of the end-point becomes difficult.

For the thiocyanate determination the average error was 0.9% and the coefficient of variation 1.1%. Similar results were found in the catalytic titration of bromide. The titrand concentration must be in the range 3×10^{-5}–$10^{-3}M$ for the titration of thiocyanate or bromide. More dilute solutions cannot be titrated because the catalysis then takes place at a considerable rate before the equivalence point is reached.

As always in the use of chart-recorded titration curves, errors can arise from extrapolation, line thickness, variation in chart-speed *etc.*, and this is reflected in the higher coefficients of variation for the lower levels of analyte.

KINETIC DETERMINATION OF TRACES OF CYSTEINE BY ITS INHIBITORY EFFECT ON THE SILVER-CATALYSED PHLOXIN–PERSULPHATE REACTION

M. HERNANDEZ CORDOBA, P. VIÑAS and C. SANCHEZ-PEDREÑO*
Department of Analytical Chemistry, University of Murcia, Murcia, Spain

(*Received* 13 *June* 1984. *Revised* 19 *September* 1984. *Accepted* 5 *October* 1984)

Summary—Cysteine has an inhibitory effect on the silver-catalysed phloxin–persulphate reaction at pH 5. When the cysteine/silver ratio is < 1, a decrease in the reaction rate is the only observed effect. However, when the ratio is > 1, an induction period appears. The length of the induction period is proportional to the cysteine concentration and allows the quantitative determination of cysteine and silver.

Many kinetic determinations of microquantities of inorganic ions have been reported, but few for organic compounds.[1] Recently, some kinetic methods for amino-acid determination based on inhibition of a given catalytic reaction have been proposed.[2–7]

We have reported earlier[8] the kinetic determination of silver by means of its catalytic action on the phloxin–persulphate system, with 2,2′-bipyridyl as activator. We have found that cysteine has an inhibitory effect on this reaction. A similar action of cysteine on a silver-catalysed reaction has already been reported by Alexiev and Angelova,[6] but in our work a different process is involved, since the nature of the inhibitory effect depends on the cysteine/silver ratio, resulting in either an induction period (with a length related to the cysteine/silver ratio) or reduction in the reaction rate. Based on this, a new method has been developed for the determination of cysteine in the presence of various amino-acids.

EXPERIMENTAL

Apparatus

A Pye Unicam SP8-100 double-beam spectrophotometer with 1-cm cells and constant-temperature cell-holder was used for recording absorbance–time curves.

Reagents

All chemicals used were analytical-reagent grade and the solutions were prepared with doubly distilled water. Aqueous $5 \times 10^{-4}M$ phloxin solution was prepared from the commercial product (Geigy), without further purification, by dissolving 0.2074 g in 500 ml of water. A $5 \times 10^{-3}M$ cysteine stock solution was prepared in $0.01M$ hydrochloric acid in order to stabilize it. The solution was prepared every week and stored in a dark bottle.

Other reagent stock solutions were: $1M$ acetate buffer, pH 5, $3 \times 10^{-3}M$ 2,2′-bipyridyl and $0.01M$ silver nitrate.

Working solutions of silver, cysteine and $0.15M$ potassium persulphate were prepared daily.

*Author to whom correspondence should be addressed.

Procedure

In a 25-ml standard flask place 1 ml of $5 \times 10^{-4}M$ phloxin, 5 ml of $1M$ acetate buffer, 5 ml of $3 \times 10^{-3}M$ 2,2′-bipyridyl and appropriate volumes of silver nitrate and cysteine solutions. Keep the flask in a thermostat at $25.0 \pm 0.1°$ for 30 min and then add 5 ml of $0.15M$ potassium persulphate solution and dilute to volume with water, but do not mix. Turn on the recorder, mix the solution by vigorous shaking, transfer it to the spectrophotometer cell (kept at $25.0 \pm 0.1°$) and record the absorbance–time curve. Evaluate the length of the induction period by extrapolation of the two segments of the reaction curve, and measurement of the elapsed time corresponding to the point of intersection. Prepare a calibration graph by the same procedure.

RESULTS AND DISCUSSION

The oxidation of phloxin by persulphate is catalysed by silver, in presence of 2,2′-bipyridyl as activator. The reaction can be followed spectrophotometrically by measuring the change in absorbance at 537 nm.[8]

When cysteine is present in this system, the catalytic effect of silver is decreased because the silver is bound by the thiol group of the cysteine, which thus acts as an inhibitor. The nature of the inhibitory effect depends on the cysteine/silver ratio in the sample.

Influence of the cysteine concentration

At cysteine/silver ratios < 1 the only effect is a decrease in the reaction rate. At cysteine/silver ratios > 1, however, an induction period appears (Fig. 1), which increases in length with increase in cysteine concentration.

Figure 2 shows the dependence of the induction period on the pH. A pH of 5 was selected for use because it maximizes the catalysed reaction rate and gives adequate length of the induction period for a given concentration of cysteine and silver.

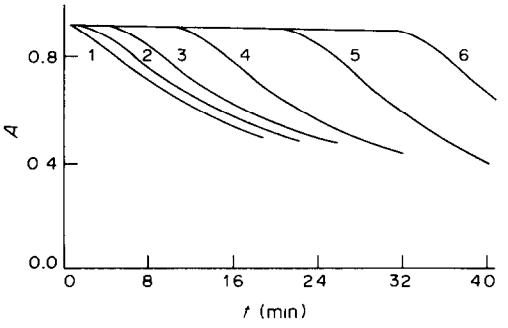

Fig. 1. Absorbance–time curves for [Cys]/[Ag] > 1: $2 \times 10^{-5}M$ phloxin, $0.2M$ acetate buffer (pH 5), $6 \times 10^{-4}M$ 2,2′-bipyridyl, $4.82 \times 10^{-7}M$ Ag^+, $0.03M$ potassium persulphate, 25°, λ 537 nm. [Cys]: (1) $0.6 \times 10^{-6}M$, (2) $1.0 \times 10^{-6}M$, (3) $1.4 \times 10^{-6}M$, (4) $2.0 \times 10^{-6}M$, (5) $3.0 \times 10^{-6}M$, (6) $4.0 \times 10^{-6}M$.

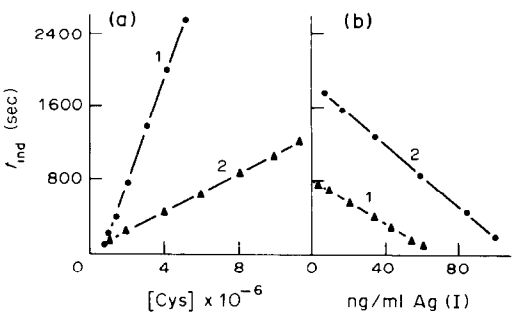

Fig. 3. Calibration graphs for cysteine and silver determination by the induction-period method. (*a*) Cysteine; (1) $4.82 \times 10^{-7}M$ Ag^+, (2) $9.64 \times 10^{-7}M$ Ag^+. (*b*) Silver; (1) $10^{-6}M$ cysteine, (2) $2 \times 10^{-6}M$ cysteine.

The other experimental variables were also chosen to give maximum rate of the catalysed reaction and hence sharper indication of the end of the induction period.[8] They were: $2 \times 10^{-5}M$ phloxin, $0.2M$ acetate buffer (pH 5), $6 \times 10^{-4}M$ 2,2′-bipyridyl, $0.03M$ potassium persulphate and temperature $25 \pm 0.1°$.

The following mechanism for the inhibitory effect is proposed. When the cysteine/silver ratio is below 1, some of the silver is bound by the thiol group of the amino-acid, so the concentration of the catalytically active Ag–bipyridyl complex is decreased, and consequently so is the rate of oxidation of phloxin.

The presence of excess of cysteine produces an induction period, however. Presumably all the silver is bound as the catalytically inactive Ag–cysteine complex and the persulphate acts on the excess of amino-acid. When all the free cysteine has been oxidized, the oxidant acts on the Ag–cysteine complex, releasing the metal ion, which can then combine with the activator so the induction period ends and the catalytic cycle starts.

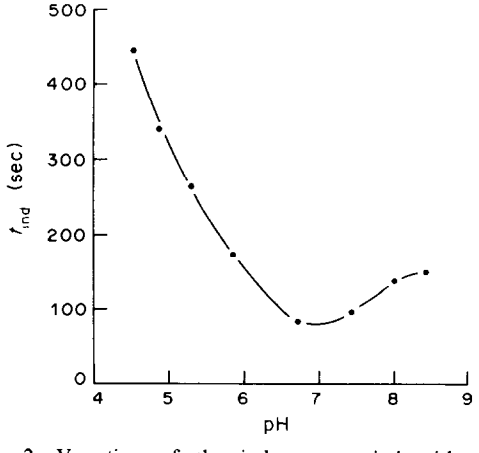

Fig. 2. Variation of the induction period with pH: $2 \times 10^{-5}M$ phloxin, $6 \times 10^{-4}M$ 2,2′-bipyridyl, $9.64 \times 10^{-7}M$ Ag^+, $2 \times 10^{-6}M$ cysteine, $0.03M$ potassium persulphate, 25°, λ 537 nm.

Thus, the cysteine can be determined by measurement of the induction period. Obviously, the measurable cysteine concentration range varies according to the silver concentration in the medium. Figure 3a shows two calibration graphs for the kinetic determination of cysteine by this procedure.

The relative error for ten measurements of $1.6 \times 10^{-6}M$ cysteine in the presence of $4.82 \times 10^{-7}M$ silver was $\pm 2.8\%$. A value of $t = 0.47$ was obtained in a Student's t-test, showing the absence of a systematic error in the method (the tabulated t-value for the 95% confidence level is 2.26).

If the cysteine concentration is kept constant, the length of the induction period decreases with increase in silver concentration, and calibration graphs for silver determination can be obtained (Fig. 3b).

Interference studies

The influence of the most important amino-acids on the determination of $1.5 \times 10^{-6}M$ cysteine was studied, and the results are summarized in Table 1. The tolerance limit was taken as the concentration which causes an error of not more than 5% in the cysteine determination.

The effect of adding greater amounts of interfering amino-acids is always to increase the length of the induction period.

Table 1. Interference of the most important amino-acids on the determination of $1.5 \times 10^{-6}M$ cysteine

Limiting molar ratio [Amino-acid]/[Cys]	Amino-acid
200*	Glycine, alanine, valine, leucine, isoleucine, threonine, serine, histidine, proline, lysine, asparagine, glutamine, aspartate, glutamate, arginine, phenylalanine
12	Methionine
4	Cystine
0.5	Tryptophan, tyrosine

*Maximum ratio tested.

SPECTROPHOTOMETRIC DETERMINATION OF FLUORIDE IN FLUORIDE-BEARING MINERALS AFTER DECOMPOSITION BY FUSION WITH SODIUM HYDROXIDE

J. V. GIMENO ADELANTADO, V. PERIS MARTINEZ, A. CHECA MORENO and F. BOSCH REIG

Department of Analytical Chemistry, Faculty of Chemistry, University of Valencia, Burjasot (Valencia), Spain

(*Received* 9 *May* 1984. *Revised* 24 *August* 1984. *Accepted* 5 *October* 1984)

Summary—The decomposition of highly insoluble minerals (fluorspar and cryolite) by fusion with molten alkali-metal hydroxides is studied. The introduction of additives such as aluminium compounds or sodium peroxide to obtain total liberation of fluoride from calcium fluoride samples, is tested. The fusion is done in a silver crucible with a Bunsen burner. The cooled melt is easily soluble, giving solutions suitable for spectrophotometric fluoride determination by the Zr(IV)–fluoride–Erichrome Cyanine R method.

The difficulty of decomposing highly insoluble fluoride compounds such as fluorspar or cryolite for fluoride determination is well-known. Most methods employ fusion with silica and alkali-metal carbonates to bind the fluoride. Adolph uses an equimolar ratio of silica to fluoride, and a 6-fold molar ratio of sodium–potassium carbonate mixture,[1] whereas Hawley says that a 4-fold ratio of the carbonate is enough.[2] Treadwell recommends mixing the sample with twice its weight of silica and six times its weight of sodium–potassium carbonate, and Shehyn a weight ratio of 0.2:4:0.7 for CaF_2, $NaKCO_3$ and SiO_2.[3] Shell and Craig[4] and Grimaldi *et al.*[5] advise addition of zinc oxide to the mixture. Even so, the residue from the fusion must still be distilled by using the Willard and Winter method[6] or one of its modifications.[7–9] Distillation without previous carbonate fusion has been used but is slow and needs complicated apparatus.[10–12] Other methods use pyrohydrolysis,[13] fusion with vanadium pentoxide[14] or treatment with aluminium chloride solution.[15]

In the opening-out of cryolite samples, sodium–potassium carbonate and silica in various ratios,[3,6] or potassium carbonate and silica,[17] are used for the fusion.

Although molten alkali-metal hydroxides are powerful decomposition agents, according to Bogen, they are little used because platinum crucibles cannot be employed, and gold, silver or nickel crucibles become damaged;[18] this is a pity, because they completely retain even highly volatile elements such as arsenic.[19] Fusion with these hydroxides has been used to decompose compounds containing fluoride such as fluorinated minerals,[20–22] silicate materials,[23–25] zinc concentrates[26] and even organic compounds.[27]

The effectiveness of molten alkali-metal hydroxides in the decomposition of fluoride compounds and its improvement by introduction of some chemicals which have an influence on the solvent action are studied in this paper. A silver crucible is used, as recommended earlier by us[18,28] because the melt is less contaminated.[29] Fluoride can then be determined spectrophotometrically by the Zr(IV)–F^-–Eriochrome Cyanine R method.[30,31]

EXPERIMENTAL

Reagents

Eriochrome Cyanine R solution, 0.18%.

Zirconium solution. Dissolve 0.2650 g of $ZrO_2Cl_2 \cdot 8H_2O$ in 700 ml of concentrated hydrochloric acid and dilute to 1 litre.

Fluoride solution. Dissolve 0.2210 g of sodium fluoride in distilled water and dilute to 1 litre. Store in a polyethylene bottle.

Procedures

Alkaline fusion. In a silver crucible fuse 1 g of sodium hydroxide pellets. Allow to cool, shaking the crucible so that the melt solidifies on the bottom and walls. Add 0.1 g of cryolite or fluorspar sample (for the latter also add 0.1 g of sodium peroxide or an aluminium salt or alumina). Heat gently with a moderate flame until the alkali is molten, swirling the crucible to assist dissolution. Then heat more strongly, increasing the intensity of the flame, and continue heating for 2 min. Cool to room temperature. Leach the melt with small portions of hot water, transferring them to a 250-ml polyethylene beaker, dilute to 100 ml and cool. Add 0.2 g of boric acid or 0.1 g of an aluminium salt if a fluorspar sample has been decomposed in the presence of sodium peroxide. Add 3*M* hydrochloric acid dropwise with vigorous stirring to expel the carbon dioxide released, until a clear solution is obtained. Transfer to a 250-ml standard flask and dilute to the mark.

Fluoride determination. Transfer a 2-ml aliquot of the solution to a 100-ml standard flask and dilute to volume. Pipette a 10-ml aliquot into a 50-ml standard flask (if aluminium is present add one drop of 0.1% phenolphthalein solution and then 0.1 M sodium hydroxide dropwise until the colour changes). Add 5 ml each of the Eriochrome

Cyanine R and zirconium solutions. Dilute to the mark, mix, wait for 15–20 min, and read the absorbance at 527–528 nm against a reference prepared with 10 ml of Eriochrome Cyanine R solution and 7 ml of concentrated hydrochloric acid, diluted to 100 ml.[32]

Prepare a calibration curve with aliquots of standard fluoride solution to cover the fluoride range 0.2–1.2 ppm in the solution measured.

RESULTS AND DISCUSSION

Determination of fluoride

The suitability of the changes in the spectrophotometric method has been checked for samples that contain interfering elements arising either in the sample or in its treatment.

Boron. Boric acid is added to avoid loss of fluoride from fluorspar samples when the solution of the alkaline melt is acidified. Because of the ready complexation of boron with fluoride, its influence on the Zr(IV)–F^-–Eriochrome Cyanine system was studied. Solutions containing 0, 10, 20, 30 and 40 ppm of boric acid and 1 ppm of fluoride were found to give the same absorbance (which was stable) provided that the measurements were taken after 5–10 min.

Aluminium salts. Aluminium will be present in cryolite analyses as a component of the sample, and in fluorite analyses because it is added to ensure complete decomposition and/or to avoid loss of fluoride by volatilization when the solution of the cooled melt is acidified.

Aluminium interferes in the spectrophotometric determination of fluoride by retarding the formation of the zirconium–fluoride complex, so the modification proposed by Megregian is used.[30] The tolerance level for aluminium was tested with 1 ppm of fluoride and 0, 10, 20, 30 and 40 ppm of aluminium. For up to 20 ppm of aluminium the results were satisfactory if the absorbance was measured after a development time of 15 min; for 30 ppm a stable reading may be obtained after 45 min, but the delay time increases with aluminium concentration and for 40 ppm even an hour is not long enough for complete reaction.

Sulphate does not produce appreciable interference[30] when potassium alum is used as the additive, because its concentration is low.

Decomposition of the sample

The molten alkali appears to dissolve the whole sample, giving a clear fluid which may contain greyish-white suspended matter, principally calcium oxide.[33] The suspension does not affect the subsequent analytical treatment.

The trials performed are shown schematically in Table 1. The use of potassium hydroxide, recommended by some authors,[26] proved not to be advisable, because it causes greater attack on the crucible but does not give better decomposition than sodium hydroxide does.

The low recoveries obtained with potassium nitrate as additive seem to indicate that sodium peroxide does not produce only an oxidative effect.

The aluminium compounds tested as auxiliary agents were the nitrate, chloride, potassium alum and the oxide.

In all cases the effect of fusion time and amount of sodium peroxide or aluminium added was studied. The optimum working conditions found are included in the procedure.

Fluoride determination

Fluorspar and fluorite. Table 2 shows the results for calcium fluoride recoveries for the samples studied.

The accuracy of the proposed method when applied to a BCS standard fluorspar (certificate value 97.2% CaF_2) was studied for both decomposition procedures (*i.e.*, with sodium peroxide or aluminium compounds as auxiliary agents). If the fusion is done with added sodium peroxide, then boric acid or aluminium salts are added after the fusion, to retain fluoride. The mean values were statistically the same as the certificate values (t-test), with no systematic error (95% probability level). The relative standard deviation was 0.2%. Analysis of the standard by the reference method gave a mean CaF_2 content of 96.9%, relative standard deviation 0.2% (10 replicates). All r.s.d. values were calculated[34] as $ts/\bar{x}\sqrt{n}$.

a_1, auxiliary reactant sodium peroxide, boric acid added; a_2, *idem*, aluminium compounds added.
b, auxiliary reactant aluminium compounds.
c, without auxilary reactant; c_1, *idem*, boric acid added; c_2, *idem*, aluminium salts added.
*Samples (1–5): sodium carbonate (1.75 g) + potassium carbonate (2.25 g) + silica (0.7 g)/0.2 g of sample; (6): sodium carbonate (2.2 g) + potassium carbonate (2.8 g) + silica (1.0 g)/0.5 g of sample.

A statistical study[34] showed that both decomposition methods were equally effective. The relative standard deviations for calcium fluoride recovery ranged between 0.2 and 0.6 (95% probability level). The mean values obtained by the proposed method and a reference method gave t-values indicating no significant difference in performance. This was confirmed by the Snedecor F-test, but the proposed method always gave better precision.

Cryolite. The cryolite sample was decomposed by fusion with molten sodium hydroxide, auxiliary agents not being necessary. Additives for retention of fluoride during acidification are not required, because there is already aluminium in the solution, from the cryolite itself. The recoveries obtained by the proposed method and a reference method[3] are shown in Table 2. The proposed method gave a relative standard deviation of 0.2% (95% probability level).

The mean values obtained by both procedures were statistically comparable (t-test and F-test), but the proposed method gave better precision).

DETERMINATION OF *N*-ACETYLMURAMOYL-L-ALANYL-D-ISOGLUTAMINE IN LIPOSOMES BY HPLC

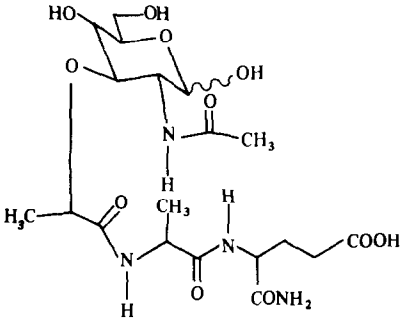
E. POSTAIRE*, M. HAMON*, E. SPONTON† and D. PRADEAU*

Laboratoires de contrôle de qualité* et de mise au point galéniquet, Pharmacie Centrale des Hôpitaux de Paris, 7, rue de Fer à Moulin, 75221 Paris Cedex 05, France

(*Received* 9 *August* 1984. *Accepted* 5 *October* 1984)

Summary—A method using reversed-phase high-pressure liquid chromatography (with spectrometric detection at 218 nm) is described for the determination in new pharmaceutical preparations (liposomes) of a new immunostimulating agent (*N*-acetylmuramoyl-L-alanyl-D-isoglutamine). Separation was achieved with a μ-bondapak column and phosphate buffer (pH 2.5)–methanol mixture (93:7 v/v) as eluent, at a flow-rate of 2 ml/min. Sodium acetate was used as an internal standard. The detector response at 218 nm was linear in the range 10–170 μg/ml. The method is simple and accurate.

N-Acetylmuramoyl-L-alanyl-D-isoglutamine (MDP) is a combination of a dipeptide and an *N*-acetylosamine. It is a new compound marketed as a lyophilisate (Institut Pasteur production). MDP is characterized by marked adjuvant activity, and thus can be a helpful substitute for Freund's complete adjuvant immunotherapy.[1-3]



MDP

Administered in aqueous solution, MDP increases non-specific immunity of mice after *Klebsiella pneumoniae* injection.[4-6] Even oral administration is effective. In this study MDP encapsulated in liposomes has been tested. Many antitumoral drugs are currently proposed in this pharmaceutical form.[8]

Using such a vehicle for MDP seems to be of interest for various reasons: plasmatic wash-out decreases, but drug activity increases,[9] and liposomes have shown a specific tropism toward the tumoral cells.[10,11]

Direct analytical techniques (spectroscopy, polarimetry) cannot be applied because of the nature of the liposome constituents (phospholipids, sterols, ions) and the structure of MDP. Therefore a liquid chromatography technique has been chosen to separate the MDP from the vehicle. Liquid chromatography is widely used in peptide determination,[12-14] and is simple, specific and sensitive. This technique can also be applied to the control of pharmaceutical preparations containing MDP.

EXPERIMENTAL

Apparatus

The chromatographic system was equipped with a pump (Chromatem-Model 330), a universal injector (Rheodyne 7125, 20 μl), a stainless-steel column (15 cm long, 4.6 mm bore) packed with μ-bondapack (5 μm) (Touzart et Matignon) and a variable wavelength detector (Schoffel GM 70).

Standards

Internal standard solution. A 1-mg/ml aqueous sodium acetate solution (solution A).

Standard preparation. Made by weighing 170 mg of MDP into a 10-ml standard flask and dissolving and diluting to volume.

Sample preparation

Solution B. Liposome "suspension" containing 40 μg of MDP per ml.

Solution C. Lyophilisate containing 2 mg of MDP and 10 mg of lactose. This lyophilisate was dissolved and diluted to volume in a 50-ml standard flask with eluent.

Solutions D and E. Solutions B and C were diluted tenfold to give D and E respectively.

Chromatographic conditions

The eluent was a 93:7 v/v mixture of pH-2.5 phosphate buffer (0.1*M* phosphoric acid/0.1*M* disodium phosphate) and methanol.

The detector was set at 218 nm, and a 20-μl portion of solution D or E was injected into the column and eluted at a flow-rate of 2 ml/min. The chromatographic peaks were recorded and integrated. Quantitative analysis was accomplished by use of a peak area calibration graph obtained by use of standard preparations (170, 85, 42.5 and 21.25 μg/ml).

RESULTS AND DISCUSSION

As shown in Fig. 1 the two anomeric forms of MDP (pyranose or furanose form of the α or β

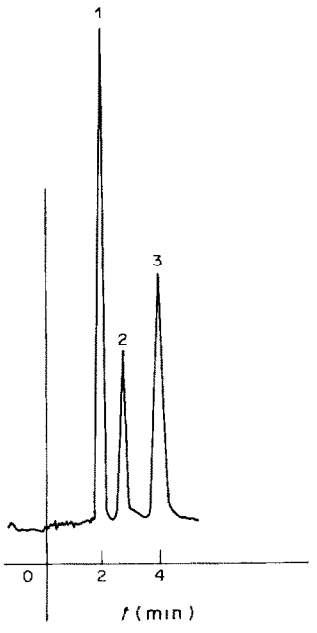


Fig. 1. HPLC analysis of MDP injection (42.5 μg/ml). 1, internal standard; 2, α-D anomer, 3, β-D anomer.

osamine) and sodium acetate as an internal standard were distinctly separated under the conditions used, having retention times of 4.11, 2.86 and 2.05 min, respectively. Blank samples tested by the same procedure showed no significant interfering peaks. It is of interest to separate these two anomeric forms; since the pharmacological activity of each form has yet not been studied.

The precision and accuracy of the method were demonstrated by replicate analyses of the lyophilisate and liposome suspension containing known concentrations of MDP. The overall relative standard deviations ranged from 2.1 to 4.0% (Table 1).

Table 1. Reproducibility of replicate standards at four concentrations

[MDP], μg/ml	RSD ($n = 10$), %
170	4.0
85	2.5
42.5	2.1
21.2	3.2

The limit of detection (10 μg/ml) could be improved by using a more concentrated internal standard solution. For example, with a 5-mg/ml sodium acetate solution, solutions B or C could be diluted only twofold with solution A.

During the development of the method, a number of variations were tested. Methanol and acetonitrile performed equally well as the mobile phase; methanol was chosen because it has lower absorptivity at 218 nm. The pH, buffer concentration and methanol concentration were chosen to give retention times < 6 min and good resolution. The absorption maximum of MDP is at wavelength shorter than 200 nm, but the absorbance at 218 nm is high enough to allow evaluation by liquid chromatography with ultraviolet detection. Sodium acetate was chosen as the internal standard, first because of its rapid elution under the conditions used and secondly because its absorbance is similar to that of MDP at 218 nm (Table 2).

Further investigations showed that the chromatographic system is not only suitable for the determination of the relative amounts of each component but also for determination of the lyophilisate stability. There are no reports in the literature which discuss the decomposition products of MDP. Knowledge of its liquid-chromatography behaviour might provide valuable insight into the decomposition of MDP.

Conclusion

Liquid chromatography allows the easy separation and determination of both anomeric forms of MDP, which would not be easily achieved by direct spectroscopic methods. It thus provides information complementary to that from direct spectroscopy. It appears to have considerable value as a rapid and sensitive method to be used as a routine procedure, and should help in the analysis of MDP pharmaceutical preparations.

(*Received* 1 *August* 1984. *Accepted* 5 *October* 1984)

Summary—An automated flow-injection system is described, with a computer-controlled sample changer, injection device and photometer. The modular software package is understandable, flexible and easily adaptable to different computers.

Flow-injection analysis is a widely used, reliable and versatile routine method for the determination of various chemical constituents, such as nitrate, phosphate, chloride, glucose.[1] An automated version is attractive for processing large numbers of samples, because it offers the possibility of on-line calibration and evaluation of unknown samples.[2] Our aim was to develop a system which is able to function for some hours without supervision.

The system described below uses a computer for the execution of some basic tasks, such as control of the sample changer, control of the injection valve, and registration of the signal. The program can easily be extended to other tasks such as data-processing and report-generation.

Hardware

The entire system comprises:

(1) an HP9845B desk-top computer with a real-time clock;
(2) a 16-bit parallel I/O interface (HP98032A);
(3) a BIFOK FIA 05 flow-injection device equipped with L100-1 valve; after the injection the valve returns to its normal position within an adjustable time period;
(4) a BIFOK FIA 06 photometer with electronic equipment provided with a 3-digit BCD parallel output (0–1 V);
(5) a Gilson Minipuls II pump;
(6) a Skalar Sampler 1000 sample changer.

The following modifications have been made. The sample changer is connected to the I/O interface of the computer. In the "external mode" the switches for the wash, turntable disk, and two sampler arm motors (left and right) are controlled by the parallel output. The status of the microrelays indicating the positions of the disk and the sampler arm is read in by the parallel input. Thus the computer may take over all the functions of the sample changer. In the "internal mode" these connections are non-effective and the sample changer is manually operated. In a similar way the injection valve is rotated by the computer. The BCD-output of the photometric device is connected to the parallel input of the computer (12 bits for 3 digits).

An example of an automated flow-injection system is depicted in Fig. 1. The interface connections between the computer and the instrumental set-up are shown in Fig. 2.

Software

The software package comprises ten subroutines and functions written in BASIC. The program is written in a top/down structure, meaning that the more advanced routines are found at the highest level, and call lower-level routines, down to the most

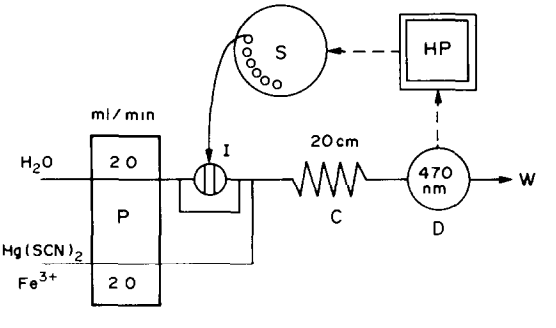

Fig. 1. Scheme of the flow-injection system for the determination of chloride with $Hg(SCN)_2$ and Fe^{3+}. The hardware consists of a peristaltic pump P, an automatic sample changer S, an injection valve I, the waste W, a reaction coil C, a photometric detector D (set at 470 nm) and an interfaced computer HP.

*Author for correspondence.

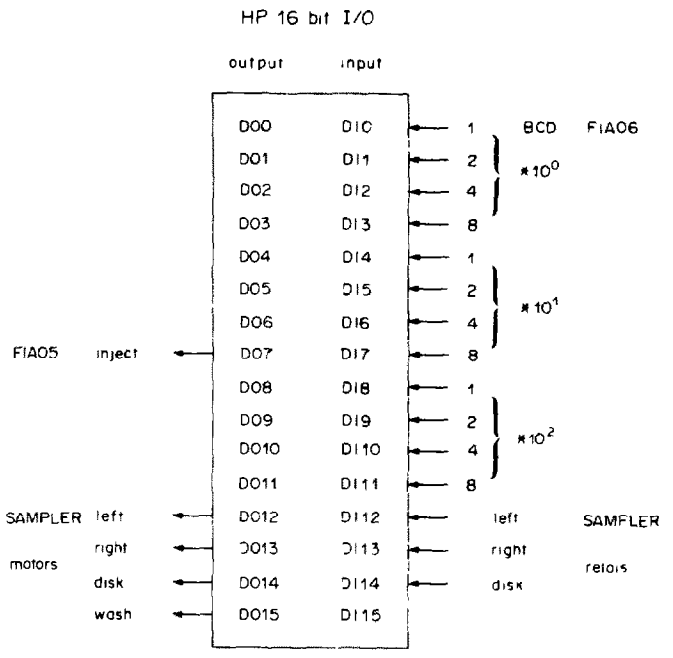

Fig. 2. Scheme of the most important connections of the computer, sample changer, injection device and photometer. The different functions are explained in the text.

primitive ones. The user has only to deal with the highest levels and to initialize some strings and variables.

The program structure is as follows:

level 2: main section;

level 1: subroutines Init, Check, Plot, Read_bcd, Inject, Wash, Disk and Sampler;

level 0: subroutine Output and function FNInput.

In the main section, after initialization the program checks the status of the system and asks for the number of samples. Thereafter, the samples are repeatedly taken, injected and measured and the results are plotted. The disk and sampler arm are manipulated in between other operations, to economise in time.

The lower level routines can be described briefly as follows.

Init: defines and initializes the connections of the 16-bit parallel I/O interface, *i.e.*, clock, input, output, inject, left motor, right motor, disk and wash.

Check: the status of the interface card and the position of the disk and sampler arm are checked for a proper start; if they are not correct, the routine will signal and ask for action.

Plot [Y(*),Names$,Number,Ymax]: performs the layout for the graphics and plotting on the screen.

Read_bcd [Y(*),Number,Delay]: reads a number of measurements, each with a given delay time, from the photometric device and converts the BCD code into a decimal value.

Inject: rotates the injection valve that introduces the sample into the flow system.

Wash: switches the wash motor either on or off.

Disk (Step): steps the disk a given number of places forward.

Sampler: the sampler arm is moved to the right-hand position when the arm is in the left-hand position, and *vice versa*.

Output (Bit): switches and masks the desired bit to the parallel output.

FNInput (Bit): returns the required bit from the parallel input.

The parameters involved are as follows,

Y(*): is an array in which the measurements are stored.

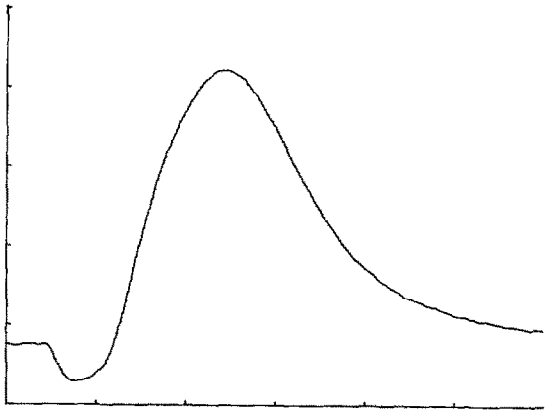

Fig. 3. An example of a digitized peak as displayed by the graphics part of the software package. Number = 600 and Delay = 40.

Number: denotes the number of data-points to be measured.

Delay: denotes the time between measurements (msec).

Name$: is the heading text used in the graphics plot.

Ymax: is a scaling variable to plot the measurements.

Step: is the number of steps the disk moves forward.

Bit: is the required I/O-line of the parallel interface.

Implementation

The computer-controlled flow-injection system has been employed for the determination of chloride in aqueous samples with mercuric thiocyanate in the presence of iron(III), with spectrophotometric measurement at 470 nm. The photometric signal is sampled 600 times during 24 sec and the time for plotting of the measurements, inclusive of taking the sample into the injection loop (100 μl), is about 16 sec, so for each sample a total of 40 sec is required. An example of the graphics plot of a flow-injection peak for a 10-ppm sample is shown in Fig. 3.

Although the package was developed for use with a professional computer, a similar set-up should be possible with a low-cost personal computer. The software package is flexible and may easily be extended to advanced data-processing techniques.

EFFECT OF EDTA/NaF SOLUTIONS ON THE ORION Cu(II) ION-SELECTIVE ELECTRODE

HENRY F. STEGER
Canada Centre for Mineral and Energy Technology, 555, Booth St., Ottawa, Canada

(*Received* 9 *May* 1984. *Revised* 26 *June* 1984. *Accepted* 29 *September* 1984)

Summary—The titration of ethylenediaminetetra-acetic acid in fluoride medium with Cu(II) solution with the Orion Cu(II) ion-selective electrode as indicator, results (after several titrations) in a broad end-point which is unsatisfactory for exact analytical purposes. This effect has been found to arise from an enhanced rate of response to changes in EDTA concentration when the electrode has been exposed to an EDTA/NaF medium for prolonged periods.

In 1979, the Canadian Certified Reference Materials Project (CCRMP) initiated a programme to confirm the homogeneity of a suite of seven zinc–aluminium alloys (Al 7–30%). For aluminium, a method was developed in which an excess of ethylenediaminetetra-acetic acid (EDTA) was added to the sample and the mixture was boiled to form the Al–EDTA complex; the uncomplexed EDTA was titrated with standard Cu(II) solution. The Al–EDTA complex was then decomposed by the addition of fluoride and boiling; the EDTA released was also titrated with the Cu(II) solution. The end-points were detected with an Orion Cu(II)-selective electrode.[1]

The quality of the response of this electrode was found to deteriorate on continuous use, until a single sharp end-point was not obtained unless the electrode was permitted sufficient recovery time in water or Cu(II) solution between titrations. This paper reports the results of an investigation on the reduced response of the Orion Cu(II)-selective electrode (Ag_2S/CuS homogeneous membrane) under the conditions used in the determination of aluminium in these alloys.

EXPERIMENTAL

Apparatus and titration procedure

Titrations of EDTA with standard Cu(II) solution were performed with a Mettler Automatic Titrator equipped with an Orion 94–29 Cu(II) ion-selective electrode and a calomel reference electrode. All data were collected and mathematically treated by a home-made dedicated microprocessor. The titrations were of 6.00 ml of 0.1000*M* EDTA, 10.00 ml of pH 5.20 acetate buffer (75.0 g of sodium acetate and 8 ml of glacial acetic acid per litre) and 84.0 ml of water and were performed in a water-jacketed vessel maintained at 25°. Copper titrant (0.1000*M*) was added in 0.5 or 1 ml increments until the total volume added was 5.5 ml or greater than 6.5 ml. Within this range, however, titrant was added either at the minimum continuous rate possible, 0.003 ml/sec or in an "equilibrium" titration mode, wherein 0.1-ml increments were added at 3-min intervals. The end-points of the titration were calculated by the method of Wolf.[2]

General conditions

EDTA solutions, 10^{-2}, 10^{-3} and $10^{-4}M$, containing 10.0 ml of acetate buffer per 100 ml were prepared in order to establish electrode calibration graphs. To simulate the effect of continuous titration in a fluoride-medium,[1] the Cu(II)-selective electrode was stored for various periods in a mixture of 6 ml of 0.1*M* of acetate buffer, 54 ml of water and 25 ml of sodium fluoride solution (42 g/l.).

RESULTS AND DISCUSSION

Storing the Cu(II)-selective electrode in a solution similar to the titration samples containing fluoride hastened the degradation of the end-point response of the electrode. Indeed a 16-hr or longer storage period makes the electrode ineffective as an end-point indicator in EDTA/Cu(II) titrations. Figure 1 shows the titration curves and corresponding $\Delta E/\Delta V$ *vs.* V curves for the titration of EDTA with Cu(II), with end-point detection by use of the Cu(II)-selective electrode in (*a*) polished condition and (*b*) after treatment for 24 hr with EDTA/NaF solution. The earlier break in the titration curve when the treated electrode is used is typical whenever the $\Delta E/\Delta V$ *vs.* V curve displays multiple peaks or appreciable broadening.

When the titration data are presented as plots of electrode potential *vs.* either log [EDTA] or log [Cu(II)], linear plots are obtained for the region where the potential increases after the first few additions of Cu(II) titrant. Figure 2 illustrates this for the titration data in Fig. 1. Table 1 summarizes the slopes of such plots for different treatments of the Cu(II)-selective electrode. It must be pointed out that the electrode potentials, particularly those near the end-point in titrations, do not necessarily attain a steady value before the next addition of titrant. For most applications, this does not have a significant effect on the accuracy of the titration.

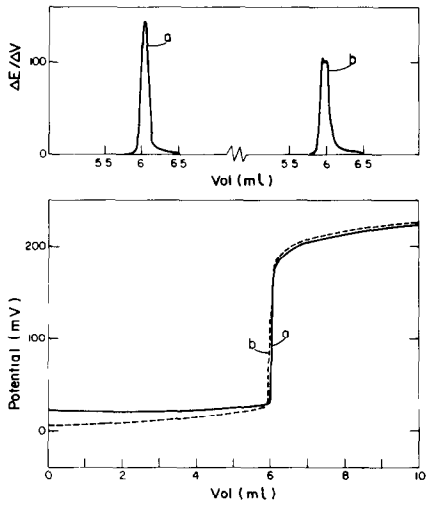

Fig. 1. Titration and $\Delta E/\Delta V$ *vs.* V curves obtained by continuous addition of titrant, with detection by use of (*a*) the polished electrode and (*b*) the electrode stored in EDTA/NaF solution.

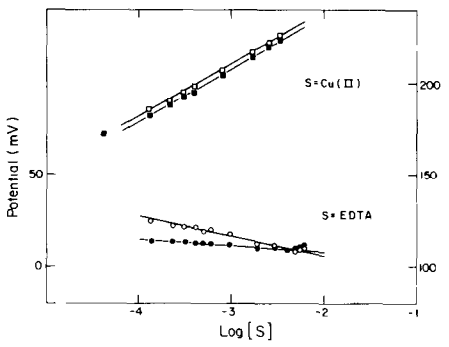

Fig. 2. Plot of electrode potential log [EDTA] and log [Cu(II)] for the curves of Fig. 1: ●—polished electrode, ○—electrode stored in EDTA/NaF solution.

The major point of interest in Table 1 is that storing the electrode in EDTA/NaF solution appears to increase its sensitivity to changes in [EDTA]. Since the rate of titrant addition was the same in these titrations, the electrode sensitivity is in effect the rate of electrode response to changes in [EDTA] before the end-point and to changes in [Cu(II)] after the end-point. To study the effect of response time, several "equilibrium" titrations of EDTA with Cu(II) solution were performed in which there were 3-min intervals between additions of titrant, to allow the potential of the electrode (in polished condition) to reach a steady value. Figure 3a shows a typical titration curve for these "equilibrium" titrations. It is evident that the break in the curve occurs earlier than when the continuous-addition procedure is used. The corresponding $\Delta E/\Delta V$ *vs.* V peak is broadened and can be resolved into two peaks. These observations are best explained as due to the rate of response of the polished electrode to changes in [EDTA] being appreciably slower than that to changes in [Cu(II)]. The rate of electrode response to relative changes in [EDTA] is not important until the end-point is closely approached because such changes are small for a given increment of Cu(II) titrant. Very near the end-point, however, the relative changes in [EDTA] become large for a given increment of titrant, but in a continuous-addition titration the electrode cannot give full response unless complete response is instantaneous. The result is a potential increase that is delayed and smaller than expected. Indeed, the end-point has been passed and the electrode is responding to free Cu(II) before it has been able to respond fully to EDTA. The steep potential increase associated with the single end-point suggests that in a continuous-addition titration the polished electrode responds only in a minor fashion to change in [EDTA] and essentially reflects changes in [Cu(II)]. In "equilibrium" titrations, however, the electrode has time to respond fully to changes in [EDTA] before the end-point and to changes in [Cu(II)] after it. That there appear to be two end-points where only one true end-point exists suggests that the electrode cannot respond instantaneously to free Cu(II) immediately after the end-point. This delay is analogous to the time required for the electrode to reach a stable potential on a change in sample composition. The existence of such a delay is also strongly implied in continuous-addition titrations of EDTA with Cu(II). In 29 titrations of $0.1000M$ EDTA with $0.1000M$ Cu(II), the concentration of EDTA in the reagent solution was calculated to be $0.1008M$ ($\sigma = 0.002M$) if [Cu(II)] = $0.1000M$. With the same reagents, the reverse titration, where the electrode responds initially to decreasing [Cu(II)] gave the EDTA concentration as $0.1000M$ ($\sigma = 0.0002M$) for 11 runs. The titration of EDTA with Cu(II) has a small bias that is consistent with a delay in the response of the Cu(II)-selective electrode to the initial free Cu(II) immediately after the end-point in titrations of EDTA.

Table 1. Slopes of plots of titration curves

Electrode condition	Slope, *mV/decade*	
	log [EDTA]	log [Cu(II)]
Polished	−7.8	29.1
Stored in EDTA/NaF for 24 hr	−10.0	29.8
Stored in EDTA/NaF for 48 hr	−12 6	30.0
Stored in EDTA/NaF for 96 hr	−15.4	30.4

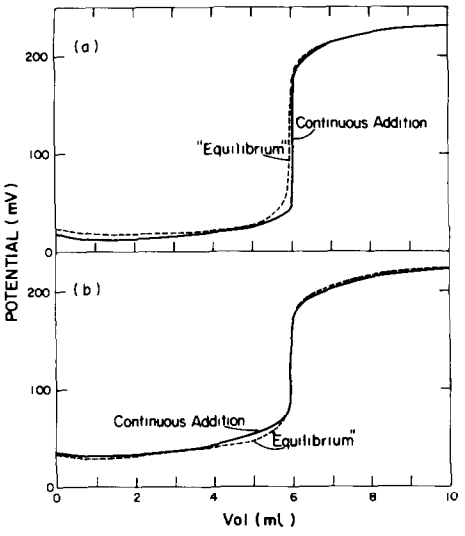

Fig. 3. Titration curves for continuous-addition and "equilibrium" procedures with (*a*) the polished electrode and (*b*) the electrode stored for 48 hr in EDTA/NaF solution.

The similarity in the curves for the "equilibrium" titrations with the polished electrode and for the continuous-addition titrations with the electrode treated with EDTA/NaF solution, strongly suggests the same cause. Storage or continuous use of the electrode in EDTA/NaF medium results in an enhanced rate of response to changes in [EDTA]. Figure 3b compares the titration curves of EDTA with Cu(II), using the electrode treated for 48 hr with EDTA/NaF solution, by the continuous-addition and "equilibrium" procedures. The strong similarity, especially in the end-point region, substantiates the contention that the EDTA/NaF treatment of the electrode leads to an enhanced rate of response to changes in [EDTA] before the end-point. Neither titration gave a satisfactory single end-point.

The treatment of the Cu(II)-selective electrode with EDTA/NaF solution has been postulated to form a sparingly-soluble fluoride compound, because the normal response of the electrode is readily restored by light polishing of the surface.[1] The physical presence of such a compound has not been unequivocally established. There is, however, a visually detectable dulling of the lustre and a corresponding slight decrease in the specular reflectance (in the region 5100–6000 Å) of the electrode surface on treatment with EDTA/NaF. The results of this investigation nevertheless do indicate that the surface of the electrode is affected by storage in EDTA/NaF solution.

This effect of storage in EDTA/NaF solution was investigated for two Orion 94–29 Cu(II) electrodes. The first, purchased in 1976 but used very infrequently until 1980,[1] displayed an immediate sensitivity to storage or continuous use in EDTA/NaF solutions. This electrode was accidentally broken during the initial stages of the present study. The second electrode, obtained in March 1983, remained unaffected by EDTA/NaF solutions for approximately two weeks but thereafter rapidly developed a sensitivity to EDTA-NaF comparable to that observed for the first electrode. This report summarizes the experimental results for the second electrode.

It should be emphasized that the findings of this study should not be taken to mean that all EDTA titrations with Cu(II) are unsatisfactory. Indeed, the opposite is true for all but very exact analysis. The phenomenon discussed here is observed primarily because of the resolving power of an up-to-date microcomputerized collection and reduction of data. Without it, the end-point in the titrations of EDTA with Cu(II) and of Cu(II) with EDTA could not have been determined with sufficient precision to show the slight differences observed. Indeed, the analyst must wonder if, in practical terms, there is any difference. The degeneration of the sharpness of the end-point in titrations of EDTA with Cu(II) after the electrode has been used or stored in EDTA/fluoride medium may not be noticed at all under less favourable conditions, and only be observed as a reduction in the reproducibility of the end-point.

SPECTROPHOTOMETRIC DETERMINATION OF PARACETAMOL WITH IODYLBENZENE

KRISHNA K. VERMA and ARCHANA JAIN
Department of Chemistry, R.D. University of Jabalpur, Jabalpur 482001, India

(*Received* 29 *May* 1984. *Accepted* 29 *September* 1984)

Summary—Paracetamol (*N*-acetyl-4-aminophenol) has been determined spectrophotometrically by its oxidation with iodylbenzene in acetone to produce the yellow-orange *N*-acetyl-1,4-benzoquinoneimine, which attains maximum colour intensity within 1 min and absorbs maximally at 430 nm. The maximum molar absorptivity is 1.58×10^3 l.mole^{-1}.cm^{-1}. The method is simple and rapid and has been found to be unaffected by the presence of salicylamide, oxyphenbutazone, acetylsalicylic acid, dipyrone and a number of other excipients.

Paracetamol (acetaminophen, *N*-acetyl-4-aminophenol) is an extensively employed antipyretic analgesic drug. Dipyrone (analgin), oxyphenbutazone, acetylsalicylic acid and salicylamide are found along with it in various pharmaceutical preparations. These substances interfere severely in one or another of the currently available methods of determining paracetamol. The titrimetric methods involve the reaction of either the phenolic group with a base in dimethylformamide medium[1,2] or of the aromatic amino group (formed by hydrolysis) with nitrite,[3] but there is interference with the acid–base method by salicylamide, oxyphenbutazone and acetylsalicylic acid (which are also acidic), and any free 4-aminophenol present (which is a product of decomposition). In the other method, Vitamin C, dipyrone and 4-aminophenol will all consume nitrous acid. Hydrolysis of paracetamol to 4-aminophenol which is then reacted with a substituted benzaldehyde[4–6] or 4-dimethylaminocinnamaldehyde[7] to form coloured Schiff's bases is naturally affected by the presence of 4-aminophenol and phenetidine (formed by hydrolysis of phenacetin). The nitrosation and chelation reaction[8] of paracetamol is also given by salicylamide[8] and oxyphenbutazone.[9] Indophenol formation[10,11] constitutes a simple spectrophotometric determination, but it is based on the oxidative coupling of 4-aminophenol with alkaline phenol, so dipyrone (being a strong antioxidant) interferes and causes low results for paracetamol. Determinations based on ultraviolet absorption[12] and its change with pH[13] are too sensitive to be of general use for compound drug tablets.

A rapid and highly selective spectrophotometric method for the determination of paracetamol in drug formulations is now reported. Iodylbenzene (iodoxybenzene) is insoluble in common organic solvents but its suspension in acetone brings about specific oxidation of paracetamol to a yellow-orange substance that shows maximum absorption at 430 nm. The colour is stable for about an hour and obeys Beer's law over a wide range of paracetamol concentration.

EXPERIMENTAL

Reagent

Iodylbenzene was synthesized by the procedure described by Fieser and Fieser,[14] and by the bromate oxidation method of Banerjee *et al.*[15] modified as follows.

To a mixture of 20 g of iodobenzene, 200 ml of 40% v/v sulphuric acid and 50 ml of glacial acetic acid, heated on a boiling water-bath, slowly add a solution of 15 g of potassium bromate in 150 ml of warm water during a period of 30 min with vigorous stirring (in a fume-chamber). Continue the heating for 90 min, during which all the bromine evolved is removed. Cool to room temperature, decant the supernatant liquid, wash the product (oily owing to unreacted iodobenzene) with water, macerate it with 50 ml of chloroform, filter it off and wash it with chloroform to furnish a silky white solid, m.p. 222° (decomposition). The product obtained in this way (12 g, 50% yield) was found to be 98% pure, by iodometric analysis.[16]

Samples

A high-purity sample of paracetamol, found to be 98.8% pure by the indophenol method[10] and 98.6% pure by the nitrosation method,[8] was used. All drug samples tested were fresh.

Procedure

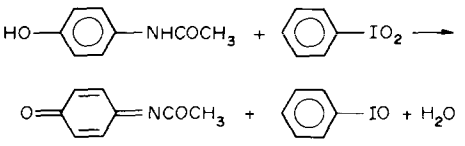
Preparation of calibration graph. Into a 50-ml calibrated flask accurately weigh 10 mg of paracetamol, dissolve it in acetone and make up to the mark with the same solvent; mix 1–5 ml portions of this solution with about 20 mg of finely powdered iodylbenzene in 10-ml beakers, dilute each to about 5 ml with acetone and stir for 1 min. Filter the coloured solution through a small fluted Whatman No. 41 filter paper into a 10-ml standard flask, washing the residue and making up to the mark with acetone. Measure the absorbance at 430 nm in a 1-cm cell against acetone.

Drug samples. Grind a known number of tablets, accurately weighed, into a fine powder, weigh out a portion containing about 10 mg of paracetamol and stir it with 20 ml of acetone. Filter off the residue on a fluted Whatman No. 41 filter paper, wash it with three successive 5-ml portions of acetone and make up filtrate and washings to volume with acetone in a 50-ml standard flask. Treat a 2-ml

portion of this solution by the procedure described for preparation of the calibration graph.

RESULTS AND DISCUSSION

Iodylbenzene is insoluble in the commonly used organic solvents, but a suspension of it in acetone oxidizes paracetamol to a yellow-orange product that has maximum absorption at 430 nm. The reaction is reversible, the product being decolorized on addition of ascorbic acid and reoxidized to the coloured product by iodylbenzene. The observation that iodosobenzene does not yield a colour reaction and that paracetamol acetylated at the phenolic group fails to give any colour with iodylbenzene, led us to believe that the colour reaction is:



The colour develops almost instantaneously and remains stable for about 1 hr. There is a 10% decrease in colour intensity after 2 hr. Other common oxidizing agents, *e.g.*, iodosobenzene diacetate or dichloride, chloramine-T and *N*-bromosuccinimide, do not produce a colour, perhaps because the

oxidation continues beyond the *N*-acetyl-1,4-benzoquinoneimine. The visible spectrum of the chromogen is shown in Fig. 1. The molar absorptivity is 1.58×10^3 l.mole^{-1}.cm^{-1} at 430 nm. The method is more rapid and simple than the existing procedures, and Beer's law is obeyed over a wide range of paracetamol concentration, 0–100 μg/ml in the final solution. The absorption spectrum is unaffected by the use of as high as 100-fold molar excess of iodylbenzene.

A large number of pharmaceutical preparations containing paracetamol have been analysed by the method and the results are given in Table 1 together with comparative values obtained by using established methods. Dipyrone, oxyphenbutazone, acetylsalicylic acid, salicylamide, vitamin C, phenacetin and caffeine do not affect the results. Other substances which can be tolerated are listed in a footnote to Table 1. 4-Aminophenol is a product of decomposition of paracetamol and interferes in almost all available methods for determining paracetamol, but the present method is free from this interference.

PHOSPHATE DETERMINATION BY USE OF MOLYBDOANTIMONYLPHOSPHORIC ACID AND POLYURETHANE FOAM

A. S. KHAN and A. CHOW*
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba, Canada

(*Received* 1 *August* 1984. *Accepted* 14 *September* 1984)

Summary—Preconcentration of phosphate as molybdoantimonylphosphoric acid on polyurethane foam has been combined with X-ray fluorescence measurement of antimony for the indirect determination of phosphate. The extraction is optimum between pH 1 and 3.6 and no interference is observed from silicate. The precision is 5% RSD at the 0.25-μg/ml level and the detection limit is 20 ng/ml for 100 ml of sample solution.

The most widely used spectrophotometric procedures for the determination of phosphate in aqueous solutions are based on the formation of 12-molybdophosphate in reduced or non-reduced forms. At the trace level, the reduced (heteropoly blue) form is preferred, owing to the higher absorptivity. The Murphy and Riley method,[1] using ascorbic acid and potassium antimony tartrate as the reducing agent, has become one of the standard procedures[2] for phosphate determination. Going and Eisenreich,[3] have established the stoichiometry of the reduced heteropoly product as $PSb_2Mo_{10}O_{40}$. Besides the traditional spectrophometric methods,[4] the determination of phosphate can be based on extraction of molybdoantimonylphosphoric acid ($PSb_2Mo_{10}O_{40}$) into isobutyl acetate and measurement of the antimony content in the extract by atomic-fluorescence spectrophotometry.[5]

X-Ray fluorescence (XRF) has also been employed for phosphate determination. Phosphate has been extracted[6] as 12-molybdophosphoric acid ($H_3PMo_{12}O_{40}$) into ethyl acetate, the organic layer then being coated onto a specially treated silica gel, pressed into pellets and analysed for molybdenum. Dube *et al.*[7] have estimated phosphate directly by XRF after precipitating it as quinine molybdophosphate.

Recently polyurethane foam has been used for the preconcentration and *in situ* XRF determination of trace elements.[8,9] In an earlier communication,[10] we reported the indirect XRF determination of phosphate after its extraction as molybdophosphoric acid into polyether foam. Further study has shown that molybdoantimonylphosphoric acid can be used similarly, and gives a selective and more sensitive method.

EXPERIMENTAL

Apparatus

The energy-dispersive XRF unit used to measure the intensity of the antimony K_α line included an annular 0.5-Ci ^{241}Am source (New England Nuclear) coupled with an Si(Li) detector, a Nuclear SemiConductor 512 amplifier and a Tracor Northern TN1705 pulse-height analyser. A thermostatically-controlled multiple automatic squeezer was used for squeezing the foam in the sample solutions.

Reagents

The stock solutions of molybdate, phosphate and antimony were prepared by dissolving the required amounts of sodium molybdate, potassium dihydrogen phosphate and potassium antimony tartrate. A 1% solution of ascorbic acid was prepared daily.

A mixed reagent was prepared as described by Going and Eisenreich,[3] except that half of the recommended amount of potassium antimony tartrate was used. Sodium molybdate dihydrate (2.12 g) was dissolved in 150 ml of water, and 20.8 ml of concentrated sulphuric acid were added slowly with continuous stirring. The solution was cooled to room temperature, 0.344 g of potassium antimony tartrate was added, and the volume was made up to 250 ml. This solution was usable for several weeks.

All chemicals were of reagent grade. and doubly distilled and demineralized water was used for dilutions. The phosphate, molybdate and mixed reagent solutions were stored in plastic bottles. Extran "300" (B.D.H.), a phosphate-free cleaning agent, was used to clean all glassware.

Foam discs, approximately 2 cm in diameter and 0.8 cm in thickness were cut from a sheet of polyether-based polyurethane foam obtained locally and washed according to a procedure described earlier.[11]

Procedure

An aliquot of phosphate solution, containing not more than 0.1 mg of phosphate, was transferred into a 100-ml standard flask, followed by 2.5 ml of the mixed reagent and 1 ml of ascorbic acid solution. This solution was diluted and mixed and after 10–15 min was equilibrated with a foam disc in an extraction cell for 30 min. The foam disc was then removed from the solution, washed with water and finally dried by squeezing between paper towels. The dried foam disc was placed on Mylar film, which was then stretched across the X-ray source and analysed for 200 sec. The area under the antimony K_α peak was obtained by integration with the TN1705 unit.

RESULTS AND DISCUSSION

Using the procedure recommended by Going *et al.*[4] for the extraction of molybdoantimonyl phosphate

*Author for correspondence.

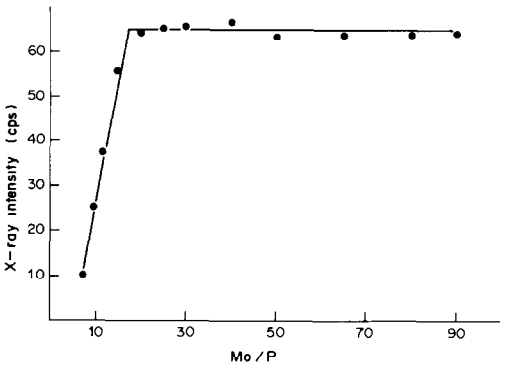

Fig. 1. Extraction of molybdoantimonylphosphoric acid as a function of initial molybdate concentration.

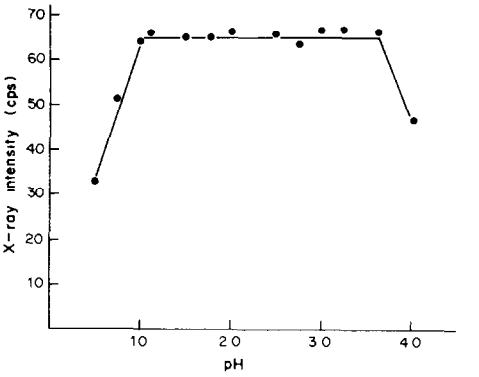

Fig. 2. Extraction of molybdoantimonylphosphoric acid as a function of solution acidity.

into organic solvents, it was found by absorption spectrophotometry that the extraction of molybdoantimonyl phosphate (MSbP) by polyurethane foam is quantitative. Initial experiments also showed that the extraction efficiency remains almost constant if the squeezing time is 15 min or more. In all later studies, the foam discs were squeezed in the sample solutions for half an hour or more to ensure equilibration.

The effect of molybdate concentration on the extraction was tested by squeezing foam discs in a series of solutions, 100 ml in volume, $1.5 \times 10^{-5} M$ in phosphate, $4 \times 10^{-5} M$ in antimony and containing varying amounts of molybdate and sufficient acid to maintain the H^+/Mo ratio at 75. It has been established that the formation of MSbP is maximal under these conditions.[3] From the results shown in Fig. 1, it is clear that a 20-fold excess of molybdate is sufficient for optimal extraction of MSbP. Similar results were obtained for the extraction of 12-molybdophosphoric acid by polyurethane foam,[12] but more molybdate is necessary for the quantitative extraction of molybdoarsenate.[13] It is most likely that the excess of molybdate is necessary to ensure complete formation of the particular heteropolymolybdate rather than to maximize the extraction efficiency.

The optimal pH range for the extraction was studied with a series of solutions (100 ml) with fixed concentrations of phosphate ($1.5 \times 10^{-5} M$), antimony ($4 \times 10^{-5} M$) and molybdate ($1 \times 10^{-3} M$). Figure 2 shows that pH 1–3.6 is optimal. Similar results have been reported by Going *et al.*[4] The optimum range for extraction of 12-molybdophosphate by polyurethane foam is pH 1–2,[12] owing to $PSb_2Mo_{10}O_{40}$ being stable over a wider pH range than the $PMo_{12}O_{40}$ complex is.

The effect of the Sb/P ratio was also studied. The results indicate that at least a 2:1 ratio is necessary for the efficient extraction of MSbP (since this concentration is required stoichiometrically), but a large excess of antimony results in precipitation.

It is evident that the extraction of MSbP by polyurethane foam is optimal under the conditions for maximum complex formation. For this Going and Eisenreich[3] recommended use of a mixed reagent containing sufficient molybdate, antimony and acid. Use of this mixed reagent was examined and it was found that 2 ml will suffice for the extraction of 100 μg of phosphate from 100 ml of sample solution.

The X-ray response was studied with 100-ml samples containing 0–100 μg of phosphate, 2.5 ml of mixed reagent and 1 ml of ascorbic acid solution. It was linear over this concentration range (correlation coefficient 0.998). The detection limit (X) defined as the mean blank value ($\bar{X}$) plus three standard deviations (σ) of the blank value, (*i.e.*, $X = \bar{X} + 3\sigma$), is 20 ng/ml for 100-ml sample solutions. The detection limit can be improved by using a more sensitive X-ray instrument or larger sample volumes.

The precision (relative standard deviation) was evaluated from replicate analyses for 25 μg of phosphate, and found to be 5%. As the extraction of MSbP by polyurethane foam is quantitative under the conditions used, it is most likely that the X-ray measurement is the major source of uncertainty.

The effect of As, Si and Ge was evaluated by analysing a series of 100-ml sample solutions containing 50 μg of phosphate and various amounts of the interfering elements. It was found that silicon did not interfere even when present in large excess (up to 10 mg) whereas only 250 μg of germanium and less than 50 μg arsenic can be tolerated. Although the solution chemistry of these systems has not been reported in the literature, it seems likely that germanium and arsenic also form mixed heteropoly complexes containing antimony. Since the heteropolymolybdate complexes of germanium and arsenic are extractable by polyurethane,[14] these mixed complexes are probably also extractable and thus give positive interference.

The X-ray fluorescence technique in conjunction with foam extraction can be used for the determination of phosphate, with a performance comparable to that of the existing solvent extraction methods, and should produce greater sensitivity when used with better X-ray equipment. The technique has several advantages over the previous method based

on molybdenum determination.[10] The antimony determination has a detection limit of 0.02 ppm compared with 0.10 ppm for molybdenum, and is more selective since phosphate can be determined even in the presence of large amounts of silicon, and also the optimal pH-range is wider.

MICMAC—UN PROGRAMME GENERAL ET RIGOUREUX D'AFFINEMENT MULTIPARAMETRIQUE POUR LA DETERMINATION DE CONSTANTES D'EQUILIBRE A PARTIR DE METHODES PHYSIQUES VARIEES

ANDRÉ LAOUENAN* et ELISABETH SUET
Laboratoire de Chimie Analytique, LA CNRS 322, Université de Bretagne Occidentale, 6, Avenue le Gorgeu, 29283 Brest-Cédex, France

(*Reçu le* 9 *âout* 1984. *Accepté le* 12 *décembre* 1984)

Résumé—Le programme basic MICMAC a été développé pour l'ajustement sur micro-ordinateur de constantes d'équilibre à partir de méthodes physiques très variées. Le programme utilise la méthode particulièrement fiable de Gauss–Newton–Marquardt et permet l'ajustement multiparamétrique de fonctions non linéaires. Hautement interactif, d'utilisation aisée et de conception modulaire, il fait intervenir une pondération rigoureuse et peut prendre en compte des erreurs systématiques. Ce programme autorise la résolution de problèmes où interviennent plusieurs variables dépendantes, indépendantes et plusieurs séries de mesures. Quelques exemples traitant de polarographie, pH-métrie et RMN, illustrent la généralité du programme MICMAC et donnent lieu à une étude comparative avec des programmes récents.

Depuis les premiers travaux de Sillén,[1] de nombreux programmes permettant la détermination de constantes de stabilité ont vu le jour[2,3] et les résolutions graphiques tendent à être remplacées de plus en plus par des techniques numériques fondées sur la méthode des moindres carrés. Cependant, en dépit des avantages que présentent ces techniques (estimations objectives des incertitudes selon des critères statistiques, aptitude à traiter des problèmes complexes sans recourir à des approximations parfois discutables ou être conduit à linéariser à tout prix les équations descriptives du modèle), il est assez surprenant de constater que de nombreux travaux récents continuent à faire appel aux résolutions graphiques. Nous pensons que cet état de fait, à l'heure où tant de programmes ont été publiés, peut s'expliquer de la façon suivante:

—d'une part, la familiarisation avec des programmes généraux, tel LETAGROP-VRID,[4] exige un effort assez considérable et leur exécution nécessite de gros moyens informatiques;

—d'autre part, la plupart des programmes existants ne permettent de traiter qu'un seul type d'expérience: potentiométrie (SCOGS,[5] MINIQUAD,[6] BEST,[7] TITFIT,[8] MUCOMP[9]), spectrophotométrie (MINISPEF,[10] DCLET,[11] SQUAD[12]), résonance magnétique nucléaire (PHFIT[13]), polarographie (POLAG[14]).

Il nous semble que la demande du chimiste analyticien est de pouvoir disposer d'un programme d'utilisation aisée (*i.e.*, interactif, ne nécessitant pas de connaissances informatiques approfondies et éxécutable sur micro- ou mini-ordinateur) et d'une généralité telle qu'il puisse s'adapter à différents types d'expériences. En effet, devant un problème chimique, le choix primordial quant à la technique expérimentale doit être un *choix chimique* (il n'est pas souhaitable qu'un seul type de manipulation soit systématiquement utilisé quel que soit le problème envisagé). Ce choix ne pourra être fait librement que si l'on est assuré de disposer d'une méthode de calcul appropriée. Ainsi, la seule démarche valable est d'adapter un programme à l'expérience, et non de concevoir l'expérience en fonction du programme dont on dispose. En clair, le plus important est d'assurer le libre choix des manipulations. Qui plus est, il arrive que pour une expérience donnée des modèles différents conduisent à des ajustements comparables. La discrimination entre les modèles nécessite alors d'autres approches expérimentales; il est donc important de pouvoir traiter différents types de données.

Ces diverses constatations nous ont conduits à écrire un programme *d'utilisation générale* pouvant s'adapter à l'exploitation de résultats expérimentaux acquis par diverses techniques. L'investissement nécessaire à l'utilisation de ce programme sera donc largement rentabilisé par ses applications multiples. Le programme MICMAC, écrit en BASIC standard (Microsoft) est éxécutable sur micro-ordinateur.

Ce programme est conçu de façon à ce que tout paramètre expérimental puisse être rendu ajustable sans difficulté. Jusqu'ici, seuls des programmes comme LETAGROP,[4] DALSFEK,[15] TITFIT[8] et MUCOMP[9] permettent de rendre ajustables certains paramètres autres que les constantes d'équilibre.

*Auteur pour correspondance.

TRAITEMENT MATHEMATIQUE

Pour un modèle donné, la variable observée est fonction des paramètres $\alpha_j (j = 1, \ldots n)$ et des variables indépendantes $x_l (l = 1, \ldots k)$

$$y = f(\alpha_1, \ldots \alpha_n, x_1, \ldots, x_k) \tag{1}$$

(Pour la clarté de l'exposé, nous nous limitons à une variable dépendante. L'extension au cas de plusieurs variables se fait sans difficulté.)

Le but est d'obtenir les "meilleures" estimations des paramètres (au sens des moindres carrés), c'est-à-dire de minimiser la somme des carrés des résiduels:

$$U = \sum_{i=1}^{m} W_i [y_{i(\text{exp})} - f(\alpha_1, \ldots \alpha_n, x_{i1}, \ldots x_{ik})]^2 \tag{2}$$

où W_i représente le poids du point i ($i = 1$ à m, nombre de mesures).

Cette somme doit être rendue minimum par rapport à chacun des paramètres ajustables, ce qui conduit à un système de n équations

$$\frac{\partial U}{\partial \alpha_j} = 0; \; j = 1 \text{ à } n \tag{3}$$

La fonction f est développée en série de Taylor, en négligeant les termes d'ordre supérieur. Si y_i^0 représente la valeur calculée de y_i à partir d'un jeu de paramètres initiaux α_j^0, le développement en série de Taylor de f s'écrit:

$$f(\alpha_1, \ldots \alpha_n, x_{i1}, \ldots x_{ik}) = y_i^0 + \sum_j \frac{\partial f_i}{\partial \alpha_j} \Delta\alpha_j \qquad \begin{matrix} i = 1 \text{ à } m \\ j = 1 \text{ à } n \end{matrix}$$

soit

$$y_i - y_i^0 = \sum_j \frac{\partial f_i}{\partial \alpha_j} \Delta\alpha_j \tag{4}$$

Il est plus facile pour la programmation d'utiliser la notation matricielle selon laquelle l'équation (4) s'écrit

$$\Delta y = \mathbf{J} \cdot \Delta\alpha \tag{5}$$

Δy représente l'incrément sur la fonction f_i produit par l'incrément $\Delta\alpha$ sur les paramètres α_j. $\mathbf{J}$ est la matrice jacobienne dont les éléments sont définis par

$$\mathbf{J}_{ij} = \frac{\partial f_i}{\partial \alpha_j}; \quad i = 1 \text{ à } m, \quad j = 1 \text{ à } n.$$

Soit $\boldsymbol{\varepsilon}$ le vecteur des résiduels dont les éléments ε_i correspondent à la différence $(y_{i(\text{exp})} - y_i^0)$, y_i^0 étant calculé à partir du jeu de paramètres estimés. La fonction U à minimiser devient:

$$U = \widetilde{[\boldsymbol{\varepsilon} - \mathbf{J} \cdot \Delta\alpha]} \cdot \mathbf{W} \cdot [\boldsymbol{\varepsilon} - \mathbf{J} \cdot \Delta\alpha] \tag{6}$$

où $\mathbf{W}$ désigne la matrice de pondération (le symbole $\sim$ désigne la transposée de la matrice considérée). La condition de minimisation (3) s'écrit alors:

$$\frac{\partial U}{\partial \alpha_j} = -2\tilde{\boldsymbol{\varepsilon}} \cdot \mathbf{W} \cdot \mathbf{J} + 2\widetilde{\Delta\alpha} \cdot \tilde{\mathbf{J}} \cdot \mathbf{W} \cdot \mathbf{J} = 0$$

d'où l'on tire la relation, après transposition:

$$\mathbf{A} \cdot \Delta\alpha = \mathbf{S} \tag{7}$$

où

$\mathbf{A} = \tilde{\mathbf{J}} \cdot \mathbf{W} \cdot \mathbf{J}$ est le Hessien
$\mathbf{S} = \tilde{\mathbf{J}} \cdot \mathbf{W} \cdot \boldsymbol{\varepsilon}$ le vecteur des seconds membres.

L'expression des déplacements sur les paramètres $(\Delta\alpha_j)$ est donc:

$$\Delta\alpha = \mathbf{B} \cdot \mathbf{S} \tag{8}$$

où $\mathbf{B} = (\tilde{\mathbf{J}} \cdot \mathbf{W} \cdot \mathbf{J})^{-1}$ représente l'inverse du Hessien $\mathbf{A}$ et peut être calculé lorsque celui-ci n'est pas singulier. Le problème n'étant généralement pas linéaire, la nouvelle estimation des paramètres $\alpha_j = \alpha_j^0 + \Delta\alpha_j$ ne conduit pas directement au minimum de U; un ajustement itératif est nécessaire, et le calcul précédent est répété à partir des nouvelles estimations jusqu'à convergence. Chaque itération conduit idéalement à une valeur plus faible de la variance sur y:

$$\sigma^2 = \frac{1}{m - n} \sum_i W_i (y_{i(\text{exp})} - y_{i(\text{calc})})^2 \tag{9}$$

La variance sur chaque paramètre est obtenue à partir des éléments diagonaux de la matrice de variance-covariance $\mathbf{B}\sigma^2$ et la racine carrée de ses éléments conduit à la déviation standard sur le paramètre correspondant.

Enfin, la matrice de corrélation $\mathbf{C}$ s'obtient en normalisant la matrice $\mathbf{B}$ selon

$$\mathbf{C}_{ij} = \frac{b_{ij}}{\sqrt{b_{ii}}\sqrt{b_{jj}}} \tag{10}$$

LE PROGRAMME MICMAC

Caractéristiques du programme

Les équations mathématiques écrites ci-dessus permettent de constater que la méthode des moindres carrés n'est nullement restrictive. L'essentiel du traitement mathématique est indépendant de la forme de la fonction $f(\alpha_1, \ldots, \alpha_n, x_1, \ldots, x_k)$, qui le plus souvent ne sera pas connue de façon explicite. Nous avons cherché à exploiter cette qualité en écrivant un programme qui soit, lui aussi, le plus indépendant possible quant à la forme de f.

Un choix correct de la variable y sur laquelle est effectué l'ajustement est primordial. Il nous paraît naturel que la grandeur ajustée soit la *grandeur mesurée*. Il est ainsi possible d'interpréter en termes chimiques le déroulement du calcul. Les résidus ont une signification directe et peuvent être immédiatement comparés à une estimation de l'erreur expérimentale. L'étude des écarts observés pourra consti-

tuer pour l'expérimentateur un guide précieux dans sa recherche d'un modèle plus satisfaisant. Dans le cas où existent des erreurs systématiques, leur détection sera facilitée par l'examen critique des déviations sur telle ou telle fraction des valeurs calculées de y. De plus, lorsque l'ajustement se fait sur la grandeur mesurée, la pondération en $1/\sigma^2$ est aisément établie, et peut à l'occasion être prise égale à l'unité. Par contre, l'utilisation de fonctions indirectes impose une pondération plus complexe qui doit tenir compte de la propagation des erreurs, afin que l'analyse statistique demeure rigoureuse.[16] Ainsi, lorsque l'on utilise $\bar{n}$, les expressions mathématiques deviennent rapidement inextricables.[17]

Dans le cas d'analyse de dosages pH-métriques par exemple, la minimisation de $\Sigma(\mathrm{pH_{calc}} - \mathrm{pH_{exp}})^2$ constitue, comme l'affirment les auteurs de BEST,[7] le bon choix tant au sens chimique que mathématique. Dans ce cas, la pondération établie en tenant compte des erreurs sur la mesure du pH et le volume de titrant est nécessaire, afin de ne pas donner une importance dangereuse aux zones de plus grande pente.

Il faut remarquer que la distinction introduite précédemment entre variables indépendantes (x) et paramètres ajustables (α) est purement arbitraire. Il est d'un grand intérêt que cette distinction soit faite par l'utilisateur en fonction de ses besoins, et non imposée par la structure du programme. Une caractéristique majeure de notre programme est la *banalisation* de toutes les grandeurs utiles à la définition de f. Chacune de ces grandeurs, selon qu'elle sera déclarée fixe ou ajustable au moment de l'exécution, jouera le rôle d'un x ou d'un α. Ceci permet de prendre en compte d'éventuelles erreurs systématiques, comme le préconisent Sillén[18] et Wentworth *et al.*[19] De telles erreurs sont souvent compensées par l'introduction d'une espèce artificielle, qui devient inutile lorsque l'erreur est corrigée. La correction des erreurs systématiques permet donc une analyse plus fine du modèle et autorise une plus grande confiance dans la détection d'espèces mineures. Bien entendu, la valeur ainsi ajustée d'un paramètre ne pourra être retenue que si elle est raisonnable; l'examen des nouveaux coefficients de corrélation infirmera ou confirmera l'opportunité d'une telle démarche. En effet, si la corrélation de ce nouveau paramètre avec chacun des paramètres initiaux est grande, il est indispensable de procéder à d'autres mesures expérimentales selon un nouveau protocole.

Afin de maintenir au programme un haut degré de généralité, nous avons opté pour la *dérivation numérique*. L'obtention d'un code compact et plus lisible est une conséquence avantageuse de ce choix. L'écriture de programmes généraux utilisant la dérivation analytique est possible,[20] mais nécessite une capacité-mémoire supplémentaire.

Pour la recherche des coordonnées du minimum de U, la méthode de Gauss–Newton, facile à mettre en oeuvre, converge rapidement à partir d'estimations initiales satisfaisantes. Lorsque celles-ci sont trop éloignées de la solution, la fonction U n'est plus correctement approximée par le développement en série de Taylor limité au premier ordre, et il n'est pas rare que le calcul diverge. Nous avons donc introduit la modification proposée par Marquardt,[21] qui combine l'approche précédente avec la méthode du gradient (connue pour être plus sûre, mais extrêmement lente lorsque l'on approche de la solution). L'algorithme de Gauss–Newton–Marquardt permet d'assurer la convergence à partir d'estimations initiales mêmes médiocres, tout en conservant la rapidité de la méthode de Gauss–Newton. L'équation (7) est remplacée par

$$\mathbf{A}^* \cdot \Delta\alpha^* = \mathbf{S}^* \tag{11}$$

$\mathbf{A}^*$ est le Hessien normalisé selon:

$$\mathbf{A}^* = (a_{ij})^* = \frac{a_{ij}}{\sqrt{a_{ii}}\sqrt{a_{jj}}} \tag{12}$$

$\mathbf{S}^*$ est le nouveau vecteur des seconds membres

$$\mathbf{S}^* = (s_i)^* = \frac{s_i}{\sqrt{a_{ii}}} \tag{13}$$

L'expression des déplacements sur les paramètres devient

$$\Delta\alpha_j = (\Delta\alpha_j)^*/\sqrt{a_{jj}} \tag{14}$$

Le facteur de Marquardt c est alors introduit dans l'équation (11):

$$(\mathbf{A}^* + c\mathbf{I}) \cdot \Delta\alpha^* = \mathbf{S}^* \tag{15}$$

L'algorithme est construit de façon à ce que c augmente lors d'une itération divergente, et diminue jusqu'à tendre vers zéro lorsqu'il y a convergence. Cette méthode s'avère remarquablement efficace, et confère au programme une grande fiabilité.

L'hypothèse fondamentale de la méthode des moindres carrés repose sur le caractère aléatoire des erreurs et leur distribution gaussienne. L'emploi de cette méthode impose donc que chaque observation soit affectée d'un poids qui reflète exactement l'erreur commise. Le point a été largement discuté par Wentworth.[16,19,22] Il est toutefois surprenant de constater que beaucoup de programmes se limitent à la pondération unité.[3] D'autres n'introduisent que les variances sur les observables, ce qui est parfois insuffisant, les variances sur les variables indépendantes n'étant pas toujours négligeables. La théorie de la propagation des erreurs permet d'écrire, pour plusieurs observables et plusieurs variables indépendantes:

$$\frac{1}{W_{ij}} = \sigma^2_{y_{ij}} + \sum_k \sigma^2_{x_{ik}} \left(\frac{\partial y_{ij}}{\partial x_{ik}}\right)^2 \tag{16}$$

(i-ème mesure, j-ième observable).

La somme des carrés des résiduels s'écrit donc:

$$U = \sum_i \sum_j W_{ij}(y_{ij_{calc}} - y_{ij_{exp}})^2 \qquad (17)$$

La matrice de pondération obtenue est une matrice diagonale d'ordre $m \times n$ (m = nombre de mesures, n = nombre d'observables). Quand plusieurs observations sont faites sur une même solution (spectrophotométrie à plusieurs longueurs d'onde en particulier), il est théoriquement nécessaire de faire intervenir les termes de covariance. Cependant, Lingane et Hugus[23] ont démontré que, lorsque les mesures sont précises, la covariance peut être négligée sans inconvénient.

Toutes les caractéristiques que nous venons de mentionner sont inhérentes au programme principal. Il est bien sûr nécessaire d'introduire un module spécifique (MOSP) à chaque type d'expérience.

—Ce module, dont la longueur n'excède pas quelques dizaines de lignes, inclut la définition de la fonction f, ainsi que l'expression adéquate du facteur de pondération dans les cas où les poids calculés selon l'expression (16) ne sont pas adaptés. Notre schéma général de pondération suppose en effet que la variance sur les x et les y est constante. Dans le cas où cette hypothèse n'est pas vérifiée, il est nécessaire d'introduire une estimation de la variance en chaque point expérimental. Cette option d'une expression spécifique de la pondération pourra également être utilisée dans le cas d'un changement de variables (Fig. 1).

—Dans la plupart des cas, le calcul des concentrations des constituants sous forme libre, à partir de leur concentration analytique est une étape nécessaire. Les équations de conservation de la masse sont introduites dans le module MOSP selon

$$T_j = t_j + a_{j1}c_1 + \cdots + a_{jn}c_n \qquad (18)$$

où T_j représente la concentration analytique du constituant j, avec a_{ji} = nombre d'atomes de ce constituant dans l'espèce i, c_i = concentration de l'espèce i définie à partir des constantes β_i ou K_i.

—Ce module pourra également inclure une correction sur les y, utile notamment en potentiométrie (par exemple, correction de l'erreur alcaline de l'électrode de verre), ou permettre un changement de variables (Fig. 1).

Cette conception permet une économie appréciable de mémoire centrale et une plus grande rapidité d'exécution; elle autorise également une grande souplesse. Ainsi, l'écriture de l'expression des bilans (18), selon qu'elle fera intervenir β, $\log\beta$, K ou pK, entraînera l'ajustement sur ces mêmes grandeurs. Le problème est en effet communément posé.[3] L'ajustement sur $\log\beta$, fréquemment employé, conduit à des ordres de grandeur comparables des éléments du Hessien. Toutefois, il arrive que celui-ci soit alors mal conditionne.[18,24] L'étape de normalisation du Hessien (12) permet de s'affranchir de ces considérations et d'ajuster directement sur les constantes.

En ce qui concerne l'utilisation des constantes globales de formation β ou des constantes successives K, nous n'avons pas observé de différence significative sur les valeurs obtenues lors de l'emploi de l'une ou l'autre de ces constantes. Cependant, l'utilisation d'un micro-ordinateur peut orienter le choix en faveur des constantes K; il n'est pas rare, en effet, de rencontrer des valeurs de β supérieures à 10^{38}, dont la représentation en virgule flottante est impossible sur la plupart des micro-ordinateurs. Ce fut le cas lors de nos études sur les tétra-azamacrocycles.[25,26] Cependant, nous avons parfois observé un abaissement notable des coefficients de corrélation lors de l'emploi de constantes β. Ainsi, il n'y a pas de règle générale quant à l'utilisation de l'une ou l'autre des constantes, le choix qui conduit aux coefficients de corrélation les plus faibles dépend du degré de recouvrement des équilibres.

Tous les appels entraînant le calcul des diverses fonctions définies dans le module MOSP sont gérés exclusivement par le programme principal; aucune modification de celui-ci n'est nécessaire.

La résolution du système d'équations non linéaires (18) utilise la méthode de Newton–Raphson. Si cette méthode est généralement satisfaisante, on observe parfois une absence de convergence, notamment à l'équivalence et dans son voisinage où les concentrations calculées en un point ne constituent pas une bonne approximation pour le point suivant. Pour remédier à cet inconvénient majeur, nous limitons l'accroissement relatif de la concentration d'un constituant ce qui assure également que les concentrations restent positives. Cet accroissement relatif, correspondant dans le programme au "facteur pour Newton–Raphson", doit être compris entre 0 et 1; la valeur 0,8 est généralement satisfaisante. Cette technique peut s'avérer parfois insuffisante; une seconde modification, apparentée à la méthode de la cible mouvante,[27] est alors introduite automatiquement. Une cible intermédiaire est choisie suffisamment proche du point initial de telle sorte que l'itération soit convergente. En se déplaçant ainsi de proche en proche vers la cible finale, la convergence peut toujours être forcée. Lors des cycles d'itérations suivants, on dispose d'approximations satisfaisantes, et la méthode de Newton–Raphson s'avère alors très efficace. La modification de cette méthode proposée par Marquardt[21] ne semble pas intéressante pour le calcul des concentrations, probablement en raison d'une trop forte corrélation.

Utilisation de BASIC

L'utilisation d'un micro-ordinateur présente de nombreux avantages. Parmi ceux-ci, il faut noter le faible coût du matériel, sa disponibilité constante et la familiarisation rapide avec la machine en raison de sa simplicité d'utilisation. BASIC est le langage le plus largement répandu sur ce type de matériel. D'un

apprentissage aisé, il permet l'écriture de programmes lisibles et hautement interactifs. Ces avantages nous paraissent compenser largement les inconvénients inhérents à ce langage, au nombre desquels il faut compter la lenteur d'exécution.

L'introduction d'un module approprié au problème traité entraine bien entendu la nécessité de son écriture en BASIC, donc une connaissance minimale du langage. D'autre part, le module doit être partiellement réécrit quand le modèle est modifié. Afin de limiter ces contraintes, nous avons écrit un programme BASIC interactif GENPROG, qui permet de générer facilement le module nécessaire pour le problème le plus courant: l'analyse de courbes pH-métriques ou potentiométriques. A partir de la description du modéle (nomenclature des espèces,

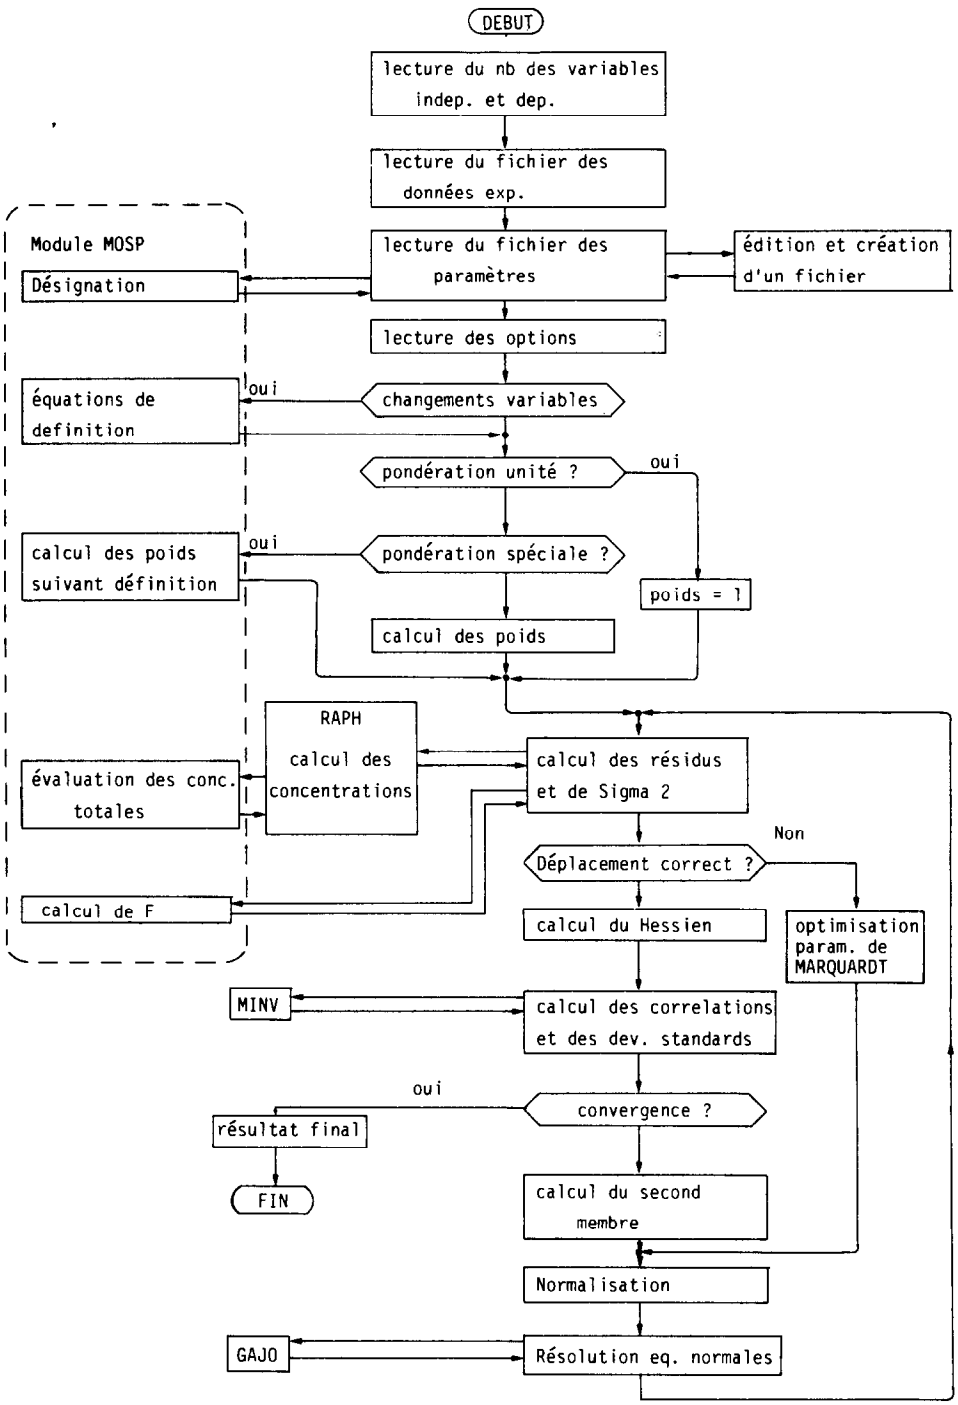

Fig. 1.

stoechiométrie, définition des constantes), le code engendré est très proche de l'écriture chimique et se résume à quelques expressions algébriques (bilans, équations). Aucun constituant ne joue de rôle particulier; leur nombre, ainsi que celui des espèces formées, n'est limité que par la capacité mémoire du système. Le BASIC étant interprété, le problème de la compilation du nouveau module ne se pose pas. Celui-ci vient simplement s'ajouter au programme principal.

Mise en oeuvre

L'éxécution débute par la lecture sur disquette du module MOSP et son chargement en mémoire centrale à la suite du programme principal. L'entrée des données et le choix des différentes options se font de manière interactive, les messages suivants sont affichés à l'écran.

1—Simulation (O/N)?
2—Nombre de variables indépendantes et de variables mesurées?
Nom du ficher des mesures?
Impression des couples (O/N)?
3—Nombre de points lus: *m*
Nombre de points à éliminer?
4—Nom du fichier des paramètres:
Corrections?
Nom du fichier des paramètres à créer:
5—Impressions intermédiares
Mise au point?
Edition du tableau valeurs calculées?
Edition des concentrations?
Edition de la courbe?
6—Valeurs initiales des concentrations:
7—Valeur initiale du facteur de Marquardt:
Facteur pour Newton–Raphson: 0.8
Facteur pour dérivation/paramètres: 1.001
Facteur pour dérivation/concentrations: 1.001
Précision: 10
OK?
8—Nombre maximum de cycles?
Calcul du Hessien tous les N cycles?
9—Correction sur les Y_i/Changement de variable?
10—Déviation standard sur les var. dépendantes?
Déviation standard sur les var. indépendantes?
Pondération (ENTER si poids égaux)?
Pondération spéciale? (ENTER = non).

Point 1—Si la réponse est oui, le calcul des observables conformément au modèle est fait à partir des valeurs fournies, l'étape de minimisation n'est pas effectuée; à l'issue de ce calcul, l'utilisateur est appelé à modifier tout ou partie des paramètres d'entrée, ce qui lui permet d'en évaluer l'incidence. Cette option pourra être utile notamment pour obtenir des approximations initiales satisfaisantes. Elle permet également d'évaluer l'intérêt potentiel d'une manipulation envisagée.

Point 2—Le fichier des mesures a été créé auparavant à l'aide d'un programme auxiliaire SAISIE V6. Ce programme est un éditeur de texte simplifié et adapté à la saisie des mesures, il évite le recours à un éditeur de texte standard.

Point 4—S'il existe déjà, le fichier des paramètres est lu. Sinon, la saisie se fait au clavier, elle est guidée par les informations présentes dans le module MOSP (la désignation de chaque paramétre s'affiche à l'écran). L'utilisateur répond en fournissant une valeur qu'il déclarera fixe ou ajustable. Une procédure de correction est prévue, et les données définitives sont éventuellement copiées dans un fichier.

Point 5—Ces diverses options assurent un contrôle des impressions des résultats intermédiaires.

Point 6—L'utilisateur fournit les valeurs des estimations initiales nécessaires au premier calcul des concentrations.

Point 7—Après avoir fourni une valeur initiale du facteur de Marquardt, (généralement 0.01), l'utilisateur peut, s'il le souhaite, modifier les valeurs par défaut des facteurs répertoriés. La constante introduite à la question "précision" est un terme multiplicatif qui contrôle la précision demandée sur les concentrations. Ainsi, la valeur typique 10 conduit à une précision $10^{-7}M$.

Point 8—Lorsque l'on est proche de la solution, un gain de temps appréciable peut fréquemment être obtenu en n'effectuant le calcul du Hessien que tous les deux ou trois cycles d'itération. Dans tous les cas, le Hessien sera calculé lors de l'itération finale.

Point 9—Une réponse positive entraîne le calcul de la correction ou du changement de variables définis dans le module MOSP.

Point 10—L'utilisateur est appelé à introduire les déviations standards sur les différentes variables dépendantes et indépendantes. Si l'option par défaut est retenue, un poids unité est affecté à chaque point. Sinon, l'évaluation des poids est faite selon l'expression générale (16) dans le programme principal, ou selon les modalités définies si l'option pondération spéciale a été retenue. Le calcul des dérivées partielles (16) au point i se fait en calculant les coefficients d'un polynôme du second degré approximant la courbe aux points de rang $(i-1)$, i, $(i+1)$; on en déduit la valeur de la dérivée au point i.

L'essentiel des données est rappelé sur l'imprimante au fur et à mesure de la saisie. A l'issue de celle-ci, on entre dans la boucle itérative principale (Fig. 1). En chaque point sont calculés les valeurs de Y et le résiduel correspondant en appelant RAPH, routine de calcul des concentrations selon Newton–Raphson. Cette routine incorpore les instructions d'appel du module MOSP qui fournit les expressions algébriques nécessaires au calcul des bilans. La somme pondérée des carrés des résiduels SIGMA est alors calculée.

Si le SIGMA ainsi obtenu est inférieur à la valeur de la précédente itération (à la première itération, la

comparaison se fait avec 10^{10}), les estimations des paramètres sont actualisées. On calcule le Jacobien, le Hessien, puis la matrice des coefficients de corrélation. Le Hessien est inversé dans la routine MINV utilisant la méthode du pivot maximal, et les variances sont calculées. La somme des carrés des résiduels SIGMA, la matrice de corrélation et les variances sont imprimées à chaque itération.

Dans le cas d'une itération divergente, le facteur de Marquardt est augmenté. Le système des équations normales modifiées (15) est à nouveau résolu et un nouveau SIGMA calculé. L'opération est répétée jusqu'à obtenir une itération convergente. Lorsque l'amélioration relative sur SIGMA devient inférieure à 0.001, le calcul se termine. Sinon, on procède à l'évaluation des seconds membres des équations normales, et de nouveaux déplacements sont calculés.

Les systèmes linéaires sont résolus par la méthode de Gauss–Jordan dans la routine GAJO.

Le développement de ce programme a été réalisé sur un TRS80 Model I Level II (48 K) équipé de deux unités de minidisquettes travaillant en double densité sous NEWDOS-80 V2 0. Le programme occupe 20 koctets (5 koctets sont dûs aux commentaires): 18 koctets sont donc utilisables pour les données. Tous les calculs sont exécutés en simple précision. Un listing du programme est disponible auprès des auteurs qui envisagent de réaliser une version utilisable sous CP/M 2.0.

RESULTATS

Afin d'illustrer quelques-unes des possibilités du programme MICMAC et d'en apprécier la validité, nous avons effectué une étude comparative avec des programmes récents traitant de problèmes divers.

Polarographie

Les travaux de Heath et Hefter[28] sur la détermination des constantes de stabilité des complexes cadmium–chlorure ont été exploités par Leggett[14] à l'aide du programme POLAG, puis plus récemment par Gomez-Nieto *et al.*[29] Il nous a donc semblé intéressant d'analyser à notre tour les mesures de Heath et Hefter.

L'ajustement sur la grandeur mesurée E_p conduit à minimiser l'expression:

$$U = \sum_i (E_{p_i}^{calc} - E_{p_i}^{exp})^2$$

avec

$$E_p^{calc} = E_p^0 - \frac{RT}{nF}\left(\log\frac{M_T}{M} - \log\frac{I_{p_0}}{I_p}\right)$$

où

M est solution des deux équations:

$M_T = M + M \cdot L \cdot \beta_1 + M \cdot L^2 \cdot \beta_2 + M \cdot L^3 \cdot \beta_3$ métal total

$L_T = L + M \cdot L \cdot \beta_1 + 2M \cdot L^2 \cdot \beta_2 + 3 \cdot M \cdot L^3 \cdot \beta_3$ ligand total

Il est également possible d'utiliser le traitement de DeFord et Hume[30] qui conduit à minimiser:

$$U = \sum_i (F0_i^{calc} - F0_i^{exp})^2$$

avec

$$F0^{calc} = \frac{M_T}{M}$$

$$F0^{exp} = \exp\left[\frac{nF}{RT}(E_p^0 - E_p) + \log\frac{I_{p_0}}{I_p}\right]$$

Nos résultats, ainsi que ceux de la littérature, sont rassemblés dans le tableau 1.

Nos valeurs de constantes sont identiques à celles obtenues par Gomez-Nieto *et al.* à l'aide des programmes F0W et GIP II.

Les différences observées avec Leggett ne peuvent s'expliquer par la simple lecture de son article. Par contre, l'examen de son listing permet de constater des erreurs dans les données ($10^{-3}M$ en cadmium au lieu de $4 \times 10^{-5}M$, ainsi que $I_p = 7.40$ au lieu de 7.37

pour $[Cl^-]_T = 0.4M$). Nous ne mettons pas en cause le programme POLAG puisque, en introduisant ces mêmes données, nous retrouvons des résultats identiques à ceux publiés par Leggett.

Il est assez remarquable de constater que les résultats obtenus en ajustant sur la grandeur mesurée E_p, sont identiques à ceux obtenus par ajustement pondéré, sur $F0$, mettant ainsi en évidence la nécessité de pondérer lorsque l'on n'ajuste pas sur la grandeur mesurée. Dans ce cas précis, nous avons estimé que l'erreur sur les concentrations était négligeable. L'expression du poids est donc:

$$\frac{1}{W_i} = \left(\frac{\partial F0}{\partial y}\sigma y\right)_i^2 = \left(\frac{nF}{RT}F0\,\sigma y\right)_i^2$$

pH-métrie: comparaison avec BEST

BEST[7] est l'un des rares programmes à ajuster sur la grandeur mesurée, ici le pH, se prêtant ainsi particulièrement bien à une étude comparative, d'autant plus que les auteurs fournissent un tableau des résiduels.

Complexes du cobalt. L'étude porte sur les complexes du cobalt en présence de deux ligands sous atmosphère d'oxygène; le système ne comporte pas moins de vingt-quatre espèces. Nous avons été satisfaits de constater l'excellent accord avec les auteurs de BEST, les résiduels obtenus à partir des mêmes paramètres étant strictement identiques. Les auteurs soulignant l'existence d'un léger déséquilibre des concentrations en acide et en base, nous avons entrepris d'ajuster conjointement le titre en acide et la constante β_{2210} de l'espèce 24. Les résultats sont rassemblés dans les tableaux 2 et 3.

L'ajustement simultané du titre en acide et de la constante améliore les résidus (σ^2 divisé par 2,5), les écarts autour des stoechiométries 1 et 5 sont moindres. La valeur $1.5009 \times 10^{-2}M$ obtenue pour l'acide est proche de la valeur initiale $1.5002 \times 10^{-2}M$, la variance est très faible et la corrélation entre les deux paramètres ajustés est de 0,2. L'ajustement du titre en acide nous paraît donc justifié et satisfaisant.

Nous avons d'autre part effectué les calculs avec et sans poids ($\sigma_x = 0.02$ ml; $\sigma_y = 0.002$ pH). Il apparaît que les deux valeurs sont compatibles entre elles, celle obtenue avec pondération se rapprochant davantage de celle de BEST; on peut cependant regretter que les auteurs ne donnent pas d'incertitude sur leur constante.

Dans le cadre de cette étude, nous avons pu vérifier l'efficacité de la méthode de la cible mouvante sans laquelle le calcul des concentrations diverge aux stoechiométries 1 et 5. Les auteurs de BEST, quant à eux, introduisent de nouvelles estimations initiales aux points critiques.

Base de Schiff. Le système étudié comporte treize espèces, l'ajustement porte sur les constantes de formation de la base de Schiff et de ses trois formes protonées. Comme précédemment, l'introduction des

*Déviation standard.

paramètres obtenus par BEST donne des résiduels identiques. Par contre, l'ajustement nous conduit à des conclusions différentes (Tableau 4).

Que ce soit avec ou sans pondération, la constante de formation de la base de Schiff β_{110} est rejetée par le programme (valeurs négatives, déviations standards démesurées, corrélation importante). Nous avons donc repris les calculs en éliminant cette espèce; l'ajustement est meilleur et les déviations standards diminuent de façon significative. L'influence du poids est plus particulièrement sensible lorsque cette espèce (110) est prise en compte: la colonne 1 se distingue des colonnes 2, 3 et 4 où les résultats obtenus sont très voisins.

Au vu de ces résultats, nous concluons que la base de Schiff totalement déprotonée n'existe pas et que le programme MICMAC semble à même de déterminer le minimum avec plus de précision. Cette différence est peut-être imputable au fait que BEST utilise un algorithme de type heuristique.

pH-métrie: comparaison avec TITFIT[8]

Le système Ni^{2+}–glycine a été très largement étudié ces dernières années. Il constitue donc une bonne base de comparaison. Nous avons repris les mesures des auteurs de TITFIT à partir des données figurant dans leur listing (ces données correspondent aux trois courbes de la figure 2 de leur article[8]). La comparaison nous paraît d'autant plus intéressante que TITFIT réalise l'ajustement sur les volumes de base titrante, alors que notre ajustement porte sur le pH.

Dans un premier temps, nous avons ajusté sur chacune des courbes les concentrations de l'acide fort ajouté et de la base titrante; cette démarche est analogue à l'ajustement des grandeurs Exac et EQ effectué par les auteurs.[8] L'ajustement des constantes a ensuite été réalisé en traitant simultanément les trois courbes et en utilisant les concentrations en acide et en base précédemment calculées (Tableau 5).

Nous sommes satisfaits de constater que deux programmes utilisant des démarches différentes conduisent à des valeurs de constantes identiques à partir des mêmes données. Dans ce cas précis, les résiduels sont très faibles, y compris au voisinage des points d'équivalence; la pondération faisant intervenir σ_{ml} et σ_{pH} n'a donc que peu d'influence. D'autre part, nous sommes en accord aves les auteurs de TITFIT lorsqu'ils rejettent l'hypothése d'un complexe hydroxylé Ni(gly)OH. En effet, l'introduction d'un tel complexe n'entraîne aucune amélioration de l'ajustement.

Résonance magnétique nucléaire du carbone-13

La résonance magnétique nucléaire, largement employée à des fins d'identification, a suscité relativement peu d'études quantitatives; cette méthode se prête pourtant bien à la détermination des constantes de stabilité, comme le montre l'étude menée par Surprenant *et al.*[13] sur la protonation de la lysine (programme PHFIT). Ne disposant pas de leurs données originales (couples déplacement chimique–pH), nous avons choisi de générer des courbes synthétiques à partir des résultats publiés par les auteurs (constantes d'acidité, déplacements chimiques des espèces libres et protonées). Nous avons ensuite ajouté aux déplacements chimiques ainsi calculés des erreurs aléatoires normalement distribuées afin d'obtenir des pseudo-valeurs expérimentales. L'ajustement porte sur les déplacements chimiques des deux carbones: C=O et C_δ, qui sont les plus influencés en présence de proton. La fonction à minimiser est:

$$U = \Sigma\Sigma\,(\delta_{calc} - \delta_{exp})^2$$

avec

$$\delta_{calc} = \sum_{i=1}^{4} F_i \delta_i$$

où F_i = fraction molaire de l'espèce i et δ_i son déplacement chimique. Les paramètres ajustables sont les trois constantes d'acidité de la lysine et, pour chaque carbone, les déplacements chimiques des espèces libres et protonées, soient onze paramètres ajustables. Nos résultats sont rassemblés dans le Tableau 6.

Les estimations des paramètres sont très proches des valeurs exactes et la variance obtenue est inférieure à la valeur attendue, ce qui indique un excellent ajustement. De plus, les écarts entre valeurs exactes et valeurs calculées sont en plein accord avec les estimations des déviations standards.

Cet exemple illustre la capacité du programme à effectuer l'ajustement de nombreux paramètres (onze ici) sur deux grandeurs observées. Des mesures spectrophotométriques à deux longueurs d'ondes, qui conduisent à des équations de même forme, peuvent être traitées de manière similaire.

Cette étude comparative démontre la validité du programme MICMAC et illustre sa très grande généralité et son aptitude à traiter des problèmes très divers, puisque nous avons pu montrer la capacité de ce seul programme à traiter des sujets nécessitant cinq programmes spécifiques. De plus, MICMAC semble dans certains cas à même de cerner le minimum avec plus de précision.

DISCUSSION

Le programme MICMAC exploite les avantages liés à l'utilisation d'un micro-ordinateur sans sacrifier aucunement à la rigueur du traitement statistique. Son champ d'applications est potentiellement très vaste et nous avons fait en sorte qu'il n'y ait aucune limitation (autre que la capacité-mémoire) dans la complexité du problème envisagé. Ce programme réunit diverses caractéristiques qui nous semblent particulièrement importantes: ajustement sur la grandeur mesurée, prise en compte des erreurs systématiques, expression rigoureuse de la pondération, utilisation de la méthode de Marquardt, estimations des erreurs. A notre connaissance, aucun programme publié à ce jour, excepté DALSFEK,[15] n'offre simultanément ces possibilités.

Cette approche générale n'est vraisemblablement pas la plus efficace pour l'étude spectrophotométrique à plus de trois ou quatre longueurs d'onde. Le programme de Maeder et Gampp[32] est dans ce cas plus performant. Par contre, le programme MICMAC est bien adapté au traitement simultané de plusieurs variables dépendantes (absorbance et pH par exemple à quelques longueurs d'onde).

En conclusion, le programme MICMAC offre de nombreuses possibilités dans le domaine de la détermination des constantes de stabilité. Il est également applicable à la détermination de concentrations lors de l'analyse des solutions par différents moyens. De plus, son côté hautement interactif et le fait qu'il permette une approche heuristique le rendent utilisable à des fins d'enseignement.

Remerciements—Certains auteurs cités dans ce travail nous ont fait parvenir leur listing et nous tenons à les en remercier.

Summary—The basic computer program MICMAC has been developed to fit equilibrium constants to various types of experimental data with a microcomputer. The program uses the very efficient Gauss–Newton–Marquardt algorithm for non-linear least-squares multiparametric refinement. Highly interactive, convenient to use and of modular design, it allows for a rigorous weighting scheme, and it takes account of possible systematic errors. This program is useful for solving problems with several sets of experimental data. Some examples dealing with polarography, pH-metric titration and ^{13}C-NMR are given, illustrating the versatility of MICMAC. Comparison is made with some recently published programs.

CALCULATION OF EQUILIBRIUM CONSTANTS FROM MULTIWAVELENGTH SPECTROSCOPIC DATA—II*

SPECFIT: TWO USER-FRIENDLY PROGRAMS IN BASIC AND STANDARD FORTRAN 77

HARALD GAMPP, MARCEL MAEDER, CHARLES J. MEYER and ANDREAS D. ZUBERBÜHLER
Institute of Inorganic Chemistry, University of Basel, CH-4056 Basel, Switzerland

(*Received* 5 *October* 1984. *Accepted* 5 *December* 1984)

Summary—A new program (SPECFIT), written in HP BASIC or FORTRAN 77, for the calculation of stability constants from spectroscopic data, is presented. Stability constants have been successfully calculated from multiwavelength spectrophotometric and EPR data, but the program can be equally well applied to the numerical treatment of other spectroscopic measurements. The special features included in SPECFIT to improve convergence, increase numerical reliability, and minimize memory as well as computing time requirements, include (*i*) elimination of the linear parameters (*i.e.*, molar absorptivities), (*ii*) the use of analytical instead of numerical derivatives and (*iii*) factor analysis. Calculation of stability constants from spectroscopic data is then as straightforward as from potentiometric titration curves and gives results of analogous reproducibility. The spectroscopic method has proved, however, to be superior in discrimination between chemical models.

Spectrophotometry has long been used for analysis of chemical equilibria,[1–3] but generally only for relatively simple systems which can be described by linearized functions, as for example in the Benesi–Hildebrand method.[4] This may be partly due to the still widespread belief that spectrophotometric measurements are inherently less precise than potentiometric ones,[5] though this is definitely not the case with suitable instrumentation.[6] The paucity of reliable general computer programs that could deal successfully with spectrophotometric data for more complicated equilibrium systems[2,3,7,8] may be another reason.

As discussed in Part I of this work,[9] three main features have been combined in our program SPECFIT with the Marquardt algorithm[10,11] for the non-linear least-squares refinement of the unknown equilibrium constants. (*i*) The molar absorptivities (ε) are replaced by their least-squares estimates ($\hat{\varepsilon}$), making the matrix of the residuals (**R**) a function of only the species concentrations (**C**) and the measured absorbances (**Y**):[12–15]

$$\mathbf{R} = \mathbf{F} - \mathbf{Y} = \mathbf{C}\varepsilon - \mathbf{Y} = \mathbf{C}\hat{\varepsilon} - \mathbf{Y}$$
$$= \mathbf{C}(\mathbf{C}^t\mathbf{C})^{-1}\mathbf{C}^t\mathbf{Y} - \mathbf{Y} \qquad (1)$$

R, **F** and **Y** all are $M \times W$ matrices for M solutions measured at W wavelengths. (*ii*) The numerical derivatives generally used in previous programs for the treatment of spectrophotometric data[7,13–15] are replaced by the exact analytical expressions in the calculation of the Jacobian matrix **J** (the partial derivatives of the fitting function **F** with respect to the unknown equilibrium constants):

$$\mathbf{J} = \mathbf{DR} = \mathbf{DF} = \mathbf{D}(\mathbf{C}\hat{\varepsilon}) = \mathbf{DC}\hat{\varepsilon} + \mathbf{CD}\hat{\varepsilon} \qquad (2)$$

J and **DC** are tensors with dimensions $M \times W \times N$ and $M \times S \times N$, respectively (S = number of absorbing species, N = number of unknown stability constants).

Analytical derivatives have been used in the calculation of equilibrium constants from potentiometric data[16–19] and a general expression for functions containing both linear and non-linear parameters as in equation (1) has been discussed,[20] but the algorithm implemented in SPECFIT does not seem to have been previously applied to the determination of equilibrium constants from spectroscopic data. (*iii*) The original data matrix **Y** is subjected to factor analysis:

$$\mathbf{Y} = \mathbf{LV} \simeq \mathbf{L}_I\mathbf{V}_I \qquad (3)$$

where **V** contains the eigenvectors of the second moment matrix $\mathbf{Y}^t\mathbf{Y}$ and **L** is the matrix of the corresponding linear coefficients, and parameter refinement is then done with the $M \times I$ matrix $\mathbf{L}_I$ instead of **Y** in equations (1) and (2). Factor analysis has been used to find the number of linearly independent absorbing species in a chemical system[21–24] and applied to the determination of equilibrium constants from spectrophotometric data.[25,26] In the absence of experimental errors, the number of significant eigenvectors, I, would be identical with the mathematical rank of **Y**. Replacement of **Y** by $\mathbf{L}_I$ saves a lot of computer space without significant loss of information from multiwavelength data.

SPECFIT—HP 9835 VERSION

We have long advocated use of desk-top computers,[15,19,27,28] and as we collect all our data online,[6,28] our first (and preferred) version of SPECFIT, which is analogous to TITFIT,[19] was developed for

*Part I: *Talanta*, 1985, **32**, 95.

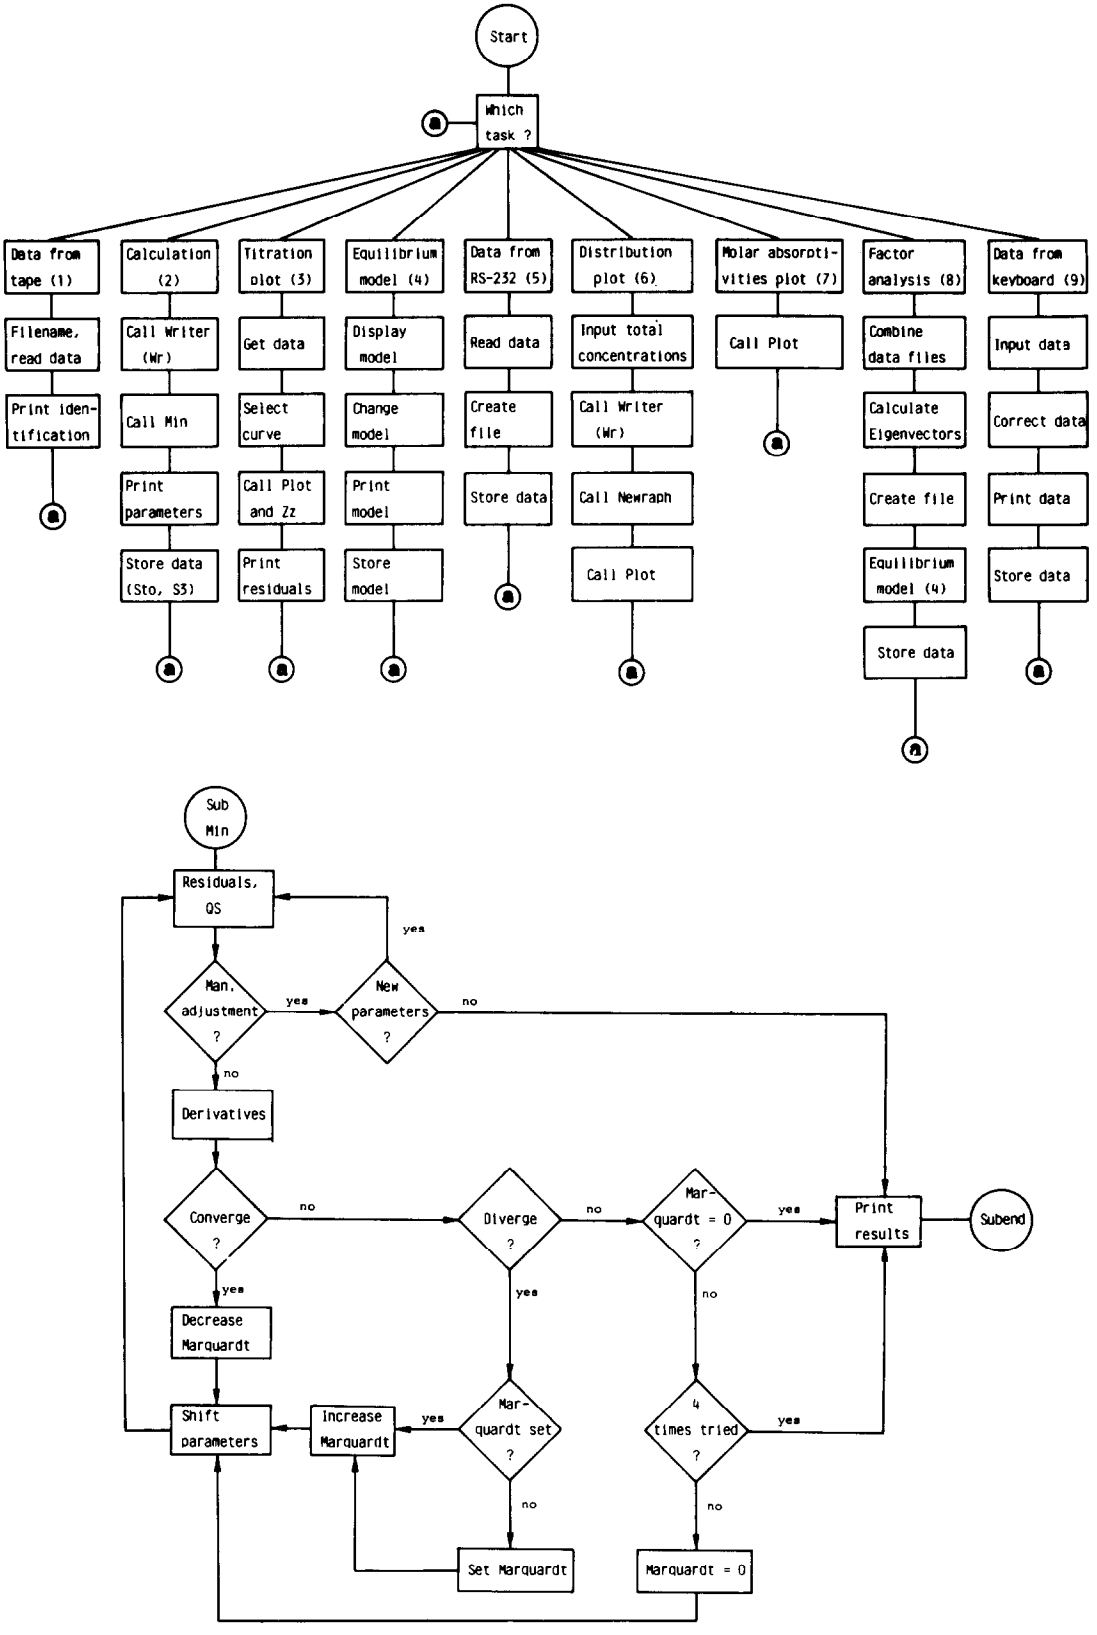

Fig. 1. Flow diagram for the program SPECFIT.

a 128-K Hewlett-Packard HP 9835 calculator. It performs nine different tasks, shown in Fig. 1.

Our experimental data are read through an RS-232 serial interface (task 5) from our data-acquisition system,[6,15] but data can also be input through the keyboard (task 9). In both cases, the number of wavelengths (W) and spectra (M), the maximum wavelength (Lm) and the interval between the wavelengths used for absorbance readings (Dl) are read first, followed by the arrays of absorbances, proton activities and analytical concentrations of metal and ligand. The data are then stored on tape and can be retrieved by task 1.

The least-squares fitting can be done on the original data, but the absorbances are usually first subjected to factor analysis (task 8). Data from up to 6 experiments are combined into a single array and the maximum number of eigenvectors Ne is entered. The program then tries to obtain the Ne most significant eigenvectors by vector iteration.[29] If the residual standard error falls below a prespecified limit or no convergence is obtained after 50 cycles for a given eigenvector, the calculation is terminated and the number of eigenvectors is set accordingly. The appropriate model is then defined (task 4) and the eigenvectors, their linear coefficients, and the chemical model are stored on tape. All the tasks are independent and can be accessed in any logical order by stopping execution of the program at any time, and executing CONTF from the keyboard.

When task 4 is called, the current model is displayed on the screen. Each species is defined by a number, the value of the stability constant $\beta_{mlh} = [M_m L_l H_h]/[M]^m[L]^l[H]^h$, the defining code (*e.g.*, $11-2$ for MLH_{-2}), an index (0 for fixed parameters, 1 for variable parameters, 2 to eliminate the species from the model), and whether the species is absorbing (Y) or not (N). An example is given in Table 1. Species may be added or deleted in any given order. After correction the model is stored on tape and a flag set to indicate whether the model or only the stability constant values had been changed.

The least-squares refinement is done in task 2, as already described in detail for TITFIT.[19] A simplified flow diagram of the minimization routine Min is also given in Fig. 1. In Newraph, the $M \times S$ concentration matrix **C** is established along with the tensor of partial derivatives **DC** with $M \times S \times N$ elements $\partial \mathbf{C}(m, s)/\partial \log\beta_n$. Back in the main minimization routine, the residuals and their dot product (sum of squares, SQ) are calculated.

If manual adjustment of parameters has been selected, the program now asks for their change and repeats the calculation. Normally, however, the refinement is done fully automatically, the Jacobian matrix $\mathbf{J} = \mathbf{DF}$ [equation (2)] being calculated in the subprogram Deriv and the Hessian[30] $\mathbf{J}^t\mathbf{J}$ as well as $\mathbf{J}^t\mathbf{R}$ built; calculation of the parameter shifts and the iterative refinement then proceed, essentially as in TITFIT.[19] Again it is advantageous to introduce the Marquardt correction only in the case of divergence, and to change the Marquardt parameter by less than a factor of 10. There is no unique optimal strategy, but increase by a factor of 5 for divergence and decrease by a factor of 3 for convergence perform satisfactorily. When the final set of parameters has been found or manual adjustment abandoned, the spectra of all absorbing species are calculated and all species concentrations, equilibrium constants and molar absorptivities are printed, with their standard errors. Finally, λ_{max} and ε_{max} are calculated by quadratic interpolation and all parameters and species concentrations are stored on tape.

Various plotting routines are available for graphical presentation of the results. Task 3 can plot experimental data and calculated titration curves for any selected wavelength(s) or can print out the complete matrix of residuals, **R**, and/or its graphical representation. For economy in memory Newraph is destroyed if this last option is selected, and is automatically reconstructed before further calculation of equilibrium constants.

Task 6 calculates the species distributions between pH 2 and 12 for a given chemical model and associated equilibrium constants, for any selected analytical (total) concentrations of the components. Again, Newraph is destroyed and then rewritten for further calculations.

Task 7 automatically plots the spectra of all the absorbing species from the latest calculation. In our HP 9835 version of SPECFIT, **C** and ε are kept on tape for only the latest calculation, for purely economic reasons; this can easily be changed by rewriting three or four lines of program code, or **C** and ε can be recalculated in a single iterative cycle with the final complexation model.

This version of SPECFIT provides for the handling of up to 125 spectra with 9 absorbing species and 16

Table 1. Display of defining model for Cu^{2+}/L-alaninamide

No.	Formula	Value	log K*	Parameters fixed/variable	log[(K + s)/K]*	Colour
1	011	1.510×10^8	8.18	0	0.0000	N
2	110	1.800×10^5	5.26	1	0.0000	Y

*Taken care of by the program.

equilibrium constants. Since the matrices can be redimensioned, more spectra can be handled with models made up of fewer species, and vice versa. SPECFIT is about 30 kbytes long and needs 2–4 additional kbytes for Newraph, but not all dimensions can be set simultaneously at their maximum values without producing memory overflow. The $M \times S \times N$ tensor DC [equation (2)] is the most problematic in this respect (the other tensor J is needed only column by column in SPECFIT). For 100 spectra, 9 species, 9 unknown equilibrium constants and normal precision (10 bytes per data variable) DC would occupy 81 kbytes of memory, which is not allowed, since no single array may occupy more than 64 kbytes of memory. The situation can be eased by using the SHORT notation (6 bytes per variable) but some restrictions remain. Because of the variability of the program code and the size of many matrices it is impossible to give exact limits. The complexation of Cu^{2+} with L-alaninamide (L), see below (62 spectra, 17 wavelengths, 7 eigenvectors) could be handled in the normal way for the model Cu^{2+}, L, LH^{+}, CuL^{2+}, CuL_2^{2+}, $CuLH_{-1}^{+}$, $CuL_2H_{-1}^{+}$ and CuL_2H_{-2} with 6 (5 unknown) equilibrium constants, but the SHORT notation was necessary with the additional species $CuLH_{-2}$.

Space may also be saved by loading only those parts of the program which are actually needed, or by continuous shuffling of data between memory and the data cartridge. A calculator of the HP 9835 type has its limits, however, and the algorithm developed for SPECFIT[9] can handle bigger problems.

SPECFIT—FORTRAN 77 VERSION

For the reasons just given, SPECFIT has been rewritten in standard FORTRAN 77 and implemented on a UNIVAC 1100/61 computer. Only standard instructions were used, and the program should run with almost any version of FORTRAN IV with a minimum of alterations. Our data are transferred directly from an APPLE II (which is used as an intelligent terminal; *cf.* task 5 in Fig. 1) and tasks 1, 2, 4, 8 and 9 are performed under remote control through a DIGITAL VT 132 terminal. Plotting routines are not implemented, but otherwise the interactive facilities of this program are practically identical with the HP 9835 version. However, the program is not easily transferable to other computers or usable without the necessary on-line facilities. We have therefore developed a third and easily transferable version designed to operate in batch mode. The FORTRAN programs differ from the HP 9835 version in several points. (*i*) The number of components (metal ions and ligands) is not restricted to two. (*ii*) A completely general subroutine is used for calculation of the concentration matrix C and its derivative DC. (*iii*) Known spectra may be included and kept constant as described earlier.[9] (*iv*) Dimensions have been set at 6 components, 10 absorbing species and eigenvectors, 20 equilibrium constants (10 adjustable), 15 fixed spectra, 150 measurements at 50 wavelengths, all changeable by simple modification of the PARAMETER statements, to allow for more involved models or less powerful computer systems. Data input differs from the interactive versions, because all the options must now be defined at the

Listings of both the HP 9835 and the FORTRAN 77 version are available from the authors upon request. The programs may also be provided on an HP 200 data Cartridge, in the form of punched cards, or on tape (FORTRAN version), together with the sample data for the complexation of Cu^{2+} by 3,6,9-triazaundecane. Detailed input instructions will be provided with the FORTRAN 77 version.

RESULTS AND DISCUSSION

SPECFIT has been successfully used both for spectrophotometric[31–35] and for EPR[36,37] titration data. Over 30 equilibrium systems have been studied. Complexation models containing between two[32] and ten[35] absorbing species (1–9 equilibrium constants) were successfully fitted to the experimental data. Additional results have been obtained with the precursor of SPECFIT, ELORMA.[15,38–40] In all cases which permitted direct comparison, the spectrophotometric method was equal to or better than potentiometric titration in discriminatory power between different models,[34,35,40] with comparable reproducibility and estimated standard errors. Spectrophotometric titrations have the additional advantage of providing valuable structural information through the spectra of the individual species, which is not possible by potentiometry.

Some aspects of practical interest will now be discussed, namely the ability of SPECFIT to find the correct parameters, starting from poor estimates; the usefulness of SPECFIT for discrimination between several chemical models of complexation; the application of SPECFIT to rather complicated equilibrium systems.

(*i*) In order to test the ability of the program to find the best set of parameters, starting from poor estimates, a spectrophotometric titration of Cu^{2+} and 3,6,9-triazaundecane (diethyldien, DED) was selected. In this system, which has been studied both potentiometrically and spectrophotometrically, the complexes $CuLH^{3+}$, CuL^{2+} and $CuLH_{-1}^{+}$ [$=CuL(OH)^{+}$] are formed.[34] Under the experimental conditions (*cf.* footnote to Table 2) $CuLH^{3+}$ is never more than 10% of the total, with a maximum at around pH 4, which makes the system reasonably critical. In Table 2 the results of systematically varying the estimates are given. The same parameters and sum of squares of residuals are calculated, even if the estimates are out by a factor of 1000 in either direction. A factor of 1000 is in fact close to a blind guess and substantially better estimates can normally be obtained even without inspection of the actual data. For instance, the deprotonation of CuL^{2+} to

Table 2. Results of varying the estimates of the non-linear parameters for the titration of Cu^{2+} and 3,6,9-triazaundecane (DED)*

Initial estimates†			Number of iterations required with

1.03×10^{15}	$/f$	1.85×10^{5}‡	3	3	3	3

*Experimental conditions: $[Cu^{2+}] = 4mM$, $[DED] = 5mM$, $[H^+] = 10mM$; 31 spectra between pH 2 and 12 were taken at 10-nm intervals between 800 and 550 nm.[34]

†As initial estimates, the least-squares estimates $\beta_{110} = 1.04 \times 10^{15}$, $\beta_{111} = 3.79 \times 10^{18}$, and $\beta_{11-1} = 2.21 \times 10^{5}$, were used and multiplied ($\times$) or divided ($/$) by the factor f. The overall standard deviation of the data is $\sigma_y = 0.0008$.

‡For β_{110} and β_{11-1} the results of the calculation without taking into account $CuLH^{3+}$ (1.03×10^{15} and 1.85×10^{5}, respectively) were used as estimates. The reduced model gave $\sigma_y = 0.004$.

form the hydroxo complex $CuLH_{-1}^{+}$ must occur around pH 9–10, while pK^{H}-values of 6 and 12 are equally absurd for this complex with an N_3O set of donor atoms. As one iteration takes 62.5 sec on the HP 9835, even with the poorest and quite unrealistic estimates the calculation does not take more than about 30 min.

A remarkable fact shown in Table 2 is that the number of iterations is not strongly correlated to the quality of the estimates unless all of them are chosen too small. However, starting from low estimates still seems to be the best approach since the number of iterations is always less than for any other combination.

Of course, more realistically the calculation would first be done with a reduced model, where only β_{110} and β_{11-1} (corresponding to the major and primarily expected species[34]) are refined. $CuLH^{3+}$ would only be introduced at a later stage, when it had become obvious that the simple model was unsatisfactory. The corresponding results are summarized in Table 2 (last two lines) and show that the best strategy is to start from estimates which are likely to be too small (*i.e.*, assuming a low stability of the complex), if an additional species has to be introduced. This consistently requires only three iterations, even if the estimate is out by three orders of magnitude, whereas with too large a starting value for β_{111} the use of good estimates for the other parameters is of no advantage.

(*ii*) The fact that spectrophotometric titrations are superior to potentiometric ones with respect to differentiation between several models of complexation has already been demonstrated for several systems.[34,35,40] Here we want to show that EPR titration data also allow an easy distinction between chemical models and are useful for the calculation of equilibrium constants. As an example we discuss the equilibria between Cu(II) and the ligand 4,7,10-triazatridecane-1,13-diamine (AMINE).[37] The experimental conditions are given in the caption to Fig. 2. The data set consisting of 31 spectra at 50 magnetic field strengths was first subjected to an eigenvector analysis. Representing the data by three eigenvectors resulted in a standard deviation of 1.7%. Including a fourth eigenvector reduced this value to 1.0% of the average measured signal (median of the first derivative of the intensity with respect to the magnetic field strength) as is to be expected for a representation of the data within the limits of the experimental error.[36] Therefore, it can be concluded that four paramagnetic species occur in the chemical system, in accordance with the results of a combined potentiometric and spectrophotometric study[34] which revealed the paramagnetic species Cu^{2+}, $CuLH_2^{4+}$, $CuLH^{3+}$ and CuL^{2+}. Nevertheless, we first tried to omit $CuLH_4^{2+}$ (a complex which is never more than 30% of the total, with a maximum at around pH 3.5 under the experimental conditions). The standard deviation thus obtained was 6.0% and the parameters $\log\beta_{110}$ and $\log\beta_{111}$ were calculated to be 20.91 (± 0.07) and 30.55 (± 0.02), respectively. Including the species $CuLH_2^{4+}$ reduced the overall standard deviation by a factor of five to 1.1% and gave $\log\beta$-values of 21.63, 30.58 and 33.78. The standard error in the calculated parameters was decreased to 0.01 in each case. The satisfactory description of the data by the complete model is nicely demonstrated by the respective plots of the residuals, Fig. 2. With the complete model a rather smooth error surface is obtained (Fig. 2a), but this is not at all the case if the complex $CuLH_2^{4+}$ is omitted (Fig. 2b), the errors then being much larger and also by no means randomly distributed, but obviously giving a spectrum-like distribution, corresponding to the missing species. This illustrates how clearly we can distinguish between different chemical models, even in cases where not all the complexes are formed to a major extent.

It is also satisfying to note the easy adaptation of the method to use of data other than spectrophotometric, especially EPR, which so far has hardly been used for the numerical analysis of complexation equilibria involving several species.[36,41]

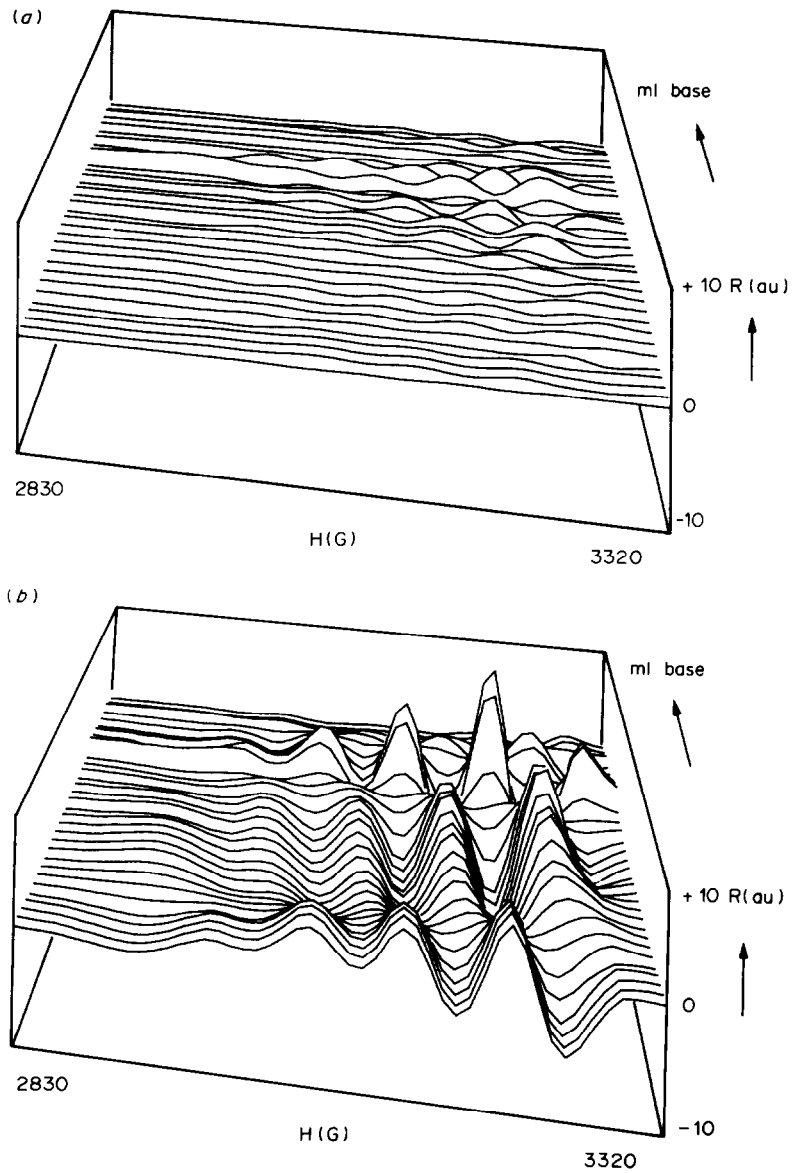

Fig. 2. Three-dimensional plot of the residuals from EPR titration of the Cu^{2+}/AMINE system. A mixture of Cu^{2+} (19.4m*M*), AMINE (20.0m*M*), and HCl (20.0m*M*) was titrated with NaOH (0.5*M*) at 25°, $I = 0.5M$; (*a*) complete model, including Cu^{2+}, $CuLH_2^{4+}$, $CuLH^{3+}$ and CuL^{2+}; overall standard error 1.1% (=0.4 arbitrary units) (*b*) same without $CuLH_2^{4+}$; overall standard error 6% (=2.0 arbitrary units).

(*iii*) Spectrophotometric data have been successfully used to deal with rather complicated systems described by six,[40] seven,[40] or even ten[35] absorbing species. We may cite the performance of SPECFIT in elucidating the equilibria between Cu^{2+} and L-alaninamide. A previous potentiometric study had shown the existence of Cu^{2+}, CuL^{2+}, $CuLH_{-1}^{+}$, CuL_2^{2+}, $CuL_2H_{-1}^{+}$ and CuL_2H_{-2}, *i.e.*, six cupric species.[31] Because the 1:1 and 1:2 complexes coexist the stability constants cannot be determined from a single experiment, and two titrations with metal:ligand ratios of 0.46 and 0.25 were combined for the calculation.

The data set consisted of 62 spectra recorded at 17 wavelengths, between 460 and 780 nm, *i.e.*, 1054 absorbance data. Representing the measured spectra as a linear combination of 7 eigenvectors reduced the number of data to be handled in the least-squares calculation to $7 \times 62 = 434$. Even if the data had been collected at many more wavelengths, the eigenvector representation would have reduced the data set to this same number.

With the model suggested by potentiometry, an overall standard deviation of 0.0009 for the absorbance was calculated. Although this value indicates a satisfactory fit of the data (corresponding to 0.35% of the maximum measured absorbance, or to 0.9% of the average of the data), the calculated logarithmic

Table 3. Stability constants for the Cu^{2+}/L-alaninamide system with standard errors

Stoichiometry MLH	$\log \beta^*_{mlh}$	$\log \beta^\dagger_{mlh}$	$\log \beta^\ddagger_{mlh}$
110	5.06 (0.009)	5.07 (0.004)	5.08 ($\leq$0.02)

11 − 1	−2.13 (0.023)	−2.14 (0.010)	−2.14 (0.04)
12 − 1	1.84 (0.025)	1.95 (0.011)	2.01 ($\leq$0.02)
12 − 2	−6.31 (0.027)	−6.19 (0.012)	−6.14 ($\leq$0.02)
11 − 2		−10.87 (0.046)	

*From spectrophotometry, without $CuLH_{-2}$, $\sigma_y = 0.0009$.
†From spectrophotometry, complete model, $\sigma_y = 0.0003$.
‡From potentiometry.[31]

stability constants of the 1:2 complexes were on average smaller than the corresponding potentiometric values by 0.16, as shown in Table 3. Inclusion of the species $CuLH_{-2}$, a species which is to be expected from chemical reasoning (but could not be found potentiometrically), significantly improves the fit of the data. As shown in Table 3, the overall standard deviation of the absorbance is reduced to 0.0003 and the discrepancy between the logarithmic stability constants obtained by the two methods becomes 0.06. Surprisingly, although $CuLH_{-2}$ significantly improves the fit to the data, it forms no more than 2% of the total, as can be seen from the distribution curves in Fig. 3.

The standard error of the logarithmic stability constants (*cf.* Table 3) is 0.01; only for $\log \beta_{11-2}$ is a larger value (0.05) obtained. In contrast, potentiometry[34] did not suggest a species $CuLH_{-2}$ and even the error for β_{11-1} was relatively large. That spectrophotometry leads to a more complete description of this complicated system is indicated not only by statistical criteria. The calculated stability of $CuLH_{-2}$ corresponds to the formation of this species at pH 8.73, which is as expected for a Cu^{2+} complex containing the N_2O_2 donor set, with one amino and one deprotonated amide group.[42] The spectra of the individual species (Fig. 4) are typical for Cu(II), and their characteristics are readily understood in terms of the expected structures.[34] Even the spectrum of $CuLH_{-2}$ is reasonably well defined. Because of the small concentration of this species, it is not a perfectly smooth curve, however.

Thus, equilibrium constants calculated from potentiometric or from spectrophotometric data compare very well in the system Cu(II)–L-alaninamide. Again, spectrophotometry has proved superior in its discriminatory power between different chemical models of complexation. It should be noted that determination of $CuLH_{-2}$ with a maximum formation of 2% is close to the limits of the spectrophotometric method in our laboratory. In fact, overall standard deviations of 0.0003 for the absorbance cannot be obtained consistently for the combination of two or more titrations. As working criteria, errors of 0.0006–0.0009 in the absorbances and a minimum of 5% complex formation would be more realistic. This has, however, nothing to do with the performance of SPECFIT, but is simply a question of the quality of the experimental data.

In conclusion, we state that with use of SPECFIT the evaluation of spectroscopic titrations is completely straightforward. Both versions are easily handled because the programs can be used as black boxes and only estimates for the stability constants are

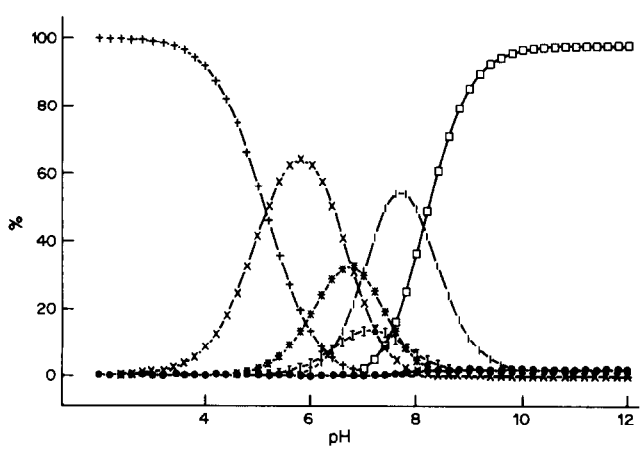

Fig. 3. Species distribution as a function of pH for the Cu^{2+}/L-alaninamide system. + Cu^{2+}_{aq}, × CuL^{2+}, ★ CuL_2^{2+}, I $CuLH^{+}_{-1}$, I $CuL_2H^{+}_{-1}$, □ CuL_2H_{-2}, ● $CuLH_{-2}$. The results are given as the percentage of the total metal present and are calculated for $[Cu^{2+}] = 5.5mM$ and $[L] = 12mM$) with the stability constants obtained spectrophotometrically (*cf.* Table 3).

required. Owing to the eigenvector representation, both computer memory and time requirements are minimized, and rather complicated systems can be treated even by a chemist who has no access to a mainframe computer.

GRAPHICAL EVALUATION OF COMPLEXOMETRIC TITRATION CURVES

JOSE L. GUINON
Departamento de Química, E.T.S.I. Industriales, Universidad Politécnica de Valencia, Spain

(*Received* 4 *October* 1983. *Revised* 15 *May* 1984. *Accepted* 5 *December* 1984)

Summary—A graphical method, based on logarithmic concentration diagrams, for construction, without any calculations, of complexometric titration curves is examined. The titration curves obtained for different kinds of unidentate, bidentate and quadridentate ligands clearly show why only chelating ligands are usually used in titrimetric analysis. The method has also been applied to two practical cases where unidentate ligands are used: (*a*) the complexometric determination of mercury(II) with halides and (*b*) the determination of cyanide with silver, which involves both a complexation and a precipitation system; for this purpose construction of the diagrams for the $HgCl_2/HgCl^+/Hg^{2+}$ and $Ag(CN)_2^-/AgCN/CN^-$ systems is considered in detail.

In the teaching of titrimetric analysis, titration curves are effective illustrations of the sharp jump in certain parameters (pH, pM, pL, *etc.*) in the vicinity of the equivalence point, which allows detection of the end-point by means of chemical indicators or instrumental methods (*e.g.* potentiometry).

For complexometric titrations, however, the usual textbooks give calculations of points on the theoretical titration curve only for the chelating ligands which form ML complexes, whereas for unidentate and bidentate ligands forming compounds of type ML, only the graphs of the corresponding titration curves are shown, without details of the calculation. The reader may therefore miss the reason why the curves for titration with unidentate or bidentate ligands do not generally show sharp jumps in pM or pL in the region of the points corresponding to the individual complexes which are formed stepwise.

The logarithmic concentration diagrams developed and popularized by Scandinavian chemists have been used for solving graphically several problems related to equilibria in solution and/or titrimetric analysis, *e.g.*, in the determination of the sharpness index at the equivalence point of acid–base titrations,[1] evaluation of the solubility of hydrolysable salts,[2] estimation of titration errors in acid–base titration,[3] and the theoretical feasibility of complexometric back-titrations.[4] The graphical method has several times been applied to construction of complexometric titration curves,[5–8] but has either been used only for chelating ligands,[5,6] or has failed to prove of general application.[7,8]

The present paper reports the use of logarithmic concentration diagrams for obtaining complexometric titration curves for several types of ligand, and its application to some particular cases, such as the determination of mercury(II) with halides and the titration of cyanide with a standard solution of a silver salt.

TITRATION CURVES OF METAL IONS WITH LIGANDS

Let us consider a metal ion M with a co-ordination number of 4, and unidentate, bidentate and quadridentate ligands (L), which form different complexes with it, all of them having the same value of the overall formation constant, $\beta_1 = \beta_2 = \beta_4 = 10^{20}$. We will use the values employed in Skoog and West's textbook.[9] Charges are omitted, for both clarity and generality.

Quadridentate ligand

$$M + L \rightleftharpoons ML \qquad K_1 = [ML]/[M][L] = 10^{20} \qquad (1)$$

Bidentate ligand

$$M + L \rightleftharpoons ML \qquad K_1 = [ML/[M][L] = 10^{12} \qquad (2)$$

$$ML + L \rightleftharpoons ML_2 \qquad K_2 = [ML_2]/[ML][L] = 10^{8} \qquad (3)$$

Unidentate ligand

$$M + L \rightleftharpoons ML \qquad K_1 = [ML]/[M][L] = 10^{8} \qquad (4)$$

$$ML + L \rightleftharpoons ML_2 \qquad K_2 = [ML_2]/[ML][L] = 10^{6} \qquad (5)$$

$$ML_2 + L \rightleftharpoons ML_3 \qquad K_3 = [ML_3]/[ML_2][L] = 10^{4} \qquad (6)$$

$$ML_3 + L \rightleftharpoons ML_4 \qquad K_4 = [ML_4]/[ML_3][L] = 10^{2} \qquad (7)$$

To conform with practical use, these equilibrium constants, K_i, should be considered to be conditional stability constants, K_i'.

Example 1. *Quadridentate ligand*

The concentrations of the various species can be expressed for different concentrations of L by the following equations, obtained by combining the mass balance, $c_M = [M] + [ML]$, with equation (1):

$$\log [M] = \log c_M - \log (1 + K_1[L]) \qquad (8)$$

$$\log [ML] = \log c_M + \log K_1 - pL - \log (1 + K_1[L]) \qquad (9)$$

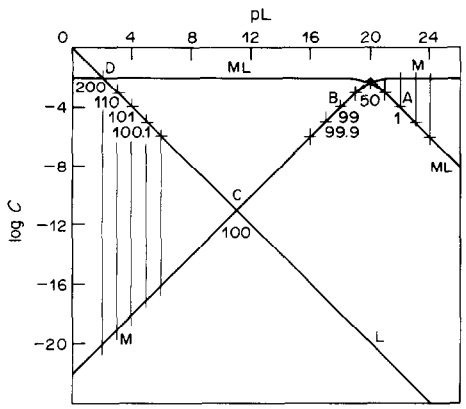

Fig. 1. Logarithmic concentration diagram of system ML/M, $c_M = 10^{-2}M$, $\log K_1 = 20$.

The master variable is the free ligand concentration [L], expressed as $pL = -\log [L]$. On the basis of these equations, graphs of $\log [M]$ and $\log [ML]$ *vs.* pL can be drawn by the usual procedure.[10-13] The logarithmic concentration diagram of system ML/M for $c_M = 10^{-2}M$ and $\log K_1 = 20$ is shown in Fig. 1.

The titration curve of pM *vs.* X, where $X = 100\, c_L/c_M$ is the degree of titration expressed as a percentage, is easily obtained from the logarithmic diagram in the way discussed by various authors.[5-8] In Fig. 1, several values of X (point A, $X = 1\%$, pM = 2; point S, $X = 50\%$, pM = 2.3; point B, $X = 99\%$, pM = 4; .... point C, $X = 100\%$, pM = 11; ... point D, $X = 200\%$, pM = 20) are shown on lines ML, M and L of the diagram, and from them the titration curve of pM *vs.* X is plotted, as shown in Fig. 2.

Example 2. Bidentate ligand

The concentration of the various species can be expressed in a similar way as for the case of the quadridentate ligand, for different concentrations of L, by the following equations, which are obtained by combining the mass balance, $c_M = [M] + [ML] + [ML_2]$, with equations (2) and (3).

$$\log [M] = \log c_M - \log (1 + K_1[L] + K_1K_2[L]^2) \quad (10)$$

$$\log [ML] = \log c_M + \log K_1[L] - \log (1 + K_1[L] + K_1K_2[L]^2) \quad (11)$$

$$\log [ML_2] = \log c_M + \log K_1K_2[L]^2 - \log (1 + K_1[L] + K_1K_2[L]_2) \quad (12)$$

Equations (10)–(12) yield a family of curves, the shapes of which depend on the ratio of the two formation constants. The logarithmic concentration diagram of system $ML_2/ML/M$ for $c_M = 10^{-2}M$ and $\log K_1 = 12$, $\log K_2 = 8$, is shown in Fig. 3.

The graphical method outlined above may be extended to obtain the titration curve of pM *vs.* X. The first part of the titration, corresponding to the formation of the complex ML, will be similar to that for the quadridentate ligand ($X = 1\%$, pM = 2; $X = 10\%$, pM = 2; $X = 50\%$, pM = 2.3; $X = 90\%$, pM = 3) (see Fig. 3). The crossing point A corresponds to the equality $[M] = [ML_2]$, so the equilibrium $2ML \rightleftharpoons M + ML_2$ gives

$$[ML] = c_M - [M] - [ML_2] = c_M - 2[ML_2],$$

and

$$[ML] = c_L - 2[ML_2] - [L] \sim c_L - 2[ML_2].$$

Thus, $c_M = c_L$ and therefore $X = 100\%$, so at the first equivalence point, $pM_{x=100} = 4$.

The formation of the complex ML_2 occurs mainly after the first equivalence point, according to the reaction $ML + L \rightleftharpoons ML_2$, and the corresponding values of X and pM are obtained in an analogous way ($X = 110\%$, pM = 5; $X = 150\%$, pM = 6.3; $X = 190\%$, pM = 8; $X = 199\%$, pM = 10) (see Fig. 3). The crossing point B corresponds to the equality $[ML] = [L] = 10^{-5}M$, and $[M] = 10^{-12}$, so

$$[ML_2] = c_M - [ML] - [M] \sim c_M,$$

and

$$c_L = [L] + [ML] + 2[ML_2] \sim 2[ML_2] \sim 2c_M,$$

so $X = 200\%$, and at the second equivalence point $pM_{X=200\%} = 12$.

After the second equivalence point, there is excess of free ligand and therefore the values of X and pM ($X = 20\%$, pM = 14; $X = 210\%$, pM = 16; $X = 300\%$, pM = 18) (see Fig. 3), are obtained analogously to those for the quadridentate ligand.

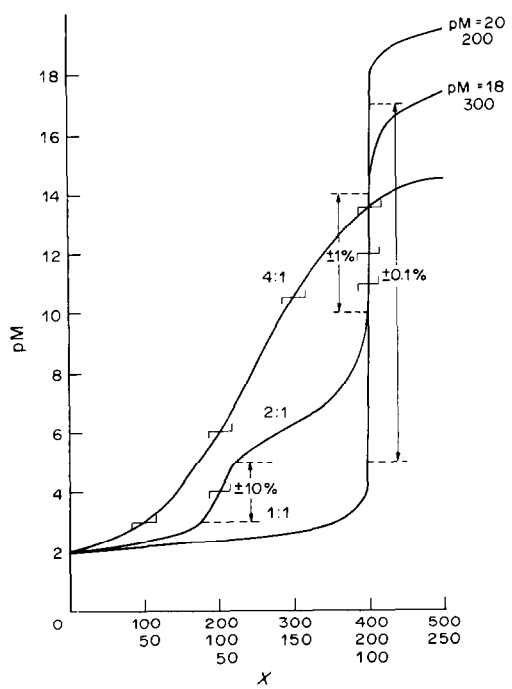

Fig. 2. Titration curves, pM *vs.* $X\%$, of $10^{-2}M$ metal ion M with monodentate (4:1), bidentate (2:1), tetradentate (1:1) ligands.

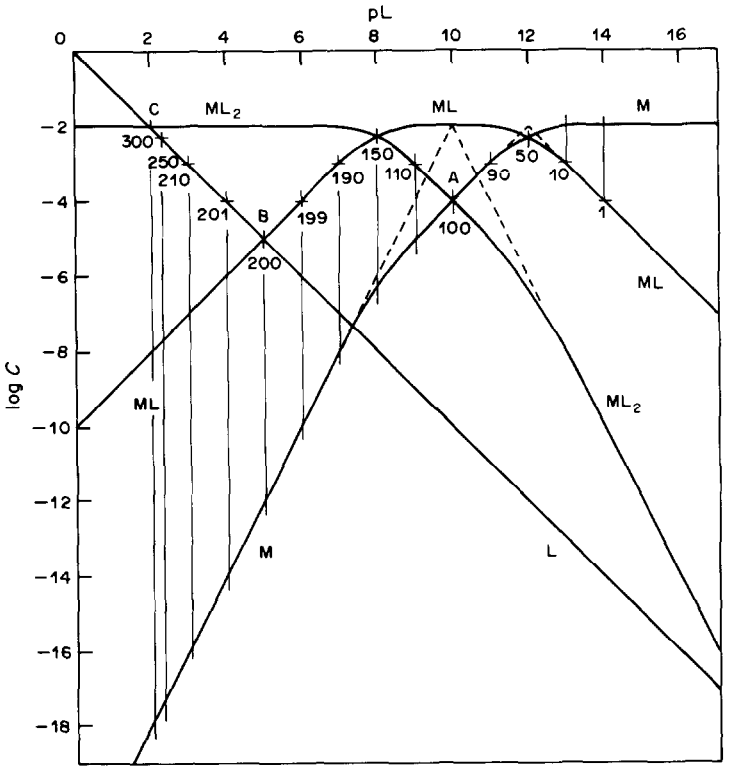

Fig. 3. Logarithmic concentration diagram of system $ML_2/ML/M$, $c_M = 10^{-2}M$, $\log K_1 = 12$, $\log K_2 = 8$.

With the set of values of X and pM shown in Fig. 3, the titration curve is easily plotted, as shown in Fig. 2.

Example 3. *Unidentate ligand*

The concentrations of the various ions can be expressed for different concentrations of L by the following equations, which are obtained by combining the mass balance

$$c_M = [M] + [ML] + [ML_2] + [ML_3] + [ML_4],$$

with equations (4)–(7).

$$\log [M] = \log c_M - \log A \quad (13)$$

$$\log [ML] = \log c_M + \log K_1[L] - \log A \quad (14)$$

$$\log [ML_2] = \log c_M + \log K_1K_2[L]^2 - \log A \quad (15)$$

$$\log [ML_3] = \log c_M + \log K_1K_2K_3[L]^3 - \log A \quad (16)$$

$$\log [ML_4] = \log c_M + \log K_1K_2K_3K_4[L]^4 - \log A \quad (17)$$

where

$$A = (1 + K_1[L] + K_1K_2[L]^2 + K_1K_2K_3[L]^3 + K_1K_2K_3K_4[L]^4)$$

Equations (13)–(17) yield a family of curves, the shapes of which depend on the ratios of the successive formation constants. The logarithmic concentration diagram for the system $ML_4/ML_3/ML_2/ML/M$ for $c_M = 10^{-2}M$ and $\log K_1 = 8$, $\log K_2 = 6$, $\log K_3 = 4$, $\log K_4 = 2$, is shown in Fig. 4. In this case, because of the closeness of the values of K_i and $K_{(i+1)}$, equations (13)–(17) cannot be simplified and hence

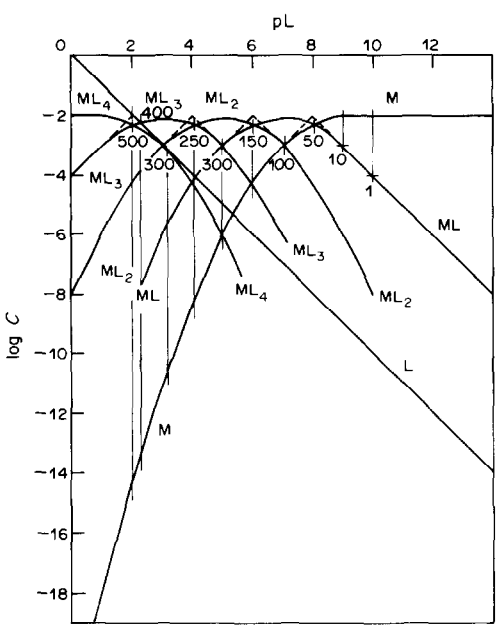

Fig. 4. Logarithmic concentration diagram of system $ML_4/ML_3/ML_2/ML/M$, $c_M = 10^{-2}M$, $\log K_1 = 8$, $\log K_2 = 6$, $\log K_3 = 4$, $\log K_4 = 2$.

log c_i would be given by curves for the whole range of values of pL. For convenience of plotting, and since we are mainly interested in knowing the variation of $-\log [M] = pM$ during the course of the titration, only the variation of log [M] with pL is plotted in Fig. 4.

The same procedure as for quadridentate and bidentate ligands can be used to obtain the titration curve of pM *vs.* X (for X up to 250%) from Fig. 4. Thus we have $X = 0\%$, pM = 2; $X = 50\%$, pM = 2.3; $X = 100\%$, pM = 3; $X = 150\%$, pM = 4.3; $X = 200\%$, pM = 6; $X = 250\%$, pM = 8.3. For values of $X = 300$, 400, 500%, however, the values of pM are obtained in a different way, since the concentration of L is of the same order as the concentrations of ML_3 or ML_4, as can be observed in Fig. 4. Thus, for $X = 300\%$, we have $c_L = 3c_M = 3 \times 10^{-2} M$, and substituting these values in the mass balance gives

$$c_L = [L] + [ML] + 2[ML_2] + 3[ML_3] + 4[ML_4] \quad (18)$$

$$c_M = [M] + [ML] + [ML_2] + [ML_3] + [ML_4] \quad (19)$$

From (18) and (19) we obtain

$$[L] + [ML_4] = 3[M] + 2[ML] + [ML_2] \sim [ML_2] \quad (20)$$

In this equation [M] and [ML] are neglected, owing to the predominance of $[ML_2]$ in the range $\log K_4 < pL < \log K_3$, as can be observed in Fig. 4. Let us suppose that for $X = 300\%$, the graphical procedure were followed as for $X = 100$ or 200%; then we would reach the condition $[ML_4] = [ML_2]$, and the value $pM_{x=300} = 11$ read from the diagram would be incorrect. The graphical solution of equation (20) can be achieved by putting $[L] \sim [ML_4]$, and thus obtaining the condition $\log [L] + 0.30 = \log [ML_2]$, which allows us to obtain graphically the value $pM_{x=300} = 10.5$

At the fourth equivalence point, $X = 400\%$, we have $c_L = 4c_M = 4 \times 10^{-2} M$, and substitution of these values in the mass balances gives, after some rearrangements,

$$[L] = 4[M] + 3[ML] + 2[ML_2] + [ML_3] \sim [ML_3] \quad (21)$$

Here [M], [ML] and $[ML_2]$ are neglected because of the predominance of ML_3 in the range $pL \sim \log K_4$, as can be observed in the diagram. The condition $[L] \sim [ML_3]$ yields graphically the value $pM_{X=400} = 13.5$.

For $X = 500\%$, we have $c_L = 5c_M = 5 \times 10^{-2} M$, and with a first approximation of $[L] \sim 10^{-2} M$, the diagram yields the value $pM_{X=500} = 14.6$.

If instead of using the graphical method just described, we consider the exact solution of the system of equations which results from combining the mass balances

$$c_L = [L] + [ML] + 2[ML_2] + 3[ML_3] + 4[ML_4],$$

and

$$c_M = 10^{-2} M = [M] + [ML_2] + [ML_3] + [ML_4],$$

with equations (4)–(7) we obtain the fifth degree polynomial equations

$$10^{20}[L]^5 + (5 - a)10^{18}L^4 + (3 - a - 10^{-2})10^{16}[L]^3 + (2 - a - 10^{-4})10^{12}[L]^2 + (1 - a - 10^{-6})10^6[L] - 10^{-2}a = 0 \quad (22)$$

where $a = c_L/c_M = 0, 1, 2, \ldots 5$.

This equation can be evaluated with a computer or a programmable calculator, *e.g.*, a Hewlett-Packard HP97. Once the value of [L] has been obtained we can evaluate [M] by using the equation:

$$[M] = c_M/(1 + 10^8[L] + 10^{14}[L]^2 + 10^{18}[L]^3 + 10^{20}[L]^4) \quad (23)$$

In this way, we obtain the table

a	$pM_{computed}$	$pM_{graphical}$
1	3.08	3
2	6.08	6
3	10.65	10.5
4	13.62	13.5
5	14.82	14.6

The agreement between the graphically evaluated pM values and those obtained by computer calculations is good.

DISCUSSION

The analysis shown in these examples gives us the fundamentals for a systematic and rapid approach for obtaining titration curves from the logarithmic concentration diagrams. The values of X are marked on the corresponding log c_i lines, and from them we can obtain directly the values of pM or pL. Note that the values of $X = 10, 90, 190, 210\%$ *etc.*, can be found on the respective log c_i lines, at $\log c_i = \log c_M - 1.0$. Analogously, the values of $X = 1, 99, 199, 210\%$, *etc.*, can be found on the log c_i lines, $\log c_i = \log c_M - 2.0$, and so on. The values of $X = 50, 150, 250\%$ *etc.*, are at the crossing points of log [M] and log [ML], log [ML] and log $[ML_2]$, log $[ML_2]$ and log $[ML_3]$, *etc.*, for values of $pL = \log K_1$, $\log K_2$, $\log K_3$, *etc.* Finally, the values of $X = 100, 200, 300\%$ *etc.*, can be found, in general, for the maximum concentration of species ML, ML_2, ML_3, *etc.*, respectively, and are easily obtained according to the stoichiometry at the successive equivalence points.

This graphical treatment does not take dilution into account, however. The effect of dilution on the pM and pL values at the end-point of the titration depends on the equilibrium constants and the stoichiometry of the complex ion. If we use equimolar metal and ligand solutions, we will have two-, three- and five-fold dilution by the end of the titration, for

quadridentate, bidentate and unidentate ligands respectively, which will correspondingly shift log c_M by $-\log 2$, $-\log 3$ and $-\log 5$. The new pM and pL values so obtained will be: pM = 11.15, 12 and 12.4, pL = 11.15, 5.25 and 2.8 respectively (compared with pM = 11, 12 and 13.5, pL = 11, 5 and 2.2 if the dilution is ignored). The dilution effect on the pM and pL value is only significant for a unidentate ligand.

The titration curves of pM *vs.* X for the different kinds of ligand are plotted in Fig. 2. Note that in the case of unidentate ligands, there is no sharp jump at any of the four equivalence points and therefore they cannot be commonly used in complexometric determination of metal ions. For the bidentate ligand two jumps are observed, the first of them moderate, but the second sharp enough to allow a potentiometric determination of metal ion. Finally, with the quadridentate ligand there is a big jump in pM in the vicinity of the equivalence point, which allows an accurate determination and explains why the chelating ligands which form stable 1:1 chelates with metal ions are the most often used in complexometric titration.

THE USE OF UNIDENTATE LIGANDS IN COMPLEXOMETRIC TITRATIONS

Metal ions form several complexes with most of the unidentate ligands, and even when exactly stoichiometric amounts of metal ion and ligand have been mixed, there is not a rapid enough change in the concentration of any of the species to indicate an end-point. Only when one species of a family of successive complexes is very much more stable than any of the others, is a successful titrimetric determination possible. Examples are the titration of mercury(II) with halides (and *vice versa*) and the titration of cyanide with a standard solution of silver or nickel (and *vice versa*), with either potentiometric or visual detection of the end-point. The calculation of the titration curves is not generally included in textbooks, so let us consider the application of logarithmic concentration diagrams for the purpose.

Example 1. *Titration of Hg(II) with* X^- (Cl^-, Br^-, I^-, CN^-, SCN^-)

Plotting the titration curve. To illustrate the approach, the curve for titration with chloride will be considered. In this case, the equilibrium constants are:

$$Hg^{2+} + Cl^- \rightleftharpoons HgCl^+$$

$$K_1 = [HgCl^+]/[Hg^{2+}][Cl^-] = 10^{6.74} \quad (24)$$

$$HgCl^+ + Cl^- \rightleftharpoons HgCl_2$$

$$K_2 = [HgCl_2]/[HgCl^+][Cl^-] = 10^{6.48} \quad (25)$$

$$HgCl_2 + Cl^- \rightleftharpoons HgCl_3^-$$

$$K_3 = [HgCl_3^-]/[HgCl_2][Cl^-] = 10^{0.85} \quad (26)$$

$$HgCl_3^- + Cl^- \rightleftharpoons HgCl_4^{2-}$$

$$K_4 = [HgCl_4^{2-}]/[HgCl_3^-][Cl^-] = 10^{1.00} \quad (27)$$

By substitution of these values of K_i into equations (13)–(17), the corresponding family of curves of log c_i *vs.* pCl can be obtained. Nevertheless, given the values of log $K_3 = 0.85$ and log $K_4 = 1.00$, it is clear that at low chloride concentrations meaningful amounts of the complexes $HgCl_3^-$ and $HgCl_4^{2-}$ will not be formed, so these will not be taken into account in the following discussion. Hence, by combining the mass balance $c_{Hg} \sim [Hg^{2+}] + [HgCl^+] + [HgCl_2]$ and equations (24) and (25), we obtain:

$$\log [Hg^{2+}] = \log c_{Hg} - \log A \quad (28)$$

$$\log [HgCl^+] = \log c_{Hg} + \log K_1[Cl^-] - \log A \quad (29)$$

$$\log [HgCl_2] = \log c_{Hg} + \log K_1K_2[Cl^-]^2 - \log A \quad (30)$$

where $A = 1 + K_1[Cl^-] + K_1K_2[Cl^-]^2$. Equations (28)–(30) are valid only when pCl is $> \log K_3$.

The construction of the logarithmic concentration diagram for the system $HgCl_2/HgCl^+/Hg^{2+}$ needs an additional explanation, because although equations (28)–(30) have the same mathematical form as equations (10)–(12) respectively, they cannot be simplified to give straight lines for the range pCl $\sim \log k_1 \sim \log K_2$, and so the curves must be plotted point by point. However, we can obtain approximate plots of these curves, if we take into account that two singular points exist; one point, S_1, corresponds to the maximum concentration of the complex ion $HgCl^+$. By expressing the mass-balance equation,

$$c_{Hg} = 10^{-2}M = [Hg^{2+}] + [HgCl^+] + [HgCl_2]$$

as a function of $[HgCl^+]$, and equating its first derivative to zero, we obtain $[HgCl^+]_{max}$ at pCl $= \frac{1}{2}$ log $K_1K_2 = 6.61$. The other singular point, S_2, corresponds to the equality $[HgCl_2] = [Hg^{2+}]$ and by introducing this value into the evaluation of $\beta_2 = K_1K_2 = 10^{13.22}$, we obtain pCl = 13.22/2 = 6.61. Considering now the expressions for the mass balance and the value of K_1, and operating with $[Cl^-] = 10^{-6.61}M$ and $[HgCl_2] = [Hg^{2+}]$, we obtain $[HgCl^+] = 10^{-2.40}M$ and $[HgCl_2] = [Hg^{2+}] = 10^{-2.53}M$. Therefore, the two singular points are S_1 (pCl = 6.61, log $[HgCl^+] = -2.40$) and S_2 (pCl = 6.61, log $[HgCl_2] =$ log $[Hg^{2+}] = -2.53$). The two singular points S_1 and S_2, and the simplified linear relationship of equations (28)–(30) for pCl $>$ log K_1 and log $K_3 <$ pCl $<$ log K_2, allow us to draw readily the logarithmic diagram of the system $HgCl_2/HgCl^+/Hg^{2+}$ for $c_{Hg} = 10^{-2}M$, as shown in Fig. 5.

Figure 5 also shows the values of X from which the corresponding values of pHg and pCl can be obtained. In Fig. 6 the titration curves pHg *vs.* X and pCl *vs.* X are plotted. Note that the first equivalence point, $X = 100\%$, cannot be distinguished on the

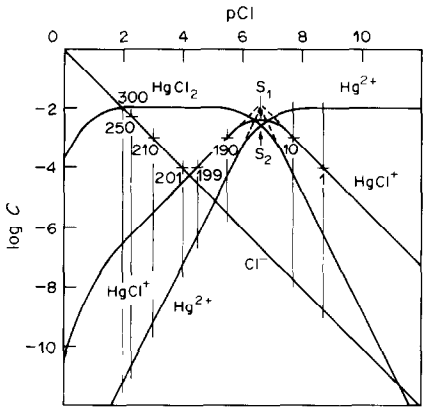

Fig. 5. Logarithmic concentration diagram of system $HgCl_2/HgCl^+/Hg^{2+}$, $c_{Hg} = 10^{-2}M$, log $K_1 = 6.74$, log $K_2 = 6.48$.

titration curve and that there is only one sharp jump in pHg or pCl, at the second equivalence point. The curves for titration of Hg(II) with Br^-, I^-, CN^- or SCN^- can be obtained analogously.

Practical examples. Practical examples of titration of Hg(II) with X^-, with use of the graphical method, can be presented as a laboratory exercise. For instance, 20 ml of $10^{-2}M$ mercuric nitrate, acidified with nitric acid, can be titrated potentiometrically with $10^{-2}M$ MX, where MX can be NaCl, KCl, KBr, KI, KCN or KSCN. The reference electrode can be an Hg/Hg_2SO_4 electrode, or a calomel electrode (used with an auxiliary salt-bridge for titration with Cl^- and Br^-). As indicator electrode an ion-selective electrode for Cl^-, Br^-, I^-, CN^- or SCN^-, as appropriate, or a silver electrode can be used. The experimental titration curves can then be compared with the curves for pHg *vs.* X or pX *vs.* X obtained from logarithmic diagrams of the system $HgX_2/HgX^+/Hg^{2+}$ for $c_{Hg} = 10^{-2}M$. It will be found that the first equivalence point can hardly be distinguished on the titration curve, but the sharp jump of potential is similar to the jump of pX and pHg in the vicinity of the second equivalence point.

It is interesting to note that because the equilibrium constant for $HgX_{2(s)} \rightleftharpoons HgX_{2(aq)}$ is $> 10^{-2}$ for $X = Cl^-$, Br^-, CN^- and SCN^-, the species HgX_2 formed during the titration of $10^{-2}M$ mercury(II) will not be precipitated. However, when $X = I^-$, this equilibrium constant is $10^{-3.88}$. This means that in the logarithmic diagram, the line corresponding to this equilibrium, log $[HgI_2] = -3.88$, is a straight line independent of pI, which intercepts the line log $[HgI_2]_{aq} = \log c_{Hg} + \log K_1K_2 - 2pI$, at pI = 12.85, a value very close to log K_1 (12.87). As outlined above, when pX = pI = log K_1, the degree of titration is $X = 50\%$, so we conclude that precipitation of HgI_2 theoretically begins close to the first half-titration point. In the experimental titration of 20 ml of $10^{-2}M$ mercury(II) with $10^{-2}M$ potassium iodide, the first turbidity due to precipitation of HgI_2 is observed at a somewhat larger degree of titration (about 70%).

Example 2. Titration of CN^- with Ag^+

Silver reacts with cyanide to form a series of species:

$$AgCN_{(s)} \rightleftharpoons Ag^+ + CN^-$$

$$K_{s0} = [Ag^+][CN^-] = 10^{-15.92} \quad (31)$$

$$AgCN_{(s)} + CN^- \rightleftharpoons Ag(CN)_2^-$$

$$K_2 = [Ag(CN)_2^-]/[CN^-] = 10^{4.62} \quad (32)$$

$$Ag(CN)_2^- + CN^- \rightleftharpoons Ag(CN)_3^{2-}$$

$$K_3 = [Ag(CN)_3^{2-}]/[Ag(CN)_2^-][CN^-] = 10^{1.00} \quad (33)$$

$$Ag(CN)_3^{2-} + CN^- \rightleftharpoons Ag(CN)_4^{3-}$$

$$K_4 = [Ag(CN)_4^{3-}]/[Ag(CN)_3^{2-}][CN^-] = 10^{0.50} \quad (34)$$

To obtain the curve for titration of CN^- with Ag^+, we must first plot the logarithmic concentration diagram of the system $Ag(CN)_2^-/AgCN_{(s)}/CN^-$ for $c_{CN} = 10^{-2}M$, with pAg as master variable. In this diagram, the higher complexes $Ag(CN)_3^{2-}$ and $Ag(CN)_4^{3-}$ need not be represented, since from the values of K_3 and K_4 it is clear that with sufficiently dilute cyanide solutions only the complex $Ag(CN)_2^-$ will be formed.

The log c_i lines can be obtained as follows. If we consider the mass balance $c_{CN} = 10^{-2}M = [CN^-] + 2[Ag(CN)_2^-]$ and the expression for the overall formation constant for $Ag(CN)_2^-$, $\beta_2 = K_2/K_{s0} = 10^{20.54}$, we obtain:

$$[CN^-] = \frac{-1 + (1 + 8c_{CN}\beta_2[Ag^+])^{1/2}}{4\beta_2[Ag^+]} \quad (35)$$

$$[Ag(CN)_2^-] = \frac{[-1 + (1 + 8c_{CN}\beta_2[Ag^+])^{1/2}]^2}{16\beta_2[Ag^+]} \quad (36)$$

Equations (35) and (36) can be simplified to linear relationships when (*a*) pAg > log β_2 + log c_{CN}, (*b*) pAg < log β_2 + log c_{CN}.

(*a*) For pAg > log β_2 + log c_{CN}, if $1 \gg 8c_{CN}\beta_2[Ag^+]$, the series expansion of the square-root term gives the approximation value $(1 + 4c_{CN}\beta_2[Ag^+])$, and substitution into (35) and (36) gives $[CN^-] = c_{CN}$ and

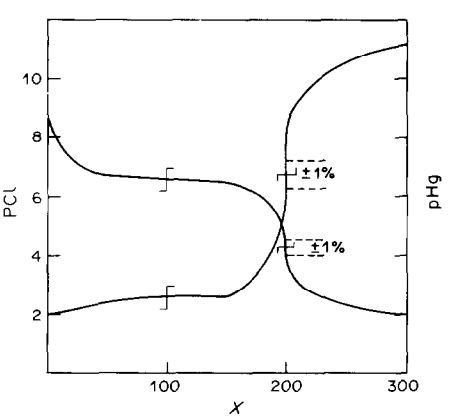

Fig. 6. Titration curves, pCl *vs.* $X\%$, pHg *vs.* $X\%$, of $10^{-2}M$ Hg^{2+} with chloride as titrant.

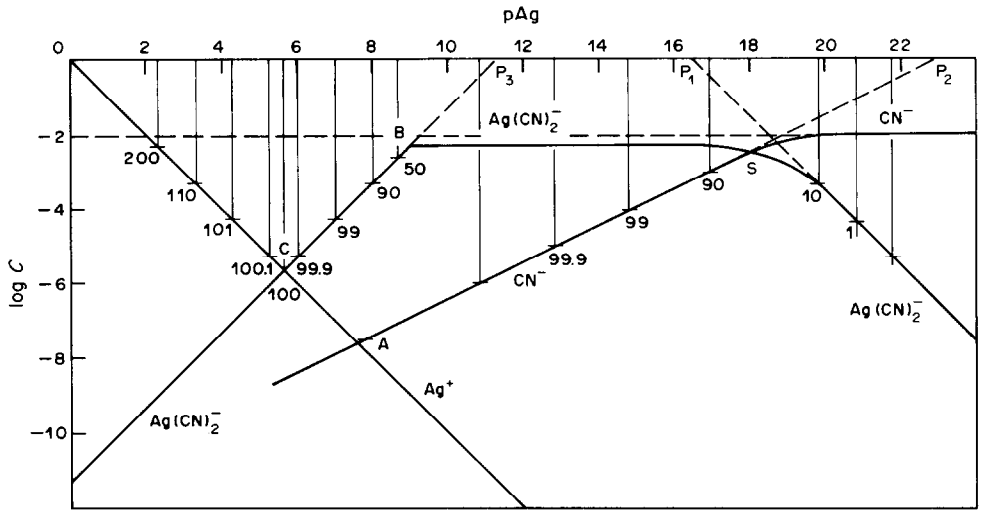

Fig. 7. Logarithmic concentration diagram of system $Ag(CN)_2^-/AgCN_2/CN^-$, $c_{CN} = 10^{-2}M$, log $K_{s0} = -15.92$, log $K_2 = 4.62$.

$[Ag(CN)_2^-] = c_{CN}^2\beta_2[Ag^+]$. Therefore, for a total concentration $c_{CN} = 10^{-2}M$, log $[CN^-] = \log c_{CN} = -2$, and log $[Ag(CN)_2^-] = 2 \log c_{CN} + \log \beta_2 - pAg = 16.54 - pAg$.

The plot of log $[Ag(CN)_2^-]$ *vs.* pAg is a straight line of slope -1 and when extrapolated reaches the point P_1 (pAg = 16.54; log $[Ag(CN)_2^-] = 0$) (see Fig. 7).

(*b*) For $pAg < \log \beta_2 + \log c_{CN}$, $1 \ll 8c_{CN}\beta_2[Ag^+]$. Substituting in (35) and (36), we obtain $[CN^-] = \{c_{CN}/2\beta_2[Ag^+]\}^{1/2}$ and $[Ag(CN)_2^-] = c_{CN}/2$. Hence for $c_{CN} = 10^{-2}M$, log $[CN^-] = \frac{1}{2}\log c_{CN} = \frac{1}{2}\log 2 - \frac{1}{2} \log \beta_2 + \frac{1}{2}pAg = 11.42 + \frac{1}{2}pAg$, and log $[Ag(CN)_2^-] = \log c_{CN} - \log 2 = -2.3$.

The plot of log $[CN^-]$*vs.* pAg is a straight line of slope $+0.5$ and when extrapolated reaches the point P_2 (pAg = 22.84; log $[CN^-] = 0$) (see Fig. 7).

When $pAg \sim (\log \beta_2 + \log c_{CN})$, however, equations (35) and (36) cannot be approximated by linear relationships and the points on the curves must be calculated pointwise. Nevertheless, an approximate diagram can be obtained if we know the crossing point, S, of the lines for log $[CN^-]$ and log $[Ag(CN)_2^-]$. For this purpose, we consider the cyanide mass balance and the overall formation constant β_2, and operating with $[CN^-] = [Ag(CN)_2^-]$, we obtain $[CN^-] = [Ag(CN)_2^-] = 10^{-2.48}M$ and $[Ag^+] = 10^{-18.06}M$. Therefore, the coordinates of point S are pAg = 18.06; log $[CN^-] = \log [Ag(CN)_2^-] = -2.48$ (see Fig. 7).

If, once $Ag(CN)_2^-$ is completely formed, we continue to add successive amounts of Ag^+, pAg decreases and the precipitation reaction $Ag(CN)_2^- + Ag^+ \rightleftharpoons Ag_2(CN)_{2(s)}$ (or $2AgCN_{(s)}$) takes place, for which the effective equilibrium constant is $K = K_{s0}K_2 = 10^{-11.3}$. Therefore, in the range of pAg where $AgCN_{(s)}$ precipitates, the line for log $[Ag(CN)_2^-]$ has the equation log $[Ag(CN)_2^-] = -11.3 + pAg$, slope $+1$, and when extrapolated reaches the point P_3 (pAg = 11.3; log $[Ag(CN)_2^- = 0]$) (Fig. 7).

The logarithmic diagram for the system $Ag(CN)_2^-/AgCN_{(s)}/CN^-$ for $c_{CN} = 10^{-2}M$ is shown in Fig. 7 and from this the titration curve pAg *vs.* X can be obtained, as for the preceding examples. Note that in the first titration, the one corresponding to the reaction $2CN^- + Ag^+ \rightleftharpoons Ag(CN)_2^-$, the degree of titration is $X = 200c_{Ag}/c_{CN}$, so the values of $X = \ldots 0.1, 1, 10\%$ shown on the log $Ag(CN)_2^-$ line will be situated at $\ldots 3.3, 2.3, 1.3$ logarithmic units below log c_{CN}. It is interesting that before the first equivalence point, given by the condition $[CN^-] = 2[Ag^+]$, *i.e.*, log $[CN^-] = \log [Ag^+] + 0.30$, point A (pAg = 7.8), is reached, precipitation begins according to the reaction $Ag(CN)_2^- + Ag^+ \rightleftharpoons 2AgCN_{(s)}$, since in the vicinity of the first equivalence point $[Ag(CN)_2^-] \sim 0.5 \times 10^{-2}M$ and the

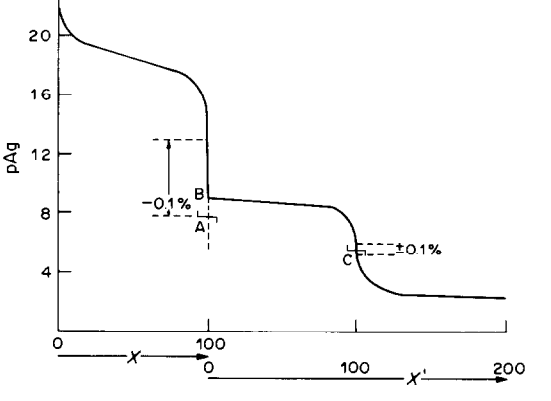

Fig. 8. Titration curve of pAg *vs.* X% for $10^{-2}M$ cyanide ion with silver as titrant.

$[Ag^+]$ necessary to begin the precipitation will be $10^{-11.3}/10^{-2.3} = 10^{-9}M$, point B (pAg = 9.0).

The second stage of the titration corresponds to the precipitation reaction of a solution of $Ag(CN)_2^-$ of initial concentration $\sim 0.5 \times 10^{-2}M$. The titration plot of pAg *vs.* X', where $X' = 100\ c_{Ag}/c_{Ag(CN)_2}$ can easily be obtained from the logarithmic diagram in an analogous way to that for the complexometric titration.[6,8]

In Fig. 7 the several values of X and X' and the corresponding values of pAg are shown, and the titration curve deduced from them is plotted in Fig. 8. Theoretically, the first end-point (at the break point at pAg = 9) could be detected by means of the turbidity due to precipitation of $AgCN_{(s)}$, but a slight excess of silver nitrate would have to be added to yield a perceptible turbidity. Both end-points can be detected potentiometrically, with a cyanide-selective or silver electrode as indicator electrode and an Hg/Hg_2SO_4 reference electrode.

DIFFERENTIAL PULSE STRIPPING VOLTAMMETRY FOR THE DETERMINATION OF NICKEL AND COBALT IN SIMULATED PWR COOLANT

K. TORRANCE and C. GATFORD
Central Electricity Generating Board, Central Electricity Research Laboratories, Kelvin Avenue, Leatherhead, Surrey, England

(*Received* 24 *August* 1984. *Revised* 22 *November* 1984. *Accepted* 5 *December* 1984)

Summary—The determination of ionic nickel and cobalt in simulated PWR coolant at concentrations below 1 μg/l. by differential pulse stripping voltammetry at a hanging mercury-drop electrode has been investigated. The high sensitivity for these ions results from the adsorptive accumulation of their dimethylglyoximate complexes on the mercury drop. Boric acid does not interfere and if the samples are adjusted to pH 9 with an ammonia–ammonium chloride buffer, both nickel and cobalt can be determined in the same run. The relative standard deviations at concentrations below 2 μg/l. are of the order of 5–7% and the limits of detection for nickel and cobalt are about 8 and 2 ng/l. respectively. These performance statistics show that this method is the most sensitive method currently available for determination of soluble nickel and cobalt in PWR coolant and it should prove to be most valuable in any corrosion studies of the materials of construction of the primary circuit of a PWR.

The coolant used in the primary circuit of a pressurized water reactor (PWR) is a dilute solution of boric acid and lithium hydroxide to which hydrogen gas has been added. The concentrations of these additives are carefully controlled and operational experience has shown that only slight corrosion of the materials of construction occurs. It is necessary, however, to confirm the efficacy of the chemical treatment by periodic analysis of the coolant for corrosion products of the materials of construction, and nickel and cobalt derived from stainless steels are two of the principal elements of interest. Hitherto, the determination of these elements has involved either a lengthy accumulation on ion-exchange filters, or concentration, followed by γ-ray spectroscopy and/or electrothermal atomic-absorption spectrometry. This paper describes the determination of ionic nickel and cobalt in simulated PWR coolant by differential pulse stripping voltammetry after adsorptive accumulation of their dimethylglyoximate (DMG) complexes at a hanging mercury-drop electrode. Pihlar *et al.*[1] used this technique for the determination of nickel in natural waters, and Meyer and Neeb[2] used it for the determination of nickel and cobalt in ashed plant samples. The reported limits of detection of a few ng/l. were much lower than those obtained with the same reagents by differential pulse polarography at a dropping mercury electrode.[3–5] The increased sensitivity arises from the adsorptive accumulation of the metal DMG complexes on the mercury drop during a period in which the potential at the drop is held at a value more positive than that required for reduction of the complexes. This accumulation step is followed by a differential pulse voltammetric stripping scan during which the accumulated complexes are reduced.

EXPERIMENTAL

Reagents

All the reagents used were analytical reagent grade or better and, for accurate determinations below the 1-μg/l. level, all the reagents were purified.

Dimethylglyoxime. Analytical reagent grade dimethylglyoxime was recrystallized twice from methanol, and dried at 40°. A 1% solution was prepared in "Spectrosol" ethanol.

Boric acid. A standard solution containing 6000 mg of boron per litre was prepared from "Aristar" boric acid. It contained a small amount of nickel, but this could be substantially removed by adsorption on manganese dioxide powder.[6] Solutions containing lower concentrations of boric acid were prepared by dilution with demineralized water.

Ammonia–ammonium chloride buffer. Pure hydrochloric acid and ammonia solutions were prepared in polythene vessels by isothermal distillation, and mixed in 1:2 molar ratio (acid:base) to give a final concentration of 0.5*M* ammonium chloride at a pH of 9.2 ± 0.1.

Standard nickel and cobalt solutions. These were prepared by sequential dilution of 100-mg/l. Ni and Co solutions prepared from $Ni(NO_3)_2 \cdot 6H_2O$ and $CoSO_4 \cdot 7H_2O$ respectively. Solutions with metal-ion concentrations of 0.1–10 μg/l. were prepared by micropipette additions of 100-μg/l. solutions directly into the 10-ml portions of analysis solution taken in the polarographic cell.

Demineralized water. Prepared by circulating a bulk supply of water continuously through a mixed cation/anion-exchange column to give a final product with a conductivity of 0.06–0.07 μS/cm at 25°. The best quality water was obtained from a unit which had a microfilter and an activated-carbon column after the ion-exchange column.

Storage of reagents. Polythene containers were used exclusively, but cleaning by filling with 0.1*M* hydrochloric acid, leaving for a week, then washing thoroughly was shown to be inadequate. A cleaning procedure based on that described by Moody and Lindstrom[7] was therefore used, in which the bottles were filled with hydrochloric acid (1 + 1), let stand for a week, emptied, rinsed and refilled with nitric acid (1 + 1), let stand for a further week at room temperature, then subsequently rinsed and left filled with demineralized water, the water being changed every day for a week.

Polarograph and voltammetric conditions

An EG&G Princeton Applied Research model 264 polarographic analyser in conjunction with a model 303 mercury electrode assembly and a model RE0089 X-Y recorder was used. The polarograph incorporates a microprocessor which was programmed for differential pulse stripping analysis, involving deaeration of the sample solution, suspension of a mercury drop, a deposition period and a voltage sweep between preset values. The deaeration period necessary to reduce the background current over the voltage range from −0.9 to −1.0 V was 12 min for concentrations above 1 μg/l. and 16 min for lower concentrations. The purge gas used was 99.999% pure nitrogen, further purified by bubbling through pyrogallol solution. In the deposition period, the metal complexes are adsorbed onto the hanging mercury drop; for concentrations below 0.1 μg/l. a 200-sec adsorption time was used, and 100 sec for higher concentrations. The voltage was held at −0.75 V during this period, and then scanned to −1.25 V. Although some advantage in sensitivity can be gained by increasing the drop-size and the voltage scan-rate the best compromise between resolution and sensitivity was obtained by using either a medium (2.5 mg) or small (1.25 mg) drop and a scan-rate of 5 mV/sec. In all cases 50-mV pulses were applied at a rate of 2 per sec.

The standard reference half-cell supplied with the model 303 dropping mercury assembly has a "Vycor" frit liquid junction. Experiments indicated that the prolonged washing necessary to reduce the nickel response for blank solutions was largely associated with this junction. Washing for 2 hr was required after two days of disuse. Comments on nickel and cobalt contamination from Vycor frits have been made by Mart.[8] An experimental junction (Fig. 2) was constructed from a borosilicate glass tube and a crack-junction was formed by controlled local heating applied to a surface scratch. The resistance of this junction, when the reservoir was filled with 3*M* potassium chloride, was 5–6 kΩ. No prolonged washing was necessary with this junction.

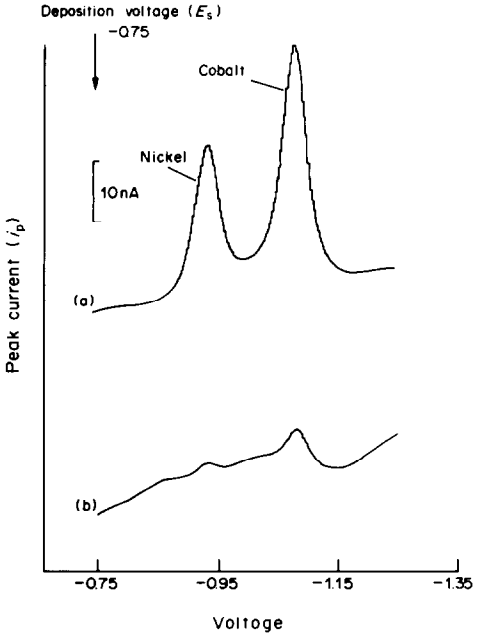

Fig. 1. Typical voltamperograms from precision experiments: (a) $Nc^{2+} = Co^{2+} = 0.4$ μg/l., (b) blank (plus 10 μg of Co^{2+} per litre). Scan-rate, 5 mV/sec; pulse amplitude, 50 mV; drop size, medium; deposition time (a) = 100 sec, (b) = 200 sec; applied voltage *vs.* Ag/AgCl (3*M* KCl).

Most experiments were done at room temperature (25 ± 2°) but for accurate temperature control a glass cell fitted with a water-jacket was used, with water circulated from a constant-temperature water-bath.

RESULTS

Preliminary experiments

In previously reported work on linear sweep voltammetric determination of nickel[1] and of nickel and cobalt[4] by adsorption of the dimethylglyoxime complexes on a mercury drop, an ammonia–ammonium chloride electrolyte was added to the sample. The pH of the test solution was found to affect the sensitivity, particularly for cobalt, which gave optimal response over only a narrow range of pH.[4]

Solutions containing 5 μg each of nickel and cobalt and 1000 mg of boron (as boric acid) per litre and buffered to pH 8.7, 9.0 and 9.4 with ammonia–ammonium chloride buffer were prepared. Voltamperograms of these solutions were recorded and the peak currents for the reduction of the metal ion complexes measured. The nickel peak was relatively unaffected (< 5% change) by the variation in pH. The cobalt peak was reduced by 13% when the pH was changed from 9.0 to 9.4 and it was therefore decided to control the pH at 9.0 ± 0.1. Under these conditions the peaks for reduction of the nickel and cobalt complexes were separated by about 130 mV (Fig. 1). The nickel peak was at −0.93 V and the cobalt peak at −1.06 V *vs.* the silver–silver chloride (3*M* potassium chloride) reference electrode.

The peak heights for reduction of the complexes increase with increasing concentration of dimethylglyoxime but above a certain excess no further advantage is gained.[3] In our experiments an approximately 1000-fold molar excess of DMG was added, and at this level essentially all the metal was complexed.

Adsorptive accumulation of nickel and cobalt

The adsorptive accumulation of the metal complexes on a hanging mercury drop is dependent on a number of factors and a closer examination was

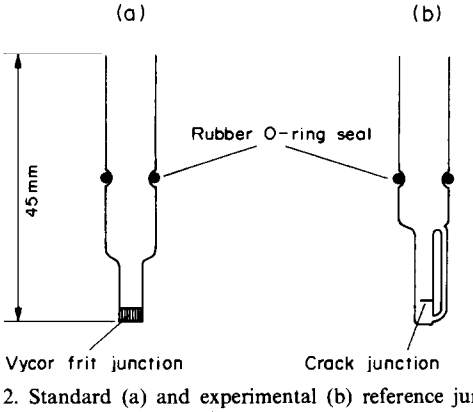

Fig. 2. Standard (a) and experimental (b) reference junctions.

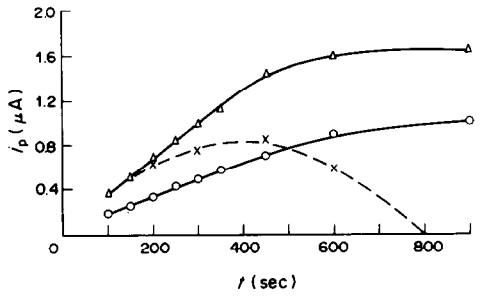

Fig. 3. Peak current *vs.* time curves for nickel at 25°: [Ni^{2+}], μg/l.—○ 2.5; △ 5; × 5 (in presence of Co^{2+}, 5 μg/l).

made of the effects of deposition time and temperature on the peak current, with metal:DMG mole ratio 1:10^3, pH 9.0, and 1100-mg/l. boron concentration (as boric acid).

The effect of deposition time was investigated at 25°. The results for solutions containing only nickel (2.5 and 5 μg/l.) are shown in Fig. 3. The peak currents initially increase linearly with time, then approach a constant value asymptotically and the general form is analogous to an adsorption isotherm. The corresponding plots for cobalt (Fig. 4) were similar in the initial stages, but a constant value was not reached in a reasonably short accumulation time.

When nickel and cobalt were both present there was a significant difference in behaviour. The values of i_p for nickel were suppressed (see Fig. 3) and passed through a maximum, whereas the values for cobalt in the same solution (Fig. 4) were significantly higher than in the absence of nickel, but there was no obvious stoichiometric relationship between the simultaneous changes in i_p for nickel and cobalt. The mutual effects of nickel and cobalt obviously change the slopes of the calibration graphs.

The effect of temperature was investigated at 15, 25 and 35°. In solutions containing only nickel or cobalt

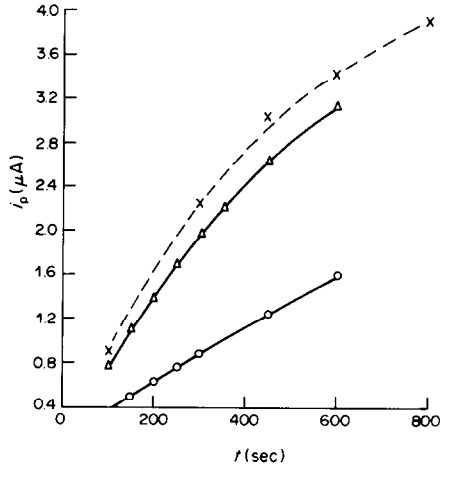

Fig. 4. Peak current *vs.* time curves for cobalt at 25°: [Co^{2+}] μg/l.—○ 2.5; △ 5; × 5 (in presence of Ni^{2+}, 5 μg/l.).

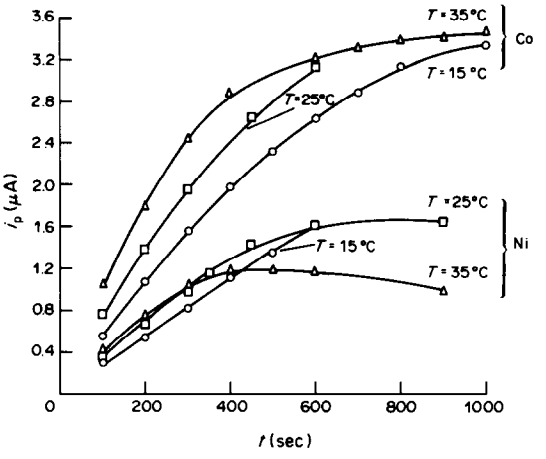

Fig. 5. Effect of temperature on i_p *vs.* time curves for 5-μg/l. nickel and 5-μg/l. cobalt solutions.

(Fig. 5), the slope of the initial linear portion increased with temperature. For nickel, the values at 35° passed through a maximum.

The major difference when nickel and cobalt were both present was shortening of the linear portion of the plots for nickel, and at 35° there was no useful linear range (Fig. 6).

For analytical purposes it is preferable to operate within the linear portion of the i_p *vs.* time plot. At the concentrations of interest in this paper, suitable adsorptive accumulation will be obtained at room temperature with deposition times of 100–400 sec.

Calibration graphs

Preliminary experiments indicated that calibration graphs for nickel in the presence of boric acid were linear over the range 0.1–10 μg/l. Detailed calibration data were obtained at concentrations < 3 μg/l., the

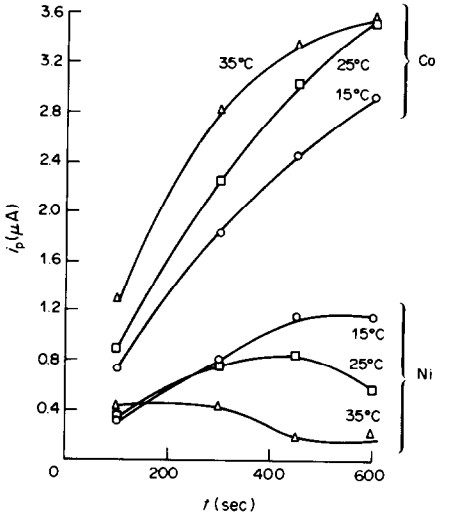

Fig. 6. Effect of temperature on i_p *vs.* time curves for a solution containing both nickel and cobalt at 5 μg/l.

most pertinent region for PWR coolant. Portions of nickel nitrate solution were added by micropipette to a mixture of 10 μl of 1% DMG solution, 2 ml of ammonium chloride buffer and 8 ml of simulated coolant containing boric acid at a concentration equivalent to 1100 mg of boron per litre. The voltamperograms were recorded and the peak currents corrected for that for a reagent blank. Peak current data for nickel in the concentration range 0.12–2.4 μg/l. were obtained at scan-rates of 5, 10 and 20 mV/sec. Linear regression analysis gave correlation coefficients, r^2, > 0.999 for all these sets of data. The sensitivity at 20 mV/sec was about twice that at 5 mV/sec but the gain in sensitivity was offset by a loss of resolution. This is a very important consideration when cobalt and nickel are both being determined since their peaks are separated by only 130 mV. For 5-mV/sec scan-rate, i_p (nA) was equal to $1.51 + 53.7c_{Ni}$, where c_{Ni} was the nickel concentration in μg/l.

Linear calibration graphs, $r^2 > 0.999$; $i_p = 0.09 + 96.9\ c_{Co}$, were similarly obtained for cobalt over the concentration range 0.13–1.11 μg/l. The sensitivity for cobalt was about 70% greater than that for nickel.

Blank-corrected calibration graphs prepared with solutions containing equal w/v concentrations of nickel and cobalt were linear ($r^2 > 0.999$, $i_p = 0.65 + 51.4\ c_{Ni}$ and $i_p = 0.01 + 105.7\ c_{Co}$), but significant day-to-day variation in slope was found, making the use of permanent calibration graphs impractical. In addition, the slope of the cobalt calibration graph (*cf.* 86.9 c_{Co} and 105.7 c_{Co}) is dependent on the nickel:cobalt ratio. For these reasons calibration by standard addition is recommended.

Interferences

The effect of other metal ions expected to be present in the primary coolant because of corrosion of the materials of construction was investigated. The principal ions expected are iron, chromium and manganese. The presence of Fe(III) (40 μg/l.), Mn(II) (10 μg/l.) and Cr(III) (10 μg/l.) had no significant effect (95% confidence level) on the peak heights for nickel (0.8 μg/l.) and cobalt (0.2 μg/l.).

The effect of oil was investigated by recording voltamperograms for nickel (0.2 μg/l.) and cobalt (0.1 μg/l.) in demineralized water saturated at 25° with a pump oil typical of those used in reactor feed-pumps, and for equivalent solutions prepared from uncontaminated demineralized water. A deposition time of 200 sec was used. There was no significant difference for nickel, but in the presence of oil the cobalt peak was largely obscured by a broad asymmetric peak and no determination was possible. Voltamperograms of the oil-saturated water containing no added metal ions did not have this broad peak and it was concluded that the oil interfered with the adsorption of the cobalt complex at the metal surface but not that of the nickel.

Precision

The standard deviations of the peak heights corresponding to the reduction of the nickel and cobalt complexes were determined for concentrations of 5 and 0.4 μg/l., and for blanks (six replicates). The results are given in Table 1, and typical traces are shown in Fig. 1. The relative standard deviations of nickel and cobalt were about the same at both levels and were in the range 5–7%. For the blanks, prepared with solutions purified as described, the voltamperograms always displayed a small peak for nickel but none for cobalt. A small amount (~10 ng/l.) of cobalt was added to the blank, which was estimated to contain about 10 ng/l. nickel, and it was assumed that the standard deviation at this level (Table 1) would be typical of that for a blank. The statistical limit of detection was calculated (95% confidence level) as 4.65 times the standard deviation of the blank. For nickel, the limit of detection was 8 ng/l. and for cobalt 2 ng/l.

Recovery tests on synthetic samples

Synthetic PWR coolant was prepared at two levels of boric acid and lithium hydroxide; B 2000 mg/l., Li 2.2 mg/l., and B 1100 mg/l., Li 2 mg/l., and known amounts of nickel and cobalt were added. The resulting solutions were analysed by the standard-addition technique. First the voltamperogram (peak current i_S) for V ml of a solution consisting of 8 ml of sample, 2 ml of buffer, and 10 μl of DMG solution was recorded. A small known volume, δ_A, of standard metal solution of concentration c_A was then added and a second voltamperogram recorded (peak current i_{S+A}). The concentration, c_S, of the determinand in the test solution was then calculated from:

$$c_S = \frac{i_S\,\delta_A c_A}{i_{S+A}\delta_A + (i_{S+A} - i_S)V}.$$

The original concentration of the metal in the sample before addition of the buffer was then 1.25 c_S. The results for solutions containing a number of different proportions of nickel and cobalt are given in Table 2. The recoveries were mainly in the range 100 ± 10% and the variations between duplicate values were 3–6%.

A water sample obtained from a rig operating under simulated PWR coolant conditions was analysed by the standard-addition technique and the nickel content was found to be 0.37 μg/l. and the cobalt content 0.014 μg/l. Analysis of the same sample by electrothermal atomic-absorption spectroscopy gave the nickel content as < 1 μg/l. and no cobalt was detectable. No alternative method of analysis was available for comparison with the voltammetric results at these very low levels.

DISCUSSION

Adsorption process

A characteristic of the differential pulse stripping voltammetry for nickel and cobalt is the higher sensitivity for the latter under identical analytical conditions. This is unexpected in view of the similarity of their complexes with dimethylglyoxime.[9] In addition, the i_p *vs.* time plots for nickel and cobalt present in the same solution are considerably different from those obtained for separate solutions of the two. In every case, for the mixed solution the cobalt signal is enhanced while the nickel signal is reduced (see the broken lines of Figs. 3 and 4). Figure 3 shows the value of i_p for nickel was reduced to zero if the collection time was long enough, suggesting that the complex had been completely displaced from the surface. These observations indicate a far from simple adsorption process at the electrode surface.

This interaction of cobalt and nickel was not observed when similar experimental conditions were used, but with a dropping mercury electrode,[10] and in DPP experiments only small differences in the slopes of the nickel and cobalt calibration graphs were detected. Figure 7 shows a polarogram and a voltamperogram of a solution containing nickel and cobalt (both at the 5-μg/l. level) and the ratios of the peak currents i_p(Ni):i_p(Co) were 0.8:1 in the former and 0.43:1 in the latter.

Purity of reagents

At the determination levels discussed here, the purity of the reagents is critical. The quality of the demineralized water has already been emphasized, and the water obtained after passage through an activated carbon bed after the ion-exchange did not have the broad peak (from -0.85 to -1.0 V) otherwise present. Similar broad peaks were associated with the presence of oxygen, and extensive deoxygenation (for 16 min) was necessary.

Appreciable blanks were found even for Aristar-grade reagents, and the boric acid, dimethylglyoxime, ammonia and hydrochloric acid all required purification. Purification of boric acid solutions by adsorption of trace metals on a manganese dioxide suspension was very successful and the cobalt content of a 1000-mg/l. boron solution was reduced from about 20 to <2 ng/l. Dimethylglyoxime was readily recrystallized from methanol, but tended to give an unidentifiable voltammetric peak after storage of the

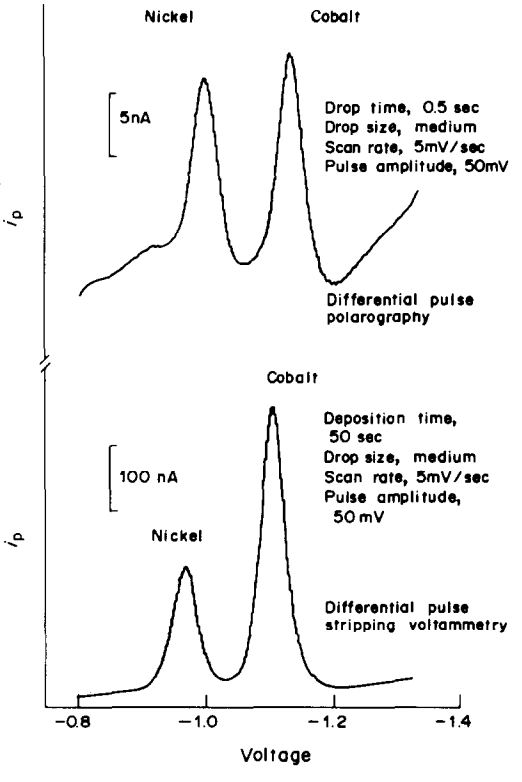

Fig. 7. Comparison of relative peak heights for solution containing 5 μg/l. each of nickel and cobalt.

1% ethanol solution in a polythene bottle for approximately two weeks. This was perhaps due to dissolution of the plasticizer from the bottle. The isothermal distillation of hydrochloric acid and ammonia was entirely successful. In blank solutions containing boric acid and prepared from these purified reagents no cobalt could be detected and the nickel levels were 10–15 ng/l. The nickel was considered to be present in the water used and reduction of its concentration was not attempted since the sensitivity was satisfactory for the immediate applications.

Analytical precision and limits of detection

It has been shown[10] that boric acid does not affect the determination of nickel and cobalt by differential pulse polarography provided consideration is given to the change in pH brought about by the weak acid. The same was found for the differential pulse stripping voltammetry. Of the substances normally expected in PWR coolant only the transition metal ions were considered as possible interferents and excesses of these were shown to have no significant effect.

Because of the interaction of nickel and cobalt in the adsorption step, a fixed calibration graph is impractical when the Ni:Co ratio varies from sample to sample. The standard-addition method gives recoveries of 88–103% for nickel and 86–105% for cobalt, which are considered satisfactory for the very low levels investigated. The relative standard deviations are in the range 5–7% for determination of nickel or cobalt (each in the absence of the other) in simulated PWR coolant. In any determination using a single standard-addition, the standard deviation will be greater, since the calculation involves a ratio as well as a sum and difference of measurements, and an overall relative standard deviation in the range 10–14% would be more appropriate. The limits of detection were calculated from the standard deviations for blank solutions which contained only traces of the two metals. At the 95% confidence level the limits of detection for nickel and cobalt were about 8 and 2 ng/l. respectively. These levels are very much lower than those obtainable by electrothermal atomic-absorption spectrometry, thus making this form of stripping voltammetry the most sensitive method for trace determinations of these metal ions in PWR coolant.

MONITORING OF AROMATIC AMINES BY HPLC WITH ELECTROCHEMICAL DETECTION

COMPARISON OF METHODS FOR DESTRUCTION OF CARCINOGENIC AROMATIC AMINES IN LABORATORY WASTES

JIŘÍ BAREK, VĚRA PACÁKOVÁ, KAREL ŠTULÍK* and JIŘÍ ZIMA
Department of Analytical Chemistry, Charles University, Albertov 2030, 128 40 Prague 2, Czechoslovakia

(*Received* 21 *May* 1984. *Revised* 31 *October* 1984. *Accepted* 21 *November* 1984)

Summary—A new chemical method for destruction of carcinogenic aromatic amines in laboratory wastes has been developed. The method is based on enzymatic oxidation of the amines in solution (with hydrogen peroxide and horseradish peroxidase), followed by oxidation of the solid residues with permanganate in sulphuric acid medium. To monitor the efficiency of destruction, a reversed-phase HPLC system has been developed, with voltammetric detection with a carbon-fibre detector, which is substantially more sensitive (detection limits from a few ng down to a few pg of amine) than the commonly used ultraviolet photometric detection. It has been demonstrated that the proposed method of destruction is highly efficient (>99.8% destruction).

Many aromatic amines are known or suspected to be carcinogenic towards humans,[1] and therefore must be effectively destroyed in industrial and laboratory wastes before these are disposed of. Solution of this problem requires first a sufficiently effective, simple, cheap and rapid procedure for conversion of the carcinogens into harmless products, and secondly a reliable analytical method to check the completeness of destruction.

Several methods have been proposed[2] for the destruction. The most useful involves oxidation with permanganate in sulphuric acid medium,[3] but is unsuitable for wastes containing oxidizable solvents, such as methanol or ethanol, or large amounts of other oxidizable substances. Decontamination of large volumes of aqueous solution is also inconvenient, as large amounts of permanganate are required.

A very promising method has been proposed by Kalibanov and Morris,[4] based on oxidation of the aromatic amines by hydrogen peroxide, catalysed by horseradish peroxidase, to give the corresponding aromatic amine free radicals, which diffuse from the enzyme active site into the solution, where they polymerize. In contrast to the monomers the polymers are virtually insoluble in water, and can be separated by sedimentation, filtration or centrifugation. Unfortunately, the solid residues have been found to be mutagenic.[5]

The present work deals with the combination of these two methods, the enzymatic oxidation to preconcentrate the carcinogens from large volumes of wastes, and the permanganate treatment to destroy the solid residues. Representative aromatic amines were selected for the study (see Table 1).

Various methods can be used to determine trace concentrations of aromatic amines, and hence to monitor the effectiveness of their destruction.[6] Titration and spectrophotometric methods are insufficiently selective for analysis of complex samples, and better results are obtained by combining spectrofluorimetric determination with TLC separation.[7] Gas chromatography has been widely used[6] but mostly requires use of derivatives, which complicates the determination and increases the error. HPLC is therefore most suitable, as direct determination of the aromatic amines is then possible.[6,8–15] With ultraviolet photometric detection, a detection limit of $5 \times 10^{-6} M$ has been achieved.[3] The sensitivity can be considerably improved by use of electrochemical detection.[9–15] In view of the polar character of amines, non-polar stationary phases (*e.g.*, C_{18} bonded phases) are suitable in combination with aqueous solutions of methanol or acetonitrile; to increase the electrical conductivity of the mobile phase, aqueous buffers or salt solutions are used. Amines are readily oxidized at solid electrodes, monoamines at potentials close to +1.0 V (*vs.* SCE), diamines at around +0.5 V (*vs.* SCE).

In the present work, the conditions for HPLC determination of selected aromatic amines in a reversed-phase system with a C_{18} chemically bonded stationary phase and a methanol–aqueous buffer mobile phase, with combined ultraviolet photometric and voltammetric detection were studied. The method was then applied to monitor the effectiveness of degradation of some amines.

EXPERIMENTAL

Apparatus

The polarization curves of the substances were obtained with a PA-3 polarographic analyser (Laboratorní Přístroje, Czechoslovakia) with a glassy-carbon rotating disk electrode or a dropping mercury electrode. For determination of the conditional dissociation constants of the amines, an ABU13/TTT60/REC61 automatic titrator (Radiometer) was used. The pH values in mixed water–methanol media were not corrected.

The chromatographic system included a Pye Unicam LC-XP liquid chromatograph with a TZ4200 dual-line recorder (Laboratorní Přístroje), a stainless-steel column 25 cm long, 3 mm bore, packed with 10 μm Partisil ODS (Pye Unicam), an LC-UV variable-wavelength photometric detector (Pye Unicam), and a carbon-fibre voltammetric detector constructed by the authors and described elsewhere.[17] The two detectors were connected in series by a short (5 cm long, 0.2 mm bore) stainless-steel capillary. On the basis of published data,[2,18] the photometric detector was operated at 280 nm, and the voltammetric detector (see Table 1) at a potential of +0.6 V for a mobile-phase pH of *ca.* 7 and a potential of +0.9 V for a pH of *ca.* 3.5. The samples were injected through a 20-μl loop.

The mobile phase was deaerated by continuous passage of helium. The measurements were made at laboratory temperature and all the potentials were measured *vs.* the SCE.

Reagents

The aromatic amines were of analytical purity and obtained from Fluka (benzidine), Merck (3,3′-dimethoxybenzidine and 3,3′-dichlorobenzidine), Sigma (2-naphthylamine, 1-naphthylamine, 4-aminobiphenyl, 2,5-diaminotoluene and 4-nitrobiphenyl), Lachema, Czechoslovakia (3,3′-diaminobenzidine) and Serlabo, France [4,4′-methylenebis(*o*-chloroaniline)]. The substances were dissolved in 0.1*M* hydrochloric acid to give $5 \times 10^{-3}M$ concentration. If necessary, the dissolution was hastened by sonication.

Horseradish peroxidase (hydrogen peroxidase oxidoreductase), from Sigma, was used as a salt-free powder with a specific activity of 175 purpurogallin units per mg.

All other solvents and chemicals used were of analytical purity.

The mobile phase consisted of 0.1*M* ammonium acetate containing various amounts of methanol; the pH was adjusted with perchloric acid and sodium hydroxide.

Procedures

Determination of the conditional dissociation constants of the conjugate acids. A 20-ml portion of a $10^{-3}M$ solution of amine in a 1:1 mixture of methanol and 0.2*M* aqueous sodium perchlorate was potentiometrically titrated with 0.01*M* hydrochloric acid standardized with sodium tetraborate. The pK_a values were taken as the pH corresponding to half-neutralization. The values given in Table 1 are averages of two determinations.

Determination of the half-wave (peak) potentials. The polarization curves were obtained by using a three-electrode circuit with a 1:1 v/v mixture of methanol and aqueous 0.1*M* ammonium acetate, with an SCE (aqueous inner solution) as reference; no correction was made for liquid-junction potential. The solution was deaerated by passage of purified nitrogen.

Decontamination of laboratory wastes

Simple permanganate method. About 9 mg of test amine was dissolved in 10 ml of 0.1*M* hydrochloric acid (10 ml of glacial acetic acid for substances Nos. 6 and 11), then 5 ml of 0.2*M* potassium permanganate and 5 ml of 2*M* sulphuric acid were added and the mixture was allowed to react overnight. The solution was then subjected to HPLC analysis to check the completeness of degradation.

Combined enzymatic and permanganate oxidation. The pH of the waste solution (containing up to 100 mg of an aromatic amine per litre and up to 20% v/v methanol or ethanol) was adjusted to pH 5–7 with sodium hydroxide or sulphuric acid, and 3.5 ml of 3% hydrogen peroxide solution and 1000 units of horseradish peroxidase (*i.e.*, *ca.* 6 mg) were added per litre of waste solution. After 3 hr, the precipitate formed was filtered off with a porosity-4 frit. The frit and precipitate were then immersed in a mixture of 50 ml of 0.2*M* potassium permanganate and 50 ml of 2*M* sulphuric acid and stirred magnetically overnight. The precipitate was thus completely dissolved, and the solution was then subjected to HPLC analysis.

HPLC analysis

Solid ascorbic acid was gradually added to an aliquot of the solution from the permanganate oxidation until the solution became colourless, then the pH was adjusted to about 8 with 10*M* sodium hydroxide and the solution was centrifuged. One ml of the supernatant liquid was diluted with 3 ml of methanol and centrifuged, and 20 μl of the supernatant solution were injected into the column. The

separation was done with a mobile phase consisting of 40% methanol and 60% aqueous 0.1*M* ammonium acetate, pH 3.5–4.0, at a flow-rate of 1 ml/min. The detectors were operated at 280 nm and +0.9 V respectively and the amine concentration was determined from the voltammetric peak height by the standard-addition method (standard amine solution added to the sample immediately after the ascorbic acid).

RESULTS AND DISCUSSION

HPLC of aromatic amines

The substances studied are listed in Table 1, and the conjugate acids had very similar conditional dissociation constants in water–methanol mixtures. The pK_a values of substances Nos. 3 and 4 could not be measured by the technique used, because the substances were available only as the hydrochlorides.

The absorption maxima[2,18] given in Table 1 indicate that the optimal wavelength for detection of the studied substances is around 280 nm.

All the substances studied, except 4-nitrobiphenyl, are readily oxidized at a glassy-carbon electrode. The values given in Table 1 were obtained for a 1:1 mixture of methanol and aqueous 0.1*M* ammonium acetate, pH 7.1. With some substances (Nos. 3, 6, 8 and 9) there is strong adsorption of the oxidation products on the electrode surface, leading to pronounced drops in the limiting currents; the polarization curves then appear as peaks rather than normal waves and in these cases the peak potentials are given in Table 1 instead of the half-wave potentials. It follows from Table 1 that a potential of *ca.* +0.6 V is sufficient for the detection of all the substances (except No. 7) at pH 7.1. However, the anodic waves shift to more positive potentials with decreasing pH, by about 80 mV/pH. Therefore, the working electrode potential of the detector must be made more positive than +0.6 V when working at lower pH. To maximize the signal-to-noise ratio, the working electrode potential should be as low as possible (to suppress the background current); the best compromise is a potential of +0.9 V and a mobile-phase pH of 3.5.

As 4-nitrobiphenyl is not oxidized at carbon electrodes, it cannot be voltammetrically determined. However, as seen from Table 1, it can be reduced at a dropping mercury electrode and thus can be detected polarographically.

With the mobile phase used, methanol/aqueous ammonium acetate, the separation efficiency and resolution can in principle be modified by varying the methanol content and the pH. The dependence of the capacity factors on the methanol content of the mobile phase is given in Fig. 1. The dependences are similar for all the substances studied and thus it is impossible to attain a substantial improvement in the separation by changing the methanol content. To optimize the absolute values of the capacity factors (between *ca.* 1.0 and 10.0), a methanol content of 40% v/v is most suitable.

With a 40% v/v methanol mobile phase, the

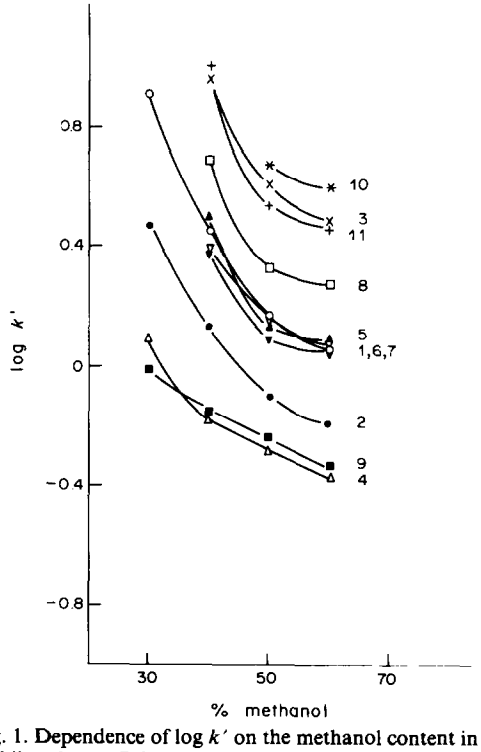

Fig. 1. Dependence of log k' on the methanol content in the mobile phase. Substance: 1—○, 2—●, 3—×, 4—△, 5—▲, 6—▽, 7—▼, 8—□, 9—■, 10—✳, 11—+. Conditions: 0.1*M* aqueous ammonium acetate +x% v/v methanol, pH 7.1; flow-rate, 1 ml/min. For list of substances see Table 1.

dependences of log k' on pH were then measured (Fig. 2). Although the pK_a values of the studied substances are similar, the pH-dependence of the capacity factors varies more significantly than the methanol-dependence. The greatest changes occur between pH 3 and 5, corresponding to the pK_a values of most of the substances. A decrease in the pH leads to a greater protonation of the amines, *i.e.*, to an increase in their polarity (and solubility), and thus to a decrease in their retention times. With some substances the elution order is also changed (Nos. 1, 5, 6 and 7). As follows from Fig. 2, the optimal mobile-phase pH for the separation is about 3.5–4.0. However, the detector electrode potential must be increased accordingly, see above.

The optimal conditions for the separation and determination are: a mobile phase consisting of 40% methanol +60% aqueous 0.1*M* ammonium acetate, pH 3.5–4.0; photometric detector wavelength 280 nm; detector electrode potential, +0.9 V *vs.* SCE.

The response of the two detectors to the studied substances was measured under these conditions for various amounts injected. The detection limits (for a signal equal to twice the absolute noise value) are given in Table 1. It can be seen that for most of the substances the voltammetric detector is substantially more sensitive than the photometric detector and the lowest detection limit is a few picograms. The greatest difference in sensitivity between the two detectors is

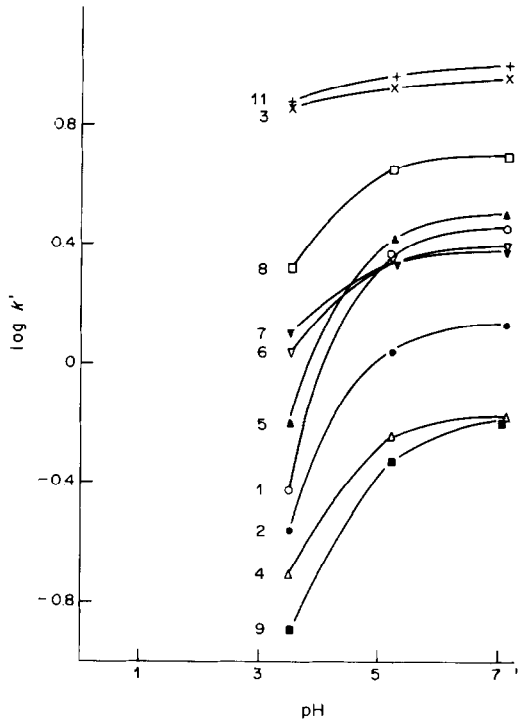

Fig. 2. Dependence of log k' on the mobile phase pH. For list of symbols see Fig. 1. Conditions: 0.1*M* aqueous ammonium acetate +40% v/v methanol; flow-rate, 1 ml/min. For list of substances see Table 1.

for substances Nos. 1, 2, 4, 5 and 10, for which the voltammetric detector is 2–3 orders of magnitude more sensitive than the photometric detector; the difference is *ca.* one order of magnitude for substances Nos. 3, 6 and 8, and the sensitivities are similar for substances Nos. 9 and 11.

It follows that the voltammetric detector is clearly preferable for use in trace analyses. The calibration data show that the linear dynamic range of the voltammetric detector extends from the detection limit to *ca.* 50 ng. The calibration graphs exhibit good linearity (correlation coefficients ranging from 0.9996 for 1-naphthylamine to 0.9978 for 2-naphthylamine) and satisfactory precision (the relative standard deviations of the peak height amount to only a few per cent and do not exceed 10–12% (5 replicates, 95% limits) even at the lowest measured concentrations. Therefore, the method can be used to monitor the effectiveness of the degradation treatment. A chromatogram of the solution after degradation of 3,3′-diaminobenzidine is shown in Fig. 3.

Chemical degradation of the amines

Typical results for the degradation procedures, as monitored by HPLC with electrochemical detection, are summarized in Table 2. The degradation methods are highly efficient and lead to destruction of more than 99.95% of most of the substances tested. The efficiencies found by electrochemical detection are higher than those found by photometric detection[3] because of the higher sensitivity. The apparently less

(*a*) Simple permanganate method, (*b*) after oxidation of the residues formed by the enzymatic oxidation of the solution containing 10 mg of the test amine per 100 ml, (*c*) no precipitate formed during the enzymatic oxidation.
Note: The final concentration values are recalculated to refer to the original volume of the waste solution.

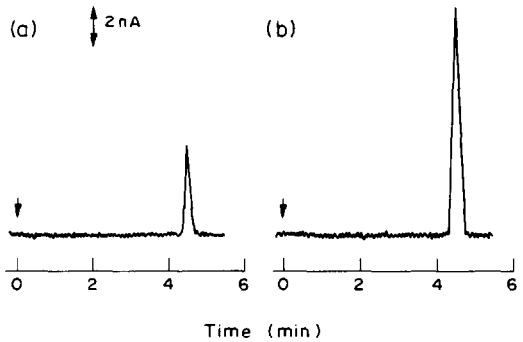

Fig. 3. Chromatogram of 3,3′-diaminobenzidine after the decomposition of the waste solution (a) and the same with a standard addition corresponding to $7.65 \times 10^{-7} M$ concentration (b). Conditions: 0.1*M* aqueous ammonium acetate + 40% v/v methanol; pH 3.7; flow-rate 1 ml/min, voltammetric detection at +0.9 V.

favourable values for substances Nos. 9 and 11 are probably due to the poorer detection sensitivity (for substances Nos. 2, 3, 9 and 11 the detection limit was higher than the residual amine concentration). The enzymatic method cannot be used for 2,5-diaminotoluene, as no precipitate is formed. For all the other amines tested, the permanganate oxidation is a highly efficient method for destruction of the solid mutagenic residues. It has been found[5] that the resulting solutions have no mutagenic effects and are thus environmentally harmless. It can be concluded that the method combining the enzymatic and chemical oxidation is suitable for large volumes of wastes containing small amounts of aromatic amines, and in the presence of oxidizable solvents and other oxidizable substances, where the simple permanganate method fails. The combined method is also somewhat more efficient than the simple permanganate method (see Table 2).

The HPLC method with electrochemical detection is suitable not only for monitoring the effectiveness of such degradation procedures, but also for trace analyses for these important substances in general.

FLUORIMETRIC DETECTION OF TAUTOMERIC EQUILIBRIA IN 8-AMINOQUINOLINES

PEDRO J. ZAVALA, MARC D. RADCLIFFE* and STEPHEN G. SCHULMAN†
College of Pharmacy, University of Florida, Gainesville, Florida 32610, U.S.A.

(*Received* 28 *June* 1984. *Revised* 9 *November* 1984. *Accepted* 20 *November* 1984)

Summary—The 1-methylquinolinium cations derived from 8-aminoquinoline and 8-amino-6-methoxyquinoline were prepared by methylation of the corresponding nitroquinolines and reduction of the nitro-compounds. The dissociation constants of the protonated species of these compounds are almost identical to those of doubly-protonated 8-aminoquinoline and 8-amino-6-methoxyquinoline, respectively, suggesting that the parent quinolines are exclusively first protonated at the ring nitrogen atom. However, the molar absorptivities of the 1-methyl derivatives at their longest-wavelength absorption maxima are substantially greater than the corresponding absorptivities of the unmethylated aminoquinolines, a result which suggests tautomerism of the singly-protonated parent quinolines, with a proportion of the population protonated at the amino group. Fluorescence spectroscopy reveals a single emission from the 8-amino-6-methoxy-1-methylquinolinium ion and two excitation-wavelength-dependent fluorescences from the 8-amino-6-methoxyquinolinium ion, confirming the occurrence of tautomerism and supporting choice of the absorptiometric approach rather than the titrimetric approach as the preferred method for the detection of tautomerism and the calculation of tautomeric equilibrium constants.

The aminoquinolines have long been known to form singly-charged cations by protonation of their ring nitrogen atoms.[1-4] The assignments of the protonation sites were based on the red-shift of the ultraviolet and visible region spectra of the neutral aminoquinolines on protonation. However, the arylamino groups and the ring nitrogen atoms have inherently comparable basicity. If the amino groups in some of the molecules and the heterocyclic nitrogen atoms in the others were protonated, there would be a tautomeric equilibrium (Fig. 1). While protonation of a ring nitrogen atom should indeed cause a red-shift of the electronic absorption spectrum, protonation of an amino group would cause a blue-shift. If both phenomena occurred as a result of tautomerism, the red-shift would be the more obvious because the long-wavelength side of the spectrum would shift into regions which would be devoid of absorption bands for the neutral molecule. The blue-shift would be much less obvious, especially if the tautomeric equilibrium favoured protonation of the ring nitrogen atom.

To test the possibility of tautomerism in aminoquinolines the pH-dependence of the absorption spectra of 8-aminoquinoline and 8-amino-6-methoxyquinoline and their ring *N*-methylated cations was examined. Two methods commonly used to detect and measure tautomeric equilibria, one titrimetric and the other spectroscopic, were used to analyse the data. Since these approaches gave conflicting results, a third method, fluorescence spectroscopy, was used to establish the existence of the tautomeric equilibria.

EXPERIMENTAL

8-Aminoquinoline was recrystallized from n-hexane and stored under nitrogen. The purified material gave a single spot ($R_f = 0.71$) on a silica gel TLC plate with methanol as the mobile phase and had m.p. (corrected) 64–65° (dec.) (literature value[5] 65°). 8-Amino-6-methoxyquinoline was purified by column chromatography on silica gel, with 1:24 v/v acetone–benzene solution as mobile phase. The compound was collected as a yellow oil which gave a single spot on a silica gel TLC plate with 15:85 v/v acetone/benzene as the mobile phase ($R_f = 0.6$). Crystals were obtainable from the oil only on standing for two months at −10°. The crystals were stored under nitrogen and had m.p. 49–50° (literature values of 38°,[6] and 53°,[7] have been reported). However, the red-shift (followed by a blue-shift) in the absorption spectrum with decreasing pH, together with the agreement of the proton NMR spectrum ($CDCl_3$), with the literature,[8] as well as the TLC check for purity seems convincing evidence that the compound isolated was 8-amino-6-methoxyquinoline.

8-Amino-1-methylquinolinium perchlorate was prepared by methylating 8-nitroquinoline with dimethyl sulphate and then reducing the 1-methyl derivative with iron and glacial acetic acid according to the method of Deady and Yusoff.[9] The product had m.p. 159–160°, in excellent agreement with the literature.[9] 8-Amino-6-methoxy-1-methylquinolinium perchlorate was similarly prepared from 6-methyl-8-nitroquinoline; the product was recrystallized twice from ethanol and obtained as orange crystals which decomposed at 165° to a brown material which melted sharply at 193°. The proton NMR spectrum (d_6-DMSO) corresponded to that predicted for the 8-amino-6-methoxy-1-methylquinolium ion.

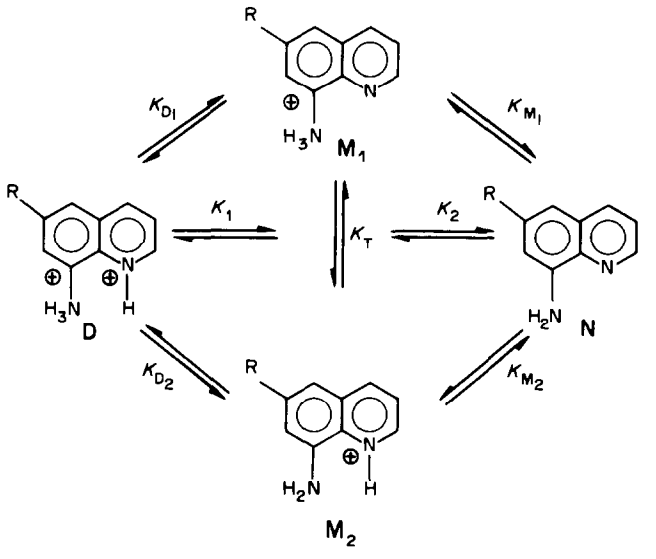

Fig. 1. Dissociation scheme for doubly-protonated (D) 8-aminoquinoline (R = −H) and 8-amino-6-methoxyquinoline (R = $-OCH_3$). K_{D_1} and K_{D_2} are the equilibrium constants for the dissociation pathways to M_1 and M_2, the amino-protonated and ring-protonated singly-charged cations, respectively. K_1 is the macro-equilibrium constant for dissociation of D to all singly-charged species. K_{M_1} and K_{M_2} are the respective dissociation constants for M_1 and M_2 dissociating to the neutral molecule (N). K_2 is the macro-equilibrium constant for dissociation of all single-charged cations to A and K_T is the tautomeric equilibrium constant for $M_2 \rightleftharpoons M_1$.

Absorption spectra were taken on a Beckman DB-GT spectrophotometer. Fluorescence spectra were taken on a Perkin-Elmer MPF-2A fluorescence spectrophotometer with monochromators calibrated against the xenon line-emission spectrum and its output corrected for instrumental response by means of a Rhodamine-B quantum-counter. All pH measurements were made with an Orion 801 pH-meter with a Sargent-Welch combination Ag/AgCl–glass electrode.

Sulphuric acid solutions were prepared by dilution with distilled, demineralized water and those with pH < 2 were calibrated by the H_+ acidity scale of Vetešnik *et al.*[10] Solutions used for absorption and fluorescence spectroscopy were *ca.* $2 \times 10^{-5} M$. All spectral measurements were made at $25.5 \pm 0.3°$.

RESULTS AND DISCUSSION

The dissociation constants of 8-aminoquinoline, 8-amino-6-methoxyquinoline and their protonated 1-methyl derivatives, determined absorptiometrically, are presented in Table 1. Representative titration curves for 6-methoxyguinoline and its 1-methyl derivative are shown in Figs. 2–4. The pK_2 of singly-protonated 8-aminoquinoline is in excellent agreement with the literature value.[5] The pK_1 of doubly-protonated 8-aminoquinoline reported previously[11] was based on calculations using an H_0 acidity scale for the moderately concentrated acid solutions employed in the determination. In the present study, the H_+ scale was used to determine pK_1, because the conjugate base is singly positively charged. The value obtained is in good agreement with that reported previously.[11] To the best of our knowledge the dissociation constants of protonated 8-amino-6-methoxyquinoline have not been reported previously.

The dissociation constants, pK_1, of the protonated 1-methylated aminoquinolines are for all intents and purposes identical to those of the doubly-protonated 8-aminoquinolines. According to Ebert's method,[12] which identifies the pK of the protonated *N*-methylated derivative (D in Fig. 5) with pK_{D_2} in Fig. 1, the 8-aminoquinolines do not measurably exist in tautomeric forms but rather are singly-protonated exclusively at the heterocyclic nitrogen atoms. If tautomerism of the protonated 8-aminoquinolines *did*

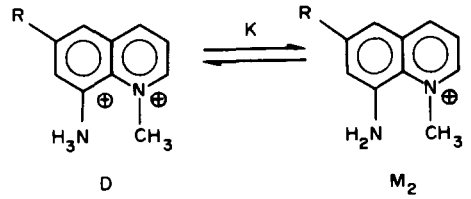

Fig. 5. Dissociation scheme for protonated (D) 8-amino-1-methylquinolinium cations (R = –H or –OCH_3) to the singly-charged cations (M_2).

occur, the pK values of the doubly-protonated 8-aminoquinolines and of the singly-protonated 1-methyl-8-aminoquinolines should differ by at least 0.3.

The molar absorptivities of the longest-wavelength absorption bands of the aminoquinolines and their 1-methyl derivatives are presented in Table 2 and give information about the tautomerism of the 8-aminoquinolines which is in conflict with that from the titrimetric approach (Ebert's method). At pH 1.9, where 8-aminoquinoline and 8-amino-6-methoxyquinoline are more than 99% in their singly-protonated forms, the absorbance, A_M, at some chosen analytical wavelength is given (if tautomerism occurs) by

$$A_M = A_{M_1} + A_{M_2} \quad (1)$$

where A_{M_1} and A_{M_2} are the absorbances due to the amino-protonated and ring-protonated singly-charged cations, respectively. Equation (1) may be rewritten

$$\epsilon_M[M]l = \epsilon_{M_1}[M_1]l + + \epsilon_{M_2}[M_2]l \quad (2)$$

where $[M_1]$ and $[M_2]$ are the equilibrium concentrations of the amino-protonated and ring-protonated species, respectively, ϵ_{M_1} and ϵ_{M_2} are the corresponding molar absorptivities and l is the optical path-length. Equation (2) can be rewritten as

$$\epsilon_M[M_1] + \epsilon_M[M_2] = \epsilon_{M_1}[M_1] + \epsilon_{M_2}[M_2] \quad (3)$$

so if the tautomeric ratio (equilibrium constant) is

$$K_t = [M_1]/[M_2] \quad (4)$$

then

$$K_t = (\epsilon_{M_2} - \epsilon_M)/(\epsilon_M - \epsilon_{M_1}) \quad (5)$$

According to equation (5) a non-zero numerator would imply the occurrence of tautomerism. In the

Table 2. Molar absorptivities and tautomeric ratios (K_t) of the singly charged cations at 25.5° and pH 1.8

Cation	λ_{max}, *nm*	ϵ_{max}, $10^3 l.mole^{-1}.cm^{-1}$	K_t*

*K_t = [amino-protonated ion]/[ring-nitrogen protonated ion].

systems of interest here, ϵ_M would be the apparent molar absorptivity of 8-aminoquinoline or 8-amino-6-methoxyquinoline measured at pH 1.9, and ϵ_{M_2} could be estimated from the corresponding spectral features of the 1-methyl derivatives. A particularly useful analytical wavelength to use in each case would be that of the maximum of the longest-wavelength absorption band in each compound. Not only would these wavelengths correspond to the same spectral features in the aminoquinolines and in their ring-methylated derivatives, but the use of these spectral bands would also obviate the necessity to prepare the trimethylammonium derivatives of the aminoquinolines. It is assumed that the methylated and non-methylated cations have equal transition probabilities and that because the band-widths at half peak-height are almost identical, the molar absorptivities at λ_{max} will also be the same. Because of the shift of the absorption spectra of amino-aromatics to shorter wavelengths on protonation of the amino group, at the long-wavelength absorption maxima of the ring-protonated or methylated aminoquinolines $\epsilon_{M_1} = 0$. Equation (5) then becomes

$$K_t = (\epsilon_{M_2} - \epsilon_M)/\epsilon_M \qquad (6)$$

Also presented in Table 2 are the values of K_t for the 8-aminoquinolinium and 8-amino-6-methoxyquinolinium singly-charged cations. The spectroscopic method just described and the data of Table 2 indicate that there is substantial tautomerism between the two singly-charged cations for both 8-aminoquinoline and 8-amino-6-methoxyquinoline. These results are clearly in conflict with those obtained by Ebert's method.[12]

In order to resolve the apparent dilemma it was decided to find whether the various tautomeric species in question are fluorescent. For 8-aminoquinoline, no fluorescence could be found at any pH, in agreement with an earlier investigation of this compound.[13] Nor could fluorescence from the 8-amino-1-methylquinolinium ion be detected in aqueous solutions at any pH. The 8-amino-6-methoxy-1-methylquinolinium ion, however, did demonstrate a single moderately intense fluorescence band with a maximum at 440 nm at pH 1–10. The excitation spectrum or this species had maxima near the absorption maxima of the methylated derivative at 393, 338 and 272 nm. At pH < 1 the emission at 440 nm increased in intensity (Fig. 6) and shifted to 435 nm. Presumably, the latter emission originated from the doubly-charged cation. The fluorescences of the singly- and doubly-charged 8-amino-6-methoxy-1-methylquinolinium ions are both close to the fluorescence maximum of protonated 6-methoxquinoline, which lies at 438 nm.[14] This would certainly be expected for the doubly-charged cation, in which the protonated amino group can have almost no effect on the position of the bands in the electronic spectra. The similarity of the fluorescence of the singly-charged ring-nitrogen methylated cation to that of protonated 6-methoxyquinoline indicates that either the interaction of the lone-pair of the amino group with the aromatic ring does not appreciably affect the state from which the emission originates, or that the interaction leads to an emitting state which is accidentally essentially isoenergetic with the emitting state of protonated 6-methoxyquinoline.

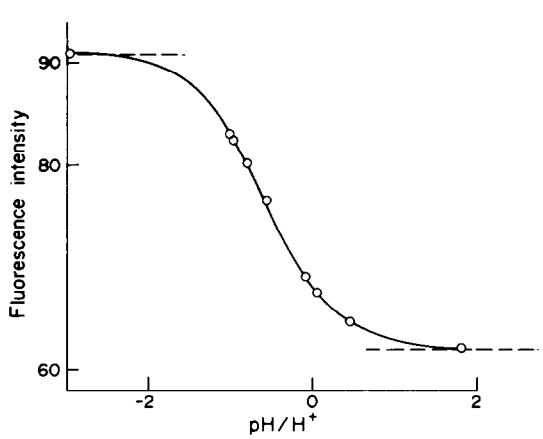

Fig. 6. Fluorescence intensity *vs.* pH/H_+ for $1 \times 10^{-5}M$ 8-amino-6-methoxy-1-methylquinolinium ion in dilute sulphuric acid ($\lambda_{ex} = 316$ nm., $\lambda_{em} = 435$ nm) at 25.5°C.

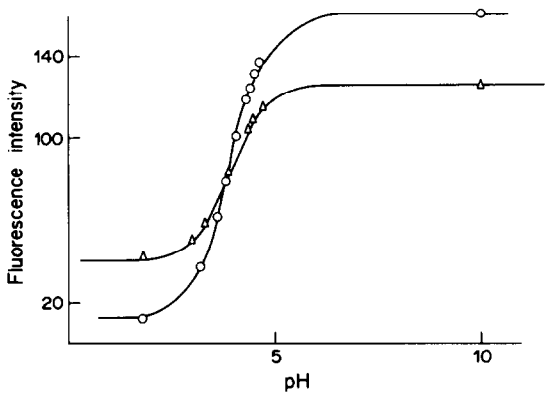

Fig. 7. Fluorescence intensity *vs.* pH for $1 \times 10^{-4}M$ 8-amino-6-methoxyquinoline in water (△, $\lambda_{ex} = 354$ nm, $\lambda_{em} = 460$ nm; ⊙, $\lambda_{ex} = 280$ nm, $\lambda_{em} = 365$ nm) at 25.5°C.

At pH 1.9, 8-amino-6-methoxyquinoline has two fluorescence bands, at 365 and 460 nm. As the pH is varied, both bands increase in intensity and coalesce to give a single fluorescence band which at high pH is centred at 380 nm. The inflection region of the fluorescence *vs.* pH graph is centred at pH 3.9 (Fig. 7), corresponding to pK for dissociation of the singly-charged species. This suggests that the emissions at both 365 and 460 nm arise from the singly-protonated species. Moreover, at pH < 1 the two emissions decrease and give way to a single fluorescence band at 435 nm, presumably that of the doubly-charged cation. The inflection for this change is centred at $H_+ = -0.5$, corresponding to the pK of the doubly-charged cation.

The fluorescence bands of 8-amino-6-methoxyquinoline at pH 1.9 have different excitation spectra. That at 460 nm has excitation peaks near 380, 333 and 269 nm, similar to the excitation spectrum of the 1-methyl derivative, and the emission at 365 nm has excitation peaks near 325 and 272 nm, not unlike the excitation spectrum of neutral 6-methoxyquinoline.[14] The fluorescence at 365 nm is, moreover, close to the emission maximum of neutral 6-methoxyquinoline,[14] which lies at 362 nm. The fact that the two fluorescence bands which seem to originate from singly-protonated 8-amino-6-methoxyquinoline have very different excitation spectra indicates that there are two ground-state species of substantially different electronic structure, rather than a single species giving two emissions. The most likely explanation for this would be that there are two tautomeric forms of the singly-charged cation. One, protonated at the ring nitrogen atom, would have emission and excitation spectra similar to those of the 8-amino-6-methoxy-1-methylquinolinium ion in which the 1-methyl group is similar to a "non-dissociating proton." The other, protonated at the 8-amino group, would have emission and excitation spectra similar to those of uncharged 6-methoxyquinoline (protonation of the amino group alone would effectively prevent it from having a substantial effect on the aromatic portion of 8-amino-6-methoxyquinoline, and give it essentially the electronic structure of 6-methoxyquinoline). Presumably, singly-protonated 8-aminoquinoline also exists as two tautomers. Unfortunately, the fluorescence approach, though qualitatively indicating the occurrence of tautomers, requires the specification of too many parameters for the acquisition of quantitative information about the tautomeric ratios. It may be concluded, however, that the use of the absorption spectra of alkylated model compounds to evaluate tautomeric equilibria is more accurate than the evaluation of the tautomeric equilibria by comparison of the dissociation constants of the model compounds with those of the substances in question.

SENSITIVE FLOTATION-SPECTROPHOTOMETRIC DETERMINATION OF GOLD, BASED ON THE GOLD(I)–IODIDE–METHYLENE BLUE SYSTEM

Z. MARCZENKO and K. JANKOWSKI
Department of Analytical Chemistry, Technical University, Warsaw, Poland

(*Received* 25 *February* 1984. *Revised* 7 *October* 1984. *Accepted* 8 *November* 1984)

Summary—The gold(I)–iodide–Methylene Blue (MB) system is suitable for flotation separation and spectrophotometric determination of gold. Under the optimum conditions $[(MB^+)(AuI_2^-)]\cdot 3[(MB^+)(I_3^-)]$ is formed, and floated with cyclohexane. The product is dissolved in methanol and its absorbance measured. The molar absorptivity is 3.4×10^5 l.mole^{-1}.cm^{-1} at 655 nm. The proposed method is more than three times as sensitive as the Rhodamine B method. Pt, Pd, Ag and Hg interfere seriously, and Ir, Rh, Bi and Cd to a smaller extent. Preliminary separation of gold by precipitation with tellurium as a collector is recommended. The method has been applied to determination of gold traces (about 1×10^{-4}%) in a copper sample.

We have used the sparingly soluble ion-association compounds formed by some anionic complexes of platinum metals with appropriate basic dyes to develop very sensitive flotation–spectrophotometric methods for determination of all six platinum metals.[1–8] The molar absorptivities (ε) are in the range $1.7–4.0 \times 10^5$ l.mole^{-1}.cm^{-1}, because one atom of metal is associated with 2–5 dye molecules. The sparingly soluble compounds accumulate at the phase boundary or on the wall of the separatory funnel when the aqueous phase is shaken with a suitable solvent of low polarity. The washed precipitate is dissolved in a polar solvent and the absorbance of the solution is measured. In this modification of flotation separation, droplets of the low-polarity solvent, dispersed in the aqueous phase by shaking, act like inert gas bubbles and cause flotation of the precipitate.[9,10] The ion-association compounds formed with the basic dyes are hydrophobic, which makes it useless to add surfactants to the system.

This paper describes extension of the technique to spectrophotometric determination of gold. Some of the most sensitive spectrophotometric methods of gold determination yet reported are based on the extraction of ion-pairs of $AuCl_4^-$ or $AuBr_4^-$ with univalent basic dye cations,[11–17] the Rhodamine B method ($\varepsilon = 9.7 \times 10^4$) being the best known; the determination with thio-Michler's ketone[18,19] ($\varepsilon = 1.2 \times 10^5$) is slightly more sensitive.

EXPERIMENTAL

Reagents

Gold(III) standard solution (1 *mg/ml*). Dissolve 0.1000 g of pure gold in 4 ml of *aqua regia*. Evaporate the solution almost to dryness on a water-bath. Add 4 ml of concentrated hydrochloric acid, evaporate to half the volume, and dilute to the mark with water in a 100-ml standard flask. Dilute further with 0.1*M* hydrochloric acid as required.

Methylene Blue hydrochloride (*MB*) (*Merck*) *solution*, 1×10^{-3}M.

Potassium iodide, *0.01*M *solution.*

Potassium iodate, 5×10^{-5}M *solution.*

*Iodine-125, as sodium iodide, in 0.1*M *sodium hydroxide.*

Procedure

Place the sample solution (in about 0.5*M* hydrochloric acid, containing not more than 4 μg of gold) in a separatory funnel, and add 2 ml of iodide solution and 2 ml of iodate solution, with swirling, followed by enough hydrochloric acid to give 0.5*M* concentration. Then add 1.5 ml of Methylene Blue solution and shake with 10 ml of cyclohexane for 1 min. After separation of the phases, remove the aqueous phase and wash the precipitate and organic solvent by shaking (for 1 min) with 20 ml of water. After separation of the phases, remove them carefully, and dissolve the precipitate off the wall with methanol. Dilute the solution to volume with methanol in a 10-ml standard flask and measure its absorbance at 655 nm against a reagent blank prepared in the same way.

RESULTS AND DISCUSSION

Preliminary investigations

The extraction of the anionic complexes of gold with chloride, bromide, iodide, thiocyanate, thiosulphate and oxalate by means of Methylene Blue, Toluidine Blue, Methylene Green, Azure II (thiazine dyes), Capri Blue, Meldola Blue, Nile Blue A (oxazine dyes), Crystal Violet, Brilliant Green, Malachite Green (triphenylmethane dyes), Rhodamine 6G and Rhodamine B (xanthene dyes) from various media (ranging from pH 3 to 3*M* hydrochloric acid or sulphuric acid) into benzene, toluene, xylene, cylcohexane and di-isopropyl ether was examined.

Only the iodide, bromide and thiocyanate systems gave flotation, mainly with the azine dyes. Most of the systems (but not thiosulphate and oxalate systems) gave products extractable into the organic phase.

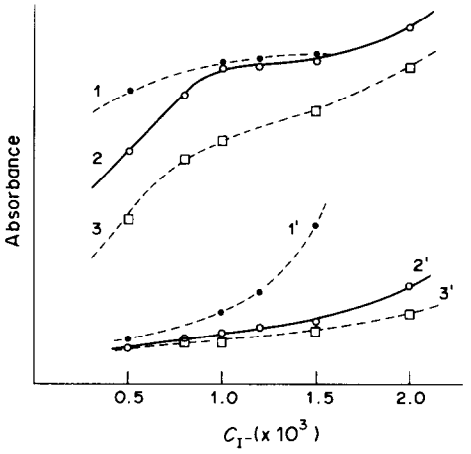

Fig. 1. Effect of the iodide and iodate concentrations on formation and flotation of the gold compound. Concentration of IO_3^-: curve 1, $6 \times 10^{-6}M$; 2, $5 \times 10^{-6}M$; 3, $3.5 \times 10^{-6}M$ (absorbance measurements against the blank). Blank values (curves 1′, 2′, 3′) measured against methanol.

The iodide/Methylene Blue system was the most promising and was investigated further.

Formation and flotation of the gold compound

When dilute hydrochloric or sulphuric acid containing gold (as $AuCl_4^-$), is mixed with iodide and Methylene Blue, and shaken with cyclohexane, a dark precipitate, containing all the gold, accumulates on the wall of the separatory funnel. The absorbance of a methanolic solution of the precipitate indicates that several dye molecules are associated with each gold atom, but this high absorbance is achieved only if iodine was also present in the aqueous phase.

It is known[12] that in acid medium gold(III) is reduced to gold(I):

$$AuCl_4^- + 4I^- \rightarrow AuI_2^- + I_2 + 4Cl^-$$

and it appears that the simple ion-pair $[(MB^+)(AuI_2^-)]$ may be associated with the tri-iodide/dyestuff ion-pair $[(MB^+)(I_3^-)]$.

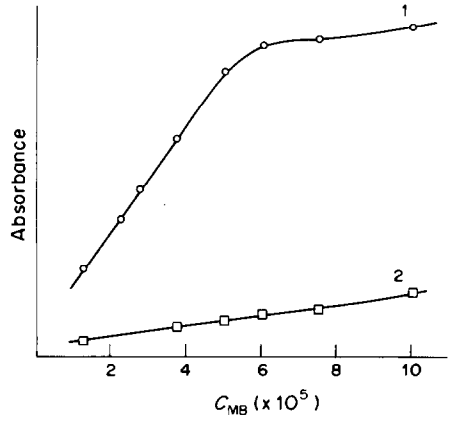

Fig. 2. Dependence of the absorbance of the methanol solution of the gold compound on the Methylene Blue concentration: curve 1, absorbance of the gold compound solution measured against the blank; 2, blank absorbance measured against methanol.

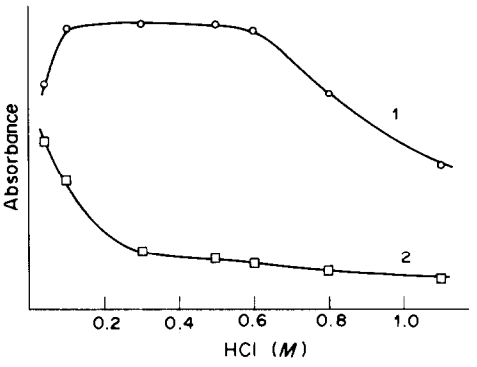

Fig. 3. Effect of the hydrochloric acid concentration on formation and flotation of the gold compound: curve 1, absorbance of the gold compound solution measured against the blank; 2, blank absorbance measured against methanol.

Reproducible and maximal absorbances are obtained if the aqueous phase, before the flotation, contains a fixed iodine concentration that is stoichiometrically smaller than the amount of dye added afterwards. The amount of iodine can be controlled by adding a known amount of potassium iodate and a suitable excess of potassium iodide. The solution should be protected from direct sunlight to avoid photochemical oxidation of the iodide. From Fig. 1, it is evident that at an iodate concentration of $5 \times 10^{-6}M$, the iodide concentration should be $1.0\text{–}1.3 \times 10^{-3}M$.

A Methylene Blue concentration of $6 \times 10^{-5}M$ (60–80-fold molar excess with respect to 2 μg of gold) gives maximal absorbance (Fig. 2). The optimum acidity range is rather narrow: 0.3–0.6M hydrochloric acid (Fig. 3). From a practical point of view, hydrochloric acid medium is more convenient than sulphuric acid medium, and gives lower blank values. Cyclohexane appears to be the best organic phase, its use resulting in maximum dye:metal molar ratio.

The precipitate accumulates on the wall of the separatory funnel above the liquid-phase level when the shaking has been completed, if the separatory funnel is opened, and presumably the precipitate clings to the wall as the thin film of organic solvent evaporates. Complete separation requires shaking of the phases for about 1 min. The volume of organic solvent is not critical and may be much smaller than that of the aqueous solution.

The precipitate, after removal of the liquid phase, must be washed free from excess of dye. A single washing with 20 ml of water (shaking for 60 sec) gives reproducible results, and the absorbance of the reagent blank is about 0.10.

The washed compound is readily dissolved in methanol or acetone but the methanolic solution is more stable. There is a small shift of about 5 nm in λ_{max} for the gold compound relative to the dye

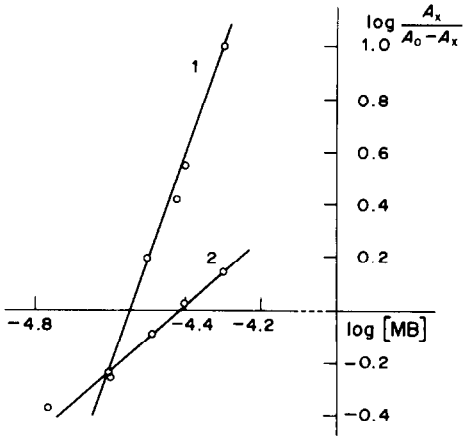

Fig. 4. Determination of the Au:MB molar ratio in the floated compound: curve 1, single washing; 2, double washing.

solution, which can be attributed to the influence of I_3^- and AuI_2^- on the dyestuff ions.

Composition of the gold compound

The molar ratio of metal to Methylene Blue in the complex was found to be 1:4 (on the basis of the ratio of the absorbance of the gold compound in the methanol to the absorbance of the solution of the free dye. This ratio was confirmed by the Bent and French method[20] (line 1 in Fig. 4).

Additional shaking (for 60 sec) of the precipitate with a second portion of water leads to a compound in which the gold:dye ratio is only 1:1 (line 2 in Fig. 4). Shaking for at least 45 sec is necessary to ensure complete conversion into the 1:1 complex.

Attempts were made to determine radiometrically, with ^{125}I, the ratio of gold to iodine in the precipitate separated by flotation. From 9 tests, it was found that on average one gold atom corresponds to 11 or 12 iodine atoms (the range of results was 9.7–13.2). Taking into consideration the limited precision of the method, this ratio may be postulated to be 1:11, which would correspond to the precipitate separated and washed with one portion of water being an adduct of two ion-association complexes:

$$[(MB^+)(AuI_2^-)]\cdot 3[(MB^+)(I_3^-)]$$

This adduct is rather unstable and decomposes during the second washing. The dye and iodide (I^-) pass to the aqueous phase and the iodine (I_2) to the residual cyclohexane present. The remaining compound is the simple ion-association complex $[(MB^+)(AuI_2^-)]$. From the analytical point of view, only the first compound is of interest, because it leads to a very sensitive spectrophotometric method for the determination of gold.

It must be emphasized that in contrast to the flotation–spectrophotometric methods for the determination of platinum metals[1-8] and other methods of this kind, based on ion-association complexes, the basis of the present method is a compound which does not contain a multivalent anionic complex of the element to be determined.

Determination of gold

The calibration graph obtained according to the procedure obeys Beer's law up to a gold concentration of 0.4 μg/ml. The molar absorptivity is 3.4×10^5 l.mole^{-1}.cm^{-1} at 655 nm. The method is therefore about 3.5 times as sensitive as the commonly used Rhodamine B method.

The method has been used for determination of gold at three concentration levels. The statistical evaluation of the results is presented in Table 1. The results for determination of trace amounts of gold in the presence of certain elements are listed in Table 2. Platinum, palladium, silver and mercury interfere considerably. Small quantities of iridium, rhodium, bismuth and cadmium can be tolerated. Copper does not interfere at 1000-fold weight ratio to gold, and tellurium practically does not interfere at all. It follows that before traces of gold are determined by the method, they can be separated by precipitation with tellurium as collector.[11-13]

The method was applied to determination of trace amounts of gold in copper. The sample was dissolved in 2–3*M* nitric acid, then diluted, some filter-paper pulp was added, and filtered off, washed with dilute nitric acid and water, then ignited. The residue from

the ignition was dissolved in *aqua regia* and the solution was evaporated to dryness. Hydrochloric acid was added to the residue and the solution again evaporated to dryness, and this step was repeated twice more. The residue was taken up in 1.5*M* hydrochloric acid and the gold was precipitated with tellurium as collector and hydrazine as reductant.[13] The precipitate was filtered off, washed with 1.5*M* hydrochloric acid and water and ignited. The product was dissolved in *aqua regia*, 20 mg of sodium chloride were added, and the solution was evaporated to dryness on a boiling water-bath. The evaporation was repeated after addition of hydrochloric acid. Gold was then determined according to the procedure given. Table 3 gives the results. The recovery of a known amount of gold added was 90–95%. The same result was obtained for the gold content of the copper by the Rhodamine B method.

Summary—Two liquid-membrane electrodes, one sensitive to Cu^{2+} and the other to Ag^+, were used for the determination of various sulpha-drugs with $pK_a \geqslant 6$ (as the sodium salts) by potentiometric titration with $CuSO_4$ and $AgNO_3$. The construction and basic characteristics of these two electrodes are discussed.

For the determination of sulpha-drugs with the aid of ion-selective electrodes, the literature so far gives only two methods. The first uses electrodes sensitive to sulphamerazine and sulphisomidine.[1] These electrodes are based on a nitrobenzene solution of the ion-association complex of the iron(II)–bathophenanthroline chelate and the respective sulpha-drug. The second,[2] which is more rapid and accurate, is based on the well-known ability of these compounds to form highly insoluble mercury(II) compounds.[3,4] For the determination, an Hg^{2+}-selective electrode and a commercial silver sulphide crystal electrode were used. Recently, new results for the determination of some sulpha-drugs by using Ag^+- or Cu^{2+}-membrane electrodes have been reported.[5–7]

In this paper, we report our further researches in the field of sulpha-drug determination with ion-selective electrodes, dealing with their determination in alkaline medium, in which they are found as sodium salts. We have chosen this direction for research because the injectable solutions of these sulpha-drugs are prepared by dissolving the sulpha-drug in 20% sodium hydroxide solution. The determination method we are proposing is based on the metathetic reaction:

$$z(R\text{–}SO_2\text{–}\underset{\displaystyle R'}{\underset{|}{N}}\text{–}Na) + M^{z+} \rightarrow (R\text{–}SO_2\text{–}\underset{\displaystyle R'}{\underset{|}{N}}\text{–})M^{z+} + z\,Na^+$$

$$(M^{z+} = Cu^{2+}, Ag^+)$$

The copper and silver salts of the sulpha-drugs are insoluble, so the sulpha-drugs may be determined by direct titration with copper sulphate or silver nitrate.

We have used both commercially available Cu^{2+}- and Ag^+-selective electrodes, and two electrodes of our own construction. The literature mentions numerous Cu^{2+}- and Ag^+-selective electrodes, having membranes which consist of copper or silver complexes, dissolved in suitable organic solvents.[8–18]

The electrodes prepared by us have membranes

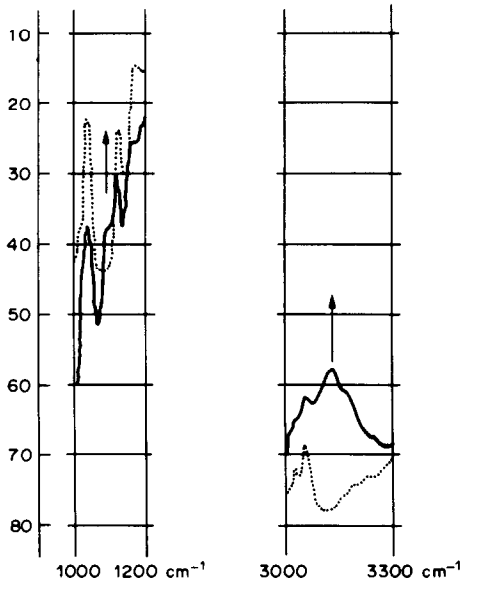

Fig. 1. Infrared spectra of the HRI ligand and $Cu(RI)_2$ complex —— HRI. ----- $Cu(RI)_2$.

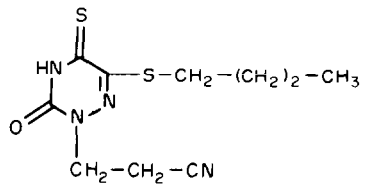
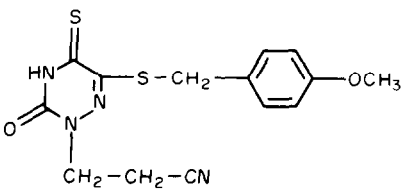
*To whom correspondence may be sent.



(HRI)



(HRII)

made with the copper and silver complexes of two derivatives (HRI and HRII) of aza-uracil.[19]

The functional groups of these compounds react in the thiol form, binding the metal to nitrogen and sulphur atoms; this is confirmed by the infrared spectra (Fig. 1). The characteristic band for thiocarbonyl ($C=S$) which appears in the ligand spectrum at 1113 cm^{-1} (as a shoulder), disappears in the spectra of the complexes. Further proof of coordination of the metal ion to the ligand in thiolic form is the disappearance of the ν_{NH} stretching band at 3100 cm^{-1}.

The proposed composition of the Cu^{2+} and Ag^{+} complexes was confirmed by elementary analysis of the compounds obtained in the solid state ($Cu_{theory} = 9.52\%$; $S_{theory} = 21.14\%$; $Cu_{found} = 9.86\%$; $S_{found} = 21.2\%$; $Ag_{theory} = 24.43\%$; $S_{theory} = 14.50\%$; $Ag_{found} = 24.0\%$; $S_{found} = 14.8\%$) and by determination of the combining ratios (1:2, 1:1) by the method of continuous variations.

EXPERIMENTAL

Apparatus and reagents

The e.m.f. values were measured at room temperature in stirred solutions, with an MV-87 digital pH/mV—meter (Prăcitronic, East Germany). The potentiometric titration curves were recorded with an automated outfit composed of a Radiometer TTT2 titrator, ABU 12 autoburette and SBR 2c recorder. A saturated calomel electrode (Radiometer K 401) was used as reference electrode. The pH measurements were made with a glass–calomel electrode pair (Radiometer types G 202 C and K 401).

All reagents used were of analytical grade, except HRI and HRII, which were obtained and purified by Cristescu.[19]

Preparation of the Cu^{2+}-selective membrane

Ten ml of $10^{-2}M$ $CuSO_4 \cdot 5H_2O$ were shaken in a separating funnel for 5 min with 15 ml of chloroform containing 0.0406 g of HRI, then the phases were separated and the organic layer was dried by passage through anhydrous sodium sulphate, transferred to a 100-ml standard flask and diluted to volume with chloroform. The concentration of the complex in this solution was $5 \times 10^{-4}M$.

Preparation of the Ag^{+}-selective membrane

Ten ml of $10^{-2}M$ $AgNO_3$ were mixed with 10 ml of chloroform containing 6.68 mg of HRII and shaken for 10 min. The phases were separated and the organic layer was dried and diluted to 100 ml as described above. The concentration of the complex in this solution was $10^{-3}M$.

Construction of electrodes

The construction of the electrodes has been described previously[20] and consists of impregnating the support material (a graphite rod 15 mm long, 6.5 mm in diameter, made water-repellent) with Cu–HRI or Ag–HRII solution in chloroform. The internal reference electrodes were eliminated by using a stainless-steel wire introduced into the graphite rod. The electrodes were stored in the appropriate organic phase and washed with distilled water between measurements.

Procedures

Potentiometric titration. The pair of electrodes (Cu^{2+}- or Ag^{+}-selective as indicator electrode and SCE as reference) were placed in the sample solution (20–30 ml, concentration *ca.* $10^{-2}M$). The sample was titrated with $0.1M$ $CuSO_4$ and/or $0.1M$ $AgNO_3$ solution. The end-point corresponds to the maximum slope on the E *vs.* volume titration curve.

Injectable aqueous solution of sulphamethoxidiazine. The contents of an ampoule were transferred with distilled water into a 25-ml standard flask and diluted to volume. A volume of 2.5 ml of this solution was transferred to a 50-ml beaker and 20 ml of distilled water were added. The solution was potentiometrically titrated with $0.1M$ $CuSO_4$ and/or $0.1M$ $AgNO_3$ solution, as above.

RESULTS AND DISCUSSIONS

The electrode function, E–pM^{z+}

The e.m.f. measurements were made with the electrochemical cell:

M^{z+}-selective membrane electrode	M^{z+} ($C_{Cu^{2+}}$, $C_{Ag^{+}}$) $I = 0.4M$ KNO_3 for Cu^{2+} $I = 0.1M$ KNO_3 for Ag^{+}	Satd. KNO_3 soln.	SCE	(I)

where $C_{Cu^{2+}}$ and $C_{Ag^{+}}$ represent the Cu^{2+} and Ag^{+} concentrations, respectively, varied in the range 10^{-6}–$10^{-1}M$. The measurements were made at constant ionic strength ($0.4M$ for Cu^{2+} and $0.1M$ for Ag^{+} adjusted with potassium nitrate) and the junction potential was kept constant. The variation of e.m.f. with pM^{z+} is presented in Fig. 2.

For the Cu^{2+}-selective electrode, the linear response range is 10^{-5}–$10^{-1}M$ with a slope of 30.6 mV/decade and for the Ag^{+}-selective electrode the linear response range is smaller (10^{-4}–$10^{-1}M$) but the slope is nearly Nernstian (59.7 mV/decade). The inability to obtain a better detection limit with this electrode is probably due to the adsorption of Ag^{+} ions at the end of the electrolyte bridge and on the surface of the glass vessel.

Extrapolation of both lines to $pM^{z+} = 0$ leads to values of $E_0' = 400$ mV for the Cu^{2+}-selective electrode and $E_0' = 548$ mV for the Ag^{+}-selective electrode.

Table 1. Effect of solvent on sensitivity of the Ag^+-selective membrane electrode

Solvent	Dielectric constant	Slope, *mV/decade*	Concentration range of linear response, M
Nitrobenzene	34.8	59.7	10^{-4}–10^{-1}
1,2-Dichloroethane	10.4	60	10^{-3}–10^{-1}
Chloroform	4.8	61	10^{-3}–10^{-1}

The linear response range of the Ag^+-selective electrode is reduced to 10^{-3}–$10^{-1}M$ when 1,2-dichloroethane or chloroform is used as solvent for the liquid membrane (Table 1).

Influence of pH. The pH range in which the potential remains constant is 3–7 for the Ag^+-selective electrode and 3–5.5 for the Cu^{2+}-selective electrode. The direct potential measurements for calibration of both electrodes were done at pH 5.

Response time. The response characteristics of the electrodes were evaluated by introducing them into copper sulphate and silver nitrate solutions, as appropriate, of different concentrations but identical acidity (pH 5) and recording the e.m.f. values as a function of time. The response time of the electrodes in dilute solutions ($pM^{z+} = 4$ and 5) is about 4 min, and in concentrated solutions only a few seconds.

Selectivity. The selectivity coefficients $K_{M^{z+},M^{z'+}}$ were calculated by the method of Srinivasan and Rechnitz[21] from the relation:

$$\log K_{M^{z+},M^{z'+}} = \frac{E_{II} - E_I}{S} + \log [M^{z+}] - \log [M^{z'+}]^{z/z'}$$

where S is the slope of the electrode function, E_I is the e.m.f. of cell (I) for $C_{M^{z+}} = 0.01M$ and E_{II} is the e.m.f. of an electrochemical cell of the type:

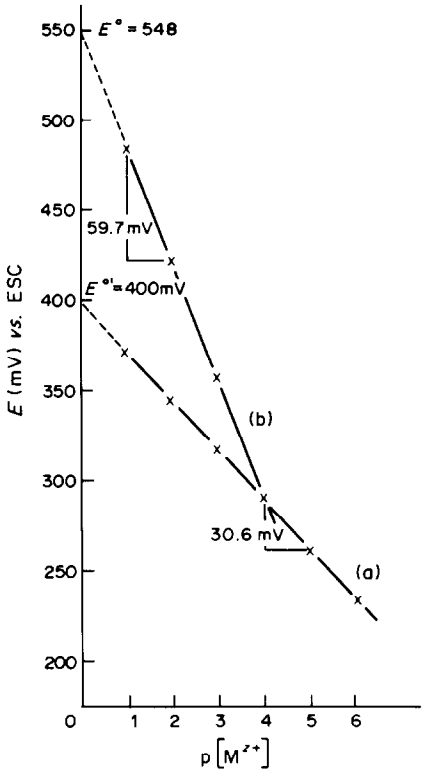


Fig. 2. The electrode functions of (*a*) the Cu^{2+}- and (*b*) Ag^+-selective electrodes.

M^{z+}-selective membrane electrode	$M^{z'+}$ ($C_{M^{z'+}} = 10^{-2}M$ $I = 0.4M$ for Cu^{2+} $I = 0.1M$ for Ag^+	Satd. KNO_3 soln.	SCE	(II)

where $M^{z'+}$ represents the main metal cations that form more or less stable compounds with HRI and HRII. With the exception of copper, all cations tested were in the form of the nitrates, at pH 3. The values of the selectivity coefficients may be seen in Table 2. The cations which interfere in the Cu^{2+}-selective electrode response are Ag^+ and Hg^{2+}, and Hg^{2+} also interferes in the response of the Ag^+-selective electrode.

Applications to sulpha-drug determination

All the sulpha-drugs listed in Table 3 could be directly titrated (as the sodium salts) with $CuSO_4$ and/or $AgNO_3$ solutions.

The potentiometric jumps at the equivalence point are big enough for the maximum error of determination to be 0.5% with the Ag^+-selective electrode and 1.9% with the Cu^{2+}-selective electrode. The amounts of sulpha-drug taken for determination varied from 25 to 87 mg.

Table 3 also lists the values of the acidity constants of the sulpha-drugs. The proposed method is applicable only to sulpha-drugs with $pK_a \geqslant 6$. Sulphafurazol

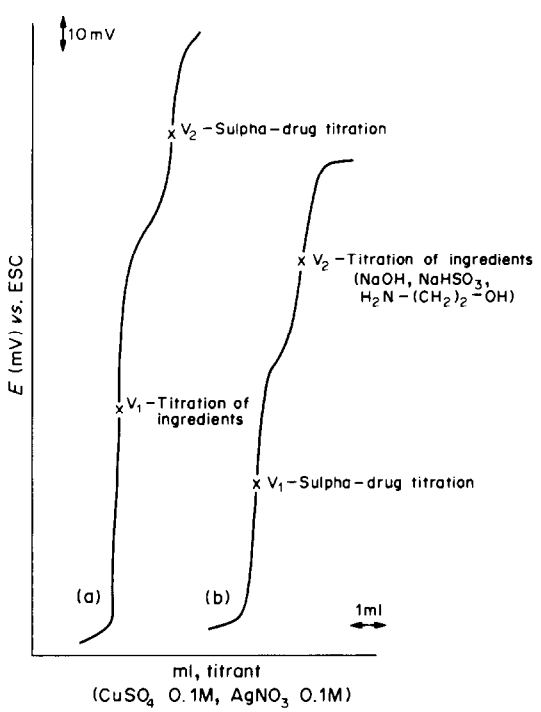

Fig. 3. Potentiometric titration of an injectable solution of sulphamethoxidiazine with the (a) Cu^{2+}-selective electrode; (b) Ag^+-selective electrode.

(pK_a = 5.5) does not form insoluble salts with $CuSO_4$ or $AgNO_3$.

Further, the determination of sulphamethoxidiazine (Sulphametin, Bayerena) in injectable solutions for veterinary use was examined. These solutions contain the sulpha-drug dissolved in 20% sodium hydroxide solution, together with $NaHSO_3$ and ethanolamine. All these ingredients can form salts or complexes with both $CuSO_4$ and $AgNO_3$. The potentiometric titration curves obtained are presented in Fig. 3; two significant potential jumps are obtained.

In the titration with $CuSO_4$, all the ingredients are titrated together in the first step of the titration curve, whereas in the titration with $AgNO_3$, the first potential jump corresponds to the sulpha-drug and the second to the other ingredients. For this reason we prefer the titration with $AgNO_3$ for determination of sulphamethoxidiazine in injectable solutions. The method is not applicable to formulations containing more than one titratable sulpha-drug.

SPECTROPHOTOMETRIC DETERMINATION OF ALIPHATIC PRIMARY AND SECONDARY AMINES BY REACTION WITH *p*-BENZOQUINONE

SAAD S. M. HASSAN*, M. L. ISKANDER and N. E. NASHED
Department of Chemistry, Faculty of Science, Ain Shams University, Cairo, Egypt

(*Received* 12 *March* 1984. *Revised* 3 *October* 1984. *Accepted* 5 *November* 1984)

Summary—A simple, sensitive and selective spectrophotometric method has been developed for determination of aliphatic primary and secondary amines. It is based on a reaction with excess of *p*-benzoquinone in ethanol whereby 1:1 (amine:quinone) coloured products are obtained, which have maximum absorption at 510 nm and $E^{1\%}_{1cm}$ in the range 400–650. The effect of solvent, temperature, concentration of quinone and the presence of water have been kinetically investigated by the initial rate method. The conditions for monitoring amine concentrations as low as 0.1 μg/ml are optimized in the light of the kinetic data. Results with an average recovery of 98.5% and mean standard deviation of 1.9% are obtained with 9 different amines without interference from tertiary amines, ammonia, amides, imides, anilides, hydrazines and α-amino-acids.

Existing methods for the spectrophotometric determination of aliphatic primary and secondary amines are based on reactions with nitro compounds substituted with active halogen or sulphonic groups, carbonyl compounds, organic dyes and inorganic reagents. In this connection, chromogenic reagents such as 2,4-dinitrofluorobenzene,[1] nitrophenylazobenzoyl chloride,[2] dinitrobenzyl chloride,[3] dinitrobenzenesulphonyl chloride,[4] and trinitrobenzenesulphonic acid[5] have been suggested. A method based on the reaction of aliphatic amines with picric acid and 18-crown-6-ether to yield a 1:1:1 complex, followed by extraction of the complex and absorbance measurement at 377 nm, has been proposed.[6] Reaction of *cis*-α,β-dinitrostilbene with aliphatic amines, and subsequent treatment with alkali, gives a coloured product with maximum absorption at 410 nm.[7] Many of these methods, however, entail a time-consuming extraction step, involve the use of water-sensitive reagents and suffer from lack of selectivity.

Aliphatic amines have also been spectrophotometrically determined by reaction with 1,2-naphthoquinone-4-sulphonic acid,[8] salicylaldehyde,[9,10] acetyl chloride and iron(III),[11] Methyl Orange,[12] Bromothymol Blue,[13] Chrome Azurol-S and aluminium,[14] alcoholic copper(II) chloride,[15] ascorbic acid and dimethylformamide,[16] and cobalt(II) thiocyanate.[17] The initial rate of colour development with chloranil,[18] and the depressive effect of amines on the absorbance of the copper–EDTA complex in aqueous and non-aqueous solvents[15,19,20] have been adapted for the determination of some aliphatic amines. Many of these methods suffer serious interference from metal ions, amines and α-amino-acids.

On the other hand, quinones have long been known to react with amines to give coloured products. Some of these reactions have been utilized for qualitative and quantitative determination of some quinones[21–24] and amines.[25–27] The present work demonstrates that the fairly simple reaction of aliphatic primary and secondary amines with *p*-benzoquinone under optimized conditions is suitable for determination of low levels of amines without interference from many compounds containing nitrogen and hydrogen.

EXPERIMENTAL

Reagents

All reagents used were of analytical grade unless otherwise stated. Doubly distilled water and solvents were used throughout. The aliphatic amines (purity ≮ 97%) were obtained commercially and used without purification. Ethanolic stock solutions ($10^{-3}M$) were prepared and standardized by potentiometric titration with copper.[28] *p*-Benzoquinone was purified by repeated sublimation and a $10^{-2}M$ stock solution in ethanol prepared.

Procedures

Kinetic measurements. Stock solutions ($1–25 \times 10^{-4}M$) of piperidine and of *p*-benzoquinone in ethanol, acetonitrile and dioxan, and the pure solvents were brought to the required temperature (25, 30 or 35 ± 0.1°) by standing them in a water-bath for 20 min. Then 1.00, 1.50, 2.00, 2.50, 3.00, 4.00 and 5.00 ml portions of *p*-benzoquinone solution were transferred to 25-ml standard flasks (brought to the same temperature) and containing 1.00–5.00 ml of piperidine solution and enough solvent to bring the mixture to the mark, and the solutions were mixed. The quinone:piperidine molar ratio covered the range from 1:5 to 5:1. A portion of the mixture was immediately transferred to a 1.00-cm silica cuvette placed in the constant-temperature cell-

compartment of the spectrometer. The absorbance at 510 nm was monitored as a function of time, against a blank similarly prepared without piperidine. From the absorbance–time curves, the initial slopes (dA/dt), initial rates, rate constants and thermodynamic parameters were calculated by standard methods.[29,30]

Determination of aliphatic amines. Portions (0.05, 0.10, 0.50, 1.00, 2.00, 3.00 and 5.00 ml) of $10^{-3}M$ standard amine solution in ethanol were transferred into 10-ml standard flasks, followed by 1.0-ml portions of $10^{-2}M$ ethanolic *p*-benzoquinone. Each test was run in triplicate. The flasks were left for 30 min in a water-bath kept at 50 ± 5°, then cooled, diluted to the mark with pure ethanol and mixed. The absorbance was measured at 510 nm in a matched set of 1.00-cm silica cuvettes against a blank prepared similarly but without the amine. A calibration graph was drawn for each amine and used for subsequent measurement of unknown concentrations.

RESULTS AND DISCUSSION

p-Benzoquinone has a maximum absorption at 430 nm with $E^{1\%}_{1\,cm} \sim 2$, and readily reacts with aliphatic primary and secondary amines in various water-miscible organic solvents to give an intense colour with maximum absorption at 510 nm and $E^{1\%}_{1\,cm}$ in the range 400–650. In the presence of >20% v/v water or low concentrations of the quinone reagent, two absorption maxima, at 370 and 510 nm, are obtained (Fig. 1). The nature, stability and rate of colour development are mainly dependent on the reactivity of the amines, nature of the solvent, concentration of quinone and presence of water.

Effect of solvent

The slopes of log–log plots of initial concentration of piperidine or *p*-benzoquinone *vs.* initial rate of colour development in pure ethanol are both unity, indicating first-order kinetics with respect to the amine and quinone, and that the overall reaction is second-order.[29,30] Similar results were obtained with 50% v/v water–ethanol mixture, and pure dioxan and acetonitrile as media. Thus the rate-determining step involves an equimolar ratio of the reactants.

The kinetic data (Table 1) show that the rate of reaction decreases in the order: ethanol > acetonitrile > dioxan. The reaction in dioxan requires an induction period of at least 22 min, and the rate constant is two orders of magnitude less than that for ethanol medium. This is probably due to the low dielectric constant and polarity of dioxan and also to solvent–solute interaction. Dioxan solvates piperidine and thus deactivates it in the reaction with *p*-benzoquinone. This was confirmed from the infrared spectra of piperidine, dioxan and a mixture of both. The N–H stretching absorption band at 3450 cm^{-1} in the spectrum of pure piperidine appears at 3400 cm^{-1} in the spectrum of piperidine–dioxan mixture but not in the spectra of piperidine in either ethanol or acetonitrile, where the band-shift did not exceed 10 cm^{-1}.

Table 1. Kinetics and thermodynamic parameters of the reaction of *p*-benzoquinone with piperidine in different pure solvents

Solvent	K_2, $l.mole^{-1}.sec^{-1}$ 25°C	30°C	35°C	$\Delta E^{\#}$, *kcal/mole*	$\Delta H^{\#}$, *kcal/mole*	$\Delta S^{\#}$, $cal.mole^{-1}.deg^{-1}$	$\Delta G^{\#}$, *kcal/mole*
Ethanol	0.46	0.70	1.22	16.0	15.4	−8.4	18.0
Acetonitrile	0.33	0.54	0.85	17.2	16.6	−5.1	18.1
Dioxan	0.017	0.026	0.045	19.1	18.5	−9.2	21.9

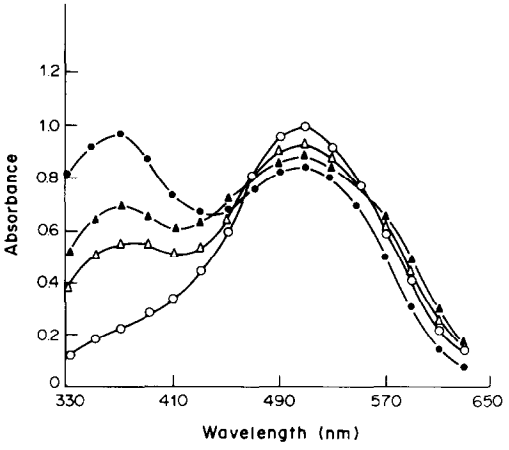

Fig. 3. Effect of *p*-benzoquinone concentration on the absorption spectrum of piperidine in pure ethanol at 30°. Piperidine:quinone molar ratios were: (●) 1:5; (▲) 1:10; (△) 1:30; (○) 1:40–1:60.

The activation parameters at 30° were calculated by the Arrhenius equation.[29,30] $\Delta G^{\#}$ in ethanol was very close to that in acetonitrile and both were less by about 4 kcal/mole than that in dioxan, indicating that dioxan is a less favourable medium. In ethanol, however, $\Delta H^{\#}$, $\Delta S^{\#}$ and $\Delta E^{\#}$ are all smaller.

Effect of water and quinone concentration

In ethanolic solutions containing 20–80% v/v water, the products from all the amines investigated display two maxima, at 510 and 370 nm. Although the order of the reaction is not affected by the presence of water, the rate of colour development substantially increases to a maximum and constant value ($k_2 = 4.51\ \text{l.mole}^{-1}.\text{sec}^{-1}$ at 30°) in 50–80% v/v water–ethanol mixtures. The stoichiometry of the reaction of piperidine with *p*-benzoquinone at a total molar concentration of $2.5 \times 10^{-4}M$ and temperature of 30° was examined in pure ethanol and 50% v/v aqueous ethanol by the continuous-variations method,[31] with measurement at 510 and 370 nm. Maximum absorbances were obtained at mole ratios of about 2:1 and 3:2 (quinone:piperidine) in the pure and aqueous ethanolic solutions, respectively. No evidence for formation of other species was noticed when the amine and quinone concentrations were varied in the range $0.6–5.0 \times 10^{-4}M$. Mole-ratio plots confirmed these conclusions.

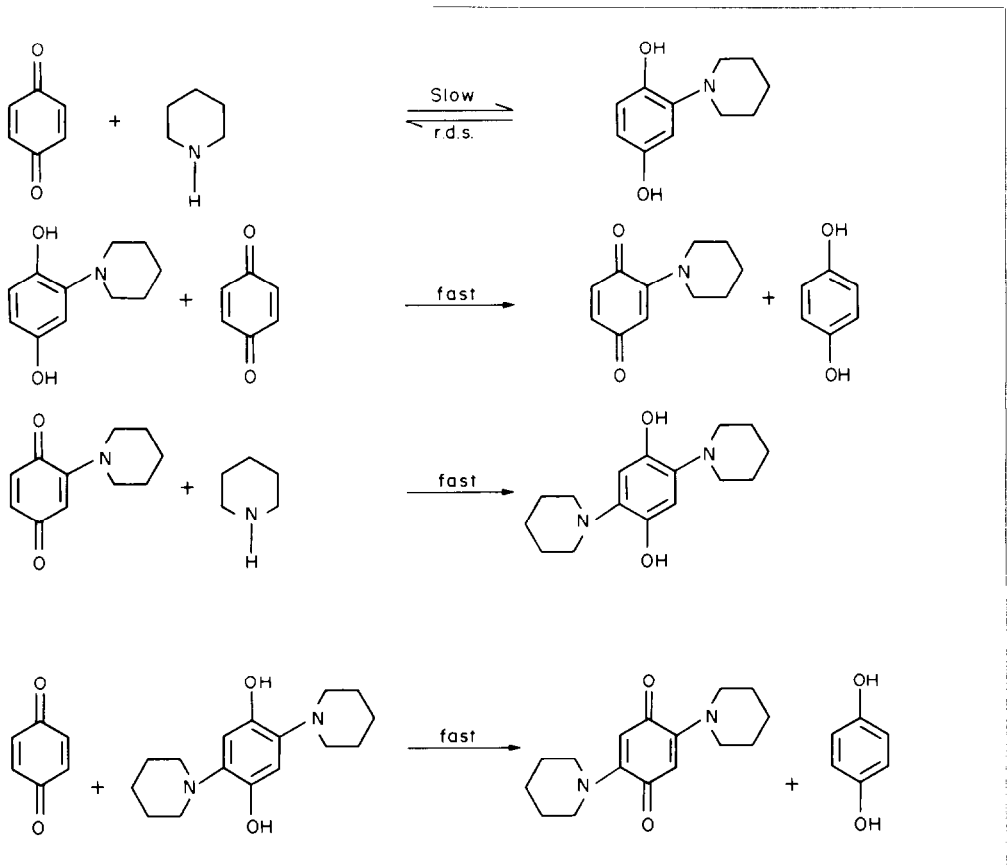
The effect of quinone concentration on the nature of the spectra was also investigated by varying the piperidine:*p*-benzoquinone mole ratio (in pure ethanol) from 1:5 to 1:60. Figure 3 shows only one maximum (at 510 nm) when the quinone:piperidine mole ratio is greater than 30. As the mole-ratio of the quinone decreases, a band at 370 nm begins to appear and increases in intensity with decrease in quinone:piperidine mole ratio. The product when the reaction is done in ethanolic solutions containing >20% v/v water has an absorption spectrum with two maxima at 510 and 370 nm, irrespective of the quinone:piperidine mole ratio. These data indicate the possible formation of two different chromogens. Further studies showed that absorbance measurement at 370 nm, though sensitive for most amines, is not analytically useful, owing to irreproducible readings and poor precision.

Nature of the reaction and products

The chromogen produced by reaction of piperidine with excess of *p*-benzoquinone (quinone:piperidine mole ratio ~30) in pure ethanol was isolated as red crystals, m.p. 140°. The elemental analysis corresponded to formation of piperidyl-*p*-benzoquinone. The absorption spectrum of the compound displays maximum absorption at 510 nm. The infrared spectrum confirms the identity of the product, showing absorption bands at 2930, 1635, 1645, 880 and 810 cm^{-1}, due to the stretching vibrations of piperidyl C–H, quinonoid carbonyl, conjugated double bonds, and wagging vibrations of one isolated and two adjacent aromatic hydrogen atoms, respectively. Another chromogen was isolated as brown crystals (m.p. 177°) from an aqueous ethanolic reaction mixture containing an equimolar ratio of both reactants. This product has only one absorption maximum, at 370 nm, and both the elemental analysis and infrared data agree with the formation of 2,5-bis(dipiperidyl)-*p*-benzoquinone.

It is possible to suggest that the reaction of amines with *p*-benzoquinone in pure ethanol proceeds by 1,4 addition of one mole of amine to one mole of quinone to give piperidylhydroquinone, which on oxidation with a second mole of quinone gives piperidyl-*p*-benzoquinone (1:2 amine–quinone reaction). The latter product adds a second mole of amine in the presence of water or low concentrations of the quinone, to give 2,5-bis(dipiperidyl)-*p*-hydroquinone, which on further oxidation with a third mole of quinone yields 2,5-bis(dipiperidyl)-*p*-benzoquinone (2:3 amine–quinone reaction). Water probably en-

hances the reactivity and polarizability of the quinone carbonyl group by increasing the dielectric constant of the reaction medium. The reaction can thus be represented by the following scheme:



Optimum reaction conditions

The time required for maximum colour development at 510 nm by reaction of various aliphatic amines with >30-fold mole ratio of *p*-benzoquinone in pure ethanol at 30° is ~2 hr. At 50 ± 5°, the colour intensity reaches 95% of its maximum after ~30 min (Fig. 4). The presence of up to 15% v/v water has no significant effect on the absorbance and 1 ml of 10 ^{2}M ethanolic *p*-benzoquinone solution is adequate for the determination of various amines in the concentration range 0.1–20 μg/ml. These conditions give reproducible results and small variations in timing, quinone concentration, temperature and water content introduce no significant error. The intensity and nature of the colour are independent of pH in the range 7.5–10. At pH <5, no reaction takes place, probably because of the low nucleophilicity of the protonated amines.

Determination of amines

The colour developed at 510 nm with primary and secondary aliphatic amines under the optimized conditions is stable after 1 hr, and remains so for at least 24 hr. Beer's law holds over the amine concentration range 0.1–20 μg/ml. Linear regression analysis of the calibration data for some amines gave the values shown in Table 2 for the relation $A = a + bc$ where A is the absorbance at 510 nm in a 1.00-cm cell, a and b are respectively the intercept and slope of the calibration graph, and c is the concentration of the amine (μg/ml) in the final solution. The relative standard deviation (5 replicates) for 1–10 μg/ml concentration of the amines was 1.9%, and the average recovery 98.2%.

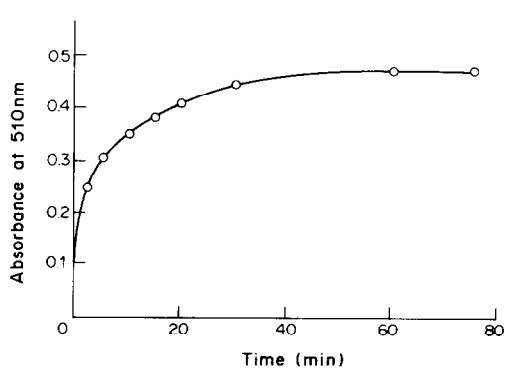


Fig. 4. Effect of time on the absorbance of the colour developed by reaction of 9.4 μg/ml piperidine with excess of *p*-benzoquinone in pure ethanol at 50°.

Table 2. Statistical analysis of the calibration graphs ($A = a + bc$) and results for the determination of some aliphatic amines by reaction with *p*-benzoquinone in pure ethanol at 50°C

*Absorbance.

†Absorbance.ml.μg^{-1}.

§The calibration graphs were prepared by use of amine solutions standardized by potentiometric titration with copper sulphate; the recovery values are based on nominal concentrations of amines assumed to be 100% pure.

Aromatic primary amines under the same conditions give a less intense colour, which depends on both the nature and position of the substituent group. Electron-attracting groups tend to give lower colour intensity than electron-repelling groups do. This effect decreases with substitutional position in the order *para* > *meta* > *ortho*. The $E^{1\%}_{1cm}$ values at 510 nm for aniline and its *p*-Cl, *m*-Cl, *o*-Cl, *p*-NO_2, *m*-NO_2, *p*-CH_3, *m*-CH_3 and *o*-CH_3 derivatives are 380, 280, 170, 90, 50, 130, 450, 360 and 340, respectively. No interference is caused by up to 1 mg/ml of ammonia, tertiary amines (*e.g.*, tripropylamine), amides (*e.g.*, benzamide, acetamide), imide (*e.g.*, succinimide), anilides (*e.g.*, acetanilide, benzanilide), α-amino-acids (*e.g.*, glycine, alanine) and hydrazines (*e.g.*, phenylhydrazine, methylhydrazine).

It can be seen that the present method offers the advantages of: (*a*) reagent availability and stability; (*b*) reasonable selectivity in the presence of many other NH-containing compounds; (*c*) less time consumption and fewer manipulation steps; (*d*) higher sensitivity than many of the most commonly used[5,8,9,11] or recently proposed[6,7,14] spectrophotometric procedures.

CORROSION MEASUREMENTS BY POTENTIAL-STEP CHRONOAMPEROMETRY

R. VON WANDRUSZKA, S. W. ORCHARD and A. GREEFF
Department of Chemistry, University of the Witwatersrand, Johannesburg, South Africa

(*Received* 20 *July* 1984. *Revised* 20 *September* 1984. *Accepted* 31 *October* 1984)

Summary—A solid-state computer-controlled system has been developed for the measurement of corrosion currents under potentiostatic anodic conditions. The system applies a potential step and measures the resulting current for a variable number of cycles. Data are stored and manipulated by the computer. Tests show that corrosion behaviour of metals in various environments can be evaluated.

Potentiostatic current–time curves have been used to study the attack on the passive surface of steel by chloride ions.[1,2] Similar studies on aluminium were reported subsequently,[3] and various aspects of the measurements involved have been discussed. In all cases the metal surfaces were passivated anodically in sulphuric acid medium and then disturbed by the addition of an aggressive anion[1-3] or by mechanical means.[4]

The similar technique of potential-step chronoamperometry with a clean surface is well-suited as an alternative procedure for the comparative evaluation of the corrosive behaviour of different environments on metals. The metal electrode is subjected to an anodic potential step and the resulting current is monitored for a period of about 30 sec. Depending on the nature of the metal and its environment, the current varies in a characteristic manner during this relatively short time. The potential preceding the anodic step must be sufficiently cathodic to prevent premature attack on the metal.

In principle, these measurements may be done with a potentiostat linked to a chart recorder. In such an arrangement, however, some readings within the first second of the potential step may be missed because of recorder lag. Furthermore, it may be difficult to eliminate the noise that invariably arises.[3]

The present paper describes a microcomputer-controlled system comprising a solid-state potentiostat and a synchronized current-measurement circuit. Current readings are taken at a rate of 4 per sec, and data manipulation, such as plotting, smoothing and storing, is done quickly and easily by the computer. Relevant calculations can be done conveniently on the stored data. The system was tested with representative chronoamperometric measurements involving mild steel and two stainless steels in a variety of electrolyte solutions. Comparative assessment of corrosion and passivation behaviour appears to be possible.

EXPERIMENTAL

Apparatus

A standard three-electrode cell, comprising a steel working electrode, a platinum counter-electrode and a calomel reference electrode, was used for the measurments. The cell contained 40 ml of solution and had a water jacket for temperature control. It was closed from the atmosphere by a standard titration-cell lid. A solid-state potentiostat and a current-measurement circuit were custom-built on a single board and interfaced to an Apple IIe microcomputer. The interface circuitry was included on the same board.

Circuit construction

The circuit is shown in Fig. 1. The computer interface is based on a Motorola 6821 peripheral interface adaptor (PIA), which has two peripheral registers, PA and PB, each comprising an 8-bit bus. The buses function independently and may be configured for either input or output. They are accessed through a bi-directional data bus, which is linked directly to the corresponding data lines in the computer input/output (I/O) slot. Register selection in the PIA is achieved by means of two "Register Select" lines, RS-0 and RS-1. These lines are controlled by the two least significant bits (lsb; A0 and A1) of the computer address bus. While all 16 bits of the address bus appear in the I/O slot, only the 12 most significant ones are involved in slot addressing, leaving the 4 lsb free for interfacing use. The circuit construction allows for PIA register selection in every address directed at the I/O slot.

The PIA is enabled by means of three "Chip Select" (CS) lines and the Read/Write selection is made through the R/$\overline{W}$ bit. These controls are manipulated with the "$\overline{\text{Dev Sel}}$" and "R/W" bits in the I/O slot. The $\overline{\text{Dev Sel}}$ line pulses low when the I/O slot is addressed and the R/$\overline{W}$ line assumes the state corresponding to either input or output. The signals are decoded as shown in Fig. 1, the PIA being enabled only when the I/O signals are true, during the 300-nsec period following an I/O address. This lay-out eliminates the possibility of accidental decoding of random I/O signals.

In the present application, the PA-bus is configured for input and the PB-bus for output. The PB-bus is linked to an 8-bit digital-to-analogue converter (DAC-08, PMI),[6] which generates the potential step. It is connected to an adder-type solid-state potentiostat[7] and controls the potential applied to the counter-electrode. The reference electrode is included in the feedback loop of the control amplifier, which also contains a voltage follower for impedance matching. The current at the working electrode is converted into a voltage by a current follower with adjustable feedback resistance. For the duration of the measurement the voltage is held constant by a sample-and-hold amplifier (SMP-11, PMI) with a gain of unity.

The analogue signal is digitized with a 12-bit analogue-to-digital converter (ADC 7109, Intersil). This is a dual-slope integrating converter, operating on a 5-MHz time base provided by an external crystal oscillator. Completion of a conversion is indicated by a "Status" line, which is used to interrupt the computer.

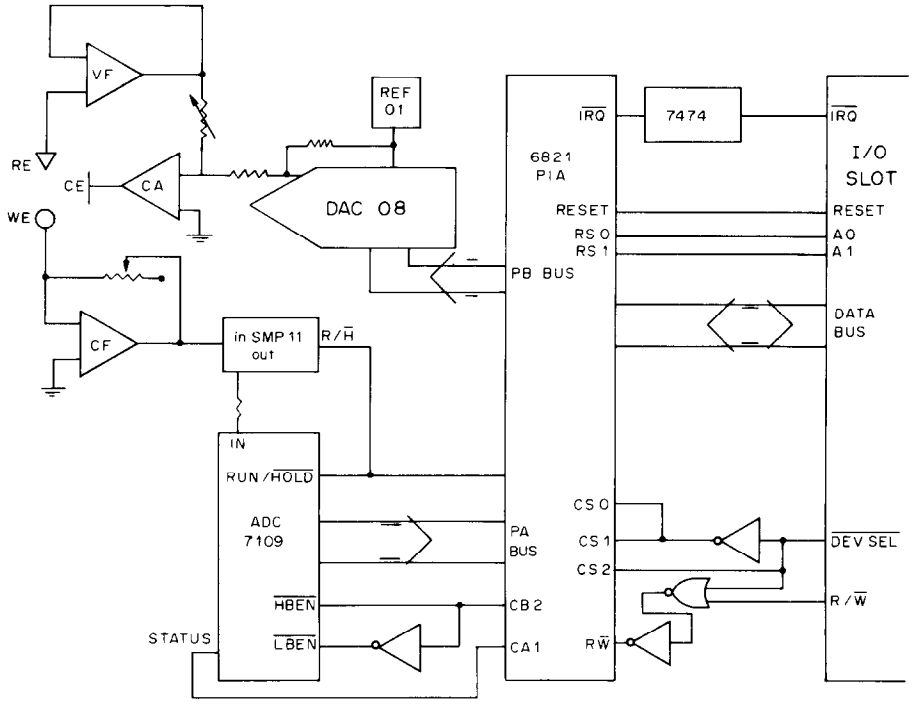

Fig. 1. Potentiostat and corrosion measurement circuit. WE = working electrode; CE = counter-electrode; RE = reference electrode; CA = control amplifier; CF = current follower; VF = voltage follower.

The interrupt signal is processed through the PIA (CA-2 line), giving a negative transition on the IRQ line on activation. It was found that direct application of this signal to the I/O interrupt line was not satisfactory: it invariably caused the program to crash after a few cycles. This problem was eliminated by the inclusion of a 7474 flip-flop as shown in Fig. 1. The flip-flop is clocked with the Apple Φ0 clock, allowing the interrupt to pass only after completion of a timing cycle.

The ADC output comprises 12 bits, as well as an over-range and a polarity bit. This necessitates a 2-part reading protocol for each conversion, the Apple data bus being only 8 bits long. This is facilitated by the provision of separate enabling lines on the ADC: LBEN for the 8 lower bits and HBEN for the 4 higher, and the over-range and polarity bits. All these are 3-state outputs, so enabled and disabled lines can simply be connected together to allow for 14-to-8 bit multiplexing.

Enabling control is achieved with a PIA control line (CB-2), which is in turn controlled through internal registers. The bits in these registers, and hence the CB-2 output, can be changed with a single computer command. As shown in Fig. 1, high-byte and low-byte enabling are mutually exclusive.

A further ADC input, the "Run/Hold" line, is controlled by the CA-2 output of the PIA. This output is similar to CB-2 and can be similarly accessed. The ADC is configured with external RC-components to give the maximum reading of 4095 for a working electrode current of 3 mA.

Circuit operation

The relatively slow reading speed required for the experiments allows for various circuit operations to be performed under software control. The first step consists of the application of a starting potential to the counter-electrode. This is achieved by placing the appropriate byte on the DAC. Next, by the same method, the potential is stepped anodically to a value at which current flows. The DAC has an output settling time of 85 nsec and the 741 operational amplifier has a rise time of less than 0.5 μsec, so the circuit responds virtually instantaneously relative to the experimental time scale of 4 readings per second.

During these manipulations the ADC is in the HOLD mode, switched by the software-controlled CA2 line of the PIA. Following the potential step, the ADC RUN mode is instituted by a high transition on CA2. The same line is used to put the SMP-11 in the HOLD mode, to prevent changes of signal during the measurement. Completion of a conversion is signalled by the status line and used to interrupt the computer. The program responds by switching the ADC to the HOLD mode and reading the output.

The high-byte and low-byte readings thus obtained are each temporarily stored as a variable. During each cycle, the contents of the two variables are combined to give a single decimal number. This number is stored in an array for later manipulation. The process is repeated for a software-controlled number of cycles. The conversion speed of the ADC depends to some degree on the magnitude of the signal. However, comparative tests revealed that in this circuit the differences involved are negligible.

A flow chart of the control program is shown in Fig. 2. The data obtained are filed on a floppy disk for future reference. A program for data manipulation and plotting current/time curves was written. This includes Savitsky–Golay smoothing,[8] curve-area determination by Simpson's rule integration, and passivation time and charge calculations. Hard copies of plots can be obtained on a dot matrix printer.

Sample preparation

The steels used in this study were mild steel, 409SS stainless steel and 316L stainless steel. The compositions of

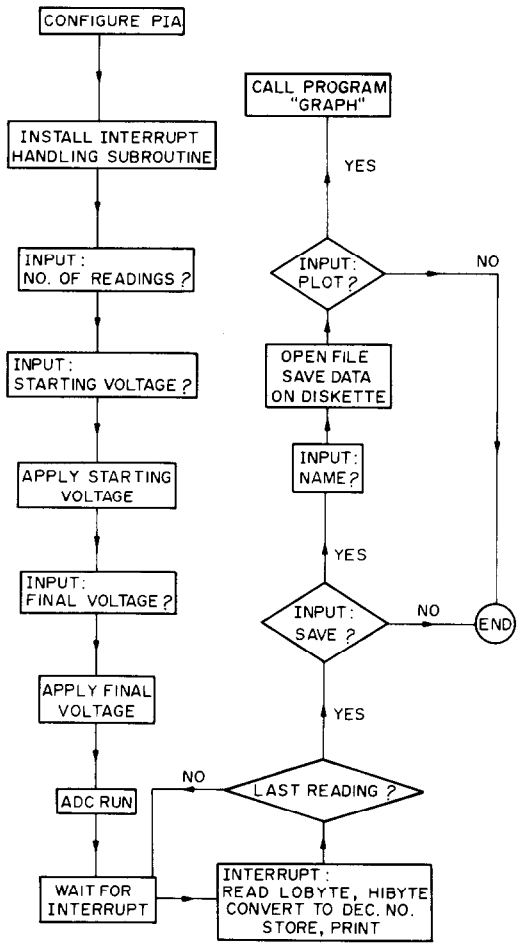

Fig. 2. Flow-chart of circuit control program.

the stainless steels are given in Table 1. The steels were formed into cylindrical electrodes and polished to optical smoothness. The electrode areas exposed to the solution were 79.8 mm^2 (mild steel), 153.15 mm^2 (409SS) and 157.87 mm^2 (316L). After each run the electrodes were thoroughly cleaned with ultrafine emery paper.

The deaerated solutions used in certain measurements were prepared by passage of high-purity nitrogen for 20 min.

RESULTS AND DISCUSSION

Mild steel

The results of measurements taken with mild steel are summarized in Table 2. The height of the potential step was limited by the maximum allowable corrosion current (3 mA). However, depending on the passivation characteristics of the system under investigation, the anodic voltages employed gave rise to significant currents. Figure 3 shows a number of current/time curves for non-passivating systems.

It can be seen that the aggressive sodium chloride solution gave a steadily rising current after an initial decrease. This decrease probably arose because the very first reading was high, owing to a brief capacitive surge accompanying the potential step. The sulphate solution gave a similar curve, but with a more gradual initial rise. Moreover, from measurements taken over a longer time, it was found that the current in the sulphate solution reached a steady value after about 50 sec, whereas the current in the chloride solution continued to rise after 90 sec. This is consistent with pitting corrosion and hence progressive surface-area enlargement in the chloride solution.

The fluoride solution gave a constant current after 20 sec, whereas in the thiocyanate solution the current first fell and then rose slowly. Interestingly, in the latter solution the current still continued to rise after 100 sec. This indicates that thiocyanate, too, has a surface-roughening effect.

After the initial surge, the current in the perchlorate solution first rose, resembling that in sulphate medium, but then gradually decreased. It reached a relatively high constant value after about 22 sec.

The curve for the passivating nitrate solutions is shown in Fig. 4. Clearly, the current decreased strongly in the passivation process. If, for the present purpose, "passivity" is defined as the situation in which the current has fallen to 3% of its initial maximum value, then the passivation time was 6 sec. The area under the curve was integrated and the charge involved in passivation was found to be 2.02 mC. This corresponds to 25 $\mu C/mm^2$. Nitrate concentrations of 0.1, 0.25 and 0.5*M* gave similar passivation times and charges.

Table 1. Compositions of stainless steels (%)

Element	409SS	316L
C	0.025	0.024

P	0.018	0.024
Mn	0.89	1.25
Si	0.63	0.55
Cu	0.08	0
Co	0.08	0.08
Ti	0.24	0
Mo	0.08	2.05
Cr	11.12	16.41
Ni	0.33	16.08

Table 2. Passivation behaviour of mild steel in various solutions

Solution (1*M*)	Observation	Potential step, *V vs.* SCE
NaCl	No passivation	−0.7 to −0.45
Na_2SO_4	No passivation	−0.7 to −0.3
$NaClO_4$	No passivation	−0.7 to −0.45
KF	No passivation	−0.3 to −0.11
LiCl	No passivation	−0.55 to −0.3
KSCN	No passivation	−0.55 to −0.4
KNO_3	Passivation	−0.3 to +0.63
$NaClO_3$	Passivation	−0.55 to −0.06
$Ca(NO_3)_2$	Passivation	−0.55 to +0.6

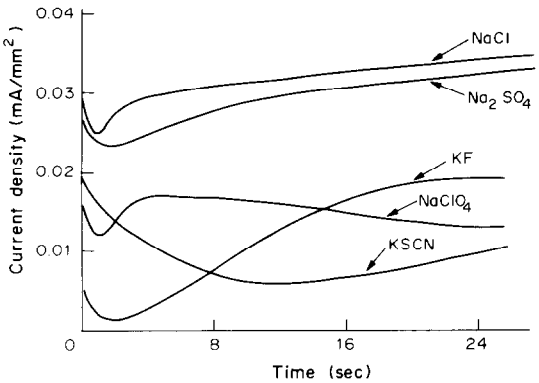

Fig. 3. Current/time curves for mild steel in non-passivating solutions (all 1*M*). Potential step from −0.55 to −0.2 V *vs.* SCE.

Passivation was also observed with chlorate solutions (Fig. 4). The initial currents involved were about a quarter of those found for nitrate solutions. At these low currents, passivation (3% criterion) was reached after 16 sec. However, in absolute terms, a current similar to that flowing at passivity in the nitrate solution (0.09 mA) was reached after only 4.7 sec. The anodic range of voltages which led to passivation was larger for nitrate solutions than chlorate solutions. With nitrate, passivity resulted even with potential steps from −0.55 to +0.67 V. In chlorate medium it was no longer reached at anodic potentials of 0.03 V and higher (all voltages *vs.* SCE).

Phosphate and benzoate are known corrosion inhibitors. It was found that 1*M* sodium chloride prepared in pH-7 phosphate and benzoate buffers gave current–time curves closely resembling those obtained in nitrate solutions. Initial current densities were generally below 13 μA/mm^2.

Dissolved oxygen

The role of oxygen in passivation was monitored chronoamperometrically. A 1*M* potassium nitrate solution was saturated with oxygen by passage of the gas for 20 min. Immediately after this, the determinations were done as described above. Further measurements were taken at approximately 15-min intervals and finally the solution was deoxygenated with nitrogen. The results are shown in Table 3.

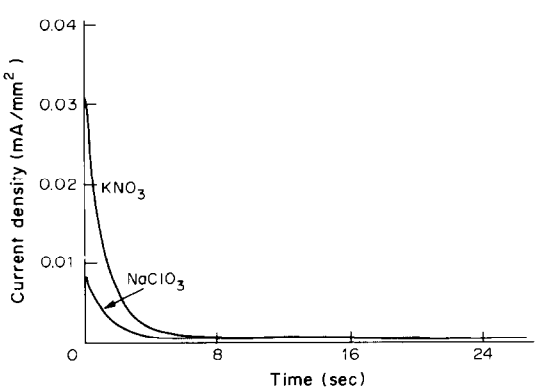

Fig. 4. Current/time curves for mild steel in passivating solutions (1*M*). Potential step from −0.55 to −0.2 V *vs.* SCE.

Table 3. The role of oxygen in passivation of mild steel in 1*M* KNO_3; potential step from −0.55 to +0.08 V *vs.* SCE

Time after oxygenation, *min*	Passivation time, *sec*	Passivation charge, *mC*
0	5	0.77
15	7	1.01
30	9	2.40
45	12	5.11
Deaerated	14	7.00

Table 4. The effect of temperature on passivation of mild steel in 1*M* KNO_3; potential step from −0.55 to +0.08 V *vs.* SCE

Temperature, °C	Passivation time, *sec*	Passivation charge, *mC*
6	2	0.16
15	6	1.65
20	8	3.31
31	14	6.22
41	No passivation	—
50	No passivation	—
60	No passivation	—

Clearly, passivation times and charges decreased with increasing oxygen content of the solution. As noted elsewhere,[4] however, passivation still occurred in deaerated nitrate solutions. Oxygenation of chloride solutions did not lead to passivating behaviour.

Temperature

The effects of temperature on mild steel passivation in 1*M* potassium nitrate are shown in Table 4. As expected, passivation time and charge increased with temperature. Above 41° no passivation was observed, although the current–time curves retained their original shape. At these higher temperatures the corrosion currents still initially decreased with time, but then settled to a relatively high constant value (*e.g.*, 8 μA/mm^2 at 50°).

Stainless steel

Table 5 shows that the stainless steels were passivated more rapidly than mild steel in 1*M* potassium nitrate and 1*M* sodium chlorate. Passivation charges

Table 5. Passivation times (sec) for stainless steels in various solutions

Solution (1*M*)	409SS	316L	Potential step, *V vs.* SCE
KNO_3	2	2	−0.55 to −0.06
$NaClO_3$	1	2	−0.55 to −0.06
$NaClO_3$	9	6	−0.55 to +0.08
NaCl	No passivation	5	−0.55 to −0.06
NaCl (60 C)	No passivation	10	−0.55 to −0.06

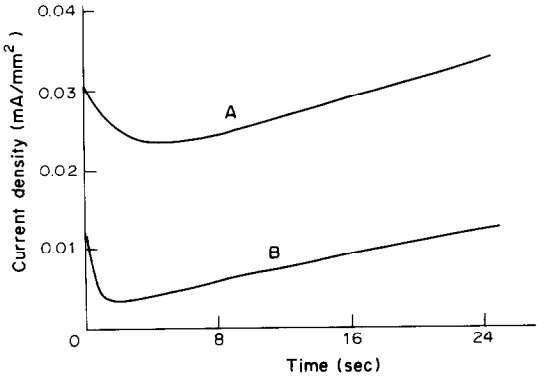

Fig. 5. Current/time curves for 409SS stainless steel in 1*M* NaCl. Potential steps: A, from −0.55 to +0.08 V; B, from −0.55 to −0.06 V *vs.* SCE.

were relatively low. In both cases passivation occurred at temperatures up to 60°. However, in 1*M* sodium chloride the 409SS steel did not become passivated, but gave a current–time curve similar to that for mild steel. Figure 5 shows the corrosion currents for two different potential steps. In contrast, the 316L steel was passivated in 1*M* sodium chloride at temperatures up to 60°.

The results show that the system and method described can be used for comparative evaluation of corrosion behaviour. Advantages include quickness and convenience of measurements, as well as the relatively low price of the system. Importantly, a potentiostat and an X–Y recorder are not needed.

SEPARATION OF IRON-52 FROM CHROMIUM CYCLOTRON TARGETS ON THE 2% CROSS-LINKED ANION-EXCHANGE RESIN AG1-X2 IN HYDROCHLORIC ACID

TJAART N. VAN DER WALT and FRANZ W. E. STRELOW
National Chemical Research Laboratory, P.O. Box 395, Pretoria 0001, Republic of South Africa

FLORIS J. HAASBROEK
National Accelerator Centre, P.O. Box 395, Pretoria 0001, Republic of South Africa

(*Received* 26 *June* 1984. *Revised* 26 *September* 1984. *Accepted* 29 *October* 1984)

Summary—Iron-52 can be separated from solutions of chromium cyclotron targets by eluting chromium, copper and radioactive impurities with 9.0*M* hydrochloric acid from a column containing 1.0 g of AG1-X2 anion-exchange resin. Iron-52 is retained and can then be eluted with 6.0*M* hydrochloric acid containing 0.05*M* hydrogen iodide or 0.05*M* sodium iodide. The separations are sharp and quantitative. Less than 2 μg of chromium will remain with the iron-52, from 2.0 g originally present.

Iron-52 is a radioisotope which is useful in nuclear medicine.[1–4] It has a short half-life ($t_{1/2} = 8.27$ hr), permitting studies to be repeated at short intervals. The decay is by positron emission (56%, 0.80 MeV) and electron capture.[5] Both decay modes involve de-excitation solely through a 169-keV level into manganese-52m ($t_{1/2} = 21$ min).

Many nuclear reactions can be utilized for the production of iron-52: $^{50}Cr(^{4}He, 2n)^{52}Fe$, $^{52}Cr(^{3}He, 3n)^{52}Fe$, $^{55}Mn(p, 4n)^{52}Fe$ and p-spallation. Some experimental methods and results have been discussed by Atcher *et al.*[6] The energy and type of accelerated particles available determine the method chosen for production. The reaction should be one that yields a maximum amount of iron-52 and a minimum amount of iron-55, because iron-55 ($t_{1/2} = 2.6$ yr) adds significantly to the radiation dose received by the patient.[7] In the Pretoria cyclotron natural chromium is bombarded with 32-MeV ^{3}He particles to obtain iron-52.

The preparation of chromium cyclotron targets[8,9] and the separation of iron-52 from chromium targets[6,7,9–14] have been described by several authors. Solvent extraction and ion-exchange methods or a combination of both have been applied. In this laboratory a solvent extraction method has been used, the iron-52 being extracted with di-isopropyl ether from 8*M* hydrochloric acid.

The most common impurities found in the final iron-52 fractions are residual amounts of copper and chromium (from the target), zinc-65 ($t_{1/2} = 244$ d), gallium-66 ($t_{1/2} = 9.4$ hr), gallium-67 ($t_{1/2} = 78.3$ hr), copper-64 ($t_{1/2} = 12.70$ hr), manganese-52 ($t_{1/2} = 5.6$ d), manganese-54 ($t_{1/2} = 312.2$ d), manganese-56 ($t_{1/2} = 2.58$ hr) and chromium-51 ($t_{1/2} = 27.70$ d), depending on the nuclear particles used for irradiation. In the Pretoria cyclotron some of these radioisotopes are formed by the reactions $^{65}Cu(^{3}He,n)^{67}Ga$, $^{65}Cu(^{3}He, 2n)^{66}Ga$ and $^{63}Cu(^{3}He,p)^{65}Zn$. In order to obtain a product of high purity the separation procedure should make provision for the removal of all these impurities. Our extraction method separated iron-52 from chromium, copper and zinc-65, but not from the radioactive gallium isotopes, and small amounts of the first two also remained with the iron.

Furthermore, copper, zinc-65 and the gallium radioisotopes are not completely separated from iron-52 when anion-exchange chromatography on AG1-X8 resin is applied at hydrochloric acid concentrations ranging from 4 to 12*M*. However it has been shown that the anion-exchange separation of iron(III) from copper at high concentrations of hydrochloric acid can be considerably improved by using the 4% cross-linked anion-exchanger AG1-X4 instead of the usual 8% cross-linked resin AG1-X8.[15] Additional studies conducted in this laboratory indicated that separation of iron(III) from copper is further improved by use of a 2% cross-linked resin, and quantitative separation of zinc also becomes possible.

Distribution coefficients were determined for copper, zinc, gallium, manganese, iron(III) and chromium(III) with the 2% cross-linked anion-exchanger AG1-X2 in 9.0*M* hydrochloric acid. From the results obtained a separation procedure was developed to purify iron-52 from large amounts of chromium and copper and from radioisotope impurities of manganese, zinc and gallium, by a single-column procedure.

EXPERIMENTAL

Reagents and apparatus

Analytical-reagent grade chemicals were used and purified from iron by anion-exchange chromatography. "Suprapur" hydrochloric acid was used. Water was distilled

Table 1. Analytical methods used

Element	Method
Cu	complexometric titration with DCTA at pH 5.5 in acetate medium; Methylthymol Blue plus, 1,10-phenanthroline as indicator
Zn	complexometric titration with EDTA at pH 5.5; Xylenol Orange as indicator
Mn	complexometric titration with DTPA at pH 10.0 in presence of ascorbic acid; Methylthymol Blue as indicator
Ga	complexometric titration, excess of DCTA and back-titration with thorium at pH 2.5–3.0; Xylenol Orange as indicator
Fe	oxidation to Fe(III) with bromine water; complexometric titration, excess of EDTA and back-titration with bismuth at pH 2.5–3.0; Methylthymol Blue as indicator
Cr	atomic-absorption spectrometry; air–acetylene flame at 357.9 nm

and then passed through an Elgastat demineralizer. Hydriodic acid was obtained by passing a solution of potassium iodide through a cation-exchanger (H^+ form) and eluting with water. The resin used was AG1-X2 polystyrene anion-exchanger with quaternary ammonium exchange groups, (Bio-Rad Laboratories, Richmond, California). A borosilicate glass tube (10 mm bore and 350 mm long) fitted with a fused-in porosity-1 glass sinter and a tap, was used as a column. It was filled with a slurry of resin until the settled resin reached a mark at 4.4 ml ($\equiv$ 1.0 g dry resin). The resin was then equilibrated with 10 ml of 9.0*M* hydrochloric acid.

Cyclotron-produced gallium-66, gallium-67 and zinc-65 were used to simulate the separation of gallium and zinc radioisotope impurities from iron-52 made by bombarding a chromium cyclotron target with ^{3}He particles.

Atomic-absorption measurements were made with a Varian-Techtron AA-5 instrument. An automatic fractionator was used to collect fractions for construction of the elution curve. A 4096-channel analyser, coupled to a Ge(Li) detector, was used to identify the radioisotopes and to measure their activities.

Distribution coefficients

The resin was dried at 60° over anhydrous silica gel in a vacuum pistol and stored over the same drying agent in a desiccator.

Distribution coefficients were determined by equilibrating 2.500 g of dry resin with 250 ml of 9.0*M* hydrochloric acid containing one of the following: 1.0 mmole of copper, zinc or manganese(II), or 0.67 mmole of gallium, chromium(III) or iron(III). The mixture was shaken for 24 hr at 20° in a mechanical shaker. After equilibration the resin was filtered off with a short borosilicate glass tube, and blown dry. The adsorbed fraction was then eluted with 150 ml of 0.50*M* hydrochloric acid (150 ml of 1.0*M* nitric acid for zinc) and determined by appropriate analytical methods (Table 1). The mass equilibrium distribution coefficients

$$K_d = \frac{\text{mass of element on resin}}{\text{mass of element in solution}} \times 100,$$

were calculated (Table 2).

Elution curves

Cu–Cr(III)–Fe(III). Hydrochloric acid (9.0*M*, 100 ml) containing 2.0 g of chromium(III), 100 mg of copper and 1.0 mg of iron(III) was passed through an equilibrated AG1-X2 resin column as described above, and the resin washed with small portions of 9.0*M* hydrochloric acid; chromium and copper were eluted with more 9.0*M* hydrochloric acid (300 ml in total). Iron was then eluted with 100 ml of 0.5*M* hydrochloric acid; 20-ml fractions were collected and a flow-rate of 5.5 $\pm$ 0.3 ml/min was maintained throughout. The 9.0*M* hydrochloric acid fractions were evaporated to dryness on a steam-bath and the residues dissolved, each in 20 ml of 0.5*M* hydrochloric acid. These solutions were analysed by atomic-absorption spectrometry, with an air–acetylene flame and the 357.9, 324.8 and 248.3 nm lines for chromium, copper and iron, respectively. The elution curve is presented in Fig. 1.

Mn–Zn–Fe(III)–Ga. Figure 2 shows an elution curve for a mixture containing 2.0 mg of manganese, 2.0 mg of zinc, 1.0 mg of iron(III) and 1.0 mg of gallium, dissolved in 50 ml of 9.0*M* hydrochloric acid. Zinc and manganese were eluted with 250 ml of 9.0*M* hydrochloric acid, and iron with 100 ml of 6.0*M* hydrochloric acid/0.05*M* hydriodic acid (freshly prepared), gallium being retained on the column. The mixed acid was then displaced with 20 ml of 6.0*M* hydrochloric acid and gallium was eluted with 100 ml of 0.5*M* hydrochloric acid/1% sodium sulphite, to reduce any iodine to iodide. The flow-rate was again 5.5 $\pm$ 0.3 ml/min and 20-ml fractions were collected throughout. Manganese, zinc and iron were determined in each fraction by atomic-absorption spectrometry (air–acetylene flame) at the 279.5, 213.9 and 248.3 nm lines for manganese, zinc and iron, respectively. For gallium the acetylene–nitrous oxide flame and the 294.4 nm line were used.

Separation of iron-52 from chromium and other impurities

A cyclotron target was prepared by electroplating a chromium layer onto a water-cooled copper base. It was bombarded in the cyclotron with 32-MeV α-particles for 8 hr at a beam current of 95 μA, and "cooled" for 2 hr to let the short-lived radioactive impurities decay. Chromium was etched from the surface of the target with 10-ml portions of

Table 2. Distribution coefficients on anion-exchange resin AG1-X2 in 9.0*M* hydrochloric acid

Element	K_d
Ga(III)	2570
Fe(III)	1660
Zn(II)	39.9
Mn(II)	4.5
Cu(II)	3.4
Cr(III)	2.7

hot concentrated hydrochloric acid to which 1 ml of concentrated nitric acid had been added. After all the chromium had dissolved, accurately measured gallium-66, gallium-67 and zinc-65 activities were added to the combined portions, which were then evaporated to 50 ml, and the activities of ^{52}Fe, ^{51}Cr, ^{54}Mn, ^{56}Mn, ^{65}Zn, ^{66}Ga and ^{67}Ga were measured. The solution was then evaporated to dryness and the nitrates were converted into chlorides. These were dissolved in 100 ml of 9.0*M* hydrochloric acid and the solution was passed through an equilibrated AG1-X2 resin column as described. Chromium and other impurities were eluted with 9.0*M* hydrochloric acid (200 ml in total) and the solution was evaporated to 50 ml. Finally, iron-52 was eluted with three 50-ml portions of 6.0*M* hydrochloric acid/0.05*M* sodium iodide. Gallium isotopes were retained by the resin. ^{52}Fe activities were measured in the "iron-52" eluates and the results are presented in Table 3. The combined iron-52 fractions were evaporated almost to dryness, then treated with nitric acid to expel iodide, and the nitrates were converted into chlorides. The salts were dissolved in 50 ml of 0.1*M* hydrochloric acid and the activities of the radioisotope impurities, ^{51}Cr, ^{54}Mn, ^{56}Mn, ^{65}Zn, ^{66}Ga and ^{67}Ga, were measured, the results are presented in Table 4.

RESULTS AND DISCUSSION

According to the distribution coefficients of the elements on AG1-X2 (Table 2) chromium, copper

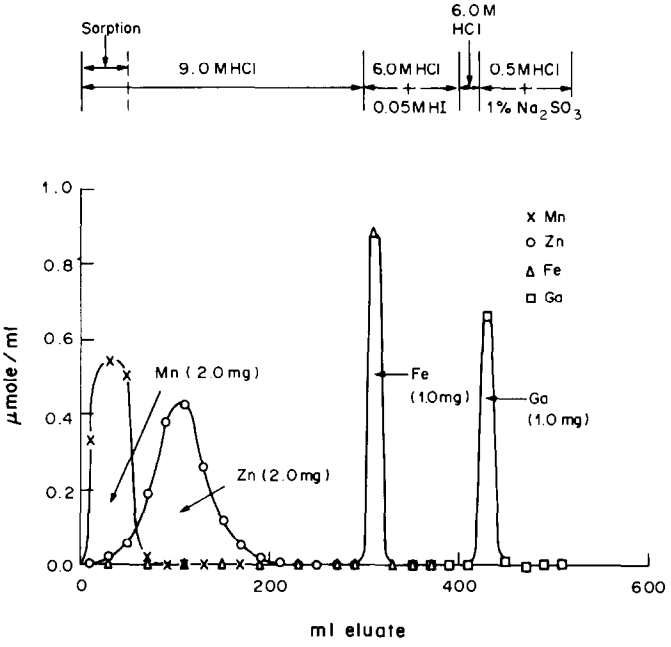

Fig. 2. Elution curve for Mn–Zn–Fe(III)–Ga.

Table 3. Separation of iron-52 from chromium cyclotron-target material on anion-exchange resin AG1-X2

Fraction	^{52}Fe activity*, *counts*/200 *sec*	Recovery, %
Solution (before separation)	7766 (± 5%)	—
"Other element" eluate (eluted with 9.0*M* HCl)	30 (± 5%)	0.4
First "^{52}Fe" fraction (eluted with 6.0*M* HCl + 0.05*M* NaI)	6887 (± 5%)	88.7
Second "^{52}Fe" fraction (eluted with 6.0*M* HCl + 0.05*M* NaI)	430 (± 5%)	5.5
Third "^{52}Fe" fraction (eluted with 6.0*M* HCl + 0.05*M* NaI)	244 (± 5%)	3.1

*All measurements on a volume of 50 ml in a 100-ml beaker, and corrected for decay.

and manganese should easily be eluted with 9.0*M* hydrochloric acid. This was confirmed by the elution curves (Figs. 1 and 2). Although zinc has a relatively large distribution coefficient ($K_d = 39.9$) on AG1-X2 resin in 9.0*M* hydrochloric acid, 2.0 mg of zinc were completely eluted with 9.0*M* hydrochloric acid. This is because the 2% cross-linked resin has exchange kinetics much superior to those of the 8% cross-linked resin. Zinc also has a distribution coefficient of *ca.* 40 on AG1-X8 resin in 12*M* hydrochloric acid, but cannot be eluted completely and shows serious tailing.

In ion-exchange procedures gallium behaves similarly to iron(III). For this reason iron(III) is usually reduced to iron(II) before separation from gallium. Hydriodic acid is especially effective as a reducing reagent[16] and does not introduce foreign solids, but has to be freshly prepared because free iodine forms very easily. For medical purposes iron-52 is usually prepared in an isotonic solution and hydriodic acid can be replaced by sodium iodide.

Less than 2 μg of chromium, copper, zinc, manganese or gallium was found in the "iron-52" fraction when 2.0 g of chromium, 100 mg of copper, 2.0 mg of manganese, 2.0 mg of zinc and 1.0 mg of gallium were present originally. In most cases the amounts of chromium in the iron fraction were below the detection limit of the atomic-absorption method (*ca.* 0.05 μg/ml). It can be expected that the amounts of chromium found in the iron fraction will further decrease with decreasing amounts of total chromium, though not linearly. Less than 50 μg of iron was found in the "iron-52" fraction after a separation done without iron-52 radiotracer. This iron was apparently present as a trace component in the reagents used.

Table 3 shows that the recovery of iron-52 is better than 90% in a typical separation. The product is of high purity, as indicated by Table 4. The amounts of gallium-66, gallium-67 and zinc-65 activities originally present, 3.6, 215 and 0.7 MBq, respectively, are much higher than would be encountered in practice, and were used merely to demonstrate the efficiency of the separation. The time for the total procedure including the target etching, is between 2 and 3 hr. An advantage is that the whole operation can easily be performed behind a lead shield in a fume cupboard. This considerably reduces the irradiation dose received by the operator, compared with that received when the di-isopropyl ether extraction of iron-52 is used. In addition the product contains considerably fewer impurities. The procedure is less tedious and more reliable, and has completely replaced the solvent extraction procedure for the production of iron-52 at the Pretoria Cyclotron. The purified iron-52 can also be used as a ^{52}Fe/^{52m}Mn generator, by selective elution of manganese-52m from an anion-exchange resin column with 8 or 9*M* hydrochloric acid.[18]

PREDICTION OF THE BEHAVIOUR OF A SINGLE FLOW-INJECTION MANIFOLD

MIGUEL ANGEL GOMEZ-NIETO*, MARIA DOLORES LUQUE DE CASTRO*
ANTONIO MARTIN† and MIGUEL VALCARCEL*
Department of Analytical Chemistry* and Department of Chemical Engineering,† Faculty of Sciences, University of Córdoba, Córdoba, Spain

(*Received* 19 *October* 1983. *Revised* 19 *July* 1984. *Accepted* 4 *October* 1984)

Summary—This paper suggests a handy method of obtaining equations to predict the fundamental parameters of an FIA peak—travel time, baseline-to-baseline time, peak height and appearance time of the maximum for a simple configuration—by performing a small number of preliminary experiments in the region in which FIA system usually operates.

The theory of FIA has not yet been definitively established, particularly that of the profile of the signal peak. Up till now, three different approaches have been taken. Růžička and Hansen use the traditional tanks-in-series model.[1,2] The theoretical expressions derived from this model are basically related to the height of the peak, expressed in terms of the dispersion coefficient.[3] Vanderslice *et al.*[4] examined the breadth of the peak, developing expressions to define the travel time and baseline-to-baseline time, deduced from numerical solutions of the general diffusion and convection equations for the conditions normally employed in FIA.[4] Painton and Mottola[5] considered the chemical contribution to the dispersion coefficient.

The theoretical approaches mentioned above must be judged not only in terms of the agreement given with experimental results but also in terms of the ability to predict the behaviour of any FIA manifold. The expression that relates the dispersion coefficient to various experimental parameters has the practical drawback of including the Levenspiel and Smith dispersion number,[6] which prevents its immediate application. One of the shortcomings of the expressions given by Vanderslice *et al.*[4] is the existence of the accommodation factor which, as shown in this paper, has to be experimentally calculated beforehand for each FIA manifold.

Our aim was to develop a simple alternative to the theoretical approaches taken by Vanderslice *et al.* and Růžička *et al.* It requires a simple experimental programme which allows development of expressions relating the characteristics of the manifold to the factors determining an FIA peak: travel time, appearance time of the maximum, and baseline peak-width. We have found that the equations of Vanderslice *et al.* do not always agree with the experimental results and that the accommodation factors are not constant. The expressions given here are applicable to simple FIA configurations without confluence points and in which no chemical reaction occurs during the transport process.

EXPERIMENTAL

Reagents

A Bromocresol Green stock solution was prepared by dissolving 0.400 g of the dye in 25 ml of 96% ethanol and diluting to 100 ml with 0.01*M* borax. The working solution was prepared by mixing 1 ml of the stock solution with 199 ml of 0.01*M* borax. The carrier stream was 0.01*M* borax.

The diffusion coefficient of the monitored substance was calculated by a traditional method.[7]

Apparatus

A Pye Unicam SP-500 spectrophotometer, equipped with a Hellma 178.12 QS flow-cell (inner volume 18 μl) was used. Gilson Minipuls 2 and Ismatec S.840 peristaltic pumps, a Tecator L 100-1 injection valve and a Tecator TM III "chemifold" were employed.

As can be seen from Fig. 1, the experiments were monitored with a Hewlett-Packard HP-85 microcomputer with built-in tape-cartridge drive, equipped with an HP-IB interface connected to the detector by an HP-3478A digital multimeter. A program for data-acquisition control was written in BASIC. The program was self-documented and easily operated. The input data necessary were L (the system length, cm), q (flow-rate, ml/min), d (tube internal diameter, mm), D (diffusion coefficient of the monitored substance, cm^2/sec), and A^* (the maximum absorbance obtained when the sample, without carrier, is passed through the flow-cell). The program allowed use of up to 1500 data points (absorbance, time) per sample. From these points the parameters such as peak area, residence time, statistical residence time, equivalent length, accommodation factors, co-ordinates of the maximum, travel time and baseline-to-baseline time

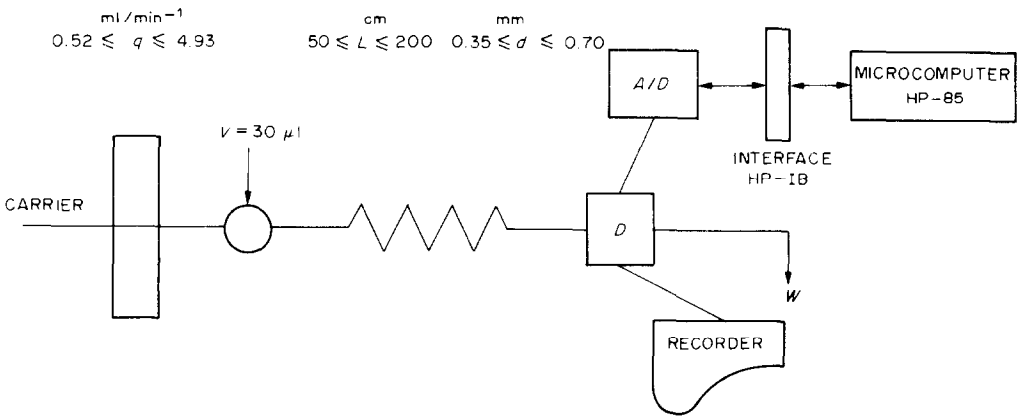

Fig. 1. Microcomputer system and interfacing to flow system (for details see text).

were calculated. The recorded signals were corrected for the background signal, taken as the average of three measurements. The system permitted plotting of the FIA peak by means of an $X-Y$ recorder connected in parallel to the microcomputer.

RESULTS AND DISCUSSION

Corroboration of the Vanderslice et al. *equations*

Vanderslice *et al.*[4] reported equations which, according to them, can predict two characteristic and very important parameters of an FIA peak: travel time, t_A, and dispersion or baseline-to-baseline time, Δt_B. These equations are:

$$t_A = \frac{109 a^2 D^{0.025}}{f} \left| \frac{L}{q} \right|^{1.025} \quad (1)$$

$$\Delta t_B = \frac{35.4 \alpha^2 f}{D^{0.36}} \left| \frac{L}{q} \right|^{0.64} \quad (2)$$

where D is the diffusion coefficient of the injected sample, L the length (cm) and a the inner radius (mm) of the tubing, q the flow-rate (ml/min) and f the accommodation factor, which according to these authors is characteristic for each system and depends on the bore of the tubing.

In order to test these expressions we have performed series of experiments in which both the flow-rate and the length and inner diameter of the tubing were changed. Some results are given in Table 1, in which the calculated data, such as theoretical travel time, baseline-to-baseline time, mean residence time and statistical residence time are also listed. The accommodation factors are denoted by f_{t_A} for expression (1) and $f_{\Delta t_B}$ for expression (2), since they are different. Thus,

$$f_{t_A} = \frac{(t_A)_{\text{calculated}}}{(t_A)_{\text{experimental}}}; \quad f_{\Delta t_B} = \frac{(\Delta t_B)_{\text{experimental}}}{(\Delta t_B)_{\text{calculated}}}$$

These factors were calculated for each run from the experimental values of t_A and Δt_B and from those calculated from expressions (1) and (2) with f taken as unity. As seen from Table 1, values for the two factors are not constant, but vary markedly as a function of the parameters of the system.

To test equations (1) and (2) we made a regression analysis of $\ln(t_A/a^2)$ and $\ln(\Delta t_B/a^2)$ *vs.* $\ln(L/q)$. Theoretically we should have obtained straight lines with slopes of 1.025 and 0.64, respectively, but in fact we did not. There are two fundamental reasons for this.

(*a*) The working conditions used by Vanderslice *et al.* are very extreme. These authors used very low flow-rates ($q < 0.1$ ml/min) and very small injection volumes (2 μl). Generally higher flow-rates (1–4 ml/min) and larger sample volumes (20–100 μl) are used in FIA. (*b*) The accommodation factors are not identical. The variation of the calculated accommodation factors with the length and bore of the tubing and flow-rate is plotted in Fig. 2. From the data in Table 1 and from these plots it is obvious that f_{t_A} and $f_{\Delta t_B}$ are different, and affected differently by the three variables.

The concept of "equivalent length", which takes into account connections, injection valves and irregularities in diameter throughout the whole manifold, besides the reactor length, allows us to eliminate the Vanderslice accommodation factor from expressions (1) and (2) by substitution of this parameter (L_{eq}) for the tube length.

For calculating the equivalent length in an FIA system, it is necessary to know the statistical residence time $(t_r)_{st}$, deduced from integration of the peak, by means of the Levenspiel–Smith equation:[8]

$$(t_r)_{st} = \frac{\int_0^\infty t C \, dt}{\int_0^\infty C \, dt} \quad (3)$$

where C is the molar concentration of the monitored substance at time t. Then L_{eq} can be obtained from

$$(t_r)_{st} = \frac{L_{eq}}{2\bar{u}} = \frac{\pi L_{eq} d^2}{8q} \quad (4)$$

Since $\bar{u} = 4q/\pi d^2$ is the mean linear velocity of the fluid.

In the regression analysis of $\ln(t_A/a^2)$ *vs.* $\ln(L_{eq}/q)$

* $A_t = 0.845$.

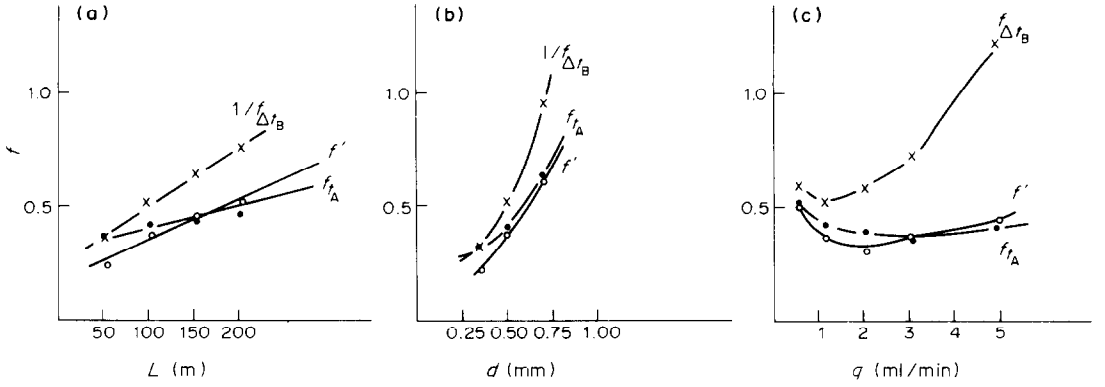

Fig. 2. Behaviour of accommodation factors *vs.* FIA variables. (a) $d = 0.50$ mm, $q = 1.14$ ml.min^{-1}; (b) $L = 104$ cm, $q = 1.14$ ml.min^{-1}; (c) $L = 104$ cm, $d = 0.50$ mm.

we found that the slope was very close to 1.025, the value suggested by Vanderslice *et al.*, confirming that our equation for L_{eq} gives results in agreement with $f_{t_A} = (L_{tube}L_{eq})^{1.025}$.

However, this alone does not advance or improve the theory and practice of FIA, since to be able to predict the travel time it is first necessary to calculate the equivalent length of the system (which depends on physical factors, such as q, d and the dimensions of the experimental manifold) and also to integrate the experimental FIA peaks, to calculate the statistical residence time $(t_r)_{st}$.

We must therefore examine $f_{\Delta t_B}$. Qualitatively, f_{t_A} and $f_{\Delta t_B}$ both depend on L and on d, but in different ways. The influence of these variables is roughly similar for f_{t_A} and $1/f_{\Delta t_B}$ but that of q on $1/f_{\Delta t_B}$ is considerably different from that on f_{t_A} (Fig. 2). The error in the measurement of $(t_r)_{st}$, and hence of f_{t_A} and $f_{\Delta t_B}$, is higher than that of the travel time, owing to the shape of the FIA peaks. Vanderslice *et al.* did not report the uncertainty in the exponents of the variables, and we predict that these exponents should be higher than those in equation (1). From regression analysis of the data obtained in our experiments, values very different from those reported by Vanderslice *et al.* were found, together with uncertainties in the values, which leads us to conclude the inapplicability of equation (2) under the general working conditions of FIA.

Accommodation factor f'.

A new factor, f', is therefore defined here as the ratio of the mean residence time, (t_r, calculated from geometric considerations) to the statistical residence time, $(t_r)_{st}$, deduced from equation (3).

The influence of L and d on f' is qualitatively similar to that on f_{t_A} and $1/f_{\Delta t_B}$, but is closest to that on $1/f_{\Delta t_B}$. On the other hand, the influence of the flow-rate on f_{t_A} and f' is similar, but very different from that on $1/f_{\Delta t_B}$.

The dependence of these accommodation factors on the diffusion coefficients has not been taken into account, since all the experiments were done with the same compound. Nevertheless, we can predict that its effect will be minimal, owing to the small value of its exponents. The varied influence of the dimensional parameters of an FIA system on the f values considerably restricts the application of the Vanderslice *et al.* equations. It is not possible to predict the features of an FIA peak from them since it is necessary to know the value of the f factors, which can only be found experimentally.

A NEW METHOD OF DEVELOPING EQUATIONS TO DESCRIBE A GIVEN FIA MANIFOLD

The experimental data obtained in the runs (Table 1) were statistically analysed as follows.

First the variables were grouped in various combinations, and by multiple regression analysis the exponents of these variables were calculated. In this and subsequent analysis the diffusion coefficient was not regarded as an independent variable, since a single compound was used. However, the equations tested, such as:

$$\frac{Dt}{L^2} = f\left|\frac{q}{DL}, \frac{L}{d}\right|; \frac{D\Delta t}{L^2} = f\left|\frac{q}{DL}, \frac{L}{d}\right|$$

did not give satisfactory results.

The problem was therefore approached in a different manner. The multiple regression analysis was performed directly with the original variables for two cases: (*a*) equations with two parameters, (*b*) equations with three parameters, *i.e.*, with (L/q) considered as one variable [case (*a*)] or as two independent ones [case (*b*)].

The same behaviour was found for the travel time in both cases, so for simplicity the two-parameter system was chosen, and gave the following equation:

$$t_A = 0.465\, d^{0.950}\left|\frac{L}{q}\right|^{0.850} \quad (5)$$

This equation correctly predicts the travel time for more than 85% of the experiments performed, with a relative error of less than 10%.

To predict the baseline-to-baseline time the three-parameter model is necessary, since there is rather a

large error when the two-parameter model is used. The following equation is proposed:

$$\Delta t_B = 56.7\, d^{0.293}\, L^{0.107}\, q^{1.057} \quad (6)$$

This equation predicts the results of more than 85% of the experiments, with a relative error of less than 15%.

Neither equation involves the diffusion coefficient, which is taken as constant as already explained, and its influence is included in the intercept of both equations, along with that of the type of FIA manifold.

It should be pointed out that in both equations only variables known beforehand are used; for this reason the equations are suitable for predicting the two time-parameters (travel time and dispersion time) for an FIA run, with an error similar to that of the measurement.

Equations (5) and (6) define characteristic parameters of an FIA peak that provide information about the time characteristics of this peak. In order to define the peak fully, two other parameters are necessary: the appearance time of the maximum and the peak height. A statistical procedure similar to the one already used was applied to find two equations that permit prediction of these parameters. The equations obtained are as follows:

$$\mathbf{D} = \frac{C_0}{C} = 2.342\, L^{0.167}\, q^{-0.206}\, d^{0.496} \quad (7)$$

$$t_{max} = 0.840\, L^{0.801}\, d^{0.683}\, q^{-0.977} \quad (8)$$

where **D** is the dispersion, C the concentration of the test substance monitored at time t, and C_0 the concentration of test substance monitored for zero dispersion.

Both equations predict the results of over 85% of the experiments with an error of less than 10%. As in equations (5) and (6), the diffusion coefficient and the injected volume have not been taken into account; both are kept constant throughout the experiments and their influence is included in the intercept of both equations.

These expressions are partially justified by the dispersion model deduced by Levenspiel,[8] but as he has demonstrated, the shape of the curve obtained is dramatically influenced by the methods of injection and the measurement of the tracer concentration.

These four expressions (5)–(8) provide sufficient information to characterize an FIA system, with the advantage that the features of a peak can be predicted. Obviously, from one FIA system to another, the injection valve, detector, coils and type volume of sample are likely to be changed, so the coefficients in the four equations will vary, but the variation will not be appreciable since it will mainly affect the intercepts of the expressions, since all the modified factors (L, d, q) are included in it. Therefore, the experimenter must adapt these equations to his own system, by a few simple operations, as follows.

(1) Running experiments in which the values of L, d and q are varied between the limits to be used in applications. At least 5 points in triplicate must be obtained for each variable, whilst the other two are kept constant.

(2) From the runs in (1), the data for travel time, baseline-to-baseline time, peak height and appearance time of the maximum are obtained.

(3) Multiple regressions for the logarithmic forms of equations (5)–(8) are performed. From the coefficients, the exponents of the variables and the intercept are obtained.

By this method and in a short time, with a few runs and the aid of multiple regression analysis [either manual or by computer (software packages are commercially available)] the experimenter can work out the equations for his own FIA system. From these equations the features of the FIA peaks obtained can be predicted for future experiments with an error of less than 10%.

CONCLUSIONS

The equations of Vanderslice *et al.* are not suitable for predicting the travel time and dispersion time of an FIA peak obtained under normal working conditions, because of the dependence of f_{t_A} and $f_{\Delta t_B}$ on L, d and q and the need to perform preliminary runs for the calculation of f_{t_A} or $f_{\Delta t_B}$ or equivalent length (since the equations are only fulfilled by this parameter, and not by the tube length).

Nor is the Ramsing *et al.* equation[3] related to the peak height practical for predicting the dispersion, since it is necessary to find experimentally the Levenspiel–Smith dispersion number, which is a function of the shape of the curve.

The dispersion volume, ΔV_B, can be predicted from equation (6). Since $\Delta V_B = q\Delta t_B$, the following expression is obtained:

$$\Delta V_B = 56.7\, d^{0.293}\, L^{0.107}\, q^{-0.057} \quad (9)$$

The equations reported in this paper permit the prediction of the fundamental parameters of an FIA peak with relative errors of under 10%, and a simple method is proposed for adapting them to the features of any given FIA system.

SHORT COMMUNICATION

SPECTROPHOTOMETRIC DETERMINATION OF SACCHARIN IN DIFFERENT MATERIALS BY A SOLVENT EXTRACTION METHOD USING NILE BLUE AS REAGENT

M. HERNANDEZ CORDOBA, I. LOPEZ GARCIA and C. SANCHEZ-PEDREÑO*
Department of Analytical Chemistry, University of Murcia, Murcia, Spain

(*Received* 26 *June* 1984. *Revised* 3 *October* 1984. *Accepted* 6 *November* 1984)

Summary—In a slightly acidic medium (sodium acetate–acetic acid buffer, pH 4) saccharin and Nile Blue form an ion-association compound which is extractable into methyl isobutyl ketone and allows the spectrophotometric determination of saccharin. At 630 nm Beer's law is obeyed over the saccharin concentration range 0.1–3.5 μg/ml in the aqueous phase and the apparent molar absorptivity is 5.8×10^4 $l.mole^{-1}.cm^{-1}$. The method shows good selectivity and can be applied to the determination of saccharin in artificial sweeteners, soft drinks and toothpastes.

Saccharin and its salts are widely used as non-fattening sweetening agents. Several methods for their determination have been proposed.[1–6] Some are time-consuming and others need costly equipment. The formation and extraction of ion-association compounds of saccharin with basic dyes may offer a simple alternative for rapid spectrophotometric determination of saccharin, and thiazine dyes,[7–9] Basic Fuchsin[10] and phenazines[11] have been proposed for the purpose, but some of the methods have limitations in sensitivity and selectivity. We have therefore examined a large number of ion-association systems, looking for a compromise between minimum blank reading and maximum extraction of saccharin, with the aim of developing a rapid, highly sensitive and selective spectrophotometric method for the determination of saccharin. Nile Blue is the best of the reagents tested.

EXPERIMENTAL

Reagents

All inorganic chemicals used were of analytical reagent grade and doubly distilled water was used throughout.

Saccharin solution. A stock solution was prepared by dissolving 200 mg of the sodium salt in water and diluting to 200 ml. Working solutions were prepared daily by further dilution.

Sodium acetate–acetic acid buffer. A pH 4 buffer was prepared by mixing 90 ml of 1*M* sodium acetate and 410 ml of 1*M* acetic acid.

Nile Blue solution. An aqueous solution of the dye (Basic Blue 12, C.I. 51180) (Carlo Erba) was prepared and purified as follows before use. In a separating funnel, 375 ml of $2 \times 10^{-3}M$ dye solution, 50 ml of 1*M* acetate buffer (pH 4) and 75 ml of water were mixed and shaken for 10 min with 100 ml of methyl isobutyl ketone (MIBK). The organic layer was discarded and the aqueous phase, to be employed in the analysis, was filtered through filter-paper.

General procedure

Place the sample saccharin solution (no more than 9 ml, containing up to 35 μg of saccharin) in a separating funnel, add 1 ml of the purified and buffered dye solution and dilute to 10 ml with water. Add 5 ml of MIBK, shake the funnel vigorously for about 2 min and allow the phases to separate. Transfer the organic layer into a centrifuge tube and centrifuge it. Measure the absorbance of the organic layer at 630 nm against a reagent blank prepared in a similar way.

Prepare a calibration graph by applying the procedure to different volumes of standard saccharin solution. Beer's law is obeyed over the concentration range 1–35 μg of saccharin per 10 ml of aqueous phase.

Procedure for tablets and liquid sweeteners

Weigh accurately 10 saccharin tablets and grind them to a fine powder in an agate mortar. Transfer an accurately weighed amount of the powder, containing about 50 mg of saccharin, into a 100-ml standard flask. Dissolve with water and make up to the mark. Dilute 5 ml of this solution accurately to 100 ml with water. Take a 1-ml aliquot and apply the general procedure.

For the analysis of liquid sweeteners pipette 1 ml of the sample into a 100-ml standard flask and make up to the mark with water. Dilute 1 ml of this solution accurately to 100 ml with water. Apply the general procedure to a 1-ml aliquot of this solution.

Analysis of soft drinks

Remove carbon dioxide from the sample by repeated shaking. Take up to 10 ml of sample containing no more than 35 μg of saccharin, and transfer it into a separating funnel, add 1 ml of 1*N* sulphuric acid and 9 ml of 0.5*M* potassium sulphate, shake with 5 ml of MIBK for about 2 min, allow the phases to separate and discard the aqueous phase. Add 1 ml of the dye solution and 9 ml of water and shake for about 2 min. After separation of the phases measure the absorbance of the organic layer as described in the general procedure. Prepare a calibration graph with different amounts of saccharin treated in the same way.

Analysis of toothpastes

Extract a 1-g sample with water, filter, and dilute the filtrate to volume in a 100-ml standard flask. Transfer up to 5 ml of the solution into a separating funnel and add 10 ml of 0.5*M* potassium sulphate. Extract with 5 ml of MIBK and discard the organic layer. Add 1 ml of 1*N* sulphuric acid and extract with 5 ml of MIBK. Discard the aqueous phase, add 1 ml of the dye solution and 9 ml of water and shake for about 2 min. Measure the absorbance of the organic layer. Prepare a calibration graph, by treating different amounts of saccharin in the same way.

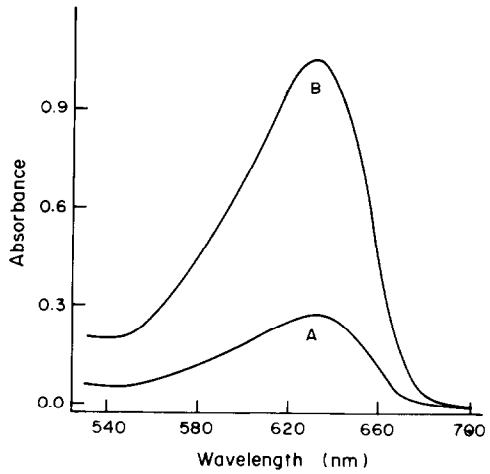

Fig. 1. Absorption spectra of extracts into MIBK: (A) reagent blank; (B) in the presence of 28 μg of saccharin.

RESULTS AND DISCUSSION

In the preliminary experiments several basic dyes (phenosafranine, Acridine Yellow, Acridine Orange, Rhodamine B, Pyronine G, Ethyl Violet, Malachite Green, gallocyanine, new Methylene Blue, Brilliant Cresyl Blue and Nile Blue) were tested at different pH values as ion-pairing reagents for the extraction of saccharin (Sac^-). Chloroform, carbon tetrachloride, benzene, toluene, isobutyl acetate, ethyl acetate, isoamyl acetate, cyclohexanone, isobutyl alcohol and methyl isobutyl ketone were tried as the solvents.

None of these systems showed better results than the Nile Blue (NB^+) and methyl isobutyl ketone (MIBK) system. The absorbance of the reagent blank is not high and this system gave the highest degree of extraction of saccharin.

Absorption spectra

Figure 1 shows the absorption spectra of the ion-pair [NB^+, Sac^-] extracted into MIBK and of the reagent blank, obtained as described in the procedure. The spectra are very similar in shape to the absorption spectrum of an aqueous solution of the dye, and all three spectra have maximum absorption at 630 nm.

Effect of pH and Nile Blue concentration

Figure 2 shows that the absorbance is maximal and constant over the pH range 3.2–4.8. The decrease in the absorbance at pH < 3.2 may be attributed to protonation of the saccharin anion, and at pH > 4.8 to conversion of Nile Blue into neutral form.

The extraction is also affected by the dye concentration. Figure 3 shows that maximal and constant absorbance is obtained by use of at least 1 ml of $10^{-3}M$ Nile Blue. It was found that better reproducibility and a lower reagent blank were achieved if the dye was purified by extraction with MIBK.

Characteristics of the ion-pair

The continuous-variations method with measurement at three different wavelengths showed that the ion-pair [NB^+, Sac^-] is the only compound extracted into MIBK under the recommended conditions.

The extraction efficiency was about 65%. However, a single extraction is recommended, because further extractions would complicate the procedure and the increased volume of organic phase would reduce the sensitivity. Hence accurate volume measurement is essential.

There were no measurable changes in the absorbance of the extract even after standing for 8 hr in a glass-stoppered tube at room temperature. Shaking times ranging from 1.5 to 5 min produced no change in absorbance, so a 2-min shaking time was selected.

Calibration graph

The calibration graph is linear in the range 1–35 μg

of saccharin per 10 ml of aqueous phase. The apparent molar absorptivity at 630 nm is 5.8×10^4 l.mole^{-1}.cm^{-1}. The precision was estimated from 10 analyses for 9-ml aliquots of $7.2 \times 10^{-6}M$ saccharin. The standard deviation of the absorbance and the relative standard deviation were 0.006 and 1.3% respectively. The standard deviation of the absorbance of the reagent blank was less than 0.005.

Effect of foreign substances

The tolerance limit for permissible foreign substances was taken as the concentration which caused an error of not more than $\pm 3\%$ in the absorbance for 5 μg of saccharin in the sample. The selectivity can be enhanced by a previous separation of saccharin with MIBK from 0.1*N* sulphuric acid medium. In that way, 6 μg of dodecyl sulphate, 50 μg of acetylsalicylic acid, 400 μg of cyclamate, 1000 μg of sorbic acid and benzoic acid and 10 mg of tartrate, citrate and bicarbonate can be tolerated. Even with the use of this separation step, sodium dodecyl sulphate and acetylsalicylic acid are serious interferents, but their interference is easily overcome if the sample is treated with a large excess of potassium sulphate (0.5*M*) and extracted at pH 4 with MIBK. Potassium dodecyl sulphate and acetylsalicylate are transferred into the organic layer and the saccharin remains in the aqueous phase. Experimental results are given in Table 1.

Table 2. Determination of saccharin in artificial sweeteners

Sample	Saccharin content, *mg/tablet or g/l.* Label claim	Found*
Tablets A	5	4.92

C	125	123
D	15	15.9

*Average of four determinations.

Table 4. Determination of saccharin in toothpastes

Sample	Label claim, %	Saccharin found, %*
1	0.3	0.31
2	0.1	0.98
3	0.2	0.21
4	0.05	0.06

*Average of four determinations.

Determination of saccharin in samples

The method has been successfully applied to the determination of saccharin in tablets and liquid sweeteners, soft drinks and toothpastes, by the procedures given. The results are given in Tables 2–4.

Some of the soft drinks assayed did not contain saccharin and a known amount of saccharin was added to these to assess the recovery.

Conclusion

In comparison with the earlier spectrophotometric methods using ion-pairing reagents,[7–11] the extraction with Nile Blue reported here is highly sensitive and selective for the determination of saccharin, and is suitable for routine analysis.

ANNOTATIONS

CADMIUM-113 AND CARBON-13 NUCLEAR MAGNETIC RESONANCE SPECTROMETRY OF CADMIUM PEPTIDE COMPLEXES

S. M. WANG* and R. K. GILPIN†
Kent State Universtiy, Kent, Ohio 44242, U.S.A.

(*Received* 14 *November* 1983. *Revised* 24 *October* 1984. *Accepted* 4 *December* 1984)

Summary—The cadmium complexes of glycylglycine, glycylglycylglycine, glycyl-γ-aminobutyric acid and β-alanylglycine (β-Ala-Gly) have been investigated by ^{113}Cd and ^{13}C nuclear magnetic resonance spectrometry. The minima observed in plots of the ^{113}Cd chemical shift *vs.* pH are consistent with cadmium binding first at the carboxylic site and then at the amino-group site. The chemical shift *vs.* pH profile for the β-Ala-Gly system is different from that for the other peptides, and is interpreted as suggesting formation of a five-membered chelate between Cd(II) and glycyl residues at the N-terminal groups and not at the C-terminal groups. The data further indicate that the NH groups of the peptide linkages are probably not involved in complexation with cadmium. Finally, a reported pH-dependent ^{113}Cd resonance for parvalbumin has been reassigned.

The role of several trace metals in living organisms has been designated as either structure-promotion or enzyme activation/deactivation. For elements such as zinc, cadmium and mercury, general complexation studies are important in obtaining a more fundamental understanding of the biochemical systems. However, because zinc, cadmium and mercury have completely filled *d*-orbitals, ultraviolet spectrometry is unsuitable for investigating their complexation, and hence other techniques such as nuclear magnetic resonance (NMR) spectometry have become popular, especially for acquiring information at the molecular level.

The ^{113}Cd nucleus, with its chemical shift range of over 800 ppm, gives an NMR sensitivity five times that of the ^{13}C nucleus[1] and thus is better suited for probing metal–ligand interactions. In addition to metallothionein,[2–7] a cadmium-induced metalloprotein, a variety of metalloproteins and metalloenzymes have been examined by ^{113}Cd NMR techniques.

NMR studies with cadmium as the probe ion have been used to elucidate the nature of metal binding in zinc-activated metalloenzymes,[8–18] and in metalloproteins modulated by calcium.[19–25] Also, Sudmeier *et al.*[25,26] have studied zinc and calcium binding sites in insulin.

Although considerable amounts of data on various cadmium systems have been collected, wide variations in results have been reported,[10,11] which may often be ascribed to the effect of changes in solution parameters, or to exchange of co-ordinated solvent molecules. As summarized in Table 1, the chemical shift of ^{113}Cd is especially sensitive to changes in pH and the counter-ions studied. As a result, systematic fundamental investigations of model compounds and systems are needed before the nature of more complex interactions such as metal binding in metalloproteins can be pictured clearly.

Combined ^{113}Cd and ^{13}C NMR studies of a homologous series of cadmium–amino-acid complexes have already been reported,[27] and interpreted as suggesting that five-membered chelate rings form between cadmium and molecules similar to glycine. In aqueous solutions, the highest complex formed with glycine was found to be $CdGly_3$. Similar results for supercooled aqueous solutions have been reported by Jakobsen and Ellis.[28]

To extend our earlier work, cadmium binding with selected peptides has been studied. Such studies are important in establishing general models for protein systems and as aids in elucidating specific properties such as the biological activity of carboxypepidase A, which breaks up polypeptide chains from the C-terminal end to give the consituent amino-acids[29] and also catalyses the hydrolysis of esters. The first of these properties is attributed to increase in the susceptibility of the peptide linkage to hydrolysis, owing to binding of the C-terminal group of the peptide to the zinc atom at the active site of the enzyme. Replacement of zinc by cadmium, lead or mercury results in partial loss of the catalytic activity for cleavage of the C-terminal amino-acid residue, but the modified enzymes still catalyse the hydrolysis of esters.[30] Indeed, with the cadmium-substituted car-

boxypeptidase A, the hydrolysis is even faster than with the natural enzyme.

In the current investigation, binding of cadmium with glycylglycine (Gly-Gly), glycylglycylglycine (Gly-Gly-Gly), glycyl-γ-aminobutyric acid (Gly-γ-ABA) and β-alanylglycine (β-Ala-Gly) has been examined by use of ^{113}Cd and ^{13}C NMR.

EXPERIMENTAL

Reagents

Fisher buffers, pH 4.00, 7.00 and 10.00, were used as calibration standards. Gly-Gly, Gly-Gly-Gly, Gly-γ-ABA and β-Ala-Gly (Sigma) were used as received.

The deuterium oxide (Merck Isotope) was NMR spectroscopic grade. All additional chemicals, unless otherwise specified, were reagent grade.

Solid chemicals were weighed directly into standard flasks, and dissolved and diluted to volume with triply distilled water, which was degassed by boiling. These solutions were stored under nitrogen. The cadmium perchlorate solutions were standardized either titrimetrically with EDTA or by atomic-absorption spectrometry.

Measurements

All pH and NMR measurements were made at 25° as described earlier,[27] with the following exceptions. All the ^{13}C measurements except those for β-Ala-Gly were made with a Varian FT-80 NMR spectrometer using a 25° flip angle and a 1.20-sec acquisition time. The ^{13}C spectra of β-Al-Gly and its cadmium complex were measured at 50.3 MHz on a Varian model XL-200 NMR spectrometer at 25°.

For the ^{113}Cd measurements, an aqueous 1.0*M* solution of cadmium perchlorate was used as an external standard, but all reported chemical shifts are referred to 0.1*M* cadmium perchlorate, for which the signal is 1.87 ppm upfield from that of the 1.0*M* solution. Chemical shifts at higher and lower frequencies than the reference value are reported as positive and negative values respectively. No bulk susceptibility correction was applied, since it was negligible.

RESULTS AND DISCUSSION

Figure 1 shows the ^{113}Cd chemical shifts plotted *vs.* pH for the cadmium–peptide systems. Because of solubility problems, data could not be collected for solutions with pH values below 4.5 or above 7.6 for the Cd–Gly-Gly-Gly complex or for Cd–Gly-Gly,

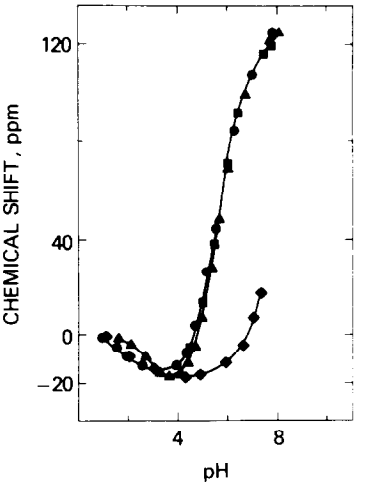

Fig. 1. ^{113}Cd chemical shift for mixtures of 0.3*M* $Cd(ClO_4)_2$ with 0.6*M* peptides, *vs.* pH. Gly-Gly (●), Gly-Gly-Gly (■), Gly-γ-ABA (▲), β-Ala-Gly (◆).

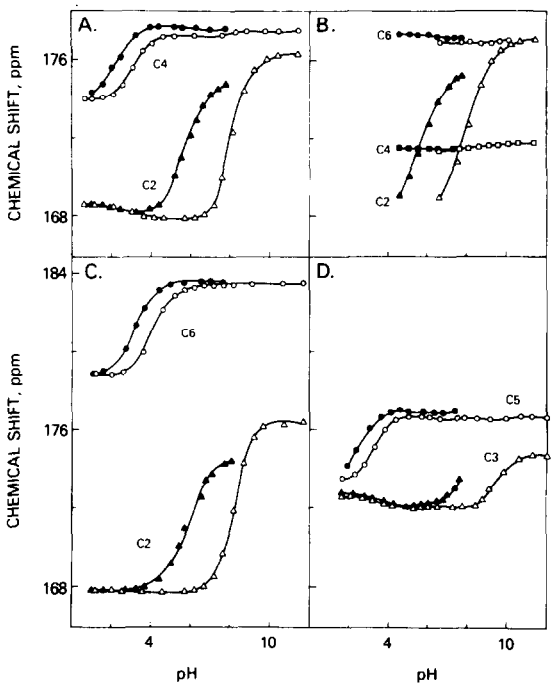

Fig. 2. ^{13}C chemical shift of carbonyl carbon atoms for 0.6*M* peptides alone (○, △, □) and with 0.3*M* $Cd(ClO_4)_2$ (●, ▲, ■), *vs.* pH. Symbols as for Fig. 1. A. C_2 and C_4 carbons of Gly-Gly. B. C_2, C_4 and C_6 carbons of Gly-Gly-Gly. C. C_2 and C_6 carbons of Gly-γ-ABA. D. C_3 and C_5 carbons of β-Ala-Gly.

Cd–Gly-γ-ABA and Cd–γ-Ala-Gly at pH above 8. As the pH is increased, there is first a negative shift, and then a positive shift, and this is consistent with cadmium binding initially at the carboxylate site, and then at the amino site analogously to the simpler amino-acid systems already reported,[27] but the minimum in the curve is sharper.

The difference between the profiles of the curves for Gly-Gly and Gly-γ-ABA at low pH is not unexpected, since the C-terminal group of the latter contains a longer alkyl chain, *cf.* the simple cadmium–amino-acid complexes.[27] The minima on the curves (pH_{min}) for Cd–Gly-Gly and Cd–Gly-γ-ABA were at pH 3.8 and 3.9 respectively, *cf.* Cd–glycine.[27] The difference between pK_{a2} and pH_{min} for these two peptides was 4.4, (Table 2) significantly smaller than that obtained for Cd–glycine (5.9) and suggests that the cadmium does not promote deprotonation of the amide groups in the peptides. Further, within experimental error, the chemical shift profiles for the three complexes were superimposable at pH > 5, which is reasonable since all three peptides contain an N-terminal glycyl group.

The curves for Cd–Gly-Gly and Cd–β-Ala-Gly were superimposable at lower pH. Both compounds contain the C-terminal glycyl group. Also of interest is the difference (Fig. 1) between the profile for the β-Ala-Gly system at pH > 4 and those for the other two systems. The chemical shift minimum was broader for the β-Ala-Gly system, in which there is a longer carbon chain at the N-terminal end. The pH for the chemical shift minimum was close to that reported for the β-alanine system,[27] and the smaller value of $pK_{a2} - pH_{min}$ (Table 2) suggests the absence of a chelate ring. The chemical shift profiles also demonstrate that chain-lengthening has a more significant effect when it occurs at the N-terminal position (*e.g.*, Cd–Gly-γ-Gly) than it does when at the C-terminal position (*e.g.*, Cd–Gly-γ-ABA). The results suggest that five-membered chelates of cadmium with glycyl residues may form only at the N-terminal groups of peptides.

Figure 2 shows the ^{13}C chemical shift *vs.* pH for the carbonyl carbon atoms of the free peptides and their complexes. Usually, for dipeptides which have large differences in consecutive pK_a values, assignments of NMR peaks to carbon atoms can be made directly from the pH-dependence of the ^{13}C resonances. However, for Gly-Gly-Gly the assignment is no longer straightforward. We have to make two assumptions in making assignments. First, that the chemical shifts for the carboxylate carbon atom of Gly-Gly-Gly before and after deprotonation are similar to those for Gly-Gly, 174 and 177 ppm. Secondly, that the changes in chemical shifts of the N-terminal carbonyl group, 8 ppm, due to the deprotonation of the protonated amino group, are similar for all glycyl groups in the N-terminal position, *e.g.*, in Gly-Gly, Gly-Gly-Gly, and Gly-γ-ABA. A method adapted from Feeney *et al.*[31] was also used to help make assignments. In solutions, exchange of solvent with the peptide-linkage proton is slower than that with quarternary amino-group protons or carboxylic-group protons. Therefore, in a 1:1 v/v mixture of H_2O and D_2O, the slow exchange of solvent with the peptide-linkage protons gives rise to doublet resonances for neighbouring carbonyl carbon atoms and α-carbon atoms, but singlets for carboxylic-group carbon atoms and other more remote groups. As shown in Fig. 3A, at pH 6.5, a doublet was observed at 171.8 ppm for Gly-Gly-Gly. Since the β-peptide proton is exchanged more quickly than the α-peptide proton,[32] the doublet was assigned to the C_4 carbon in the α-peptide linkage of Gly-Gly-Gly (numbering is shown in Fig. 4). A doublet was also observed for Cd–Gly-Gly-Gly at pH 5.5 under similar conditions. Figure 3B shows the full spectrum of Gly-Gly-Gly.

Another problem arises from ^{13}C resonance cross-over, which occurs as the solution pH is altered. This leads to serious ambiguities in using the chemical shift data to construct a titration curve. In the current studies cross-over ambiguities were minimized by collecting spectra at closely spaced pH values or by fitting the data to the Henderson–Hasselbalch equation,

$$pH = pK_a + \frac{\log [A^-]}{[HA]}$$

$$\delta_{obs} = \chi_{HA}\delta_{HA} + (1 - \chi_{HA})\delta_{\bar{A}}$$

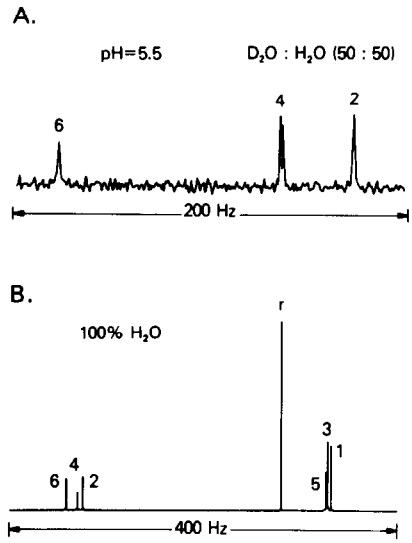

Fig. 3. A. ^{13}C spectrum of Gly-Gly-Gly in 50% D_2O, at pH 6.5, carbonyl region only. B. ^{13}C spectrum of Gly-Gly-Gly in 100% H_2O; r is dioxan (as reference, 67.39 ppm from TMS); C_1–C_6 correspond to the carbon atoms numbered in Fig. 4.

where HA and A^- are a peptide and its conjugate base, respectively, χ_{HA} is the mole fraction of the undissociated form of the peptide, δ_{HA} and δ_{A^-} are the chemical shift values before and after dissociation, respectively, and δ_{obs} is the observed chemical shift value.

The assignments made for the ^{13}C data by these methods are shown in Fig. 2. At low pH cadmium is bound weakly with the carboxylic groups of Gly-Gly (C_4), Gly-γ-ABA (C_6) and β-Ala-Gly (C_5). The pH shift caused by binding was approximately -0.9. Because of the solubility problem previously mentioned, the NMR behaviour of Gly-Gly-Gly could not be observed in this pH region.

In the pH range 4–10, the pH shift caused by the binding is -2.5 for Gly-Gly and Gly-γ-ABA, -2.1 for Gly-Gly-Gly, and -2.0 for β-Ala-Gly. Although all of these shifts are smaller than that for the Cd–glycine complex (-3.8) they are similar to that for Cd–β-Ala (-2.5).[27] This may be taken as indicating that the cadmium binding in these complexes does not involve deprotonation of the protonated amino group. Since a six-membered chelate ring is less stable than a five-membered ring, the pH shift on binding is smaller for β-Ala-Gly than for Gly-Gly and Gly-γ-ABA. Nearly the same chemical shifts were obtained from the C_4 atoms in free and complexed Gly-Gly-Gly, which implies that the α-peptide linkage does not serve as a binding site.

In the pH region 4–8 where cadmium binding occurs through the amino-group of the peptide, the small changes in chemical shifts observed for the C-terminal carboxylic group suggest simultaneous co-ordination with cadmium. However, from molecular models it seems unlikely that the amino nitrogen atom, the carbonyl oxygen atoms of the α- and β-peptide linkage and the carboxylate group for Gly-Gly-Gly can all be co-ordinated to the same metal ion. Although the amino nitrogen atom, the carbonyl oxygen atom of the β-peptide linkage and carboxylate group could be brought together, only the first two would form a thermodynamically stable structure, since the carboxylate group would be involved in a chelate ring with at least 10 members, which would be thermodynamically unstable. Therefore, it seems more likely that simultaneous co-ordination of the amino and the carboxylate ends would involve binding by metal ions to form polynuclear complexes. Likewise, competition for the metal co-ordination sites by the amino end potentially explains the reduced binding at the carboxylate end. As a result, smaller changes in the shifts of the C_6 carbonyl groups were observed at higher pH values.

Evidence for such polynuclear complexes has been reported, *e.g.*, by Kim and Martell,[34] who used ^1H-NMR to study copper and nickel complexes of

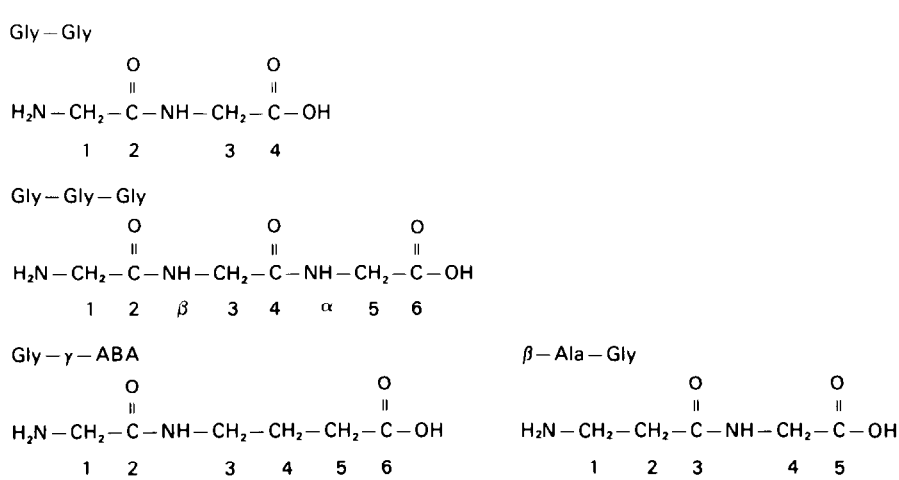

Fig. 4. Numbering of formulae of Gly-Gly, Gly-Gly-Gly, Gly-γ-ABA and β-Ala-Gly.

glycine peptides, and by Rabenstein and Libich[32] who reported on heavy metal complexes of the same peptides.

It has been suggested that Co(II), Ni(II) and Pb(II) can cause deprotonation of the peptide linkage,[35,36] but the present work gave no evidence for this. The plots of ^{13}C shift *vs.* pH were all simple S-shaped curves, not multi-stepped.

The α-peptide proton of Gly-Gly-Gly has been reported as being labilized by metal ions such as Zn(II) and Cd(II).[32] However, in the presence of cadmium the exchange between solvent and an α-peptide proton is slow on the NMR time scale, which is indicated by a doublet when 50% D_2O medium is used. In addition, the competition from a more stable five-membered chelate ring forming between cadmium ion and the N-terminal group, makes the C-terminal co-ordination become less likely at higher pH. The activity of carboxypeptidase A may thus be decreased in the presence of cadmium.

The results reported here provide at least partial explanation of the literature data for metalloproteins and metalloenzymes summarized in Table 1. For parvalbumin, in addition to the two signals (at -90 and -100 ppm) which correspond to the EF site and the CD site respectively, a pH-dependent signal was also observed. This resonance shifted from 0 to 67 ppm as the solution pH was changed from 4 to 8. This signal was assigned by Drakenberg[21] to the result of excess of cadmium complexing with the glycyl residues of parvalbumin. However, that chemical shift profile does not fit the curves obtained in the present study for either the C-terminal glycyl or the N-terminal glycyl group. Additionally, the current study shows that the binding between cadmium and the peptide linkage of the glycyl group is minimal. Therefore, the pH-dependent ^{113}Cd signal reported by Drakenberg[21] might be attributed to complexation of excess of cadmium with the Tris buffer used (pK_a for Tris is 8.5).

COMMENTS ON THE PAPER BY GOMEZ-NIETO, LUQUE DE CASTRO, MARTIN AND VALCARCEL*

JOSEPH T. VANDERSLICE and GARY R. BEECHER
U.S. Department of Agriculture, Agricultural Research Service, Nutrient Composition Laboratory, Beltsville, Maryland 20705, U.S.A.

(*Received* 13 *November* 1984. *Accepted* 1 *February* 1985)

Gomez-Nieto *et al.* have correctly concluded that the equations derived by Vanderslice *et al.*[1] for flow in small capillary tubes do not apply to their system. They also infer, incorrectly, that the equations are inappropriate for any flow-injection analysis studies. However, these equations were derived under certain restrictive conditions,[2] and were obtained by numerical solution of the convection–diffusion equation for laminar flow in straight cylindrical tubing, on the assumption that the heights of peaks for components eluted at different times would all be $80 \pm 5\%$ of full-scale deflection on the recorder chart. The scaling factor, f, was introduced[2] to allow for the fact that experimenters would not necessarily adjust the recorder sensitivity to achieve this relative constancy of signal height. The initial purpose of the study was to elucidate what was happening at the molecular level in capillary tubing. In our laboratory, the equations do predict reasonably well not only the appearance times, t_a, and the baseline-to-baseline times, Δt_B, for simple systems, but also the peak shapes; they have also been used by others for accurate determination of diffusion coefficients for molecules of biochemical interest.[3]

To see why our equations would not apply to the system used by Gomez-Nieto *et al.* we have only to look at their experimental parameters for each of the twenty different configurations they studied and consider two imaginary situations: (1) where the bolus retains its original shape and moves down a straight tube at the average flow-rate, q; (2) where a true laminar situation exists with no diffusion, and the sample at the centre of the tube moves ahead of the bolus at a maximum flow-rate, q_{max}, which is twice the average velocity. For these two imaginary situations, the initial appearance times would be for case 1, $t_1\,(\text{sec}) = (60\pi a^2 L)/q$ and, for case 2, $t_2\,(\text{sec}) = (30\pi a^2 L)/q$. These times, together with the experimental appearance times given by Gomez-Nieto *et al.* are given in Table 1. Also shown are the appearance times, t_A, calculated from our original expression with $f = 1$. Note that t_2 is much smaller than t_{meas} and t_1 is also smaller than t_{meas} in three-quarters of the cases. Note also that t_A is very close to t_2, as it should be, since the effect of axial diffusion is small under these conditions.[4]

What are we to conclude from these results? First, as far as appearance times are concerned, the experimental conditions are such that they do not all resemble laminar flow systems. Secondly, the measured initial appearance times more nearly correspond to a non-distorted slug moving at the average flow-rate q; even here, in about three-quarters of the experiments, the slug seems to be moving at less than the average flow-rate. Such results are hardly compatible with laminar flow in a straight tube. It may be that the flow-injection system used contained one or more unsuspected mixing volumes which would tend to slow down the movement of sample. If so, this would also tend to increase Δt_B and indeed, the measured Δt_B values were larger than expected in three-quarters of the configurations studied. If the measured peak heights were not kept at similar values, this would introduce more uncertainty into the meaning of the measured t_A and Δt_B.

It is our experience that our proposed expressions for t_A and Δt_B, when used under the stated[2] re-

Table 1. Peak appearance times calculated on different assumptions

strictions and applied to simple laminar flow systems, will give approximate values for these times over a wide range of experimental parameters. It it becomes necessary to determine a value for the scaling factor, f, then the instrument can be calibrated with a substance of known diffusion coefficient, as shown by Gerhardt and Adams.[3] We would prefer this method to the procedure proposed by Gomez-Nieto *et al.* It seems to us that these authors have taken laminar-flow expressions designed for simple systems and attempted to apply them to situations for which they were not designed. A sounder approach, it seems to us, would be to start with the simplest of systems and perturb it by adding connectors, mixing volumes, *etc.*, in a step-by-step sequence to see what effect each would have on the measured times. In this way, guidelines might be obtained developing practical working systems which, at present, are well-nigh impossible to design theoretically. One caveat is in order, however. With departure from simple laminar-flow systems, it becomes more difficult to determine, unambiguously, molecular parameters such as diffusion coefficients and rate constants.[2,5]

No apologies have to be made for the fact that our expressions are restricted to simple systems, for if we do not know what is happening at the molecular level in such systems, it is going to be impossible to understand what is occurring in more complicated ones.

PRELIMINARY COMMUNICATION

FLUORESCENT REAGENT FOR VARIOUS REDUCING AGENTS

HARVEY W. YUROW

Chemical Research and Development Center, Aberdeen Proving Ground, Maryland 21010-5423, USA

(Received 7 January 1985. Accepted 6 February 1985)

The basis of many fluorescence-producing reactions of analytical importance is the displacement of a quenching and labile halogen moiety from an inherently fluorescent molecule. The quenching effect is assumed to involve an increase in the rate of internal conversion for the compound in question. Most of these reactions[1] involve the breaking of halogen-carbon or halogen-sulphur bonds. We wish to report fluorescence production from the cleavage of a halogen-nitrogen bond.

It was observed in our laboratory that though acridone sulphonamide in aqueous solution exhibited an intense blue fluorescence, chlorination of the nitrogen moiety in basic solution gave a non-fluorescent oxidizing agent. Reaction of the latter with a variety of reductants returned the fluorescence, presumably by reformation of the sulphonamide.

The sulphonamide was synthesized by heating acridone with an equimolar amount of pyrosulphuryl chloride (prepared[2] from sulphur trioxide and carbon tetrachloride) in a ten-fold excess of chlorosulphonic acid for 1 hr at 110°. The cooled mixture was poured onto ice to precipitate the sulphonyl chloride,[3] which was converted into the sulphonamide in 30% yield by dissolution in concentrated ammonia solution, removal of residual ammonia under reduced pressure, and precipitation with excess of dilute acid. Thin-layer chromatography (TLC) on silica gel[4] gave two spots having blue fluorescence, indicating the probable presence of the isomeric 2- and 4-sulphonamides.

The N,N-dichloroacridone sulphonamide was prepared by dissolving the acridone sulphonamide in dilute base, and passing chlorine through the solution. The precipitate was collected and dried, yielding a yellow powder which was found to be essentially insoluble in water. Stored in a freezer, the substance remained stable for extended periods.

Several media for application of the reagent to the determination of trace amounts of reducing agents were studied. Fluorescence rapidly developed when the compound was dissolved in acetone - water (9:1 v/v) or in acetonitrile ("Spectro" grade) or was formed directly on a silica-gel TLC plate. Greater sensitivity was obtained in a procedure in which the solid was shaken with aqueous test solution. Thus, when 0.1 mg of the solid was shaken for 1 min with 1 ml of aqueous 0.5 ppm sodium sulphide solution, a noticeable blue fluorescence was produced. Similar behaviour at this concentration was shown by sodium thiosulphate, sodium sulphide, ascorbic acid, hydrazine hydrochloride and pentamethylene sulphide, among others. Therefore, the reagent may have applicability to trace analysis for certain reducing agents in water samples or in the atmosphere. In this connection, further studies are being made on the purification and utilization of this novel reagent.

LETTER TO THE EDITOR

REPLY TO THE COMMENTS BY VANDERSLICE AND BEECHER*

SIR,

The aim of our work[1] was not to refute the expressions proposed by Vanderslice *et al.*[2] and by Ramsing *et al.*,[3] but rather to develop a simple and practical method for predicting the behaviour of an FIA system under the usual working conditions of this technique and hence to establish a relationship between the set of parameters (*L*, *q*, *d*) defining the flow system and those defining the FIA peak (t_A, Δt_B, t_{max} and D).

The experimental facts and therefore the contribution of the injection system, connectors, flow-cell geometry, *etc.* to the dispersion of the injected plug have been taken into account.

Vanderslice *et al.* state later[4] that their expressions were obtained (and are valid) for seven restrictive conditions, and in this respect their work differs from ours, because our method is subject to no restriction and should therefore be applicable to any FIA system.

The less restrictive (and so the more in accord with general practice) the working conditions, the more significant is the *f* factor. Vanderslice *et al.* do not enlarge on the importance of this factor, and do not indicate that it is different for the t_A and Δt_B expressions. Nor do they clearly indicate its critical dependence on the experimental variables of the FIA configurations. The conclusions obtained in our paper do not differ appreciably from those reported by Painton and Mottola.[5]

The fact that the Vanderslice expressions are adequate for the determination of molecular diffusion coefficients[6] does not imply that the *f* factor is insignificant, since those experiments were always performed with the same FIA system and under the same working conditions, *i.e.*, with a constant *f*.

The table in the comment by Vanderslice and Beecher is an excellent corroboration of how divergent the theoretical values are from the experimental data. This discrepancy was the main cause for development of our work. Furthermore, the correspondence between the t_2 values (second theoretical situation) and the t_a values (from the general expression in which $f = 1$) should not be at all surprising. Both are calculated from what are essentially almost identical theoretical expressions.

We agree with Vanderslice and Beecher that the usual working conditions in FIA distort the results in such a manner that a purely laminar flow cannot be considered. These systems themselves have distorting effects which contribute in a decisive way to the dispersion, thus increasing the appearance time values.

The method proposed by us, which is based on the experimental facts, can also be applied to more complex configurations (several channels with splitting and confluence points, *etc.*) which, like the simple ones considered in our work, will show a deviation from the theoretical behaviour at molecular level in a laminar flow, owing to the influence of these design factors, but the appropriate correction (or accommodation) factors can easily be assessed, as described in our paper.[1]

DIFFERENTIAL DETERMINATION OF ANTIMONY(III) AND ANTIMONY(V) BY SOLVENT EXTRACTION–SPECTROPHOTOMETRY WITH MANDELIC ACID AND MALACHITE GREEN, BASED ON THE DIFFERENCE IN REACTION RATES

SHIGEYA SATO
Faculty of Education, Kumamoto University, 2-40-1, Kurokami, Kumamoto 860, Japan

(*Received* 6 *June* 1984. *Revised* 29 *December* 1984. *Accepted* 11 *January* 1985)

Summary—Highly sensitive and reproducible extraction–spectrophotometric methods for differential determination of antimony(III) and antimony(V) were investigated. It was found that antimony(III) reacts easily with mandelic acid to form a complex anion extractable into chlorobenzene with Malachite Green from weakly acidic media (pH 2.2–3.5) at room temperature, whereas antimony(V) reacts only slowly, and heating for 15 min at 45° is needed to obtain maximum sensitivity. The significant difference between the rates of reaction of mandelic acid with antimony(III) and antimony(V) was applied to the differential determination of these two species. The calibration graph was linear over the range 0.15–6.0 μg for antimony(III), and 0.20–10 μg for antimony(V).

A number of spectrophotometric determinations of antimony have been reported.[1-7] Most of them are based on the extraction of antimony as $SbCl_6^-$, prepared by the addition of an oxidizing agent such as cerium(IV) in acidic medium (6*M* hydrochloric acid), but often suffer from poor reproducibility.[8,9] Few studies have been made of the determination of antimony(III) or the differential determination of antimony(III) and antimony(V) by spectrophotometry, although several atomic-absorption studies have been made.[10-14]

We have recently reported that antimony(III) reacts with mandelic acid to form a complex anion extractable into chlorobenzene with Malachite Green from weakly acidic media at room temperature.[15] In further work, it was found that antimony(V) reacts similarly with mandelic acid on heating for 15 min at 45°, to give a complex extractable into chlorobenzene, but the rate of reaction of antimony(V) with mandelic acid at room temperature is very slow compared with that of antimony(III). This difference in reaction rate can be used for determination of both antimony(III) and antimony(V). In this differential method, no redox reagents are necessary and the reproducibility is very good because of the stability of the antimony complex at low acidity.

EXPERIMENTAL

Reagents

Standard antimony(III) solution, 1000 μg/ml. Prepared by dissolving potassium antimony tartrate in demineralized water; working solutions were prepared by suitable dilution.

Standard antimony(V) solution, 1000 μg/ml. Prepared by dissolving potassium pyroantimonate in water; working solutions were prepared by dilution.

Malachite Green (MG) solution, 1×10^{-3}M.

*Mandelic acid (MA) solution, 0.10*M. Adjusted to pH 3.0 with sodium hydroxide.

Standard procedure A

Transfer 1.0 ml of the sample solution containing up to 6.00 μg of antimony to a stoppered 10-ml test-tube, and add 0.2 ml of the mandelic acid solution, 1.0 ml of Malachite Green solution and dilute to 4.0 ml with water. Shake the solution with 4.0 ml of chlorobenzene for 5 min. After phase separation, measure the absorbance of the organic phase at 628 nm, in a 10-mm glass cell, against a reagent blank as a reference.

Standard procedure B

Transfer 1.0 ml of the sample solution containing up to 6.00 μg of antimony to a stoppered 10-ml test-tube, add 0.2 ml of mandelic acid solution, heat the solution for 15 min at 45°, then follow the extraction method given in procedure (A).

RESULTS AND DISCUSSION

Reaction conditions

Various complexing agents, dyes and solvents were tested for determination of antimony(III): glycollic acid, lactic acid, 2-hydroxyisobutyric acid, 2-hydroxy-2-methylbutyric acid, 2-hydroxyisocaproic acid and mandelic acid as complexing agents; Ethyl Violet, Methyl Violet, Crystal Violet, Brilliant Green, Malachite Green, Rhodamine B, Methylene Blue and fuchsin as dyes; 1,2-dichloroethane, dichloromethane, *o*-dichlorobenzene, chlorobenzene, benzene, toluene, chloroform, carbon tetrachloride, n-hexane and cyclohexane as solvents.

With each acid, different combinations of solvents and dyes were examined. From the apparent molar absorptivity (ε) of the extracted complexes and the

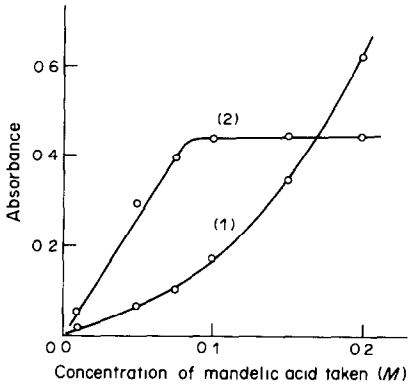

Fig. 1. Effect of mandelic acid concentration (0.2 ml of solution added). (1) Reagent blank. (2) Net absorbance [Sb(V) = 5.0 μg], Malachite Green $2.5 \times 10^{-4} M$; pH 3.0.

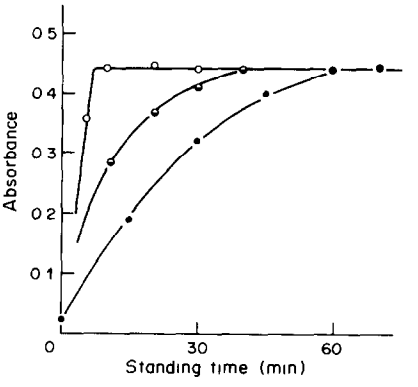

Fig. 2. Effect of standing time. Sb(V) = 5.0 μg; mandelic acid $5.0 \times 10^{-3} M$; Malachite Green $2.5 \times 10^{-4} M$; pH 3.0; reference chlorobenzene: ●——● at 20°, ◒——◒ at 30°, ○——○ at 45°.

absorbances of the reagent blanks, it was concluded that the mandelic acid–Malachite Green–chlorobenzene system was the most useful for determination of antimony(III) because it gave the highest sensitivity and lower reagent blank.

In the previous work[15] a phosphate buffer was used, but the mandelic acid solution (pH 3.0) has some buffering ability, and it was found that use of a phosphate buffer made no significant difference.

The experimental variables for the determination of antimony(V) with mandelic acid and malachite Green were similarly examined. The reaction rate was very slow at room temperature. The effect of the mandelic acid concentration in procedure B was examined and Fig. 1 shows that increasing it led to increased absorbance of both the reagent blank and sample extract, but maximum constant extraction was obtained with more than 0.2 ml of 0.1M mandelic acid, when the reagent blank was used as reference. Accordingly, 1.0 ml of sample solution and 0.2 ml of 0.1M mandelic acid were used, to keep the reagent blank as low as possible.

The effect of reaction temperature and time on the complex formation were also examined. Figure 2 shows that use of higher reaction temperatures considerably shortens the reaction time needed, from more than 60 min at room temperature (20°) to only 10 min at 45°. Once formed, the complex was stable for at least two weeks. Accordingly, heating the mixture of antimony(V) and mandelic acid at 45° for 15 min was chosen. The effect of pH was examined by heating the mixture at various pH values, then adjusting the pH to 3.0 for the extraction. The optimal range for complex formation was found to be 2.2–3.5. Mandelic acid solution adjusted to pH 3.0 was chosen for use.

Dichloromethane, chloroform, chlorobenzene, benzene and toluene were tested as solvents for the extraction, and Ethyl Violet, Crystal Violet, Methyl Violet, Brilliant Green, Malachite Green and Methylene Blue as the cationic dyestuffs. As shown in Table 1, the Malachite Green–chlorobenzene system gave the highest molar absorptivity. The net absorbance reached a constant plateau with Malachite Green concentrations exceeding $2.0 \times 10^{-4} M$, and a concentration of $2.5 \times 10^{-4} M$ was selected for use. The effect of pH on the extraction was examined and the range 2.2–3.5 found optimal. A pH of 3.0 is therefore convenient for both the complex formation and the extraction. An extraction time of about 3 min was found necessary for constant absorbance to be obtained. It was fixed at 5 min for safety.

Reaction mechanism

To confirm that antimony(V) is not reduced to antimony(III) by heating with mandelic acid, the Brilliant Green method[16] for antimony(V) was applied to a mixture of antimony(III) and antimony(V) heated with mandelic acid for various times. It was found that no antimony(III) or mandelic acid was extracted with Brilliant Green, and that the degree of

extraction of antimony(V) was not changed even when the heating time was as long as 60 min.

Further evidence was obtained by heating antimony(V) with mandelic acid and applying ammonium pyrrolidinedithiocarbamate/chloroform extraction at pH 5, followed by atomic-absorption spectrometry[10,14] to detect any antimony(III) formed; no antimony(III) was found. Antimony(V) at about the $10^{-5}M$ level exists mainly as $Sb(OH)_6^-$ in weakly acid media,[17] and the reaction of antimony(V) with mandelic acid is probably very slow because of the inert nature of the hydroxo-complex. The composition of the Sb(V)–MA–MG species extracted could not be determined by the continuous-variations and mole-ratio methods, because of the large excess of complexing agent and dyestuff required for its formation. It is suggested that a complex anion $[Sb(MA)_2(OH)_2]^-$ is formed and extracted as its ion-pair with Malachite Green. The antimony(III) species extracted is most likely the ion-pair $[Sb(MA)_2]^-[MG]^+$.

Calibration graph

At 628 nm Beer's law was obeyed over the range 0.20–10.0 μg of antimony(V). The apparent molar absorptivity [$\varepsilon_{V(45°)}$] calculated from the slope of the graph was 4.31×10^4 $l.mole^{-1}.cm^{-1}$. The absorbance of the reagent blank was 0.175 with chlorobenzene as reference, and the coefficient of variation was 2.8% for ten runs with 5.00 μg of antimony(V). The absorbance of the organic phase did not vary during at least 60 min. If the volume of extracting solvent was halved, the apparent molar absorptivity was increased by a factor of 1.8, but the absorbance of the reagent blank increased to only 0.318.

†Standard deviation ± 0.07 μg.
§Standard deviation 0.05 μg.

Effect of other ions

The permissible amounts of foreign ions which strongly interfere with the determination of antimony(V) and antimony(III) are shown in Table 2. Borate gives a positive error because it reacts with mandelic acid to form an extractable complex anion. Iodide, perchlorate, thiocyanate and nitrate, which are bulky and of low surface charge-density, cause positive errors even when present at low levels. Arsenic(III) gives a positive error when present in 58-fold w/w ratio to antimony(V), and iron(III) gives a negative error when present in 10-fold ratio to antimony(V). These errors seem likely to be due to formation of an extractable anionic arsenic complex and the adsorption of antimony by iron(III) hydroxide, respectively. Tin(II) gives rise to a positive error for the determination of antimony(V) because of the reduction of antimony(V) to antimony(III), whereas the interference of tin(IV) is not as severe as that of tin(II).

*Sb(V) 5.0 μg/4 ml; Sb(III) 2.5 μg/4 ml.
†Amounts added per 4 ml.

The effect of other ions is shown in Table 3, where recovery of antimony(V) or antimony(III) is described. Sulphate and phosphate do not interfere even at very high concentrations. Most cations do not interfere when present in 100-fold ratio to antimony(V) or antimony(III).

Differential determination of antimony(III) and antimony(V)

The most characteristic difference between the methods for antimony(III) and antimony(V) was the rate of reaction with mandelic acid. Antimony(III) reacts quickly irrespective of the temperature, but antimony(V) reacts very slowly at room temperature (20°), but rapidly on heating. Therefore, antimony(III) and (V) can be differentially determined by means of this difference in reaction rate. The method previously reported[15] for antimony(III) was modified to give standard procedure A, with which the calibration graph was linear over the range 0.15–6.00 μg of antimony(III), and the apparent molar absorptivity (ε_{III}) was 6.88×10^4 l.mole^{-1}.cm^{-1}, and the coefficient of variation 2.8% for ten runs with 2.50 μg of antimony(III). Under the same conditions the apparent molar absorptivity [$\varepsilon_{V(20)}$] for antimony(V) was $4.60 \pm 0.14 \times 10^3$ l.mole^{-1}.cm^{-1}.

Calibration graphs for antimony(V) were prepared by procedures A and B for antimony(V) in the range 0–10 μg, in the presence of fixed amounts of antimony(III) up to 5.00 μg. Linear graphs were obtained and the apparent molar absorptivities calculated from the slopes were the same irrespective of the antimony(III) concentration. Similarly, the apparent molar absorptivity of antimony(III) was found not to be affected by the concentration of antimony(V). Consequently, the concentrations of antimony(III) and (V) can be calculated from the total absorbances (Ab_A and Ab_B) obtained by procedures A and B respectively:

$$Ab_A = \varepsilon_{III}[Sb(III)] + \varepsilon_{V(20)}[Sb(V)]$$

$$Ab_B = \varepsilon_{III}[Sb(III)] + \varepsilon_{V(45)}[Sb(V)]$$

$$[Sb(V)] = (Ab_B - Ab_A)/[\varepsilon_{V(45)} - \varepsilon_{V(20)}]$$

$$[Sb(III)] = \{Ab_A - \varepsilon_{V(20)}[Sb(V)]\}/\varepsilon_{III}.$$

Recovery tests showed (Table 4) that the combination of the recommended procedures gave satisfactory results.

ION-EXCHANGER PHASE ABSORPTIOMETRY FOR TRACE ANALYSIS

KAZUHISA YOSHIMURA and HIROHIKO WAKI
Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashiku, Fukuoka 812, Japan

(*Received* 17 *July* 1984. *Revised* 18 *December* 1984. *Accepted* 11 *January* 1985)

Summary—Ion-exchanger phase absorptiometry is based on the direct measurement of the degree of light-absorption by an ion-exchange resin phase which has sorbed a sample component. Direct application of the method makes it possible to determine trace elements in natural water samples without preconcentration. In this paper, all systems hitherto developed are reviewed and the theoretical background of solid-phase absorptiometry is described.

Although a number of chemical methods have been employed for the determination of chemical components present in solution at low levels, absorptiometry is most frequently used because of improvements in instrumental design and the development of more sensitive and selective chromogenic agents. Direct application of absorption spectrophotometry to the determination of trace elements in natural water samples is, however, difficult. Preliminary concentration procedures such as solvent extraction or ion-exchange have been used in some cases. With solvent extraction, a high phase-volume ratio to give an effective concentration of the traces cannot be adopted, because of difficulties in phase separation and mutual solubility. Ion-exchange concentration may often be more convenient, but the chemical components sorbed on the ion-exchanger usually have to be eluted for spectrophotometric measurement, leading to an undesirable dilution of the component. A higher sensitivity can be expected if the sorbed sample species is determined directly in the solid phase by absorption spectrophotometry.

A spot-test using ion-exchange resin beads and a visual observation of the coloured component on the ion-exchanger was proposed by Fujimoto[1] and by Kakihana and Murase.[2] Although this test has been proposed as a highly sensitive method of detection, it cannot be considered as a reliable colorimetric method for quantitative or even semi-quantitative analysis, because of interference by other coloured substances and difficulties in expression of colour intensity.

Measurement of the resin phase colour with a spectrophotometer was first suggested by us.[3] We found a linear relation between the resin-phase light-absorbance and the sample-component concentration in the initial solution. Ion-exchanger phase absorption spectra of metal complexes with inorganic ligands had been reported earlier[4] and have since been used for various investigative purposes.[5–7] The first analytical application was for the sensitive determination of chromium, iron, copper and cobalt in water. Even with a resin layer only 1 mm thick the sensitivity obtained was much higher than with the corresponding solution spectrophotometry. Several further systems have been developed for the analysis of natural water samples (see Table 1).

A technique for rapid collection of the resin beads and preparation of the sample resin layers for measurement has been proposed,[8] and the spectral range has been extended from the visible to the ultraviolet region by the use of aliphatic ion-exchangers.[9] Furthermore, the employment of thicker ion-exchanger layers (*e.g.*, 1 cm) is being investigated in order to enhance analytical sensitivity.[10] Another technical approach, based on analyses of differential spectra, has been tried to give more certain measurement in ion-exchanger phase absorptiometry.[11] Solid-phase spectrophotometry can also be applied with other types of sorbent[12] and other spectroscopic methods such as fluorimetry.[13]

All the systems developed are listed in Table 1 and described in the individual sections below.

Procedure for colour development in the ion-exchanger phase

There are three ways of developing the colour in the ion-exchanger phase, depending on the nature of the individual sample component and the chromogenic agent.

(1) The ion-exchanger is added to the sample solution together with the chromogenic agent. This procedure can be applied when the colour reaction is highly specific for the analyte and the complex formed can be sorbed on the ion-exchanger. Examples are the systems: chromium–diphenylcarbazide,[3,8,14,15] iron–1,10-phenanthroline,[3,16] iron–bathophenanthroline,[17] iron–Ferrozine,[18] cobalt–thiocyanate,[3,19] copper–tetrakis(4-*N*-methylpyridyl)-

porphine,[20] bismuth–iodide,[21] bismuth–chloride,[22] uranium–thiocyanate,[9] phosphate–molybdate,[23,24] and sulphide–*N*,*N*-dimethyl-*p*-phenylenediamine.[25]

(2) The chromogenic agent, presorbed on the ion-exchanger, is added to the sample solution. This procedure is applied when the coloured complex cannot be directly sorbed from the sample solution. The chromogenic agent should be sorbed irreversibly on the ion-exchanger under conditions such that it is retained on the exchanger during the equilibration with the sample solution. In this case the ion-exchanger behaves like a chelating resin. Examples are the systems: nickel–PAN,[26] copper–Zincon,[3] copper–TAN-3,6-disulphonic acid,[27] silicate–molybdate,[28] and phosphate–molybdate.[29]

(3) The analyte is first sorbed on the ion-exchanger from solution and then the chromogenic agent is added. This procedure is applied when the chromogenic agent has poor selectivity for the analyte, for example zinc[30] or cadmium[31] (as complex anions) or hexacyanoferrate[32] can be concentrated on an anion-exchanger and then reacted with Zincon, PAR and ammonium iron(II) sulphate, respectively, to give the coloured species.

Light-absorption measurement

Some of the ion-exchanger containing the coloured sample species is packed as a slurry into a quartz cell (with or without an appropriate transparent spacer), after most of the equilibrated solution has been decanted or filtered. The sedimentation and collection may be accelerated by adding finely powdered oppositely-charged ion-exchanger as coagulant. In this case the coagulated particles are collected on a filter paper under suction, to make a uniform thin layer. The cell containing the ion-exchanger is set in a spectrophotometer and the light transmitted through the cell is measured. When necessary, a reference ion-exchanger layer or a perforated metal plate may be inserted in the reference beam to cancel out the scattering background in the spectrum.

Here the term "attenuance" is conveniently introduced instead of "absorbance", because in the solid-particle layer both absorption and scattering of light contribute to the attenuation of the incident radiation intensity. The overall attenuance of the sample layer is given by

$$A = A_{RC} + A_{soln} + A_R + A_{RL} \qquad (1)$$

where A_{RC} represents the net absorbance by the complex species in the solid phase, A_{soln} the absorbance of the interstitial solution between the solid beads, A_{RL} the absorbance of the free chromogenic agent in the solid phase and A_R the background attenuance due to light scattering and absorption by the matrix material itself. Of course, A_{soln} may be neglected when the distribution ratios of the sample components are very high. A_R is a function of the packing in the cell and the values of A_{RC} and A_{RL} also depend on the packing. In an ideal case, A_{RC} could be obtained directly by measuring the absorbance at the wavelength characteristic of the sample species, with a reference layer containing no sample component and prepared under exactly the same conditions. In general, however, complete cancellation of the background attenuance cannot be expected, and it is more reliable to compare the difference (ΔA) between the values measured at the wavelength characteristic of the coloured species and at a wavelength at which the sample species does not absorb, with the difference (ΔA_{ref}) measured at the same two wavelengths for the reference layer, as shown in Fig. 1. Then, if $A_{RL} = 0$,

$$\Delta A^* = \Delta A - \Delta A_{ref} = A_{RC} + (A_R - A'_R) - (A_{R,ref} - A'_{R,ref}) \qquad (2)$$

where attenuance at the non-absorption wavelength is identified by a prime. In most cases, the ion-exchanger background spectra are parallel provided that the packing is not greatly different. Accordingly, $(A_R - A'_R) - (A_{R,ref} - A'_{R,ref}) = 0$ to a first approximation and $\Delta A^* = A_{RC}$. The use of a reference layer may be omitted if the spectral behaviour of the ion-exchanger layer is completely known, *i.e.*, $(A_R - A'_R)$ in equation (2) is a known constant. The sample attenuance may then be measured against air, which simplifies the procedure.

The sample concentration can be evaluated by means of a calibration graph or the standard-additions method.

If m g of ion-exchanger are equilibrated with V ml of sample solution, the concentration of sample species sorbed, C_{RC} (mole/kg), is

$$C_{RC} = \frac{C_0 V}{mv(1 + V/Dm)} \qquad (3)$$

where C_0 is the initial concentration in the sample solution (mole/l.), v the equilibrated ion-exchanger

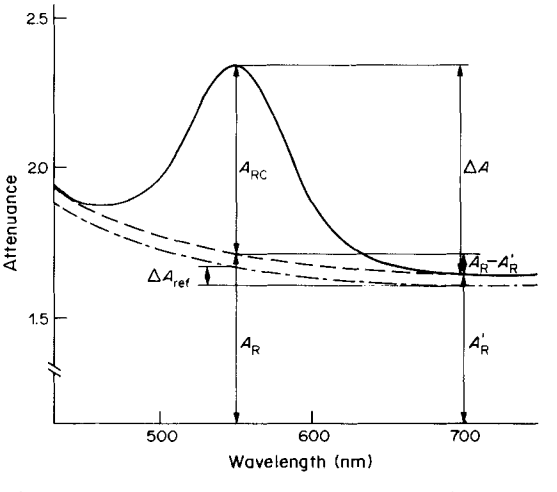

Fig. 1. Absorption spectra of Dowex 50W-X2 resin containing chromium diphenylcarbazide complex: --- assumed resin background of sample; —·— reference resin spectrum.

volume per unit weight (ml/g) and D the distribution ratio of the sample component (ml/g). The net absorbance due to the sample species sorbed, A_{RC}, is given by

$$A_{RC} = \varepsilon_{RC} l_R C_{RC} = \varepsilon_{RC} l_R C_0 V/[mv(1 + V/Dm)] \quad (4)$$

where ε_{RC} is the molar absorptivity of the sample species in the ion-exchanger phase and l_R the mean light-path length through the solid phase (which is different from the cell length). A good linear relationship is often found between A_{RC} and C_0.

Sensitivity

Equation (4) indicates that high sensitivity is attained by use of large ε_{RC}, V/mv, D and l_R values. In general, a sensitive reagent for conventional solution absorptiometry may also be satisfactory for the ion-exchanger method, provided that the resulting complex is strongly retained by the ion-exchanger. For example, porphyrin has been proposed[20] for the determination of copper at concentrations less than 1 ng/ml by ion-exchanger spectrophotometry.

In a heterogeneous method the sensitivity depends on the volume ratio of the phases. Using a high V/mv ratio leads to enhancement of sensitivity provided that a sufficiently high D value can be attained. Therefore it may be desirable to use just enough ion-exchanger to provide the sample layer in the cell. The use of a large sample volume increases the time required for equilibration and is inconvenient for handling, so the practical limit may be a few litres.

A further way of increasing the sensitivity is to use a thicker sample layer to increase l_R. However, measurements at very large values of l_R may be made difficult by the large light loss due to scattering and/or background absorption. So far, it has been customary to use a 1-mm cell for ion-exchanger spectrophotometry, but it has recently been found that increasing the cell length gives only a moderate increase in the background attenuance (in contradiction to Lambert's law).[33] On the other hand, increasing the cell length gives a proportional (or sometimes even greater) increase in the absorbance of the sample species. This suggests that it is advantageous to use the longest cell length compatible with accurate absorbance measurement. To minimize the light-loss by scattering, the cell can be set as close as possible to the light detector window to give the best

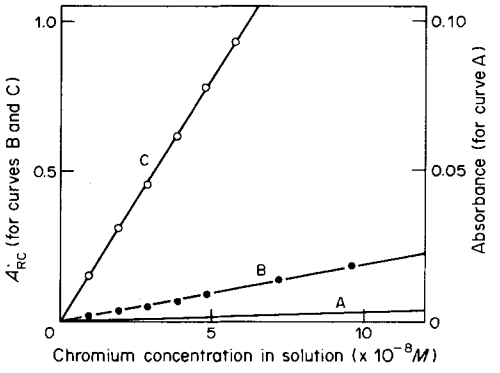

Fig. 2. Comparison of calibration graphs for the chromium–diphenylcarbazide system: A, conventional absorptiometry; B and C, ion-exchanger absorptiometry. Sample volume 1 litre; resin AG 50W-X2-H^+ (200–400 mesh), 0.50 g; stirring time 30 min; cell length, A 10 mm, B 1 mm, C 10 mm.

geometry for light-collection, or a slotted cylinder, with its inner surface a mirror, can be placed between the cell and the detector to collect to some extent the light scattered from the layer. With these modifications a cell length of 1–2 cm is the limit for reliable measurements with a commercial spectrophotometer. A longer cell requires use of more ion-exchanger, of course, and hence of a proportionately larger volume of sample solution to preserve high sensitivity. Use of spacers so that only the light-path is occupied by the resin, or use of a narrow black-sided cell has been tried to reduce the amount of ion-exchangers required.[10]

In these ways, ion-exchanger spectrophotometry is made 100–1000 times more sensitive than the corresponding solution methods, provided that the analysis is performed with a 1-cm cell and a 1-litre sample volume and that high distribution ratios are achieved. A typical comparison is given in Fig. 2, for the chromium–diphenylcarbazide system.

Precision

It might be thought that the precision of the ion-exchanger spectrophotometric method, involving as it does, an unorthodox solid-phase optical medium, would be inferior to that obtainable with conventional solution spectrophotometry. However, the analytical data given in Table 2 show that the errors are not serious for such low sample concen-

trations, for which the conventional solution method is inapplicable.

Determination of trace concentrations in solution

Silicate. Silicic acid in solutions at pH 3–9 was sorbed on an anion-exchange resin in the molybdate form. Molybdosilicate in the resin phase was reduced to "molybdenum blue" and the resin phase absorbance at 700 nm measured.[28] Sephadex gels strongly retain this blue species and this has been utilized as a new solid-phase colorimetric method for trace determination of silicate in industrial waters of high purity.[12]

Phosphate. Anion-exchange resins in the molybdate form can concentrate phosphate as molybdophosphate from 0.2–1*M* acid. The blue colour obtained on reduction has been measured for the determination of phosphate, although the sensitivity is not very high.[29] As an alternative, the reduced molybdophosphate was rapidly sorbed on a finely-divided macroreticular anion-exchanger, Amberlyst A-27 (0.2–30 μm), and the resin particles were coagulated by adding a finely-divided cation-exchanger, Amberlyst 15 (0.2–30 μm). After filtration, the coagulated resin was immersed in a solution containing sulphuric acid, ascorbic acid and potassium antimonyl tartrate. The orthophosphate or total phosphate (including organophosphates) at ng/ml levels in environmental water samples such as rain, snow, lake and sea waters was determined.[23,24]

Sulphide. Sulphide ions were converted into Methylene Blue by reaction with *N,N*-dimethyl-*p*-phenylenediamine (DPDA) in the presence of iron(II). The coagulation technique has been employed to concentrate the resulting coloured species.[25]

Chromium. Diphenylcarbazide selectively forms a soluble red-violet cationic complex with chromium(VI) and the complex can easily be concentrated with cation-exchangers.[3,8,14] Total chromium can also be determined by oxidizing chromium(III) to chromium(VI) with ceric sulphate.[15] Only copper(II) at ten times the chromium level interferes. Chromium(VI) in urine[14] and total chromium in natural waters[15] have been determined without preconcentration.

Iron. Ion-exchanger spectrophotometry for iron was developed with 1,10-phenanthroline[3,16] and 4,7-diphenyl-1,10-phenanthroline (bathophenanthroline).[17] Total iron could be determined after reduction of iron(III) to iron(II) with hydroxylamine. If citrate is used to mask iron(III), only iron(II) is determined.[16] Copper interferes considerably in the 1,10-phenanthroline method. The bathophenanthroline complex of iron(II) can also be strongly retained by finely divided cation/anion-exchange resin mixture. In this case copper does not interfere even in 40-fold amount relative to iron.[17]

Hexacyanoferrate(III). Hexacyanoferrate was concentrated on an anion-exchange resin and a coagulation technique was employed. The sorbed species was converted into Turnbull's Blue by treatment with ammonium iron(II) sulphate.[32]

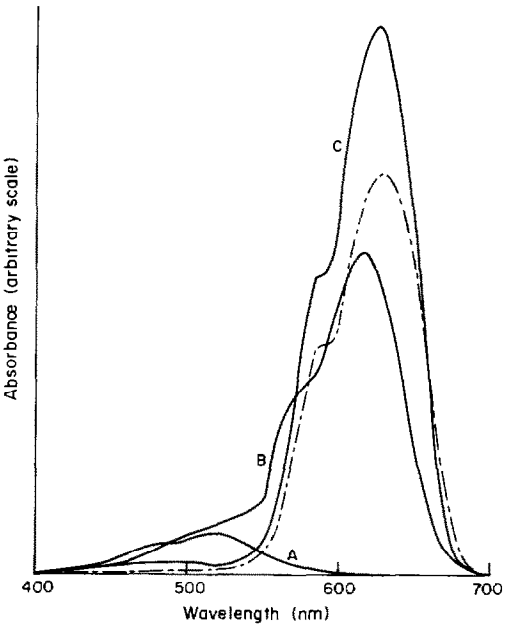

Fig. 3. Absorption spectra of isothiocyanato complexes of cobalt(II): —— solution spectra, A, 0.7*M* NH_4SCN + Co(II); B, 8*M* NH_4SCN + Co(II); C, 0.7*M* NH_4SCN + Co(II), in 1:1 acetone–water; –·–·– resin-phase spectrum (equilibrated with solution A), resin Dowex 1-X2-Cl^- (100–200 mesh).

Cobalt. Figure 3 shows the absorption spectrum of cobalt(II)–thiocyanate complexes sorbed on the anion-exchanger Dowex 1-X4.[3] The complexes formed in thiocyanate solution are also shown for comparison. It was found that the absorption spectra for the anion-exchanger correspond to the complexes formed at much higher ligand concentrations than those in the equilibrating solution. The sorbed complex is taken to be $Co(NCS)_4^{2-}$. This enhancing effect on ligand number when anion-exchangers are used has often been observed in inorganic complex systems and is advantageous in view of analytical sensitivity. The calibration graph is linear in the range 1–15 μg of cobalt in 40 ml of sample.[19] Interference by iron(III) or copper(II) can be removed by masking with fluoride or EGTA.

Nickel. 1-(2-Pyridylazo)-2-naphthol (PAN) shows high sorbability on a cation-exchange resin from an acidic alcohol solution. The PAN cannot be desorbed from the resin with aqueous solutions and therefore the resin behaves as a chelating resin. The resin phase develops a colour (λ_{max} 566 nm) with a very small amount of nickel. Copper and zinc, which form coloured complexes with PAN in the resin phase, can be completely stripped with a masking solution composed of EDTA and thioglycollic acid (pH 7.8). Cobalt can be determined in the presence of nickel by measurement at 628 nm.[26]

Copper. Both *o*-{2-[α-(2-hydroxy-5-sulphophenylazo)-benzylidene]hydrazino}benzoic acid (Zincon)[3]

and 1-(2-thiazolylazo)-2-naphthol-3,6-disulphonic acid (TAN-3,6S)[27] are irreversibly sorbed on anion-exchange resins. These reagent-loaded resins have been utilized for ion-exchanger colorimetry of copper. The mechanism of copper sorption from mixed solvents was deduced from the dependence of sorption rate on particle size and on the nature and content of the organic solvent.[27] The sorption of copper is controlled by the diffusion of copper ions through the film surrounding the ion-exchange resin particle.

The porphyrin $\alpha,\beta,\gamma,\delta$-tetrakis(4-*N*-methylpyridyl)porphine [T(4-MPy)P] has also been used as the chromogenic agent. After complexation at pH 4.5 and 40°, the surplus ligand was converted into the protonated species by addition of sulphuric acid. The complex and the ligand were easily sorbed on the cation-exchange resin because of their high positive charge. The resin-phase attenuance of the complex species at 424 nm and of the background at 510 nm were used for the measurements. There were no interferences by the foreign ions expected to be present in natural waters.[20] The copper contents of ground-waters in the Akiyoshi-dai karst area (Japan) were determined by this method.[34] The content in a ground-water dissolving only Akiyoshi limestone could be calculated to be 0.03 ng/ml from the average content of copper of the limestone, and this value was in good agreement with the lowest content of copper in the ground-waters.

Zinc. Zinc in water samples can be determined by its sorption onto an anion-exchange resin from 2*M* chloride solution, followed by transformation into a coloured complex with Zincon.[30] The Zincon complex of zinc has an absorption maximum at 650 nm in the resin phase, but at 620 nm in solution. This complex is stable in the pH range 8.5–9.5. The zinc:Zincon ratio of the complex in the resin phase was found to be 1:1 by the molar-ratio method, the same as that in solution. The difference between the absorption spectra in the two phases may be due to Zincon in the resin phase being deformed owing to spatial restriction and subject to non-electrostatic interaction with the resin skeleton.

Cadmium. 4-(2-Pyridylazo)resorcinol (PAR) forms soluble complexes of very high absorptivity with many metal ions, and is not selective for cadmium. Therefore cadmium in a water sample was first concentrated selectively as iodo-complexes on an anion-exchange resin, by sorption from 0.015*M* potassium iodide solution, and thereafter PAR was applied to the resin phase. Only copper and lead interfere (when present in concentrations greater than that of cadmium). By use of an anion-exchange resin column cadmium can be concentrated as chloro-complex anions and separated from the interfering ions. The combination of preliminary column operation and ion-exchanger colorimetry makes it possible to determine cadmium at ng/ml concentrations, or below, in natural water samples.[31]

Bismuth. The yellow bismuth–iodide complexes are specifically and strongly sorbed on an anion-exchange resin in the sulphate form, with $D > 10^7$. The spectrum of the resin phase indicates that the absorption maximum significantly shifts to longer wavelengths (492 nm), corresponding to the formation of higher ligand-number complexes than those formed in solution. This can be attributed to the effective ligand concentration being much higher in an anion-exchange resin than in solution. Bismuth in the ng/ml–μg/ml range can be determined without interference, except in the presence of a large amount of copper(II), silver and lead.[21] Very recently, ultraviolet spectrophotometry was applied to the ion-exchanger system of bismuth, chloride and QAE-Sephadex.[22] By use of a cell of long path-length (10 mm), ng/ml levels of bismuth could be determined.

Uranium. Ion-exchanger phase ultraviolet spectrophotometry was used for the determination of uranium.[9] Although aromatic ion-exchange resins show very high absorption background in the ultraviolet region, crosslinked dextran-type ion-exchangers, such as Sephadex ion-exchangers, have a much lower background. Isothiocyanato complexes of the uranyl ion are sorbed on Sephadex anion-exchanger and have an absorption maximum at about 300 nm. The difference between the attenuances at 300 or 330 and 600 nm is linear up to a uranium concentration of 0.5 ppm in the sample solution.

2,4,6-Trinitrotoluene (TNT). The fluorescence of the ion-exchanger phase was used for the microdetermination of TNT. The fluorescence of fluorescein sorbed on Dowex 2-X10 (cyanide form; 35–60 mesh) was quenched by traces of TNT. The resin, in a Pyrex U-tube, was subjected to ultraviolet radiation and the fluorescence measured with a photomultiplier. The detection limit was 70 ng/ml.[13]

SPECTROPHOTOMETRIC DETERMINATION OF SILICON IN SILICATES BY FLOW-INJECTION ANALYSIS

ROKURO KURODA, IWAO IDA and HIDEKI KIMURA
Laboratory for Analytical Chemistry, Faculty of Engineering, University of Chiba, Yayoi-cho, Chiba, Japan

(*Received* 25 *July* 1984. *Revised* 13 *December* 1984. *Accepted* 11 *January* 1985)

Summary—A flow-injection spectrophotometric method has been developed for the accurate, continuous determination of silicon in silicate rocks. A rock sample solution is prepared by fusion with a 1:1 mixture of lithium carbonate and boric acid and subsequent dissolution of the cake in 1*M* hydrochloric acid. The preparation technique is the same as that used for the determination of total iron, aluminium, calcium, titanium, and phosphorus in silicate rocks by flow-injection spectrophotometry. Because of the marked polymerization of silicic acid in acid solution, silicic acid is depolymerized in alkaline medium after a simple cation-exchange column filtration of the rock sample solution and then determined by a static or an FIA spectrophotometric method. The FIA system consists of two channels which carry the carrier solution and molybdate reagent, and allows the colour reaction to proceed under controlled conditions. The FIA system permits high throughput of 70 samples per hour. The procedure has been applied to a variety of standard silicate rocks of the U.S. Geological Survey and the Geological Survey of Japan, and gave satisfactory agreement with the recommended values.

Flow-injection analysis (FIA) has been widely used for automatic continuous analysis in agricultural, clinical, pharmaceutical and environmental chemistry, *etc.*, owing to the high throughput and cost performance. We have been attempting to apply FIA to the determination of major and minor elements in silicate rocks, and have already reported on aluminium and iron,[1] titanium,[2] calcium[3] and phosphorus.[4] The work has now been extended to silicon. Little information is available about the determination of silicon by FIA. Spectrophotometric methods based on silicomolybdic acid have been reported[5,6] and recently the determination of reactive silicate in seawater has been automated by FIA, with use of the molybdenum blue method. A flow-injection voltammetric method has been worked out for the determination of soluble silicate and total phosphate in commercial washing powders.[8] Since FIA is concerned with liquid samples, we decided to use the same rock sample solution as in our earlier work.[1–4] A simple cation-exchange column filtration was used before the FIA, in order to isolate silicic acid, which was then depolymerized in alkaline medium to allow its photometric determination as yellow silicomolybdic acid. FIA is advantageous in that the critical conditions in silicomolybdic acid method, including reaction time, temperature, reagent concentrations, *etc.*, can be precisely controlled, so reproducible, continuous, rapid determination of silicon can be achieved.

EXPERIMENTAL

Reagents

Stock silicon solution, 1000 μg/ml in 0.1M sodium hydroxide. A piece of high-purity silicon was crushed between nickel plates, digested with 1*M* hydrochloric acid, and then washed with distilled water and ethanol; 0.05 g of the crushed silicon was fused with a mixture of 0.45 g sodium carbonate and 0.05 g of potassium nitrate for 15 min. The cooled melt was dissolved in 0.1*M* sodium hydroxide and diluted to exactly 50 ml with the same base.

Molybdate reagent. For the FIA work, 5.0 g of ammonium heptamolybdate, $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ was dissolved in 0.2*M* sulphuric acid and diluted to 500 ml with the same acid, and used after standing overnight. For the conventional spectrophotometry 5.0 g of the ammonium molybdate was dissolved in distilled water to yield 100 ml of solution.

Flux solution. Lithium carbonate and boric acid mixture (1:1, 600 mg) was fused for 15 min at *ca.* 1000°. The cooled cake was dissolved in 1*M* hydrochloric acid and the solution diluted to 100 ml with the same acid.

Apparatus

The FIA system is shown in Fig. 1. It consisted of a reciprocating pump (plunger type, KHU-W-104, Kyowa Seimitsu), six-way sample-injection valve (NV-508-6M, Nihon Seimitsu), spectrophotometer (UV-180, Shimazu) with a flow-through cell (volume 8 μl, 1 mm bore, 10 mm long), an analogue/digital converter data-processor (Chromatopac C-RIA, Shimazu) and a thermostatic water-bath. The flow line was made from 1.0-mm bore Teflon tubing, except for the back-pressure coil (0.5 mm bore).

Procedures

Decomposition. Weigh out about 100 mg of rock sample into a platinum crucible and mix it with 600 mg of 1:1 mixture of lithium carbonate and boric acid. Fuse the mixture for 15 min at 1000°. Dissolve the cooled melt in 1*M* hydrochloric acid (with magnetic stirring) and dilute to exactly 100 ml with the same acid. Store in an air-tight polyethylene bottle.

Pretreatment of sample solution. Take a 2.5-ml aliquot of sample solution, add 2.5 ml of distilled water and load the mixture into a cation-exchange column (Bio-Rad AG 50W-X8, hydrogen form, 100–200 mesh; bore 8 mm, bed 30 mm long). Wash the column with five 2-ml portions of 0.5*M* hydrochloric acid, collecting all the effluent in a 50-ml

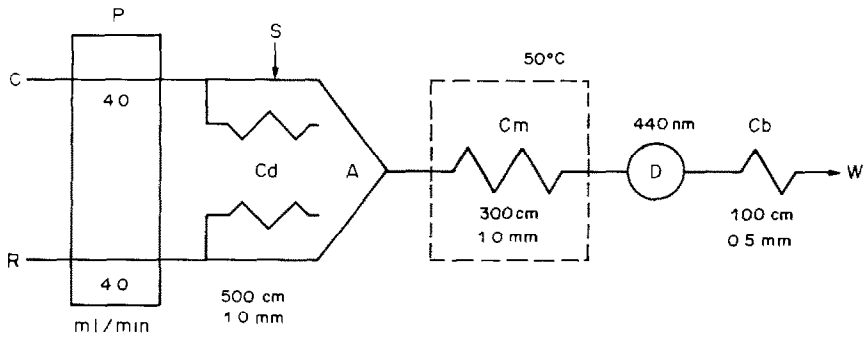

Fig. 1. Flow diagram. C, carrier (0.1*M* NaOH); R, reagent solution (1% ammonium molybdate in 0.2*M* sulphuric acid); S, sample (318 μl); Cd, damper coil; A, confluence point; Cm, mixing coil; D, spectrophotometer; Cb, back-pressure coil; P, pump; W, waste.

Teflon beaker. Add 4 ml of 2.5*M* sodium hydroxide to the combined effluent. Heat the mixture at 80° for 20 min to depolymerize the silicic acid. Cool and transfer to a 25-ml polypropylene standard flask. For FIA dilute this solution to the mark with distilled water, but for conventional spectrophotometry use a 50-ml polypropylene standard flask and proceed as described below.

Determination

Conventional spectrophotometry. Add 10 ml of a 1:1 v/v mixture of the 5% molybdate reagent and 1*M* sulphuric acid to the standard flask. Dilute to the mark with distilled water. Let stand for 20 min and measure the absorbance at 440 nm against distilled water as reference. For calibration place 2.5 ml of the flux solution, 10 ml of 0.5*M* hydrochloric acid, 4 ml of 2.5*M* sodium hydroxide and appropriate amounts of standard silicon solution into 50-ml standard flasks, and proceed as just described for samples.

Flow-injection analysis. Use the flow system illustrated in Fig. 1. Inject the pretreated sample solution (318 μl) into the carrier solution (0.1*M* sodium hydroxide) flowing at 4.0 ml/min and merging at A with the molybdate reagent stream (R) flowing at the same rate. Allow the sample slug to pass through a mixing coil Cm in a water-bath kept at 50°, to accelerate the colour-forming reaction. Read the absorbance in the flow-through cell at 440 nm against air as reference. Prepare a series of standard solutions by placing 2.5 ml of flux solution, 10 ml of 0.5*M* hydrochloric acid, 4 ml of 2.5*M* sodium hydroxide solution, and appropriate amounts of silicon stock solution in 25-ml polypropylene standard flasks and diluting to the mark with distilled water. Injected these into the carrier solution, as for sample solutions, before and after the sample run.

RESULTS AND DISCUSSION

Polymerization of silicic acid

There are many papers describing the spectrophotometric determination of silicon, but almost all are variations of two basic methods, *i.e.*, the yellow silicomolybdate and the molybdenum blue methods. The conditions for colour development in the yellow silicomolybdate method are rather critical and polysilicic acids react more slowly at higher degrees of polymerization, and at a certain degree of polymerization do not react at all with molybdate.[9] Formation of polysilicic acid is dependent on acidity and other conditions,[10–12] and proceeds rather rapidly even in 1*M* hydrochloric acid.[12] Since it is essential in this work to determine all species of silicic acid in the sample solutions (which are in 1*M* hydrochloric acid), the solution is made alkaline (0.13*M* in sodium hydroxide) and heated to depolymerize the polysilicic acid. Addition of EDTA to prevent precipitation of hydroxides was examined, and it was found that for iron-rich silicate rocks some brownish precipitate always appeared, and somewhat low results for silicon were obtained. We therefore decided to remove heavy metals and magnesium by cation-exchange before depolymerization of the silicic acid. This can simply be accomplished by passing the sample solution (diluted with distilled water to be 0.5*M* in hydrochloric acid) through a small cation-exchange column (hydrogen form). Results thus obtained for the recovery of silicon in the presence of iron and magnesium are quoted in Table 1. Though the data are somewhat scattered, the overall recovery of silicon is 99.5 ± 1.7% ($n = 16$), and there is no indication that silicate is adsorbed on the magnesium and iron forms of the resin that are formed during the ion-exchange.

Special attention should be drawn to possible error arising from use of commercially available standard

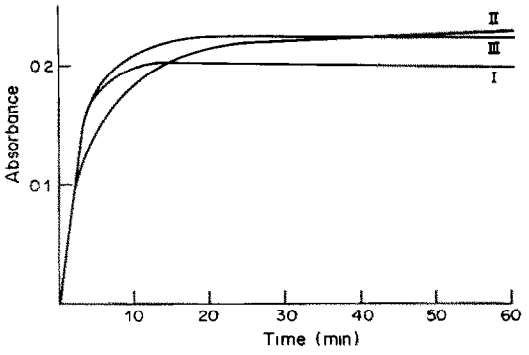

Fig. 2. Colour development of yellow silicomolybdate as a function of time. I: Rock sample (andesite AGV-1); rock solution treated as described in procedure. II: Silicic acid alone; standard solution of silicic acid treated as described in procedure without addition of flux solution. III: Silicic acid + flux solution; processed as described for the preparation of calibration standards in procedure.

silicon solutions for atomic-absorption. When used as received, silicon standards (nominal Si contents 1003, 990, 1000 ppm) obtained from three companies yielded apparent contents of 958, 927 and 756 ppm when used instead of our standard prepared as described above. This is partly because of polymerization of the silicic acid, which can occur even in weakly alkaline media[11,12] as well as in acid media.

Colour development

To obtain accurate results, matrix matching of samples and standards is of primary importance in the yellow silicomolybdate method. When an appropriate amount of silicon stock solution was diluted with 0.1*M* sodium hydroxide to yield a working standard, and aliquots of this solution and of a standard rock sample solution (prepared as described in the procedure) were taken, the colour was developed, and the absorbance of both solutions was plotted as a function of time (Fig. 2), the colour development for the silicon standard was much slower than that for the rock sample. This could obviously cause a systematic error for silicon determination since the absorbance is measured within an hour. If the working standard is prepared in the same way as the rock samples, however, colour development proceeds at the same rate for both standards and samples (Fig. 2). Therefore, the presence of the flux solution is of importance for obtaining accurate results in the silicomolybdate method.

Table 2. Effect of foreign ions on the determination of silicon (623 μg)

Ion	Amount present, μg	Si found, % Spectrophotometric	FIA
Fe(III)	528	$100._3$	$101._3$
Al(III)	436	$100._2$	$101._7$
Ca(II)	450	$101._1$	$100._8$
Mg(II)	1190	$99._2$	$101._5$
Ti(IV)	80	$101._1$	$99._6$
Mn(II)	11	$100._5$	$101._2$
P(V)	14	$100._5$	$99._0$
V(V)	2	$99._9$	$100._8$

Five ml of solution 0.5*M* in hydrochloric acid, which contained 2.5 ml of the flux solution, 623 μg of Si and a varied amount of foreign ion, was loaded on the column in accordance with the procedure, and the silicon in the effluent was determined.

Table 3. Effect of phosphorus on the determination of silicon (spectrophotometric method)

Si taken, μg	P taken, μg	Si found, %		
594	6.7	$101._6$	$101._3$	$99._6$
	13.5	$100._6$	$100._5$	$100._3$
	26.9	$101._4$	$100._3$	$100._3$
	40.4	$101._8$	$99._3$	$99._3$
891	6.7	$100._8$	$98._8$	$99._5$
	13.5	$100._4$	$99._6$	$99._3$
	26.9	$100._8$	$99._1$	$100._1$
	40.4	$100._7$	$100._3$	$99._9$

See Table 2, footnote, for the conditions. For a 2.5 mg sample in a 5-ml aliquot, 40.4 μg of P corresponds to 3.7% P_2O_5.

Interferences

The effect of foreign ions on the determination is summarized in Table 2. Five-ml portions of 0.5*M* hydrochloric acid, which contained silicic acid, flux, and either a major or a minor element were analysed for silicon in accordance with the full procedure. These elements do not interfere. A more detailed study of phosphorus was made (Table 3). For two levels of silicon (equivalent to 50.8 and 76.3% SiO_2 in rocks), 6.7–40.4 μg of phosphorus (equivalent to 0.6–3.7% P_2O_5 in rocks) do not interfere. The phosphorus content in igneous rocks ranges up to about 2% P_2O_5. The abundance in common sediments, sedimentary rocks and metamorphic rocks seldom exceeds 0.5% P_2O_5. Therefore the method can be applied to analysis of silicate rocks without interference from phosphorus. The reason seems to be that the molybdate method is not sensitive to phosphorus in the conditions used.

To assess the accuracy the spectrophotometric method was applied to 12 U.S. Geological Survey standard rocks and two standard rocks of the Geological Survey of Japan. Results are given in Table 4. The values refer to individual rock samples, each processed completely. Agreement of the results with the literature values is excellent, showing that the method is applicable to at least the rock types represented by these standard rocks. The rock sample solutions G2, GSP-1, AGV-1 and BCR-1 were prepared 10 months before the determination of silicon. The results indicate that the rock sample solutions are very stable, and able to serve as master solutions for the determination of other major and minor elements.

Table 4. Determination of silicon in standard rocks

Sample	SiO_2 found, %		1972 values,* Flanagan[13]	1980 usable values, Abbey[14]

JG-1 granodiorite	72.1, 72.5	72.5, 71.8	72.24 (av.)	72.36

*r = recommended value; av. = average; m = magnitude.

Determination of silicon by FIA

The FIA colour development system was designed to reproduce the spectrophotometric method with respect to acidity, reagent concentration, *etc.* However, as shown in Fig. 2, the colour formation reaction is rather slow at room temperature. Hence, the reaction was accelerated by raising the temperature of the water-bath containing the mixing coil Cm (Fig. 1) to 50° (35° at the outlet of Cm). The stopped-flow signal for these conditions is given in Fig. 3. As can be seen, the colour formation reaction is complete at this temperature, below which the reaction proceeded more or less incompletely.

Secondly, the effect of mixing-coil length was tested as a function of the flow-rate of the carrier and the reagent solution (both these being the same). The result is illustrated in Fig. 4. The peak height is maximal with 200-cm coil length, over the flow-rate range tested. The variation of peak height is somewhat larger for shorter coil lengths (100, 200 cm), so a length of 300 cm was finally chosen, with a flow-rate of 4.0 ml/min, which gives a sufficiently high throughput, with good precision. The effect of concentration of molybdate reagent is also shown in Fig. 4, as a function of the flow-rate, with the mixing coil length fixed at 300 cm. As 1% and 2% molybdate solutions yield almost the same response, we decided to use 1.0% molybdate solution for economy.

The sample injection volume also has a significant effect on the peak height. Injection (214, 318, 406 μl) of standard silicon solutions of various concentration (5–40 μg/ml), gave results which showed that larger sample volumes led to higher peak heights, and for each injection volume a linear working curve passing through the origin was obtained over the silicon concentration range tested. We chose an injection volume of 318 μl, taking into account the throughput.

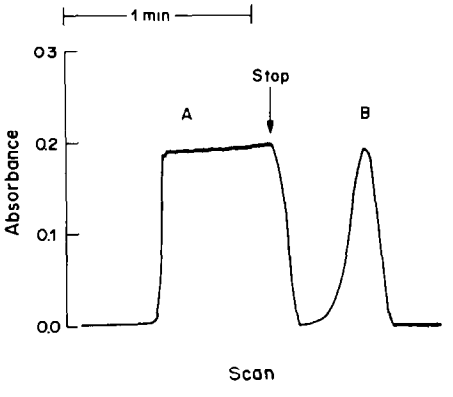

Fig. 3. Stopped-flow signal (A) and normal FIA peak (B) obtained with the flow system.

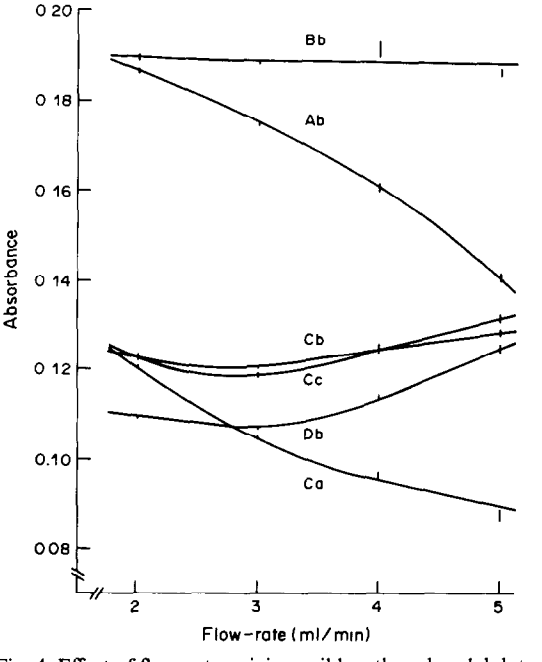

Fig. 4. Effect of flow-rate, mixing coil length and molybdate reagent concentration on peak height (absorbance). Coil length: A, 100 cm; B, 200 cm; C, 300 cm; D, 500 cm. Concentration: a, 0.5%; b, 1.0%; c, 2.0%.

Under the optimized conditions the colour development reached completion, and the dispersion D, defined by $D = H_0/H_{max}$, where H_0 is the peak height for the undiluted coloured species and H_{max} is that for the coloured slug in the flow system, was 2.2, *i.e.*, there was medium dispersion.

The FIA method described here gave good precision (0.5% relative standard deviation) and accuracy, and a throughput of 70 samples per hour, with no carry-over, and is applicable to a wide range of silicon content. It is particularly convenient to be able to use the method with a master sample solution prepared for determination of iron, aluminium, titanium, phosphorus and calcium in silicate rocks.

INFLUENCE OF SOME METAL IONS ON OXIDATION OF NADH AND ON FORMATION OF THE SUPEROXIDE ANION RADICAL (O_2^-), DURING ENZYMATIC CATALYSIS BY E.C. 1.2.3.2 XANTHINE OXIDASE*

ANNA MARIA GHE†, CLAUDIO STEFANELLI, PAGONA TSINTIKI and GABRIELE VESCHI

(*Received* 3 *July* 1984. *Revised* 14 *November* 1984. *Accepted* 11 *January* 1985)

Summary—The inhibitory effect of selected metal ions [Ag(I), Hg(II), Cu(II), Cr(VI), V(V), Au(III), Tl(I) and Zn(II)], on the xanthine oxidase (XOD) catalysis of xanthine oxidation, has been investigated with reference to the XOD catalysis of oxidation of NADH. Hg(II), Ag(I), Zn(II) and Au(III) act as inhibitors, Tl(I) has no effect and Cu(II), Cr(VI) and V(V) act as activators. The formation of O_2^- during XOD catalysis of oxidation of either xanthine or NADH has also been studied. All the metal ions considered act as inhibitors with respect to O_2^- production when the reducing substrate is xanthine, but only a few of them when the substrate is NADH, the others showing no effect whatsoever whether or not they activate NADH oxidation in the course of the same reaction. Vanadium (V) has an anomalous effect: it inhibits xanthine oxidation but considerably increases NADH oxidation, and thus appears to modify the catalytic properties of the enzyme. This behaviour appears promising as the basis for a kinetic method for determination of V(V).

Xanthine oxidase (E.C. 1.2.3.2 XOD) is a complex enzyme containing four different prosthetic groups in each subunit: one molybdenum atom, a flavin adeninedinucleotide molecule (FAD), and two iron/sulphur centres.

The enzyme catalyses the oxidation of xanthine to uric acid, molecular oxygen acting as electron acceptor and being reduced to hydrogen peroxide and the superoxide radical anion O_2^-.

The overall reaction is very complex and can be subdivided into two half-reactions: the enzyme reductive step, that takes place at the molybdenum active site, leading to the formation of uric acid,[1] and the oxidative half-reaction, at the flavine site, leading to the formation of H_2O_2 and O_2^-.[2-4]

The fully reduced enzyme is reoxidized by a four-step six-electron mechanism. During the first and second steps electrons are transferred in pairs to oxygen molecules, producing two H_2O_2 molecules, and in the third and fourth steps only one electron at a time is transferred, with consequent reduction of O_2 to O_2^-, according to the scheme:

$$XOD_6 \xrightarrow[O_2]{H_2O_2} XOD_4 \xrightarrow[O_2]{H_2O_2} XOD_2 \xrightarrow[O_2]{O_2^-} XOD_1 \xrightarrow[O_2]{O_2^-} XOD_0 \qquad (I)$$

where the subscript to XOD stands for the number of electrons used in reduction of the original enzyme (XOD_0).

In a previous paper[5] we reported on the influence of metal ions on the XOD-catalysed oxidation of xanthine to uric acid and the inhibitory action of Ag(I), Hg(II), Cu(II), Cr(VI), V(V), Au(III), and Tl(I). In the present work we have concentrated our attention on the interactions of these inhibitors with the flavin site of the enzyme, studying their effects on the XOD-catalysed NADH → NAD^+ oxidation.

We have also examined the influence of the same species on the formation of O_2^- during the catalytic action of XOD, because of the importance of this radical in the biological context. The superoxide radical, reacting with the H_2O_2 formed in reaction scheme (I), may originate other highly reactive intermediates,[6] such as the hydroxyl radical ·OH, in the presence of metal chelates as catalysts,[7-9] and singlet oxygen O_2 ($^1\Delta g$).[10,11] All these species are extremely toxic and have profound effects on biological structures, and especially on macromolecular systems such as nucleic acids and biomembranes.[12] The oxygen free radicals are involved in several pathological processes,[13-16] but on the other hand they may also be involved in the defence mechanisms of the organisms;[17,18] hence the importance of the factors affecting the production of O_2^-.

EXPERIMENTAL

Reagents

Xanthine oxidase, Grade I, specific activity 0.76 U/mg of protein at 25°; NADH (β-nicotinamide adenine dinu-

*Work done with the financial support of the Ministero della Pubblica Istruzione (Italy), for research of national interest, no. 11835.
†Author to whom correspondence should be addressed.

cleotide, reduced form, disodium salt) Grade III; cytochrome C, type IV, from horse heart, Trizma base and Trizma-HCl, were obtained from Sigma Chemical Co. Xanthine was from U.S. Biochemical Corp., Cleveland, Ohio, and the salts of the metal ions were Merck analytical grade reagents. All solutions were prepared with doubly distilled demineralized water (conductance = 1×10^{-6} mho at 25°). The 0.05*M* Tris-HCl buffer (pH 7.4 at 37°), xanthine, and metal ion solutions were prepared as described earlier.[5]

The following solutions were prepared daily in Tris-buffer and stored at 4°.

NADH. The concentration ($1 \times 10^{-3}M$) was checked spectrophotometrically on the basis of a molar absorptivity of 6.21.mole^{-1}.cm^{-1} at 340 nm; this solution gave a ratio $\leqslant 2.3$ for the absorbances at 260 and 340 nm, as recommended.[19]

Cytochrome C. 1.5×10^{-4}M.

Xanthine oxidase. Concentration 0.37 mg/ml for the experiments with xanthine alone as reducing substrate, and 3.0 mg/ml when NADH was also present.

Analytical procedure

The reactions were monitored spectrophotometrically, with a Perkin-Elmer 554 double-beam spectrophotometer, a microcomputer-driven recorder, and constant-temperature 10-mm quartz cells.

All experiments were done with 0.05*M* Tris-HCl buffer (or Tris-HNO_3 if Ag^+ was present), pH 7.4 at 37 ± 0.1°, ionic strength 0.04*M*, final volume 3 ml, as reaction medium, containing all the reagents except the enzyme. The reaction mixture was brought to 37°, then the reaction was started by adding the enzyme.

The oxidation of NADH to NAD^+ was monitored by measuring the decrease in absorbance at 340 nm. The NADH concentration was $1 \times 10^{-4}M$; the reaction was started by addition of 50 μl of 3-mg/ml XOD solution (final enzyme concentration in cell = 50 μg/ml, corresponding to about $1.7 \times 10^{-7}M$).

The formation of the superoxide anion radical was examined by following at 550 nm the reduction of cytochrome $C_{Fe(III)}$ ($1 \times 10^{-5}M$ in the cell) by the reaction:

$$O_2^- + \text{cytochrome } C_{Fe(III)} \rightarrow O_2 + \text{cytochrome } C_{Fe(II)}.$$

When NADH was the reducing substrate the procedure was similar to that for NADH oxidation, except that cytochrome C was present in the reaction mixture.

When xanthine was the reducing substrate, its concentration was $6 \times 10^{-5}M$: the reaction was started by adding 20 μl of 0.37-mg/ml XOD solution to give a final enzyme concentration in the cell equal to 2.5 μg/ml (corresponding to about $8.9 \times 10^{-9}M$).

Absorbance readings were taken against a reagent blank containing no enzyme; the kinetic behaviour was studied by means of the initial-rate method.[20] Plots of absorbance *vs.* time were used to determine the initial reaction rate v_0 expressed as ΔA/min, in the presence or absence of metal ions.

In order to minimize errors due to possible loss of activity of the enzyme, the relative activity α was used:

$$\alpha = \frac{v_0 \text{ in presence of interfering metal ion}}{v_0 \text{ in absence of interfering metal ion}} = \frac{v_{0_i}}{v_0}.$$

RESULTS AND DISCUSSION

Influence of metals on NADH oxidation

The possibility of the flavin group being the active site for interaction with the metals which inhibit the XOD-catalysed xanthine oxidation, was explored by studying the XOD-catalysed oxidation of NADH to NAD^+. NADH, in fact, directly interacts with the flavin site of the enzyme,[21,22] instead of acting on the molybdenum site, as other reducing substrates such as xanthine do. In this way, the transfer of electrons is from NAD to FAD to molecular oxygen, and the remaining prosthetic groups of the enzyme are not involved.

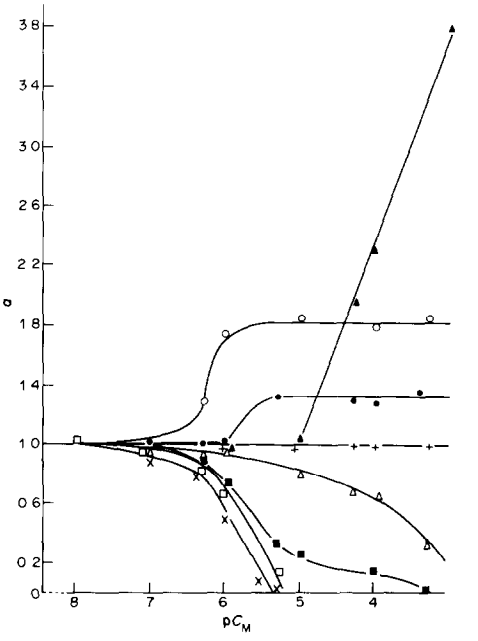

Fig. 1. Effect of various metal ions on the rate of the XOD-catalysed NADH → NAD^+ oxidation (α), *vs.* metal ion concentration (pC_M). $\alpha = v_{0_i}/v_0$; $pC_M = -\log[\text{metal}]$. [NADH] = $1 \times 10^{-4}M$; [XOD] = 50 μg/ml. × Hg(II); □ Ag(I); ■ Zn(II); △ Au(III); + Tl(I); ● Cu(II); ○ Cr(VI); ▲ V(V).

Some of the metal ions examined and found to be inhibitors of xanthine oxidation[5] exhibit a different effect on NADH oxidation (Fig. 1). Tl(I) has no effect on the reaction, whereas Cu(II), Cr(VI) and V(V), particularly the last,[23] are activators.

The effect of V(V) is proportional to its concentration when this is $> 1 \times 10^{-5}M$, but Cu(II) and Cr(VI), for which the threshold concentrations are 1×10^{-6} and $1 \times 10^{-7}M$ respectively, show a plateau region at $1 \times 10^{-5}M$.

Hg(II), Ag(I), Zn(II), and Au(III), in low concentration ($< 1 \times 10^{-6}M$), inhibit the XOD-catalysed NADH oxidation [Zn(II) behaves as an inhibitor of xanthine oxidation only at concentrations higher than $1 \times 10^{-2}M$].

The inhibiting effect of these metals in the XOD-catalysed NADH oxidation suggests the presence of an essential thiol group, presumably close to the flavin site, with which the metal can interact. The presence of such a group would be a prerequisite for oxidation of NADH to be catalysed by the enzyme.

Influence of metal ions on O_2^- formation

The effect of the metal ions which inhibit uric acid formation in the XOD-catalysed xanthine oxidation,[5]

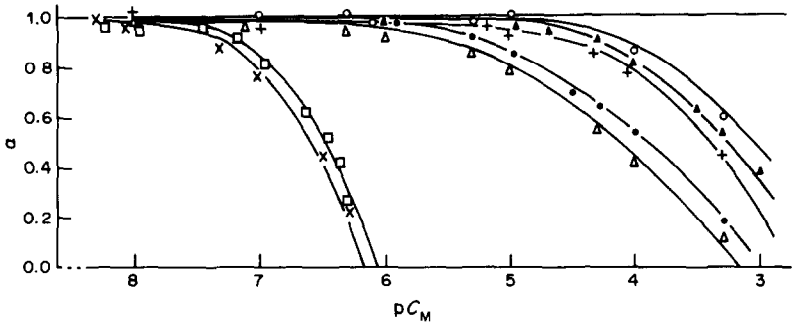

Fig. 2. Effect of various metal ions on the rate of formation of O_2^- during XOD-catalysed conversion of xanthine into uric acid (α), *vs.* metal ion concentration (pC_M). $\alpha = v_0/v_0$; $pC_M = -\log[\text{metal}]$. [Xanthine] = $6 \times 10^{-5}M$; [XOD] = 2.5 μg/ml; [cytochrome C] = $1 \times 10^{-5}M$. × Hg(II); □ Ag(I); △ Au(III); ● Cu(II); + Tl(I); ▲ V(V); ○ Cr(VI).

was studied—with the same reaction—with reference to O_2^- formation.

All those tested behave as inhibitors (see Fig. 2), although the inhibitory strength, related to O_2^- formation, shows values and sequences different from those observed for uric acid formation.

The sequence of inhibitory power was found to be

$$\text{Hg(II)} \geqslant \text{Ag(I)} >>> \text{Au(III)} > \text{Cu(II)} > \text{Tl(I)} > \text{V(V)} > \text{Cr(VI)}$$

with respect to the formation of O_2^-, whereas it was

$$\text{Ag(I)} > \text{Hg(II)} >>> \text{Cu(II)} > \text{Cr(VI)} > \text{V(V)} > \text{Au(III)} > \text{Tl(I)}$$

in the case of uric acid formation.[5]

The difference in sequence can be explained by assuming that the metal ion might act directly on the active site (flavin) at which the superoxide is produced; this action might influence the one- or two-electron reduction of O_2 (see introduction), consequently varying the ratio of H_2O_2 to O_2^- formed.

The influence of the same metal ions on the rate of O_2^- production during NADH oxidation is shown in Fig. 3. It can be seen that all the metal ions examined act as inhibitors, except Tl(I), which has no effect on the O_2^- formation.

The inhibition curves show a complex behaviour, which could be due to the effect of the metal ions on the successive reactions of newly formed O_2^-, such as its spontaneous dismutation;[12] however, the possibility of interference in the O_2^- detection system [O_2^- + cytochrome $C_{Fe(III)} \rightarrow O_2$ + cytochrome $C_{Fe(II)}$] cannot be ruled out.

It deserves mention that Cu(II), Cr(VI) and V(V), which are activators of NADH oxidation (see Fig. 1), either have no effect at all or inhibit O_2^- formation in this reaction (see Fig. 3); this is particularly evident in the case of V(V). A possible explanation of this behaviour would be that these ions are capable of oxidizing NADH directly, *e.g.*, in Tris-buffer (pH 7.4) there is slight oxidation of NADH by V(V) concentrations higher than 0.1M.

However, the enzyme-bound NADH (in an enzyme–substrate complex) might be more susceptible to oxidation occurring at lower metal concentrations by direct electron-transfer from nucleotide to the metal ion. The normal electron transfer sequence NADH → FAD → O_2 would thus be interrupted, which would explain the increased oxidation of NADH and the concomitant decrease of O_2^- formation.

Another explanation could be formation of an NADH–metal ion complex which would render the

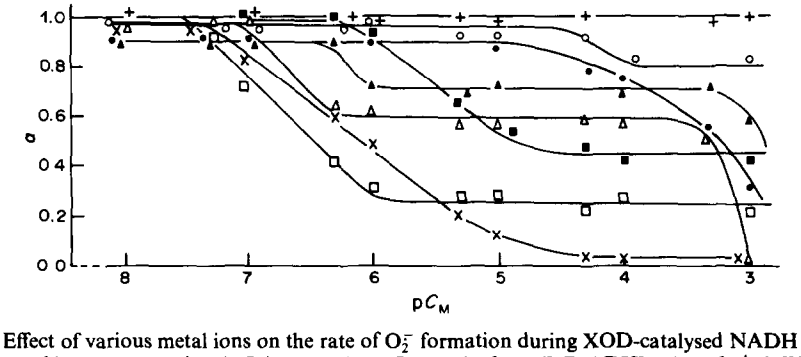

Fig. 3. Effect of various metal ions on the rate of O_2^- formation during XOD-catalysed NADH oxidation (α), *vs.* metal ion concentration (pC_M). $\alpha = v_0/v_0$; $pC_M = -\log[\text{metal}]$. [NADH] = $1 \times 10^{-4}M$; [XOD] = 50 μg/ml; [cytochrome C] = $1 \times 10^{-5}M$. □ Ag(I); × Hg(II); △ Au(III); ▲ V(V); ■ Zn(II); ● Cu(II); ○ Cr(VI); + Tl(I).

nucleotide easily oxidizable by O_2^-, with consequent decrease of the radical levels, and a simultaneous rise in NAD^+ formation.

In conclusion, all the metals tested are either inhibitors or have no effect on O_2^- formation during the enzymatic catalysis of XOD, with both xanthine and NADH as reducing substrates, but some are activators of NADH oxidation.

It should be pointed out that V(V) inhibits xanthine oxidation,[5] but at the same concentrations is a strong activator of NADH oxidation (see Fig. 2), substantially modifying the catalytic properties of the enzyme. This differential behaviour can be used for kinetic determination of V(V).[24]

Résumé—Les spectres Raman complets du chlorhydrate de cocaïne à l'état polycristallin et en solution aqueuse saturée ont été enregistrés à température ambiante de 0 à 4000 cm^{-1} et à 9 K de 0 à 200 cm^{-1} (pour l'état polycristallin). Une attribution des raies observée est proposée. Elle montre que la cocaïne (méthyl benzoyl ecgonine) de structure bicyclique (noyau tropane) peut être caractérisée par les éléments suivants: la présence du noyau tropane peut être affirmée essentiellement par les raies intenses apparaissant à 851 et 786 cm^{-1} pour la partie pipéridinique et par les raies observées à 896 et 870 cm^{-1} pour la partie pyrrolidinique (ces raies sont attribuées aux vibrations ν_{C-C} des cycles); les fonctions esters qui se manifestent par les raies situées à 1713 cm^{-1} ($\nu_{C=O}$) et 1203 cm^{-1} (ν_{C-O-C}); la présence du noyau benzénique qui marque particulièrement le spectre du chlorhydrate de cocaïne et dont les raies les plus spécifiques se trouvent à 616, 990, 1000, 1026 et 1596 cm^{-1}. Une mention particulière a été faite en ce qui concerne les études réalisées dans le domaine des basses fréquences à température ambiante et à 9 K, et les études de polarisation en solution aqueuse saturée entre 700 et 1726 cm^{-1}. Ces résultats forment un ensemble de caractéristiques analytiques destinées à être utilisées à des fins d'identifications toxicologiques et montrent les multiples possibilités de la spectrométrie Raman dans ce domaine.

Ce travail s'inscrit dans le cadre d'une étude par spectrométrie Raman de composés polycycliques à propriétés thérapeutiques dont le but initial était la constitution d'un catalogue de spectres Raman destinés à des fins d'identifications toxicologiques utilisant des moyens informatisés. Cependant il nous est apparu indispensable de compléter ce travail en proposant d'une part une attribution des fréquences caractéristiques des produits concernés et d'autre part de mettre en évidence l'intérêt de la spectrométrie Raman dans l'étude de tels composés.

Nous présentons et discutons dans cet article les spectres Raman complets en phase solide et en phase liquide d'un composé bicyclique à propriété anesthésique locale dérivant du noyau tropane: le chlorhydrate de cocaïne. L'importance de ce noyau est considérable puisque cette structure est non seulement retrouvée chez les alcaloïdes du groupe de la cocaïne mais aussi chez les alcaloïdes du groupe de l'atropine à propriétés parasympatholytiques. Il est par ailleurs important de préciser que les indications thérapeutiques de l'atropine sont extrêmement nombreuses ce qui a induit la recherche de succédanés de synthèse d'où le développement extrêmement intense de cette série.

Avant d'entreprendre la description de la partie expérimentale et l'exposé des résultats obtenus il nous a semblé nécessaire de faire succintement le point des études diverses réalisées pour établir la structure de la cocaïne.

CONSIDERATIONS GENERALES SUR LA STRUCTURE DE LA COCAINE

La structure générale du noyau tropane est constituée par la fusion de deux hétérocycles, l'un pipéridinique et l'autre pyrrolidinique, avec une charnière commune de trois atomes, dont l'atome d'azote central est méthylé.

La cocaïne est un dérivé d'estérification de l'ecognine (acide tropanol carboxylique) par méthylation et benzoylation. Il existe quatre stéréoisomères de l'ecgonine différant par les orientations des deux substituants hydroxyle et carboxyle par rapport à l'azote. Dans les alcaloïdes naturels, ces deux fonctions sont en position *cis* par rapport à l'azote.

La configuration stéréochimique de la *l*-ecgonine et de la *l*-cocaïne fut élucidée avec certitude entre 1954 et 1956.[1] Enfin en 1963 les travaux de Gabe et Barnes[2] sur la structure cristalline du chlorhydrate de *l*-cocaïne, ont donné une preuve directe de la configuration stéréochimique de la molécule:

—le cycle pipéridinique a la forme chaise avec un groupement CH_3 sur l'atome d'azote;
—la chaîne latérale benzoxy en C_3 est en position équatoriale;
—la chaîne carbométhoxy en C_2 est en position axiale.

Par conséquent les substituants en C_2 et C_3 sont en position *cis* vis-à-vis d'eux-mêmes et de l'azote.

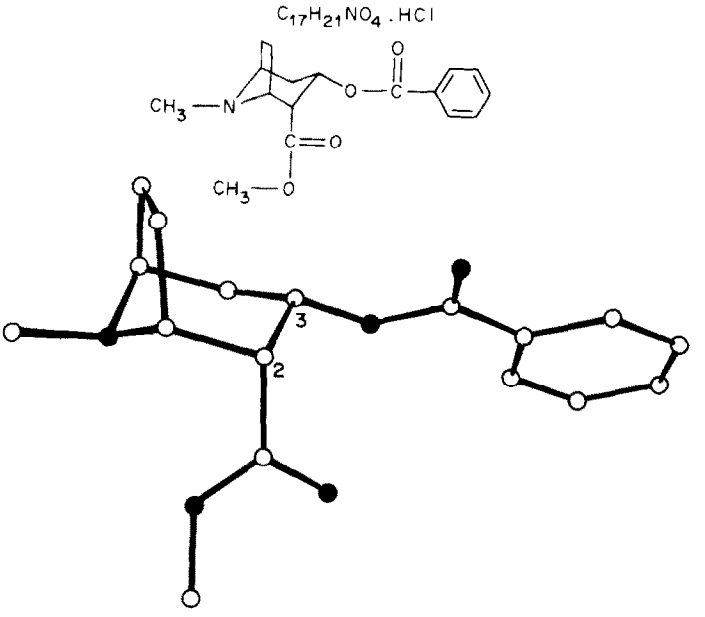

Fig. 1. Structure tridimensionelle de la cocaïne.

La figure 1 montre la structure tridimensionnelle de la cocaïne.

PARTIE EXPERIMENTALE

Appareillage

Les spectres Raman ont été enregistrés sur un spectromètre Coderg T800 comprenant un triple monochromateur de 800 mm de distance focale, équipé de trois réseaux plans gravés (1800 traits par mm) qui permet d'enregistrer toute la gamme spectrale (0–4000 cm^{-1}) en une seule fois sans changement de spectromètre.

Le principe actif est introduit, soit sous forme de poudre polycristalline dans un tube capillaire, soit sous forme de solution aqueuse saturée dans une cellule adéquate.

Un laser à argon ionisé (514,5 nm), Spectra-Physics modèle 165 03, délivre 500 mW sur l'échantillon solide et 1100 mW sur l'échantillon liquide.

L'utilisation d'un cryostat à hélium liquide a été nécessaire pour la prise des spectres de basses fréquences à 9 K.

Méthode

Le chlorhydrate de cocaïne utilisé a été purifié par recristallisation à partir de l'éthanol absolu.

Les spectres Raman de ce composé sous forme de poudre polycristalline ou en solution aqueuse saturée ont été enregistrés à la vitesse de 25 cm^{-1}/mn avec une résolution spectrale de 2 cm^{-1}. Cette vitesse a été choisie de façon à pointer les raies avec la meilleure précision. Elle peut être augmentée lors d'étude de routine pour devenir comparable à celle couramment employée en spectrométrie infra rouge. Les valeurs moyennes (Tableau 1) sont obtenues à partir de deux enregistrements par échantillon.

Bien que les deux types de spectroscopie IR et Raman soient complémentaires, la spectrométrie Raman présente un certain nombre d'avantages dont certains ont déjà été décrits dans un précédent article.[3] Cependant dans le cadre d'une étude adaptée aux problèmes biologiques et toxicologiques il en est un incontestable, découlant du principe même de la spectrométrie de diffusion Raman: les modes de vibrations actifs dans ce type de spectroscopie sont accompagnés d'une variation dans la polarisabilité de la molécule, il en résulte que l'eau est un faible diffuseur et par voie de conséquence un solvant idéal des échantillons.

Enfin dans le cas des solutions aqueuses, en utilisant une lame demi onde qui permet la rotation du champ électrique incident et en plaçant un polariseur ainsi qu'un "scrambler" ou bien une lame quart d'onde il a été possible d'analyser les composantes $I_\perp$ et $I_{/\!/}$ de la lumière diffusée. Si le mouvement de transition et le vecteur électrique de la radiation polarisée sont perpendiculaires l'un à l'autre, aucune raie de diffusion ne peut être observée. Par contre, s'ils sont parallèles, la diffusion est maximum. Entre ces deux extrêmes une transition graduelle a lieu ce qui permet en outre d'apprécier le taux de polarisation des raies.

Cette étude a été faite dans la région 700–1726 cm^{-1} en enregistrant successivement deux spectres Raman avec le plan de polarisation de la radiation excitatrice respectivement perpendiculaire et parallèle à la direction d'observation.

RESULTATS ET DISCUSSION

La substance étudiée présente une structure polycyclique sur laquelle se trouve deux chaînes latérales estérifiées en position *cis*. Nous étudierons donc dans un premier temps les vibrations de la partie bicyclique, et dans un deuxième temps les vibrations de la partie estérifiée.

Les résultats sont rassemblés dans le tableau 1 où figurent les fréquences observées dans les spectres Raman du composé sous forme polycristalline et en solution aqueuse saturée qui ont servi de base à l'attribution. Nous donnons également les fréquences infrarouge des divers composés. La discussion portera essentiellement sur les spectres Raman de la forme polycristalline du composé à température ambiante et à 9 K pour les basses fréquences. Cependant quelques commentaires seront faits à propos du spectre obtenu avec la solution saturée. Les taux de dépolarisation n'ont pas été donnés, car dans une

molécule de faible symétrie comme le chlorhydrate de cocaïne, ceux-ci ont une valeur limitée.

Il sera souvent fait référence au cours de l'exposé au spectre Raman du tropanol *trans* (alcool dérivant du noyau tropane), seul dérivé tropanique figurant à notre connaissance dans la littérature[4] en précisant toutefois:

—que la cocaïne dérive du pseudotropane ou tropanol *cis*,
—et que le spectromètre que nous avons utilisé est plus performant que celui cité dans la référence précédente.

Enfin la nomenclature adoptée pour les modes de vibration du noyau benzénique de la chaîne latérale estérifiée est celle de Wilson.[5]

Vibrations de la partie bicyclique

Cette partie dérive, comme cela a déjà été signalé, de la fusion de deux hétérocycles, l'un pipéridinique et l'autre pyrrolidinique (Fig. 1) avec une charnière

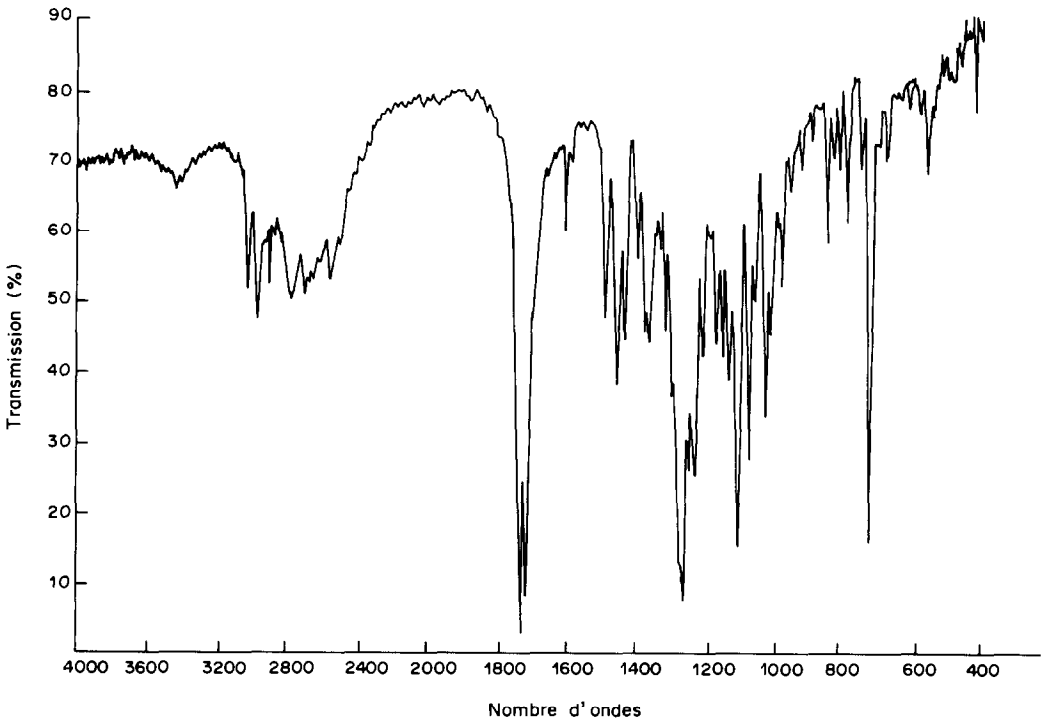

Fig. 2. Chlorhydrate de cocaïne dans KBr spectre d'absorption infrarouge.

commune de trois atomes dont l'atome d'azote central est méthylé.

L'attribution des fréquences fondamentales sera faite essentiellement par analogie avec la pyrrolidine, la N-méthyl pyrrolidine; la pipéridine, la N-méthyl pipéridine ainsi qu'avec d'autres hétérocycles et composés cycliques voisins. Enfin il sera proposé une attribution des fréquences caractéristiques de la partie bicyclique (noyau tropane).

Nous analyserons successivement:

—les vibrations du squelette carboné dans le domaine des moyennes et basses fréquences;
—les vibrations des atomes d'hydrogène;
—les vibrations du groupement alkyl ammonium.

Vibrations du squelette carboné. La cocaïne peut être considérée comme dérivant, soit de la N-méthyl pipéridine substituée en 2 et en 3, avec un pont —CH_2—CH_2— reliant les atomes de carbone 1 et 5, soit de la N-méthyl pyrrolidine avec un pont à trois chaînons CH_2 dont deux sont l'objet de substitutions. La fusion de deux hétérocycles qui permet d'obtenir un ensemble bicyclique introduit des tensions additionnelles qui modifieront, de façon plus ou moins grandes, les fréquences de base observées pour chaque hétérocycle pris séparément.

Les vibrations les plus affectées seront vraisemblablement celles qui sont communément appelées "respiration des cycles" constituées essentiellement par un mouvement de valence C—C symétrique d'espèce a_1g.

Ces vibrations d'intensité élevée qui apparaissent respectivement à 900 et 898 cm^{-1} dans le cas de la pyrrolidine et de la N-méthyl pyrrolidine[6] sont retrouvées avec une diminution importante de l'intensité des raies à 904 et 896 cm^{-1} pour le tropanol et le chlorhydrate de cocaïne.

Beaucoup plus perturbées sont les vibrations du cycle à 6 sommets traduisant la respiration: en effet dans le cas du cyclohexane elle apparaît avec une intensité forte à 802 cm^{-1}, à 815 cm^{-1} pour la pipéridine, passe à 774 cm^{-1} pour la N-méthyl pipéridine.[7] En ce qui concerne les dérivés bicycliques cette vibration est retrouvée respectivement à 744 cm^{-1} et 786 cm^{-1} pour le tropanol et le chlorhydrate de cocaïne.

Parmi les autres vibrations correspondant à l'élongation des cycles la raie située à 872 cm^{-1} de forte intensité pour la pyrrolidine et la N-méthyl pyrrolidine est retrouvée dans les spectres du tropanol et du chlorhydrate de cocaïne respectivement à 873 et 870 cm^{-1}. Enfin la vibration d'élongation du cycle située à 858–856 cm^{-1},[8] et 860 cm^{-1},[9] pour la pipéridine et son dérivé N-méthylé est retrouvée à 858 cm^{-1} pour le tropanol et à 851 cm^{-1} pour le chlorhydrate de cocaïne. Cette différence en fréquence est sans doute due à la présence de chaînes latérales sur le cycle à 6 sommets de la pipéridine.

Les spectres Raman de basses fréquences (<250 cm^{-1}) sont très caractéristiques de la structure d'un composé et sont très utiles pour leur identification. En effet les bandes observées sont très intenses, en particulier à basse température (9 K).

Dans cette région spectrale on observe généralement des raies dues aux vibrations de réseau cristallin (cas des échantillons sous forme de poudre cristalline) en plus des raies intenses dues à des mouvements de torsion (rotation interne) et à des mouvements du squelette de la molécule, donc d'un grand intérêt dans l'étude de composés polycycliques. Néanmoins l'attribution reste très difficile et nécessite l'emploi de techniques variées telles la spectroscopie d'absorption du rayonnement infra rouge lointain, l'étude de la polarisation des raies Raman observées sur un monocristal ainsi que le calcul à priori des fréquences de vibration du cristal. Un tel travail sur le chlorhydrate de cocaïne a été publié par notre équipe.[9,10]

Si le spectre de basses fréquences à température ambiante est déjà très caractéristique de la structure de la molécule de part la position et l'intensité des raies observées (notons au passage la raie intense à 19 cm^{-1}) le spectre obtenu à 9 K l'est encore plus. L'abaissement de température a pour effet de figer les molécules. Les raies observées sont beaucoup plus fines et mieux résolues d'une part et d'autre part il est possible de noter des glissements vers des fréquences plus élevées et des modifications d'intensité pour certaines d'entre elles.

Dans le tableau 1, il est proposé une attribution globale pour certaines fréquences observées. Le détail de cette attribution sort du cadre de cet article, nous nous bornerons à préciser que pour la réaliser un traitement en coordonnée normale utilisant le modèle de l'approximation du corps rigide a été utilisé.[10]

Vibration des groupements hydrocarbonés. Les vibrations de valence ν(CH) apparaissent en Raman dans l'intervalle 3000–2700 cm^{-1}. Ces vibrations sont intenses et plus ou moins faciles à attribuer spécifiquement. Cependant il a été observé un certain nombre de similitudes entre les dérivés du noyau tropane et les hétérocycles azotés qui composent ce noyau. Une attribution sera donc proposée sur ces bases.

Parmi les vibrations les plus caractéristiques citons:

—celle qui apparaît intensément à 2956 cm^{-1} dans le tropanol et le chlorhydrate de cocaïne et que l'on retrouve à 2957 cm^{-1} dans le spectre de la pyrrolidine;
—celle située à 2935 cm^{-1} pour les deux dérivés du noyau tropane et à 2936 cm^{-1} pour la pipéridine (2933 cm^{-1} pour le cyclohexane).

Ce groupe de vibrations pourrait donc être attribué dans le cas des groupements méthylènes à des vibrations antisymétriques.

Enfin citons la vibration ν(CH) à 2897 cm^{-1} que l'on peut comparer à celle de la pipéridine à 2890 cm^{-1} attribuée comme vibration d'élongation symétrique et que l'on retrouve d'ailleurs à 2897 cm^{-1} dans le cyclohexane, composé pour lequel la vibration à 2933 cm^{-1} ainsi que celle citée précédemment sont caractéristiques de la forme chaise.

Notons enfin que dans le cas du composé bicyclique étudié, la contribution des vibrations symétriques est apparemment discrète.

L'attribution spécifique des vibrations de déformation reste délicate du fait des possibilités de recouvrement de certaines raies. Dans l'intervalle étroit 1475–1450 cm^{-1} les spectres Raman peuvent présenter des bandes relativement larges dues à la contribution de plusieurs types de vibration des groupements CH_3 et CH_2. La plus caractéristique du chlorhydrate de cocaïne semble être celle qui apparaît à 1456 cm^{-1} déjà attribuée à la vibration de déformation symétrique de CH_3 du groupement acétate et qui peut aussi être attribuée à la vibration de cisaillement des groupements CH_2 du système bicyclique. Signalons que cette dernière est retrouvée[11] à 1450 cm^{-1} pour le cyclohexane [100% δ_s (CH_2)], à 1448 cm^{-1} pour la pyrrolidine et la N-méthyl pipéridine et à 1451 cm^{-1} pour la pipéridine. Notons enfin qu'elle apparaît à 1455 cm^{-1} dans le cas de cycles pentagonaux et hexagonaux (cyclopentane, cyclohexane). Ceci est donc en accord avec le fait que la cyclisation produit une légère diminution de fréquence par rapport à celle observée pour les alkanes non cycliques correspondant (vers 1468 cm^{-1}).

Parmi les vibrations de va et vient $\omega(CH_2)$ citons:

—les raies situées à 1350 et 1353 cm^{-1} pour les composés bicycliques (tropanol et chlorhydrate de cocaïne) que l'on retrouve[11] à 1349 et 1353–55 cm^{-1} dans le cyclohexane forme chaise;
—celles situées à 1260 et 1266 cm^{-1} (composés bicycliques) retrouvée à 1264 cm^{-1} dans le cas de la pipéridine.

Les vibrations de torsion $\tau(CH)_2$ sont attribuées aux raies apparaissant à 1168 cm^{-1} (chlorhydrate de cocaïne) par analogie avec la pipéridine 1166 cm^{-1} et 1268 cm^{-1} (cyclopentane).

Les vibrations de balancement $\rho(CH_2)$ sont caractérisées essentiellement par la raie à 1021 cm^{-1} (tropanol 1023 cm^{-1}) que l'on retrouve avec des intensités comparables dans la pipéridine et la pyrrolidine (1023 cm^{-1} et 1021 cm^{-1}).

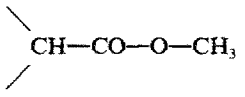
Vibrations du groupement alkyl ammonium inclus dans un cycle ($>NH^+—CH_3$). L'attribution sera faite essentiellement d'après les spectres Raman du chlorure de polyméthylammonium rapportés par Edsall[12] et interprétés par Ebsworth et Sheppard.[13] Parmi les raies les plus caractéristiques dans le cas du chlorhydrate de cocaïne citons les vibrations $\nu_{as}(CH_3)$ à 3034 cm^{-1} et $\nu_s(CH_3)$ à 2968 cm^{-1} qui représentent la contribution du groupement méthyle. En ce qui concerne les vibrations de l'atome d'azote quaternaire inclus dans le cycle pyrrolidinique ou pipéridinique les vibrations ν(—C—N^+) à 817 cm^{-1} et $\nu(C_3N^+)$ à 427 et 456 cm^{-1} sont les plus importantes.

Vibrations de la partie estérifiée

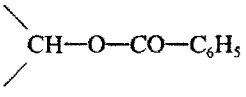
Cette partie est obtenue par estérification de la fonction acide et de la fonction alcool de l'ecgonine

(Fig. 1), respectivement par méthylation et benzoylation.

Les deux chaînes latérales



et



sont caractérisées par le groupement C=O qui se traduit pour le spectre Raman de la cocaïne par une seule bande très intense à 1713 cm^{-1} attribuée à la vibration d'élongation ν(C=O). Ceci peut s'expliquer pour les alkyl esters saturés dont le carbone adjacent au groupement C=O est inclus dans un cycle ce qui diminue les fréquences où cette vibration est le plus souvent observée (1734 cm^{-1}) de 15 à 20 cm^{-1}. En ce qui concerne les esters insaturés et en particulier les esters aromatiques, la fréquence correspondant à la vibration C=O est abaissée dans les mêmes proportions par effet de conjugaison. Signalons enfin la bande caractérisant l'élongation de la liaison C—O à 1203 cm^{-1}.

La vibration δ(O—C=O) de déformation dans le plan est caractérisée par une raie faible située à 639 cm^{-1}. Plus spécifique de l'ester méthylique sont les bandes d'intensité moyenne apparaissant à 830 cm^{-1} et 1456 cm^{-1} qui correspondent respectivement à la vibration d'élongation ν(C—CH_3) et à la vibration de déformation dans le plan $\delta(CH_3)$.

La présence d'un noyau aromatique dans la partie estérifiée confère à la molécule un moyen d'identification aisée en Raman de part le nombre et l'intensité des raies observées. En effet pour le cycle benzénique monosubstitué 24 vibrations sont essentiellement indépendantes du substituant attaché au noyau, les 6 autres sont sensibles aux substitutions puisque dans ces modes le substituant vibre avec une amplitude appréciable.[3]

Il y a 5 vibrations de valence des C—H dont les fréquences tombent dans l'intervalle 3100–3000 cm^{-1}. Pour le composé étudié la plus caractéristique est celle qui apparaît avec une intensité très forte à 3068 cm^{-1} ν(CH aromatique). Elle peut être accompagnée suivant les cas de 2 ou 3 épaulements.

La raie dégénérée e_{2g} (Tableau 1, 8a, 8b) correspondant à l'élongation du cycle n'est pas fortement perturbée par la substitution, de sorte que la fréquence résultante apparaît ici à la même fréquence que celle observée pour le benzène (1596 cm^{-1}). Cette vibration intense indique la présence d'un noyau aromatique mais ne permet pas de distinguer le type de substitution. Cependant, signalons que lors de l'étude en solution aqueuse entre 700 et 1726 cm^{-1} cette raie est la seule qui soit dépolarisée ce qui confirme l'attribution.

La vibration dégénérée e_{1u} du benzène à 1487 cm^{-1} peut aussi éclater en deux bandes (Tableau 1, 19a, 19b) qui sont très proches de la fréquence primitive. Dans le cas du chlorhydrate de cocaïne la vibration résultante est située à 1487 cm^{-1}.

La vibration b_{2u} (1310 cm^{-1}) d'élongation du cycle (Tableau 1, 14) est seulement légèrement décalée par la substitution et apparaît avec une intensité moyenne (1314 cm^{-1}) pour le composé étudié dans l'intervalle de fréquence couvert par les vibrations de torsion et de balancement des méthylènes des substituants alkyle. Elle peut donc difficilement être attribuée seule à la vibration b_{2u}.

La vibration d'élongation du cycle monosubstitué (992 cm^{-1}) correspondant à la vibration (Tableau 1, 1) a_{1g} du benzène est sensible aux substituants et selon Varsayni[14] doit se trouver dans l'intervalle 1100–1060 cm^{-1} pour les substituants lourds (masse > 25) et dans l'intervalle 830–620 cm^{-1} pour les substituants légers (masse < 25). Nous n'avons pas pu sur nos spectres caractériser avec précision cette vibration.

Plus intéressante est la vibration correspondant à la déformation du cycle dans le plan ou respiration trigonale du cycle. Elle dérive de la vibration b_{1u} du benzène (Tableau 1, 12) (1010 cm^{-1}) et donne lieu pour les benzènes monosubstitués à une intense bande Raman située dans l'intervalle 1010–990 cm^{-1}. Cette bande très caractéristique s'est manifestée sur les spectres du composé à 1000 cm^{-1}.

Pour les benzènes monosubstitués une autre vibration de déformation du cycle dérivée de la vibration du benzène (6b) (606 cm^{-1}) donne lieu à une bande d'intensité moyenne aux environs de 618 cm^{-1}. Elle s'est manifestée à 616 cm^{-1} d'une façon intense sur les spectres du chlorhydrate de cocaïne.

La fréquence de vibration 6a des benzènes monosubstitués est assez variable par conséquent il n'a pas été fait de tentative d'attribution.

Des vibrations de déformation des C—H dans le plan (3, 9a, 9b, 15, 18a, 18b) c'est celle qui dérive de la 18a qui est la plus utile pour l'identification; elle se traduit par une bande intense en Raman dans l'intervalle 1030–1018 cm^{-1}, de plus elle est caractéristique de la monosubstitution. Cette bande a aussi une intensité élevée en infrarouge. Elle a été repérée sur les spectres à 1026 cm^{-1} en Raman et à 1025 cm^{-1} en infrarouge.

La bande issue de la 18b devrait être comprise dans l'intervalle 1082–1065 cm^{-1} mais son intensité très faible aussi bien en Raman qu'en infrarouge n'a pas permis de la situer dans l'intervalle cité précédemment en raison de la présence d'autres bandes d'intensité moyenne.

La vibration e_{2g} dégénérée (9a, 9b) à 1178 cm^{-1} est perturbée et donnerait une bande spécifique en Raman à 1180–1170 cm^{-1} (9a) et une bande non spécifique à 410–160 cm^{-1} (9b). La première de ces bandes a été observée sur les spectres à 1168 cm^{-1}.

La vibration 15 (1160–1150 cm^{-1}) s'est manifestée

Tableau 2. Raies les plus caractéristiques du chlorhydrate de cocaïne ($\bar{\nu}$, cm^{-1})

	Noyau tropane	Fonction ester	Noyau benzénique

par une bande faible située à 1152 cm^{-1}. La vibration 3 (1330–1250 cm^{-1}) est très faible et n'est pas apparue sur les enregistrements de manière significative d'autant plus que cet intervalle est couvert par des bandes d'intensité moyenne et deux bandes de très forte intensité à 1266 cm^{-1} et 1275 cm^{-1} dont l'attribution a été proposée das la première partie de cet article.

Les vibrations de déformation du cycle hors du plan d'intensité moyenne 4 (700–680 cm^{-1}) et d'intensité faible 16a (420–390 cm^{-1}) sont apparues respectivement à 683 et 394 cm^{-1}.

Pour les vibrations de déformation des C—H hors du plan du cycle seule la vibration 5 donne lieu en Raman à une bande très intense (1000–970 cm^{-1}) qui est caractérisée par un épaulement du côté des basses fréquences. Cette bande et son épaulement situés respectivement à 1000 et 990 cm^{-1} sont attribué à la respiration trigonale du cycle. Enfin signalons que la bande d'intensité moyenne observée à 1203 cm^{-1} pourrait être caractéristique du groupe C_6H_5—C.

Conclusion

Les principaux résultats permettant de caractériser le chlorhydrate de cocaïne sont consignés dans le tableau 2. La partie bicyclique de ce composé peut être mise en évidence grâce aux raies intenses apparaissant dans le domaine des moyennes fréquences. De plus le domaine des basses fréquences à température ambiante et à 9 K présente lui aussi un grand intérêt pour les molécules polycycliques puisque les raies observées sont spécifiques de la molécule et dues aux vibrations du réseau cristallin (cas des échantillons à l'état polycristallin), aux mouvements de torsion (rotation interne) et aux mouvements du squelette de la molécule; cet ensemble constitue une véritable fiche d'identité du composé.

Le reste de la molécule est surtout caractérisé par la présence du noyau benzénique qui se manifeste sur les spectres par de nombreuses raies intenses et par les deux fonctions esters.

Les spectres en solutions aqueuses saturées, outre certains glissements de fréquences, ont montré lors de l'étude de polarisation que seule la raie située à 1598 cm^{-1} correspondant à la vibration e_{2g} du benzène est dépolarisée.

Ce travail montre donc l'intérêt de la spectrométrie Raman dans l'étude réalisée d'une part grâce à la commodité d'obtention des spectres à l'état polycristallin et en solution aqueuse dans un intervalle spectral de 0 à 4000 cm^{-1} et d'autre part grâce à l'importance des caractéristiques analytiques fournies. Rappelons que cette étude préliminaire est destinée à être utilisée à des fins d'identification toxicologique utilisant des moyens informatisés et une microsonde Raman ce qui permet de descendre la limite de détection d'un composé aux environs du picogramme.

Summary—Raman spectra of cocaine hydrochloride in the polycrystalline state and in saturated aqueous solutions have been recorded at room temperature from 0 to 4000 cm^{-1} and at 9 K from 0 to 200 cm^{-1} (only for the polycrystalline state). They show that cocaine can be characterized by the following proposed assignments. For the tropane nucleus the frequencies 851 and 786 cm^{-1} (piperidine) and 896, 870 cm^{-1} (pyrrolidine); these frequencies are assigned to ring carbon stretching vibrations ν_{C-C}. Bands for the ester functional groups can be observed at 1713 cm^{-1} ($\nu_{C=O}$) and 1203 cm^{-1} (ν_{C-O-C}). The benzene nucleus is also important in characterization of cocaine hydrochloride because of its bands at 616, 990, 1000, 1026 and 1596 cm^{-1}. Special reference is made first to the work in the low-frequency range at room temperature and 9 K and secondly to the polarization studies of saturated aqueous solutions in the range 700–1726 cm^{-1}. The results constitute a pool of analytical characteristics which can be used for toxicological investigations, and also show all the possibilities of Raman spectroscopy in this field.

Résumé—Les spectres Raman de trois corticostéroïdes: fluocortolone base, triméthylacétate et caproate de fluocortolone (TMAF et CAF) ont été enregistrés à l'état polycristallin entre 150 et 4000 cm^{-1}. Une attribution des raies observées est proposée. Elle a montré la complexité du problème posé à savoir la différenciation de trois composés de structure très voisine. Cependant quelques intervalles de fréquences contenant des raies spécifiques sont susceptibles d'être utilisés afin de permettre l'identification des composés étudiés. Il convient en premier lieu de distinguer tout particulièrement les raies situées entre 1500 et 1800 cm^{-1}. Dans l'intervalle 1580–1690 cm^{-1} celles-ci sont intenses et spécifiques de la structure conjuguée $\Delta^{1,4}$ 3-one des corticostéroïdes ce qui permet de distinguer la classe de médicament à laquelle appartiennent les substances étudiées. La zone de fréquence comprise entre 1690 et 1750 cm^{-1} témoigne non seulement de la présence d'une fonction cétonique sur la chaîne latérale mais aussi de l'existence d'une fonction ester suivant que l'on y trouve respectivement une ou deux raies (fluocortolone base 1701 cm^{-1}; TMAF 1728, 1745 cm^{-1}; CAF 1723, 1745 cm^{-1}). La fluocortolone base présente à 1635 cm^{-1} une raie qui n'est pas retrouvée chez les dérivés estérifiés. En second lieu, nous retiendrons les zones spectrales représentatives des chaînes latérales estérifiées fixées sur le carbone C_{21}: chaîne triméthylacétate 340–360, 570–610, 750–810 cm^{-1} (dans cette dernière région commune au caproate et au triméthylacétate la différenciation des deux composés se fait grâce à la raie à 796 cm^{-1} absente dans le spectre du caproate); chaîne caproate 1310–1350 cm^{-1} (dans cet intervalle, le caproate présente un profil très particulier avec trois raies d'intensité voisine). Cet ensemble de résultats doit être utilisé pour identifier ces substances par spectroscopie Raman sur des quantitiés de l'ordre du picogramme provenant d'éluat d'HPLC.

Ce travail s'inscrit dans le cadre de notre programme d'étude par spectrométrie Raman de composés à propriétés thérapeutiques. Son but initial était la constitution d'un catalogue de spectres Raman dont les données devaient permettre l'identification informatisée des substances étudiées. Cependant il nous est apparu indispensable de rendre ce travail plus complet en proposant une attribution des fréquences caractéristiques des composés polycycliques concernés.

Nous présentons et discutons les spectres Raman en phase solide de trois corticostéroïdes: la fluocortolone base et ses esters triméthylacétique et caproïque. Les résultats permettront de définir les caractéristiques de chaque ester afin de les identifier spécifiquement à l'état de trace (10^{-12} g) à partir d'une forme galénique, après une séparation préalable par chromatographie liquide haute pression. Ces travaux déjà réalisés seront publiés prochainement. Ils sont en quelque sorte la suite logique du travail préliminaire présenté ici.

PARTIE EXPERIMENTALE

Appareillage

Les spectres Raman ont été enregistrés sur un spectromètre Coderg T 800 comprenant un triple monochromateur de 800 mm de distance focale, équipé de trois réseaux plans gravés (1800 traits par mm). Ce monochromateur est caractérisé par un taux de lumière parasite très faible qui permet l'observation de raies Raman dans le domaine des très basses fréquences. Un laser à argon ionisé (514,5 nm), Spectra-Physics modèle 165.03, délivre 600 mW sur l'échantillon.

L'ensemble décrit est équipé d'un microordinateur Apple II permettant l'accumulation de données et la gestion du spectromètre.

Méthode

Les principes actifs étalons sont introduits sous forme de poudre polycristalline dans un tube capillaire sans purification supplémentaire. Leur pureté a été contrôlée à l'issue de leur synthèse par le fabricant. Les spectres Raman des composés corticostéroïdiques ont été enregistrés à la vitesse de 25 cm^{-1}/mn avec une résolution spectrale de 2 cm^{-1}. Les valeurs moyennes des fréquences du tableau 1 sont obtenues à partir de deux enregistrements par échantillon.

RESULTATS ET DISCUSSION

Les stéroïdes constituent une classe de composés abondamment répandus dans la nature (règne végétal et animal) dérivant du squelette du perhydrocyclopentanophénanthrène (Fig. 1) et portant en outre diverses fonctions ou insaturations, ainsi que des chaînes latérales sur le carbone 17.

Dans l'esprit d'une identification, l'attention doit être portée sur la chaîne latérale fixée sur le carbone 17 (Fig. 2). En effet, celle de la fluocortolone base

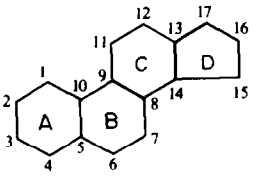

Fig. 1. Squelette du perhydrocyclopentanophénanthrène.

comprend une fonction cétone en C_{20} avec une fonction alcool primaire terminale en C_{21}. Cette chaîne est estérifiée par l'acide triméthylacétique pour le premier dérivé et par l'acide caproïque pour l'autre. C'est-à-dire une chaîne ramifiée dans le premier cas et une chaîne linéaire dans le second cas. Pour les deux esters, la différenciation ne portera que sur ce caractère et sur le nombre d'atomes de carbones et d'hydrogènes présents après la fonction ester.

Par conséquent un tel travail constitue un réel problème analytique, problème qui ne peut être solutionné que par la connaissance parfaite des spectres Raman dont une attribution est proposée sur les spectres établis à partir des substances étalons.

Il nous a semblé logique de concevoir cette attribution non pas par régions spectrales mais plutôt en présentant les éléments permettant d'identifier la classe de médicaments en se rapportant donc à la structure commune, puis par la suite en présentant ceux qui permettront d'identifier chaque substance.

ETUDE DES SPECTRES DES PRODUITS PURS SOUS FORME POLYCRISTALLINE

Les raies correspondant aux spectres des trois composes sont répertoriées dans le tableau 1.

Ces spectres ont été enregistrés en continu entre 150 et 3100 cm^{-1}. Leur interprétation a été rendue possible en partie grâce aux travaux de Schrader et Steigner[1-4] qui ont étudié les vibrations les plus caractéristiques du noyau stéroïdique ainsi que les variations possibles lors d'adjonction de substituants ou de deshydrogénation à l'intérieur du noyau perhydrocyclopentanophénanthrène.

Nous citerons également, dans le domaine des stéroïdes en spectrométrie Raman, un travail

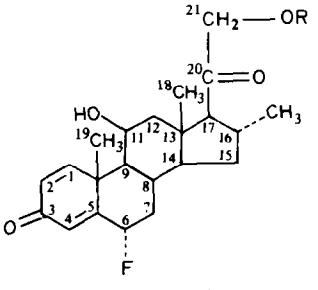

Fig. 2. Structure des corticostéroïdes etudiés: R=H, fluocortolone base; R = —(CO)C(CH$_3$)$_3$, fluocortolone triméthylacétate; R = —(CO)(CH$_2$)$_4$CH$_3$, fluocortolone caproate. Fluocortolone base = 6α fluoro-16α méthyl $\Delta^{1,4}$ pregnanedieñe 11β, 21 diol-3,20 dione.

d'interprétation du spectre de basses fréquences que nous avons effectué à basse température sur le caproate de fluocortolone.[5] Cet aspect que nous ne développerons pas dans ce travail mérite cependant d'être signalé puisque les raies observées sont très intenses d'une part, et d'autre part, celles-ci sont dûes essentiellement aux vibrations du réseau cristallin en plus des raies dûes à des mouvements de torsion et à des mouvements du squelette de la molécule. Elles constituent donc une "fiche d'identité" très spécifique de la molécule. Néanmoins, dans ce domaine de fréquence, l'attribution est difficile et nécessite l'emploi de techniques variées telles que la spectroscopie d'absorption du rayonnement infrarouge lointain, l'étude de la polarisation des raies Raman observées sur un monocristal ainsi que le calcul à priori des fréquences de vibration du cristal.

Vibrations des éléments de structure communs aux trois corticostéroïdes

Une forte modulation de la polarisabilité apparaît avec les vibrations localisées sur des liaisons riches en électrons; c'est pourquoi il est possible de prévoir que les raies Raman les plus intenses apparaîtront pour des vibrations dûes aux liaisons multiples. Les stéroïdes étudiés présentent en commun cette particularité de structure dite $\Delta^{1,4}$ 3-one.

Par ailleurs, les vibrations "en phase" du squelette carboné donneront aussi des vibrations intenses caractéristiques.

Enfin la fonction cétonique en 20 est aussi un élément d'identification important dans cet ordre d'idée.

Structure $\Delta^{1,4}$ 3-one. La vibration d'élongation d'une double liaison ν(C=C) isolée (1620–1672 cm^{-1}) présente une très forte intensité en spectroscopie Raman. Une liaison C=O isolée possède normalement une vibration d'élongation plus faible que celle de C=C. En Raman, deux doubles liaisons isolées C=O et C=C peuvent vibrer au même nombre d'onde, ainsi qu'en infrarouge où la vibration très importante du C=O peut masquer complètement la vibration du C=C. Par contre, pour des liaisons conjuguées C=O et C=C, on obtiendra un système très caractéristique avec autant de raies qu'il existe de doubles liaisons. La place de ces doubles liaisons peut être aisément déterminée en s'inspirant des travaux de Schrader. Des raies supplémentaires dans la région spectrale 900–1300 cm^{-1} peuvent aider à la confirmation des résultats.

Il apparait avec toutes les molécules de ce type, trois raies caractéristiques vers 1600–1620 et 1660 cm^{-1}. Si l'on considère des molécules plus simples comme:

—le cyclohexène qui présente une vibration d'élongation dûe à la liaison C=C à 1656 cm^{-1};[6]

—le 1,4 cyclohexadiène, molécule parfaitement symétrique à deux doubles liaisons qui ne donne qu'une seule raie très intense située aux alentours de 1675 cm^{-1};[7]

—la cyclohexanone pour laquelle en spectrométrie Raman n'est observée qu'une raie moyenne représentative de la vibration d'élongation ν(C=O) vers 1710 cm^{-1} pour les alkyls-cétones;[8] par des effets de conjugaison, cette raie peut se déplacer vers de plus faibles nombres d'onde comme par exemple avec la 1,2 cyclohexane dione qui présente une raie d'intensité moyenne à 1658 cm^{-1};[9]

—la parabenzoquinone qui montre trois raies d'intensités différentes: deux moyennes à 1610 et 1680 cm^{-1} et une raie intense à 1655 cm^{-1}.[10]

Il est donc possible de penser que la présence d'une fonction cétonique s'intercalant dans un système de deux doubles liaisons et établissant de ce fait un système conjugué, fera apparaître des raies d'un profil très particulier; l'ensemble constituant un moyen d'identification de la molécule en caractérisant la structure $\Delta^{1,4}$ 3-one. La position des raies, du fait des différentes interactions existantes, se trouve modifiée par rapport aux valeurs de fréquences décrites précédemment pour des molécules plus simples.

L'étude des profils de raies dans l'intervalle 1500–1700 cm^{-1} donné par Schrader[4] confirme les observations faites à propos des trois corticoïdes étudiés dans ce travail. La raie située vers 1600 cm^{-1} dans le cas des Δ^1 3-one et Δ^4 3-one stéroïdes se dédouble ce qui permet d'observer dans le cas des $\Delta^{1,4}$ 3-one stéroïdes trois raies caractéristiques dans cette zone de fréquences (voir tableau 1).

Signalons par ailleurs que le passage d'un Δ^1 3-one stéroïde à un Δ^4 3-one stéroïde fait apparaitre en spectrométrie Raman un dédoublement de la raie située à 1662 cm^{-1} (tableau 2).

Groupements CH, CH_2 du cycle et CH_3 substitués. Parmi les vibrations de valence ν(CH) les plus caractéristiques des stéroïdes, il faut citer celles du cycle A correspondant aux vibrations C–H des carbones doublement liés qui apparaissent dans l'intervalle 3030–3070 cm^{-1}. Les trois composés présentent ce type de raies à 3046 pour la fluocortolone base (F), 3045 pour le triméthylacétate (TMAF), 3048 pour le caproate (CAF) et 3066 (F), 3067 (TMAF), 3069 (CAF) et reflètent l'insaturation du cycle.[11] En dessous de 3000 cm^{-1} sont retrouvées les vibrations ν(CH) correspondant aux groupements CH_2 et CH_3. Les valeurs observées généralement attribuées dans l'ordre croissant des fréquences avec en premier lieu les vibrations symétriques ν_s puis les vibrations antisymétriques ν_a.

Des informations supplémentaires sur le squelette de la molécule stéroïdique peuvent être obtenues en considérant les intensités des bandes dans différentes régions du spectre.

Notamment la région 1440–1460 cm^{-1} montre une bande intense attribuée aux vibrations de déformation δ_s des groupements CH_2 et CH_3 et que l'on retrouve dans les spectres de tous les stéroïdes.[1] Cette bande a été observée pour les stéroïdes étudiés respectivement à 1454 (F), 1452 (TMAF) et 1450 cm^{-1} (CAF). L'intensité de cette bande comparée à celle des bandes situées de part et d'autre permet par ailleurs d'obtenir des informations concernant le type de stéroïde étudié. En effet:

—pour les stéroïdes saturés la vibration à 1450 cm^{-1} correspond à la bande la plus intense,

—pour ceux présentant des systèmes de doubles liaisons conjuguées, intracycliques ou branchées sur les cycles, les bandes situées au-dessus et en dessous sont plus intenses; ce fait a été noté pour les stéroïdes que nous avons étudiés,

—pour les systèmes non conjugués, des bandes de forte intensité sont observées à des fréquences plus élevées que 1450 cm^{-1},

—pour les stéroïdes comprenant des cycles aro-

Δ^{1} 3-one	 	Schrader[6]	1614		1650 et 1669

matiques, les bandes les plus intenses se trouvent en dessous de 1450 cm^{-1}.

En ce qui concerne les fréquences inférieures à 1450 cm^{-1}, l'intervalle 1360–1390 cm^{-1} montre pour les trois composés une bande située à 1374 (F), (TMAF), 1379 (CAF) qui peut correspondre à la déformation symétrique $\omega(CH_3)$ du groupement CH_3 porté par le carbone en α de la double liaison en 1–2,[12] bien que le phénomène d'exaltation escompté n'apparaisse pas de façon significative.

Parmi les autres bandes, citons les plus intenses qui se situent à 1232 (F), 1233 (TMAF), 1235 (CAF), 1117 (F), 1115 (TMAF), 1119 (CAF) et qui sont caractéristiques des composés étudiés. Il en est de même pour les raies observées à 966 (F), 972 (TMAF), 965 (CAF) et 933 (F), 937 (TMAF), 936 (CAF). Toutes ces raies sont difficilement attribuables, en effet dans la région 1350–800 cm^{-1} on trouve[1] les vibrations d'élongation du squelette de la molécule en même temps que les vibrations de déformation hors du plan, symétrique (wagging) et antisymétrique (twisting), ainsi que les vibrations asymétriques dans le plan (rocking) des liaisons C–H. Elles constituent cependant une bonne "empreinte digitale" de la molécule.

Enfin, parmi les bandes observées entre 800 et 200 cm^{-1}, les plus caractéristiques sont situées à 717 (F), 717 (TMAF), 720–712 (doublet, CAF) et 550 (F), 551 (TMAF), 551 (CAF). Elles correspondent aux déformations du squelette de la molécule et peu d'entre elles peuvent être attribuées directement.

Fonction cétonique en C_{20}. Des deux fonctions cétoniques fixées sur la molécule stéroïdique, nous avions envisagé la possibilité de distinguer celle provenant du système conjugué $\Delta^{1,4}$ 3-one donnant lieu à un ensemble très particulier de trois raies entre 1500 et 1690 cm^{-1}.

L'autre fonction cétonique, appartenant à la chaîne latérale fixée sur le carbone C_{17} va pouvoir être différenciée de la précédente de par son caractère aliphatique. En effet, la fréquence de la vibration d'élongation ν(C=O) d'une cétone de type R—CO—R a pour valeur moyenne 1715 cm^{-1}.[15] Cette valeur peut varier pour ce groupement dans l'intervalle 1705–1725 cm^{-1}.[14,15]

Le spectre de la fluocortolone base montre une raie à 1701 cm^{-1} pour la vibration ν(C=O). Celle-ci est d'ailleurs retrouvée à 1699 cm^{-1} dans le spectre Raman d'un Δ^{5} 20-one stéroïde,[2] comprenant une double liaison isolée et un groupement cétonique isolé sur une chaîne aliphatique. Par ailleurs d'autres $\Delta^{1,4}$ stéroïde[2] comme le $\Delta^{1,4}$ pregnadiène 3,20-dione, possédant une chaîne acétyle (CH_3—CO—) en C_{17}, présente cette raie à 1700 cm^{-1}.

Par contre pour les esters de la fluocortolone, la vibration ν(C=O) est déplacée vers de plus hautes

fréquences: 1728 cm^{-1} (TMAF) et 1723 cm^{-1} (CAF). Ce phénomène pourrait être induit par la présence dans les chaînes latérales d'une fonction carbonylée de type ester.

Parmi les autres vibrations caractéristiques de cette cétone, on peut citer:

—une vibration d'élongation antisymétrique ν_a (C—CO—C) d'intensité moyenne dans la zone allant de 1110 à 1170 cm^{-1} et que nous pourrions attribuer aux raies à 1149 cm^{-1} (F), 1149 cm^{-1} (TMAF) et 1150 cm^{-1} (CAF);[15]

—une vibration d'élongation symétrique ν_s (C—CO—C) vers 770 cm^{-1};[16]

—une vibration de déformation dans le plan de δ(C—CO) vers 630 cm^{-1};[17]

—une vibration de déformation hors du plan attribuable à l'une des deux raies situées dans la zone 460–490 cm^{-1};[17]

—une vibration de déformation dans le plan de l'ensemble C—CO—C dans la région allant de 390 à 430 cm^{-1},[17] et que nous n'avons pu discerner parmi les trois raies communes situées dans cette zone;

—enfin, une raie qui n'est pas spécifique d'une cètone mais qui en découle, a pu être mis en évidence.

Il s'agit de la déformation du CH_2 en α de la cétone qui varie peu quelque soit le type de cétone et qui se situe entre 1405 et 1420 cm^{-1}.[15,16]

Vibrations caractéristiques de la fonction ester

La raie la plus caractéristique est celle qui est dûe à la fréquence d'élongation ν(C=O) située entre 1730 et 1750 cm^{-1}.[18,19] Quant à la raie correspondant à l'élongation de la liaison —C—O—, inexistante en Raman, elle présente comme attendue une forte intensité vers 1150–1160 cm^{-1} en spectroscopie infrarouge. Une autre raie bien définie, située à 782 cm^{-1} peut être attribuée à une vibration de déformation dans le plan du groupement O—C=0.[18]

Habituellement, dans le cas des esters, on peut trouver de nombreuses bandes entre 1000 et 1300 cm^{-1} qui forment une "empreinte digitale" permettant d'identifier le type d'ester.[20] Nous n'avons pas pu mettre en évidence, dans nos spectres, de raies qui puissent être communes, dans cette région, aux deux seuls esters.

Vibrations caractéristiques de la chaîne latérale

Les chaînes latérales, constituées par des CH_2 et CH_3, présenteront de très nombreuses raies de vibration, que ce soit d'élongation ou de déformation. Elles vont se retrouver dans plusieurs régions du spectre, bien souvent en association avec les vibrations CH, CH_2 et CH_3 du noyau stèroïdique. Du fait de ces recouvrements possibles, il sera très difficile d'attribuer avec certitude les différentes bandes spectrales retrouvées.

Triméthylacétate. Le groupement *ter*-butyl—$C(CH_3)_3$ du triméthylacétate devrait théoriquement présenter des raies caractéristiques dans les zones spectrales hachurées sur la figure 3.

Sur les spectres, nous avons observé les raies suivantes, spécifiques du triméthylacétate:

—une raie à 959 cm^{-1} légèrement décalée vers les plus hautes fréquences par rapport à ce que l'on peut observer avec un 2,2,3,3-tétraméthylbutane ou un 2,2,3 triméthylpentane où cette raie se situe entre 930 et 940 cm^{-1};[21,22] cette raie correspond à un mode couplé: élongation ν(C—C) et $\delta_r(CH_3)$ (rocking);

—une raie à 796 cm^{-1} dûe à une élongation ν(C—C)[23] et à l'ensemble élongation symétrique du groupe en C_5;[23]

—une raie à 595 cm^{-1} qui est présente uniquement dans le triméthylacétate mais qui ne semble pas provenir du groupement *ter*butyl;

—de par les groupements méthyles, on retrouve des vibrations d'élongation antisymétriques vers 2960 cm^{-1} et symétriques vers 2870 cm^{-1}.

Caproate. En raison de sa chaîne latérale linéaire en CH_2 et CH_3, le spectre de ce produit présente de nombreuses raies spécifiques:

—un épaulement qui semble se situer vers 1465 cm^{-1} et qui est attribué à la vibration de cisaillement du groupement méthylène $\delta(CH_2)$;[24]

—à 1459 cm^{-1}, une vibration de déformation asymétrique du groupement méthyle $\delta_a(CH_3)$;[24]

—une raie très caractéristique à 1325 cm^{-1} provenant de la vibration de balancement $\delta_b(CH_2)$;[25]

—une autre également très spécifique à 990 cm^{-1} qui est une élongation C—C;[25]

—à 948 cm^{-1}, une raie attribuée à la vibration $\delta_r(CH_3)$ d'un groupement méthyle terminal;[25]

—comme pour le triméthylacétate, le spectre présente des vibrations d'élongation symétriques et antisymétriques dans les mêmes zones, avec en plus des raies à 2927 cm^{-1} d'intensité forte et 2859 cm^{-1} d'intensité moyenne, responsables respectivement des élongations antisymétriques et symétriques des groupements CH_2.[26]

Base: groupement alcoolique primaire en C_{21}. Dans le paragraphe qui suit, quelques informations d'ordre général seront indiquées pour la fluocortolone base. Rappelons tout d'abord que seuls les deux dérivés estérifiés entrent dans la composition de la prépara-

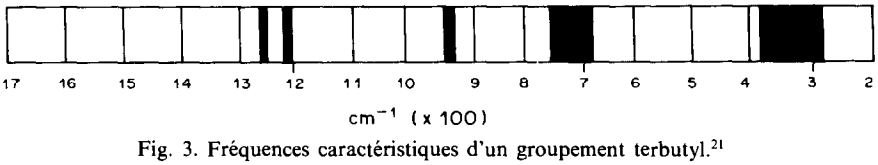

Fig. 3. Fréquences caractéristiques d'un groupement terbutyl.[21]

tion galénique pour laquelle l'étude préalable en spectrométrie Raman avait été envisagée.

Par rapport à ses dérivés d'estérification, la fluocortolone base ne présente que le groupement hydroxyle en C_{21} comme élément possible de différenciation. L'hydroxyle du cycle C en 11 présent sur les molécules des trois corticoïdes ajoutera sans aucun doute un élément de complexité au problème.

De plus, la vibration d'élongation ν(O–H) est très peu intense en spectrométrie Raman (environ vingt fois moins que le massif correspondant aux vibrations ν(C—H).[27] C'est pourquoi dans ce cas précis la spectrométrie d'absorption infrarouge se révèle plus démonstrative par l'intensité et la position des bandes observées.

Sans envisager de façon exhaustive le problème des différents types de liaisons hydrogène, qui nécessiterait une étude plus complète, il a été possible de noter pour la fluocortolone base une bande intense à 3421 cm^{-1} avec un épaulement à 3529 cm^{-1}. Les deux autres esters présentent une bande d'intensité moyenne à 3478 cm^{-1} avec un épaulement à 3357 cm^{-1} (TMAF) et une raie fine intense à 3464 cm^{-1} (CAF). Ces bandes et cette raie peuvent être attribuées à la vibration ν(O–H) des groupements hydroxyles en 11 pour les esters et dans le case de la fluocortolone base, la bande intense et large témoignerait de la contribution du groupement hydroxyle en 11 (groupement alcoolique secondaire cyclique) et du groupement alcoolique primaire en C_{21}.

La région spectrale 1000–1075 cm^{-1} qui signale l'existence des vibrations ν(C—O) des groupements alcooliques, primaire aliphatique et secondaire cyclique[28] reste difficile à interpréter pour ce type de composé.

Par contre, la vibration ν(C=O) des composés estérifiés apparait de façon très intense à 1154 cm^{-1} (TMAF) et 1160 cm^{-1} (CAF) alors que l'on ne la retrouve pas pour la fluocortolone base. Son absence, ainsi que la présence à 3421 cm^{-1} d'une bande d'élongation ν(O—H) peuvent confirmer une fonction alcoolique primaire non estérifiée.

ETUDE DES INTERVALLES DE FREQUENCES UTILISABLES POUR LA CARACTERISATION DE CHAQUE SUBSTANCE

Le paragraphe précédent concernant l'étude des spectres des produits purs sous forme polycristalline et les essais d'attribution, a montré la complexité du problème posé, à savoir la différenciation de trois composés polycycliques de structure très voisine. Cependant quelques intervalles de fréquences sont susceptibles d'être utilisés afin de permettre l'identification de la fluocortolone et de ses dérivés dans les éluats receuillis en sortie de colonne HPLC.

En premier lieu, il convient tout particulièrement de distinguer les raies situés entre 1500 et 1800 cm^{-1} (Fig. 4):

—dans l'intervalle 1580–1690 cm^{-1}, il a été démontré qu'elles sont intenses et spécifiques de la structure conjugée $\Delta^{1,4}$ 3-one des stéroïdes, ce qui permet de distinguer la classe à laquelle appartiennent les substances étudiées;

—la zone de fréquences comprise entre 1690 et 1750 cm^{-1} témoigne non seulement de la présence d'une fonction cétonique sur la chaîne latérale mais

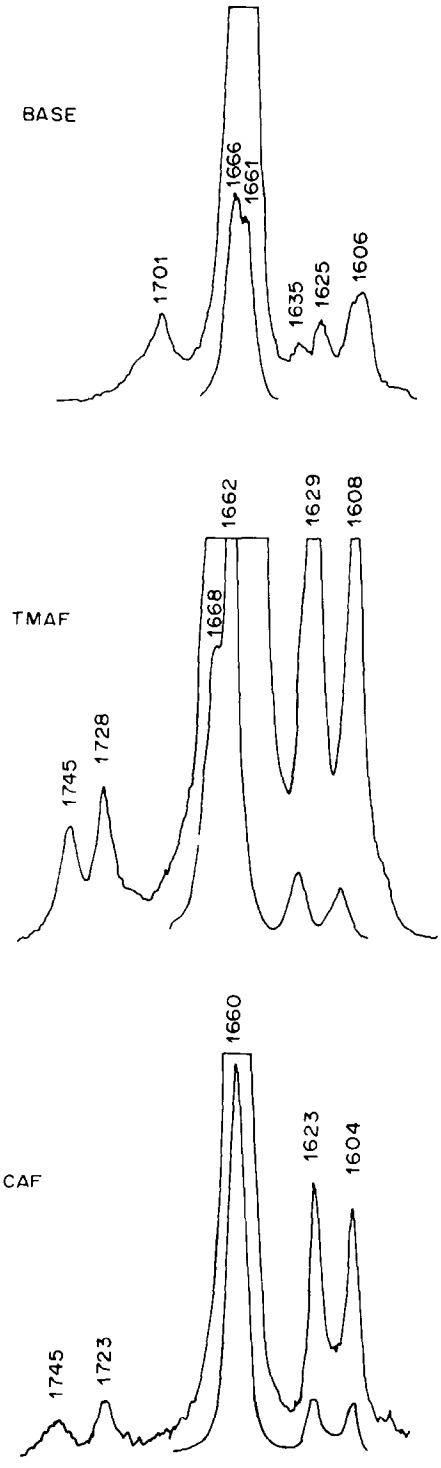

Fig. 4. Spectres Raman; région 1500–1800 cm^{-1}.

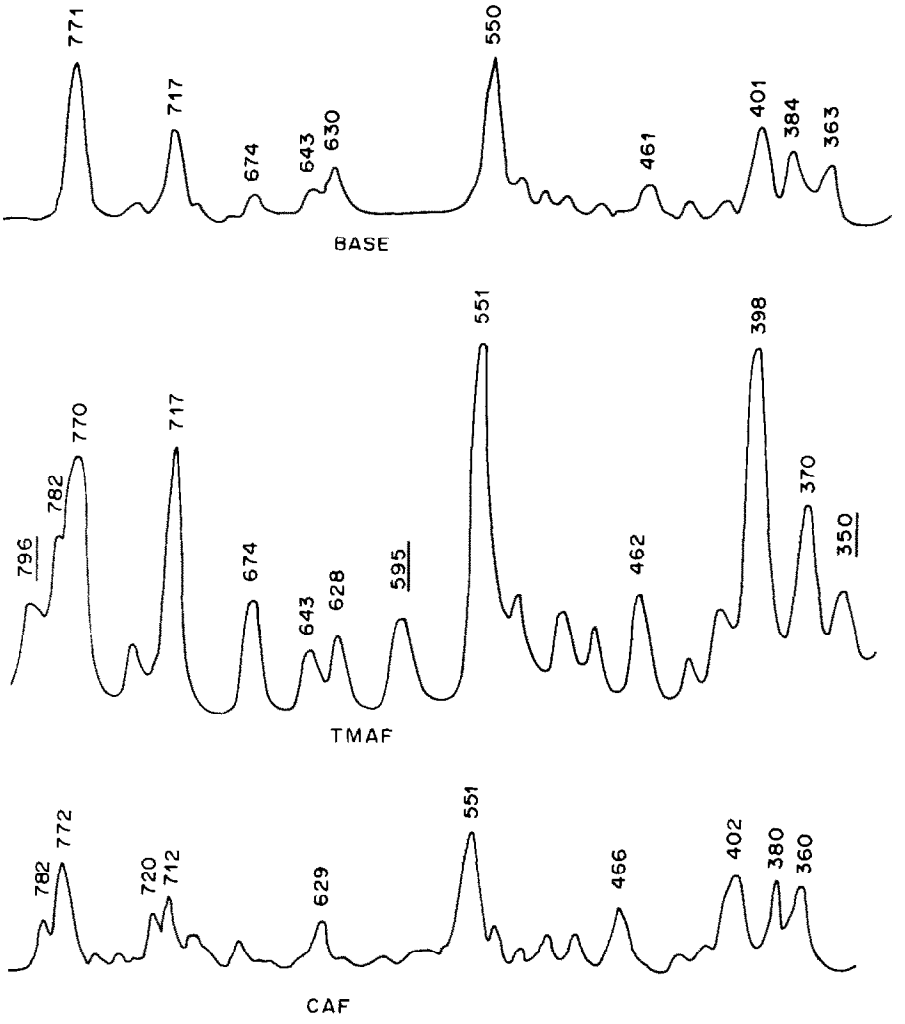

Fig. 5. Spectres Raman; région 340–810 cm^{-1} permettant de caractériser le triméthylacétate.

aussi de l'existence d'une fonction ester suivant que l'on y trouve respectivement une ou deux raies;

—rappelons que la fluocortolone base présente à 1635 cm^{-1} une raie qui n'est pas retrouvée chez les dérivés estérifiés.

En second lieu, nous retiendrons également les zones spectrales représentatives des chaînes latérales estérifiées fixées sur le carbone 21:

—chaîne triméthylacétate (Fig. 5): 340–360 cm^{-1}, 570–610 cm^{-1}, 750–810 cm^{-1}; dans cette dernière région, commune au caproate et au triméthylacétate, la differenciation des deux composés se fait grâce à la raie à 796 cm^{-1} absente dans le spectre du caproate;

—chaîne caproate (Fig. 6): 1310–1350 cm^{-1}; dans cet intervalle, le caproate présente un profil très particulier avec trois raies d'intensité voisine.

CONCLUSION

Ce travail portant sur l'étude par spectrométrie Raman d'esters de la fluocortolone (TMAF) (CAF) a montré qu'il était possible de caractériser aisément cette classe de médicaments corticostéroïdiques marqués par leur structure $\Delta^{1,4}$ 3-one. Nous avons par ailleurs apporté des éléments permettant de différencier d'une part la fluocortolone base de ses deux esters et d'autre part chacun des deux esters. Ces éléments essentiels ont été regroupés dans cette publication et sont destinés à être utilisés comme nous l'avons annoncé dans l'introduction, pour un travail d'identification fine par microspectrométrie Raman permettant d'atteindre la limite du picogramme.

Summary—Raman spectra of a series of three corticosteroid drugs: fluocortolone and its trimethylacetate and caproate esters (TMAF and CAF) in the polycrystalline state have been recorded from 150 to 4000 cm^{-1}. Assignment of the observed frequencies is proposed. The problem is complex because the drugs have the same polycyclic structure, but frequency ranges with specific bands can be used to characterize the compounds. We first mention the frequencies observed between 1500 and 1800 cm^{-1}: in the range 1580–1690 cm^{-1} strong and specific bands assigned to the $\Delta^{1,4}$-3-one conjugated structure of corticosteroids characterize the class of drugs; the frequencies in the range 1690–1750 cm^{-1} characterize not only a ketone group on the side-chain but also an ester group, which gives one or two bands (fluocortolone base 1701 cm^{-1}; TMAF 1728, 1745 cm^{-1}; CAF 1723, 1745 cm^{-1}). Fluocortolone base shows a band at 1635 cm^{-1} which is not found in the spectra of the esters. Secondly we mention the specific spectral ranges of the esterified side chain on C_{21}: trimethylacetate chain 340–360, 570–610, 750–810 cm^{-1} (this last range is common to the two esters, and differentiation is made with the band found at 796 cm^{-1}, which is absent from the caproate spectrum); caproate chain 1310–1350 cm^{-1} (in this range, caproate shows a specific pattern with three bands of the same intensity). These results can be used to characterize these compounds by Raman spectroscopy of pg quantities in HPLC eluates

Istituto di Chimica Analitica Strumentale del C.N.R., c/o Istituto di Chimica Analitica ed Elettrochimica dell'Università di Pisa, Via Risorgimento 35, 56100 Pisa, Italy

(*Received* 18 *October* 1984. *Accepted* 19 *December* 1984)

Summary—Non-dispersive atomic-fluorescence spectrometry combined with hydride-generation has been developed for lead determination. A radiofrequency-excited electrodeless discharge lamp was used as light-source and a small argon–hydrogen flame as atomizer. The detection limit was 0.06 ng/ml and the linear calibration graph was linear up to 300 ng/ml, with a precision of 5–6% over the dynamic range. Interference studies and optimization of the experimental parameters are reported. Severe suppression of the lead signal was observed in presence of Cu, Se or Te. An empirical equation was obtained for predicting the effect of copper on the lead signal at various concentration ratios. The strong effect of complexing agents such as EDTA was removed by addition of zinc salts.

Over the past ten years the spectroscopic determination of lead with use of sodium tetrahydroborate for generation of plumbane (PbH_4) has been attempted by several authors,[1–8] but because of the poor reaction efficiency the method was unsuitable until Fleming and Ide[2] and Vijan and Wood[3] discovered that the efficiency can be consistently enhanced by addition of an oxidant before injection of the tetrahydroborate. It was assumed that Pb(IV) is obtained in the oxidation step and is much more suitable than Pb(II) for formation of PbH_4.

Various oxidants and acids have been proposed as the reaction matrices,[2–8] but use of 10% hydrogen peroxide and 0.1–0.12*M* perchloric or nitric acid in the sample solution appears to be the best compromise in terms of sensitivity, reagent blank and interference effects.

Atomic-absorption spectrometry (AAS) was used in all the studies mentioned, except that by Ikeda *et al.*,[8] who used inductively-coupled plasma atomic-emission spectrometry (ICP–AES). Owing to the variation in the definitions of sensitivity and detection limit, the merits of the different procedures are difficult to compare. In the AAS methods, a typical sensitivity was an absorbance of 0.0044 for a lead concentration of 1 ng/ml. Taking the blank concentration as 1–2 ng/ml and the instability of the output of a commercial instrument as an absorbance of at least 0.003, a realistic estimate of the standard deviation, based on a small set of observation data, would be 0.004 absorbance at the blank concentration level. This corresponds to a detection limit (three times the standard deviation) of 3–4 ng/ml.

This value is comparable with those recently obtained by Sthapit[10] and Omenetto[11] by microwave-EDL or laser-excited atomic-fluorescence spectrometry with direct aspiration of the sample into the flame.

To achieve a lower detection limit and extend the linear dynamic range, we have tested the use of non-dispersive atomic-fluorescence spectrometry (NDAFS) with the instrument described previously.[9]

EXPERIMENTAL

Apparatus

A home-made non-dispersive atomic-fluorescence spectrometer with multielement capabilities was used, in the single-channel mode. The light-source was a Perkin-Elmer electrodeless discharge lamp (EDL) operating at 10 W mean power. The input power was square-wave modulated at 7500 Hz with 100% amplitude modulation and 0.5 duty cycle (duty cycle = pulse width/pulse period). Details of the non-dispersive apparatus and EDL behaviour are reported elsewhere.[9]

A hydride-reaction vessel (70 ml in volume) similar to those reported by other authors[1,12] was constructed from borosilicate glass. It had two ports, for the injection of the oxidizing and reducing solutions.

Disposable micropipettes (0.5 and 1 ml) were employed for manual injection of the reagents. The atomizer was a small argon–hydrogen/entrained-air flame[12] obtained with flow-rates of 0.3 l./min for the hydrogen and 1.0 l./min for the argon. Argon also acted as the carrier for volatile hydrides. The flame was supported on a simple glass tube (8.5 mm bore). A summary of the experimental conditions is reported in Table 1.

Reagents

A stock solution of lead (1000 μg/ml) was prepared from lead nitrate. More dilute solutions were prepared just before use. Demineralized doubly-distilled water was used in all operations.

All reagents were high purity products (Merck, "Suprapur" grade), unless otherwise specified.

Hydrogen peroxide solution (10% w/w) was used as oxidant. Sodium tetrahydroborate solution (10%) was used as reductant and prepared by dissolving the solid reagent

Table 1. Experimental conditions

Radiofrequency power for EDL	10 W (expressed as mean power)
Power modulation for EDL	Square-wave, 0–100% amplitude modulation, 0.5 duty cycle
Modulation frequency	7500 Hz
Photomultiplier voltage	750 V
Focusing height	8 mm above the burner top
Gas flow-rates	Hydrogen 0.3 l./min, argon 1.0 l./min
Sample size	5 ml
Acidity	0.12*M* HCl
Oxidant	0.5 ml of 10% H_2O_2 solution
Oxidation time	40–50 sec
Reductant	1 ml of 10% $NaBH_4$ solution
RC time-constant	10 sec

(BDH, reagent for AAS, pellets) in 0.1*M* sodium hydroxide and filtering with a 0.45-μm filter.

Lead-free sodium chloride solution (5*M*) was obtained by co-precipitating[13] lead with lanthanum hydroxide at pH 10–11 (by addition of sodium hydroxide), filtering, and neutralizing the filtrate with dilute hydrochloric acid.

Procedure

Five ml of sample or standard solution were transferred into the reaction vessel. Two micropipettes, one containing 0.5 ml of hydrogen peroxide solution and the other 1 ml of tetrahydroborate solution, were placed in the injection ports. Argon was then allowed to flow through the reaction vessel. Once the baseline was stabilized, the peroxide was injected and 40 sec later the tetrahydroborate; no stirring was used. The standard-additions method should be used (with correction for the blank), and if complexing agents such as EDTA are thought to be present, 0.05 ml of 10^{-3}*M* zinc solution should be added before injection of the peroxide. All the other experimental conditions are summarized in Table 1.

RESULTS AND DISCUSSION

Optimization of parameters

Burner. Observation at 8–10 mm above the burner top was found to give the best signal to noise ratio (SNR) and the highest signal. By increasing the burner bore, the path-length of the optical cell and the signal are enhanced, but the enhancement is not a linear function of the burner bore (Fig. 1). With a burner bore larger than 6 mm the hydrogen flow-rate can be reduced to 0.3 l./min without the flame being extinguished after the tetrahydroborate injection.

Argon. Changing the argon flow-rate in the range 0.9–1.2 l./min does not affect the signal. At an argon flow of 1.0 l./min the peak-width of the signal at half-height was about 12 sec, so using a 10-sec time-constant at the output of the lock-in amplifier gives a further increase in SNR.

Hydride generation. The effect of sample acidity, and peroxide and tetrahydroborate concentrations was studied in order to achieve higher sensitivity. Patterns similar to those observed by Vijan and Wood[3] were found (see Figs. 2–4). The maximal sensitivity was obtained with 0.1–0.12*M* hydrochloric acid, 8–10% hydrogen peroxide and 10–12% sodium tetrahydroborate solution.

The chemical parameters involved in the hydride generation were also optimized for 0.5*M* sodium chloride medium, in view of a possible application to sea-water analysis. The effect of sodium chloride is discussed below.

When magnetic stirring was used, a 70% suppression of the signal was always observed.

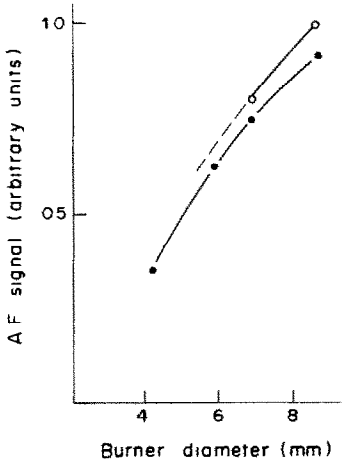

Fig. 1. Effect of glass burner internal diameter on lead signal. Conditions: see Table 1, hydrogen 0.4 (—●—) and 0.3 (—○—) l./min, lead 10 ng/ml. Flame extinguished (----).

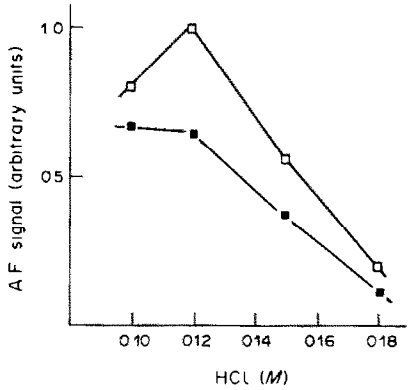

Fig. 2. Effect of sample acidity on lead signal. Conditions: see Table 1, lead 10 ng/ml; in absence (—■—) and in presence of 0.5*M* NaCl (—□—).

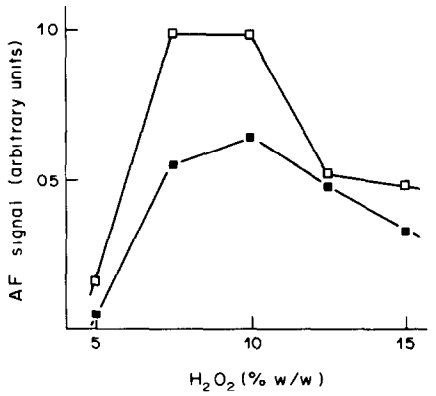

Fig. 3. Effect of concentration of added H_2O_2 solution. Added volume 0.5 ml. Conditions: see Table 1, lead 10 ng/ml; in absence (—■—) and in presence of 0.5*M* NaCl (—□—).

Detection limit, dynamic range and precision

Blank signal. To identify various contributions to the blank, the signal was recorded (*a*) before the addition of borohydride; (*b*) after its addition to a reagent blank solution; (*c*) as in (*b*) except for the presence of 2 μg/ml of copper and the absence of peroxide, to suppress the plumbane formation. It was found that the EDL light reflected by the surroundings onto the photomultiplier was responsible for the continuum component (14% of the peak amplitude for the blank), and that the flame contributes about 8%, the solution droplets dispersed in the flame 15%, and the lead present in the reagent about 63% of the blank. A silaned glass-wool filter placed before the atomizer retains the solution droplets and suppresses their effect.

With the present purity of available reagents, the reagent blank was found to be 0.35 ng/ml, with 6% RSD ($n = 10$). The calculated detection limit (three times the RSD of the blank) was 0.06 ng/ml.

Calibration graphs and precision. Calibration graphs were linear up to 300 ng/ml (4 decades). The

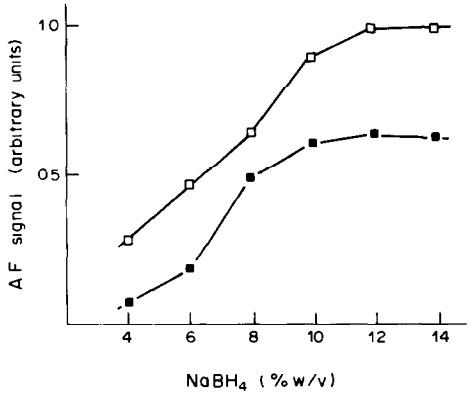

Fig. 4. Effect of concentration of added $NaBH_4$ solution. Added volume 1 ml. Conditions: see Table 1, lead 10 ng/ml; in absence (—■—) and in presence of 0.5*M* NaCl (—□—).

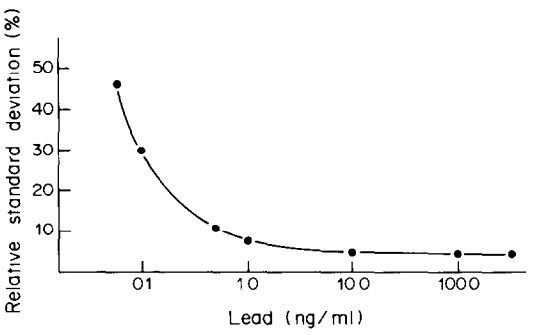

Fig. 5. Precision diagram for lead determination. Conditions: see Table 1.

relative standard deviation over the range 0.06–300 ng/ml was given by

$$\mathrm{RSD} = [(0.06S_B)^2 + (0.05S_i)^2]^{1/2}/S_i,$$

where S_B was the blank signal, S_i the signal relevant to concentration i and 0.06 and 0.05 were the relative standard deviations ($n = 10$) of S_B and S_i respectively. The precision is shown in Fig. 5. The intercept in the $(S_i + S_B)$ *vs.* C_i plot, obtained from the experimental points in the lead range 0–5 ng/ml was equivalent to 0.4 ng/ml. The fairly good agreement with the value calculated in the direct measurement of the blank shows that S_B is constant in the concentration range tested.

Effect of foreign compounds

Anions. Chloride (KCl, NaCl) and bromide (KBr) were found to enhance S_i by up to 50%. Figure 6 shows the effect of increasing concentration of chloride on the peak amplitude of lead. The effect was found to be independent of the lead concentration within the dynamic range. In the absence of hydrogen peroxide the small signal due to the quantity of PbH_4 produced by direct reduction of Pb(II) was further decreased by the presence of chloride. These effects can be explained by considering that Pb(IV) forms more stable complexes than Pb(II) with chloride, so the redox reaction:

$$PbCl_m^{(m-2)-} + 2H_2O_2 + 4H^+ + \overset{Cl^-}{\rightleftharpoons} PbCl_n^{(n-4)-} + 4H_2O$$

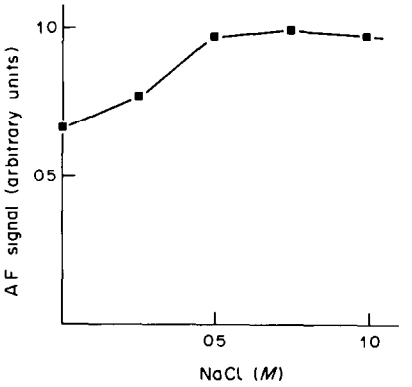

Fig. 6. Effect of sodium chloride present in the sample. Conditions: see Table 1, lead 10 ng/ml.

Table 2. Interference effect of foreign elements (200 ng/ml)*

Element	Interference, %	Element	Interference, %
As(III)	−50(−45)†	Cd(II)	0(0)
Sb(III)	−25(−25)	Co(II)	0(0)
Bi(III)	−13(0)	Ni(II)	0(0)
Sn(IV)	0(0)	Cu(II)	−85(−85)
Se(IV)	−78(−68)	Cr(III)	0(0)
Te(IV)	−77(−65)	Fe(III)	0(0)

*Expressed as percentage variation with respect to the signal of lead alone.
†Interference effect in presence of 0.5*M* NaCl.
Conditions: see Table 1, lead 5 ng/ml.

is shifted toward the right and the yield of PbH_4 in the subsequent reaction with borohydride is increased.

Sulphate ($5 \times 10^{-3}M$), perchlorate ($0.2M$), phosphate ($2 \times 10^{-3}M$) and EDTA ($5 \times 10^{-7}M$; 0.2 ppm) do not affect the signal for a 5-ng/ml level of lead. EDTA at 2 ppm level does not affect the signal for lead at 5-ng/ml level if the solution is made $10^{-5}M$ in zinc

Interferences. Several elements which are reported to have a strong effect on plumbane generation[2-8] were studied. The effect of these elements at the 200-ng/ml level on the signal for 5-ng/ml lead is reported in Table 2. More detailed information on copper, selenium and tellurium interference is given in Tables 3 and 4.

An empirical equation which allows prediction of the signal decrease as a function of lead and copper concentration was found to be: % decrease = $1.15C_{Cu}/C_{Pb}^{0.55}$ (C expressed in ng/ml). Thus for any matrix composition the problem is how much the detection limit and linearity of the calibration graphs are affected by interferents. Whenever a fairly linear calibration graph is obtained for a real sample, it is necessary to calculate the value of S'_B—the blank signal in the presence of interferences—in order to calculate S_l. S'_B is given by $S'_B = S_B\, m'/m$, where m' and m are the sensitivities in the presence and absence of the interferences, respectively. It was found that in presence of copper at the 50-ng/ml level, the standard-addition procedure gives a linear plot for lead from 0.2 to 7 ng/ml, which allows determination of an initial lead concentration in the range from about 0.2 to 2 ng/ml.

Table 3. Concentration interference effect of Se, Te and Cu*

Interferent concentration, ng/ml	Interference, %		
	Se(IV)	Te(IV)	Cu(II)
2.5	0	0	0
5	0	−12	0

Conditions: see Table 1.

Experiments are in progress for comparison of the results obtained by this procedure with those obtained by anodic-stripping voltammetry in analysis of sea-water.

Conclusions

Non-dispersive atomic-fluorescence spectrometry combined with hydride-generation has proved to be superior to hydride generation and AAS or ICP–AES[1-8] in terms of detection limits and dynamic range, although the most sensitive fluorescence line of lead (at 405.1 nm) lies outside the spectral response of the solar-blind photomultiplier used in the present work.

Proper modulation of the EDL source,[9] adjustment of the burner parameters, and careful choice of the experimental conditions in the hydride generation step are essential for obtaining a low detection limit.

Chloride and bromide enhance the lead signal, but the enhancement is independent of the lead concentration. The depressant effects of other interferents are comparable with those observed in the continuous-flow automatic generation of the lead hydride.[7]

SPECTROPHOTOMETRIC DETERMINATION OF IRON AND COPPER IN MILK, FOODSTUFFS AND BODY TISSUES WITH 1-(2-QUINOLYLAZO)-2,4,5-TRIHYDROXYBENZENE

ISHWAR SINGH, MRS. POONAM and P. S. KADYAN
Department of Chemistry, Maharshi Dayanand University, Rohtak-124001, India

(*Received* 26 *September* 1984. *Accepted* 19 *December* 1984)

Summary—1-(2-Quinolylazo)-2,4,5-trihydroxybenzene has been proposed as a sensitive chromogenic reagent for the simultaneous determination of iron and copper in presence of thiosemicarbazide. The molar absorptivities are 1.86×10^4 l.mole^{-1}.cm^{-1} at 510 nm for iron and 2.54×10^4 l.mole^{-1}.cm^{-1} at 550 nm for copper. Trace levels of these two metals have been determined in some foodstuffs, body tissues and milk samples.

Iron and copper are widely distributed in foods of plant and animal origin, but are present in very low concentrations in milk. In the northern areas of India, adults as well as infants are dependent on a milk diet. Excess of copper is objectionable in milk as it oxidizes the ascorbic acid content and causes an off-flavour.[1] These two metals are also distributed in blood and body tissues in the human system, and in some cases can be a pointer to various diseases (*e.g.*, copper, in Wilson's disease).

In an earlier publication,[2] we described use of a new reagent, 1-(2-quinolylazo)-2,4,5-trihydroxybenzene (QATB), for determination of manganese in foodstuffs, and now extend its use to determination of iron and copper.

EXPERIMENTAL

Reagents

QATB was synthesized[2] as described earlier, and used as a $2 \times 10^{-3}M$ solution prepared by dissolving 0.562 g in 1 litre of ethanol. Solutions more than a week old were discarded. Stock solutions ($0.01M$) of iron(II) and copper(II) were prepared by dissolving appropriate amounts of analytical grade ferrous ammonium sulphate hexahydrate and copper sulphate pentahydrate in doubly distilled water and were standardized with EDTA.[3] A 2% solution of thiosemicarbazide was prepared in water.

All other reagents were of analytical grade and doubly distilled water was used throughout.

Procedures

Calibration graphs. To each of a series of 1-ml aliquots (taken in dry 10-ml standard flasks) containing 4–28 μg of iron(II) or 3–30 μg of copper(II), add 2 ml of $2 \times 10^{-3}M$ QATB, 1 ml of $1M$ sodium acetate and dilute to volume with 1:1 v/v water–ethanol mixture. Record the absorbance at 510 nm for iron(II) and 550 nm for copper(II) against a reagent blank prepared under similar conditions. Draw the calibration graphs.

Determination of iron(II) in presence of copper(II). To 1 ml of sample solution (taken in dry 10-ml standard flask) containing not more than 28 μg of iron(II) and 100 μg of copper(II), add 1 ml of 2% thiosemicarbazide solution and after a minute, 2 ml of $2 \times 10^{-3}M$ QATB, 1 ml of $1M$ sodium acetate and 1 ml of ethanol. Dilute to volume with 1:1 water–ethanol mixture. Measure the absorbance at 510 nm against a reagent blank and deduce the amount of iron(II) from the calibration curve.

Determination of iron(II) and copper(II). Treat 1 ml of sample solution containing not more than 30 μg of iron(II) and/or copper(II) as just described, and measure the absorbance at 510 and 550 nm (readings 1 and 2, respectively) against a reagent blank. Repeat the procedure without adding the thiosemicarbazide, but measure only the absorbance at 550 nm (reading 3). Absorbance 1 gives the iron concentration from the calibration graph for iron(II). The difference between absorbances 2 and 3 gives the copper concentration from the calibration graph for copper(II).

RESULTS AND DISCUSSION

QATB immediately gives a very stable dark brown complex with iron(II) and a red complex with copper(II) in the neutral pH range, but corresponding precipitates when the ethanol concentration is below 40%. At ethanol concentrations >40% the precipitates dissolve. Higher ethanol levels do not affect the absorbance of the complex. Figure 1 shows the spectra of the complexes in 50% v/v aqueous ethanol solution buffered with sodium acetate (final concentration $0.1M$), the optimal conditions. Table 1 records the physicochemical characteristics of the complexes. Both complexes have 1:2 metal:ligand molar ratio.

In sodium acetate medium only iron(II) and copper(II) produce colour reactions with QATB; other transition metals only form coloured complexes in either concentrated sodium hydroxide medium or at above pH 10. Addition of 1–2 ml of 2% thiosemicarbazide solution completely prevents interaction of copper(II) with QATB but has no effect on formation of the iron(II) complex. The iron(II) complex has considerable absorbance at 550 nm, at which the copper complex has maximum absorbance, but

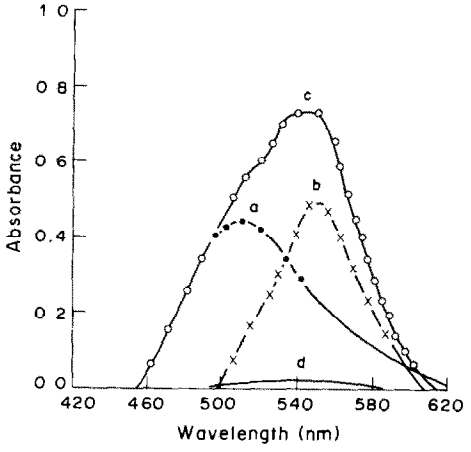

Fig. 1. Absorption spectra of (a) iron-QATB (b) copper-QATB complexes, (c) mixed in equal concentration (d) copper-QATB complex in presence of thiosemicarbazide, measured against reagent blank in sodium acetate medium; Fe 1.1 ppm, Cu 1.3 ppm, QATB $4 \times 10^{-4} M$.

this can be corrected for as described in the procedure, by measuring the absorbance at 550 nm in the presence and absence of thiosemicarbazide, for equal aliquots of sample.

Iron(II) also forms a coloured complex with QATB at neutral pH. When iron(II) is oxidized to iron(III) with nitric acid or persulphate and the pH is adjusted to 7.0–8.0, QATB produces a dark brown 1:2 complex with molar extinction coefficient of 1.8×10^4 $l.mole^{-1}.cm^{-1}$ at 510 nm, but hydrogen peroxide prevents the colour formation when it is used for oxidation purposes. Iron can, therefore, be determined in either of the oxidation states with the same accuracy at pH 8.0.

Effect of diverse ions

In the determination of iron(II) and copper(II) at the 1.12 μg/ml and 1.27 μg/ml level respectively, fluoride, chloride, bromide, iodide, thiocyanate, nitrate, nitrite, sulphite, sulphate, alkaline-earth metals, lanthanides, aluminium, indium, antimony(III), bismuth, chromium(III), platinum metals [except palladium(II)], thorium, cerium and tin(II) do not interfere. Cyanide, EDTA, nickel, cobalt(II) and vanadium(V) interfere seriously in both cases, even in 1:1 mole ratio to the analyte. Sulphide and phosphate also interfere in the iron(II) determination. Certain metal ions are precipitated at the pH used and the precipitates should be removed by centrifugation. For other ions, the tolerance limits, defined as the concentration (μg/ml in the final solution) causing a deviation of less than ±2% in the absorbance, are as follows. For iron(II): thiosulphate, 200; citrate, 50; molybdenum(VI), tungsten(VI), 40; oxalate, borate, uranium(VI), cadmium, mercury(II), palladium(II), 20; copper(II), silver (both masked by thiosemicarbazide), 10. For copper(II): sulphide, thiocyanate, citrate, tartrate, 100; phosphate, oxalate, molybdenum(VI), tungsten(VI), 40; borate, 25; cadmium, mercury(II), 20; palladium (II), silver (without masking), 10 (masking with thiocyanate and iodide respectively), 25; zinc, manganese(II), 5.

APPLICATIONS

Some foodstuffs and fruits which contain negligible amounts of cobalt and nickel in comparison to iron or copper were selected for analysis. Body tissues are also found to contain negligible amounts of cobalt and nickel, but fair amounts of iron and copper. Milk contains very little iron, so only copper was determined in the milk samples.

Determination of iron and copper in foodstuffs

Wet-ash 5 g of food or fruit (dried for ~24 hr at ~70° in an oven) with nitric and perchloric acids.[4,5] Take up the ash with 5 ml of hydrochloric acid (1 + 9) and evaporate to dryness; repeat this step. Dissolve the dry residue in water, filter the solution into a 25-ml standard flask, add 1 or 2 drops of concentrated hydrochloric acid and make up to volume. Analyse 1-ml aliquots as already described, adjusting the pH to 7–8 with dilute sodium hydroxide solution.

Determination of iron in body tissues

Wet-ash 5-g sample with a 1:1 mixture of nitric acid and perchloric acids.[6,7] Evaporate the solution to dryness and ash the residue at 300°. Dissolve the ash in 2 ml of 1*M* sulphuric acid, make up to volume in a 25-ml standard flask and determine iron as already described, adjusting the pH to 7–8 with dilute sodium hydroxide solution.

Determination of copper in milk samples

The amount of natural copper present in fresh raw milk is rather low and the "oxidized" flavour of milk is correlated with the copper content.[1] Excess of copper is objectionable and is indicative of contamination. Hence its determination in milk is of importance during processing. Milk samples are usually dry-ashed for copper determination, and though time-consuming, this method is considered to be the most accurate.[8,9]

Add 100 ml of milk dropwise to a heated crucible to evaporate it without frothing. After the moisture has been removed, heat strongly to 450–500°. Cool and add 1 ml of concentrated nitric acid. Evaporate to dryness and ignite again at 450–500° for ~1 hr. Take utmost care to avoid loss by sputtering. Dissolve the white ash in the minimum of dilute nitric acid and make up to volume in a 10-ml standard flask. Pipette a 1-ml aliquot and determine the copper

Table 4. Contents of iron in body tissues (quadruplicate 5-g samples)

Sample	Aliquot taken, ml	Fe found, μg	Fe added, μg	Total Fe recovered, μg	Range of recovery, %
Prostate	1.0	6.77, 6.57, 6.48, 6.32	11.2	18.4, 18.0, 17.4, 17.0	98.4–102.4
Benign enlargement of prostate	0.5	12.9, 12.8, 12.8, 12.7	11.2	24.2, 23.5, 23.8, 23.6	97.8–100.6

Table 5. Recovery of copper from various milk samples by the dry-ashing procedure (quadruplicate analyses)

Sample	Cu found, μg	Cu added, μg	Cu recovered, μg	Range of recovery, %
Cow milk	4.06, 4.09, 4.08, 3.39	12.7	16.5, 17.1, 16.2, 16.2	96.8–101.9
Buffalo milk	3.86, 3.94, 3.58, 3.73	12.7	16.4, 16.9, 16.6, 16.1	98.9–101.7

contents as already described (in all cases adjust the pH to 7–8 with dilute sodium hydroxide).

Results for these analyses are given in Tables 2–5. Recovery experiments with spiked samples gave 95–104% recovery for iron and 93–103% for copper.

APPLICATION OF ORGANIC SOLVENT-SOLUBLE MEMBRANE FILTERS IN THE PRECONCENTRATION AND DETERMINATION OF TRACE ELEMENTS: SPECTROPHOTOMETRIC DETERMINATION OF PHOSPHORUS AS PHOSPHOMOLYBDENUM BLUE

SHIGERU TAGUCHI, EIYUKI ITO-OKA, KEIKO MASUYAMA,

(*Received* 25 *July* 1984. *Accepted* 19 *December* 1984)

Summary—A simple and rapid preconcentration technique, based on collecting trace elements on a membrane filter and dissolving the membrane filter in an organic solvent, has been applied to the spectrophotometric determination of phosphorus in water. Phosphorus, 0.5–7 μg in 50–500 ml of water sample, is collected as phosphomolybdenum blue on a nitrocellulose or acetylcellulose membrane in the presence of n-dodecyltrimethylammonium bromide, the membrane is dissolved in 5 ml of dimethylsulphoxide (DMSO), and the absorbance of the DMSO solution is measured at 710 nm against a reagent blank. Moderate concentrations of silicate, anionic and non-ionic surfactants and high concentrations of sodium chloride do not interfere. Interference from arsenate can be eliminated by reducing the arsenate to arsenite. Condensed and organic phosphates can be determined if they are first converted into orthophosphoric acid by digestion with persulphate. The limit of determination is 0.002 μg of phosphorus in 100 ml of sample.

Adsorption on hydrophobic adsorbents is a simple and reliable means of preconcentrating trace elements from water.[1] We have proposed the use of C_{18}-bonded glass beads, C_{18}-bonded silica gel and polypropylene wool for this purpose. Traces of metals, phosphorus and arsenic can be adsorbed as coloured complexes on these adsorbents, eluted with a small volume of eluent, and determined either by spectrophotometry, inductively-coupled plasma atomic emission spectrometry or anodic stripping voltammetry.[2–9]

Recently we have proposed a simpler and faster preconcentration technique,[10] which is based on collecting trace elements as complexes on a membrane filter and dissolving the filter in a small volume of organic solvent. This technique was applied to the spectrophotometric determination of phosphorus. The phosphorus was collected as phosphomolybdenum blue on a nitrocellulose or acetylcellulose membrane in the presence of n-dodecyltrimethylammonium bromide, and the membrane was dissolved in a small volume of dimethylsulphoxide (DMSO). The absorbance of the DMSO solution was measured at 710 nm against a reagent blank. A 100-fold enrichment could easily be achieved and μg/l. levels of phosphorus determined with satisfactory precision. Because our earlier paper was only a preliminary report, we now present the method in more detail.

EXPERIMENTAL

Reagents

Ammonium molybdate solution.[11] Dissolve 6 g of ammonium heptamolybdate tetrahydrate and 0.24 g of potassium antimonyl tartrate in 500 ml of 3*M* sulphuric acid.

L-Ascorbic acid solution.[11] Dissolve 7.2 g of L-ascorbic acid in 100 ml of water. Prepare fresh daily.

Mixed reagent.[11] Mix 50 ml of the ammonium molybdate solution and 10 ml of the L-ascorbic acid solution. Prepare fresh daily.

Standard phosphorus solution. Prepare by dissolving an appropriate amount of potassium dihydrogen phosphate in water.

n-Dodecyltrimethylammonium bromide (C_{12}TMAB) solution. Dissolve 0.08 g of C_{12}TMAB in 100 ml of water. If necessary, remove any phosphate in this solution in the following manner:[12] add 0.5 ml of 10% aluminium sulphate solution to 100 ml of the C_{12}TMAB solution, adjust the pH to 8.5 with aqueous ammonia, stir for about 15 min, and filter off the aluminium hydroxide formed.

Reducing agent. Prepared as described by Schouwenburg and Walinga[13] and modified by Johnson.[14] Mix 20 ml of 1.75*M* sulphuric acid, 40 ml of 14% sodium metabisulphite solution and 40 ml of 1.4% sodium thiosulphate solution. Prepare fresh daily.

Membrane filters and holder

Most of the data presented in this paper were obtained with Toyo TM2 membranes (25 mm in diameter, 0.45-μm pore size, nitrocellulose membrane), but other membranes can be used equally satisfactorily as long as they are made of nitrocellulose or acetylcellulose. A Toyo KG-25 filter holder (effective filtration area 1.3 cm^2) was used.

Procedure

Take 100 ml of sample solution, containing less than 7 μg of phosphorus, add 8 ml of the mixed reagent, set aside for at least 15 min in a water-bath controlled at 20–40°, then add 1 ml of C_{12}TMAB solution (samples up to 500 ml in volume can be used if 8 ml of mixed reagent and 1 ml of C_{12}TMAB solution are added per 100 ml of sample). Filter off the phosphomolybdenum blue on the membrane filter, and wash the membrane with about 20 ml of water. Dissolve the filter in 5 ml of DMSO, and measure the absorbance of the DMSO solution at 710 nm against a reagent blank.

RESULTS AND DISCUSSION

Optimum conditions for colour development

The conditions for the formation of the phosphomolybdenum blue[11] and the masking of arsenic(V)[13,14] are similar to those reported by earlier workers. The volumes of reagents added are varied in proportion to the sample volume. A 15-min reaction time is sufficient for complete colour development.

Cationic surfactant

The collection of phosphorus as phosphomolybdenum blue on membrane filters was originally proposed by Hiiro *et al.*,[15] but was not quantitative, and the fraction retained on the filter varied widely, depending on the manufacturer and the pore size of the membranes used.

During the course of our study, our attention was drawn to a paper by Ohashi *et al.*,[16] stating that the addition of zephiramine, a cationic surfactant, greatly enhanced the extractability of phosphomolybdenum blue. This led us to examine the use of cationic surfactants to enhance the adsorption of phosphomolybdenum blue on membrane filters. Of those tested, dodecyltrimethylammonium bromide (C_{12}TMAB) was the most satisfactory.

Figure 1 shows that the absorbance of the DMSO solution increases with increasing amount of C_{12}TMAB added and reaches a constant value with at least 0.5 ml of 0.08% solution per 100 ml of sample.

Membrane filter for collection

Several filters of different sorts and pore-sizes were examined for their usefulness for collecting phosphomolybdenum blue. Nitrocellulose and acetylcellulose membrane filters are suitable because they readily dissolve in DMSO. Although any nitrocellulose membrane filter with pore sizes between 0.2 and 0.45 μm can be used, 0.45-μm filters are recommended because of their higher filtration rate.

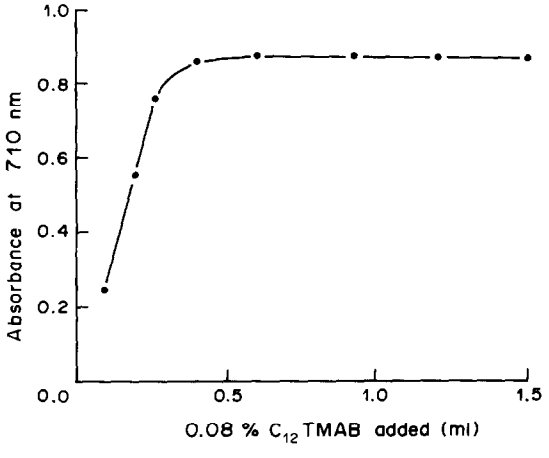

Fig. 1. Effect of C_{12}TMAB on the absorbance from 7.3 μg of P per 100 ml.

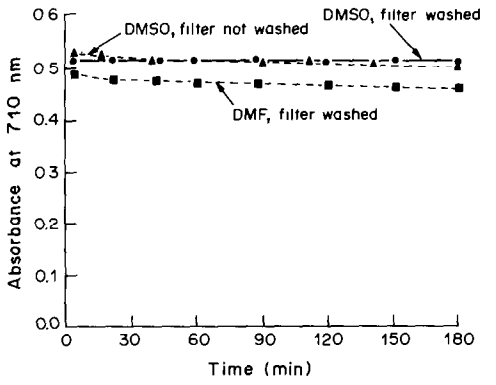

Fig. 2. Effect of different solvents on the absorbance and stability of phosphomolybdenum blue (P 4.17 μg).

Solvent

Several water-miscible organic solvents were tested as solvents for the wet membranes. DMSO, *N,N*-dimethylformamide (DMF) and acetone readily dissolve the nitrocellulose and acetylcellulose membranes, but acetone is not recommended, because of its high volatility.

Figure 2 shows the stability of the colour of phosphomolybdenum blue in DMSO and DMF. The colour intensity decreases slightly with time in DMF, but only very slowly in DMSO. If the membrane is washed with water before being dissolved in DMSO, the colour intensity is stable for at least 3 hr. Other water-miscible solvents, such as ethanol, methanol and acetonitrile, will not dissolve the membrane at room temperature.

Absorption spectrum

The visible-region absorption spectrum of phosphomolybdenum blue in DMSO is shown in Fig. 3. There are two absorption maxima: one at 710 nm and the other at 875 nm. The first was chosen for use, in view of the useful wavelength range of most spectrophotometers. Beer's law is obeyed for 0.5–7 μg of phosphorus in 5 ml of DMSO at both wavelengths.

Sensitivity and precision

Table 1 shows that microgram quantities of phosphorus in 50–500 ml of sample can be determined

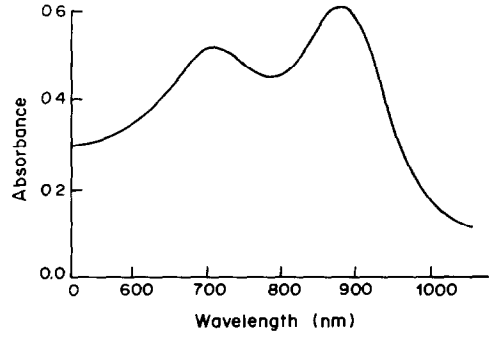

Fig. 3. Absorption spectrum of phosphomolybdenum blue in DMSO (P 0.834 μg/ml).

*Filter dissolved in 5 ml of DMSO.
†Coefficient of variation.

with satisfactory precision. The lower limit of determination (taken as three times the standard deviation of the blank) is about 0.002 μg of phosphorus per 100 ml of sample.

Efficiency of collection

The collection efficiency was estimated by determining the phosphorus on the membrane after digestion of the membrane in a mixture of nitric and perchloric acids.[17] The results indicated that more than 99% of the phosphorus was retained on the filter from 100 ml of water containing 3 μg of phosphorus.

*Sodium di(2-ethylhexyl)sulphosuccinate; anionic surfactant.
†Non-ionic surfactant.
§In the presence of 10 ml of reducing agent

Effect of foreign substances

Silicate, arsenate and germanate also form molybdenum blues. Of these, germanate is not likely to be present in concentrations high enough to cause significant interference. Table 2 shows the effects of commonly occurring substances on the determination of phosphorus. It is clear that moderate concentrations of silicate and anionic and non-ionic surfactants, and high concentrations of sodium chloride, do not interfere.

Arsenate causes large positive errors even when present at very low concentrations, but this interference can be eliminated by reducing the arsenate to arsenite, as shown in Table 3.

Condensed phosphates and organic phosphorus compounds

Phosphorus in the forms of condensed phosphates and organic phosphorus compounds can be determined after conversion into orthophosphoric acid. A common procedure for this step is to heat the sample with potassium persulphate in an autoclave.[18] The Environmental Agency of Japan uses this as the official method. Table 3 shows results for the determination of pyrophosphate, tripolyphosphate and

Table 3. Determination of condensed and organic phosphates after treatment with potassium persulphate (sample volume 100 ml)

phenylphosphate after persulphate digestion. It is clear that our proposed method can be applied successfully to samples digested with persulphate.

Application to river water and sea-water

The proposed method was applied for the analysis of river water and sea-water samples filtered through a 0.45-μm membrane filter. Table 4 shows the analyses of original samples and samples to which known quantities of phosphorus had been added. Recovery of the added phosphorus was nearly quantitative as shown in this table.

CONCLUSION

Solvent extraction is the commonest of the techniques used for the preconcentration of trace elements,[19-21] but can be tedious and time-consuming, and solubility of the organic solvents in the aqueous phase poses limitations on the enrichment factor which can be achieved.

The preconcentration technique proposed in the present paper is simple and very rapid. Once the phosphorus has been converted into phosphomolybdenum blue, collection on a membrane filter and the measurement of the absorbance can be completed in less than 5 min. An enrichment factor of 100 can easily be attained. The proposed technique may find many other applications for the determination of trace elements in water samples.

A METHOD FOR THE DETERMINATION OF VANADIUM AND IRON OXIDATION STATES IN NATURALLY OCCURRING OXIDES AND SILICATES

RICHARD B. WANTY and MARTIN B. GOLDHABER
U.S. Geological Survey, MS 916, Box 25046 Denver Federal Center, Denver, CO 80225, U.S.A.

(*Received* 21 *September* 1984. *Accepted* 14 *December* 1984)

Summary—A valence-specific analytical method for determining V^{3+} in ore minerals has been developed that involves two steps: dissolution of a mineral sample without disturbing the V^{3+}/V^{tot} ratio, followed by determination of V^{3+} in the presence of V^{4+}. The samples are dissolved in a mixture of hydrofluoric and sulphuric acids at 100° in Teflon-lined reaction vessels. Tervalent vanadium is then determined colorimetrically by formation of a V^{3+}-thiocyanate complex in aqueous-acetone medium. Fe^{3+} is measured semi-quantitatively in the same solution. The method has been tested with two naturally occurring samples containing vanadium and iron. The results obtained were supported by those obtained by other methods, including electron spin resonance spectroscopy, thermogravimetric analysis, and Mössbauer spectroscopy.

In natural systems, vanadium is present in minerals and waters in the +3, +4 and +5 oxidation states. This fact may be advantageously applied in the determination of the redox state of an entire system. For instance, the presence of tervalent vanadium is an indication of an extremely reducing environment,[1–3] whereas the quadrivalent and quinquevalent states predominate in systems of intermediate and high oxidation potential, respectively. Many analytical techniques have been developed for the determination of total vanadium in rock samples,[4–7] but no techniques have been reported whereby one vanadium oxidation state in a mineral sample is measured in the presence of another. This paper presents an analytical procedure that has been developed to detect tervalent vanadium in minerals in the presence of quadrivalent vanadium. Tervalent iron in the minerals is also measured. The method has been tested with samples of the mineral roscoelite, a vanadiferous mica, and of a vanadium oxide phase from a sandstone-hosted vanadium–uranium orebody from the Colorado Plateaus. The results should aid in the interpretation of the processes of ore genesis and contribute to our understanding of the importance of redox processes in ore genesis.

EXPERIMENTAL

Sample collection and handling

Vanadium(III) is unstable in the presence of oxygen. Therefore, all sample handling must be done in an inert atmosphere. In this study, high-purity nitrogen containing <50 ppm of oxygen was used. Roscoelite samples were obtained from an inactive mine at Placerville, Colorado. Samples of vanadium oxide were collected from freshly exposed faces in the Tony M mine, near Hanksville, Utah. The samples were stored in Mason jars flushed with nitrogen immediately after sample collection.

Once the samples had been collected and brought back to the laboratory, all sample handling (grinding, size and density separation) was done under nitrogen in a glove-bag. All reagents which were to contact the samples were purged with nitrogen for at least 30 min. The efficiency of this purging process was verified by Winkler titration.[9] Heavy-mineral separations were performed with fresh bromoform which had been purged with nitrogen for >2 hr, and the samples were then rinsed with nitrogen-purged acetone. All size and density fractions were dried in a vacuum desiccator and stored in nitrogen-purged desiccators.

Although the roscoelite samples were not collected from freshly exposed mine faces, repeated analyses over the course of several months showed no change in the V^{3+}/V^{tot} ratio. Similar experiments on the vanadium oxide mineral showed that after several weeks significant oxidation had occurred. Typical results (vanadium oxide sample TM-5 from the Tony M mine) are shown in Fig. 1. The analysis at zero time corresponds to a fresh sample stored under nitrogen. After one week of exposure to air, the V^{3+}/V^{tot} ratio was virtually unchanged from the initial value of 0.82. After 6 weeks, the ratio had dropped to a value of 0.46. A split of the sample was stored in a cloth bag to allow complete exposure to air. Analysis of this split after 22 months exposure to air gave a V^{3+}/V^{tot} ratio of 0.10, assumed to be the lowest achievable value. It is interesting to note that two of the four analyses reported by Weeks *et al.*[8] on the vanadium oxide mineral montroseite yielded V^{3+}/V^{tot} ratios of approximately 0.15, and a third showed no V^{3+}. These values are close to our "infinite time" value of 0.10, suggesting that the earlier analyses[8] were performed on oxidized material.

Reagents

Ammonium thiocyanate solution (*2.50*M) *in acetone*. Dissolve 28.5 g of reagent-grade ammonium thiocyanate in 150 ml of acetone. Prepare fresh daily.

Stock vanadium solution (*0.050*M). Dissolve 0.585 g of reagent-grade ammonium metavanadate, NH_4VO_3, in 100 ml of 6*M* hydrochloric acid. On standing for about 2 months, this solution will turn bright blue as quinquevalent vanadium is reduced to the quadrivalent form, with liberation of chlorine.

Procedure

Introduce the samples (approximately 0.1 g) into the reaction vessels. Add to each 5.0 ml of 5*M* sulphuric acid and 5 ml of concentrated hydrofluoric acid, and seal the

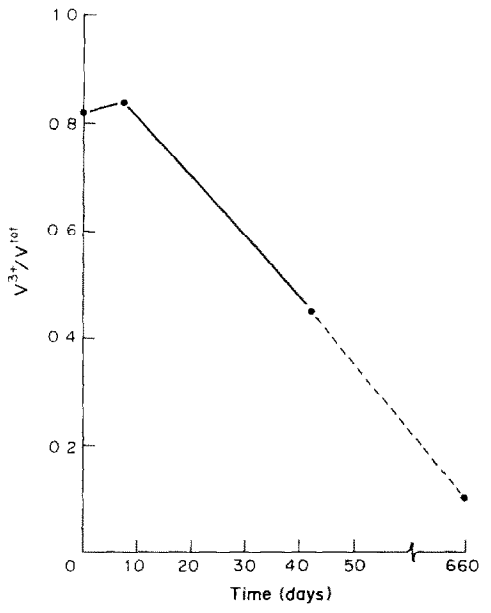

Fig. 1. Effect of time on the oxidation of the vanadium oxide sample TM-5 collected from the Tony M mine. The data point at 660 days represents the V^{3+}/V^{tot} ratio of the sample stored in air.

bombs. Heat the bombs at 100° for 3 hr in a vacuum oven. Prepare standard solutions of V^{3+} in 25-ml standard flasks by mixing portions of V^{4+} stock solution (2, 5, 10 and 25 μl) with 2 ml of concentrated hydrochloric acid and adding about 50 mg of crystalline stannous chloride dihydrate, and leave for an hour to reduce the V^{4+} quantitatively to V^{3+}. Prepare two reagent blanks, one with and one without stannous chloride. Set aside two standard flasks for each sample, one with and one without stannous chloride. On completion of the 3-hr digestion period, quench the bombs and put them in a glove-bag filled with nitrogen. Withdraw 5 ml of solution from each of the bombs and accurately dilute each to 50 ml with saturated boric acid solution. Using an automatic pipette, transfer pairs of 1.0-ml portions of these solutions to the pairs of sample flasks. Add 15 ml of thiocyanate solution to each flask, and dilute to volume with distilled water. Quickly measure the absorbance of the unreduced solutions at 475 and 395 nm. Calculate the V^{3+} content from the calibration graph for the standards measured at 395 nm. Determine the Fe^{3+} content from the differences in absorbance at 475 nm for the pairs of unreduced and reduced solutions. Use distilled water as reference, and correct the sample absorbances for the absorbance of appropriate reagent blanks. Determine the total V and Fe concentrations by atomic-absorption spectroscopy or some other method.

RESULTS AND DISCUSSION

Sample decomposition and analysis

The samples were decomposed in Teflon-lined reaction vessels similar to those described by Bernas.[10] The Teflon liners were found to be somewhat porous. To avoid oxidation by residual air in the pores during sample dissolution, all the Teflon liners were kept for at least 3 days in a vacuum oven at 100° prior to use. Experiments in which a V^{3+} solution was kept in the degassed bombs for the normal digestion period showed that no oxidation then occurred. Therefore, the three-day purging process is sufficient to remove all air.

Initial dissolution experiments involved heating with a 1:1 mixture of 5*M* hydrochloric acid and concentrated hydrofluoric acid at 100° for 3 hr. The results were widely scattered and did not vary systematically with any of the controlled variables (temperature, duration of decomposition, *etc.*). In subsequent experiments, this acid mixture was found to reduce V^{4+} to V^{3+} spontaneously under the conditions of the dissolution.[11] This reduction seems to be catalysed by iron, and the varied concentrations of iron in the samples (and subsequent solutions) may have been the cause for the wide scatter in the data. After this finding, the acid mixture was replaced by a 1:1 mixture of 5*M* sulphuric acid and concentrated hydrofluoric acid in all further experiments. "Blank" decompositions done with a V^{4+} or V^{3+} solution in the new acid mixture verified that no oxidation or reduction occurs as a result of redox reactions between vanadium and the acids used. Approximately 0.1–0.2 g of sample was used with 10 ml of the acid mixture. The mineral samples were completely dissolved by heating for 3 hr at 100°.

After formation of the strongly coloured vanadium thiocyanate complex, the solutions were analysed colorimetrically. This method was first proposed by Furman and Garner.[12] Crouthamel *et al.*[13] modified the method by using an acetone–water (3:2 v/v) medium. We have further modified the technique as described below, to remove the interference by ferric iron, which is present in the samples and also forms a strongly coloured thiocyanate complex. The absorbance maximum, λ_{max}, for the V^{3+}–thiocyanate complex is at 395 nm, and λ_{max} for the Fe^{3+}–thiocyanate complex is at 475 nm.

The Fe^{3+}–thiocyanate complex absorbs significantly at the λ_{max} of the V^{3+}–SCN complex. This interference may be easily removed by the addition of a small amount ($\sim$50 mg) of crystalline stannous chloride. The ferric iron is immediately reduced to the ferrous state, which has no coloured thiocyanate complex, but the V^{3+} is not affected. Any V^{4+} in solution is also unaffected during the time needed for the analysis (<1 hr after preparation of the solutions). To prove this point, V^{4+} solution was added to a test solution containing V^{3+} and stannous chloride. The absorbance was monitored for about 1 hr, and no change was detected. The absorbance of the V^{3+}–thiocyanate complex at λ_{max} for the Fe^{3+}–thiocyanate complex is minimal and automatically compensated in the procedure, since it should be identical for the reduced and unreduced solutions, and the difference between the absorbances gives the absorbance of the ferric iron complex.

The V^{3+} complex obeys Beer's law at 395 nm up to a V^{3+} concentration of $5 \times 10^{-5}M$. The ferric complex obeys Beer's law up to an Fe^{3+} concentration of $3.6 \times 10^{-5}M$. The concentration of thiocyanate is kept constant at 1.50*M*. The molar

absorptivities are 1.2×10^4 l.mole^{-1}.cm^{-1} for the V^{3+}-complex at 395 nm and 2.3×10^4 for the ferric complex at 475 nm. The limit of detection for V^{3+} is approximately $5.0 \times 10^{-7}M$, and that for Fe^{3+} is approximately $3.6 \times 10^{-7}M$. Repeated runs gave V^{3+}/V^{tot} ratios that agreed within ± 0.07. The technique was validated as described below.

Typical concentrations of V^{3+} in the sample solutions ranged from 0.2 to $4.0 \times 10^{-5}M$, and Fe^{3+} concentrations in the same solutions ranged from 0.72 to $7.2 \times 10^{-6}M$. The vanadium oxide minerals had V^{3+}/Fe^{3+} molar ratios between 2 and 7, and the vanadiferous clays had ratios close to unity.

The stoichiometry of the V^{3+}–thiocyanate complex is somewhat uncertain. Furman and Garner[12] applied Job's method and found the complex was probably 1:1, but the Job plot indicates that the complex is quite weak and does not preclude the existence of higher complexes. The ferric thiocyanate complex is 1:1, as determined by a variety of techniques.[14,15]

Validation of the procedure

Various simple experiments were run in order to show that the results are not affected by any redox reactions that occur during the decomposition or analysis. In addition, samples were analysed by the procedure developed and the results compared favourably with those of other techniques that do not require sample decomposition prior to analysis. The advantage of the technique reported here is that it does not require any exotic apparatus or expensive electronic equipment.

Three sets of experiments were performed to ascertain that no redox reactions occur during the decomposition procedure. In the first set, a solution of V^{3+} was added to the sulphuric/hydrofluoric acid mixture and heated for 3 hr at 100°; all the V^{3+} was recovered, *i.e.*, no oxidation of V^{3+} had occurred. A corresponding run with V^{4+} verified that no reduction of V^{4+} took place. Finally, in a run with V^{4+} and a known mixture of ferrous and ferric iron no V^{3+} was produced, and the initial and final ferrous/ferric ratios were identical. The samples that were to be analysed by this and other independent methods contained tervalent vanadium and iron, so there was the possibility of a redox reaction between them to produce V^{4+} and Fe^{2+}. Test runs were performed in which known amounts of Fe^{3+} or V^{3+} were added to the reaction vessel with a sample. In all cases, the additional V^{3+} or Fe^{3+} was recovered, verifying that no redox reactions occur. A possible reason for this is the formation of fluoride complexes of V^{3+} and Fe^{3+}, which would tend to inhibit any such reaction, though the fluoride present should be almost all in the protonated form at the acidity used.

The validity of the method when applied to minerals was established by analysing two standard samples and comparing the results with those of independent techniques.

The first standard was roscoelite, a vanadiferous mica, from Placerville, Colorado. Roscoelite from other localities has been reported to contain predominantly tervalent vanadium.[16–18] In the sample used in this study, 85% of the vanadium was found to be in the tervalent state. The presence of a small amount of quadrivalent vanadium was confirmed by electron spin resonance (ESR) spectroscopy, but the result was not quantitative. The V^{3+}/V^{tot} ratio (0.85) was also supported by thermogravimetric analysis (TGA). The TGA was run from 20° to 900° in two phases. The first phase was executed under an atmosphere of high-purity nitrogen. The sample was observed to lose weight as adsorbed water, structural water, and structural hydroxide ions were lost. The apparatus was then cooled, and the TGA was rerun under an oxygen atmosphere. The sample gained weight as V^{3+} was oxidized to V^{4+}, and then to V^{5+}, and as Fe^{2+} was oxidized to Fe^{3+}. After correction for the weight gain due to Fe^{2+} oxidation, the calculated V^{3+}/V^{tot} ratio was approximately 0.5. Assuming the oxygen content of the high-purity nitrogen to be 50 ppm (the maximum value specified) it was calculated that the amount of oxygen that would have flowed past the sample during the first heating period would have been sufficient to cause complete oxidation of V^{3+} to V^{5+}. Therefore, the calculated V^{3+}/V^{tot} ratio of 0.5 was taken as a minimum value, consistent with the result of the chemical determination, but somewhat inconclusive. The Fe^{3+}/Fe^{tot} ratio was found to be approximately 0.05 by our technique, near the detection limit for Fe^{3+}. This result compares favourably with the value of 0.10 found by Mössbauer spectroscopy.[19]

The second sample (TM-1) was a vanadium oxide mineral collected in the Tony M mine near Hanksville, Utah. The sample was collected as already described. The V^{3+}/V^{tot} ratio found by our method was 0.37 and the Fe^{3+}/Fe^{tot} ratio 0.75 ± 0.08. The Fe^{3+}/Fe^{tot} ratio determined by Mössbauer spectroscopy[19] was 0.75 ± 0.05. The V^{3+}/V^{tot} ratio was not checked by independent methods. The results of four replicate analyses of sample TM-1 (Table 1) are fairly close, and the Fe^{3+}/Fe^{tot} ratio agrees very well with the Mössbauer result, indicating that the analysis is reliable. Similar precision was obtained for replicate analyses of the roscoelite sample. The presence of V^{3+} and Fe^{3+} in the same sample indicates a narrow range of redox conditions that could have prevailed during formation of the Tony M orebody. Work is continuing to explore further the implications of this for the ore-forming processes.

Table 1. Replicate analyses of the vanadium oxide sample TM-1 collected in the Tony M mine

V^{3+}/V^{tot}	Fe^{3+}/Fe^{tot}	V^{tot}/Fe^{tot}
0.41	0.76	4.4
0.39	0.83	4.3
0.37	0.72	4.1
0.31	0.68	4.3

Acknowledgements—We wish to thank Dr. C. G. Whitney of the U.S. Geological Survey for help with the thermogravimetric analysis and Dr. D. L. Williamson of the Colorado School of Mines for performing the Mössbauer analysis. We also thank Mr. D. Underhill of Plateau Resources, Ltd. for permitting access to the Tony M mine. Drs. T. T. Chao and W. H. Ficklin of the U.S. Geological Survey provided excellent constructive reviews of the manuscript. Special thanks go to Dixie Termin for careful typing of the manuscript.

SORPTION AND PERMEATION BEHAVIOUR OF METAL THIOCYANATE COMPLEXES ON CELLULOSE ACETATE POLYMERS

TAKASHI HAYASHITA and MAKOTO TAKAGI
Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Higashi-ku, Fukuoka 812, Japan

(*Received* 28 *August* 1984. *Accepted* 14 *December* 1984)

Summary—Various metal thiocyanate complexes in aqueous solution were sorbed on solid cellulose acetate polymers. The sorption selectivity increased in the order $Zn^{2+} > Fe^{3+} > Cu^{2+} > Co^{2+} > Ni^{2+}$. The sorption behaviour followed a Langmuir-type adsorption isotherm, and the maximum adsorption capacity was 6.1×10^{-5} mole of complex per g of polymer under optimum conditions. The zinc species sorbed appear to be $NH_4Zn(H_2O)(SCN)_3$ or $(NH_4)_2Zn(SCN)_4$ according to analysis of the sorption equilibrium. The ion-association species formed by the complex zinc anion and the ammonium ion was supposed to be sorbed (or "extracted") onto the polymer matrix. As an application of sorption of metal complexes, a new hyperfiltration process was proposed for selective separation of metal ions. Thus, a mixture of metal thiocyanate complexes was hyperfiltered through cellulose acetate membranes. Permeation of certain metal complexes was preferred, and the selectivity was found to be similar to the sorption selectivity. These findings lead to a generalized idea that hyperfiltration separation of ionic species, particularly anionic metal complexes, can be attained by using polymer membranes which selectively adsorb or extract such ionic species as ion-association complexes onto the polymer matrix.

It is known that metal thiocyanate complexes are effectively extracted in the form of ion-association complexes into oxygen-containing organic solvents,[1,2] and this has been widely used for the separation of metals,[3] but the volatility and toxicity of organic solvents sometimes pose problems in the practical operation of the process. The sorption behaviour of solid polymers has recently been studied, and polymers such as polyurethane foam are found to be effective substitutes for organic solvents for the sorption or "extraction" of some ion-association complexes.[4,5] Several metal thiocyanate complexes are effectively extracted by solid polymers.[6–9]

Metal-selective separation by solid polymer membranes under hydraulic pressure is one of the future membrane technologies yet to be explored. To date, only a few studies have been made of this aspect,[10–13] and the sorption of ion-association complexes may be important in the development of solid membranes which selectively reject metal species or are permeated by them. The principle is that the active membrane phase acts as a "polymer solvent" for the extraction of ion-association complexes and the extracted metal species are transported through the membrane by some coupling processes with a solvent flow under hydraulic pressure. Metal species which lack affinity for the active membrane phase do not permeate it.

The aim of the present study was to examine and verify these ideas. The sorption of metal thiocyanate complexes by polymer membrane materials was studied, and the permeation selectivity of the complexes under hyperfiltration conditions is discussed in the light of the equilibrium sorption behaviour.

EXPERIMENTAL

Reagents

Cellulose acetate (acetyl content 39.8%, ASTM viscosity 3 sec), cellulose acetate butyrate (acetyl content 29.5%, butyryl content 17%, ASTM viscosity 15 sec) and cellulose acetate hydrogen phthalate were purchased from Eastman Kodak Co. Poly(ethylene glycol) succinate, poly(neopentyl glycol) succinate (for gas chromatography) and penta-acetyl-β-D-glucose were purchased from Tokyo Kasei Co. Cellulose (100–200 mesh) and poly(vinyl chloride) ($n = 1100$) were obtained from Toyo Roshi Co. and Wako Pure Chemical Co., respectively. Polyacrylonitrile was gifted by Mitsubishi Reiyon Co. All these polymers were used in powder form (finer than 50 mesh). Other reagents were reagent-grade commercial products and used without further purification.

Stock solutions of metal nitrates (in 0.1*M* nitric acid), ammonium thiocyanate and ammonium nitrate were stored in polyethylene bottles. Concentrations of metal complexes were determined by atomic-absorption spectrophotometry with a Japan Jarrel Ash Co. AA-1 instrument.

Sorption experiment

Metal thiocyanate solutions were prepared by mixing and diluting the stock solutions. An appropriate amount of polymer (2.0 g) was suspended in the solution and the mixture was shaken on a mechanical shaker for 90 min at 25°. The residual metal-ion concentration in the bulk solution was then measured by atomic-absorption spectrophotometry after centrifuging or filtering. A preliminary 3-hr study indicated that shaking for 90 min was sufficient for evaluation of the equilibrium sorption behaviour. The effect of polymer degradation (*e.g.*, by hydrolysis) was neglected. Prolonged shaking (10–15 hr) caused a small increase (~5%) in sorption, but a compromise was made between achieving complete equilibration and risking a possible structural change of the polymer matrix during an extended experiment. In addition, the 90-min equilibration data were better related to the hyperfiltration study, since

Table 1. Sorption of metal thiocyanate complexes on solid polymers*

No.	Polymer	Fe^{3+}	Co^{2+}	Ni^{2+}	Cu^{2+}§	Zn^{2+}

2	Polyacrylonitrile (PAN)	18.0	6.8	0.8	13.8	57.6
3	Cellulose (CE)	0.0	0.0	0.0	5.6	0.4
4	Poly(vinyl chloride) (PVC)	0.0	0.0	0.0	0.0	0.0
5	Penta-acetyl-β-D-glucose (PAG)	1.2	0.0	0 0	0.0	1.6

*Polymer (2.0 g, powder) was suspended in 20 ml of aqueous solution containing 0.5*M* NH_4SCN, 0.1*M* HNO_3, and 0.5m*M* $M^{II}(NO_3)_2$ or $M^{III}(NO_3)_3$.

§Prolonged contact of cupric ion with thiocyanate ion leads to the formation of cuprous species. The extent of this reaction was difficult to assess under the sorption conditions used. The solution, however, remained completely homogeneous.

the permeation data in the latter were collected in the period from 40 min to 4 hr after the membrane had been set up in the permeation cell (see below).

The sorption behaviour of the complexes were evaluated from the degree of sorption (E) and the distribution ratio (D):

$$E = \frac{[M]_i - [M]_f}{[M]_i} \times 100 \quad (1)$$

$$D = \frac{[M]_i - [M]_f}{[M]_f} \times \frac{V_w}{W_m} \quad (2)$$

where $[M]_i$ and $[M]_f$ are the initial and final metal concentrations, respectively, in the solution; V_w is the volume of solution (ml), and W_m the weight of polymer (g).

Membranes

Cellulose acetate (CA) membranes were prepared by either the casting or the coating method. The cast CA membrane was an asymmetric membrane for reverse osmosis, similar to that described earlier[11] (membrane annealing temperature 87°, membrane thickness, 36–40 μm). Coated CA membranes were prepared by dissolving 0.2 g of cellulose acetate in 40 ml of acetone, spraying the solution onto a "Fluoropore" membrane (pore-size 0.1 μm, Sumitomo Denki Co.) and drying at room temperature, the procedure being repeated until a polymer phase of appropriate thickness was formed (0.3–0.4 mg of CA per cm^2)[13]

Hyperfiltration

A batch type hyperfiltration cell of 16.6 cm^2 effective membrane area and 300 ml feed capacity (Atsuryoku Kiki Engineering Co., Tokyo) was used. The cell was specifically designed for the present purpose. It was protected from corrosion by using either Teflon or dense polyethylene as inner cell material. Permeation experiments were performed at 20 atm and 25°. Before and after each experiment, the membrane was tested for water flux with pressurized pure water, and the absence of any damage or deterioration during the experiment was confirmed.

The permeation experiments were done with 250 ml of feed solution. The first 5 ml of solution permeated were

discarded, and the second 5 ml were collected for analysis. Further fractions were usually not collected, since they were similar to the analysed fraction in composition. The permeability (P) for metal ions was defined as follows:

$$P = \frac{\text{concentration of metal ion in the permeate}}{\text{concentration of metal ion in the feed}} \quad (3)$$

RESULTS AND DISCUSSION

Sorption of metal complexes

Sorption of metal thiocyanate complexes on some typical solid polymers is summarized in Table 1. Sorption of zinc thiocyanate complexes was studied in detail for other varieties of polymer or "monomer" sorbents, and the results are summarized in Table 2. It is seen that a hydrophilic polymer such as cellulose and a hydrophobic polymer such as poly(vinyl chloride) show no sorption capabilities. Metal thiocyanate complexes are sorbed only by polymers with intermediate polarity, such as cellulose acetate and polyacrylonitrile. Cellulose acetate has by far the highest sorption capability. As metal thiocyanates are not sorbed on the monomeric sorbent penta-acetyl glucose, a polymer environment or some microstructure of the solid polymer matrix seems to be of vital importance for sorption to take place.

The degree of sorption of metal thiocyanate complexes on cellulose acetate polymer increases in the order $Zn^{2+} > Fe^{3+} > Cu^{2+} > Co^{2+} > Ni^{2+}$. Under our conditions, cobalt was not effectively sorbed. It has also been reported that cobalt(II) and iron(III) thiocyante complexes are not sorbed on polyester type polyurethane foam.[7,14] On the other hand, it is reported that polyether-type polyurethane foam successfully sorbs these complexes.[6] It is interesting that the chemical structure of the polymer material has such a subtle effect on the sorptivity of metal complexes, analogous to that in metal extraction by organic solvents of various structure and polarity.

Sorption equilibrium

Figure 1 shows the effect of thiocyanate concentration on the sorption of zinc. The degree of sorption (E) increases with thiocyanate concentration. This suggests that complexes such as $(NH_4)_{2-n}Zn(SCN)_n$ are the main species involved in the sorption.

The effect of the medium on the sorption of zinc thiocyanate complexes was studied for cellulose polymers. Addition of ethanol to the bulk aqueous solution first tended to increase the sorption, but further addition caused a strong decrease in the sorption. Thus, plots of E *vs.* ethanol content in the bulk solution show maxima at an ethanol weight fraction of about 0.20–0.25 (Fig. 2). Addition of a small amount of ethanol is considered to promote the formation of sorption-active species (lipophilic ion-association complexes) in aqueous solution. It is also expected that ethanol brings about a sort of swelling effect and increases the effective surface area of the polymer for the sorption of such metal species.

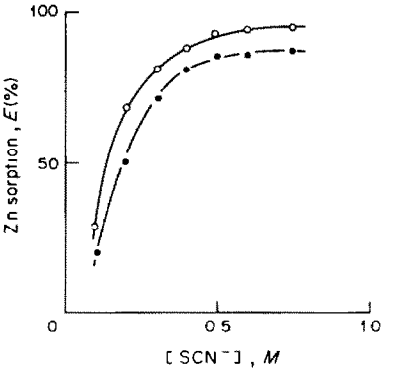

Fig. 1. Effect of thiocyanate concentration on the sorption of zinc on cellulose acetate: 20 ml of aqueous NH_4SCN–HNO_3 solution (pH 1.6) containing 0.5mM $Zn(NO_3)_2$ were used; total concentration of ammonium ion adjusted to 0.75M with NH_4NO_3. Cellulose acetate: 1.0 g (●), 2.0 g (○).

These effects seem to explain the increase in sorption (Fig. 2) when a small fraction of ethanol is added to the aqueous metal salt solution. However, excess of ethanol reduces the dielectric constant of the solution, bringing the polarities (or environments) of the bulk aqueous solution and the polymer matrix closer to each other. This in effect reduces the sorption of ion-association complexes onto the polymer matrix. This behaviour seems to be especially marked in the case of cellulose acetate butyrate.

The effect of pH on the sorption of zinc thiocyanate complexes is shown in Fig. 3. Since the solutions were not well buffered, the pH values were measured immediately after sorption equilibrium was attained. It is seen that sorption of zinc was constant in the pH range 1–6. It is known that cellulose acetate contains a small amount of carboxyl functional groups, and there is a possibility that sorption of zinc is partially due to cation-exchange at the carboxylate sites of the polymer matrix. However, the results in

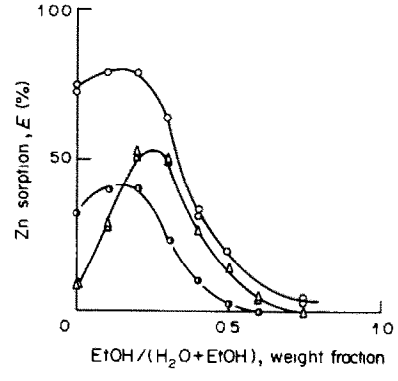

Fig. 2. Effect of ethanol content on the sorption of zinc thiocyanate complexes: 20 ml of solution containing 0.25M NH_4SCN, 25mM HCl, and 0.5mM $Zn(NO_3)_2$ were used. Polymers: cellulose acetate, 0.5 g (◑), 2.0 g (○); cellulose acetate butyrate, 2.0 g (△).

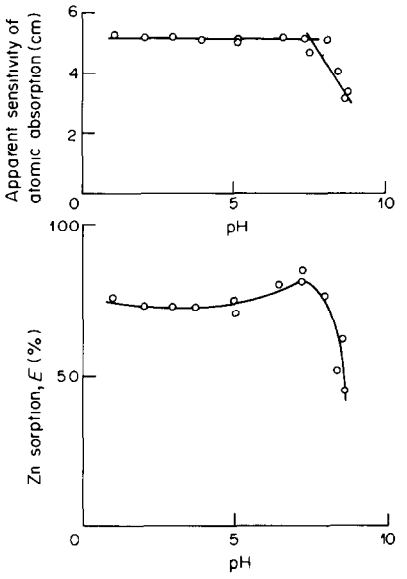

Fig. 3. Effect of pH on the sorption of zinc thiocyanate complexes; 20 ml of 0.25*M* NH_4SCN solution containing 0.5m*M* $Zn(NO_3)_2$ were used. The pH was altered by adding HCl or KOH. The amount of cellullose acetate was 2.0 g. The apparent sensitivity (peak height) of atomic absorption for 0.5m*M* $Zn(NO_3)_2$ in 0.25*M* NH_4SCN solution is shown in the upper figure as a function of pH.

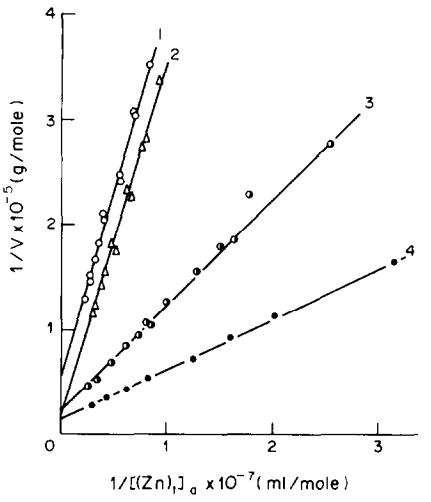

Fig. 4. Langmuir plots for the sorption of zinc thiocyanate complexes on cellulose acetate; 20 ml of solution containing $Zn(NO_3)_2$ in various concentrations were shaken with 0.5–2.0 g of cellulose acetate. The solution contained NH_4SCN in concentrations of 0.25*M* (1, ○), 0.25*M* (2, △; 25 wt% EtOH), 0.50*M* (3, ◑), and 0.75*M* (4, ●).

Fig. 3 indicate that the contribution from the ion-exchange mechanisms is negligible. The decrease in zinc sorption at pH > 7.5 was found to be due to hydrolysis of the metal ions in the bulk solution. This is also experimentally reflected in the decrease of sensitivity in the atomic-absorption measurements (Fig. 3).

Langmuir-type adsorption isotherm

When (*i*) there is no interaction between the sorbed species, (*ii*) the polymer "surface" is homogeneous and has the same sorption characteristics, and (*iii*) only monolayer sorption takes place, the sorption of metal thiocyanate complexes should follow a Langmuir-type adsorption isotherm:

$$\frac{1}{A} = \frac{1}{K_d A_M [(NH_4)_{n-2}M(SCN)_n]_a} + \frac{1}{A_M} \qquad (4)$$

where K_d is the equilibrium constant for adsorption of metal complexes from the bulk solution onto the polymer surface, A is the amount of metal species adsorbed (mole/g), and A_M the maximum adsorption capacity (mole/g). The sorbed species are assumed to have the compositions $(NH_4)_{n-2}M(SCN)_n$ (M is a bivalent metal; $n = 2$–4; co-ordinated or solvation water molecules are not shown).

When the concentration of ammonium thiocyanate in the bulk solution is kept constant, the concentration of complexed species is proportional to the total concentration of metal ion in solution. Thus,

$$[(NH_4)_{n-2}M(SCN)_n]_a = \alpha_n[(M)_t]_a \qquad (5)$$

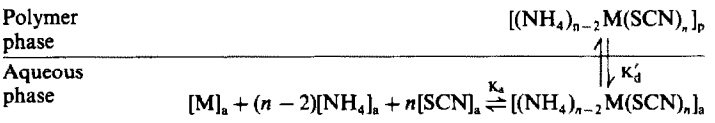
where $[(M)_t]_a$ is the total concentration of metal and α_n is a conditional proportionality constant for the nth species. Substitution of equation (5) into equation (4) gives equation (6). Plots of $1/A$ *vs.* $1/[(M)_t]_a$ should be linear if a Langmuir-type isotherm is followed (*e.g.*, Fig. 4).

$$\frac{1}{A} = \frac{1}{\alpha_n K_d A_M [(M)_t]_a} + \frac{1}{A_M} \qquad (6)$$

Though the slopes and the intercepts varied with conditions, the plots were all linear within experimental error. The values of $\alpha_n K_d$ and A_M obtained from the plots are listed in Table 3. Increasing the ammonium thiocyanate concentration increases the A_M values (Nos. 1, 3, 4). The A_M value also increases when ethanol is added (Nos. 1, 2). This change is considered to be related to the change in aggregation of the polymer chains at the surface of cellulose

Table 3. Parameters of Langmuir plots for the sorption of zinc thiocyanate complexes on cellulose acetate

No.	$[NH_4SCN]$, M	[EtOH], *wt*%	$\alpha_n K_d \times 10^{-6}$	A_M 10^{-5} *mole/g*
1	0.25	0	1.6	1.9
2	0.25	25	0.5	5.7
3	0.50	0	2.3	4.4
4	0.75	0	3.5	6.1



Scheme I. Sorption equilibrium of metal thiocyanate complexes

acetate. Increase in ammonium thiocyanate concentration also leads to increased $\alpha_n K_d$ values. This effect is most probably related to increase in α_n rather than in K_d since formation of the ion-association complexes is favoured by higher thiocyanate concentrations.

Mechanism of sorption

Scheme I shows a simplified expression of the sorption equilibrium, where the sorbent polymer is supposed to be present in sufficient excess for sorption to take place. The sorption and association constants, K'_d and K_a, respectively, are defined in the following equations, where the suffixes p and a refer to the polymer and aqueous phases, respectively:

$$K'_d = [(NH_4)_{n-2}M(SCN)_n]_p/[(NH_4)_{n-2}M(SCN)_n]_a \quad (7)$$

$$K_a = [(NH_4)_{n-2}M(SCN)_n]_a/[M]_a[NH_4]_a^{n-2}[SCN]_a^n \quad (8)$$

The metal distribution ratio (D') and the stepwise metal complex formation constants in aqueous solution are defined conventionally as follows:

$$D' = [(NH_4)_{n-2}M(SCN)_n]_p/[(M)_t]_a \quad (9)$$

$$M(SCN)_{n-1} + SCN \rightleftharpoons M(SCN)_n$$

$$K_n = [M(SCN)_n]/[M(SCN)_{n-1}][SCN] \quad (10)$$

(charges are omitted for simplicity). The concentration of free metal ion in aqueous solution is written as

$$[M]_a = [(M)_t]_a/\beta \quad (11)$$

where

$$\beta = 1 + K_1[SCN] + K_1K_2[SCN]^2 + \ldots + K_1K_2\ldots K_n[SCN]^n \quad (12)$$

Appropriate substitution and rearrangement leads to

$$\beta D' = K'_d K_a [NH_4]_a^{n-2}[SCN]_a^n \quad (13)$$

When ammonium and thiocyanate ions are present in large excess, *i.e.*, $[(NH_4)_t]_a$, $[(SCN)_t]_a \gg [(M)_t]_a$, equation (13) is more conveniently expressed as

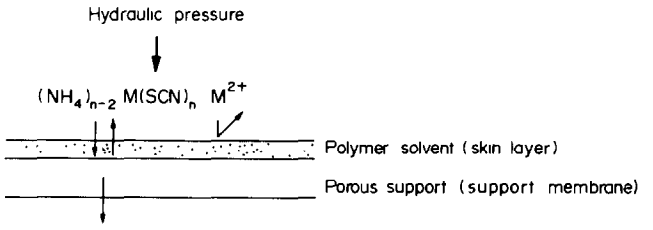
$$\log\beta D' = (n-2)\log[(NH_4)_t]_a + n\log[(SCN)_t]_a + \log K'_d K_a \quad (14)$$

Equation (14) indicates that the co-ordination number n can be determined from log–log plots of $\beta D'$ *vs.* thiocyanate concentration. The plot for zinc thiocyanate sorption is linear with a slope of $n = 3.5$.[15] Thus, $NH_4Zn(SCN)_3$ or $(NH_4)_2Zn(SCN)_4$ (or a mixture of the two) seems to be the main sorption species. This result also verifies that the sorption of zinc thiocyanate complexes occurs by sorption of the ion-association complex on the polymer matrix.

The uptake of the ion-association complex by the solid polymer may be considered as due to stabilization of either the cationic or the anionic part of the complex through some specific interaction with the polymer matrix. Hamon *et al.* recently proposed the "cation chelation mechanism" in extraction with polyether-type polyurethane foam, where a counter-cation-selective extraction of metal thiocyanate complexes was observed.[16] This was a particular case in which a cation–matrix interaction (polyether oxygens atoms acting as electron-donors to cations) dominated. However, the sorption of a neutral complex such as $M(SCN)_2$ could occur, depending on experimental conditions, as reported elsewhere.[9,17]

In the present sorption study, specific interaction (in the sense above) between the ammonium ion and the cellulose acetate is yet to be investigated. However, such sophisticated considerations may not be needed here. According to the established principles of conventional ion-pair extraction,[3] a change in the ionic components or extraction solvents exercises a considerable effect on the extraction behaviour because of the difference in the lipophilicity of the ions or the difference in ion–solvent interaction. In this sense, the polymer surface may well be deemed a pseudo-solvent, and the sorption is a solvent extraction which uses the polymer as solvent. It would be pertinent to note in this connection that the Langmuir isotherm cannot be a critical basis for discriminating between sorption (or adsorption) phenomena and conventional solvent extraction equilibria, in the present type of study. An adsorption study is usually made under conditions where the loading of sorbed species on the surface is relatively high and the saturation effect has to be taken into account in terms of the Langmuir isotherm. If the adsorption conditions are such that only a small fraction of the surface is covered by the sorbed species (*i.e.*, the saturation effect is unimportant), the Langmuir isotherm can effectively be replaced by the Nernst distribution law, on the basis of which conventional extraction equilibria are formulated. Thus, under low-loading conditions, equilibria of sorption on polymer matrix may well be treated in the same manner as those of extraction by an organic solvent.

The actual nature of the "polymer solvent" depends not only on the chemical structure of the monomer unit of the polymer but also on the state of aggregation of the polymer chain, which may be



Scheme II. Selective permeation of metal species on the basis of ion-association extraction.

classified in a simplified manner into crystalline and amorphous. It would be reasonable to suppose that the amorphous region is the site responsible for extraction of the ion-association complex. Tables 1 and 2 show that cellulose acetate is an effective sorbent whereas the chemically related penta-acetyl-β-*D*-glucose is not. The latter forms a well-defined crystalline solid, and the lack of an amorphous polymeric region is certainly the cause of its poor extraction capability.

A change in the particle size of the sorbent material had little effect on the results in Table 1 and 2. This suggests that the sorption is related not to the apparent macrosurface obtained by simple physical grinding but to the microsurface or microstructure of the polymer material. The importance of the polymer microstructure for the sorption of lipophilic chemical species has also been exemplified by studying the sorption behaviour of organic dyes in aqueous solution on asymmetric polysulphone ultrafiltration membranes.[18] The sorption obeyed the Langmuir isotherm, and took place preferentially on the "active side" or "skin layer" of the membrane.

Hyperfiltration

As an application of the idea of ion-association extraction by solid polymers, selective hyperfiltration

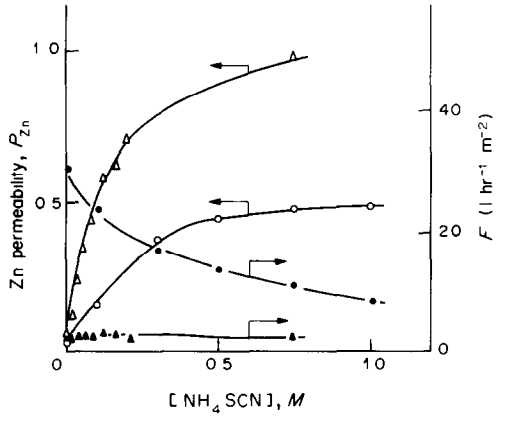


Fig. 5. Permeation of zinc thiocyanate complexes through cellulose acetate membranes; coated (△, ▲) and cast (○, ●); cellulose acetate membranes; feed solution, 250 ml of NH_4SCN–HCl solution (pH 2.0) containing 1 m*M* $Zn(NO_3)_2$; applied pressure, 20 atm at 25°C. P_{Zn}, permeability of zinc ion; *F*, flux of permeate solution.

separation of metal species in solution may be envisaged as taking place according to Scheme II. Therefore, cellulose acetate membranes were prepared by the casting or the coating method, and the permeation behaviour of the metal thiocyanate complexes under hydraulic pressure was investigated.

The effect of ammonium thiocyanate concentration on the permeation by zinc is shown in Fig. 5. The permeability increases with the increase in thiocyanate concentration. Such behaviour is particularly pronounced for coated membranes, which have effectively a much thicker polymer solvent phase than the cast membranes. This is also reflected in the lower permeation flux for coated membranes. A comparison experiment with the uncoated support material showed that there was no sorption on the support.

Permeability of metal thiocyanate complexes was also investigated in two-component systems by using zinc as the reference ion (Table 4). Selective permeation by metal thiocyanate complexes was observed, with permselectivity in the order $Zn^{2+} > Cu^{2+} > Fe^{3+} > Co^{2+} > Ni^{2+}$. It should be noted that the permselectivity is the same as that obtained for sorption experiments, except for copper (for which there is some ambiguity about the complex species in solution; see footnote to Table 1). This strongly indicates that selective separation of ionic solutes by hyperfiltration is made possible by use of the principle of ion-association extraction by solid polymers.

Finally, it is to be added that the mechanism of permeation of solutes is not fully elucidated by the present study. Not only the sorption on the mem-

brane matrix but also the coupling with solvent flow through the membrane seem to be contributory factors. The nature of the permeation process is now under study.

Conclusion

Transition-metal thiocyanate complexes [Fe(III), Co(II), Ni(II), Cu(II), Zn(II)] in aqueous solution are sorbed on various solid polymers. Polymers with relatively high polarity, particularly cellulose acetate, are effective sorbents. The sorption involves ion-association complexes formed between cations (ammonium ion) and anionic metal thiocyanate complexes. The process is well described as ion-association extraction by "polymer solvents". Such a polymer solvent is useful not only as a substitute for conventional extraction solvents but also as basic material for preparing ion-selective separation membranes. Lamination of the polymer into hyperfiltration-type membranes is useful for such purposes. The metal permeation selectively follows essentially the metal sorption selectivity on the polymer material. These findings open a new prospect for developing metal-selective hyperfiltration membranes for separating metals in solution.

POLAROGRAPHIC DETERMINATION OF ZIRCONIUM AT TRACE LEVEL

Y. CASTRILLEJO, R. PARDO, E. BARRADO and
P. SANCHEZ BATANERO
Departamento de Química Analítica, Facultad de Ciencias, Universidad de Valladolid, Valladolid, Spain

(*Received* 16 *August* 1984. *Revised* 13 *November* 1984. *Accepted* 12 *December* 1984)

Summary—An indirect polarographic method has been developed for the determination of zirconium by formation of molybdozirconophosphoric acid, its extraction with MIBK or a mixture of diethyl ether and 1-butanol, stripping with alkali and measurement of the Mo(VI) by its catalytic effect on the polarographic reduction of hydrogen peroxide. Depending on the extractant, a detection limit of 2.5 or 8.9 μg/l. can be achieved.

Zirconium is a non-electroactive element which gives refractory oxides, so a determination based on its direct reduction is not possible, and the AAS methods, when used at trace level, achieve poor results.[1] Until the advent of the spectroscopic methods with plasma source, which give lower zirconium detection limits,[2] the only possibility for determining zirconium at trace level was by spectrophotometric measurement of zirconium complexes with organic[3,4] or inorganic[5,6] reagents. The detection limits of these methods all are around 1 mg/ml.

Electrochemical determination of zirconium is only possible by means of an indirect procedure, as proposed by Harto and Sánchez Batanero,[7] who used stripping and coulometric techniques, or by Ye Hua-Li and He You-Hua, based on the adsorption polarographic wave of a Zr–oxalic acid–cupferron–diphenylguanidine complex.[8]

In this paper we describe an indirect method based on formation of molybdozirconophosphoric acid (MZrPA), its extraction with an organic solvent, stripping with alkali and determination of the resulting Mo(VI) by means of its catalytic effect on the polarographic reduction of hydrogen peroxide.[9] The method is thus a variant of that used earlier for the indirect determination of phosphorus.[10] The detection limit for the zirconium determination is significantly lowered because of the combination of release of 11 molybdenum atoms per zirconium atom in the MPZrA, and the sensitive Mo(VI) determination used. We have obtained a detection limit of 2.5 μg/l., very similar to that of the plasma techniques.

Because the Mo(VI) determination is non-specific with respect to parent molybdenum species, it is necessary to remove all these except the MZrPA before the stripping step. This is done by selective extraction of the molybdophosphoric acid (MPA) with ethyl acetate, followed by selective extraction of the MZrPA, the isopolymolybdic acid(s) being left in the aqueous phase. The molybdenum in the MZrPA can then be stripped with alkali and determined polarographically. Because of the number of conditions to be optimized a simplex technique[11–15] was preferred to the more tedious classical approach.

The optimized procedure has been applied to a certified zirconium-containing aluminium sample with good results.

EXPERIMENTAL

Apparatus

A Radiometer PO4d polarographic analyser was used with a dropping mercury electrode and a saturated calomel reference electrode. The sweep rate was 100 mV/min and deaeration of the test solution was not required. The temperature was controlled by using a double-wall polarographic cell and a Selecta thermoregulator.

Reagents

Molybdate solution, 0.1 M. Dissolve 24.20 g of sodium molybdate dihydrate in 1 litre of water.

Phosphate solution, 2.0×10^{-3} M. Dissolve 0.240 g of sodium dihydrogen phosphate in 1 litre of water.

Standard zirconium solution 1.00×10^{-2} M. Dissolve 2.86 g of zirconium oxychloride hexahydrate, dried at 110°, in 1 litre of 2*M* perchloric acid. Prepare less concentrated solutions by dilution.

All reagents were of analytical grade and demineralized water was used throughout.

Procedures

Standardization of zirconium solution. Adjust an aliquot to contain about 10% of sulphuric acid by volume. Add a 50-fold excess of 10% diammonium hydrogen phosphate solution and readjust the acidity to 10% acid content, adding 1 ml of concentrated sulphuric acid per ml of phosphate solution added. Digest the precipitate at 45° for 3 hr. Filter off the precipitate on an ashless paper and wash it with cold 5% ammonium nitrate solution until the washings are free from phosphate. Dry and ignite to ZrP_2O_7 in a platinum crucible at 1000°, cool and weigh.

Zirconium determination. Transfer 1 ml of 0.1*M* molybdate, 2 ml of 2×10^{-3}*M* phosphate and 1.3 ml of 60% perchloric acid into a separating funnel. Add a known volume of the zirconium sample and dilute with water to 25 ml. Add 25 ml of ethyl acetate, shake the mixture for 3 min and remove the organic phase 20 min later. If diethyl ether–1-butanol (2:1 v/v) mixture is used for the MZrPA extraction, shake the aqueous phase with 15 ml of it for 3 min, remove the aqueous layer 20 min later, wash the organic phase with three 10-ml portions of 0.5*M* perchloric

†"$n + 1$" rule[11] violated; point re-evaluated and mean value taken.

acid, shaking for 3 min each time, to remove any isopolymolybdic acid(s), then strip Mo(VI) from the organic phase by shaking it for 1 min with 25 ml of $1M$ sodium hydroxide. If methyl isobutyl ketone (MIBK) is used as the extractant for the MZrPA, add 5 ml of 60% perchloric acid to the aqueous phase from the ethyl acetate extraction, shake it with 15 ml of MIBK for 3 min, remove the aqueous phase 20 min later, wash the organic layer with two 10-ml portions of $2M$ perchloric acid, then strip the Mo(VI) as before.

Acidify the alkaline solution containing the stripped molybdenum to pH 2.5 with $4M$ sulphuric acid, then add 2.5 ml of $4M$ sulphuric acid and 5 ml of $0.2M$ hydrogen peroxide and dilute to volume in a 50-ml standard flask with water. Transfer an aliquot of this solution into the polarographic cell and run a d.c. polarogram between 0.40 and 0.00 V (*vs.* SCE). Deaeration is not required but the temperature must be kept constant ($25.0 \pm 0.1°$). Measure the current at 0.20 V and a run a blank solution through the whole procedure. Find the zirconium concentration of the sample from a calibration graph constructed by use of standard zirconium solutions under the same conditions.

Analysis of aluminium samples. Place a 0.5-g sample, accurately weighed, in a Teflon bomb with 3 ml of concentrated nitric acid, 2 ml of concentrated hydrofluoric acid and 1 ml of 30% hydrogen peroxide. Tightly seal the bomb and heat it at 100° for 15 min. After cooling, transfer the sample solution into a platinum crucible and evaporate it to dryness; add 2 ml of 60% perchloric acid and evaporate to fumes, repeating this step at least 5 times to ensure removal of all silicon and fluoride. Dissolve the residue in water adding the necessary perchloric acid amount to ensure its complete dissolution and make up to known volume. Adjust the pH of an aliquot with sodium hydroxide to pH 3 and analyse the solution by the procedure above, with MIBK as extractant for the MPZrA.

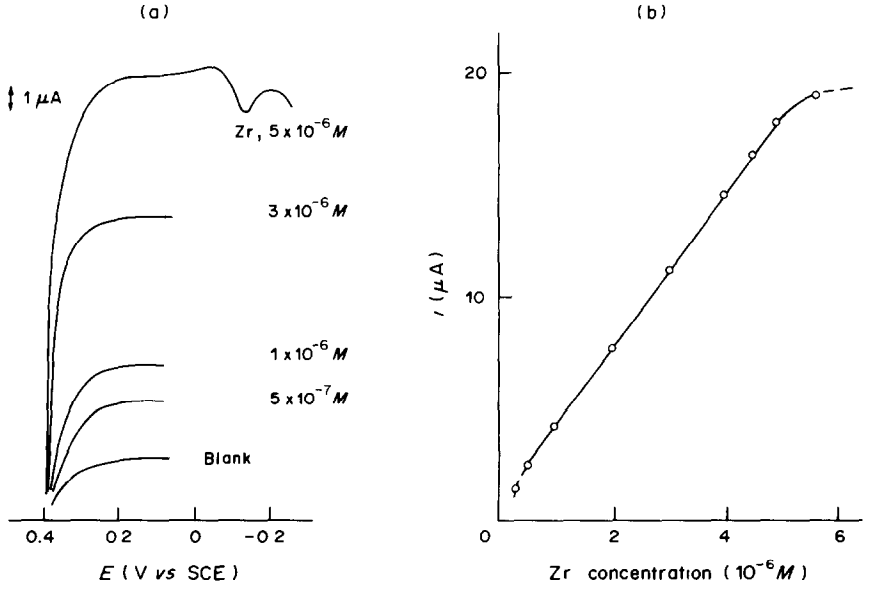

Fig. 1. Calibration graph for zirconium determined by using the 2:1 v/v diethyl ether–1-butanol mixture as extractant. (a) Polarograms; (b) calibration line.

RESULTS AND DISCUSSION

The experimental conditions to be optimized are (*a*) the pH, molybdate and phosphate concentrations, order of addition of the reagents and the reaction time for formation of MZrPA, (*b*) the solvent and pH for extracting the MPA, (*c*) the solvent and acidity for extracting the MZrPA, and the washing sequence for removal of isopolymolybdic acid(s), (*d*) stripping of Mo(VI) from the MZrPA and its polarographic determination.

The conditions for steps (*b*) and (*d*) have already been optimized and reported[10] so details need not be repeated here. The extractants for the MZrPA were chosen after a literature search and some preliminary spectrophotometric studies. Johnson *et al.*[16] concluded that ternary molybdophosphoric acids are best extracted with mixtures of oxygen-containing solvents, for example diethyl ether, mixed with aliphatic alcohols such as 1-butanol, 3-methylbutanol or 1-pentanol. Our previous work indicated that MIBK would also be suitable, so we selected 2:1 v:v diethyl ether–1-butanol mixture and MIBK for the purpose.

Although most of the conditions needed were already known, so many still needed to be optimized that a simplex method was used for economy of effort.

Simplex optimization was first proposed by Spendley *et al.*[11] and later modified by Nelder and Mead[12] and Routh *et al.*[13] These methods, usually referred to as Simplex, Modified Simplex (MS) and Super Modified Simplex (SMS) respectively, involve the movement of a simplex [an $(n + 1)$-point geometrical figure] through n-dimensional space, n being the number of experimental factors involved in the system studied. Each corner of the simplex (called a vertex) represents a different combination of the experimental factors and therefore gives a different response. The goal is to maximize (or minimize in some cases) the response, and some simple rules (depending on the variety of simplex) are used to move from regions of poor response towards regions of improved response and eventually to an optimum. We used the SMS variety.[13]

The response to be optimized was the ratio of net signal to blank signal for the currents obtained in the measurement step. The blank is due to any zirconium in the reagents and to any non-zirconium-containing molybdenum species that escape separation from the MZrPA, and must be corrected for. The order of addition of the reagents, and the reaction times were known from previous work so only the amounts of phosphate and molybdate (expressed as ml of reagent solution) and the acidity (expressed as ml of 60% perchloric acid) for formation of MZrPA needed optimization. To simplify the overall procedure, the two extractions were done at the acidity used for formation of the MZrPA, and the same acidity was used for washing the MZrPA extract.

The experimental procedure was similar to that given in the experimental section, with appropriate variations in the amounts of reagents added. Table 1 shows the progress of the optimization for the mixed solvent system. The optimization was stopped at simplex no. 10 because at this stage all the vertices retained had a similar amount of perchloric acid and a molar ratio of about 50:1 for Mo:P. An attempt to improve the response by varying the acidity for step (*c*) produced no advantage. For simplicity, the conditions chosen were the ones corresponding to vertex no. 1. Figure 1 shows a calibration graph obtained for zirconium under these conditions, together with the polarograms recorded. The linear range was from $5.0 \times 10^{-7} M$ (46 μg/l.) to $5.0 \times 10^{-6} M$ (466 μg/l.). The sensitivity was 3.28 A.l.mole^{-1} and the calculated detection limit 8.9 μg/l. The mean recovery of zirconium in the whole procedure was only $40 \pm 4\%$. Although this low value is compensated for by running the standards through the whole procedure, we also studied the use of MIBK as extractant, but not by simplex optimization. The conditions for the mixed extractant system were tried first but also gave very poor recovery. It was found that the recovery could be increased to $81 \pm 2\%$ by adding 5 ml more 60% perchloric acid before the extraction, as described in the procedure. The calibration graph obtained was linear from $1.0 \times 10^{-7} M$ (9 μg/l.) to $1.3 \times 10^{-6} M$ (120 μg/l.). The sensitivity was 9.6 A.l.mole^{-1} and the calculated detection limit 2.5 μg/l. MIBK was therefore used in all subsequent studies.

Interference may be expected from all those elements which give binary and/or ternary heteropolymolybdic acids and therefore, if they accompanied MZrPA throughout, could increase the final Mo(VI) concentration, giving a positive error. The determination of zirconium can only be made selective by choice of conditions and not by choice of organic solvent, since all those commonly used for these systems can extract all the isopoly and heteropolymolybdic acid species to some extent. The method (with MIBK as extractant) was therefore applied to solutions containing arsenic, silicon, germanium, vanadium, thorium and titanium. Table 2

shows the tolerance limits, expressed as maximum concentration and element/zirconium molar ratio allowed in "real samples".

As zirconium is often determined in metallic samples, the study was extended to metals likely to be present in such samples, and also to several anions to cover various methods of sample dissolution. Of the metals, only iron(III) gives interference, but this can be eliminated by initial reduction to iron(II) with hydroxylamine hydrochloride.[10] No interference by anions was found except for fluoride and sulphate, which produce negative errors by complexation of zirconium, and must be absent.

PRACTICAL APPLICATIONS

The recommended MIBK procedure was applied to determination of zirconium in a certified aluminium sample. The certified value of zirconium is 0.02% and all the interfering elements were at levels below their tolerance limits, except for silicon, which was removed as indicated in the experimental section. The result obtained was $0.0204 \pm 0.0002\%$ (mean of 5 determinations, 95% confidence level), which confirms the validity of the procedure. The sensitivity is greater than that of previous methods for determination of zirconium.

(*Received* 5 *October* 1984. *Accepted* 12 *December* 1984)

Summary—A simple, inexpensive, fully automated spectrophotometric system for flow-injection pseudotitrations is used to perform acid–base, redox, complexometric and catalytic "titrations". Peak widths (in time units) in the range 10–100 sec can be measured with a precision of better than 0.3% in most cases. Strong and weak acids in the range 5.0×10^{-4}–$1.0 \times 10^{-2}M$ are measured by using sodium hydroxide–Bromothymol Blue "titrant". Ascorbic acid (1×10^{-4}–$1 \times 10^{-2}M$) is "titrated" with 2,6-dichlorophenolindophenol, and calcium (5.0×10^{-4}–$5.0 \times 10^{-2}M$) with EDTA, with calmagite as indicator in the presence of magnesium. Aminopolycarboxylic acids (5×10^{-6}–$1 \times 10^{-2}M$) are measured by use of catalytic indication based on the manganese-catalysed periodate–diethylaniline reaction. The ascorbic acid method has been applied to analysis of pharmaceutical preparations, and the calcium method to water analysis.

Since its introduction in 1975,[1,2] flow-injection analysis (FIA) has aroused considerable interest amongst analysts developing high-speed routine analytical methods in various fields.[3–7] During the rapid evolution of the new approach, in only a few years, many classical techniques used in the batch mode of analysis have been adapted to the continuous mode using FIA.

The FIA titration technique is attractive and has been studied and used in several applications.[8–20] One important difference between flow-injection pseudotitrations and other FIA procedures is the use of peak width rather than peak height as the analytical measurement. As shown by Růžička *et al.*,[8] the peak width measured in time units is linearly related to the logarithm of the analyte concentration:

$$\Delta t_{eq} = k_1 \ln \frac{C_a^0}{C_t^0} + k_2$$

where Δt_{eq} is the "equivalence" time for pseudotitration, C_a^0 the original concentration of analyte, C_t^0 the original concentration of titrant, and k_1 and k_2 are constants of the FIA system used. When peak width is used as the parameter to be measured, a large dispersion of the injected sample in the carrier-reagent stream is advantageous for increasing precision. This is achieved by placing a mixer between the sample injector and the detector. However, it has recently been suggested that the mixer is not necessary. The dispersion of the sample during its movement through the tubular reactor provides a mixing stage which is capable of serving the same function as the mixing chamber.

Pardue and Fields[21] have discussed in great detail various continuous-flow pseudotitrations and suggested that very dilute carrier solutions (or even a pure water stream) should be used in order to increase sensitivity. They also emphasized the variable-time kinetic view of this procedure and suggested that it is most accurately described as a "kinetic titration". The term FIA titration or pseudotitration[19] is widely used, however.

Stewart and Rosenfeld[18] pointed out that FIA titrations are part of a more general approach in unsegmented flow systems, where exponential dilution chambers are used for scale expansion in FIA.

Spectrophotometry is the most used detection technique in FIA titrations because of the large number of visual indicators available for neutralization, complexometric and redox titrations. Potentiometry with glass and ion-selective electrodes[21] has also been used.

The most serious drawback in FIA titration is the logarithmic relation between the time interval measured and the analyte concentration. Highly accurate and precise measurements of time are required, in conjunction with high precision of the flow-rate and the sampling.

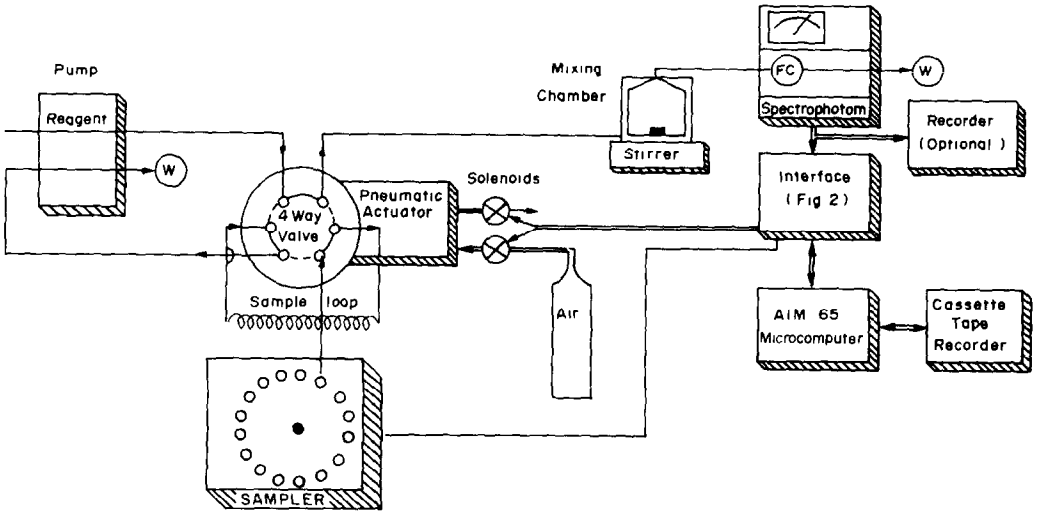

Fig. 1. Schematic diagram of the automated flow injection pseudotitration system.

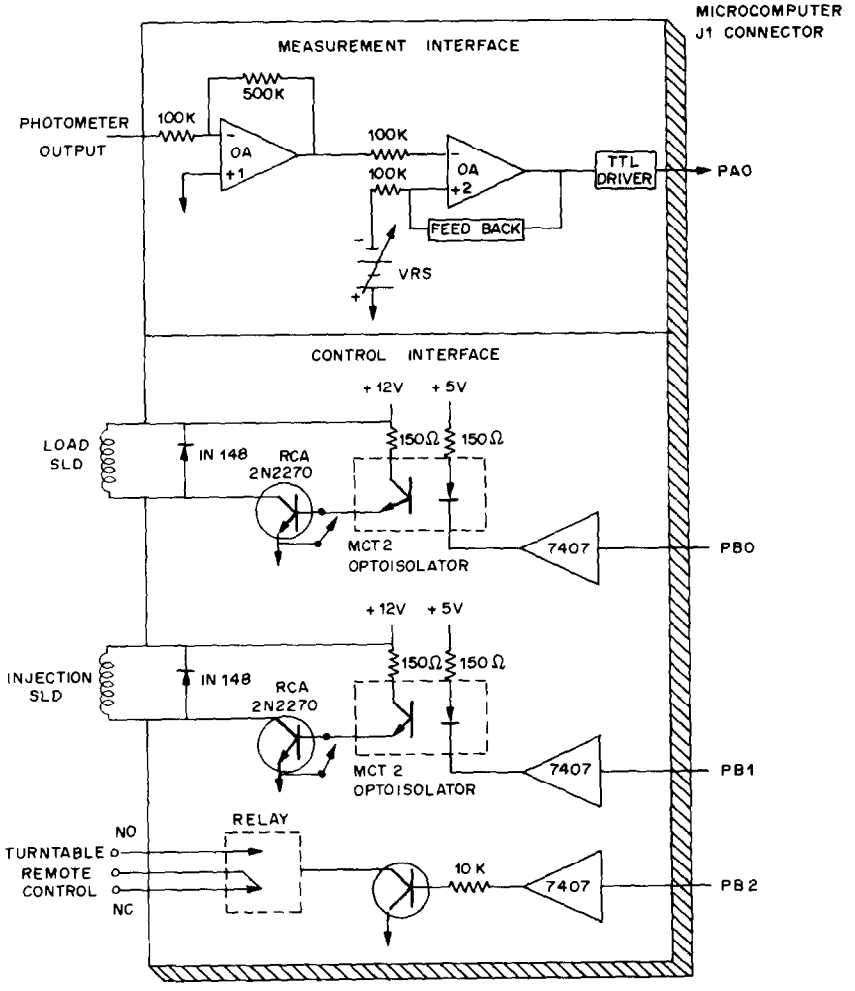

Fig. 2. Diagram of the measurement and control interface.

Microcomputers[17,18,23] and an electronic system[22] have been used to increase the precision of the measurement step. In this paper, we demonstrate the flexibility of the technique, and develop automated pseudotitrimetric acid–base, redox and complexometric determinations. The usefulness of the new concept is shown in "titrations" where secondary reactions are involved, such as the catalytic indicator reaction in aminopolycarboxylic acid determination. A simple, inexpensive, fully automated spectrophotometric system is used, based on an AIM 65 microcomputer to control all the steps—sampling, injection, time measurement and calculation.

EXPERIMENTAL

Apparatus

A block diagram of the automated system used (which is similar to previously reported systems[17,19]) is shown in Fig. 1.

The sample injection system consists of a 4-way Teflon rotary valve (Rheodyne Type 50) operated by a pneumatic two-position actuator (Rheodyne model 5001). An optional sampler (Hook and Tucker, England, model A40, modified for automatic control) is used for fully automated operation. A 1-ml capacity mixing chamber made from Plexiglas is used for sample dispersion, and the reaction and mixing coils are made from Teflon tubing, 0.8 mm bore.

The spectrophotometer used is the inexpensive Bausch and Lomb Spectronic 21 model, incorporating an 18-μl flow-cell with a 10-mm light-path. The spectrophotometer output signal [1.000 V for 100% transmittance (T)] is fed to the microcomputer interface and to an optional chart-recorder.

The microcomputer used is the Rockwell AIM 65, with visual display and a thermal printer. Input/output operations are performed through an on-board peripheral chip, the R6522 Versatile Interface Adapter (VIA) containing two 8-bit parallel I/O ports [port A (PA) and port B (PB)]. Programs are written in Basic, as a series of subroutines performing selected tasks and stored in a tape-recorder cassette.

The control and measurement interface is shown in Fig. 2. It was built with the Analog-Digital Designer[24] (E & L Instruments, model ADD 8000) provided with various useful and versatile circuit cards, power supplies and a voltage reference source (VRS). The control interface consists of two identical circuits which control the load and injection solenoids associated with the pneumatic actuator. The two control signals (low output), *load* and *injection*, are provided from outputs PB0 and PB1. The modified sampler is controlled by output PB2.

The measurement interface consists of two operational amplifiers. OA 1, acting as an inverter, amplifies the photometer output fivefold. The amplified signal (-5 V for 100% T) is then fed to OA 2 which acts as a comparator with positive feedback to avoid oscillation of the operational amplifier output, caused by transient signals in the transition region. By use of the feedback signal, the comparison voltage is divided at the amplifier input by a factor of two. In order to start the measurement at one preselected $\%T$ level, the VRS comparison voltage is set to the value calculated from the equation:

$$V_{ref} = \frac{-5 \times 2 \times \%T}{100}$$

The comparator output is fed to the PA0 input of the microcomputer. This input is high during the measurement time for pseudotitrations in which the transmittance increases, and low for those in which the transmittance decreases.

Software and system operation

The interactive routine program, written in Basic, is capable of running a series of standards and samples without attention by the operator. A selected number of standards are run, after which a complete least-squares analysis of the data is performed. This calibration curve is then used for determination of the analyte in any sample that is subsequently measured. Initially the operator provides the measurement parameters for the standards and samples that follow. The injection time (varied from 1 to 5 sec, depending on the sample volume and the flow-rate), the load time (required for the washing out of the previous sample), the number of standards and samples, the number of runs per standard and sample, and the standard concentrations are required. The direction of the titration peaks (increasing or decreasing transmittance) is also provided to the program so that it can select the appropriate statements in the measurement subroutine. After calibration of the spectrophotometer and stabilization of the base-line, a manual injection is used to select the appropriate transmittance level for triggering the time-measurement step. Half peak-height was found to be the optimum.

After each injection the program passes to the time-measurement subroutine, waiting for the transmittance to increase or decrease to the preselected trigger level, and making the PA0 input high or low respectively. The timing procedure is accurate to 0.01 sec, as tested by using a square-wave signal generator. After the "equivalence" time measurement and printing, the program waits for a preselected "load" time to ensure complete washing of the flow system before injection of the next sample. This time, 5–30 sec, depends on the sample size and the flow-rate.

EVALUATION OF THE SYSTEM

The automated system has been evaluated with typical neutralization, redox and complexometric determinations, along with determinations requiring secondary reactions such as catalytic titrations with end-point indication reactions.

Neutralization titrations

The model system chosen was the titration of hydrochloric acid with $1 \times 10^{-4}M$ sodium hydroxide, with Bromothymol Blue as indicator, added directly to the sodium hydroxide carrier stream (at a level of $8 \times 10^{-5}M$). As the carrier is blue, the detector, set at 600 nm, provides a steady base-line at 8% transmittance level. During each pseudotitration the indicator goes through two transitions (blue–yellow–blue), resulting in a peak, the width of which increases with the concentration of the acid injected. Once the indicator has turned either completely blue or yellow, the detector reaches a limiting level, and therefore all the recorded curves have a common base-line as well as a common top level, regardless of the concentration of the acid titrated. In the experiment described, a transmittance level of 50% was chosen as the triggering level, corresponding to about half the peak height.

The reagent was stored in a well-stoppered polyethylene flask provided with an Ascarite-filled guard-tube to prevent absorption of carbon dioxide from the air. A pumping rate of 5.0 ml/min was found to

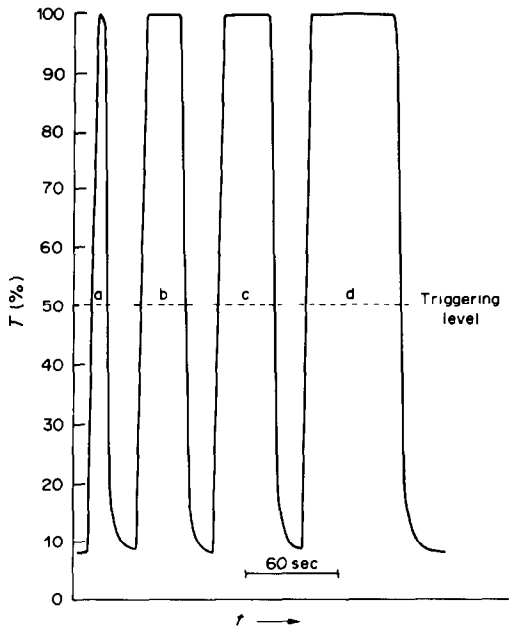

Fig. 3. Flow-injection pseudotitration curves for HCl. Carrier reagent: NaOH $1 \times 10^{-4}M$, Bromothymol Blue $8 \times 10^{-5}M$. Flow-rate 5 ml/min; sample volume 200 μl; λ 600 nm. HCl concentrations: (*a*) $1 \times 10^{-3}M$, (*b*) $5 \times 10^{-3}M$, (*c*) $1 \times 10^{-2}M$, (*d*) $1 \times 10^{-1}M$. Times measured: 10.68–59.72 sec, RSD 0.8–0.3% ($n = 5$). Calibration curve: Δt (sec) $= 84.32 + 24.56 \times \log C$, $r = 0.99994$.

be optimum, giving a compromise between good precision and high sample-throughput. Typical flow injection titrations of hydrochloric acid, along with the reproducibility and the calculated calibration curve, are shown in Fig. 3.

Three weak acids, benzoic, salicylic and citric, were also determined. The peaks were similar to those for the strong acid titration except that the falling edge was less abrupt because of the buffer-system generated during the reaction. The results obtained for calibration curves are similar in precision and linearity to those for hydrochloric acid in Fig. 3.

Redox titrations

The titration of ascorbic acid with 2,6-dichlorophenolindophenol (DCPI) was examined. The carrier stream consisted of $3 \times 10^{-5}M$ DCPI in 210-mg/l. sodium bicarbonate solution and was pumped at a rate of 5 ml/min through the mixing chamber; the spectrophotometer was set at 522 nm (the isosbestic point of DCPI). The coloured carrier solution had a transmittance level of 62%, which served as the base-line. The triggering level was set arbitrarily at 75% transmittance so that the pink–colourless–pink transitions were observed. Typical titration curves for 1×10^{-4}–$1 \times 10^{-2}M$ ascorbic acid standards (in $0.05M$ oxalic acid to prevent oxidation), along with the statistical treatment, are shown in Fig. 4. The automated method was applied to the determination of ascorbic acid in pharmaceutical preparations, and the results obtained were compared with those of the official titrimetric procedure (Table 1).

Complexometric titrations

The titration of calcium with EDTA–Mg^{2+} complex in ammonia buffer at pH 10, with calmagite as indicator, was studied as an example. The composition of the carrier stream was $5 \times 10^{-5}M$ EDTA, $5 \times 10^{-5}M$ Mg^{2+} (*i.e.*, equivalent to $5 \times 10^{-5}M$ EDTA–Mg^{2+}) and $1.3 \times 10^{-5}M$ calmagite indicator in $1M$ NH_3/NH_4Cl buffer. The carrier stream, pumped at 5 ml/min, was monitored at 520 nm. The base-line was set at 100% transmittance for the blue carrier stream (the colour of the free indicator). The triggering level was set at 92% transmittance (half the peak height), so monitoring of the indicator transition started when about 50% of the indicator was bound by the magnesium liberated from the EDTA–Mg^{2+} complex by the calcium, to give the pink calmagite–Mg^{2+} complex. Typical "titration" peaks for calcium in the range 5×10^{-4}–$5 \times 10^{-2}M$ are shown in Fig. 5 along with the statistical treatment of data used for the calibration curve. The method was also applied to determination of total hardness in synthetic and real water samples (Table 2).

Catalytic titrations

In catalytic titrations,[25] the catalyst is used as the titrant, and the solution titrated contains the reagents for the indicator reaction which is catalysed by the titrant, and also an inhibitor of this reaction. The inhibitor is the species that is to be determined, and it reacts stoichiometrically with the catalyst faster than the catalyst reacts with the indicator mixture. Catalytic titrations are especially useful for the determination of minute amounts of substances, for which conventional titrimetric methods are difficult to use, particularly in the case of complexometric titrations, where metallochromic indicators are ineffective for concentration ranges much below $10^{-4}M$.

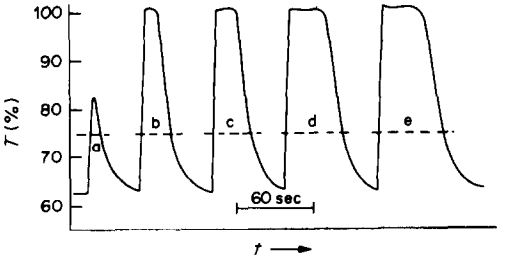

Fig. 4. Flow-injection pseudotitration curves for ascorbic acid. Carrier reagent: dichlorophenolindophenol $3 \times 10^{-5}M$. Flow-rate 5 ml/min; sample volume 200 μl; λ 522 nm. Ascorbic acid concentrations: (*a*) $1 \times 10^{-4}M$, (*b*) $5 \times 10^{-4}M$, (*c*) $1 \times 10^{-3}M$, (*d*) $5 \times 10^{-3}M$, (*e*) $1 \times 10^{-2}M$ Times measured: 9.25–49.29 sec, RSD 0.3–0.06% ($n = 5$). Calibration curve: Δt (sec) $= 89.96 + 20.10 \times \log C$, $r = 0.9997$.

The catalytic titration of aminopolycarboxylic acids (EDTA, EGTA, DCTA, and DTPA) with Mn^{2+} as titrant and the manganese-catalysed periodate–diethylaniline reaction[26,27] as indicator reaction, has been developed to demonstrate the usefulness of FIA titration in catalytic titrimetry. The analytical manifold is shown in Fig. 6. The titrant and indicator reaction reagents are mixed in a 100-cm mixing coil and the mixing chamber and then allowed to react in a 3-m reaction coil. The product of the manganese-catalysed reaction is monitored at 470 nm, and gives a stable base-line at 32% transmittance for $1 \times 10^{-6}M$ Mn^{2+} and 3% for $1 \times 10^{-5}M$ Mn^{2+}. When an aminopolycarboxylic acid sample (200 μl) is injected into the reacting flow-stream, the catalysis is inhibited by formation of the manganese–aminopolycarboxylic acid complex, and the uncatalysed reaction is monitored, resulting in the transmittance being increased to 75%. The result is a peak with a width which depends on the aminopolycarboxylic acid concentration.

The experimental parameters were optimized to give the maximum difference in transmittance for the catalysed and uncatalysed reactions, high sample throughput, and high precision. Two manganese and periodate concentrations were chosen: $1 \times 10^{-6}M$ Mn^{2+} and $7 \times 10^{-3}M$ periodate for the aminopolycarboxylic acid range 5×10^{-6}–$5 \times 10^{-4}M$, and $1 \times 10^{-5}M$ Mn^{2+} and $3.5 \times 10^{-3}M$ periodate for the 1×10^{-4}–$1 \times 10^{-2}M$ range. The triggering levels were set at 60% and 20% transmittance respectively for the two ranges.

A series of typical peaks for EDTA titration are shown in Fig. 7 and results for the calibration in Table 3. Identical results were obtained with EGTA, DCTA and DTPA.

DISCUSSION

The system described is a simple, relatively inexpensive means of automating flow-injection pseudotitrations. A sample throughput of 60 samples per hour can be obtained in most cases, with small

sample and reagent consumption. Any kind of conventional titration which can be monitored spectrophotometrically can be performed with excellent precision (less than 0.3% relative standard deviation in most cases) and accuracy. The logarithmic relation of the time measured to the concentration of the analyte can be an advantage when a wide range of sample concentrations is expected. A closed system is used for the titration, so unstable titrants can be prepared *in situ* and used in special analytical procedures.

The adaptation of catalytic titrations to the flow-injection technique provides a very fast and simple way to determine low concentrations of analytes without the tedious addition of the indicator reaction reagents and the time-consuming graphical estimation of the end-point. The automated measurement of the peak width in time units is simpler

(*Received* 22 *June* 1984. *Accepted* 12 *December* 1984)

Summary—A method is described for the sequential determination of phosphorus, arsenic and silicon at ng/ml levels by d.c. polarography. These elements are converted into their heteropolymolybdates and separated by selective solvent extraction. Determination of the molybdenum in the extract gives an enhancement factor of 12 for determination of the hetero-atom. A further enhancement by a factor of 40 is achieved by determining the molybdenum by catalytic polarography in nitrate medium. Charging-current compensation is employed to improve precision and the detection limit. The detection limits for phosphorus, arsenic and silicon are 0.5, 4.7 and 3.1 μg/l., respectively and the relative standard deviation is 2–2.5%.

Indirect methods for the estimation of phosphorus, arsenic and silicon may be based on the formation of the heteropoly molybdic acids (HPMA), extraction into an organic solvent and determination of the molybdenum in the extract either directly or after stripping into aqueous solution.[1–6]

This approach increases the sensitivity because 12 molybdenum atoms per hetero-atom become available for measurement. The sensitivity can be still further increased by choosing a highly sensitive method of measurement, such as the catalytic polarographic wave given by molybdenum under suitable conditions. The sensitivity of the catalytic polarographic wave is at least 40 times that of the corresponding diffusion wave. We have reported earlier the use of this approach for determining arsenic, phosphorus and silicon at ng/ml level by d.c. polarography.[7–9] Height *et al.* have similarly used differential pulse polarography for the determination of phosphorus.[10] Here we present a procedure for the sequential determination of phosphorus, arsenic and silicon in a mixture.

EXPERIMENTAL

Instrumentation

The polarograph used incorporates compensation for charging-current and was described earlier.[11,12] A Metrohm polarographic cell with a mercury pool as counter-electrode and an SCE as reference electrode was used with a 3-sec Sargent capillary, the drop-time being kept at 0.5 sec by an electromechanically controlled knocker. The water-jacketed polarographic cell was maintained at $34 \pm 0.1°$. Solutions were deaerated by passage of purified hydrogen for 20 min.

Reagents

Analytical grade chemicals were used throughout. Doubly distilled water was collected and stored in a polypropylene container and all reagent solutions were stored in polypropylene containers to avoid contamination with silicon.

Standard molybdenum solution (10^{-2}M). Dissolve 2.420 g of $Na_2MoO_4 \cdot 2H_2O$ in 2*M* sulphuric acid and make up to 1 litre with the same acid. Make further dilutions with 0.25*M* sulphuric acid.

Standard phosphorus solution (25 $\mu g/ml$). Dissolve 0.929 g of ammonium dihydrogen phosphate in 1 litre of distilled water.

Standard arsenic solution (100 $\mu g/ml$). Add 10 ml of concentrated nitric acid to 0.1320 g of As_2O_3 in a 100-ml beaker, heat to dissolve, and dilute to 1 litre with water.

Standard silicon solution (100 $\mu g/ml$). Fuse 0.1070 g of pure dry precipitated silica with 1 g of anhydrous sodium carbonate in a platinum crucible. Cool the melt, extract with water and dilute to 500 ml. Prepare working standard solutions by appropriate dilution of the stock solutions.

Wash solution for phosphorus. Equilibrate 2*M* hydrochloric acid with isobutyl acetate, then discard the organic phase.

Wash solution for arsenic. Equilibrate 2*M* hydrochloric acid with a 1:1 (v/v) mixture of 1-butanol and ethyl acetate, then discard the organic phase.

Wash solution for silicon. Equilibrate 2*M* hydrochloric acid with methyl isobutyl ketone (MIBK), then discard the organic phase.

Citrate solution. Dissolve 100 g of citric acid in about 80 ml of distilled water, adjust to pH 3.2 with sodium hydroxide, then dilute to 1 litre with water.

Supporting electrolyte. Dissolve 85 g of sodium nitrate in 0.25*M* sulphuric acid and dilute to 1 litre with the same acid.

Ammonium heptamolybdate tetrahydrate solution, 5%.

Procedure

Take 10 ml of sample or an aliquot containing up to 5 μg each of phosphorus, arsenic and silicon and diluted to 10 ml with distilled water. Add 2 ml of ammonium molybdate solution and adjust to pH 0.7 with dilute nitric acid. Transfer to a separatory funnel and let stand for 20 min.

Determination of phosphorus. Add 10 ml of isobutyl acetate and shake the funnel for 1 min. When the phases

have separated, carefully transfer the lower (aqueous) phase (*A*) into another separatory funnel and reserve it for determination of arsenic and silicon. Wash the organic layer three times with 15-ml portions of phosphorus wash solution (shaking time 30 sec), discarding the washings. Add 10 ml of 0.5*M* sodium hydroxide to the organic layer and shake for 1 min. When the layers have separated collect the lower layer in a 50-ml standard flask. Add 6.7 ml of 2.3*M* sulphuric acid and 4.25 g of sodium nitrate and make up to the mark. If there is less than 0.6 μg of phosphorus in the original aliquot, transfer the solution to the polarographic cell and record the polarogram. If there is more, dilute the solution suitably with supporting electrolyte and then record the polarogram. Run a blank determination simultaneously and subtract the blank value.

Determination of arsenic. To the aqueous phase (*A*) or, in the absence of phosphorus, the sample plus ammonium molybdate and adjusted to pH 0.7, add 5 ml of 1:1 v/v 1-butanol/ethyl acetate mixture and shake for 1 min. Add 5 ml of isoamyl acetate and shake again for 30 sec. Allow the phases to separate and drain the aqueous phase (*B*) into another funnel for the determination of silicon. Add exactly 5.00 ml of cylcohexane to the organic phase and wash, shaking vigorously for 30 sec each time, with three 15-ml portions of the arsenic wash solution. Discard the washings. Strip the molybdenum from the organic layer and complete the determination as for phosphorus. Further dilution is only necessary for >8 μg of arsenic.

Determination of silicon. Adjust the aqueous phase (*A* or *B*), or the sample if arsenic and phosphorus are absent, to pH 1.2–1.3 with silicon-free ammonia. Wait for 10 min, then add 2 ml of 7*M* nitric acid and wait for 10 min. Add 2 ml of citrate solution and wait for 10 min. Transfer quantitatively into a separatory funnel with the minimum of water. Add 10 ml of MIBK and shake for 1 min. Allow the phases to separate and discard the lower phase. Wash the organic phase by shaking it vigorously for 30 sec each time with three 10-ml portions of silicon wash solution, discarding the washings. Strip the molybdenum and complete the determination as for phosphorus, but adding a suitable aliquot of the 50 ml of final solution to 20 ml of supporting electrolyte, for the polarography.

Calibration graphs. Prepare these by applying the procedure to standard solutions containing 0–0.8 μg of phosphorus, 0.5–8 μg of arsenic and 0.5–5 μg of silicon.

RESULTS AND DISCUSSION

Polarographic determination of the molybdenum

Catalytic currents are given by molybdate in perchlorate,[13] nitrate[14] and chlorate[15] solutions and some arguments still remain about the character of the wave and the species involved in the catalysis.[16] Optimum conditions for the determination of molybdenum in this way have been reported.[17,18] Figure 1 shows the d.c. polarograms for 7.7-μg/l. molybdenum solution in nitrate and perchlorate media with and without charging-current compensation.

The wave is better and larger in the nitrate medium, which was therefore used for further work. Figure 1 also shows that charging-current compensation flattens the base-line and improves the precision of measurement.

The chosen concentrations of nitrate (1*M*) and sulphuric acid (0.25*M*) agree with those reported earlier.[7,17] The catalytic wave is highly temperature-dependent, and more sensitive at higher temperatures. Hence temperature control is imperative and our experiments were done at $34 \pm 0.1°$ unless otherwise stated.

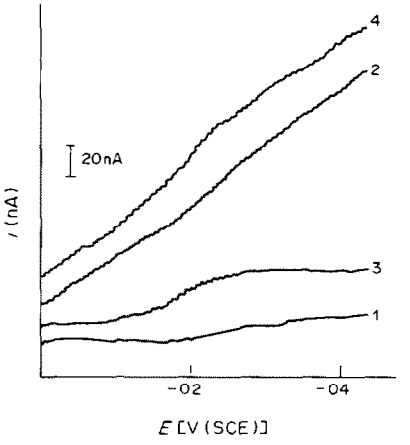

Fig. 1. Polarograms of 7.7-μg/l. molybdenum in (1) perchlorate medium with CCC (charging-current compensation), (2) perchlorate medium without CCC, (3) nitrate medium with CCC, and (4) nitrate medium without CCC.

Figure 2 shows typical polarograms used to construct the calibration graph for molybdenum. A sensitivity of 2 nA.ml.ng^{-1} was obtained at 34°; under the same conditions, the diffusion-controlled wave of molybdenum in 0.25*M* sulphuric acid gives a sensitivity of only 50 nA.ml.μg^{-1}.

The high blank problem. Whichever analytical technique is employed to determine the molybdenum stripped from the organic layer, a major problem is the high blank due to the simultaneous extraction of isopolymolybdic acid (IPMA), especially in the optical methods, where the large blank value may shift

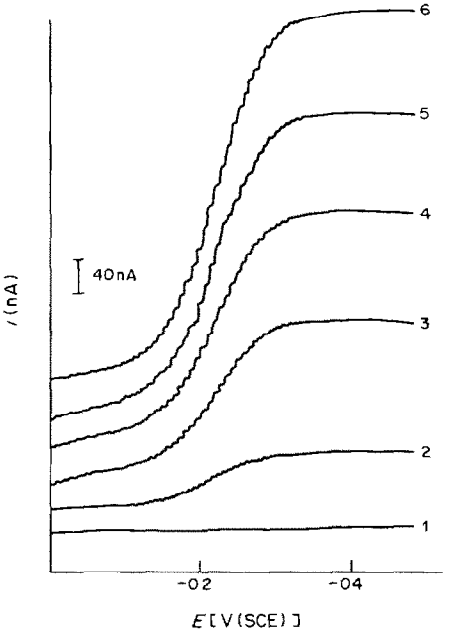

Fig. 2. Polarograms which were used for construction of the calibration graph for estimation of molybdenum in 0.25*M* sulphuric acid and 1*M* sodium nitrate. [Mo], ng/ml: (1) 0; (2) 47.5; (3) 94.1; (4) 140; (5) 184.6; (6) 230.7.

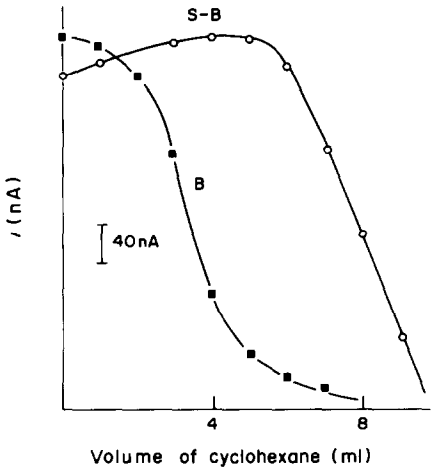

Fig. 3. Variation of blank and blank-corrected sample values with the addition of cyclohexane to the organic layer for 48 μg/l. arsenic. B = blank, S − B = blank-corrected sample values.

the sample absorbance to the non-linear region of the calibration graph. This shift does not arise in polarography because the calibration graph is linear up to a molybdenum concentration of $10^{-5}M$ (~ 1 μg/ml), but high blank values will necessitate operating the polarographic recorder at low current sensitivity, resulting in loss of overall sensitivity. Generally the organic layer is given an acidic wash to remove traces of IPMA, but the treatment varies considerably.[10,19,20] Chromatographic separation of IPMA has also been tried.[20]

A systematic study was undertaken to decrease this blank and it was found that the addition of small amounts of hydrocarbons (such as benzene or cyclohexane) to the organic layer, after extraction of the heteropoly acids, followed by a rigorous acidic wash, removed most of the IPMA from the organic layer. However, washing the isobutyl acetate extract of phosphomolybdic acid thrice with $2M$ hydrochloric acid was found to remove most of the IPMA and give maximum signal to blank ratio. Any effort to remove the residual IPMA was found to decrease the signal value as well.

In the case of arsenic, addition of hydrocarbons followed by an acid wash had a profound effect in decreasing the blank value. Figure 3 shows that addition of 5 ml of cyclohexane to the organic layer and then three washes each with 15 ml of $2M$ hydrochloric acid (30 sec shaking) was optimal.

In the case of silicomolybdic acid, addition of the citrate solution minimized the simultaneous extraction of IPMA, and acid washing still further decreased the blank value. The blank for silicon determination was quite high compared with that for arsenic and phosphorus, however, probably because of the presence of silicon as an impurity in the reagents used.

Extraction and stripping. The extraction conditions are based on earlier work[1,21] and give good sequential separation of the three heteropoly acids. For convenience, the same acidity can be used for extraction of phosphomolybdic acid and arsenomolybdic acid.

For silicon it is better to add the acid in two portions, first to form the HPMA and then to protonate it for extraction.[22,23] Although silicomolybdic acid is not formed at high acidity ($>0.7M$ H^+), once formed at lower acidity it remains quite stable on further acidification and is extractable even from $1M$ acid. Methyl isobutyl ketone (MIBK), 1-butanol, diethyl ether/1-pentanol (5:1), 1-pentanol and isoamyl alcohol were tested as solvents. The lowest blank values were obtained with the diethyl ether/pentanol mixture, but the best signal to blank ratio was obtained with MIBK, which was therefore chosen for the extraction. Shaking the organic phase for 1 min with 10 ml of $0.5M$ sodium hydroxide gave complete stripping for all three heteropoly acids.

Simultaneous determination of phosphorus, arsenic and silicon

The procedure was employed for the sequential determination of phosphorus, arsenic and silicon and the results are shown in Table 1.

Interference studies

Foreign ions may interfere at two stages: in the formation and extraction of the HPMA, and in the polarography. The first type of interference has already been studied[1] and confirmed by our observations. The second type of interference was investigated in this study and it was found that none of the reagents used in the procedure caused any interference. The shapes of the polarograms were also not distorted. This is clearly seen in Fig. 4, which shows typical polarograms for determination of arsenic, silicon and phosphorus.

Table 1. Determination of phosphorus, arsenic and silicon in the presence of each other

Phosphorus, μg		Arsenic, μg		Silicon, μg	
taken	found	taken	found	taken	found
0.020	0.017	0.50	0.52	0.50	0.55
0.050	0.058	2.00	2.17	3.00	3.15
0.50	0.51	3.00	2.94	2.00	2.03
0.20	0.25	5.00	5.04	1.00	0.94
1.00	0.98	1.00	1.10	5.00	4.90

Table 2. Sensitivity and detection limit for the estimation of phosphorus, arsenic and silicon

Element	Inherent sensitivity, $mA.l.\mu g^{-1}$	Inherent detection limit, $\mu g/l.$	Detection limit obtained by the present procedure, $\mu g/l.$
Phosphorus	80	0.1	0.5
Arsenic	8.5	0.94	4.7
Silicon	65	0.12	3.0

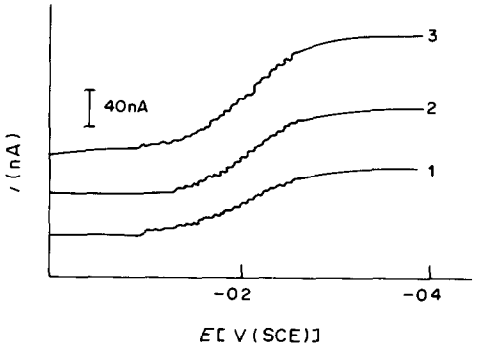

Fig. 4. Polarograms of stripped molybdenum equivalent to (1) 9.3 μg/l. arsenic; (2) 1.9 μg/l. silicon; (3) 0.8 μg/l. phosphorus.

Precision

The relative standard deviations were established (eight determinations) and were 2.3% for phosphorus (0.5 μg), 2.4% for arsenic (5.0 μg) and 2.3% for silicon (4.0 μg).

Sensitivity and detection limit

The sensitivities and detection limits are summarized in Table 2. Inherent sensitivity means the slope of the calibration graph. The values given were obtained from polarograms recorded at a recorder sensitivity of 40 nA/cm. The concentration which would give a wave-height of 8 nA (*i.e.*, twice the noise level of the instrument used) is called the inherent detection limit. The practical detection limits obtained by the present procedure were 5 times the inherent detection limit for phosphorus and arsenic, but 25 times that for silicon because of the high blank values and necessity to operate the recorder at lower sensitivity.

Conclusions

It is shown that the combination of two methods of increasing the sensitivity makes it possible to determine phosphorus, arsenic and silicon at ng/ml levels by d.c. polarography. The methods proposed give greater sensitivity than any of the other indirect methods reported earlier for determination of these elements.

APPLICATIONS OF THE DICARBOLLYLCOBALTATE(III) ANION IN THE WATER/NITROBENZENE EXTRACTION SYSTEM

EMANUEL MAKRLÍK and PETR VAŇURA
Nuclear Research Institute, 250 68 Řež, Czechoslovakia

(*Received* 25 *July* 1984. *Accepted* 31 *October* 1984)

Summary—The fundamental properties of the polyhedral sandwich dicarbollylcobaltate(III) anion $\{[\pi\text{-}(3)\text{-}1,2\text{-}B_9C_2H_{11}]_2Co(III)\}^-$ are given, together with results for extraction of alkali-metal, alkaline-earth metal and some other cations (*e.g.*, H^+, Pb^{2+}, Pd^{2+} and Ce^{3+}) into nitrobenzene and corresponding analytical applications. Considerable attention is paid to charge-transfer through the water–nitrobenzene interface in the presence of this hydrophobic anion.

The complex dicarbollylcobaltate(III) anion $\{[\pi\text{-}(3)\text{-}1,2\text{-}B_9C_2H_{11}]_2Co(III)\}^-$ may be prepared by the original method[1,2] or more advantageously by its modification[3] according to the following scheme:

$$1,2\text{-}B_{10}C_2H_{12} \xrightarrow{KOH/CH_3OH} [(3)\text{-}1,2\text{-}B_9C_2H_{12}]^- \quad (1)$$

$$[(3)\text{-}1,2\text{-}B_9C_2H_{12}] \xrightarrow{Co^{2+},KOH/H_2O} \{[\pi\text{-}(3)\text{-}1,2\text{-}B_9C_2H_{11}]_2Co(III)\}^- \quad (2)$$

The surface of this voluminous anion, the symmetric sandwich structure[4] of which is presented in Fig. 1, is formed of hydrogen atoms, which increase the hydrophobic character of the anion, and therefore the solubility of salts of this anion in non-aqueous solvents, *e.g.*, nitrobenzene, nitromethane, 2,2′-dichlorodiethyl ether, is relatively high.

Dicarbollylcobaltate(III) is a member of the group of polyhedral heteroborane anions that do not possess a free electron pair for binding a proton, so the compound $H^+\{[\pi\text{-}(3)\text{-}1,2\text{-}B_9C_2H_{11}]_2Co(III)\}^-$ is totally dissociated in aqueous as well as in nitrobenzene solutions and is one of the strongest acids at present known.

The anion $\{[\pi\text{-}(3)\text{-}1,2\text{-}B_9C_2H_{11}]_2Co(III)\}^-$ is considered to have a sandwich-type spatial configuration in which the central cobalt atom is in the formal oxidation state +III, with two hexaelectron ligands $[(3)\text{-}1,2\text{-}B_9C_2H_{11}]^{2-}$ π-bonded to it. Six vacant orbitals of the central Co(III) atom are supposed to be filled with the 2×6 binding electrons of the two $[(3)\text{-}1,2\text{-}B_9C_2H_{11}]^{2-}$ ligands so that the d^6-configuration of Co(III) is completed to give stable 18-electron valence shell. At the same time, each of the two supposed twelve-vertex fragment units of $Co(III)B_9C_2H_{11}$ (see Fig. 1) exhibits a stable[5–7] closed structure with $2n + 2$ ($n = 12$) skeletal electrons and consequently with the maximum delocalized electron density.[8] In accord with that, the skeleton of this voluminous diamagnetic anion is highly resistant to radiation,[9–13] heat,[14] and strong acids and oxidation–reduction agents.[8]

These properties of the dicarbollylcobaltate(III) anion, together with its low specific charge, make this anion and some of its halogen derivatives excellent agents for the extraction of cations from aqueous solutions into some organic solvents, especially polar ones (*e.g.*, nitrobenzene), or their mixtures.

Extraction of cations from the aqueous phase into nitrobenzene

The dicarbollylcobaltate(III) anion (henceforth referred to as DCC^-), in the form of the acid (HDCC) was first utilized by Rais *et al.*[15] as an agent mainly suitable for the extraction of caesium* or other large cations from water into organic solvents containing

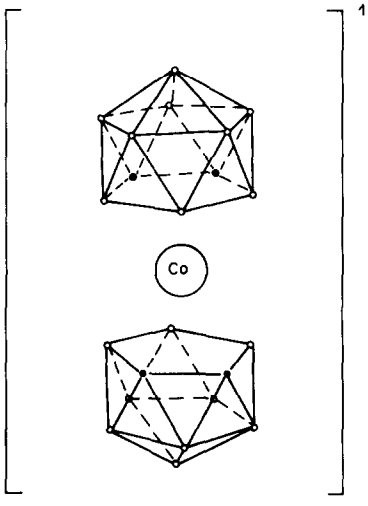

Fig. 1. Structure of dicarbollylcobaltate anion (symbols ● and ○ denote groups CH and BH, respectively).

*This has found application in a registered patent for caesium isolation[16] (*e.g.*, from irradiated nuclear fuel), that is shortly to be put into operation on at least a pilot-plant scale.

nitro-group (nitrobenzene, nitromethane, nitropropane). As the equilibrium distribution ratio of DCC^- between nitrobenzene and water in the HDCC extraction system did not depend (within experimental error) on the initial concentration of HDCC in the organic phase, the distribution of HDCC in this system may be expressed as a two-phase equilibrium

$$H^+(w) + DCC^-(w) \overset{K_{ex}(H^+,DCC^-)}{\rightleftharpoons} H^+(nb) + DCC^-(nb) \quad (3)$$

where $\log K_{ex}(H^+, DCC^-) \approx 3.1$; symbols w and nb refer to the aqueous and nitrobenzene phases, respectively. The exchange extraction constants K_M^{Cs} (M = Li, H, Na, NH_4, K, Rb) reported,[15] corresponding to the reaction

$$Cs^+(w) + M^+(nb) \overset{K_M^{Cs}}{\rightleftharpoons} Cs^+(nb) + M^+(w) \quad (4)$$

were in good agreement with those determined earlier.[17] The selectivity of the extraction separation of alkali-metal cation pairs Cs^+/M^+, estimated from the K_M^{Cs} value, did not depend on the particular DCC^- derivative used.

Macášek *et al.*[18] found that the exchange extraction constant K_H^{Cs} was practically the same whether the organic phase used was nitrobenzene–bromoform (4:1 v/v), nitrobenzene–tetrachloromethane (3:2 v/v) or nitrobenzene.

On the basis of the assumption that the ΔG values for transfer of tetraphenylarsonium cations (TPA^+) and tetraphenylborate anions (TPB^-) from water into nitrobenzene are equal, individual extraction constants of several derivatives of DCC^- have been determined radiometrically (see Table 1).[19] These constants (K'_{A^-}) express in principle the affinity of the anion for the nitrobenzene phase and are therefore a quantitative measure of the hydrophobicity of the anion. From comparison of the values for tetraphenylborate or dipicrylaminate (DPA^-) anions ($\log K'_{TPB^-} = 6.3$, $\log K'_{DPA^-} = 6.9$)[17] with the values in Table 1 it follows that the DCC^- anion and especially its derivatives are still more hydrophobic than the TPB^- and DPA^- anions.

Škarda *et al.*[20] proved by conductivity measurements that the salts of the type MDCC ($M^+ = Li^+$, H^+, Na^+, K^+, Rb^+, Cs^+, Tl^+ and Et_4N^+) were totally dissociated in nitrobenzene saturated with water, to the corresponding solvated ions M^+ and DCC^-, in contrast to the dipicrylaminates, tetraphenylborates and α-hexylates of alkali or alkaline-earth metals, which form ion-pairs in nitrobenzene.[21–23] The hydration numbers (h) of these univalent ions (mean number of water molecules co-extracted per cation in the equilibrium nitrobenzene phase) were determined:[20]

$$h_{Li^+} = 6.5,\ h_{H^+} = 5.5,\ h_{Na^+} = 3.9,\ h_{K^+} = 1.5,$$
$$h_{Rb^+} = 0.8,\ h_{Cs^+} = 0.5,\ h_{Et_4N^+} = h_{DCC^-} = 0.0.$$

It follows that the degree of hydration of these ions in the non-aqueous phase decreases with increasing affinity of the ions for the nitrobenzene phase. For the tetraethylammonium cation, no evidence of hydration was found experimentally.[20] It was also found that the degree of hydration of Li^+ and H^+ in 2,2′-dichlorodiethyl ether saturated with water was practically identical with that in water-saturated nitrobenzene, whereas in nitromethane saturated with water it was much higher.[20]

From a large number of experimental data it was found[24–26] that the extraction of both trace and weighable amounts of Ba^{2+} and Ce^{3+} from aqueous solutions of nitric or perchloric acids into nitrobenzene (in the presence of HDCC) could be satis-

factorily described by the equilibria:

$$Ba^{2+}(w) + 2H^+(nb) \overset{K_{2H}^{Ba}}{\rightleftharpoons} Ba^{2+}(nb) + 2H^+(w) \quad (5)$$

$$Ce^{3+}(w) + 3H^+(nb) \overset{K_{3H}^{Ce}}{\rightleftharpoons} Ce^{3+}(nb) + 3H^+(w) \quad (6)$$

It was proved experimentally that the hydration number h_{H^+} increases with increasing concentration of HDCC in the non-aqueous phase as well as with decreasing acidity of the aqueous phase; in the two-phase nitric acid/HDCC–nitrobenzene and perchloric acid/HDCC–nitrobenzene systems with identical initial mineral acid concentration and identical HDCC content in the initial organic phases, h_{H^+} was always higher in the nitric acid system. The mean hydration numbers of Ba^{2+} and Ce^{3+} in nitrobenzene saturated with water were also determined ($h_{Ba^{2+}} = 11.5 \pm 1.0$, $h_{Ce^{3+}} = 16.2 \pm 2.0$) together with the extraction constants ($\log K'_{Ba^{2+}} = -10.5 \pm 0.1$, $\log K'_{Ce^{3+}} = -15.8 \pm 0.2$). The logarithms of the extraction constants of the alkali-metal cations, the proton, and Ba^{2+} and Ce^{3+}, decrease linearly with the hydration number of the ions extracted into the nitrobenzene phase.[24–26]

Extraction of tervalent actinide and lanthanide ions from acidic aqueous solutions by means of HDCC or $H[B_{18}C_4H_{15}Cl_7Co]$ in nitrobenzene was studied by Benešová *et al.*[27] To increase the difference between the densities of the aqueous and organic phases, the nitrobenzene was diluted with tetrachloromethane or bromoform. The distribution ratios of the actinides and lanthanides are very similar, so these elements cannot be efficiently separated by extraction. The tervalent cations can be stripped from the organic phase with a sufficiently high concentration of nitric acid or sodium nitrate solution, or with some basic compounds (*e.g.*, 1-propanol, hydrazine, urea).[27]

Thiourea complexes of technetium (most likely cationic) have been extracted from nitric acid into nitrobenzene–bromoform (4:1 v/v) mixture with HDCC;[28] this has been employed for separation of ^{99m}Tc from ^{95}Zr–^{95}Nb nuclide decay products.

Equilibrium distribution ratios $>10^2$ have been found for palladium in the nitric acid/nitrobenzene–$H[(B_9C_2H_{10}Br)_2Co]$–1,10-phenanthroline (or α,α′-bipyridyl) systems.[29] These systems seem to be potentially useful for the isolation of palladium even from highly radioactive solutions, because 1,10-phenanthroline in particular is very stable towards radiation.

Rais *et al.*[30] observed a large synergic effect during the extraction of microamounts of Ca^{2+}, Sr^{2+}, Ba^{2+} or Pb^{2+} into nitrobenzene with hydrophobic anions (DCC^-, polyiodides, dipicrylaminate, tetraphenylborate) in the presence of polyethylene glycols with molecular weights of 200, 300, 400, 600 and 1000 (PEG 200, PEG 300, PEG 400, PEG 600, PEG 1000). This effect was ascribed to increase in the cation hydrophobicity caused by polyethylene glycol.

Šebesta *et al.*[31] studied the distribution of Ba^{2+} and Ra^{2+} between hydrochloric acid and nitrobenzene in the presence of HDCC and PEG 1000. The presence of 0.1% PEG 1000 in the aqueous phase gave the highest distribution ratios for both elements when the initial concentration of HCl in the aqueous phase (c_{HCl}) was $0.1M$ and the initial concentration of HDCC in nitrobenzene was $0.01M$. In the hydrochloric acid concentration range $0.1–1.0M$ (under otherwise unchanged conditions), the synergic effect of the PEG 1000 increased the distribution ratios by a factor of about 10^4, whereas at $c_{HCl} < 0.1M$ the distribution ratios decreased with decreasing acidity down to $c_{HCl} \approx 0.01M$, at which an antagonistic effect began. No explanation of this effect of PEG 1000 has been found. Experiments in our laboratory indicate that the original duration of shaking used was insufficient for equilibrium to be reached in the low acidity systems, and the apparent decrease in degree of extraction may have been due to a lower rate of equilibration.

Vaňura *et al.*[32] studied the extraction of microamounts of ^{85}Sr in the presence of PEG 400 with DCC^- from water into nitrobenzene. Maxima on plots of the distribution ratio of strontium as a function of the analytical concentration of polyethylene glycol in the aqueous phase was attributed to competitive action between the charged complex $SrPEG^{2+}$ and the protonated polyethylene glycol $HPEG^+$ as counter-ions of DCC^- in the organic phase. Theoretical relations were derived for the shape of these plots and also for the effect of the concentration of DCC^- in the organic phase on the shape of the plots and the positions of the maxima. The theoretically derived relationships were in accord with the experimental data.

The following equilibria characterize the distribution of microamounts of $^{85}Sr^{2+}$ or $^{133}Ba^{2+}$ in the perchloric (or nitric acid)/nitrobenzene–PEG–HDCC system[32,33]

$$M^{2+}(w) + 2H^+(nb) \overset{K_{ex}(M^{2+})}{\rightleftharpoons} M^{2+}(nb) + 2H^+(w) \quad (7)$$

$$L(w) \overset{K_D}{\rightleftharpoons} L(nb) \quad (8)$$

$$L(w) + H^+(nb) \overset{K_{ex}(HL^+)}{\rightleftharpoons} HL^+(nb) \quad (9)$$

$$M^{2+}(w) + L(w) + 2H^+(nb) \overset{K_{ex}(ML^{2+})}{\rightleftharpoons} ML^{2+}(nb) + 2H^+(w) \quad (10)$$

where $M^{2+} = Sr^{2+}$ or Ba^{2+}, L = PEG 200, PEG 300 or PEG 400, $\log K_{ex}(Sr^{2+}) = 0.70$ and $\log K_{ex}(Ba^{2+}) = 0.85$. The values of the other equilibrium constants are collected in Table 2. The hydration numbers decrease with increasing stability of the complexes.[33] Similar conclusions apply[34] to the hydration of complex cations of the ML^+ type, where $M^+ = Li^+$, Na^+, NH_4^+, K^+, Rb^+ and Cs^+.

These results[30–33] demonstrate that polyethylene glycols are effective synergic agents, especially in the extraction of alkaline-earth metals. This property of

polyethylene glycols and of some similar compounds has been utilized for extractive separation of strontium[35] and radium[36] from aqueous solutions.

Electrochemical study of the charge transfer across the water/nitrobenzene interface

The fundamental principles, concepts, and general relations that characterize the transfer of ions across the interface between two immiscible electrolyte solutions, studied by means of electroanalytical methods (polarography with the dropping electrolyte electrode, cyclic voltammetry, chronopotentiometry), together with applications and the demands made on the measuring technique and equipment, have been reviewed.[37,38]

As with classical electrochemical methods, it is necessary for both phases to be practically immiscible and to contain background electrolytes in sufficiently high concentrations. Very hydrophilic electrolytes suitable for the aqueous phase include the chlorides, bromides and sulphates of the alkali metals and magnesium. The background electrolyte of the organic phase must be very hydrophobic, and tetrabutylammonium (TBA^+), tetraphenylarsonium (TPA^+), tetraphenylborate (TPB^-) and dicarbollylcobaltate(III) compounds are suitable components. Tetrabutylammonium dicarbollylcobaltate (TBADCC) has been employed in several studies[39–42] but was probably contaminated with anionic impurities and these attempts to extend the "potential window"[38] were not successful. Only the use of sufficiently pure TBADCC or TPADCC led to this aim being achieved.

In contrast to the tetraphenylborate anion (until recently the anion most often used for the purpose, generally as TBATPB), which decomposes under the influence of light and mineral acids, DCC^- is completely inert towards strong acids (except fairly concentrated solutions of nitric acid) and light, and is also relatively thermally stable as well as not much affected by radiation. As HDCC and MDCC (M^+ is an alkali-metal cation or Tl^+) are completely dissociated in nitrobenzene saturated with water,[20] the use of TBADCC or TPADCC as background electrolyte in the nitrobenzene phase ensures that transfer of protons and M^+ across the water/nitrobenzene interface is not complicated by ion-association in the nitrobenzene phase and may be taken as a "simple" transfer.[43,44]

The transfer of caesium and tetramethylammonium (TMA^+) ions across the water–LiCl/nitrobenzene–TBADCC interface has been studied by cyclic voltammetry.[43] The temperature-dependence of the polarographic half-wave potentials for the transfer of Cs^+ and TMA^+ across the interface, together with some thermodynamic data published earlier,[17,45,46] made it possible to determine the enthalpy and entropy changes of transfer of certain ions from the aqueous into the nitrobenzene phase[43] (see Table 3). Transfer of the hydrophilic cations Li^+, Na^+ and H^+ is endothermic, the "endothermicity" increasing in the order $H^+ < Na^+ < Li^+$. Conversely, the transfer of K^+, Rb^+, Cs^+ and TMA^+, similarly to transfer of the hydrophobic dipicrylaminate anion (DPA^-) from the aqueous phase into nitrobenzene, is always exothermic. From the thermodynamic point of view it is significant that the transfer of the univalent ions listed in Table 3 is always accompanied by an entropy decrease ($\Delta S^{*,w\to nb}_{tr,i} < 0$), which means that each of these ions is in a more ordered environment in the nitrobenzene phase than in the aqueous phase. It is interesting[43] that the absolute values of the entropy changes $|\Delta S^{*,w\to nb}_{tr,i}|$ increase in the order $Li^+ < Na^+ < H^+ < K^+$ but decrease in the order $K^+ > Rb^+ > Cs^+ > TMA^+ > DPA^-$.

If TBATPB is the supporting electrolyte used in the nitrobenzene phase, then Cs^+ is transferred from the aqueous into the organic phase at a more negative Galvani potential difference, $\Delta^w_{nb}\phi = \phi(w) - \phi(nb)$, than when the electrolyte is TBADCC. This effect has been explained as due to formation of the ion-pair Cs^+TPB^- in the nitrobenzene phase:[44]

$$Cs^+(nb) + TPB^-(nb) \overset{K_a}{\rightleftharpoons} Cs^+TPB^-(nb) \qquad (11)$$

The following relation was derived for the polarographic half-wave potential $E^{(1)}_{1/2}$ for the reversible transfer of Cs^+ from the aqueous into the organic phase, in which the ion-pair Cs^+TPB^- is formed:[44]

$$E^{(1)}_{1/2} = \Delta^w_{nb}\phi^\circ_{Cs^+} + (RT/2F)\ln[D^w_{Cs^+}/(D^{nb}_{Cs^+} + D_{CsTPB}K_a c^{o,nb}_{TPB^-})(1 + K_a c^{o,nb}_{TPB^-})] \qquad (12)$$

where $\Delta^w_{nb}\phi^\circ_{Cs^+}$ is the standard Galvani potential difference for the Cs^+ cation between the aqueous

Table 3. Thermodynamic values[17,43] for transfer of some univalent ions in the mutually saturated water–nitrobenzene system at 298 K

Ion	$\Delta G^{*,w\to nb}_{tr,i}$, *kJ/mole*	$\Delta H^{*,w\to nb}_{tr,i}$, *kJ/mole*	$\Delta S^{*,w\to nb}_{tr,i}$, $J.mole^{-1}.K^{-1}$
Li^+	38.2	37.1	−3.6

TMA^+	3.4	−9.3	−42.6
DPA^-	−39.4	−44.3	−16.6

and nitrobenzene phase,[37,47] D^{w}_{Cs+} and D^{nb}_{Cs+} are the diffusion coefficients of Cs^+ in the aqueous and nitrobenzene phases respectively, D^{nb}_{CsTPB} is the diffusion coefficient of the ion-pair Cs^+TPB^- in the nitrobenzene phase, $c^{o,nb}_{TPB-}$ is the initial analytical concentration of TPB^- in the nitrobenzene phase, and K_a is the association constant corresponding to equilibrium (11). For the polarographic half-wave potential $E^{(2)}_{1/2}$ of a "simple" reversible transfer of the Cs^+ ion from water into nitrobenzene, uncomplicated by the formation of an ion-pair or by chemical reactions in both phases:

$$E^{(2)}_{1/2} = \Delta^{w}_{nb}\phi^{o}_{Cs+} + (RT/2F)\ln(D^{w}_{Cs+}/D^{nb}_{Cs+}) \qquad (13)$$

Relation (13) follows from (12) when $K_a = 0$. The difference $\Delta E_{1/2}$ between $E^{(2)}_{1/2}$ and $E^{(1)}_{1/2}$ is

$$\Delta E_{1/2} = E^{(2)}_{1/2} - E^{(1)}_{1/2} = (RT/2F)\ln\{1 + (1+\delta)K_a c^{o,nb}_{TPB-} + \delta K_a^2[c^{o,nb}_{TPB-}]^2\} \qquad (14)$$

where $\delta = D^{nb}_{CsTPB}/D^{nb}_{Cs+} \approx D^{nb}_{TPB-}/D^{nb}_{Cs+}$. Relation (14) was employed when calculating the individual K_a values in the temperature interval between 278 and 338 K from experimentally determined $\Delta E_{1/2}$ values. From the linear dependence of log K_a on $1/T$, the value of ΔH for reaction (11) was found to be -17.2 kJ/mole (for the temperature range 293–338 K). The voltammetric measurements gave a value of 1×10^2 for K_a at 298 K (corresponding to $\Delta G = -11.4$ kJ/mole), which does not significantly differ from the value $K_a = 1.2 \times 10^{-2}$, obtained from extraction measurements at 298 ± 1 K. The corresponding entropy change is $\Delta S = -19.5$ J.mole^{-1}.K^{-1}.

It was also proved by cyclic voltammetry that proton transfer across the water/nitrobenzene interface, facilitated by an electroneutral ligand L (L = 18-crown-6) in the nitrobenzene phase (Fig. 2, System 1) or by DPA^- present as TPADPA in the non-aqueous phase (Fig. 2, System 2), is in any case a very fast process controlled by diffusion of L or DPA^- to the interface.[48–50] The results can be used to determine the values of $\beta(HL^+)$ and K for the equilibria (15) and (16) in the nitrobenzene phase of Systems 1 and 2.

$$H^+(nb) + L(nb) \overset{\beta(HL^+)}{\rightleftharpoons} HL^+(nb) \qquad (15)$$

$$H^+(nb) + DPA^-(nb) \overset{K}{\rightleftharpoons} HDPA(nb) \qquad (16)$$

For the polarographic half-wave potentials $E_{1/2}$ and $E'_{1/2}$ corresponding to reversible transfer of protons from the aqueous into the nitrobenzene phase, the following relations hold[48–50] (a general relation for cation transfer facilitated by an electroneutral ligand was first published by Koryta[37]):

$$E_{1/2} = \Delta^{w}_{nb}\phi^{o}_{H+} - (RT/F)\ln[\beta(HL^+)c^{o,w}_{H+}] \qquad (17)$$

$$E'_{1/2} = \Delta^{w}_{nb}\phi^{o}_{H+} - (RT/F)\ln(Kc^{o,w}_{H+}) \qquad (18)$$

where $\Delta^{w}_{nb}\phi^{o}_{H+} = 0.337$ V is the standard Galvani potential difference for protons between the aqueous and nitrobenzene phases,[37,47] found from extraction data.[17] Relations (17) and (18) are based on the simplifying assumption (evidently justified) that the diffusion coefficients of L and DPA^- in the nitrobenzene phase do not differ substantially from those of their protonated forms, *i.e.*, $D^{nb}_{L} \approx D^{nb}_{HL+}$ and $D^{nb}_{DPA-} \approx D^{nb}_{HDPA}$. From the experimentally determined half-wave potential $E_{1/2}$ and the known values of $\Delta^{w}_{nb}\phi^{o}_{H+}$ and $c^{o,w}_{H+}$, the value log $\beta(HL^+) = 5.9$ was determined by means of relation (17). The value log $K = 6.9$ was similarly calculated from equation (18).

aqueous phase	nitrobenzene phase	aqueous phase	nitrobenzene phase
HCl	TBADCC (TPADCC) L	HCl	TPADCC TPADPA
$c^{o,w}_{H+} \gg c^{o,nb}_{L}$		$c^{o,w}_{H+} \gg c^{o,nb}_{DPA-}$	
System 1		System 2	

Fig. 2. Two-phase systems for electrochemical study of proton transfer across the water/nitrobenzene interface; TBADCC (or TPADCC) is the supporting electrolyte in the nitrobenzene phase; $c^{o,w}_{H+}$, $c^{o,nb}_{L}$ and $c^{o,nb}_{DPA-}$ denote the initial concentrations of protons, L and DPA^- in the aqueous (w) or nitrobenzene (nb) phase.

Hung[51] found that synthetic DL-α-lecithine ($C_{40}H_{82}NO_9P$) dissolved in the nitrobenzene phase considerably slowed down both the simple transfer of the picrate anion and several cations (Cs^+, TMA^+, Li^+, TBA^+), and also the transfer of Na^+ (facilitated by dibenzo-18-crown-6) from the aqueous into the nitrobenzene phase (in the presence of TBADCC). This effect most likely resulted from the existence of a compact lecithine monolayer at the interface. The effect decreased with increasing temperature, which may be explained as a result of transition of the rigid crystalline structure of the monolayer to a liquid crystal structure or as a result of thermal increase of the disorder of the lecithine monolayer.[51] Lecithine has also been observed to slow down interfacial electron transfer between the $[Fe(CN)_6]^{3-}/[Fe(CN)_6]^{4-}$ couple in the aqueous phase and ferrocene dissolved in nitrobenzene.[51] Conversely, the transport of alkaline-earth metal cations (Ca^{2+}, Sr^{2+} and Ba^{2+}) across the water/nitrobenzene interface was facilitated by lecithine in the organic phase, probably by formation of lecithine complexes of the bivalent cations.[51]

Kolicine E_3 dissolved in the aqueous phase slows down transport of Cs^+ across the water–LiCl/nitrobenzene–TBADCC interface.[52]

Analytical application of extraction systems with the dicarbollylcobaltate(III) anion

Štefek *et al.*[53] found that the extraction system Sr^{2+}–PEG 400–$H^+\{[\pi\text{-}(3)\text{-}1,2\text{-}B_9C_2H_8Br_3]_2Co(III)\}^-$–water/nitrobenzene is not suitable for substoichiometric determination of strontium but can be

used for its determination by the concentration-dependent distribution method, which could be combined with isotopic dilution to allow the determination of strontium in the presence of barium and calcium.

A rapid method of separation of ^{90}Sr and ^{137}Cs from a solution of long-lived fission products has been developed for radioanalytical purposes.[54] The ^{137}Cs is extracted from a solution containing diethylenetriaminepenta-acetic acid (DTPA) and citrate (pH = 8) by HDCC solution in nitrobenzene, followed by extraction of the strontium at pH 4 by HDCC solution in nitrobenzene in the presence of PEG 400. The separation factors for the couples Cs/Sr and Sr/fission-products exceeded 10^4.

Selucký *et al.*[55] have developed a rapid extraction separation of radium from acidic solutions of thorium and its decay products. The radium is extracted with HDCC solution in nitrobenzene in the presence of *p*-nonylphenylnonaethylene glycol (Slovafol 909). The radium can easily be stripped into aqueous solution after dilution of the organic phase with di-isopropyl ether. This method may be used for the preparation of ^{224}Ra stock solutions.

HDCC or its chlorinated derivative $H[C_4B_{18}H_{15}Cl_7Co]$ can be used for the extraction of trace amounts of ^{137}Cs from nitric acid containing some radionuclides (^{144}Ce, ^{60}Co, ^{106}Ru–^{106}Rh, ^{95}Zr–^{95}Nb, ^{65}Zn) into nitrobenzene.[56] Microamounts of ^{137}Cs were found to be extracted nearly quantitatively, especially at low acidities of the aqueous phase; ^{106}Ru and ^{95}Zr passed into the organic phase only in small amounts, and ^{144}Ce, ^{60}Co and ^{65}Zn were practically not extracted at all. The equilibrium distribution ratios of these radionuclides decreased with increasing nitric acid concentration in the aqueous phase, but the separation factors for isolation of ^{137}Cs from the other radioisotopes increased with increasing nitric acid content in the initial aqueous phase, except for that from ^{106}Ru (which did not change much).

A study of the effect of macroamounts of some alkali-metal cations (Li^+, Na^+, K^+) on the distribution ratio of caesium in the nitric acid/nitrobenzene–HDCC system showed the possibility of direct separation of caesium from acid-digests of biological materials that did not contain large amounts of potassium (Li^+ and Na^+ did not interfere).[57]

Ščasnár and Koprda[58] also studied the chemical yield for ^{137}Cs as well as the selectivity of separation of ^{137}Cs from ^{144}Ce, ^{106}Ru, ^{60}Co, ^{65}Zn and ^{95}Zr, with a model mixture in nitric acid and also with acid-digests of spiked biological tissues, for a variety of analytical separation methods (adsorption on precipitates of $Co_2[Fe(CN)_6]$, $Cu_2[Fe(CN)_6]$ and ammonium phosphomolybdate; liquid–liquid extraction in the water–nitrobenzene system by means of HDCC or its chlorinated derivative $H[C_4B_{18}H_{15}Cl_7Co]$). It was found that only the extraction method could simultaneously ensure both high separation selectivity and sufficient yield of ^{137}Cs, and it was made the basis of the rapid routine isolation of ^{137}Cs from milk,[59] urine,[60] faeces[60] and biological materials[61] contaminated with a mixture of radionuclides.

Finally, a rapid and selective method for extractive isolation of radiostrontium from urea by using a nitrobenzene solution of HDCC in the presence of PEG has been developed.[62]

Conclusions

The dicarbollylcobaltate(III) anion and some of its halogen derivatives are very useful reagents for the extraction of alkali-metal cations (especially Cs^+), and also (in the presence of polyoxyethylene compounds) for the extraction of Sr^{2+} and Ba^{2+} from aqueous solution into an organic phase consisting of pure nitrobenzene or its mixtures with some less polar solvents (*e.g.*, CCl_4, $CHBr_3$), both under laboratory conditions for purely theoretical or analytical purposes, and on the technological scale for the separation of some high-activity isotopes in the reprocessing of irradiated nuclear fuel.

The dicarbollylcobaltate(III) anion, when employed as a component of the supporting electrolyte in the organic phase, has also found application in electrochemical studies on the processes taking place at the water/nitrobenzene interface. The results of these studies provide important information on the processes taking place in biological membranes and also in classical liquid–liquid extraction, especially in the water–nitrobenzene system.

SHORT COMMUNICATION

A TIMED SOLENOID INJECTOR FOR FLOW ANALYSIS

S. D. ROTHWELL and A. A. WOOLF
School of Chemistry, Bath University, Bath, England

(*Received* 17 *July* 1984. *Revised* 18 *October* 1984. *Accepted* 12 *December* 1984)

Summary—Samples can be reproducibly injected into flow-streams by timed switching of a sample stream with a miniature solenoid valve and timer circuit. The device is simpler to assemble and use than the standard rotary valve and a direct comparison under the same operating conditions shows that the solenoid valve is an adequate replacement for the rotary valve.

Samples are generally introduced into flow-analysis systems by means of rotary valves with fixed-volume loops.[1] Such valves are expensive because they require careful construction to ensure alignment of the fine bores in the stators and rotors. Also a continuous variation in sample size is not possible. A change in sample size requires a change in the loop or rotor.

An economical timed solenoid valve is described which can provide samples in a continuous range of sizes at any time intervals desired. It can be readily assembled from "off the shelf" components and can be adapted for more complicated flow regimes. In essence it uses temporal, as opposed to spatial, control of injections. The performance of the timed solenoid valve has been compared with that of a standard rotary valve in a typical flow analysis, the determination of phosphate.

EXPERIMENTAL

Apparatus for phosphate determination

This was based on Růžička and Hansen's manifold[1] illustrated in Fig. 1, labelled according to their conventions. Different injectors were inserted at S. The rotary valve shown by Růžička and Hansen[2] was improved by inserting four O-rings (5 mm inner diameter, 8 mm outer diameter) around the bores on the inside faces of the stators, and clamping the assembly with four peripheral bolts rather than a central one. Rotary friction was reduced because the discs rotated on the small bearing surface of the compressed O-rings and not on the whole disc areas. This enabled us to dispense with the difficultly machinable polytetrafluoroethylene stator and to use only polystyrene discs. The quality of the surface finish of the polystyrene could also be lowered without causing leakage.

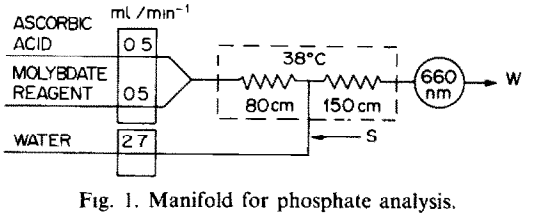

Fig. 1. Manifold for phosphate analysis.

The alternative injector was a three-way solenoid valve [Lee No. LFAA 1200118A][3] of overall size 33 × 12 mm. The actual working volume of fluid is only 100 μl and the valve-rubber travel about 1 mm on activation. At 12 V d.c. and 23 mA the solenoid will work against a pressure differential of 0.69 atm and at 19 V d.c. against a differential of up to 2 atm. The inlet and outlet had a bore of 0.8 mm and could be inserted into the 1-mm bore manifold tubing without use of special seals. This valve was attached at S as shown in Fig. 2. A simple timer circuit, which can turn the coil current on and off at fixed intervals, is shown in Fig. 3. The start switch initiates a sequence which leaves the solenoid inactive for 5–250 sec intervals, adjustable by means of R_1, followed by activation for 0.1–100 sec intervals, adjustable with R_2. The sequence carries on without resetting. The sample stream was run at a suitable flow-rate through a restricting coil to give a steady positive insertion pressure.

Reproducibility test on solenoid valve

The water emerging from the carrier-stream line during a time-period corresponding to 40 "valve open" cycles was collected and weighed. The difference between this weight and that of the water emerging from the carrier-stream line in the same period of time with the valve permanently closed gave the weight (and hence volume) of 40 samples. Times were not measured accurately, but set to approximately the required value by adjusting the timer resistances.

Dispersion measurements

Dispersions were measured with Bromothymol Blue indicator as described by Růžička and Hansen.[4] Residence times were obtained from the recorder traces and chart-speed.

RESULTS AND DISCUSSION

The mean relative deviations for injections of 380, 65.0 and 26.5 μl with the solenoid valve were 0.3, 0.3 and 1.2% respectively. The injection time for the last set of measurements was about 0.4 sec. The reproducibilities obtained with the solenoid valve were better than the range of timing error. The "555" timer has a specified maximum error of 0.5%, and for the larger volumes, averaged over 40 samples, the mean deviations were about half this value. For the smallest samples the deviations increased because the response time of the valve, quoted as 3 msec, became

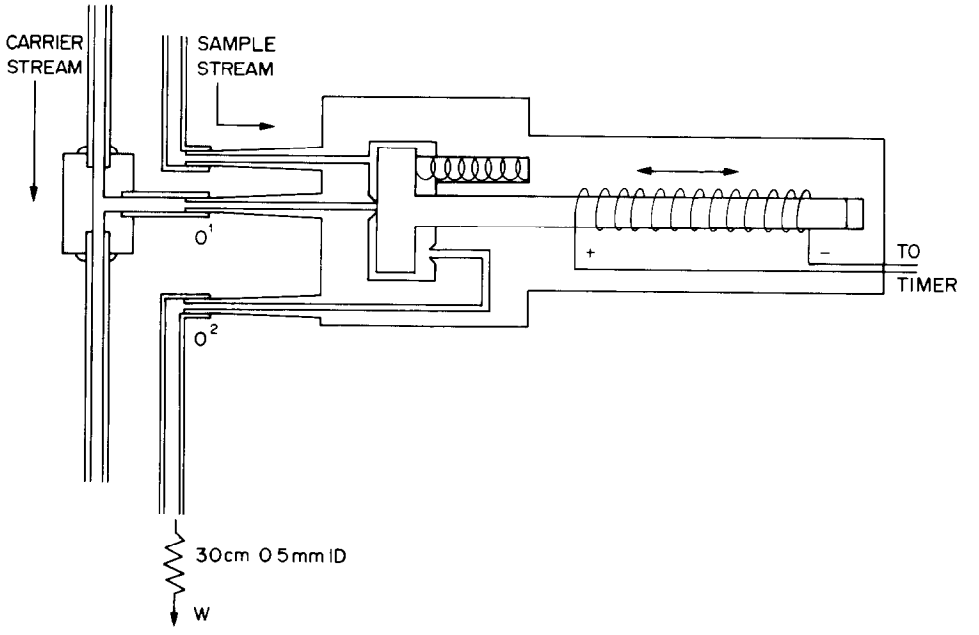

Fig. 2. Solenoid valve injector. Solenoid off, O^1 closed; solenoid on, O^2 closed.

an appreciable fraction (0.75%) of the time the valve was open. Smaller samples could be injected with the same accuracy as larger ones by reducing the sample flow-rate.

The sample residence time within the manifold was less when the solenoid valve was used, because of the higher flow-rate during injection (Table 1). A simple calculation shows that there is no appreciable change in resistance to flow on substituting the new valve. The equivalent-resistance length L of 1 mm tubing for the solenoid valve is given by:[5]

$$17.0 = \pi(0.05)^2 L \left(\frac{13}{17 Q_c} + \frac{4}{17 Q_o}\right)$$

where Q_c and Q_o are the carrier and sample stream flow-rates, with the valve closed and open respectively. This gives $L = 154$ cm for the solenoid valve, compared with $L = 151$ cm, calculated for the rotary valve at the Q_o rate, with the valve closed for

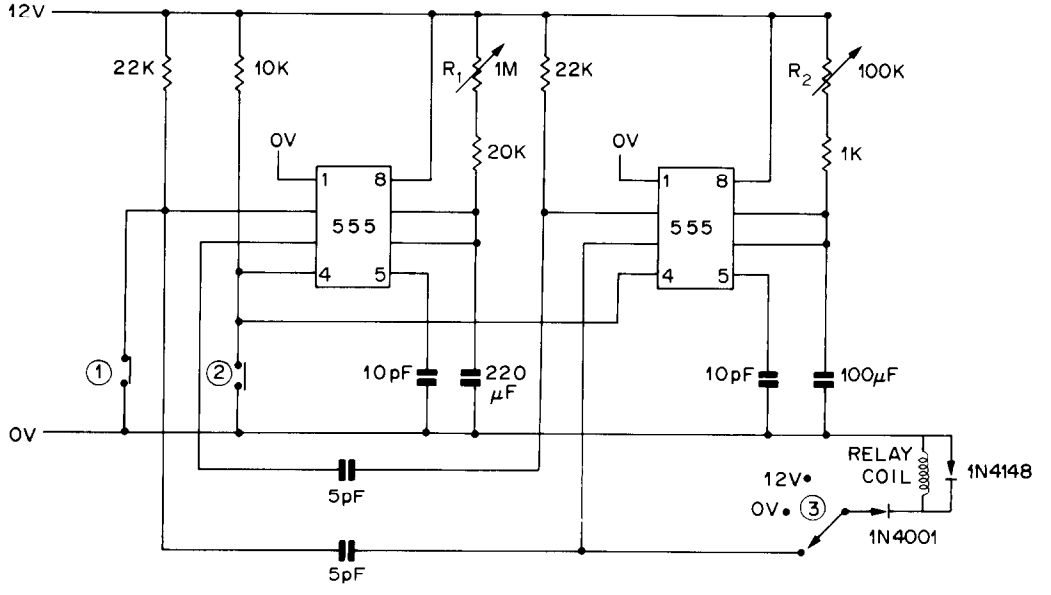

Fig. 3. Timer circuit. Start switch (1); reset switch (2); on, off and continuous cycle positions on switch (3).

Table 1. Comparison of dispersions and residence times with rotary valve (R) and solenoid valve(s)

Sample size, *µl*	Residence time, *sec*	Dispersion, *D**

289 (S)	17.0	2.47
285 (R)	19.2	2.69

* $D = C^{\circ}/C^{max}$ where C° is the undiluted dye concentration and C^{max} the concentration recorded at the peak maximum.

13 sec and open for 4 sec. The actual length of tubing used was 150 ± 1 cm.

The dispersion obtained was about 9% less with the solenoid valve, probably because the faster flow produces a shorter residence time. The absorption peaks recorded when the solenoid valve was used were still non-Gaussian (Fig. 4). If the peak width at half-height is taken as 2σ, the sampling rate can be between 110 and 170 samples/hr for peak separations of 6σ and 4σ respectively. The solenoid valve was operated at 105 samples/hr without any peak overlap resulting. This contrasted with only 77 samples/hr possible with the rotary valve. For both valves peristaltic pump pulsations were observed on the trace recorded at 50 mm/min, but were not detectable at the normal recording rate of 5 mm/min. Such fluctuations have been found not to be eliminated by using a pulse-damping device.[6]

The overall reproducibility of peak heights is marginally inferior when the solenoid valve is used (the average deviation is about 0.6% more than for rotary valve injection) (Table 2). It should be noted that almost half of the standard deviation results from errors in measuring peak heights. These readings were accurate to 0.3 mm which is 1.2, 0.6 and 0.4% of the heights of the 1, 2 and 4 ppm peaks respectively. Other inaccuracies arose from variations in sample volume (~0.3%) and colour development. The calibration graph obtained by use of the solenoid valve could be made less curved by adjusting parameters such as sample size or flow-rate.

Further miniaturization of solenoid-valve injection is an obvious development, since integrated-circuit timers accurate to 0.01% and smaller valves with fluid volumes as small as 10 µl are available, but for normal flow-injection analysis the unmodified device is a satisfactory replacement for the rotary valve. Timed-injection solenoid valves could also replace the multiple injection valves used in merging-zone flow analysis.[7]

ANNOTATION

EFFECT OF CONTAINER MATERIAL, STORAGE TIME AND TEMPERATURE ON DETERMINATIONS OF CADMIUM LEVELS IN HUMAN URINE

KUNNATH S. SUBRAMANIAN, JEAN-CHARLES MERANGER and JOHN CONNOR
Environmental Health Directorate, Health and Welfare Canada, Tunney's Pasture, Ottawa, Ontario, Canada

(*Received* 6 *July* 1984. *Revised* 6 *December* 1984. *Accepted* 11 *January* 1985)

Summary—The effect of container material (polyethylene, polypropylene, polystyrene, borosilicate glass and flint glass), storage time (0–86 days), and temperature (22° and 4°) on the cadmium content found by graphite-furnace atomic-absorption spectrometry for spiked and unspiked urine samples has been studied. No loss of cadmium occurred for at least 10 and 28 days when unspiked and spiked samples respectively, were stored in polyethylene containers at 22°. For storage up to 3–4 days at 22°, polypropylene, polystyrene, borosilicate glass and flint glass containers were also found suitable. Storage at 4° was not effective in preventing loss of cadmium.

The detection of cadmium in human urine may be used for identifying groups at risk of cadmium toxicity.[1] Sensitive and selective methods capable of determining ng/ml levels of cadmium in human urine are now available,[2] but the data obtained by their use are meaningful only if the various factors affecting the accuracy and precision of the determination have been identified and controlled. Some of these factors are: (*i*) type of container material used for collecting and storing the urine samples; (*ii*) temperature of storage; (*iii*) duration of storage. In spite of the importance of these factors no studies seem to have been made of the stability of cadmium in urine on storage. In view of this, it was thought advisable to study the effect of container type, storage time and temperature on the levels of cadmium in unspiked and spiked human urine samples. The findings of this study are reported here.

EXPERIMENTAL

Apparatus

A Perkin–Elmer model 603 atomic-absorption spectrophotometer equipped with an HGA-500 graphite furnace, a deuterium-arc background-corrector and a Hamamatsu hollow-cathode lamp operated at 10 mA and a resonance wavelength of 228.8 nm (spectral band-pass 2.0 nm) was used for the determination of cadmium. Nitrogen was used as the purge gas and its flow was interrupted during the atomization step.

The containers used for storing the spiked and unspiked urine samples were: (*i*) polyethylene bottles, 250-ml capacity, with Teflon-lined plastic screw-caps (cat. no. F10610-0008, Canus Plastics, Ottawa, Ontario); (*ii*) sterile polystyrene urine specimen containers, 90-ml capacity, with white plastic screw-caps (cat. no. C8841-57, Starplex, Scientific, Mississauga, Ontario); (*iii*) sterile polypropylene urine specimen-containers, 115-ml capacity, with polyethylene screw-caps (cat. no. C8841-201, Canadian Laboratory Supplies); (*iv*) borosilicate glass serum bottles, 100-ml capacity (cat. no. B7761-100, Canadian Laboratory Supplies); (*v*) flint glass bottles, 125-ml capacity, with polypropylene screw-caps (cat. no. B7772-125, Canadian Laboratory Supplies). The red rubber stoppers recommended by the manufacturer for the glass serum bottles were found to be contaminated with cadmium, so they were replaced with parafilm closures.

All the containers were cylindrical in shape and were purchased from Canadian Laboratory Supplies Limited, Ottawa, Ontario. Before use, all the containers were freed from traces of cadmium as described earlier,[3] by a detergent wash, tap-water rinse, soaking in 2% ultrapure nitric acid for 24 hr, distilled water rinse (6 times) and ultrapure water rinse (6 times). After the cleaning operation, any containers found to give blanks when filled with ultrapure water acidified to pH 1.0 with ultrapure nitric acid having no detectable levels of cadmium, were rejected.

Reagents

High-purity water was obtained by passing tap water through a cellulose adsorbent and two mixed-bed ion-exchange columns, and finally distilling in a Corning AG-11 unit. The quality of the water conformed to ASTM Type 1 specification.[4] In addition, the cadmium level in the water was below the graphite-furnace atomic-absorption (GFAA) detection limit (3 times the standard deviation of the blank) of 0.1 ng/ml.

A certified atomic-absorption standard containing 1000 mg of cadmium per litre was obtained from Fisher Scientific. Fresh working standards of lower concentrations were prepared daily by serial dilution of the stock solution with high-purity water.

A 10% aqueous solution of diammonium hydrogen phosphate (Baker Analyzed Reagent) was prepared and purified as described elsewhere.[5]

All other reagents and solutions used were of the highest purity available.

Sample collection and storage

For studies with unspiked urine a 24-hr sample was collected from a laboratory volunteer, in a 2-litre Nalgene linear polyethylene bottle fitted with a polyethylene screw-cap, previously freed from traces of cadmium as described above. The pooled urine was homogenized by vortex mixing and its cadmium content immediately determined by graphite-furnace atomic-absorption spectrometry with addition of diammonium hydrogen phosphate and nitric acid as matrix-modifiers.[2] The measurement was done in quintuplicate.

From the homogenized pooled sample, 25-ml aliquots were pipetted into the polypropylene (PP), polystyrene (PS), borosilicate (BS), and flint glass (FG) containers, and 50-ml aliquots into polyethylene (PE) containers. The surface area of contact of the urine with the various containers was (cm^2): PP, 96; PS, 82; BS, 99; FG, 89; PE, 111. The containers were then stored at room temperature (22°) in a Class 100 clean hood and also at refrigerator temperature (4°). Each combination of container and temperature was run in triplicate. The samples from each container were then analysed on days 0, 1, 2, 4, 6, 10, 16, 20, 28, 58 and 86. Before analysis the refrigerated samples were allowed to attain room temperature, and all the samples in the various containers were thoroughly homogenized by vigorous vortex mixing.

For the studies with spiked urine, another 24-hr sample was collected from the same donor. The sample was vigorously vortex-mixed and spiked to give an added cadmium concentration of approximately 5 ng/ml. The same storage procedure was used and the sample were analysed on days 0, 1, 3, 7, 11, 14, 21, 28, 42, 59 and 66.

Analytical procedure

The concentration of cadmium in the unspiked urine sample was monitored by using the procedure developed earlier.[2] For each container, a 0.5-ml aliquot of sample was pipetted into a precleaned 1-ml Pyrex standard flask, followed by the addition of 20 μl each of 10% diammonium hydrogen phosphate solution and 10% v/v nitric acid. The solution was made up to the mark with high-purity water and vigorously vortex-mixed for 30 sec. A 10-μl aliquot of this solution was introduced into the graphite furnace with an Eppendorf pipette fitted with a disposable polypropylene tip which had been decontaminated as described elsewhere.[3] The cadmium in the sample was atomized by raising the temperature to 120° in 20 sec and holding at that temperature for 30 sec (drying), heating to 550° in 10 sec and holding there for 30 sec (ashing), heating to 2100° in 1 sec and holding for 5 sec (atomization) and finally heating to 2500° in 1 sec and holding for 2 sec (cleaning). The peak absorbance values for four replicate injections were averaged. A duplicate was run for each container at each temperature. The cumulative averages of the duplicates from each of the three containers at each temperature (*i.e.*, the average of 24 measurements) were then used to calculate the recovery of cadmium as a function of time.

The amount of cadmium in the urine sample immediately after pooling (time "zero", in fact approximately 60 min), and on the various days of storage, were calculated by use of a calibration graph prepared from a cadmium-free control urine (Product no. 2934-80. Level I, Fisher Scientific) spiked with various amounts of cadmium (0.5, 1.0 and 2.0 ng/ml) and the matrix modifiers as already described. A blank containing only the matrix modifiers, and a urine control spiked with 1.0 ng/ml cadmium and the matrix modifiers, were run once every 30 min during the analytical measurements to compensate for any small changes in the working graphs, resulting from conditions beyond the analyst's control. Also, a fresh matrix-matched calibration graph was prepared on each day the sample were tested. In addition, the blank and the 1-ng/ml spike prepared on day 0 (zero) were re-analysed on other days of sample measurement, to obtain the day-to-day precision.

The procedure for the spiked urine sample was basically the same as that above except that the sample and the control were diluted five-fold (*i.e.*, 0.2 ml of urine plus 20 μl of each matrix modifier, diluted to 1 ml with high-purity water).

RESULTS AND DISCUSSION

Analytical methodology

The atomic-absorption method has been fully described elsewhere, and gave within-run and between-day precision values, expressed as coefficient of variation (% CV), within 3–11% at cadmium concentrations of 0.5–2.4 ng/ml in human urine.[2] In the present study the within-run and day-to-day CV were found to be 3.5 and 5.0% respectively, for a cadmium concentration of 2.17 ng/ml in the pooled 24-hr urine sample, and 3.4 and 3.8% respectively, for the urine control containing a cadmium spike concentration of 1.0 ng/ml. In the earlier work, the overall mean analytical recovery of cadmium from five urine samples (native contents ranging from 0.5 to 2.7 ng/ml, supplemented with 0.4–1.0 ng of Cd per ml) was $103.24 \pm 4.3\%$. The method has a detection limit (concentration corresponding to 3 times the standard deviation of the blank) of 0.1 ng/ml and a linear range of 0–3 ng/ml. These analytical figures of merit demonstrate the suitability of the procedure[2] for the stability study conducted here.

Storage study

Preliminary studies showed little change in the cadmium concentration of a spot urine sample stored in PE, PP, PS BS or FG containers at 22° or 4° for at least a two-day period. Therefore it was decided to use a 24-hr collection from the same donor for the stability study.

The initial cadmium concentration (*i.e.*, value on day "zero") in the unspiked and spiked urine composite were 2.17 ± 0.08 and 7.06 ± 0.11 ng/ml respectively (the latter includes a spike of approximately 5.0 ng/ml). In the ensuing discussion these values are designated as 100%; the values on subsequent days are calculated as a percentage of the level on day 0 (zero).

Table 1 shows the recovery of cadmium from the unspiked urine as a function of time. No significant change occurred for at least 10 days of storage at 22° for any of the containers except the polystyrene ones. At refrigeration temperature significant loss of cadmium occurred even on the second day of storage from all the containers except those made of polypropylene, for which no loss was found for at least 4 days.

Table 2 shows the corresponding results for the spiked urine. At 22° no loss of cadmium occurred from any of the containers for at least 3 days, whereas at 4° there was no loss for 7 days except from the flint glass containers. At room temperature, by the 7th

day of storage, losses had occurred from all the containers except those made of polyethylene or polystyrene. The urine stored in polyethylene showed no loss of cadmium for at least 28 days.

For the unspiked samples the losses at refrigeration temperature were higher than those at room temperature for at least 28 days. For the spiked samples the pattern was not so simple, but in general the loss at refrigeration temperature was lower than that at room temperature for at least 28 days, except for the samples stored in polyethylene containers.

From the results, storage of urine samples in PE at room temperature is seen to be best because no loss of cadmium occurred for at least 10 and 28 days respectively, when unspiked and spiked samples were stored in this material at 22°. For storage up to 3–4 days at 22° all five types of containers are suitable. Storage at refrigeration temperature did not improve the stability of the samples with respect to cadmium, the loss, especially from unspiked samples, being greater than at 22°. The reason for this is not clear. The loss of cadmium species from urine may occur by a number of mechanisms which could be chemical, physical or microbiological in nature. For example, urine is clear when voided but often precipitation (of uric acid and the oxalates, urates and phosphates of alkali and alkaline-earth metal ions) occurs on cooling.[6] Such crystalline substances are known to be surface-active and to remove metal ions by adsorption, occlusion and inclusion.[7] During refrigeration the extent of precipitation is generally greater, resulting in an increased loss of cadmium.

The loss of cadmium increases with storage time. On storage the urea in the urine samples is slowly converted into ammonium carbonate with release of ammonia and a consequent increase in pH.[6] It is generally known that the amount of trace metals adsorbed on surface increases with increasing pH.[8] Thus, one of the reasons for the increased loss of cadmium with increasing storage time could be the

§"0" days corresponds to measurement within 60 min of sample preparation.

increased adsorption and co-precipitation of the metal, resulting from the increase in pH.

The cadmium concentration of urine is subject to temporal and diurnal variation but the average calculated for consecutive 24-hr collections shows little change.[9] Thus, 24-hr urine collection should be used for screening programmes and for identifying groups at risk of cadmium toxicity. The present study shows further that it is desirable to analyse the 24-hr sample either immediately or within ten days of collection. Storage in polyethylene containers at room temperature is found to be the most suitable. Finally, the observation that acidification and addition of bactericidal agents to urine samples are no longer a prerequisite, at least for ten days of storage in PE containers, may facilitate speciation studies undertaken to improve our knowledge of the nature of urinary cadmium compounds and cadmium metabolism.

THE USE OF CERTIFIED REFERENCE MATERIALS IN THE VERIFICATION OF ANALYTICAL DATA AND METHODS*

R. SUTARNO and H. F. STEGER
Mineral Sciences Laboratories, CANMET, Energy, Mines and Resources Canada, Ottawa, Ontario, Canada

(*Received* 1 *June* 1984. *Revised* 24 *January* 1985. *Accepted* 7 *February* 1985)

Summary—An experimental design is proposed for the verification of the accuracy and precision of an analytical method by its application to certified reference materials.

The importance of certified reference materials, CRMs, in analytical chemistry is widely accepted. There are at least 130 producers of CRMs of all types in the Western World alone.[1] If only compositional CRMs such as ores, rocks and metal alloys are considered, there are at least 39 producers, who together offer approximately 250 reference ores, concentrates, rocks, soils and cements and over 2400 metal alloys.

CRMs are widely applied for quality control of analytical data by their use for the direct calibration of methods and instruments, verification of the precision, accuracy and sensitivity of methods used in control analyses, and the development and evaluation of new or reference methods. In spite of this, no general guidelines for the use of CRMs have been published. To remedy this, REMCO, the Council Committee on Reference Materials of the International Organization for Standardization, initiated the preparation of such a guide in September 1983.[2]

In the present paper we are not concerned with the appropriateness or the mechanics of the use of CRMs for these applications, but only the statistical transfer of the stated uncertainty in the certified value(s) and the application of this uncertainty by the analyst.

The use of CRMs in the direct calibration of methods and instruments has been studied by Oster *et al.* (France)[3] and by Mashiko *et al.* (Japan)[4] and is currently being expanded by Eberhardt (U.S.A.)[5] as contributions to the forthcoming REMCO guide. The use of CRMs in the determination of precision and accuracy and the sensitivity of methods, established or new, may have greater significance for the readers of analytical journals dedicated to the improvement of methodology. Most issues of such journals include one or more papers where CRMs are applied in this manner. A comparison of such papers readily shows that there is a variety of procedures for validating a modified or new method by applying it to CRMs. These vary from those based on statistical concepts to those based on subjective considerations. The latter approach has the potential danger that after the assessment with a CRM a user-analyst striving for high accuracy and precision may have doubts about his method that prove unfounded if the uncertainty in the certified values is taken into account.

To make analysts more aware of the concepts behind the use of CRMs, the Canadian Certified Reference Materials Project (CCRMP), on the basis of the experience of 13 years in the preparation of reference ores and related materials,[6,7] proposes the following experimental design for the use of CRMs in determination of the accuracy and precision of analytical methods†. The use of the proposed design should of course, do away with subjectivity.

Nature of CRMs

CRMs can be liquid, gaseous, or solid (as pure or mixed powders or individual artifacts). Regardless of their physical state, CRMs are packaged either in individually certified units or, more commonly, in units which are all assumed to be representative of a larger lot. In the latter case, the between-unit homogeneity is generally acceptable for all but the most exacting analytical purposes. Some CRMs however cannot be made truly homogeneous; the use of such materials will not be considered in this paper.

Certification

There are basically three types of analytical programmes for certification of a reference material. The first is by interlaboratory consensus,[8] a minimum of 10 laboratories analysing in replicate one or more units of the reference material for the elements of interest. A one-way analysis of variance is performed on the data. In one version of this programme the participating laboratories use the method of their

†This experimental design has also been submitted by CCRMP to REMCO.

choice. The following statistical parameters are then usually reported on the certification document.

A_c = the certified value for the content of an element. A_c is usually the overall mean of the results of the certification programme (or the mean of the laboratory means) but is sometimes some other central value such as the geometric mean or the median.

$V[A_c]$ = the variance of A_c, a measure of precision of the estimate of the consensus value. Alternatively, the precision may be expressed in terms of a confidence interval (usually 95%, which means that if the interlaboratory programme is repeated 100 times, it is expected that 95 of the resultant consensus means will fall within this confidence interval).

S_{Lc} = the between-laboratories standard deviation when each laboratory uses the method of its choice.

S_{rc} = the within-laboratory standard deviation when each laboratory uses the method of its choice.

In the second version of the programme, the participating laboratories use the same well-established widely-accepted analytical method. The statistical parameters usually reported are A_c, $V[A_c]$, defined as above, and σ_{Lc} and σ_{rc}.

σ_{Lc} = the between-laboratories standard deviation when all laboratories use the same method.

σ_{rc} = the within-laboratory standard deviation when all laboratories use the same method.

Certification by interlaboratory consensus is the most frequently encountered type of programme.

The second type of programme is met in certain specialized fields where it is impossible or impractical to arrive at a consensus value by a full interlaboratory programme. A small number of "expert" laboratories analyse the candidate reference material and the certified value A_c is arrived at by accepting the consensus value or taking into account "methodological" considerations.[9] There is no formal statistical evaluation of the analytical results. The uncertainty of the certified value of an element is based on chemical considerations.

In the third type of programme the certification is done by a single laboratory using a definitive method, *i.e.*, a method that is based on first principles, has high precision and for which the limits of uncertainty can be stated with a high degree of confidence.[10] In addition to accepting that the definitive method is the best available, the user assumes that the method is applied without bias. This assumption is usually made when the producer laboratory is a national or industrial reference laboratory where "superior" resources are available, or when the analysis involves a certain "art", and specialized skill is required. The statistical parameters reported are A_c and σ_{rc} of the definitive method as performed by the "expert" certifying laboratory. Some producers of reference materials also report an evaluation of any systematic error not included in σ_{rc}.

Validation of analytical methods

The concept presented here, of using CRMs to determine the precision and accuracy of an analytical method, rests on three basic premises. First, that the certified value of an element in a reference material is the best estimate of the true value. Second, when tested with a reference material certified by interlaboratory consensus, an analytical method is validated if the results are sufficiently precise and accurate to qualify for inclusion in the calculation of the statistical parameters for the interlaboratory programme for the CRM. That is, in statistical terms, they belong to the distribution used to characterize the CRM. Third, the relationship between the within-laboratory and between-laboratories standard deviation found to hold for reference materials certified by interlaboratory consensus, would also apply to a reference material certified by an "expert" certifying laboratory using a definitive method, if that material were certified by interlaboratory consensus. This last assumption is necessary because very few users can expect to achieve the same accuracy and precision as an "expert" certifying laboratory. In principle a between-laboratories variation must exist for every method.

Use of CRMs

All analytical methods have inherent errors. Random error is always present and may be accompanied by systematic error (bias). It is therefore highly unlikely that the result obtained by a method being tested will be exactly the same as the certified value of a CRM; an acceptable tolerance limit must therefore be defined for each CRM. This limit will depend partly on the mode of certification. The following criteria are proposed in assessing an analytical method by applying it to a CRM.

Precision. An analytical method is sufficiently precise if it produces results for a CRM that are statistically as precise as the within-laboratory precision stated in the certification document.

Accuracy. An analytical method is sufficiently accurate if it produces results for a CRM that do not differ from the certified value by more than can be accounted for by within- and between-laboratory statistical fluctuations.

GENERAL PROCEDURES FOR APPLYING AN ANALYTICAL METHOD TO A CRM

Validation of the CRM

Before a CRM is used, the following should be checked.

Certificate—certified value, precision, method of characterization, suggested sub-sample weight, and expiration date of certification (particularly for a relatively unstable CRM).

Visual check—segregation, discoloration and quantity.

Analysis of the CRM

Perform replicate determinations (on separate sub-samples) by the analytical method to be tested; n should be at least 10. For a periodic check of accuracy of an analytical method, duplicate analysis on each occasion is sufficient, but the total number of replicates should be at least 10.

Outliers

Use an outlier test such as the Dixon test to decide whether any of the results may be regarded as outliers. If an outlier is found, investigate possible physical causes for it. If an excessive number of results are found to be outliers and no physical cause can be identified, reinvestigate the analytical procedure.

Mean and standard deviation

Compute the following statistics for the results remaining after rejection of outliers.

$$\bar{X} = \sum_{i=1}^{n} X_i/n = \text{mean}$$

$$S_W = \sqrt{\sum_{i=1}^{n} \frac{(X_i - \bar{X})^2}{(n-1)}}$$

= estimated within-laboratory standard deviation, *i.e.*, precision of the method

Check of precision

This can only be performed if S_{rc} or σ_{rc}, the certified within-laboratory standard deviation, is given in the certificate, otherwise the precision should be judged by chemical considerations.

Compute

$$F = \frac{(S_W)^2}{(S_{rc})^2}$$

and compare F with the value of $F_c = F_{0\,95,n-1,DF_c}$ (obtainable from any statistics book). If the number of degrees of freedom DF_c for the CRM certification tests is not given in the certificate, use $DF_c = 60$. If $F \leqslant F_c$, the analytical method is sufficiently precise; if $F > F_c$, the analytical method is not as precise as those used for certification of the reference material.

Check of accuracy

If the between-laboratories standard deviation S_{Lc} or σ_{Lc} is reported for the CRM, *i.e.*, it was certified by interlaboratory consensus, then the following test should be used. If

$$|\bar{X} - A_c| \leqslant 2S_{Lc} \quad \text{or} \quad |\bar{X} - A_c| \leqslant 2\sigma_{Lc}$$

then the analytical method is sufficiently accurate. Otherwise it is not considered to be as accurate as those used by the laboratories participating in the certification programme.

For reference materials certified by interlaboratory consensus for which the between-laboratories standard deviation is not reported, or by a partial interlaboratory programme, or by interlaboratory consensus on the basis of one widely-accepted method that is not the same as the method being tested, or by

Table 1. Relation between the number of replicates (n) and the chance (β) that an analytical method will be accepted as valid, when the ratio of its standard deviation to the within-laboratories standard deviation of the CRM (at $\alpha = 0.05$) is greater than the tabulated value (calculated from data in *Handbook of Tables of Probability and Statistics*, 2nd Ed., p. 299, CRC, Cleveland, Ohio, 1968)

one "expert" laboratory using a definitive method, the following test is suggested. If

$$|\bar{X} - A_c| \leqslant 4S_W$$

then the analytical method being tested is sufficiently accurate.

STATISTICAL JUSTIFICATION

A significance level of $\alpha = 0.05$ is used for all statistical tests.

Number of replicate determinations, n

The number of replicate determinations to be performed directly affects the precision of the estimate of the within-laboratory precision, S_W. Table 1 shows the relation between n and the maximum ratio of the standard deviation of the analytical method and the within-laboratories standard deviation for the CRM, S_W/S_{rc}, at various values of β, and $\alpha = 0.05$, β being the probability that the method will be accepted if the standard deviation is greater than the ratio times the certified value of S_{rc}. For example, at $\beta = 0.05$ for $n = 10$, if the analytical method has passed the appropriate F-test, there is no more than a 5% chance that it has a standard deviation in excess of $2.26S_{rc}$.

CRMs for which S_{Lc} *is reported*

There are two factors to consider: the uncertainty of the certified value and the uncertainty of the analytical method. The following formula can be used as the criterion for acceptance.

$$|\bar{X} - A_c| \leqslant 2\sqrt{\sigma_C^2 + \sigma_D^2} \qquad (1)$$

where σ_C^2 is the uncertainty associated with the certified value and σ_D^2 is the uncertainty associated with the analytical method being examined. The factor 2 is an approximation for the fractile of *Student's* t-distribution for 95% probability. This assumption, although somewhat crude, has been widely accepted and used in various ISO standard methods. The value of σ_C^2 depends on the method of certification of the reference material.

For certification by interlaboratory consensus from use of several methods:

$$\sigma_C^2 = (S_{Lc}^2 + S_{rc}^2/n_c)/N_c \qquad (2)$$

For certification by interlaboratory consensus by use of one method:

$$\sigma_C^2 = (\sigma_{Lc}^2 + \sigma_{rc}^2/n_c)/N_c \qquad (3)$$

where N_c is the number of laboratories which produced results used in certification of the reference material, and n_c is the average number of replicate determinations performed by each participating laboratory for the certification programme. For most certifications by interlaboratory consensus, N_c is usually > 10, so σ_C^2 is small enough in relation to σ_D^2 to be neglected, and then

$$\sigma_D^2 = \sigma_{Lc}^2 + S_W^2/n \quad \text{or} \quad S_{Lc}^2 + S_W^2/n$$

depending on the type of CRM used. For $n = 10$, S_W^2/n becomes small and equation (1) can be simplified to

$$|\bar{X} - A_c| \leqslant 2S_{Lc} \quad \text{or} \quad |X - \bar{A}_c| \leqslant 2\sigma_{Lc} \qquad (4)$$

CRMs for which S_{Lc} *is not available*

Experience in interlaboratory consensus programmes based on use of one method, by ISO Technical Committee 102 on iron ores, shows that an analytical method is considered to be well standardized if $\sigma_{Lc}/\sigma_{rc} \leqslant 2$. On this basis, S_{Lc} can be replaced by $2\sigma_{rc}$ and the criterion for acceptance is:

$$|\bar{X} - A_c| \leqslant 4\sigma_{rc} \qquad (5)$$

Table 2 reports the value of S_{Lc}/S_{rc} for 135 elements and constituents that have been certified by CCRMP by interlaboratory consensus based on use of multiple methods. Of these, 77 show $S_{Lc}/S_{rc} \leqslant 2.0$ and all but 22 show S_{Lc}/S_{rc} or $\sigma_{Lc}/\sigma_{rc} \leqslant 2.5$. These data suggest that the criterion S_{Lc}/S_{rc} or $\sigma_{Lc}/\sigma_{rc} \leqslant 2.0$ is too harsh for most interlaboratory consensus programmes, but nevertheless is reasonable, particularly in view of the fact that some estimate of the between-laboratories standard deviation is required before the CRM can be used for validation of an analytical method. On this premise, S_{Lc} can be replaced by $2S_{rc}$ and the criterion for acceptance becomes:

$$|\bar{X} - A_c| \leqslant 4S_{rc} \qquad (6)$$

An analytical method can be verified for accuracy by use of equation (5) or (6) provided the value of σ_{rc} or S_{rc} for the CRM is reported. We propose, however, that the accuracy of the method can equally well be judged by:

$$|\bar{X} - A_c| \leqslant 4S_W \qquad (7)$$

if the precision of the method can be verified as stated above, *i.e.*,

$$F_0 > F = \frac{S_W^2}{S_{rc}^2} \quad \text{or} \quad \frac{S_W^2}{\sigma_{rc}^2}$$

in which case $4S_W$ is statistically equal to $4\sigma_{rc}$ or $4S_{rc}$, *i.e.*, the upper limit of $|\bar{X} - A_c|$ for acceptance of the method is not significantly raised. The advantage in the use of equation (7) is that, to be accepted, a method with higher precision must also have greater accuracy, *i.e.*, give a lower value of $|\bar{X} - A_c|$, than would be necessary if equation (5) or (6) were used as criterion.

In use of CRMs for which σ_{rc} or S_{rc} is not reported, we propose the use of equation (7) to test accuracy. The acceptability of the value of S_W must be decided by the analyst on chemical grounds.

EXAMPLES OF USE OF CRMs

Table 3 summarizes the results of the validation of some analytical methods by their application to some

CRMs from the CCRMP. The examples are taken from CCRMP certification programmes. For DL-1a,[12] SU-1a[13] and SCH-1,[14] the method illustrated was used by one laboratory participating in the interlaboratory programme. In all three instances, the method is capable of acceptable precision in comparison with the overall results of the interlaboratory programme. The atomic-absorption method used to determine cobalt in SU-1a, as used by a particular laboratory, does not give acceptable accuracy. Indeed the results from this laboratory were designated as outliers and rejected for use in the interlaboratory programme.

BL-2a[15] was certified for uranium content solely on the basis of the results obtained by the volumetric umpire method performed at the Canada Centre for Mineral and Energy Technology. The neutron-activation method being validated was applied by a commercial laboratory to confirm the between-unit homogeneity of BL-2a. A precision check for this type of CRM is not recommended but has been performed for illustrative purposes. A definitive method is sufficiently precise for almost all other methods to fail the precision check. The acceptance of the accuracy is contingent on a value of $S_W = 0.0033$ being acceptable to the experimenter.

Caveat

For certain reference materials internationally available, no certified values are given, and only "best" or "usable" values are supplied, for which uncertainties are not reported. These values are often based on very few results or on results in relatively poor agreement. The reference rocks available from many sources are a typical example. The validation of the accuracy of an analytical method, by use of such reference materials and the experimental design proposed here, should be performed with caution, and only for elements and constituents for which the reported value, V, is well defined. The criterion of accuracy is then, of course, $\lvert \bar{X} - V \rvert \leqslant 4S_W$.

EXTRACTION–SPECTROPHOTOMETRIC DETERMINATION OF BORON AND ANTIMONY IN CARBON AND LOW-ALLOY STEELS WITH MANDELIC ACID AND MALACHITE GREEN

SHIGEYA SATO
Faculty of Education, Kumamoto University, 2-40-1, Kurokami, Kumamoto 860, Japan

(*Received* 31 *August* 1984. *Revised* 9 *January* 1985. *Accepted* 23 *January* 1985)

Summary—A very simple and sensitive extraction method using mandelic acid and Malachite Green has been applied to the determination of boron and antimony in steels (carbon and low-alloy). When chlorobenzene is used as the solvent, boron and antimony are simultaneously extracted as ion-pairs of their mandelates with Malachite Green from weak acidic media, but only the boron compound is extracted in the presence of tartrate. Antimony is determined from the difference in absorbance of the extracts. In the case of benzene, boron alone was extracted and determined. Large amounts of iron(II) and other metal cations do not interfere, so the steel samples are dissolved in dilute sulphuric acid. Very low boron (0.0009–0.0091%) and antimony (0.002–0.02%) contents in steel are easily determined without any pretreatment.

Many spectrophotometric methods for determination of boron in steel have been reported. The methods using Methylene Blue[1–3] or curcumin[4–6] have been widely used routinely, but involve rather troublesome and time-consuming procedures.

Recently, methods based on extraction of ion-pairs formed by boron complex anions and large coloured cations have been developed and applied to steels.[7–8] These methods have advantages such as high sensitivity and selectivity, but again the procedures are complicated and analysis of steel samples requires pretreatment to avoid interference by iron. Most methods for the spectrophotometric determination of antimony are based on the extraction of antimony(V) as hexachloroantimonate with cationic dyes such as Rhodamine B[9] and Crystal Violet,[10] but often suffer from poor reproducibility;[11,12] they may be complicated[13] and problems may arise in the conversion of antimony(III) into $SbCl_6^-$,[14,15] and with the stability of the latter in strong acidic media.[16] Few studies have been made of the spectrophotometric determination of antimony(III), however, and for the determination of antimony in steel and various metals the Rhodamine B method[17] has been widely used, although the procedures are as troublesome as those for the boron determination.

It has recently been found that boron[18] and antimony(III)[19] both react with mandelic acid to form complex anions which are extractable as ion-pairs with Malachite Green into organic solvents from weakly acidic media at room temperature, and determined spectrophotometrically. These methods have now been combined and applied to analysis of low-alloy and carbon steels. The proposed method is very simple, rapid and reproducible; removal of the iron and the addition of redox reagents are not necessary, and the complex anion formed with mandelic acid is very stable in weakly acidic media.

EXPERIMENTAL

Reagents

Standard boron solution, *0.02*M. Prepared from boric acid; working solutions are prepared by suitable dilution.

Standard antimony(III) solution, *0.01*M. Prepared by dissolving antimony potassium tartrate in water; working solutions are prepared by dilution.

Malachite Green solution, 10^{-3}M.

Mandelic acid solution, *0.1*M. Adjusted to pH 3.0 with sodium hydroxide solution.

Tartrate solution (*pH 4.8*). Prepared from 0.1*M* tartaric acid and sodium hydroxide solution.

Sodium acetate solution, *0.1*M.

Use demineralized water throughout.

Preparation of the steel sample solution

Weigh the steel sample (up to 0.8 g) into a 100-ml silica flask, and dissolve it in 20 ml of sulphuric acid (1 + 6) by heating under reflux. Cool, rinse the condenser with 5 ml of water, and filter off any residue on a small filter paper (fine and ashless, Toyo Roshi, No. 5C) in a polyethylene funnel, and wash the paper with water. Transfer the filtrate and washings to a silica beaker, adjust to pH 1.8–2.0 with 8*M* sodium hydroxide, transfer the solution into a 100-ml standard flask and make up to volume with water.

Procedure A for boron

Transfer 1.0 ml of sample solution into a stoppered 10-ml test-tube. Add 1.0 ml of mandelic acid solution and 0.5 ml of Malachite Green solution; if necessary, adjust to pH 2.2–3.0 with sodium hydroxide solution. Dilute to 4.0 ml with water and shake the solution with 4.0 ml of benzene for 10 min. After phase separation, measure the absorbance of the organic phase at 633 nm, in a 10-mm glass cell, against benzene as reference.

Procedure B for the sum of boron and antimony

Transfer 1.5 ml of sample solution into a stoppered 10-ml test-tube. Add 0.2 ml of mandelic acid solution and 0.5 ml of Malachite Green solution, and adjust to pH 2.2–3.0 by

adding 1.0 ml of 0.1*M* sodium acetate. Dilute to 4.0 ml with water, and shake the solution with 4.0 ml of chlorobenzene for 10 min. After phase separation, measure the absorbance of the organic phase at 628 nm, in a 10-mm glass cell, against chlorobenzene as reference.

Procedure C for boron, in the presence of tartrate

Apply procedure B, but with 1.0 ml of 0.1*M* tartrate solution (pH 4.8) instead of the 0.1*M* sodium acetate.

RESULTS AND DISCUSSION

As described previously,[7,8] both borate and antimony(III) react with mandelic acid to form complex anions extractable with Malachite Green into an organic solvent from weakly acidic media (pH 2.2–3.5) at room temperature, and can be determined by measurement of the absorbance of the extract.

In further work on these systems, it has been found that iron(II) does not interfere at concentrations up to *ca.* 0.07*M* if the extraction is done at pH <3.0. When benzene is used as the solvent (procedure A), the sensitivity for boron is high (apparent molar absorptivity $\varepsilon = 6.52 \times 10^4$ l. mole^{-1}. cm^{-1}), whereas that for antimony is lower ($\varepsilon = 1.27 \pm 0.04 \times 10^4$). With chlorobenzene as solvent (procedure B), the opposite is the case, $\varepsilon_{Sb} = 6.08 \pm 0.19 \times 10^4$, $\varepsilon_B = 1.12 \pm 0.04 \times 10^4$. Antimony at concentrations $< 2.00 \times 10^{-4}M$ (25 mg/l.) cannot be extracted in the presence of tartrate ($2.5 \times 10^{-2}M$), procedure C, whereas boron can ($\varepsilon_B = 1.32 \pm 0.03 \times 10^4$). Accordingly, the three methods can cover determination of a range of boron and antimony contents in low-alloy and carbon steels.

Dissolution of steel sample

In spectrophotometric determination of boron in steels, sulphuric acid[20–23] and sulphuric–phosphoric acid mixtures have been widely used for dissolving the samples, and so have hydrochloric acid–hydrogen peroxide mixtures[6–8] and *aqua regia*.[24] However, when the last two mentioned are used, the excess of hydrogen peroxide or nitric acid must be removed by heating, or they interfere in the determination of boron. In the Japanese Industrial Standards method for determination of antimony,[25] it was concluded that sulphuric acid was a suitable solvent for low-alloy and carbon steels, so it was chosen for use in the present method, without any auxiliary oxidizing agents.

Most steels give some silicic acid and undissolved carbides when dissolved in dilute sulphuric acid. The residues from selected steels were therefore collected and analysed for boron and antimony. Each steel sample was treated as described in the procedure and the filter paper and residue were dried at 110°, then ignited in a platinum crucible at 600°. The ignition product was fused with 2.0 g of sodium carbonate, then the melt was cooled and dissolved in 8 ml of sulphuric acid (1 + 6). The solution (filtered if necessary) was transferred into a silica beaker, adjusted to pH 1.8–2.0 with 8*M* sodium hydroxide, transferred to a 50-ml standard flask and diluted to volume. This solution was analysed for boron and antimony by procedures A and B. No significant amounts were found to be present, so it is concluded that any residue from the dissolution step can safely be discarded.

It is known that boron is susceptible to volatilization during the dissolution of steel in acid, and antimony to reduction to a volatile hydride under reducing conditions. Possible loss of boron and antimony was therefore examined by dissolving the steel together with known amounts of boron, antimony and various metals and testing the recoveries. Table

§Standard deviation 0.0036 μg.

1 shows that no loss of boron or antimony was observed.

Analysis of steel samples

Table 2 shows that the values obtained for boron by procedures A and C are in good agreement with the certified values. Procedure A can be used for steels containing up to 0.01% of boron without interference by up to 0.02% antimony. In analysis for antimony and boron, their sum is determined by procedure B and the boron by procedure C, and the antimony is calculated by difference. Table 3 shows the results are in good agreement with the certified values.

STABILITY CONSTANTS OF THE TERNARY COMPLEXES OF CuDTPA, NiDCTA, CrEDTA, CoHEEDTA, NiHEEDTA AND CuHEEDTA WITH OH^-

J. KORSSE, G. A. J. LEURS and P. W. F. LOUWRIER
National Institute for Nuclear and High-Energy Physics (NIKHEF, section K), P.O. Box 4395, 1009 AJ Amsterdam, The Netherlands

(*Received* 20 *September* 1984. *Accepted* 18 *January* 1985)

Summary—The acid dissociation constants of the metal chelates H_3CuDTPA, H_2NiDCTA, HCrEDTA, HCoHEEDTA, HNiHEEDTA and HCuHEEDTA were determined by potentiometric titration. The constants determined at an ionic strength of 0.1 were $pK_{a,1} = 2.1$; $pK_{a,2} = 2.8$ and $pK_{a,3} = 4.75$ for H_3CuDTPA (296 K), $pK_{a,1} = 2.16$ for HCrEDTA (298 K); $pK_{a,1} = 1.6$ and $pK_{a,2} = 2.0$ for H_2NiDCTA (298 K); $pK_{a,1} = 2.24$ for HCoHEEDTA, $pK_{a,1} = 2.47$ for HCuHEEDTA and $pK_{a,1} = 1.73$ for HNiHEEDTA. At high pH the formation of ternary hydroxo-complexes was observed for the chelates $CrEDTA^-$ ($pK_{a,2} = 7.35$; $pK_{a,3} = 12.35$), $CoHEEDTA^-$ ($pK_{a,2} = 11.74$), $NiHEEDTA^-$ ($pK_{a,2} = 12.44$) and $CuHEEDTA^-$ ($pK_{a,2} = 10.45$).

The ligands $EDTA^{4-}$, $HEEDTA^{3-}$, $DCTA^{4-}$ and $DTPA^{5-}$† form very stable chelates with transition metal ions.[1,2] The stability constant is defined by:

$$K^{L}_{ML} = \frac{[ML]}{[M][L]} \quad (1)$$

In strongly acid and strongly alkaline solutions these chelates dissociate and free metal ions or hydroxide complexes are formed.[3] In weakly alkaline regions there is the possibility of ternary complex formation according to:

$$ML^{n-} + H_2O \rightleftharpoons ML(OH)^{(n+1)-} + H^+ \quad (2)$$

$$ML(OH)^{(n+1)-} + H_2O \rightleftharpoons ML(OH)_2^{(n+2)-} + H^+ \quad (2a)$$

The stability constants are defined by:

$$K^{OH}_{MLOH} = \frac{[MLOH]}{[ML][OH]} = \frac{1}{K_b(MLOH)} \quad (3)$$

where k_b (MLOH) is the basic dissociation constant of MLOH. In order to determine the composition of aqueous solutions of these complexes at various pH values, in kinetic experiments,[4] the stability constants were determined by using a titration procedure.

EXPERIMENTAL

Preparation of the complexes

$H_3CuDTPA.3H_2O$ was prepared according to a modification of the method of Sievers and Bailar:[5] 7.65 mmoles of H_5DTPA and 9.65 mmoles of $CuSO_4 \cdot 5H_2O$ were dissolved in 60 ml of water. The pH was brought to 10 with sodium hydroxide solution and the copper hydroxide precipitate was filtered off. The pH of the filtrate was brought to 1.7 with dilute sulphuric acid. After reduction of the volume to 8 ml by use of a rotary evaporator, 4.5 ml of absolute ethanol were added slowly to the hot solution (348 K), with stirring. After cooling, the blue solid product was collected by filtration. It was washed with 2 ml of absolute ethanol. By further reduction of the volume a second crop was obtained after addition of 2 ml of absolute ethanol. The product was recrystallized from pure water and dried at 353 K.

$HCr(III)EDTA \cdot 2H_2O$ was prepared by dissolving 4.27 mmoles of $KCr(SO_4)_2 \cdot 12H_2O$ and 4.27 mmoles of H_4EDTA in 25 ml of water. After 1 hr of refluxing, the volume of deep purple solution was reduced to 10 ml by evaporation. To the hot solution (353 K), 15 ml of absolute ethanol were added. The mixture was cooled to room temperature, then the precipitate was collected and washed with 5 ml of absolute ethanol. This product was dissolved in 50 ml of water. The volume was reduced to 25 ml by evaporation and 20 ml of tert-butanol were added. After the solution had stood for several days at 268 K, purple-black crystals formed. These were collected, washed with absolute ethanol and dried over silica gel.

$H_2NiDCTA \cdot 4H_2O$. About 7 g of H_4DCTA was dissolved in 100 ml of water by stirring and addition of sodium hydroxide pellets. The pH was kept at about 11. Subsequently the stoichiometric amount of nickel perchlorate was added, and when this had dissolved the solution was deep blue and the pH was about 2. The solution was filtered. After a few days standing at room temperature light green-blue crystals formed. The crystals were recrystallized once from pure water and dried over phosphorus pentoxide.

$HCo(II)HEEDTA \cdot H_2O$; $HNiHEEDTA \cdot H_2O$; $HCu(II)HEEDTA \cdot H_2O$. These were all formed by the same method: 9 mmoles of cobalt perchlorate, 18 mmoles of nickel perchlorate or 18 mmoles of Cu(II) as $CuCO_3 \cdot Cu(OH)_2$ were dissolved in 100 ml of water together with the stoichiometric amount of H_3HEEDTA. After the reaction the volume was reduced by evaporation to 25 ml. After the solutions had stood for a few days at room temperature, pink, blue, or light-blue crystals formed. These were recrystallized once from pure water.

Analyses. The results of the elemental analysis are given in Table 1. These values were determined at the Organisch Chemisch Instituut TNO, Zeist, The Netherlands.

†EDTA = ethylenediaminetetra-acetate;
HEEDTA = hydroxyethylethylenediaminetriacetate;
DCTA = diaminocyclohexanetetra-acetate;
DTPA = diethylenetriaminepenta-acetate.

The data indicate that the water of crystallization is only loosely bound and that it can be released during the analysis. All the results are consistent with the stoichiometric formulae except those for $HNiHEEDTA \cdot H_2O$. However, the titration results (Table 2) indicate that the composition of this compound does not differ very much from the theoretical value. Thus, the results found for NiHEEDTA by elemental analysis should be treated with reservation.

Titration procedure

The pH was measured with a Philips CA-11 combined glass electrode fitted to a Philips PW9408 digital pH-meter, readable to ± 0.01 pH. The system was calibrated with freshly prepared reference buffers: $0.25M$ Na_2HPO_4/KH_2PO_4, pH = 6.86 at 298 K, and $0.01M$ $Na_2B_4O_7 \cdot 10H_2O$, pH = 9.18 at 298 K.[6]

The titrant was $0.1M$ sodium hydroxide, prepared with CO_2-free water. Titrations were done in a 100-ml closed vessel flushed with nitrogen, a Metrohm precision burette being used. The solutions were prepared by dissolving 0.2–0.5 mmole of the acid complex in $0.1M$ sodium chloride. During the dissolution and the titration, nitrogen was continuously bubbled through the solution. The temperature was not controlled but remained constant within 0.5 K during each experiment. The titrant was standardized against potassium hydrogen phthalate that had been dried at 393 K for 2 hr. The correlation between pH reading and $[H^+]$ and $[OH^-]$ was established by a titration of hydrochloric acid under the same conditions. These correlations gave an experimental value for pK_W which was used for the conversion of pK_a values into pK_b values.

RESULTS AND DISCUSSION

We report the equilibrium constants as acid or base dissociation constants defined by:

$$K_a(HA) = \frac{[H^+][A^-]}{[HA]} \qquad (4a)$$

$$K_b(BOH) = \frac{[B^+][OH^-]}{[BOH]} \qquad (4b)$$

Equations (4a) and (4b) refer to concentrations rather than activities and thus the reported pK values are valid only at the particular ionic strength used for the experiment. For a comparison of the results with literature values activity coefficients should be taken into account: these can be estimated by using the Debye–Hückel limiting law.[7] Unfortunately, it is not always clear whether the constants reported in the literature are activity constants or concentration constants. Moreover, at high ionic strengths (>0.1) activity coefficients cannot be calculated accurately.[7]

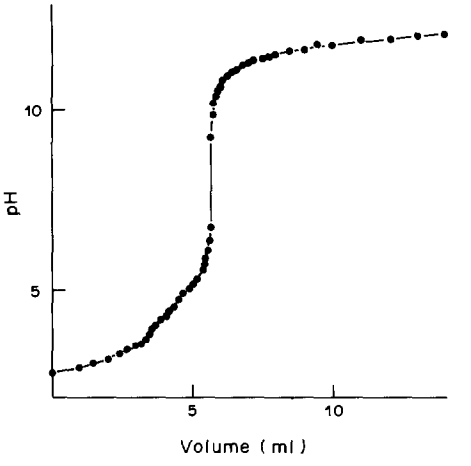

Fig. 1. Titration of 0.2129 mmole of $H_3CuDTPA$ with $0.1125M$ NaOH. Temperature 296 K, ionic strength 0.1 (NaCl). The curve was calculated by taking pK_a values of 2.1, 2.8 and 4.75. The points are the observed values

From the present experiments it appeared that equilibrium (2) is not important for pH < 12 in the case of $CuDTPA^{3-}$, $NiHEEDTA^-$ and $NiDCTA^{2-}$. Equilibrium (2a) was significant only for $CrEDTA^-$. A compilation of the results is given in Table 2. Some titration curves are shown in Figs. 1 and 2.

$H_3CuDTPA$

This complex is very stable, even at low pH. When the free ligand is in the form H_2DTPA^{3-} there are still six ligand atoms available for co-ordination to the copper ion. The stability constant $K^{H_2DTPA^{3-}}_{CuH_2DTPA^-}$ has been given as $10^{10.2}$. It was calculated that at pH 2 and a total complex concentration of $2mM$, the degree of dissociation α_D is less than 1%. Consequently, the only equilibria taken into account for our experiment are:

$$H_3CuDTPA \rightleftharpoons H^+ + H_2CuDTPA^- \qquad (5)$$

$$H_2CuDTPA^- \rightleftharpoons H^+ + HCuDTPA^{2-} \qquad (6)$$

$$HCuDTPA^{2-} \rightleftharpoons H^+ + CuDTPA^{3-} \qquad (7)$$

Table 1. Analyses of the compounds

Compound	Found, %				Calculated, %			
	C	H	N	O	C	H	N	O
$H_3CuDTPA \cdot 3H_2O$	34.3	4.8	8.5	38.0	33.04	5.35	8.25	40.87
$HCrEDTA \cdot 2H_2O$	32.3	4.3	7.5	40.9	31.84	4.54	7.42	42.41
$H_2NiDCTA \cdot 4H_2O$	38.0	4.9	6.3	34.6	35.39	5.94	5.89	40.42
$HCoHEEDTA \cdot H_2O$	33.9	5.1	7.8	36.2	34.01	5.14	7.93	36.25
$HNiHEEDTA \cdot H_2O$*	30.2	5.1	7.1	41.4	34.03	5.14	7.93	36.27
$HCuHEEDTA \cdot H_2O$	33.6	5.1	7.7	35.8	33.57	5.07	7.83	35.77

*The results for this compound are unsatisfactory; it is possible that combustion was incomplete, resulting in carbon monoxide being formed as well as carbon dioxide. From other evidence (Table 2) we believe the formula is correct.

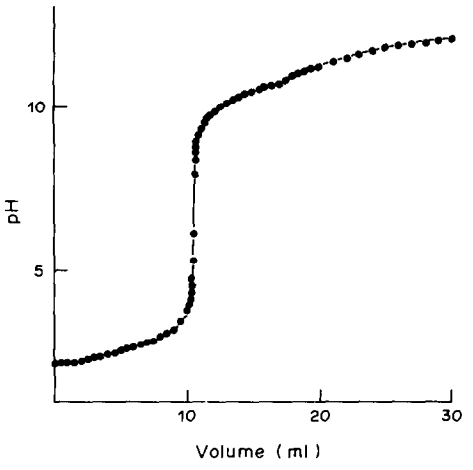

Fig. 2. Titration of 1.190 mmole of HCuHEEDTA with 0.1126*M* NaOH. Temperature 298 K, ionic strength 0.1 (NaCl). The curve is calculated by taking pK_a values of 2.44 and 10.44.

From literature data,[3] the pK_a values for equilibria (6) and (7) can be calculated:

$$\frac{[H^+][HCuDTPA^{2-}]}{[H_2CuDTPA^-]} = \frac{[H^+][HDTPA^{4-}]}{[H_2DTPA^{3-}]} \times \frac{[HCuDTPA^{2-}]}{[HDTPA^{4-}][Cu^{2+}]} \times \frac{[Cu^{2+}][H_2DTPA^{3-}]}{[H_2CuDTPA^-]} = K_a(H_2DTPA^{3-})\, K^{HDTPA^{4-}}_{CuHDTPA^{2-}} / K^{H_2DTPA^{3-}}_{CuHDTPA^-}$$

Thus

$$pK_a(H_2CuDTPA^-) = 8.59 - 15.7 + 10.2 = 3.09.$$

Similarly,[3]

$$pK_a(HCuDTPA^{2-}) = 4.75.$$

We tried to compute a curve to fit the experimental points by using these pK_a values, but the fit was not good around pH 3 for any value of pK_a (H_3CuDTPA). By using the graphical methods described by Schwarzenbach *et al.*,[8] the approximate values

$$pK_a(H_3CuDTPA) = 2.2 \pm 0.2$$

and

$$pK_a(H_2CuDTPA^-) = 2.7 \pm 0.2$$

were calculated. The values giving the best fit to the experimental points were then deduced to be

$$pK_a(H_3CuDTPA) = 2.1 \pm 0.2$$

and

$$pK_a(H_2CuDTPA^-) = 2.8 \pm 0.2$$

taking pK_a($HCuDTPA^{2-}$) as 4.75 (Fig. 1).

From the experimental points in the alkaline region it was estimated that pK_a for the complex $CuDTPA^{3-}$ is $\gtrsim 13$.

HCr(III)EDTA

Dissociation of the complex $CrEDTA^-$ into Cr^{3+} and the free ligand is of no importance even at pH 2 ($\alpha_D < 0.01\%$), because of the high stability of the complex. The stability constants are $K^{EDTA^{4-}}_{CrEDTA^-} = 10^{23.4}$ and $K^{HEDTA^{3-}}_{CrHEDTA} = 10^{15.1}$.[3]

The following equilibria were taken into account:

$$HCrEDTA \rightleftharpoons H^+ + CrEDTA^- \quad (8)$$

$$H_2O + CrEDTA^- \rightleftharpoons H^+ + CrEDTA(OH)^{2-} \quad (9)$$

$$H_2O + CrEDTA(OH)^{2-} \rightleftharpoons H^+ + CrEDTA(OH)_2^{3-} \quad (10)$$

The agreement between our experimental values and the literature data[3,9] is reasonable, especially since the lowest and the highest pK_a values lie outside the experimental pH range.

H_2NiDCTA

From the acid dissociation constants of H_4DCTA and the stability constants[3] $K^{DCTA^{4-}}_{NiDCTA^{2-}}$ and $K^{HDCTA^{3-}}_{NiHDCTA^-}$ it can be estimated that α_D of the $NiDCTA^{2-}$ chelate is about 6% at pH 2 and about 1% at pH 2.5. This dissociation was neglected in our calculations. As a consequence the calculated pK_a values will be slightly too high. However, this systematic error is smaller than the experimental error, which we estimate at about 0.2 pK unit. The pK_a values were calculated according to the graphical method,[8] leading to the approximate values 1.6 and 2.0 (at ionic strength 0.1). In the literature the values 1.8 and 2.74 are reported at ionic strength 1.25 and 25°.[10]

There seems to be a large discrepancy, as it is expected that concentration dissociation constants should increase with ionic strength; *i.e.*, the pK_a values decrease. The discrepancy, however, is not real, as the pK_a values reported by Margerum and Bydalek[10] are neither concentration constants nor activity constants. When the activity coefficient of H^+ is taken into account (according to the Debye–Hückel theory) smaller pK_a values are found.

HCo(HEEDTA), HNi(HEEDTA) and HCu(HEEDTA)

In the acid region the important equilibrium is:

$$HM(HEEDTA) \rightleftharpoons H^+ + M(HEEDTA)^- \quad (11)$$

For the calculation of the acid dissociation constants, it was assumed that no significant dissociation of $M(HEEDTA)^-$ occurred. The validity of this assumption was checked after the calculation of the pK_a values for equilibrium (11). It was found to be justified for nickel ($\alpha_D < 1\%$) and copper ($\alpha_D < 0.4\%$). In the case of cobalt, $\alpha_D < 15\%$ only at the lowest pH, so the calculated value for pK_a (HCoHEEDTA) may

Table 2. Hydrolysis reactions of some acid metal chelates studied by potentiometric titration; the pK_a and pK_b values refer to concentration constants; the medium is 0.1 *M* NaCl; $pK_w = 13.89 \pm 0.01$; the values for *n* in parentheses are the numbers of experimental points on which the calculations of the pK values are based; if no value is given, all the experimental points were used

[a] Calculated from data given in Ref. 3.
[b] Values measured at 18°C and ionic strength 0.15 (spectrophotometry).
[c] Values measured at 25°C and ionic strength 1.25 (potentiometry).

be somewhat high, as the free ligand takes up two or three protons in this pH region. This systematic error should be less than 0.1 pK unit. Table 2 shows that HNiHEEDTA appears to be a stronger acid than HCuHEEDTA, contrary to the results of Bydalek and Margerum.[11] Their values do not refer to concentration constants, which can be obtained by taking the activity coefficient of H^+ into account.

However, this cannot explain the discrepancy mentioned. Thermodynamic data reported by Brunetti *et al.*[12] show that $HNiEDTA^-$ is a somewhat weaker acid than $HCoEDTA^-$ and $HCuEDTA^-$, the respective pK_a values being 3.23, 3.01 and 3.01. In view of these results and the elemental analysis results for HNiHEEDTA (Table 1), our pK_a and pK_b values for HNiHEEDTA appear to be doubtful (Table 2).

In alkaline solutions a ternary complex with OH^- is formed:

$$MHEEDTA^- + OH^- \rightleftharpoons MHEEDTA(OH)^{2-} \quad (12)$$

The pK_b values for these equilibria (Table 2) may be compared with those for the corresponding EDTA complexes. Bhat and Krishnamurthy[13] reported concentration pK_b values at 25° and ionic strength 1. They gave $pK_b = 0.83$ for $CoEDTA(OH)^{3-}$, $pK_b = 0.48$ for $NiEDTA(OH)^{3-}$ and $pK_b = 2.40$ for $CuEDTA(OH)^{3-}$.

The order of base strength is similar to that for the $MHEEDTA(OH)^{2-}$ chelates (Table 2). Recalculation of the pK_b values reported by Bhat and Krishnamurthy to ionic strength 0.1, according to the Debye–Hückel limiting laws[7] (although only an approximate procedure), leads to pK_b values for the $MEDTA(OH)^{3-}$ chelates that are smaller by about 0.5. Thus it is concluded that the $MHEEDTA(OH)^{2-}$ species are much weaker bases than the corresponding $MEDTA(OH)^{3-}$ species. This implies that Beck's rule[14] is valid: the more stable chelate forms the less stable ternary complex (Table 3):

$$K^{L_1}_{ML_1} > K^{L_2}_{ML_2} \rightarrow K^{X}_{ML_1X} < K^{X}_{ML_2X} \quad (13)$$

The validity of Beck's rule has also been demonstrated for other cases in recent publications.[16,17]

Table 3. Relative stabilities of the HEEDTA and EDTA chelates of cobalt, nickel and copper and their ternary hydroxo-complexes

Metal	$\log \{K^{EDTA}_{MEDTA}/K^{HEEDTA}_{MHEEDTA}\}$	$\log \{K^{OH}_{MEDTA(OH)}/K^{OH}_{MHEEDTA(OH)}\}$
Co	1.7[a]	≈ -1.8[b]
Ni	1.4[a]	≈ -1.5[b]
Cu	0.9[a]	≈ -1.5[b]

SEPARATION AND CONCENTRATION OF SOME PLATINUM METAL IONS WITH A NEW CHELATING RESIN CONTAINING THIOSEMICARBAZIDE AS FUNCTIONAL GROUP

S. SIDDHANTA and H. R. DAS
Department of Chemistry, Presidency College, Calcutta-700073, India

(*Received* 13 *September* 1982. *Revised* 10 *December* 1984. *Accepted* 12 *January* 1985)

Summary—A new chelating ion-exchange resin containing thiosemicarbazide as functional group and based on macroreticular polystyrene–divinylbenzene (8%) has been prepared. Its sorption characteristics for palladium(II), platinum(IV), rhodium(III), ruthenium(III) and iridium(III) have been studied. These platinum metal ions can be quantitatively separated by sorption on this chelating resin and selective elution. The resin is highly stable in acid and alkaline solution.

Thiosemicarbazide forms chelate compounds with a number of metal ions.[1,2] Its incorporation in a resin matrix was therefore deemed of interest in connection with concentration and separation of platinum metals. This paper deals with the synthesis and sorption characteristics of a macroreticular polystyrene-based resin containing thiosemicarbazide as a functional group, with special reference to separation and concentration of platinum metals.

EXPERIMENTAL

Synthesis of the resin

Air-dried styrene–divinylbenzene copolymer beads (5 g, 100–120 mesh) were first nitrated and reduced to the amino form.[3] This resin was then converted into the isothiocyanate derivative[4] by a two-step process. In the first step a 250-ml two-necked flask equipped with a powerful mechanical stirrer was cooled in a freezing mixture of ice and salt, and 30 ml of pure carbon disulphide and 50 ml of concentrated ammonia solution were introduced into it. The mixture was stirred and the amino-resin added. The stirring was continued for 6 hr, and the product was then filtered off. In the second step the product obtained was agitated with aqueous lead nitrate solution (20%) for 12 hr, to form the isothiocyanate derivative. The product was collected and the lead sulphide formed in the reaction was removed from it by repeated washing with hot hydrochloric acid (1 + 2) until the washings were free from lead ions. The product was finally washed with water.

The isothiocyanate derivative thus obtained was then refluxed with 25 ml of 99% hydrazine hydrate solution for 30 hr, a further 5 ml of the hydrazine hydrate solution being added every 5 hr. The final product, the chelating resin containing thiosemicarbazide as functional group, was filtered off and washed with demineralized water, then extracted in a Soxhlet extractor with a 1:1 v/v alcohol and benzene mixture for 3 days. Finally it was washed with dilute hydrochloric acid and then with demineralized water, air-dried, and sieved, the particles of 100–200 mesh size being retained for use.

Resin characterization

Stability. The resin is stable towards alkalis and non-oxidizing acids. A 0.5-g portion of the resin was shaken with 50 ml of acid or alkali for 1–7 days, filtered off, washed with water until the washings were neutral, dried, and analysed for nitrogen and sulphur.

Stability in the sorption–desorption cycle was examined by shaking 0.5 g of the resin with 50 ml of 0.1*M* palladium(II) in 1*M* hydrochloric acid for 24 hr, filtering off, and eluting palladium by shaking with 4*M* hydrochloric acid for 24 hr. The palladium content was determined spectrophotometrically. This loading and acid washing cycle was repeated 25 times, and the results were studied to assess the resin stability.

Water regain. The dry resin was allowed to stand in demineralized water for 48 hr, then filtered off, pressed between filter papers, weighed, dried at 100° for 48 hr and reweighed.

Chemical analysis of the resin. The sulphur content of the resin was determined as sulphate after fusion with potassium carbonate, and the nitrogen content was determined by the Dumas method.

Exchange capacity. Palladium(II), platinum(IV), rhodium(III), ruthenium(III) and iridium(III) solutions, 0.1*M*, were prepared by dissolving the chlorides (Johnson–Matthey) in dilute hydrochloric acid. Ten-ml portions were adjusted to various acidities ranging from 5*M* hydrogen-ion concentration to pH 6.0 with hydrochloric acid and sodium acetate solution (10%) and each was equilibrated with 0.1 g of air-dried resin for 24 hr. The resin was filtered off and washed with a solution of the same acidity as the test solution until the washings were free from metal ions. Palladium(II) and platinum(IV) were desorbed with 4*M* hydrochloric acid; rhodium(III) and ruthenium(III) were eluted with 9*M* hydrochloric acid. The metal ions were determined by the *N*,*N*-diphenylthiourea method.[5]

Equilibration rate. The time required for 50% uptake of palladium(II), platinum(IV), rhodium(III) and ruthenium(III) was determined at the acidity for maximal sorption.

Column operation. A glass tube (35 cm long, 9 mm bore) was filled with a 21-cm long bed of swollen resin (prepared by standing 5 g of air-dried resin in demineralized water for 24 hr); the bed volume was 13 ml. The resin bed was thoroughly washed with 1*M* hydrochloric acid and then with demineralized water until free from acid. The sorption and elution characteristics of palladium(II), platinum(IV), rhodium(III) and ruthenium(III) were then studied.

Separation procedures

To separate the five platinum metal ions examined, 1-ml portions of their 20-ppm solutions were mixed and diluted to 25 ml with 1.0*M* hydrochloric acid. The column was equilibrated with 1*M* hydrochloric acid and the mixture passed through the column at 1.0 ml/min. For larger quantities of the metal ions it was found necessary to recycle the solution to ensure complete sorption. Iridium(III) passed through the column unsorbed, but the other four metal species were completely sorbed. Palladium(II) was selectively eluted with 15 bed-volumes of 5% *N,N*-diphenylthiourea solution in ethanol at a flow-rate of 1 ml/min, and the column was freed from the reagent by repeated washing with ethanol. Next platinum(IV) was eluted with 20 bed-volumes of 4*M* hydrochloric acid and then rhodium(III) and ruthenium(III) with 9*M* hydrochloric acid. These last two were separated by adding 10 ml of 10% hydroxylamine hydrochloride solution to the eluate containing them, adjusting the acidity to 1*M*, and passing the solution through the column (conditioned by passage of 1*M* hydrochloric acid); the rhodium(III) was sorbed but not the ruthenium. The rhodium was then desorbed with 15 bed-volumes of 9*M* hydrochloric acid.

The metal ions in the effluents were determined spectrophotometrically with *N,N*-diphenylthiourea in ethanol.

RESULTS AND DISCUSSION

Synthesis and characterization of resin

The method of preparation of the thiosemicarbazide resin is shown schematically below.

The nitrogen content of compound **V** was 9.0% and that of **VI** 7.6%, the sulphur contents being 6.2% and 2.7% respectively. Calculation shows that there should be 0.84 mmole of sulphur per gram of dry chelating resin. The maximal exchange capacity for palladium(II) was found to be 0.78 mmole/g. The resin–metal complexes therefore probably have 1:1 stoichiometry; steric factors are probably responsible for the exchange capacities being lower than theoretical (Table 1). No decrease in nitrogen and sulphur content was observed after treatment of the resin with 1–6*M* acid or 0.1*M* sodium hydroxide, but sulphur was formed after treatment with 1*M* nitric acid for 2 hr or with 1*M* sodium hydroxide for 3 days. The resin was completely stable in the 25 metal uptake–elution cycles, in 1*M* hydrochloric acid medium.

Table 1. Exchange capacities and uptake times

Metal ion	Maximal capacity, *mmole/g*	Time required for 50% uptake, *min*
Pd(II)	0.78 (pH 0)	32
Pt(IV)	0.71 (pH 0)	35
Ru(III)	0.685 (1.5*M* HCl)	40
Rh(III)	0.615 (2*M* HCl)	45

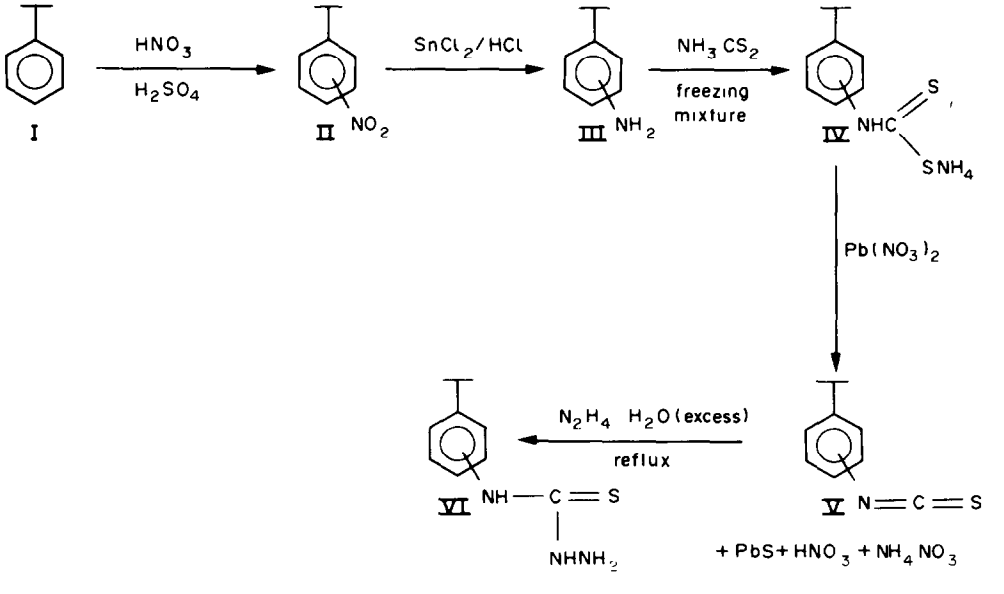
The infrared spectrum of the chelating resin has a band at 1612 cm^{-1} which may be assigned[6,7] to the C—N stretching mode in the —N—C=S grouping, a band at 1500 cm^{-1} due to the C—N stretching mode, and a band at 1340 cm^{-1} due to C=S stretching vibrations corresponding to the "Amide I" band.

The time required for 50% uptake of the metal ions by the H^+ form of the resin is shown in Table 1. From the equilibrium rate study, the resin seems suitable for column operation if the flow-rate is low enough.

The water regain of the resin (0.48 g/g) is quite satisfactory.

Sorption and desorption of metal ions

The sorption behaviour of palladium(II), platinum(IV), rhodium(III) and ruthenium(III) in the batch method is shown in Fig. 1. The capacities are maximal in 1–2*M* hydrochloric acid medium, in which these platinum metal ions form stable complexes.[8–10] Sorption of silver(I) is zero at pH 0 but increases with increase in pH. Gold(III) and osmium(VI) are instantaneously reduced to the



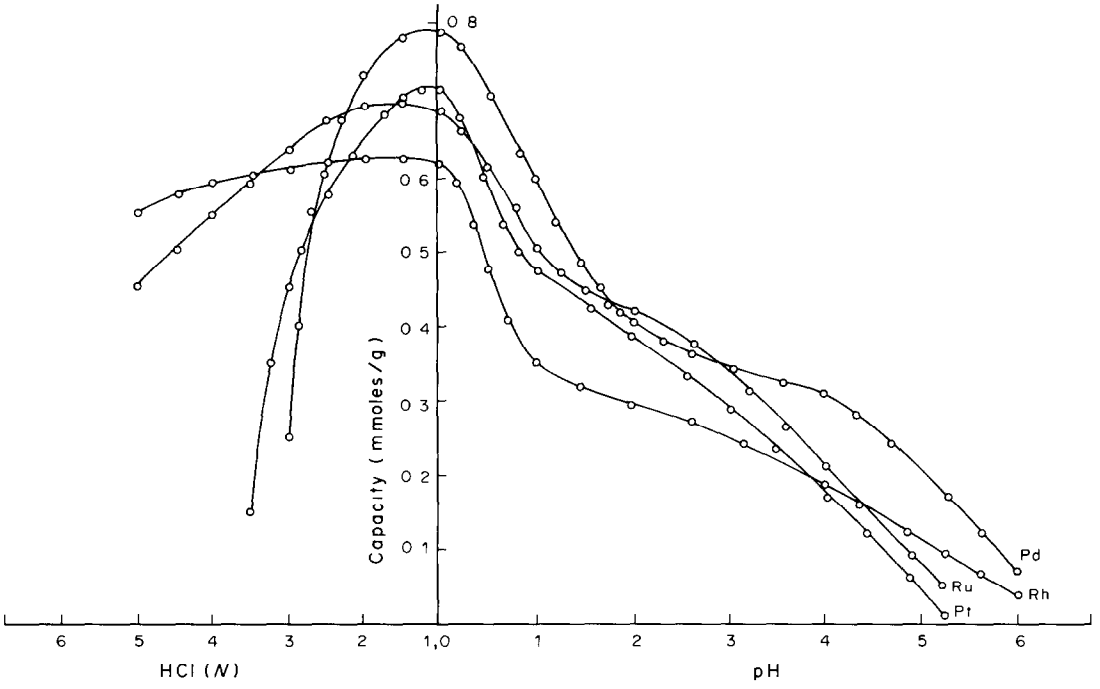


Fig. 1. Total exchange capacity of the thiosemicarbazide resin for different platinum metal ions.

metals by the resin. Base metal ions such as copper(II), bismuth, mercury(II), iron (III), vanadium(V), aluminium and uranium(VI) are not sorbed under the experimental conditions. The resin does not sorb iridium(III) at pH 0, which makes its separation from the other platinum metals easy. If the concentration ratio of palladium to the other platinum metals exceeds 10, the resin preferentially sorbs the palladium (Table 2), and a separate column is necessary for the separation of the others. In the normal case, after elution of palladium(II) and platinum(IV), the rhodium and ruthenium are eluted together with 9*M* hydrochloric acid, and the ruthenium is reduced with hydroxylamine hydrochloride to ruthenium(II),[5] which is not sorbed by the resin. The rhodium(III) can be separated from the ruthenium(II) by sorption on the resin from 1*M* hydrochloric acid and elution with 9*M* hydrochloric acid.

The recovery of platinum is 95.5% with 15 bed-volumes of eluent, and 99.5% with 20 or more bed-volumes; the recoveries of the other metals are between 99.5 and 100% (Table 2).

Results for separation from base metals are given in Table 3, which also shows the reproducibility.

Table 2. Separation of Pd(II), Pt(IV), Ru(III) and Rh(III) from mixtures

Sample	Metal ion	Taken, μg	Found, μg
1	Pd(II)	200	200
	Pt(IV)	20	0
	Ru(III)	20	0
	Rh(III)	20	0
2	Pd(II)	20	20.0
	Pt(IV)	200	199
	Ru(III)	20	19.9
	Rh(III)	20	19.8
3	Pd(II)	20	20.0
	Pt(IV)	20	19.9
	Ru(III)	200	199
	Rh(III)	20	19.8
4	Pd(II)	20	20.0
	Pt(IV)	20	19.9
	Ru(III)	20	19.9
	Rh(III)	200	198

Scheme for concentration and analysis of native Pt, Rh–Ir, Ir and most other alloys[11,12]

Mix the weighed sample with ten times its weight of sodium chloride in a porcelain boat. Place the boat in the centre of a clear fused-quartz tube and put the tube into an electric furnace for dry chlorination. Attach a receiver train, place 10 ml of water saturated with sulphur dioxide in the first receiver and 6*M* hydrochloric acid saturated with sulphur dioxide in

Table 3. Separation from a mixture of Au(III), Ag(I), Bi(III), Hg(II), Fe(III), V(V), Al(III), and Cu(II), (20 μg each)

Metal determined (20 μg)	Relative mean error, %	Standard deviation, μg
Pd(II)	0.1	0.09
Pt(IV)	0.2	0.09
Ru(III)	0.4	0.08
Rh(III)	0.6	0.08

the other three receivers. Heat the tube to 700° and pass dry chlorine through it for 7–8 hr. Cool, and displace the chlorine with nitrogen. Detach the receivers, wash the chlorinated product out of the tube with about 10 ml of hot 1*M* hydrochloric acid, into a beaker, taking care that no residue is left. Combine the contents of the receivers in a beaker and evaporate the solution to about 5–10 ml. Transfer it together with the main solution to a 500-ml distillation flask with water. Connect the flask to a distillation unit containing a trap for perchloric acid vapour, a condenser and three receiver in series. Distil the ruthenium and osmium by heating to fuming with 70% perchloric acid, collecting the tetroxides in concentrated hydrochloric acid.[13] Combine the solutions from the receivers in a beaker and evaporate the mixture slowly (Solution **I**). Solution **I** is then allowed to pass through the column at pH 0 (after conditioning at the same pH). Osmium will be reduced to the metallic state and ruthenium will be sorbed on the column and may be eluted with 9*M* hydrochloric acid (Solution **II**).

Transfer the residue from the distillation flask to a beaker, add concentrated nitric acid and evaporate to dryness. Repeat the addition of concentrated hydrochloric acid and the evaporation several times. Cool, add *aqua regia* and digest on a steam-bath. Convert into the chloride by repeated evaporation with concentrated hydrochloric acid. Take up the residue with 3*M* hydrochloric acid. Gold will be present as $AuCl_4^-$, platinum as $PtCl_6^{2-}$, iridium as $IrCl_6^{2-}$ (partly as $IrCl_6^{3-}$), rhodium as $RhCl_6^{3-}$, iron and copper as their corresponding chlorides.

Removal of gold[14]

Dilute the solution and adjust the pH to 1.5 with dilute sodium hydroxide solution. Heat and add 10 ml of 10% sodium nitrite solution. Gold is precipitated. Filter off the precipitate and wash it with water and then with hot dilute nitric acid.

Evaporate the filtrate and washings to dryness. Add concentrated hydrochloric acid and evaporate on a steam-bath; repeat this step three times. Dissolve the residue in 1*M* hydrochloric acid.

If gold is not completely separated then cycle the solution through the resin column (conditioned at pH 0) at the rate of 1 ml/min. The gold will be reduced and remain in the bed. Run 9*M* hydrochloric acid through the column. Collect the effluent and concentrate it (Solution **III**). Mix solution **II** and solution **III**, and dilute to 100 ml.

Analysis for Pd, Pt, Rh, Ru, Ir

Take an aliquot (the amount of platinum metal should not exceed 3 mg) and add 1 ml of ethanol. Adjust the acidity to 1*M* hydrochloric acid and cycle the solution through the resin column (conditioned with 1*M* hydrochloric acid) at a flow-rate of 1 ml/min. Palladium(II), platinum(IV), rhodium(III) and ruthenium(III) will be sorbed, and iridium(III) will pass through. First elute palladium(II) and then platinum(IV) as discussed above. Finally separate rhodium(III) and ruthenium(III) as discussed earlier.

MATHEMATICAL OPTIMIZATION IN THE DETERMINATION OF THE DISSOCIATION CONSTANTS OF A TRIBASIC ORGANIC ACID BY ^{13}C NMR SPECTROSCOPY

ANNE-MARIE SALONEN
Department of Chemistry and Biochemistry, University of Turku, SF-20500 Turku, Finland

(*Received* 6 *September* 1984. *Revised* 15 *December* 1984. *Accepted* 11 *January* 1985)

Summary—The calculation of dissociation constants from the chemical shifts of ^{13}C NMR spectra leads to a complicated non-linear equation. Two different mathematical methods for solution of this equation have been chosen—an iterative step method and a matrix pseudo-inversion method. When the iteration method is used the initial guesses for the parameters, the initial value of the step size and the escalation of the iteration must be optimized. For comparison the matrix pseudo-inversion method was used because it gives a unique result. With the optimized step method the results were as accurate or even better than those obtained with the matrix method. Although it takes time to optimize the system, the step method is the more suitable method of solving the problem. The matrix inversion can be done only with a computer with 13 significant digits and exponent capacity larger than ± 38.

In the case of strongly overlapping ionization processes, *i.e.*, $\Delta pK_a < 2.7$,[1] it has been difficult with classical methods to determine the dissociation constants of polyprotic acids.[2] Computers have proved their worth for resolving this problem. The purpose of this paper is to show that complicated non-linear least-squares minimization problems can be solved even with micro-computers.

An organic tribasic acid, 6-(4-carboxy-2-oxabutyl)-6-ethyl-4,8-dioxaundecanedioic acid, $C_{15}H_{26}O_9$, with both ΔpK_a values ~ 0.6, has been examined as an example.

FORMULATION OF THE PROBLEM

The chemical shifts in the NMR spectra of acids and bases are a function of pH.[3] For systems involving several ionized species the observed chemical shift is

$$\delta_{obs} = \sum x_i \delta_i \qquad (1)$$

where for the ith species x_i is the mole fraction and δ_i the chemical shift relative to the standard.[4] To calculate the mole fractions it is first necessary to derive the concentrations of the species. For an acid with n dissociable hydrogen ions the following equilibria exist:

$$\begin{aligned} H_nA &\rightleftharpoons H^+ + H_{n-1}A^- \\ H_nA &\rightleftharpoons 2H^+ + H_{n-2}A^{2-} \\ H_nA &\rightleftharpoons jH^+ + H_{n-j}A^{j-} \\ &\vdots \quad\quad \vdots \quad\quad \vdots \\ H_nA &\rightleftharpoons nH^+ + A^{n-} \end{aligned}$$

The corresponding cumulative dissociation constants are

$$\beta_i = \frac{[H_{n-i}A^{i-}][H^+]^i}{[H_nA]}; \quad i = 1, \ldots, n$$

$$\beta_n = K_1K_2 \ldots K_n = \prod_{i=1}^{n} K_i$$

The total concentration of the acid is

$$C_a = [H_nA] + [H_{n-1}A^-] + \ldots + [A^{n-}] = \sum_{i=0}^{n} [H_{n-i}A^{i-}] \qquad (2)$$

and from the expressions for the dissociation constants,

$$[H_{n-i}A^{i-}] = \frac{[H_nA]\beta_i}{[H^+]^i}$$

By substitution of these concentrations in equation (2) and rearrangement, the concentration of undissociated acid is found to be

$$[H_nA] = \frac{\sum_{i=0}^{n} [H_{n-i}A^{i-}]}{1 + \sum_{i=1}^{n} \beta_i/[H^+]^i}$$

Use of these expressions easily gives a general expression for the mole fractions:

$$x_j = \frac{[H^+]^{n-j} \prod_{i=0}^{j} K_i}{\sum_{i=0}^{n} \left([H^+]^{n-i} \prod_{i=0}^{n} K_i \right)}; \quad j = 0, 1, \ldots n$$

where K_0 is defined as unity for convenience in notation, and x_0 is the mole fraction of undissociated acid. Substitution of the mole-fraction expressions into equation (1) gives

$$\delta_{obs} = \sum_{j=0}^{n} \left\{ \frac{[H^+]^{n-j} \prod_{i=0}^{j} K_i}{\sum_{i=0}^{n} \left([H^+]^{n-i} \prod_{i=0}^{n} K_i \right)} \delta_j \right\} \quad (3)$$

After rearrangement, equation (3) can be written in the form

$$\sum_{i=1}^{n} \left(\frac{\delta_i - \delta_{obs}}{[H^+]^i (\delta_{obs} - \delta_0)} \right) \beta_i = 1 \quad (4)$$

MATHEMATICAL TREATMENT OF EQUATION (4)

Optimized iterative step method

To solve equation (4) two programs have been written in FORTRAN, program NDISS for the cumulative dissociation constants and program KDISS for the corresponding stepwise constants. Subprogram ST608[5] was chosen for iteration and subprogram QUENO[6] for error calculation. The optimization has been done by changing the initial guesses of the parameters, the initial step size and the escalation* of the iteration. The optimization criterion is minimization of the sum of the squares of the differences between the observed and calculated chemical shifts:

$$F = \sum (\delta_{obs} - \delta_{calc})^2$$

The calculations were run with an APPLE II+ (Apple Computer Inc., California) equipped with a CP/M-FORTRAN translator in addition to the standard Applesoft BASIC interpreter. The FORTRAN translator uses 6 or 7 significant digits and the exponent capacity is less than ± 38.

Error estimation

The standard deviations of the parameters were estimated by Quenouille's method,[6]

$$s(\beta) \sim \sqrt{\frac{n-1}{n} \sum_{i=1}^{n} (a - \bar{a}_i)^2}; \quad a = \frac{1}{n} \sum_{i=1}^{n} \bar{a}_i$$

where n denotes the number of data-points, and $\bar{a}_i$ is the value of a parameter when function F has been minimized with omission of the ith data-point. To find the errors of the pβ- and pK-values the variance[7] of an arbitrary function, $Z = \psi(a, b)$, must be used:

$$\text{var}(Z) = s_Z^2 = \left(\frac{\partial \psi}{\partial a}\right)^2 s_a^2 + \left(\frac{\partial \psi}{\partial b}\right)^2 s_b^2 + 2\left(\frac{\partial \psi}{\partial a}\right)\left(\frac{\partial \psi}{\partial b}\right) s_{ab}^2$$

to yield

$$\text{var}(p\beta) = s_{p\beta}^2 = \left(-\frac{\log e}{\beta} \right)^2 s_\beta^2$$

and

$$\text{var}(pK) = s_{pK}^2 = \left(-\frac{\log e}{K} \right)^2 s_K^2$$

Matrix pseudo-inversion method

For comparison with the iteration method the matrix method was used because it gives a unique result. The program was written in BASIC and the computer used was a WANG 2200 (Wang Laboratories, Massachusetts) with 13 significant digits and exponent capacity ± 99. Equation (4) must be changed into the matrix form

$$\mathbf{Nb} = \mathbf{h} \quad (5)$$

where $\mathbf{h}$ is a column vector of ones, $\mathbf{N}$ is a $k \times n$ matrix, k is the number of parameters, n the number of data-points and $\mathbf{b}$ is a column vector of the parameters.

Because $\mathbf{N}$ is not a square matrix, when $n > k$, $\mathbf{N}$ must be multiplied by its transpose, $\mathbf{N}^T$. The matrix $\mathbf{N}^T\mathbf{N}$ is then a square matrix and the solved form of equation (5) is

$$\mathbf{b} = (\mathbf{N}^T\mathbf{N})^{-1}\mathbf{N}^T\mathbf{h} \quad (6)$$

where $(\mathbf{N}^T\mathbf{N})^{-1}\mathbf{N}^T$ is the pseudo-inverse[8] of $\mathbf{N}$.

Error estimation[9]

For the matrix equation (5) it is possible to write the covariance matrix

$$\text{cov}(\mathbf{b}) = \text{cov}[(\mathbf{N}^T\mathbf{N})^{-1}\mathbf{N}^T\mathbf{h}]$$

According to the theorem

$$\text{cov}(\mathbf{AX}) = \mathbf{A}\,\text{cov}(\mathbf{X})\mathbf{A}^T$$

we can write

$$\text{cov}(\mathbf{b}) = (\mathbf{N}^T\mathbf{N})^{-1}\mathbf{N}^T\text{cov}(\mathbf{h})[(\mathbf{N}^T\mathbf{N})^{-1}\mathbf{N}^T]^T$$
$$= (\mathbf{N}^T\mathbf{N})^{-1}\mathbf{N}^T\text{cov}(\mathbf{h})\mathbf{N}(\mathbf{N}^T\mathbf{N})^{-1}.$$

It is assumed that the error is normally distributed, with mean zero and variance σ^2, and $\mathbf{h}_i$ elements are independent with equal errors, so

$$\text{cov}(\mathbf{h}) = f\mathbf{I}$$

where f = sum of squares/degrees of freedom and $\mathbf{I}$ is the identity matrix.

Thus

$$\text{cov}(\mathbf{b}) = (\mathbf{N}^T\mathbf{N})\mathbf{N}^T f\mathbf{I}\mathbf{N}(\mathbf{N}^T\mathbf{N})^{-1}$$

and

$$f = \frac{(\mathbf{h} - \mathbf{Nb})^T(\mathbf{h} - \mathbf{Nb})}{n - k}$$

The errors of the pβ- and pK-values have been calculated in the same way as in the iteration method.

EXPERIMENTAL

NMR system

The ^{13}C NMR-titrations were done at 298 ± 1 K on a Jeol FX-60 FT NMR spectrometer operating at 15.03 MHz,

*Escalation refers to the multiplication factor used in the iteration. It is sometimes called the magnification.

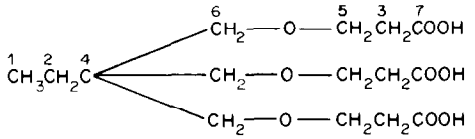

Fig. 1. The structural formula of the acid $C_{15}H_{26}O_9$.

using 8000 data-points with a precision of ± 0.06 ppm. Aqueous samples were placed in a 10-mm probe inside which was a 5-mm probe of D_2O + DSS as an external standard.

Potentiometric system

Values of pH were measured at 298 ± 0.5 K with a Radiometer ABL-3 potentiometer equipped with an Orion model 91-03-00 combined semimicro glass electrode assembly, standardized with NBS buffer solutions (pH 4.008 and 6.865 at 298 K).

Sample preparation

The concentration of the acid was $0.0501M$ ($\pm 4 \times 10^{-4}M$). The samples were delivered by micropipettes to give a total volume of 1.5 ml and the titrant used was a standard $0.9989M$ ($\pm 6 \times 10^{-4}M$) CO_2-free potassium hydroxide solution (Merck "Titrisol"). The volume change has no effect on the chemical shift.[10]

RESULTS AND DISCUSSION

The structural formula of the acid is shown in Fig. 1 and the ^{13}C NMR spectrum of the acid is shown in Fig. 2; numbering of the peaks refers to the scheme in Fig. 1 and the external standard peaks are marked with an x. The chemical shifts of the carboxyl groups—peak number 7—were the object of this study.

The chemical shifts of species H_3A and A^{3-} were measured in highly buffered solutions and $\delta(H_2A^-)$ and $\delta(HA^{2-})$ were calculated by the second method devised by Loewenstein and Roberts.[10] The ^{13}C NMR titration curve, δ *vs.* pH, is plotted in Fig. 3. In Tables 1–3 it is quite easy to find the optimal values for the calculations of the dissociation constants: they are

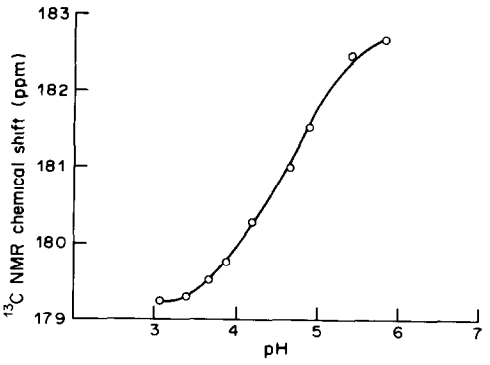

Fig. 3. ^{13}C NMR titration curve, chemical shift *vs.* pH.

denoted by asterisks. The optimum values of the initial guesses for the parameters were 10^{-4}, 10^{-9} and 10^{-14}, with initial step sizes of 10^{-10}, 10^{-15} and 10^{-20} respectively. For the optimum escalation of the iteration two values were found, 10^3 and 10^5, which both gave the minimum value 0.12154 for the function F; the lower value (10^3) was chosen for the final calculations.

The optimization of the system suggests that the error function is very complicated, so the observed data were treated by graphical analysis.[11] The error function used in the iteration process is drawn as contour plots and three-dimensional surfaces in Figs. 4 and 5. The function F splits into many minima, but the global minimum is clearly distinguishable from the local ones. The optimization of the iteration is necessary, otherwise the iteration may lead into a wrong pit and give erroneous results.

In Table 4 the results calculated by the three different methods are collected together. The calculated $p\beta$- and pK-values are very close to each other and stay within the error limits. In the matrix method the error of the first dissociation constant is smaller than in the other methods, but the errors of the second and third constants are one and a half times

as great as in the iteration method. It is thus obvious that the iteration method is quite useful after optimization. The matrix method is more rapid than the iteration method, but requires a computer capable of inverting a matrix with its elements distributed over a large number of orders of magnitude, and also requires great precision of calculation.

ASYMMETRIC DERIVATIVES OF CARBOHYDRAZIDE AND THIOCARBOHYDRAZIDE AS ANALYTICAL REAGENTS

DANIEL ROSALES, GUSTAVO GONZALEZ and JOSE L. GOMEZ ARIZA
Department of Analytical Chemistry, Faculty of Chemistry, University of Seville, Seville-4, Spain

(*Received* 26 *June* 1984. *Revised* 10 *December* 1984. *Accepted* 11 *January* 1985)

Summary—The synthesis and analytical properties of two asymmetric derivatives of carbohydrazide and thiocarbohydrazide with pyridine and phenol have been studied. The compounds tested are 1-(2-pyridylmethylideneamino)-3-(salicylideneamino)urea and 1-(2-pyridylmethylideneamino)-3-(salicylideneamino)thiourea. The analytical utility of these reagents is outlined. A spectrophotometric method for determining the formation constants of the complexes is described.

Carbohydrazones and thiocarbohydrazones have been little used in analytical chemistry. Most of the work on their use has been done in our Department, and all of those studied were symmetric derivatives.[1–8]

The present paper deals with the synthesis and analytical study of two asymmetric derivatives with pyridine and phenol: 1-(2-pyridylmethylideneamino)-3-(salicylideneamino)urea (PSU) and 1-(2-pyridylmethylideneamino)-3-(salicylideneamino)thiourea (PST)

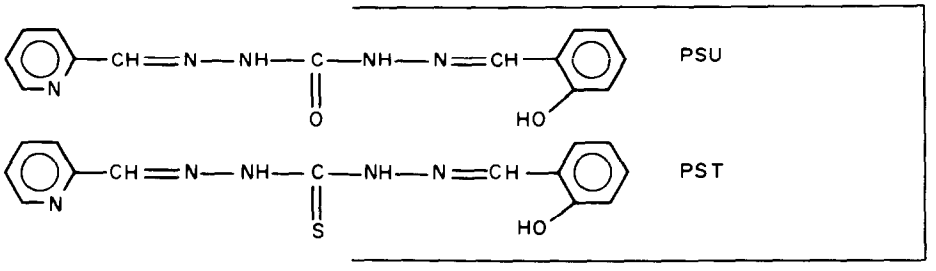
Attempts to obtain the diaminoguanidine derivative were made but were unsuccessful.



EXPERIMENTAL

Reagents

Synthesis. The reagents were obtained in two steps. First, the salicylaldehyde monoderivatives were obtained, by the method described by Brown *et al.*[9] The yields were higher than 80% and the microanalytical results in accordance with the empirical formulae. In the second step, these derivatives were condensed with 2-pyridinecarboxaldehyde in the usual way for Schiff's bases with some modifications. For PSU, to 1 g of mono(salicylidene)carbohydrazone, dissolved in 100 ml of boiling absolute ethanol, 2 ml of concentrated hydrochloric acid and 0.8 ml of 2-pyridinecarboxaldehyde were slowly added. The yellow product obtained was filtered off and washed with absolute ethanol and ether. The reagent was obtained as the monohydrochloride (m.p. 241–243°, decomp.). For PST, to 1 g of mono(salicylidene)thiocarbohydrazone, dissolved in 100 ml of boiling ethanol, 2 ml of glacial acetic acid and 0.7 ml of 2-pyridinecarboxaldehyde were added and the mixture was refluxed. After 1 hr, 200 ml of hot water were added and the mixture was cooled to room temperature. The yellow product was recrystallized from ethanol. This reagent was obtained as the monohydrate (m.p. 180–182°, decomp.).

The purity of both reagents was checked by thin-layer chromatography on silica gel. Microanalysis gave the

Other reagents. Salts and solvents were of analytical grade. All metal-ion solutions were standardized. Distilled water was used throughout.

Procedures

Evaluation of acid-dissociation constants. A 1-ml aliquot of a $10^{-3}M$ solution of PSU in 50% v/v aqueous ethanol, or a 0.75-ml aliquot of $10^{-3}M$ PST solution in ethanol, was placed in a 25-ml standard flask, and enough ethanol to make its final concentration 10% v/v was added. The ionic strength was fixed at 0.1 with potassium chloride and the pH adjusted with potassium hydroxide solution and hydrochloric acid. The solutions were then diluted to the mark with distilled water and mixed, and the absorbance, at five different wavelengths, and the pH were measured. The pH–absorbance curves were plotted for each reagent, and the pK_a values were evaluated by the two methods of Maroni and Calmon[10] (parallel straight lines and concurrent straight lines methods) and by Sommer's method.[11] The stability of the aqueous ethanol solutions at different pH values had been checked earlier.

Spectrophotometric study of reagent–metal ion reactions. The spectra of the chelates were recorded for samples with the reagent in excess (> 10-fold). The pH–absorbance curves were obtained, measurements being made at three wave-

lengths, and the buffers also serving to maintain the ionic strength at 0.01. The stoichiometry of the complexes was established by the continuous variation[12] and mole-ratio[13] methods, applied at a suitable pH, obtained with a buffer which also fixed the ionic strength at 0.01. The conditional overall formation constants were evaluated from the mole-ratio data by the method described below. For some complexes, the modification[14] of the Holme and Langmhyr method and the Asmus method[15] were also applied.

RESULTS AND DISCUSSION

Infrared spectra

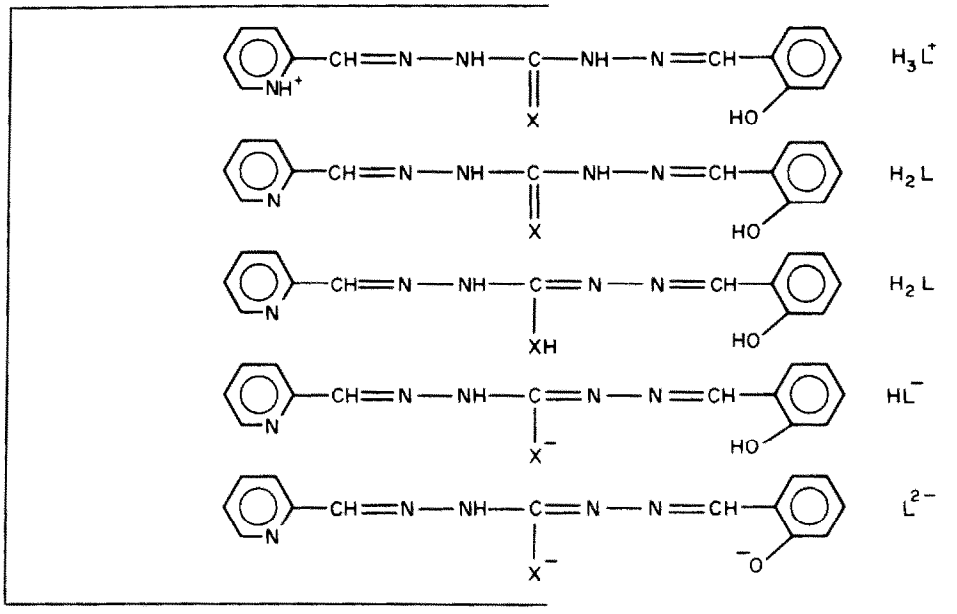
The infrared spectra of the reagents (KBr discs) are complicated because the bands overlap. However, the assignments for the spectra of pyridine[16–18] and phenol[19–21] are well established, and so are those for carbohydrazide[22] and thiocarbohydrazide.[23] On the other hand, comparison of the spectra of the salicylaldehyde monoderivatives of carbohydrazide (**I**) and thiocarbohydrazide (**II**) shows that these have several absorption bands in similar regions. The principal bands and their assignments are listed in Table 1.

Ultraviolet spectra

The results obtained are given in Table 2. In general, as the dielectric constant of the solvent decreases, the wavelengths for maximum absorption become longer and the molar absorptivities decrease. The same effect was previously observed with symmetric derivatives of carbohydrazide and thiocarbohydrazide[5,24] and is characteristic of $n\rightarrow\pi^*$ transitions.

Acid–base equilibria

The spectra of aqueous solutions of both reagents are pH-dependent. The changes can be attributed to protonation of the pyridine nitrogen atom in acid medium, the dissociation of the imidol or thioimidol group in neutral or weakly alkaline medium, and the dissociation of the phenol group in alkaline medium, as shown in the scheme:



The molar absorptivity of the fully protonated species H_3R^+ of PSU could not be found experimentally because of the instability of this reagent in acid medium (pH <2), nor could the molar absorptivities of the HR^- species for both reagents, because K_{a_2} and K_{a_3} are too close together. The dissociation constants were therefore evaluated by using graphical methods in which the values of those molar absorptivities are not needed.[10,11] The pK_a values obtained are collected in Table 3.

*Mean of five determinations; medium containing 10% ethanol; $\mu = 0.1$.

Influence of oxidizing and reducing agents

Both reagents are readily oxidized or reduced (Table 4), but the products were not identified. No catalytic effect on the oxidation with hydrogen peroxide at pH 4.8 was exerted by Fe(III), V(V), Cu(II), Zn(II), Co(II), Ni(II), UO_2(II), Mn(II) or Ti(IV) at 1 ppm level. Hydroxylamine gives the well-known exchange reaction with the C=N group.

Fluorescence spectra

Both reagents showed weak fluorescence in ethanol and in aqueous media at pH >7; that for PSU is the more intense. The fluorescence spectra were not changed by addition of metal ions (at 1.0 ppm level), except for Fe(II) and Fe(III), which decreased the fluorescence intensity by about 20%.

COMPLEX FORMATION EQUILIBRIA

Reactions with metal ions

Comparison of the absorption spectra of the PSU–metal ion complexes with those of the corresponding complexes with the symmetric derivatives of carbohydrazide with salicylaldehyde (SAU) and 2-pyridinecarboxaldehyde (PMAU) and those of the PST–metal ion complexes with those of the corresponding complexes of the thiocarbohydrazide derivatives of salicylaldehyde (SAT) and 2-pyridinecarboxaldehyde (PMAT), indicates the effect of the asymmetric reagent structure on the reactivity with metal ions.

The results obtained with acetate-buffered medium are summarized in Table 5. The data for the Fe(III) complexes are not included because these complexes are very unstable and the spectra change to those of the Fe(II) complexes. Both reagents act as general chromogenic ligands and are only selective for iron(II), which gives a complex that absorbs at much longer wavelengths than the other complexes. The PSU complexes show similar spectrophotometric characteristics to the SAU and PMAU complexes, but PST is a better spectrophotometric reagent than SAT and PMAT because the complexes have higher molar absorptivities and generally absorb at longer wavelengths.

Table 4. Effect of oxidizing and reducing agents on the absorption spectra of the reagents (decrease in absorbance, %)

Influence of pH, and the stoichiometry

For both reagents, the pH–absorbance curves of the complexes were obtained at three different wavelengths (one of them always λ_{max}), buffers being used to ensure that the sample and the blank always had identical pH values. The stoichiometry was also evaluated at three wavelengths and at a pH in the optimum range. The medium used was 32% dimethylformamide (DMF) for the PSU complexes, and 40% DMF for the PST complexes.

The results are given in Tables 6 and 7. All the PSU complexes were destroyed at pH <3, and showed only one plateau at the three wavelengths tested. The graph for the Ni(II)–PSU complex was different from the others, because at pH 4 an additional band appeared in the spectrum (λ_{max} 440 nm), without affecting the band at 380 nm. The 2:1 (M:L) stoichiometry found for the Cu(II)–PSU complex appears to indicate the presence of a polynuclear complex.

The graphs for the PST complexes differed from those for the PSU species. The Co(II) and Pd(II) complexes showed two pH-independent zones, but there were no changes in the stoichiometry, so these zones probably reflected a change in the co-ordination. The Cu(II) complex showed 1:1 stoichiometry, but there was also evidence of a 2:1 (M:L) complex, analogous to the Cu(II)–PSU complex. The absorbances of the Co(II), Cu(II) and Bi(III) complexes remained unchanged at pH <2, whereas the absorbance of the other complexes decreased, but owing to the high absorbance of the reagent in acid medium, that pH-range is not useful for analytical purposes.

Evaluation of overall formation constants

The conventional methods of determining equilibrium constants from potentiometric or solvent-extraction experiments are time-consuming. Many spectrophotometric methods are based on Job's method, but they are extremely tedious and can result in erroneous values.[25] Sommer's method uses spectrophotometric data obtained from pH–absorbance curves,[11,26–31] but because it is based on linear extrapolation it requires careful experimental work to ensure that reliable results are obtained. We have developed a method based on the experimental data obtained by the mole-ratio method. The principles involved are summarized below.

The following symbols are used:

- A,B: total metal and ligand concentrations respectively
- a,b: free metal and ligand concentrations respectively
- α_B: side-reaction coefficient for the ligand
- ϕ_N: mole fraction of the AB_N complex
- β_i: overall formation constant of complex AB_i
- h: free hydrogen-ion concentration
- E: absorbance

§Second maximum; in the presence of ascorbic acid.

The mole fraction expression for a complex AB_N can be written as a function of the overall formation constants $\beta_1, \beta_2 \ldots \beta_N$ and of the free ligand concentration b as follows:

$$\phi_N = \frac{[AB_N]}{A} = \frac{\beta_N b^N}{1 + \beta_1 b + \beta_2 b^2 + \ldots + \beta_N B^N}$$

or

$$\frac{1}{\phi_N} = \beta_N^{-1} b^{-N} + \beta_1 \beta_N^{-1} b^{1-N} + \beta_2 \beta_N^{-1} b^{2-N} + \ldots + \beta_{N-1} \beta_N^{-1} b + 1$$

and on rearranging:

$$\left(\frac{1}{\phi_N} - 1\right) b = \beta_N^{-1} b^{1-N} + \beta_1 \beta_N^{-1} b^{2-N} + \beta_2 \beta_N^{-1} b^{3-N} + \ldots + \beta_{N-1} \beta_N^{-1} \quad (1)$$

If the absorbance is measured against a reagent blank and it is assumed that the metal ion makes no contribution to the absorbance, the mole fraction ϕ_N can be experimentally obtained from the relation:

$$\phi_N = \frac{E_j}{E_{max}}$$

where E_{max} is the maximum absorbance obtained, which corresponds to the total complexation of A as AB_N, and E_j is the absorbance of the system in the range in which $B/A > (N-1)$ but $E_j < E_{max}$.

If it is further supposed that the ligand undergoes side-reactions only with the hydrogen ion, the free ligand concentration B is given approximately by:

$$b = (B - N[AB_N])/\alpha_B = (B - N\phi_N A)/\alpha_B$$

where the side-reaction coefficient α_B is:

$$\alpha_B = \frac{b'}{b} = 1 + \sum_1^q \beta_q h^q$$

in which

$$\beta_q = \frac{[H_q B]}{b\, h^q}$$

If the following substitutions are made in equation (1):

$$\left(\frac{1}{\phi_N} - 1\right) b = y;$$
$$\beta_i \beta_N^{-1} = p_i;$$
$$-1 + N = n;$$
$$b^{-1} = x,$$

we obtain:

$$y = p_0 x^n + p_1 x^{n-1} + p_2 x^{n-2} + \ldots + p_n$$

From the experimental data of the mole-ratio method a set of (x,y) values can be calculated, and by means of a least-squares procedure the p_i values can be obtained. From these, the overall formation constants can be directly evaluated. The β values obtained are "coarse", and can be refined by minimization of S in the equation:

$$S = \sum_j (\phi_{N(exp)} - \phi_{N(calc)})_j^2$$

†By the modified Holme and Langmhyr method.
§By the Asmus method.

The best β_i value, β_i^*, is given by:

$$\beta_i^* = \beta_i \, 10^{\Delta J}$$

where Δ is a positive or negative constant and J a counter.

Thus, if by successive iterations S is calculated for every J value, $J = J^*$ when S is a minimum, and the refined β_i values can evaluated from the expression:

$$\beta_i^* = \beta_i \, 10^{\Delta J^*}$$

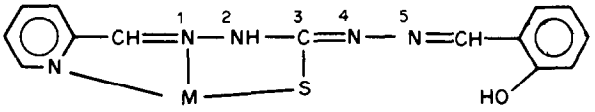
We have written a BASIC program to evaluate the overall formation constants for 1:1, 1:2 and 1:3 complexes, by use of a TOSHIBA T-100 personal computer. Figure 1 shows the flow logic used in the program.

This program was used to evaluate the β_i' values for the PSU and PST complexes in water–dimethylformamide mixtures. For some complexes, the constants were also evaluated by the Asmus[15] and the modified Holme and Langmhyr[14] methods, which also use data from the mole-ratio method. The results obtained are summarized in Tables 8 and 9. There is good agreement with the results obtained by the modified Holme and Langmhyr method, but the Asmus method consistently gives low values because it takes the free ligand concentration as equal to the total ligand concentration, which is a good approximation only for very weak complexes (for which it was originally developed).

CONCLUSIONS

PST is clearly the more useful of the two reagents, as it forms highly coloured complexes at lower pH than PSU. It is also a better spectrophotometric reagent than the symmetric derivatives of thiocarbohydrazide with 2-pyridinecarboxaldehyde or salicylaldehyde, probably because it combines the best characteristics of both: the co-ordinative grouping of PMAT (pyridine) and the chromophore grouping of SAT (2-phenol). The reagent appear to be a terdentate ligand, through the pyridine nitrogen atom, the nitrogen atom at position 1 (see structure below) and the sulphur atom. In acetate-buffered medium, most PST complexes are uncharged.

The high molar absorptivity of the PST complexes can be explained by assuming that in the thio-enol form, the double bond is preferentially formed with the nitrogen atom at position 4 and not with the one at position 2. So the conjugated system of π-electrons is connected with the phenol ring, as shown in the structure:



Hence half the molecule is involved in the co-ordination, and the other half is responsible for the colour. Further experiments in which the 2-phenol ring is replaced by other aromatic groups confirm this hypothesis.

¶Succinate buffer.
**Acetate buffer.

The sensitivity of PST is analogous to that of dithizone, a classical reagent for determination of metal ions, but PST exhibits some advantages because (*i*) the reagent solutions are stable for several weeks; (*ii*) it is not necessary to extract the complexes since they are soluble in water–dimethylformamide mixtures; (*iii*) the absorbance of the reagent blank is very low at λ_{max} of the complexes (about 0.050 at 400 nm *vs.* distilled water); (*iv*) it is more selective, since it does not react with Ag(I), Mn(II) or Sn(II); (*v*) its Pd(II) and Hg(II) complexes can be formed in EDTA medium.

On the basis of these characteristics, PST is an interesting analytical reagent.

The method developed for evaluating overall formation constants is less tiresome and time-consuming than the potentiometric or solvent-extraction methods, and far superior in accuracy to Job's method and related procedures. Furthermore, it is easy to use and does not need as many experimental results as Sommer's method does.[32] Also, the mole-ratio data on which this method is based are needed anyway, to establish the nature of the complexes.

REMOVAL OF IRON INTERFERENCES BY SOLVENT EXTRACTION FOR GEOCHEMICAL ANALYSIS BY ATOMIC-ABSORPTION SPECTROPHOTOMETRY

LIYI ZHOU*, T. T. CHAO† and R. F. SANZOLONE
U.S. Geological Survey, Box 25046, Denver, Colorado 80225, U.S.A.

(*Received* 3 *December* 1984. *Accepted* 11 *January* 1985)

Summary—Iron is a common interferent in the determination of many elements in geochemical samples. Two approaches for its removal have been taken. The first involves removal of iron by extraction with methyl isobutyl ketone (MIBK) from hydrochloric acid medium, leaving the analytes in the aqueous phase. The second consists of reduction of iron(III) to iron(II) by ascorbic acid to minimize its extraction into MIBK, so that the analytes may be isolated by extraction. Elements of interest can then be determined using the aqueous solution or the organic extract, as appropriate. Operating factors such as the concentration of hydrochloric acid, amounts of iron present, number of extractions, the presence or absence of a salting-out agent, and the optimum ratio of ascorbic acid to iron have been determined. These factors have general applications in geochemical analysis by atomic-absorption spectrophotometry.

Iron has been recognized as one of the major interfering elements in geochemical analysis, owing to its abundance and widespread occurrence in geological materials. The complex spectrum and chemical properties of iron can cause spectral as well as other matrix interferences in the determination of elements by atomic-absorption spectrophotometry.[1,2]

There are two approaches to deal with the problem of iron interferences in geoanalysis. The first involves the long-known procedure for the solvent extraction of ferric iron from hydrochloric acid medium[3–5] before the analytes are determined. The chlorides of aluminium, magnesium, lithium, and ammonium have occasionally been added as salting-out agents in the extraction of iron into organic solvents.[7–9] The second approach consists of using ascorbic acid to reduce iron(III) to iron(II) so that only the analytes to be determined are extracted into the organic solvent. This technique has been successfully employed in the determination of a number of metals by both flame and furnace atomic-absorption spectrophotometry.[10–16]

Although both approaches have been applied satisfactorily to remove iron interferences in the analysis of geological materials, there has been a clear lack of systematic studies on the quantitative relationships among operating factors such as the concentration of hydrochloric acid, amounts of iron present, number of extractions, the presence or absence of a salting-out agent, and the optimum ratio of ascorbic acid to iron. Based on results obtained by using synthetic iron solutions, this report is aimed at contributing information for some general applications in geochemical analysis by atomic-absorption spectrophotometry.

EXPERIMENTAL

Reagents

Iron solution, 10%. Dissolve 10.00 g of "Specpure" iron powder in 53 ml of concentrated hydrochloric acid in a covered beaker, with heating on a hot-plate, and then slowly add 5 ml of 50% hydrogen peroxide to oxidize the iron(II). Heat the solution to remove the excess of peroxide, cool, and dilute it to volume with water in a 100-ml standard flask. This solution is approximately 1*M* in hydrochloric acid.

Ascorbic acid solution. Prepare fresh daily.

General procedure

A series of 20-ml portions of solutions containing different amounts of iron (10, 25, 50 and 100 mg) were shaken with 10 ml of methyl isobutyl ketone on a mechanical shaker for 1 min. After centrifugation, the organic phase was discarded and an aliquot of the aqueous phase was diluted at least 2000-fold for iron determination, so that the concentration of iron would fall within the range of the calibration graph.

Operating factors examined included the concentration of hydrochloric acid, number of MIBK extractions, the presence of lithium chloride as a salting-out agent, and the effect of reduction of Fe(III) to Fe(II) by ascorbic acid.

Determination of iron

Residual iron in the aqueous phase after the MIBK extraction was determined by atomic-absorption, with a Perkin-Elmer 272 spectrophotometer‡ with a lean air–acetylene flame. In the fuel-lean flame, iron(II) and iron(III) gave the same signal.[17] The instrument settings were: wavelength, 248.2 nm; lamp current, 10 mA; bandpass, 0.2 nm; air flowmeter reading, 40; fuel flowmeter reading, 10.

The iron calibration graph was prepared daily with 0, 1, 5 and 10 μg/ml iron solutions.

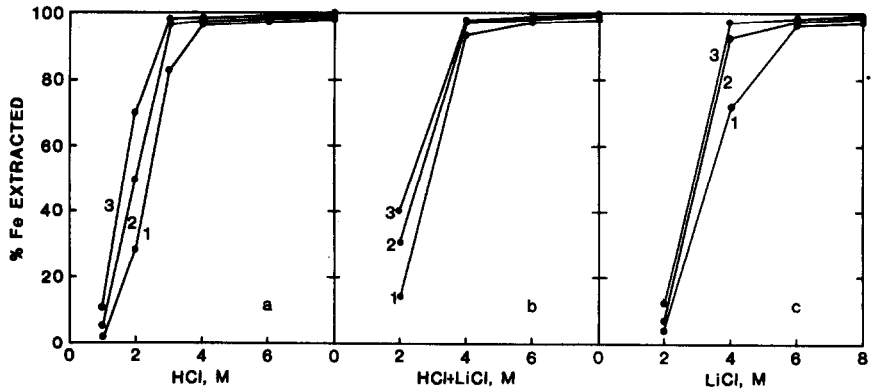

Fig. 1. Extraction of Fe (0.5 mg/ml) by MIBK as a function of the concentration of HCl, HCl + LiCl (equimolar concentrations), and LiCl in the aqueous phase. Number of extractions: 1, 2, and 3.

RESULTS AND DISCUSSION

Effect of acid concentration and the presence of lithium chloride

Because the extraction curves for different iron concentrations at various acidities and in the presence or absence of lithium chloride show similar trends, only those for 0.5 mg/ml and 5 mg/ml iron concentrations are presented, in Figs. 1 and 2. The degree of extraction of iron by MIBK is related to the concentration of hydrochloric acid in the aqueous phase (Figs. 1a and 2a). In order to remove more than 95% of the iron in the first extraction, an acidity equivalent to 6*M* hydrochloric acid in the aqueous phase is required. However, the degree of iron removal is also determined by the amount of iron present. While removal is 96.4% complete from 4*M* hydrochloric acid for the 0.5-mg/ml iron level, a second extraction is needed to reach a similar degree of removal for the 5-mg/ml iron level. Extraction from $>6M$ hydrochloric acid may cause miscibility of the phases, as observed by Menis and Rains.[4] Nearly complete removal of iron from solutions with an acidity $<6M$ hydrochloric acid can be accomplished if the extraction is repeated (Figs. 1 and 2).

Lithium chloride at concentrations equivalent to those of hydrochloric acid is not as efficient as a salting-out agent for iron removal by extraction with MIBK. The decreasing order of extraction of iron from the three systems is: HCl > HCl + LiCl > LiCl (Figs. 1 and 2). For example, for the 0.5-mg/ml iron level the degree of removal of iron in the first extraction from 4*M* background electrolyte medium is 96.4, 93.6, and 71.6% for the three systems respectively. The corresponding degree of removal at the 5 mg/ml iron level is 90.0, 82.4 and 48.0%. The comparative extraction efficiency of the three systems is readily seen by referring to Fig. 3 for the removal of iron at the 2.5 mg/ml level from the aqueous phase. Apparently a high hydrogen-ion concentration is essential for efficient extraction of iron. In the extraction of iron from various concentrations of hydrochloric acid by isopropyl ether, Dodson *et al.*[3] postulated that the chemical formula for the extracted iron chloro-complex might be $HFeCl_4$. If for some reason high acidity is not permissible, lithium chloride can be used as a salting-out agent to increase the efficiency of extraction of iron.

From the discussion above, it is evident that the extraction of iron by MIBK is influenced by the

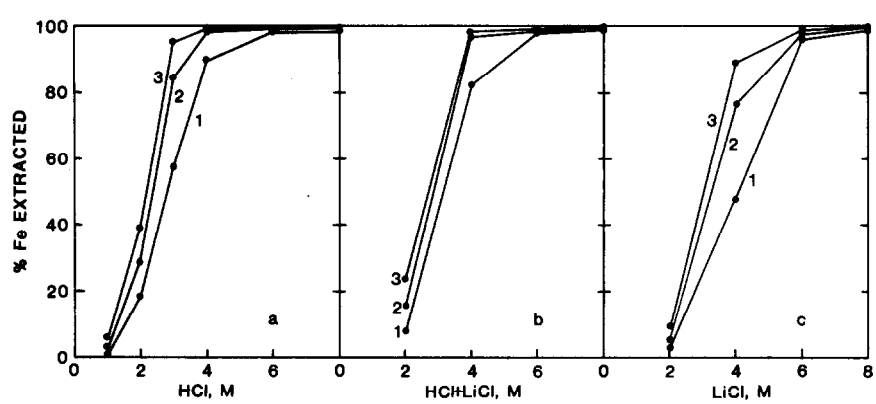

Fig. 2. Extraction of Fe (5 mg/ml) by MIBK as a function of the concentration of HCl, HCl + LiCl (equimolar concentrations), and LiCl in the aqueous phase. Number of extractions: 1, 2, and 3.

hydrochloric acid concentration in the aqueous solution, the number of extractions, the amount of iron to be extracted, and the presence of lithium chloride. Lithium chloride alone can be used if in sufficiently high concentrations and/or enough extraction steps are performed. Luke[5] has observed that iron(III) can be quantitatively extracted from 7*M* lithium chloride with MIBK.

Effect of ascorbic acid

Ascorbic acid can eliminate iron interference in the determination of various elements in geochemical analysis by virtue of its ability to reduce and complex iron so that the response of iron to solvent extraction and other chemical operations is altered. The amounts commonly used for this purpose range from an ascorbic acid/iron weight ratio from two[18] to ten.[19] Alternatively, ascorbic acid is added in increments until the iron colour fades to a light yellow or completely disappears. In this study, several iron levels (0.5, 1.25, 2.5 and 5 mg/ml) were treated with increasing amounts of ascorbic acid before MIBK extraction of iron from 1*M* and 2*M* hydrochloric acid. Only the results obtained for the highest iron level are presented in Fig. 4, as those for lower iron levels exhibit similar trends.

The degree of extraction of iron is inversely related to the amount of ascorbic acid added, but directly related to the acidity of the aqueous phase. While 200 mg of ascorbic acid is sufficient to prevent MIBK extraction of 100 mg of iron (weight ratio = 2) from 1*M* hydrochloric acid, 400 mg is necessary (weight ratio = 4) to do the same from 2*M* hydrochloric acid. In geochemical analysis, it is customary to digest the sample with mixed acids and evaporate to dryness. The residue may then be dissolved in dilute hydrochloric acid. It would be desirable to use less concentrated acid, such as 1*M*, for dissolution of the residue, so that a lower amount of ascorbic acid can be used to eliminate the iron interference. The highest iron level used in this work (5 mg/ml) is equivalent to 20.0% Fe or 28.6% Fe_2O_3 in the sample if a 0.5-g sample is taken for analysis.

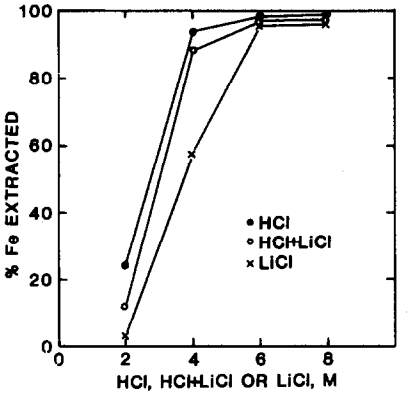

Fig. 3. Comparative efficiency of extraction for Fe (2.5 mg/ml) by MIBK as influenced by HCl, HCl + LiCl (equimolar concentrations), and LiCl in the aqueous solution.

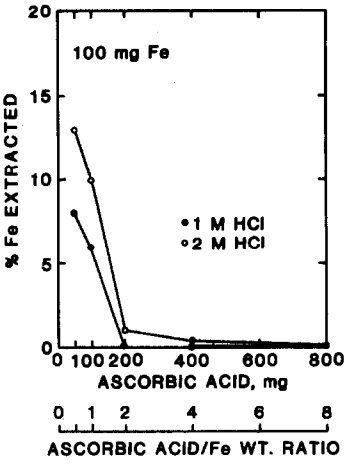

Fig. 4. Effect of different amounts of ascorbic acid on the extraction of Fe (5 mg/ml) by MIBK from 1*M* and 2*M* HCl.

From the reasoning above, geochemical samples can be analysed by atomic-absorption spectrophotometry for various elements in a hydrochloric acid medium, without iron interference, by use of the combination of reduction with ascorbic acid and solvent extraction.

Iron in hydrobromic acid medium behaves similarly toward extraction by MIBK.[20] Hubert and Chao[21] have taken advantage of this combination to circumvent iron interference in the determination of gold, indium, tellurium, and thallium in a singie sample solution of geological materials, by atomic-absorption spectrophotometry after a two-step solvent extraction. Gold and thallium are first quantitatively extracted into MIBK from 0.1*M* hydrobromic acid; the extraction of iron is minimal. The aqueous phase is then made 3*M* in hydrobromic acid and the indium and tellurium are extracted with MIBK, after reduction of iron by ascorbic acid. Before the development of this scheme, the four elements were individually determined in separate samples.[13,15,22,23]

Conclusions

Quantitative information has been provided in this paper for the removal of iron interference, by solvent extraction, in geochemical analysis. Based on the information given, adjustments can be made in procedures, either to extract the iron with MIBK from the aqueous solution adjusted to a certain concentration of hydrochloric acid, or to reduce Fe(III) to Fe(II) with ascorbic acid to prevent extraction of the iron into MIBK. The elements of interest can then be determined in the aqueous phase or the organic extract as appropriate by atomic-absorption spectrophotometry.

POLAROGRAPHY OF THE ALKALINE-EARTH METALS—II

THE ADSORPTION WAVE FOR THE MAGNESIUM–ERIOCHROME BLACK T COMPLEX

AN JINGRU, ZHOU JINKUI and WEN XIAODAN
Chemistry Department, Fuzhou University, Fuzhou, Fujian, China

(*Received* 11 *September* 1984. *Revised* 1 *December* 1984. *Accepted* 11 *January* 1985)

Summary—Magnesium–Eriochrome Black T in ethylenediamine medium gives a polarographic adsorptive wave at −0.7 V (*vs.* an Ag/Hg electrode). It gives a limit of detection for magnesium of $2 \times 10^{-8} M$. It is made the basis of a method for determination of magnesium in serum, water and various salts, without any pretreatment. The method is very rapid, sensitive and convenient for serum analysis.

Magnesium ions are very difficult to reduce at the dropping mercury electrode in aqueous solution, but give a polarographic wave at −2.2 V (*vs.* SCE) in tetramethylammonium chloride supporting electrolyte solution.[1] Richardson[2] determined magnesium in calcium carbonate by polarographically reducing the magnesium complex of Solochrome Violet R. S. at pH 11 in a piperidine buffer. In his method, calcium and iron were removed by precipitation and extraction. The detection limit for magnesium was $10^{-6} M$. Luo and Zhao[3] determined magnesium in hair by using the polarographic adsorption wave of the magnesium meso-tetra (4-trimethylammoniumphenyl)porphine complex in a methylamine buffer solution. In their method, the solution had to be heated at 100° for 50 min to form the complex. The detection limit was $10^{-7} M$.

In this report, we describe an adsorption wave for the magnesium–Eriochrome Black T complex in aqueous ethylenediamine medium. It can be used to determine magnesium in serum, water and chemical reagents, without any pretreatment.

Magnesium in serum is usually determined by flame photometry, atomic-absorption spectroscopy or spectrophotometry after appropriate sample pretreatment. Because of its sensitivity and good selectivity, our method can be used to determine magnesium in serum rapidly and conveniently.

EXPERIMENTAL

Apparatus

A single-sweep polarograph with three electrodes and a type 82-1 polarograph (made in Fuzhou University), with an Ag/Hg reference electrode. A PTFE polarographic cell was used.

Reagents

Standard magnesium solution. Magnesium oxide was ignited at 800° and 1.658 g of it was dissolved in 30 ml of 2*M* hydrochloric acid and the solution was diluted to 1000 ml. This 1000-μg/ml stock solution was further diluted as required.

Eriochrome Black T (EBT) solution, $5.0 \times 10^{-4} M$. Prepared in water as solvent. The solution was stable for two days.

Ethylenediamine, 10% aqueous solution. Demineralized water was used in all experiments.

All solutions were stored in polyethylene bottles, and contact between the solutions and glass vessels was avoided as much as possible.

Procedure

Transfer the magnesium solution into a 25-ml quartz standard flask, add 5 ml of 10% ethylenediamine solution and 3 ml of $5 \times 10^{-4} M$ EBT and dilute to the mark with water. Pour all the solution into the PTFE polarographic cell and record the derivative polarogram, starting the potential scan at −0.4 V. The temperature should be kept below 20°.

RESULTS

Oscillographic polarograms

In 2% ethylenediamine solution, EBT gave a reduction wave P_1, with a maximum at −0.53 V, and a derivative-peak potential of −0.50 V (see Fig. 1a,b). When magnesium ions were added, P_1 decreased and a new maximum P_2 appeared at a more negative potential, −0.72 V, and the derivative-peak potential was −0.70 V. The derivative mode is preferred because of its better resolution.

Dependence of peak current on the ethylenediamine concentration

The magnesium–EBT complex gives no wave in either acidic or ammoniacal medium, but does in the presence of ethylenediamine. The dependence of peak current on the concentration is shown in Fig. 2. The peak current reaches a maximum at 1% ethylenediamine and then remains constant, so 2% was chosen as the working concentration.

Dependence of peak current on the EBT concentraion

Magnesium does not give any reduction wave in ethylenediamine solution in the absence of EBT, but the Mg–EBT complex gives a polarographic wave at

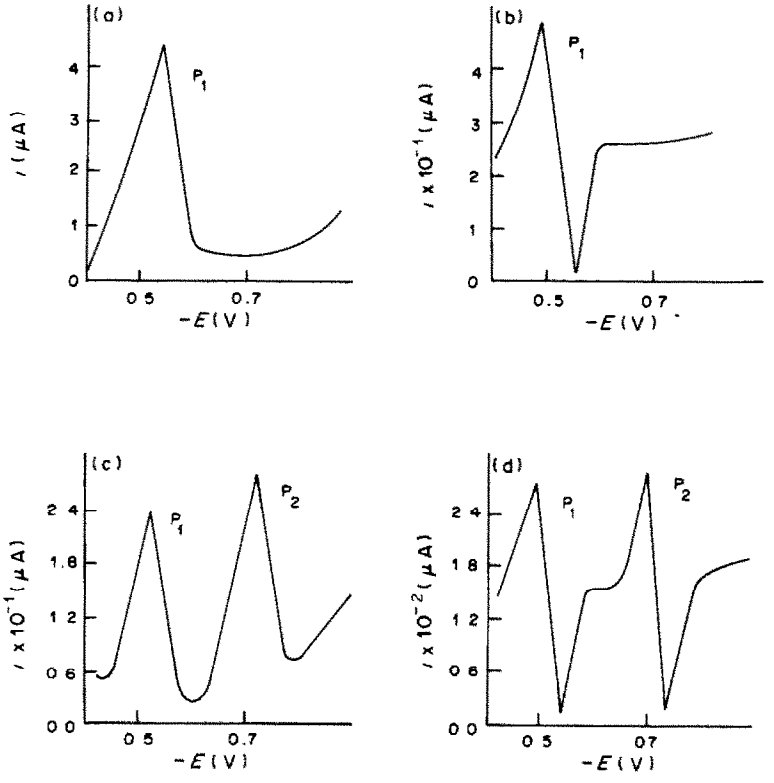

Fig. 1. Single-sweep polarograms: (a) 2% en + $6 \times 10^{-5}M$ EBT, normal wave; (b) derivative wave; (c) a + $8 \times 10^{-6}M$ Mg^{2+}, normal wave; (d) derivative wave.

-0.70 V. As shown in Fig. 3 the peak current remains maximal and constant for the EBT range 1.5×10^{-5}–$6 \times 10^{-5}M$: $6 \times 10^{-5}M$ EBT was chosen as the working concentration.

Effect of temperature

Figure 4 shows that the peak current was independent of temperature between 4° and 20°, so it is only necessary to keep the temperature below 20°.

Relation between peak current and magnesium concentration

Under the optimum conditions chosen, the peak current is proportional to the magnesium concen-

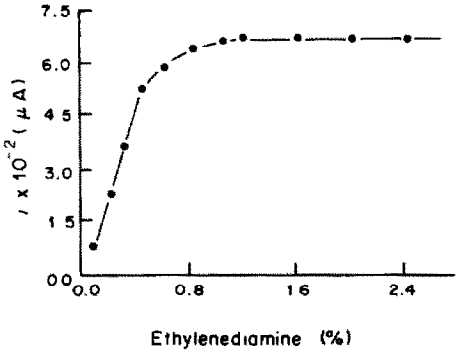

Fig. 2. Dependence of peak current on the concentration of ethylenediamine: $5 \times 10^{-6}M$ Mg^{2+} + $6 \times 10^{-5}M$ EBT.

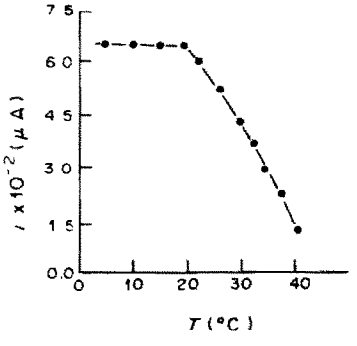

Fig 4. Effect of temperature on the peak current.

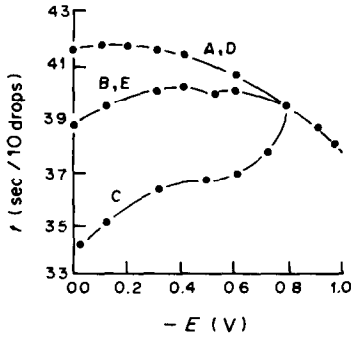

Fig. 5. Electrocapillary curves: (A) 2% ethylenediamine, (B) A + $6 \times 10^{-5}M$ EBT, (C) A + $1.8 \times 10^{-4}M$ EBT, (D) A + $1.5 \times 10^{-6}M$ Mg^{2+}, (E) B + $1.5 \times 10^{-6}M$ Mg^{2+}.

tration in the range 5×10^{-8}–$9 \times 10^{-6}M$, and the limit of detection is $2 \times 10^{-8}M$.

Effect of foreign substances

The effect of foreign substances was studied with 2 μg of magnesium in 25 ml of solution. The amounts of other ions which did not interfere (error < 10%) are as follows: large amounts of K, Na, 5 mg of Ca, Ba, Sr; 2 mg of Ge; 1 mg of Bi(III); 0.6 mg of W(VI), V(V); 0.4 mg of Mo(VI), Ag, Al; 0.3 mg of Zn; 0.2 mg of Be, Tl(III), As(III); 0.1 mg of Sn(II), Sc; 60 μg of In; 40 μg of Sb, Gd, Cr(VI); 30 μg of Pb, Cu(II); 20 μg of Ga, Ti(IV); 6 μg of Mn(II); 4 μg of Ni, Co(II); 1 μg of Fe(III). Fe(III) interfered by giving a peak at −0.67 V, but the interference of 200 μg could be eliminated by adding sodium sulphite (1 g per 25 ml). Sodium cyanide present at 0.2% concentration masked up to 80 μg of Fe(III), 100 μg of Co(II) or Ni, and 20 μg of Mn(II).

Small amounts of surfactants did not interfere, *e.g.*, 1.0 ml of 0.02% polyoxyethylene alkylphenol, 0.5 ml of 0.02% cetylpyridinium chloride, or 2.0 ml of 0.02% sodium dodecyl benzenesulphonate.

MECHANISM

Electrocapillary curves

Eriochrome Black T is a hydroxyazo dyestuff, and would be expected to be easily adsorbed at the mercury electrode. As shown in Fig. 5, the electrocapillary curves were considerably influenced by the presence of EBT, which was adsorbed very strongly at −0.50 V, resulting in the surface tension being reduced and the adsorption becoming stronger with increasing EBT concentration.

When magnesium ions were added they reacted with the EBT to form a red complex which was adsorbed at the electrode to give a reduction peak at −0.7 V. Curve A was the same as D, B the same as E, so we conclude that the adsorption depended mainly on the ligand EBT in the complex, and that the magnesium itself had little effect on the adsorption.

Relation between peak current and rest-time

The dependence of the maximum peak current on the rest-time was investigated with a hanging mercury drop electrode. For aqueous ethylenediamine solutions the peak currents for both reagents and complex increased with prolongation of the rest-time, which allowed much more reagent and complex to be adsorbed at the electrode. The conclusion from this experiment agreed with that from the electrocapillary curves.

Relationship between peak current and voltage scan-rate

The peak current i_p for the reagent and the complex varied with scan-rate V. The plot of i_p *vs.* $V^{1/2}$ is shown in Fig. 6 for scan-rates from 125 to 350 mV/sec: the plot is not linear, as it should be for a diffusion-controlled process, but is distinctly curved. Such deviations from the Randles-Ševčik equation have been explained by Anson.[4]

It is evident from the experiments described that both reagent and complex are strongly adsorbed on surface of the electrode. This has the effect of giving a significant increase in sensitivity.

Cyclic voltammetry

The cyclic voltammetry of the system was investigated with the Type 82-1 polarograph. Cyclic voltammetric curves for aqueous ethylenediamine solutions are shown in Fig. 7. EBT gives a cathodic peak at −0.5 V, owing to its reduction. If magnesium ions are present, a second peak appears at −0.7 V, due to reduction of the ligand in the complex.

No anodic peak was observed, from which we conclude that the reduction of EBT and of the Mg–EBT complex is irreversible.

Composition of the electroactive complex

The composition of the complex was examined by the linear[5] and continuous-variations methods and found to be 1:1, as expected. The conditional stability constant (2% ethylenediamine medium, pH = 11.8) was found to be 1.1×10^5.

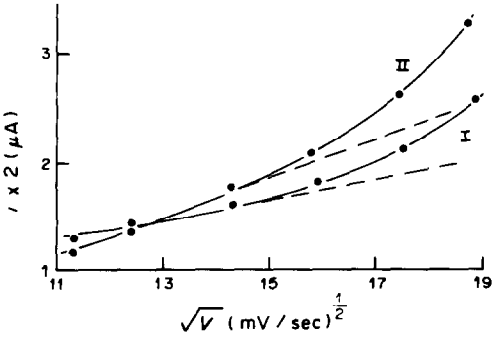

Fig. 6. Relationship between i_p and V: (I) 2% ethylenediamine + $6 \times 10^{-5}M$ EBT, (II) I + $7.5 \times 10^{-5}M$ Mg^{2+}.

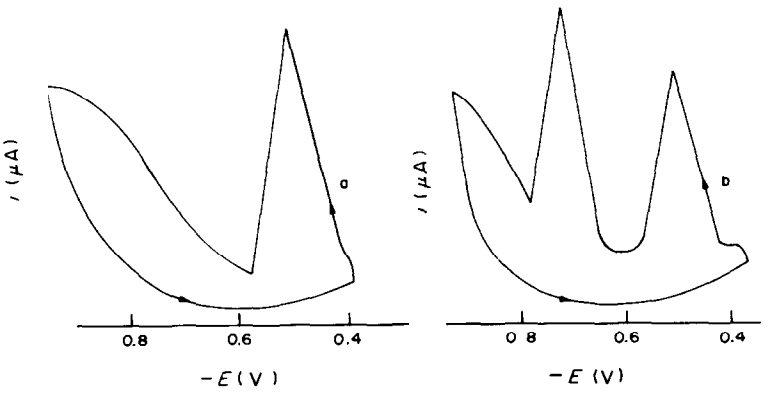

Fig. 7. Cyclic voltammetric curves.

APPLICATIONS

Determination of magnesium in water and serum

Transfer 2.5 ml of water into a 25-ml standard flask, then add 5 ml of 10% ethylenediamine and 3 ml of $5 \times 10^{-4}M$ EBT and dilute to the mark with water. Measure the peak current at −0.7 V.

Transfer 0.1 ml of serum, without any pretreatment, into a 25-ml standard flask, and continue as for a water sample. Determine the magnesium by the standard-additions method.

The results shown in Table 1 agreed satisfactorily with those obtained by atomic-absorption spectroscopy.

Table 1. Determination of Mg in water and serum

	Mg found by this method		Mg found by AAS	
Sample	μg	ppm	μg	ppm
Water	2.0	0.8	2.0	0.8
Serum A	2.26	22.6	2.21	22.1
Serum B	1.83	18.3	1.72	17.2
Serum C	2.24	22.4	2.18	21.8

Table 2. Analysis of various salts for Mg

Sample	Mg added, μg	Mg found, μg	Recovery, %	Content, %
Potassium nitrate, 200 mg	0	0.360		
	0.2	0.564	102	0.00018
Potassium chloride, 200 mg	0	0.408		
	0.2	0.600	96	0.000204
Barium nitrate, 0.8 mg	0	0.204		
	0.3	0.498	98	0.025
Strontium nitrate, 0.6 mg	0	0.276		
	0.2	0.474	99	0.046
*Calcium chloride, 0.3 mg	0	1.25		
	1.0	2.25	100	0.42

*For this sample, a chemically pure grade, the standard deviation (11 determinations) was 0.011 μg, coefficient of variation 0.9%. The other samples were analytical-reagent grade. All the results are the means of 3 determinations.

Determination of magnesium in salts

Transfer a weighed amount of salt to a 25-ml standard flask, dissolve it in water, then add the ethylenediamine and EBT solution as before and dilute to the mark with water. Record the derivative polarogram and measure as before.

THE USE OF GLASS ELECTRODES FOR THE DETERMINATION OF FORMATION CONSTANTS—II

SIMULATION OF TITRATION DATA

PETER M. MAY*, KEVIN MURRAY and DAVID R. WILLIAMS
Department of Applied Chemistry, UWIST, Cardiff, Wales

(*Received* 16 *November* 1984. *Accepted* 11 *January* 1985)

Summary—Methods for simulating titration data, including various types of corrections for changes in activity, liquid-junction potential and ion-selectivity of electrodes are described. These form the basis of a new library of computer programs, called ESTA (Equilibrium Simulation for Titration Analysis). They permit the range of titration conditions employed in the determination of formation constants to be usefully extended. Simulations have been performed to illustrate the extent to which the effects mentioned above are manifest in many titrations of practical importance.

SYMBOLS

T_i^c = calculated total concentration of component i
T_i^r = real (analytical) concentration of component i
$[X_i]$ = free concentration of component i
$[C_j]$ = concentration of complex j
$[S_i]$ = concentration of species i (component or complex)
$\{S_i\}$ = activity of species i (component or complex)
$\{S_i^s\}$, $\{S_i^b\}$ = activity of species i in the test solution and bridge solution, respectively
γ_i = activity coefficient of species i
β_j = thermodynamic formation constant of complex j
r_{ji} = stoichiometric coefficient of component i in complex j
NC = number of components appearing in complexes
NI = total number of components (including inert ions, such as from background electrolyte, not appearing in complexes)
NJ = number of complexes
NB = number of burettes
C_i^v = initial concentration of component i in titration vessel
C_{im}^B = concentration of component i in solution in burette m
v_m = volume added from burette m
V° = initial volume in vessel
E_k = electrode potential k
E_k° = electrode response intercept
E^{LJ} = liquid-junction potential
E^{sel} = contribution of sodium ions to electrode potential
s_k = electrode response slope
C_H = empirical constant for H in liquid-junction term
C_{OH} = empirical constant for OH in liquid-junction term
K_{ki} = selectivity coefficient of component i
z_i = charge on species i
R = the gas constant
T = absolute temperature
F = Faraday constant
I = ionic strength
λ_i^S = ionic conductance of species i in the test solution
λ_i^b = ionic conductance of species i in the bridge solution
$\mathring{a}$ = ionic size parameter
A, B = parameters in the Debye–Hückel equation

The procedures developed by Sillén and his colleagues over twenty years ago[1] are still widely accepted as the most accurate way of determining formation constants potentiometrically. Experimental conditions were specifically chosen to minimize the adverse effects of various assumptions that had to be made in the analysis of their data. In particular, very high concentrations of supporting background electrolytes were employed to obviate such difficulties as the characterization of activity and liquid-junction potential changes.[2]

However, for many common applications, it is inappropriate to measure formation constants under such conditions. For instance, many biological solutions such as natural waters (*e.g.*, lakes, rivers and soil solutions) and physiological fluids (*e.g.*, plant xylem sap and blood plasma) have much lower ionic strengths, so that the relevant measurements ought to be performed in concentrations of background electrolyte less than, say, 0.2*M*. Under these conditions, the assumption of constant ionic strength throughout a titration is less valid and can lead to significant errors. Moreover, many systems have formation constants that require measurements to be made at pH values at which it is known that the effects of liquid-junction potentials and alkaline errors can be of a worrying magnitude.

*Author for correspondence.

Although a multitude of computer programs have been developed for the analysis of potentiometric titration data, only a few approach the problem in a generalized way. Of these, SCOGS[3] and, especially, MINIQUAD[4] have gained widespread popularity. However, neither of these accommodates variations in ionic strength, changes in liquid-junction potential or imperfect ion-selectivity of electrodes. Some programs, such as LETAGROP,[5] do permit simulation of changes in liquid-junction potential, albeit in a restricted way, but none allows corrections to be made for all three kinds of effect.

Each of these effects is well known and has been extensively studied in its own right. This paper describes how corrections for each may be applied in generalized computer programs for the analysis of potentiometric titration data. Although it is not possible to simulate electrode behaviour entirely satisfactorily for all practical circumstances, the proposed approach satisfies two paramount objectives, namely to improve the interpretation of certain observed data and to provide mathematical forms for the corrections that allow them to be simplified, or even neglected, if that is thought to be appropriate. In this way, the useful range of titration conditions can be extended, the necessity for corrections can be investigated and different forms of the equations used for correction can be readily compared.

THEORY

Mass-balance

The conditions of mass-balance are imposed in the standard way by equating calculated total concentrations with real (analytical) concentrations:

$$T_i^r = T_i^c, \quad i = 1, \ldots, NC \tag{1}$$

where

$$T_i^c = [X_i] + \sum_{j=1}^{NJ} r_{ji}\Gamma_j\beta_j \prod_{n=1}^{NC} [X_n]^{r_{jn}} \tag{2}$$

$$T_i^r = \frac{C_i^v V^\circ + \sum_{m=1}^{NB} C_{im}^B v_m}{V^\circ + \sum_{m=1}^{NB} v_m} \tag{3}$$

$$\Gamma_j = \left(\prod_{n=1}^{NC} \gamma_n^{r_{jn}}\right) \Big/ \gamma_j. \tag{4}$$

Electrode equation

In general, the equation relating the potential of an electrode to the activity of the electrode ion can be written in the form

$$E_k = E_k^\circ + E_k^{IS} + E_k^{LJ} \tag{5}$$

where E_k° is the electrode response intercept. For the purpose of formation-constant determination, E_k^{IS} is usually given by

$$E_k^{IS} = s_k \log\{X_k\} = s_k \log\gamma_k + s_k \log[X_k] \tag{6}$$

Some programs[4-6] assume that both the liquid-junction term, E_k^{LJ}, and the activity coefficient of the electrode ion, γ_k, are constant. The resulting electrode equation is

$$E_k = E_k^{const} + s_k \log[X_k] \tag{7}$$

where

$$E_k^{const} = E_k^\circ + s_k \log\gamma_k + E_k^{LJ}.$$

Others[7-10] assume that γ_k is constant and that E_k^{LJ} is a linear function of the free proton and hydroxide ion concentrations. The electrode equation is thus

$$E_k = E_k^{const} + s_k \log[X_H] + c_H[X_H] + K_w c_{OH}/[X_H] \tag{8}$$

where $E_k^{const} = E_k^\circ + s_k \log\gamma_k$.

Electrode selectivity

None of the above programs accommodates the well-known effects of interfering ions. It is possible to extend the useful range of detection by several orders of magnitude if these effects can be taken into account. However, the simple Nikolskii[11] equation (9),

$$E_k^{IS} = s_k \log(\{X_k\} + K_{ki}\{X_i\}) \tag{9}$$

often invoked to describe how the electrode response is ultimately dominated by the interfering ion, is unsatisfactory for this purpose. This is because it describes a very sharp transition in response whereas, in fact, the change is generally much more gradual.[12] As a result, even if equation (9) is used in an entirely empirical way, corrections in the region that is most important, *i.e.*, when the effect is first manifest, can never be more than a very small fraction of the effect itself.

At least in the case of glass electrodes, the behaviour observed in the presence of one univalent interfering ion is better described by the Eisenman equation:[13]

$$E_k^{IS} = s_k \log(\{X_k\}^{1/\alpha} + K_{ki}\{X_i\}^{1/\alpha})^\alpha \tag{10}$$

where α and K_{ki} are empirical parameters. Although a corresponding general multi-ion equation has not been formulated,[14] this has been done in the case of the Nikolskii equation, leading to

$$E_k^{IS} = s_k \log(\{X_k\} + \sum_i K_{ki}\{X_i\}^{z_k/z_i} \tag{11}$$

where the charges z_i have the same sign as z_k.[15] For the purpose of titration-data simulation, we therefore propose that an equation of the following form should be used:

$$E_k^{IS} = s_k \log[\{X_k\}^{1/\alpha} + \sum_i (K_{ki}\{X_i\}^{z_k/z_i})^{1/\alpha}]^\alpha \tag{12}$$

This has the advantage that equations (6), (10) and (11) can all be accommodated by making suitable choices for α and the K_{ki} values.

Liquid-junction potential

It is common for the liquid-junction coefficients of equation (8) to be obtained empirically. An extension which reduces to this linear form at low concentrations of acid is that derived from the Henderson equation[16] by Biedermann and Sillén.[2] It has the form

$$E_k^{LJ'} = -(RT/F)\ln(1 + d[X_H]/I) \qquad (13)$$

where I is the concentration of the background univalent electrolyte. This equation has been used to correct for liquid-junction potential changes in the calibration of glass electrodes.[17] The Henderson equation itself, equation (14), predicts potentials across junctions of different univalent electrolytes at constant ionic strength, with reasonable success.[18] It has also been shown to be useful in calculation of potentials across constant-ionic-medium junctions through potentiometric titrations.[19]

$$E_k^{LJ} = \frac{-RT}{F} \times \frac{\sum_i \gamma_i^s\{S_i^s\} - \lambda_i^b\{S_i^b\}}{\sum_i z_i(\lambda_i^s\{S_i^s\} - \lambda_i^b\{S_i^b\})} \times \ln \frac{\sum_i \lambda_i^s z_i\{S_i^s\}}{\sum_i \lambda_i^b z_i\{S_i^b\}} \qquad (14)$$

Much less is known about the applicability of the Henderson equation to salt bridges that have higher concentrations than that of the test solution, although Bates[20] has tabulated some typical values predicted for bridges containing saturated potassium chloride solution. Whilst such bridges clearly violate one of the principle tenets of the Henderson equation (namely that activity coefficients remain constant across the junction), they do serve to reduce the size of the junction potential, thus making relative errors in its characterization less significant. However, it remains to be seen whether the equation can be used effectively to simulate changes in the liquid-junction potential when high-concentration salt bridges are involved.

Although equation (14) predicts absolute liquid-junction potentials, these can be observed experimentally only as a difference in potentials. It is conventional to have this difference increasingly manifest towards the extremes of pH.

This property can be preserved by defining E_k^{LJ} as follows.

$$E_k^{LJ} = E_k^{LJ'} - E_k^{LJ_0} \qquad (15)$$

where $E_k^{LJ_0}$ is the liquid junction potential [calculated from equation (14)] between the bridge solution and a solution containing the bridge ions only (*i.e.*, at pH 7) at the reference ionic strength (*i.e.*, that at which the electrode constants E_k^{const} and s_k are applicable). This results in a calculated E_k^{LJ} that tends to a constant value (usually small or zero) as the pH tends to 7. Note that with a "constant ionic strength" bridge, *i.e.*, one containing electrolyte ions of the same type and concentration as the background medium, $E_k^{LJ_0} = 0$ and its size increases with the concentration of the bridge electrolyte. The advantage of equation (14) for the purpose of simulating titration data is that its general form permits further investigation of liquid-junction-potential phenomena, yet, by an appropriate choice of the ionic conductivities for each ion, it can be used to accommodate the simpler equation (13) when that is applicable. For example, with univalent electrolytes and a constant-ionic-strength junction of the type

$$I(AB) \,||\, [X_H](HB), I(AB)$$

equation (14) reduces to equation (13), with

$$d = (\lambda_H - \lambda_A)/(\lambda_A + \lambda_B).$$

There is evidence that liquid-junction potentials calculated from the Henderson equation are generally overestimated, especially for high ionic-strength bridges.[21,22] However, for any given background-electrolyte and salt-bridge concentrations, there is often only one ion that has an appreciable effect on changes in the liquid-junction potential.[23] Hence, for junctions involving H^+, λ_H can be empirically adjusted, either at the level of equation (13) or at that of equation (14).

Activity coefficients

For the calculation of activity coefficients the most common extension to the Debye–Hückel formula has the form

$$-\log\gamma = \frac{Az^2\sqrt{I}}{1 + B\mathring{a}\sqrt{I}} + cI \qquad (15)$$

where c is an empirical constant. Guggenheim[24] simplified this by choosing $\mathring{a} = 1/B$ and, under this condition, Davies[25] proposed that $c = 0.3Az^2$. The latter proposal is the IUPAC recommended equation for formation-constant work[26] and is widely used in geochemical equilibrium calculations.[27,28] Others have used Kielland's[29] values for $\mathring{a}$ and empirically determined values for c.[30,31]

Equation (16) seems a particularly sensible choice to incorporate in a computer program since the parameters $\mathring{a}$ and c for each ion can be chosen such that all of the approaches above can be accommodated. The constants A and B can be calculated within the program from

$$A = 1.8249 \times 10^6/D^3, \quad B = 50.293/D$$

where

$$D = (3686.2T^{1/2} - 135.15T)^{1/2}.$$

Although the coefficients depend on the particular values chosen for the dielectric constant of water, these formulae yield results which are more than adequate for the present purpose over the temperature range 0–100°.

At low concentrations of background electrolyte, variations in ionic strength occur during a titration, owing to changes in complexation. By using equation (16), corrections should be made to all the formation constants at each titration point so that they refer to the calculated ionic strength at the point. Corrections of this kind over a large range of ionic strength (say, from $I = 0.0$ to 0.2) may not be adequate in precise potentiometric work; however, in the majority of cases, variations in ionic strength, although significant, are sufficiently restricted to ensure that corrections with equation (16) are wholly satisfactory.

Conversion into thermodynamic constants

Equations (2), (12) and (14) require "thermodynamic" values of the parameters β_j, E_k°, K_{kl}, λ_i^s and λ_i^b, *i.e.*, those that are defined with respect to a standard state based on reactions occurring at infinite dilution in water at zero ionic strength. However, it is established practice to work with conditional constants (${}^I\beta_j$, ${}^IE_k^\circ$, ${}^IK_{kl}$, ${}^I\lambda_i^s$, ${}^I\lambda_i^b$) which refer to some other ionic strength (I). Such constants, therefore, need to be converted into the corresponding thermodynamic values in the following way:

$$\beta_j = {}^I\beta_j / {}^I\Gamma_j$$

${}^I\Gamma_j$ is defined as in equation (4).

Expressing equation (12) in terms of concentrations, and rearranging, yields

$$E_k^{IS} = s_k \log {}^I\gamma_k + s_k \log\left\{[X_k]^{1/\alpha} + \sum_i \left(\frac{K_{ki}({}^I\gamma_i[X_i]^{z_k/z_i})}{{}^I\gamma_k}\right)^{1/\alpha}\right\}^\alpha.$$

Hence, the supplied value of ${}^IE_k^\circ$ and the ion-selectivity coefficients are converted into thermodynamic values as follows.

$$E_k^\circ = {}^IE_k^\circ - s_k \log {}^I\gamma_k$$

$$K_{kl} = {}^IK_{kl}({}^I\gamma_k/({}^I\gamma_i)^{z_k/z_i})$$

The supplied ionic conductivities to be used in the calculation of E_k^{LJ} are treated similarly:

$$\lambda_i^s = {}^I\lambda_i^s / {}^I\gamma_i^s; \quad \lambda_i^b = {}^I\lambda_i^b / {}^I\gamma_i^b$$

Whether Debye-Hückel corrections are to be invoked or not, only conditional constants thus need to be supplied by the program user. In either case, the same values (say, for electrode potential) are calculated for any point in the titration which actually has the reference ionic strength.

Solution of mass-balance equations

The NC mass-balance equations (m.b.e.), equation (1), can, in principle, be solved for any NC unknowns as long as all remaining parameters are known. In particular, there are NC free concentrations that can be determined. On the other hand, if one of the free concentrations has been measured experimentally, the remaining free concentrations and one other parameter (such as v_m, β_j, C_i^v, C_{im}^B, or T_i^r) can be calculated. Consequently, the procedures for solution of the m.b.e. falls into two categories. In the first, these equations are solved for NC free concentrations without any reference to the electrode equation. The electrode potential can subsequently be obtained by substitution into equations (5), (12) and (15). In the second category, it is necessary to solve the electrode equation to obtain the free electrode-ion concentration, $[X_k]$, (given an observed potential, E_k), before solution of the m.b.e. Solving the electrode equation for $[X_k]$ requires a knowledge of all the free concentrations so it is necessary to implement an iterative solution of this equation and the m.b.e.

A Newton–Raphson procedure is generally the most efficient way to solve the m.b.e. The corresponding set of linear equations has the form

$$\mathbf{A}\bar{\mathbf{s}} = \bar{\mathbf{b}} \tag{17}$$

where

$$A_{im} = \left[\frac{\partial(T_i^c - T_i^r)}{\partial x_m}\right]_{\bar{x}^n}, \quad m = 1, \ldots, NC: \; i = 1, \ldots, NC.$$

$s_m = \Delta x_m^n =$ shift to m^{th} unknown $= x_m^{n+1} - x_m^n$.

$b_i = T_i^r(\bar{x}^n) - T_i^c(\bar{x}^n)$,

and

$\bar{x}^n = n^{th}$ iteration estimate of the unknowns.

The equations can be set up in terms of the absolute values of unknowns except for the free concentrations, $[X_k]$, and formation constants, β_j, for which natural logarithms are more convenient. The equations (17) can then rapidly be solved by forward and backward substitution using the Crout factors for **A** (obtained by using partial pivoting).[32] Scaling of the shift vector $\bar{\mathbf{s}}$ is only required when particularly large shifts are predicted or if $\bar{\mathbf{b}}^t.\bar{\mathbf{b}}$ increases. If a failure in the Newton–Raphson procedure occurs in those tasks for which the only unknowns are free concentrations, the slower but more robust secant method[33] can be used to solve the equations.

Initial estimates

It is well known that the efficiency of the Newton–Raphson method is considerably improved if good initial estimates can be obtained for the unknowns. Here, there are two classes of unknowns to consider. The first consists of the free concentrations of the components. Unless such concentrations can be obtained from electrode equations, they are very difficult to estimate. Secondly, there are those unknowns which are experimental parameters such as total titrand and titrant concentrations and titration volumes. Formation constants can also be included in this class. Generally it is possible to estimate reasonable initial values.

At the first and second points, initial estimates for the unknowns of the second kind can readily be

provided from the experimental values. If measured electrode potentials are available, initial estimates of the corresponding free electrode-ion concentrations can readily be calculated from the simple electrode equation (7). At the first titration point, estimates of the other free concentrations can be obtained from a proportional formula of the kind used in COMICS[34] and ECCLES.[35] Initial estimates for these concentrations at the second point can then be taken as the values obtained for the solution of the equations at the first point.

Initial estimates of all parameters at the third and each subsequent point of a titration are best obtained by linear extrapolation of the solution from the previous two points. This can, in principle, be based on the change in either the observed electrode potentials or the titration volumes. Experience has shown that, when they are available, the potentials are the more effective. It is found that the number of Newton–Raphson iterations required to solve the m.b.e. at each point can be reduced by as much as 50% by this technique, compared with one which uses the solution of the previous point for the initial estimate. As storage and extrapolation of two previous solutions involves considerably less work than the application of a number of Newton–Raphson iterations, a correspondingly marked decrease in execution time is obtained. Quadratic extrapolation has also been investigated but proved to be less satisfactory, in part because the extra calculation over three points does not always lead to a decrease in the number of Newton–Raphson iterations required to solve the m.b.e.

RESULTS AND DISCUSSION

The ability to apply the more general electrode equation [see equations (5), (12) and (15)] and to correct for activity changes, forms the basis of a generalized computer library called ESTA (Equilibrium Simulation for Titration Analysis) which is currently being developed in this department.* The major objective of this project is to provide a flexible computing tool for investigating phenomena associated with chemical interactions in solution and for their quantitative characterization.

Although liquid-junction potential, sodium-ion interference and activity changes have long been individually characterized, they have been widely neglected in the context of potentiometric titrations. As no computer program for analysing titration data has hitherto incorporated all of these corrections, their importance has been difficult to assess and, as a result, has tended to be ignored. To illustrate the extent to which each effect is typically manifest in many titrations of practical importance, two simulations have been performed. These relate to the determination of proton and zinc formation constants of cysteine.[36] The titration conditions and parameters are shown in Tables 1–3. The Davies equation[25] was used to simulate activity-coefficient changes. Values for the formation constants, ionic conductivities and sodium-ion selectivity parameters were estimated from the literature, unless otherwise indicated.

The results of the simulations are shown in Tables 4 and 5. Distributions of the complexes during the titrations, as a percentage of total cysteine and total

zinc respectively, are also given. The magnitude of changes in ionic strength that commonly occur in titrations of this kind can be seen, emphasizing the need to correct formation constants to the appropriate ionic strength at each point. Secondly, the effect of sodium ion interference towards higher pH (E^{sel}), even at the concentrations which occur in these titrations, is significant. Moreover, as temperatures and sodium-ion concentrations increase, this effect will increase dramatically.[38] It is thus interesting to note that corrections of this kind are also important when higher concentrations of background electrolyte are employed to minimize ionic-strength and liquid-junction potential changes. For example, in 3.0*M* sodium perchlorate at 25°, errors of 1.0 mV may occur at pH values as low as 8.

The tables also show the liquid-junction potentials calculated from the Henderson equation for both constant ionic strength ($^1E^{LJ}$) and saturated potassium chloride ($^2E^{LJ}$) bridges. For titrations at these ionic strengths it is evident that constant-ionic-strength bridges may give rise to significant and somewhat irregular changes in liquid-junction potentials over the whole pH range. This is due to the opposing effects of hydrogen and hydroxide ions on the one hand and the steadily increasing concentration of sodium on the other. The saturated potassium chloride bridges are much less problematical in

7.4	11.74	6	0	0	71	0	0	2.8	1.1	3.5	0.179

this respect. Thus, a choice must generally be made between the better characterized constant-ionic-strength bridge and the smaller, but not so well characterized, effects of saturated potassium chloride bridges. In either case, more experimental work is probably required to match the values of these parameters to the accuracy of modern research potentiometers. However, it is clear that with saturated potassium chloride bridges, under normal circumstances, errors from *changes* in the liquid-junction potential are likely to be much less than those arising from other sources.[39] They do not, therefore, justify the use of pH buffers[40] in preference to internal calibration of glass electrodes.

As is well known, the values of liquid-junction potentials and single-ion activity coefficients calculated as described here do not have any absolute significance. They cannot be measured experimentally and, as a corollary, they cannot, in themselves, be meaningfully interpreted in any data analysis. However, the effects of *differences* in these quantities can have an experimental reality and thus can validly be taken into account, either theoretically or empirically.

Although the approaches developed in this paper allow for large changes in liquid-junction potential, ionic strength and sodium-ion interference, it obviously remains desirable to design experiments which minimize these effects whenever possible. Nevertheless, it is envisaged that programs which apply such corrections will help to establish the extent to which titration conditions can be extended beneficially. This will permit a wider variety of equilibrium systems to be satisfactorily characterized. A major advantage in this respect will lie in the ability to integrate and quantify, simply and rapidly, expected effects *in the actual context of each application.* This will provide an insight, for the system under investigation, which has hitherto often proved elusive in practice.

Summary—Two methods for the determination of polyethylene glycols (PEGs) in aqueous solution by precipitation with iodine have been developed. For PEGs with molecular weight 4×10^3–2×10^4 the excess of iodine is titrated with thiosulphate, and for PEGs with average m.w. $> 2 \times 10^4$ turbidimetric measurement is used. Both methods are relatively simple and give accurate and reproducible results.

Polyethylene glycols (PEGs) are non-toxic water-soluble polymers of ethylene oxide which have found wide application in the pharmaceutical,[1] biomedical[2] and many other sciences.[3] Most methods for their determination are based on precipitation of the Ba–PEG complex with sodium tetraphenylborate and determination of the precipitate by gravimetric,[4] potentiometric,[5] coulometric[6] or thermometric[7] analysis. The precipitates formed by the Ba–PEG complex with silicotungstic or phosphomolybdic acid can be determined gravimetrically[8] and the phosphomolybdic acid precipitate has also been determined colorimetrically.[9] Turbidimetry has been used for determination of the PEG–tannic acid precipitate[10] and of that of the Ba–PEG complex with trichloroacetic acid,[9] and nephelometry for the precipitate formed by reaction of PEG with Nessler's[11] or Mayer's[12] reagent. The oxidation of PEG with dichromate in acid solution[10,13] and splitting of the ether function with hydriodic acid[14] have also been used for the determination of PEGs.

We have developed two new and simple methods based on the reaction of PEG with iodine. In the first, the excess of iodine is titrated with thiosulphate after removal of the I_2–PEG precipitate, and in the second the turbidity of the I_2–PEG suspension is measured photometrically.

EXPERIMENTAL

Reagents

PEGs (Hoechst, Brussels), m.w. 200–20000, were "DAB 8" grade.[15] The other reagents were of analytical-reagent grade.

*Iodine (I_2) solution, 0.05*M. Made by dissolving 3.173 of iodine in a solution of 6.34 g of potassium iodide in about 50 ml of water and making up to 250 ml with water, and standardized with 0.1*M* sodium thiosulphate.

*Sodium thiosulphate solution, 0.1*M. Standardized by titration with potassium bromate. A 0.01*M* solution was made by appropriate dilution.

Apparatus

The turbidity of the I_2–PEG suspension was measured with a single-beam Coleman 55 spectrophotometer.

Procedures

Determination of iodine excess after filtration. Pipette 10 ml of PEG solution (100–200 mg/l.) into a 25-ml Erlenmeyer flask. Add 2 ml of 0.05*M* I_2 solution and mix carefully. Add 6 ml of 3M sulphuric acid and mix again. Filter off the precipitate on about 150 mg of glass wool placed on top of a sintered-glass filter (pore diameter 20–40 μm) and collect the filtrate in a 50-ml Erlenmeyer flask. Rinse the 25-ml flask and the glass wool with two 10-ml portions of 1*M* sulphuric acid and combine these with the filtrate. Titrate the iodine in the filtrate with 0.1*M* thiosulphate, adding 1 ml of 1% starch solution near the end of the titration.

Determination of iodine excess after centrifugation. Pipette 5 ml of the PEG solution into a dry 10-ml centrifuge tube. Add 1 ml of 0.05*M* I_2 solution and 3 ml of 3*M* sulphuric acid, mixing after each addition. Centrifuge for 5 min and pipette 3 ml of the clear supernatant liquid into a 50-ml Erlenmeyer flask. Add 20 ml of 1*M* sulphuric acid and titrate with 0.01*M* thiosulphate, adding 1 ml of 1% starch solution near the end of the titration.

Turbidity of the I_2-PEG suspension. Pipette 25 ml of 0.01*M* I_2 solution into a 50-ml beaker and add 5 ml of PEG solution (60–3000 mg/l.) dropwise, with vigorous magnetic stirring during addition of the PEG solution and for 3 min more. Then immediately transfer part of the suspension into a 1-cm glass cuvette and measure the absorbance at 750 nm after 5 min.

RESULTS

Titration method

On addition of iodine to a PEG solution a green ($300 \leqslant$ m.w. $\leqslant 2000$) or brown ($4000 \leqslant$ m.w. $\leqslant 20000$) precipitate is formed,[16] and becomes blue-black on acidification with sulphuric acid. The supernatant liquid is clear yellow and the iodine in it can be titrated with thiosulphate, with starch as indicator. If the titration is done in the presence of the precipitate an easily seen end-point is obtained, but within a few seconds iodine is released from the precipitate and the starch–iodine colour reappears. Very slow titration shows that all the iodine present can be released from the complex. It is therefore necessary to remove the

precipitate before the titration. The initial precipitate (before acidification) is so finely divided that it can only be separated by centrifugation at high centrifugal force, but the flocs formed by addition of sulphuric acid can be separated easily by filtration or centrifugation (at low centrifugal force).

The amount of iodine bound is linearly related to the amount of PEG. The regression equation data are summarized in Table 1. The reaction is much less sensitive for PEG 400 than for the PEGs of higher m.w. A t-test was applied to compare the regression-line slopes obtained for the filtration and centrifugation methods. The variance of the differences between the four pairs of slopes was 0.0398 and the best estimate of the population standard deviation was 0.23. The calculated t-value of 2.97 was smaller than the tabulated t-value of 3.182 (3 degrees of freedom, $P = 0.05$); the slopes were thus not significantly influenced by the separation method. The titration results were analysed statistically in more detail except for PEG 400 (excluded because it reacts very differently). Factorial analysis of variance[17] was applied to determine the influence of the following three factors on the amount of iodine bound to the PEG (μmole/mg):

M, the average molecular weight of the PEG (4000, 6000, 10000, 20000);
S, the method of separating the precipitate (filtration or centrifugation);
C, the concentration of the initial PEG solution (100, 200, 300, 400 or 500 mg/l.).

In all the determinations 0.2 ml of 0.05M I_2 solution was added per ml of PEG solution. There were 40 combinations ($2 \times 4 \times 5$) and each combination was executed twice, so 80 results were obtained.

The results of the analysis are summarized in Table 2. The variance estimates associated with the second-order (M–S–C) and first-order interactions (M–S, M–C and S–C), the separation method (S) and the PEG concentration (C) are not significantly greater than the residual variance estimate ($P = 0.05$). These results are in agreement with the conclusions drawn from the data in Table 1, where the linear relation indicated a constant I_2/PEG ratio and a t-test indicated that the slopes were not influenced by the separation method. However, the variance estimate associated with the molecular weight of the PEGs is significantly greater than the residual variance estimate (at $P = 0.01$). Since the separation method and the PEG concentration have no influence on the I_2/PEG ratio found, all results obtained for one specific PEG molecular weight were considered to belong to the same population. Thus 4 populations, each containing 20 results, were obtained (see Table 3). The "Studentized Range Procedure"[18] was used to see which means differed from the others. The pooled variance

$$S^2 = \sum(n_i - 1)\, S_i^2 \Big/ \sum_{i=l}^{i=k} (n_i - k)$$

was 0.421 and the "5% allowance" for n_i samples and n_j methods

$$\frac{Q}{\sqrt{2}} \sqrt{S^2\left(\frac{1}{n_i} + \frac{1}{n_j}\right)}$$

§Mean and standard deviation of 20 determinations.

was 0.54 ($Q = 3.74$ for 76 degrees of freedom and $P = 0.05$). In Table 3 any two means underscored by the same line do not differ statistically at $P = 0.05$ (difference smaller than 0.54). The I_2/PEG ratios for PEG 4000, 6000 and 10000 do not differ at $P = 0.05$. The I_2/PEG ratio for PEG 20000 is significantly smaller ($P = 0.05$) than the ratio for PEG 4000 and 6000 but does not differ from the ratio for PEG 10000. The EOU/I_2 molar ratios of the different PEGs are summarized. The EOU (ethylene oxide unit) concentration for a given quantity of PEG is calculated as weight of PEG per mole of EOU. The ratio is 2 for PEGs $4000 \leqslant$ m.w. $\leqslant 20000$, but 6 for PEG 400 (not included in Table 3) at PEG concentrations greater than 300 mg/l.

Turbidity method

As already mentioned, the I_2–PEG precipitate is very fine, so the particles settle slowly. Therefore turbidimetric measurement of the I_2–PEG suspension was investigated, but only for the PEG 20000 (which is frequently used in our laboratory). The absorbance was measured at 750 nm because iodine at the concentration in the assay mixture (about $8.3 \times 10^{-3} M$) does not absorb light at this wavelength. For reproducible absorbances to be obtained the suspension has to be formed by adding the PEG solution dropwise to the iodine solution and not *vice versa*. The absorbance was recorded as a function of time, after the initial standing time of 3 min, and Fig. 1 shows that the absorbance (measured for an optical path through the lower part of the cuvette) increases with time, on account of sedimentation. Hence the absorbance must be measured at a fixed time after transfer of the suspension into the cuvette. The reproducibility of the absorbance for five different PEG concentrations was studied; the absorbance was recorded immediately after transfer to the cuvette and after a time-lapse of 5 min. Each measurement was duplicated. An F-test ($F = 31.2$) indicated that the variance of the differences between duplicates is significantly smaller ($P = 0.01$) for the absorbances measured after 5 min.

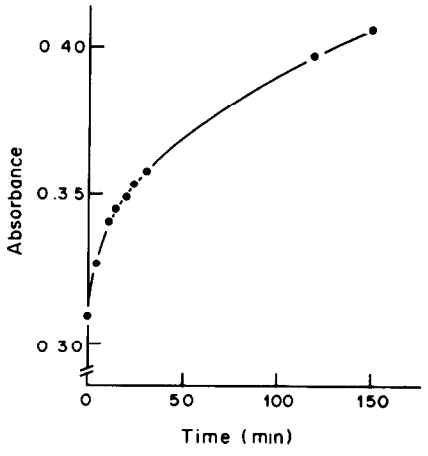

Fig. 1. Absorbance of an I_2–PEG suspension at 750 nm, as a function of time.

The calibration graph is linear over the range 60–2400 mg/l. in the final solution, which is much wider than that for the nephelometric determination of PEG 4000 with Nessler's reagent[11] (20–80 mg/l.) and the turbidimetric determination of the PEG–tannic acid precipitate (20–34 mg/l.). The results indicate that the turbidimetric method gives a simple and accurate determination of PEG 20000.

CONCLUSIONS

A novel, simple and rapid method for the accurate determination of PEG with iodine is presented. Only simple equipment is needed for the titrimetric method. In the turbidimetric method the order of addition of the reactants is important and so is the time-lapse between filling the cuvette and reading the light intensity. The concentration range for linear response is larger than for other methods.

In contrast to other methods in which the EOU/I_2 ratio found is 6, the ratio found here is 2; no explanation can be offered for the difference. An EOU/I_2 ratio of 6 was also found, but only for PEG 400 at concentrations > 300 ml/l.

DETERMINATION OF THE RARE-EARTH ELEMENTS IN GEOLOGICAL MATERIALS BY THIN-FILM X-RAY FLUORESCENCE AND INDUCTIVELY-COUPLED PLASMA ATOMIC-EMISSION SPECTROMETRY

HOU QING-LIE*, T. C. HUGHES, MAUNU HAUKKA and PHILIP HANNAKER†
Department of Geology, School of Earth Sciences, University of Melbourne, Parkville, Victoria 3052, Australia

(*Received* 24 *March* 1984. *Revised* 24 *August* 1984. *Accepted* 12 *December* 1984)

Summary—Thin-film XRF and ICP–AES analytical procedures for the determination of the rare-earth elements (REE) in rocks, involving preconcentration by ion-exchange and co-precipitation with $Fe(OH)_3$ for thin-film preparation, and matrix modification, are described. The REE in five international reference rocks have been determined, with correction for spectral line overlap whenever necessary. The results obtained by using X-ray fluorescence spectrometry compare well with those of inductively-coupled plasma atomic-emission spectrometry, and with other values reported in the literature.

Several techniques have been used for determining the rare-earth elements (REE) in geological samples at the ppm level. Both inductively-coupled plasma atomic-emission spectrometry (ICP–AES)[1–6] and electrothermal atomic-absorption spectrometry (AAS)[7] have been used for REE determinations. REE values determined by other techniques, such as neutron-activation analysis (NAA)[8] and mass spectroscopy (MS)[9] have also been documented.

X-Ray fluorescence (XRF), available in many analytical laboratories, has also been used for REE determinations,[10,11] but matrix effects and line interferences are two of the major problems associated with REE determinations by this method. To cope with these problems, a thin-film technique was investigated in our laboratories, with $Lu(OH)_3$ as an internal standard and $Fe(OH)_3$ as the carrier for preconcentration. This, combined with a matrix modification, improved the sensitivity, accuracy and precision of the determinations.

The thin-film technique has long been used in XRF analysis. Gunn[12] demonstrated the linear relationship between fluorescence intensity and concentration of various elements in the thin film. Chung[13] examined the effect of the thickness of thin films on matrix effects. The great success of the technique is attributed to the reduction of matrix effects by use of the thin film and to the efficiency of preliminary separation and quantitative recovery of REE, using an internal standard and co-precipitation, similar to Miller's[14] procedure using fluoride precipitation.

The most important step in the procedure is the ion-exchange separation, in which the REE are separated from major elements in the rocks prior to XRF determination. According to the distribution coefficients for 50W-X8 resin,[15,16] most rock-forming cations [Fe(III), Ti, Al, Ca, Mg, Mn(II), Na, K] and some other heavy metal ions [Cu(II), Ni, Co, Cr(III), Zn, Cd, Ga, In, Tl, Bi, Au, Hg(II), Pb, U and V] are eluted quantitatively by 1*M* hydrochloric acid, 2*M* nitric acid and 1*M* sulphuric acid.

This paper presents a procedure suitable for determination of REE by ICP–AES or the XRF method. It involves sample decomposition by fusion with sodium peroxide and hydroxide, and separation of the REE by ion-exchange. For the XRF determination a further preconcentration by co-precipitation with $Fe(OH)_3$ and production of a thin film on a Millipore filter is necessary, but this is not required for the ICP–AES method. Results are given for five international reference samples and compared with other published values.

EXPERIMENTAL

Apparatus and operating parameters

For XRF determinations a Siemens sequential SRS-1 X-ray fluorescence spectrometer with ten-position sample changer was used. Between the primary and secondary beams home-made extra apertures were installed to mask all but the radiation from the 16-mm diameter sample surface.

For ICP–AES determinations a 34-channel direct-reading Applied Research Laboratories ICP spectrometer, which contained 6 REE channels for comparison with the XRF results, was used. The instrumental parameters are summarized in Tables 1 and 2.

Ion-exchange columns. All ion-exchange columns prepared in the laboratory were made of borosilicate glass tubes (18 mm bore, 170 mm long) with a reservoir at the top (57 mm diameter, 130 mm long, *ca.* 330 ml volume). Bio-Rad AG 50 W-X8 polystyrene cation-exchange resin (*ca.* 22 g), 200–400 mesh, was used in the hydrogen form. A flow-rate of 1–2 ml/min was obtained by constricting the plastic outlet tube (0.7 mm bore) with a screw-clamp.

Reagents

The eluents used (1*M* and 5.5*M* hydrochloric acid, 2*M* nitric acid and 1*M* sulphuric acid) were made by dilution of the analytical-grade concentrated acids with distilled demineralized water.

Stock solutions of the rare earths (1000 ppm) were prepared from the high-purity oxides (Johnson-Matthey) and 20% v/v nitric acid except for the cerium solution, which was made up with sulphuric acid (30% v/v). Mixed rare-earth standard solutions (containing 10 ppm of Lu and 4 ppm of each of the rest) were prepared from the 1000-ppm stock solutions and 10% v/v hydrochloric acid (note: *x*% v/v means *x* ml of concentrated acid diluted to 100 ml with water). The Millipore filters were either type GS with 0.22 μm pore size or GA-6 with 0.45 μm pore size (Millipore Co., Bedford, Mass., USA). All reagents were carefully checked for REE impurities, by applying the procedure to high-purity silica.

Procedures

Sample decomposition. The sample (1 g) was transferred into a nickel crucible and mixed with 3 g of sodium peroxide and 3 g of sodium hydroxide. The mixture was fused over a Méker burner at about 600° for 10 min and allowed to cool for 1–2 min. The crucible and lid were placed in a 150-ml beaker containing 20 ml of water to leach the fusion cake. After 10 min, the contents of the crucible were transferred to a 100-ml plastic centrifuge tube and centrifuged at 2000 rpm for 5 min. The supernatant liquid was decanted into another 100-ml centrifuge tube, and 1 ml of 1% ferric chloride solution was added to ensure that any REE in solution would be co-precipitated with hydrous ferric oxide, and the mixture was centrifuged. The supernatant liquid, containing most of the sodium silicate, was then discarded. The precipitates were dissolved in 10 ml of water and 5 ml of 6*M* hydrochloric acid, with heating on a steam-bath. The acid content of the solution was kept to a minimum (2*M*) to avoid precipitation of any residual silica The solution was then transferred to the ion-exchange column.

Ion-exchange separation. Once the sample solution had passed through, the column was washed successively with 150 ml of 1*M* hydrochloric acid, 170 ml of 2*M* nitric acid, 120 ml of 1*M* sulphuric acid, 120 ml of 1*M* hydrochloric acid and 300 ml of 5.5*M* hydrochloric acid. Between each acid wash, the column was washed with 15 ml of water. The final eluate (300 ml of 5.5*M* hydrochloric acid), containing the REE, was collected in a 400-ml beaker, and evaporated to dryness on a hot-plate. The residue was dissolved in a small quantitity of water and 0.5 ml of 10*M* nitric acid. This solution was then diluted to approximately 100 ml with water, for thin-film preparation. For ICP–AES measurement, dilution to 20 ml was found to be adequate.

Thin-film preparation for XRF. To each sample solution 300 μg of iron(III) (as carrier) and 50 μg of lutetium(III) (as internal standard) were added for co-precipitation of the rare-earth elements by addition of 10 ml of concentrated ammonia solution to raise the pH to >12. The thin film for XRF measurement was then made by filtering off the precipitate on a Millipore filter. A reference thin-film disk was made by running 5 ml of a working multi-element standard solution (containing 50 μg of Lu and 20 μg of each of the other REE) directly through the column as described above for ion-exchange separation, and processing the REE fraction as above. A blank disk, containing only the iron and lutetium, was prepared by applying the whole procedure to 1 g of pure silica. For identification of overlapping spectral lines, thin-film disks were prepared for the individual REE.

Constructing the calibration line. The REE peak and background intensities for a blank disk containing only Fe and Lu were measured and the corresponding peak/background ratios calculated. Multiplication of measured sample and standard backgrounds by these ratios produced the background intensity under the peaks.

Line overlap corrections were made by measuring the intensity of interfering lines at the appropriate analyte wavelengths, for a disk containing a known amount of an interfering element. This gave counts per unit quantity of interfering element, making it possible to subtract the interfering-element count from the analyte count for the multi-element standard disk. An alternative is to calculate and subtract the amount of analyte equivalent to the interfering-element concentration (see Table 3).

The final net counts obtained for the blank and the multi-element standard were expressed as ratios to the internal standard count and used to calculate calibration factors, on the assumption that the XRF count was a linear function of analyte concentration.

By these preparation, measurement and calculation procedures the calibration is fixed indefinitely, without any subsequent standard measurement. If a new batch of chemicals is used for sample preparation, it is only necessary to prepare and measure a new blank disk.

All XRF measurements were based on a fixed counting time of 60 sec, with sequential counting of line and background for each rare-earth element. The analytical lines, background measurement positions and lower limit of detection (L.L.D.) are summarized in Table 4.

ICP–AES analysis. The six rare-earth elements measured by ICP–AES were determined at the following wavelengths (nm): La 398.85, Ce 394.28, Sm 442.43, Eu 381.97, Gd 376.84, Yb 369.42, under the operating conditions outlined in Table 2.

ICP–AES calibration was done with a series of REE standards prepared in 5% v/v nitric acid.

*Background position relative to measured peak, negative if background 2θ lower than peak 2θ.

†Peak and background counting time is 1 min and the 95% confidence limit is 2σ. L.L.D. from counting statistics = standard concentration $\times 3 \times \sqrt{N_b/(N_p - N_b)}$ where N_p and N_b = total counts for peak position and background.

RESULTS AND DISCUSSION

The results for five international reference samples are given in Table 5. The recovery of REE by elution with 5.5*M* hydrochloric acid was found satisfactory, though Fe(III), Al, Si, Ca and Ni produced a small tail. This was not found to be serious, since Fe(III) was purposely added as a carrier to collect the REE. The interference of Ni with the Ho $L\beta_1$ line was expected, but the problem was overcome by co-precipitating the REE with $Fe(OH)_3$ by adding ammonia instead of sodium hydroxide, so that nickel remained in solution as the tetra-ammine complex. Silica particles, if present above trace level in the film, may present serious problems, as they do not adhere firmly to the filter. In that case, an additional column wash with 1*M* hydrochloric acid before the final elution with 5.5*M* hydrochloric acid is necessary to remove most of the silica in order to produce a perfect film. Blank level determinations made by a similar procedure were below the L.L.D. given in Table 4.

A series of ICP–AES determinations for six rare-earth elements in the range 50–10000 μg indicated 100% recovery after the ion-exchange. The quantity of REE co-precipitated with $Fe(OH)_3$ was found to be greater than 99.7% provided the pH of the solution was above 12.

All the REE were determined by XRF except Tm and Lu, which are usually present at sub-ppm levels and below the detection limits specified in this report. Lutetium was therefore used as an internal standard in this study. It has similar behaviour to the analyte elements, so it is more efficient than non-REE elements as an internal standard for correcting for chemical yield, mechanical losses and instrumental deviations. Substantial errors will only be encountered if the lutetium in the sample is present at more than sub-ppm level. When the lutetium content is high then generally so will be that of the other REE and they may be determined directly without preconcentration.

The lines for the determination of REE in this study were chosen on the basis of the spectrum resolution and sensitivity shown in Fig. 1, for 1 g of NIM-G standard rock (same disk as in Table 5). As can be seen, most of the rare-earth lines are well resolved, except Tb $L\beta_2$ which is overlapped by Yb $L\alpha_1$, Eu $L\alpha_1$ overlapped by Pr $L\beta_2$, and Gd $L\alpha_1$ overlapped by both Ce $L\gamma_1$ (not shown) and Nd $L\beta_2$.

The procedure allows the rare-earth elements to be separated from the bulk of other constituents in the

rock. The accuracy of measurement of the rare-earth elements is improved by reducing the spectral correction errors for both ICP–AES and XRF determination. Matrix errors in this procedure were found to be negligible in comparison with the possible errors associated with direct analysis of geological material.

The accuracy was shown to be satisfactory, by comparing two independent final analytical procedures (XRF, ICP–AES), as well as two independent types of standard (natural and synthetic).

The results presented in Table 5 show good agreement with those previously obtained by using either XRF or ICP–AES, or other analytical procedures such as neutron activation or mass spectrometry.

SHORT COMMUNICATIONS

INDIRECT DETERMINATION OF THALLIUM BY DIFFERENTIAL-PULSE POLAROGRAPHY*

ALI H. BAZZI and BRIAN R. KERSTEN
Department of Natural Sciences, University of Michigan-Dearborn, Dearborn, MI 48128, U.S.A.

(*Received* 6 *June* 1984. *Revised* 15 *November* 1984. *Accepted* 21 *January* 1985)

Summary—The method is based on the separation of Tl(I) as $Tl_2HPMo_{12}O_{40}$, stripping of the molybdate, and measurement of the peak current in differential-pulse polarography of the molybdenum. The calibration graph is linear over the range 2–12 ppm of thallium. The relative standard deviation is 1.2% (7 replicates each containing 500 μg of thallium). The current due to reduction of the molybdenum is three times that for reduction of the equivalent amount of Tl(I) in the thallous phosphomolybdate precipitate, making the indirect approach more sensitive than direct polarographic determination of the Tl(I).

The development of new methods for determination of thallium is of importance because of the toxicity of the element.[1] The polarographic behaviour of thallium in pyridine and in different buffer solutions and supporting electrolytes has long been investigated.[2–5] The determination of thallium by d.c. polarography in succinic acid medium has been reported.[6] Thallium has been determined in the presence of large amounts of copper and cadmium by means of the effect of the adsorption of camphor on the DME.[7] Other methods used include a.c. polarography, stripping analysis and differential pulse polarography.[8–11]

The present work deals with indirect determination of thallium by differential-pulse polarography. Tl(I) is separated as the phosphomolybdate and the molybdenum and Tl(I) in the precipitate are determined polarographically. The ratio of molybdenum to thallium in the precipitate has been shown to be 6:1.[12]

EXPERIMENTAL

Chemicals

Stock thallium solution (*1 mg/ml*). Dissolve 1.304 g of pure $TlNO_3$ in distilled water and dilute to the mark in a 1-litre standard flask. Transfer to a polyethylene bottle.

Standard thallium solution (*100 μg/ml*). Transfer 50 ml of the stock solution to a 500-ml standard flask and dilute to the mark with distilled water. Store in a polyethylene bottle.

Basic borate buffer. Transfer 15 ml of 50% sodium hydroxide solution to a 1-litre flask. Add about 300 ml of distilled water and 48.0 g of boric acid. Swirl to dissolve and dilute to the mark with distilled water. Store in a polyethylene bottle. The pH of this solution is 8.9.

*Perchloric acid, 0.5*M. Add 43 ml of concentrated (72%) perchloric acid to about 200 ml of distilled water, cool and dilute to 1 litre. Store in a polyethylene bottle.

*Perchloric acid, 4.0*M. Add 86 ml of concentrated (72%) perchloric acid to about 100 ml of distilled water, cool and dilute to 250 ml. Store in a polyethylene bottle.

Phosphomolybdic acid solution, 10%. Dissolve 10 g of phosphomolybdic acid in 100 ml of water. Filter the solution through a fine-porosity sintered-glass crucible and transfer into a polyethylene bottle.

Apparatus

Differential-pulse polarograms were obtained with an EG&G PAR 174 Polarographic Analyzer equipped with a model 303 static mercury-drop electrode and a Houston model RE0089 *X–Y* recorder.

Procedure

Transfer a sample containing between 100 and 600 μg of thallium(I) into a 30-ml centrifuge tube, acidify with 2.0 ml of 4.0*M* perchloric acid and dilute to 10 ml with distilled water. Add 5.0 ml of 10% phosphomolybdic acid solution and wait for 10 min for complete formation of the thallous phosphomolybdate precipitate.

Centrifuge for 10 min at about 16,000 rpm. Remove and discard the supernatant liquid. Wash the precipitate with 10.0 ml of 0.5*M* perchloric acid, being sure to start washing at the top of the tube and work down to ensure removal of any phosphomolybdic acid adhering to the sides of the tube. Centrifuge for 5 min, then remove and discard the wash solution. Add 25 ml of the borate buffer to the precipitate, directing the stream of the buffer at the precipitate, and wait for dissolution to become complete. Transfer the solution to a polyethylene beaker containing 0.62 g of citric acid monohydrate, and rinse the tube with distilled water into the beaker. Rinse the tube again, with 5 ml of borate buffer, and transfer the washings to the beaker. Transfer the contents of the beaker to a 50-ml standard flask, dilute to the mark with distilled water, and mix.

Transfer a portion of the solution into a polarographic cell and record the differential-pulse polarogram, scanning from −0.2 to −1.5 V *vs.* Ag/AgCl, at 5 mV/sec, using a modulation amplitude of 50 mV, with medium drop-size, a drop-time of 0.5 sec, and a purge time of 4 min.

RESULTS AND DISCUSSION

The effect of the acidity used in precipitation of $Tl_2HPMo_{12}O_{40}$ was studied with samples containing 400 μg of Tl(I). Table 1 shows that between 1.0 and

*Presented in part at the Pittsburgh Conference on Analytical Chemistry and Applied Spectroscopy, 7 March 1984, Atlantic City, N.J., U.S.A.

Table 1. Effect of acidity on the formation of $Tl_2HPMo_{12}O_{40}$ [400 μg of Tl(I), scan-rate 2 mV/sec, drop time 1.0 sec, modulation amplitude 50 mV]

4.0*M* $HClO_4$ added, *ml*	i_p(*), μA	
	Direct, Tl(I)	Indirect, molybdate
0.5	1.89	4.18
1.0	1.93	4.45
1.5	1.90	4.35
2.0	1.93	4.45

*Mean of three values.

2.0 ml of 4.0*M* perchloric acid can be used; 2.0 ml was chosen for the recommended procedure.

The voltage at which the peak of Tl(I) appears in the polarogram is rather insensitive to pH, and is about −0.4 V (*vs.* Ag/AgCl) at both pH 8.8 and 6.1. If the precipitate is decomposed in the pH-8.78 borate buffer without addition of citric acid, only Tl(I) is reduced, at −0.4 V (Fig. 1). If the acidity is adjusted with 0.62 g of citric acid monohydrate, both Tl(I) and the released molybdate are reduced, with good resolution between the two peaks. The pH of the resulting solution is 6.07, and this was chosen as the optimum pH. At a much lower pH the resolution is not adequate. The addition of the buffer serves two purposes: the first is to dissolve the precipitate, and the second to decompose the phosphomolybdate. The addition of citric acid also serves two purposes: the first is to adjust the pH, and the second to complex the molybdate to prevent re-formation of phosphomolybdate. For seven replicate determinations of 500 μg of thallium(I) by the procedure given, the thallium(I) peak gave E_p -0.413 ± 0.002 V, i_p 2.29–2.43 μA, and the molybdate peak gave E_p -1.245 ± 0.005 V, i_p 7.04–7.32 μA.

A typical differential-pulse polarogram at pH 6.1 is shown in Fig. 2. It exhibits two peaks, the first (at −0.4 V) due to reduction of Tl(I) and the second (at −1.2 V) due to reduction of the molybdate. Thus, the heights of the two peaks can be used for the simultaneous direct and indirect determination of thallium with the one polarogram.

The precision was estimated by analysing seven samples each containing 500 μg of thallium. The average current for the thallium peak was 2.33 μA and the relative standard deviation 2.6%, and the average current for the molybdate peak was 7.19 μA, relative standard deviation 1.2%. Hence mea-

*Solutions were made in distilled water, except for $Hg(NO_3)_2$, which was dissolved in 0.032*M* HNO_3.

†Each value is the average from three separate samples.

§The relative error (RE) is calculated relative to 1.86 μA for the Tl current and 5.57 μA for the Mo current.

surement of thallium by means of the molybdate peak is more sensitive and precise.

Calibration graphs with good linearity are obtained for thallium in the range 2–12 μg/ml in the final 50 ml of solution, for both the thallium and molybdate measurements, the slope of the "molybdate" plot being about 3 times that of the "thallium" plot. Both plots give an intercept on the concentration axis at about 0.7 μg/ml thallium concentration, which implies a solubility of about $6 \times 10^{-6}M$ for $Tl_2HPMo_{12}O_{40}$ at the acidity used for the precipitation.

A study was made of the degree of interference by 100–400 μg amounts of various ions at the 400-μg Tl(I) level. Table 2 summarizes the results. The only significant interference is from the ammonium ion when present in amounts above about 100 μg, but even then only for the indirect determination, since it is due to precipitation of ammonium phosphomolybdate, which naturally results in a higher molybdate peak. The direct method is applicable in the presence of at least 400 μg of ammonium ion. Although thallous chromate is only sparingly soluble, its precipitation is prevented by the acidification of the sample with perchloric acid, because of conversion of the chromate into dichromate. Organic bases, rubidium and caesium were not tested, but would be expected to interfere in the indirect (but not the direct) determination because they form insoluble phosphomolybdate salts in acidic medium.[13–15]

The final test solution is fairly stable and there is a change of only +1.1% in peak current if the solution is kept for 24 or 48 hr before the direct measurement, and +1.3% (24-hr storage) and +2.2% (48-hr storage) in the peak current for the indirect measurement, for thallium at the 400-μg level (mean of three replicates).

FLUOROMETRIC DETERMINATION OF BIACETYL

A. J. MAROULIS*, A. N. VOULGAROPOULOS and C. P. HADJIANTONIOU-MAROULIS
Department of Chemistry, University of Thessaloniki, Thessaloniki, Greece

(*Received* 1 *August* 1984. *Revised* 12 *December* 1984. *Accepted* 11 *January* 1985)

Summary—The fluorometric determination of biacetyl is described. 3,4-Diaminoanisole reacts with biacetyl in alkaline ethanol–water solution to give strongly fluorescing 2,3-dimethyl-6-methoxyquinoxaline. Variables such as solvent composition, quenching by acetic and sulphuric acid, heating time and interference by other carbonyl compounds present are discussed. The method may be suitable for the determination of biacetyl in foodstuffs.

Biacetyl constitutes an important natural flavour component of a great variety of foodstuffs. Moreover it is a potential adulterant of frequently consumed products. As a consequence a great number of methods have been reported for its determination. The methods proposed during the past decade or so can be generally classified as those using chromatography (GLC and HPLC),[1–7] ultraviolet and visible absorption spectroscopy,[8–10] polarography[11,12] and miscellaneous techniques such as amperometric titration[13] and atomic-absorption spectrophotometry.[14]

However, none of these methods has the many advantages offered by fluorimetry and in particular its superior sensitivity and specificity.[15] Since biacetyl does not exhibit a significant native fluorescence[16] a method of developing fluorescence in the otherwise non-fluorescent biacetyl solutions had to be devised.

Here we describe a simple fluorimetric method for the estimation of biacetyl in water–ethanol solutions, which is based on formation of the strongly fluorescing 2,3-dimethyl-6-methoxyquinoxaline.

EXPERIMENTAL

Reagents

3,4-Diaminoanisole (DA) and its dichloride (DAD). These were synthesized in accord with established procedures from 4-aminoanisole, but the reagent can also be obtained commercially.

2,3-Dimethyl-6-methoxyquinoxaline (DMQ). This was obtained in crude form by refluxing equimolar amounts (0.013 mole) of 3,4-diaminoanisole and biacetyl in 80 ml of ethanol containing 1 ml of glacial acetic acid, for 1.5 hr, and then removing the solvent. Further purification by repeated recrystallization from ethanol yielded colourless crystals, m.p. 100.5–101.0° (literature value[17] 99–100°).

Biacetyl (Fluka puriss.). Distilled before use.

All other reagents were obtained from Merck and were *pro analysi* grade. The water was distilled twice and stored in polyethylene vessels.

Reagent solutions

3,4-Diaminoanisole solution. A $10^{-3}M$ solution was prepared by dissolving 0.0053 g of the dihydrochloride in 2 ml of $0.5M$ aqueous sodium hydroxide and diluting the solution to 25 ml with 10 ml of absolute ethanol and 13 ml of distilled water.

Biacetyl standard solutions. Prepared by weighing freshly distilled biacetyl, dissolving it in ethanol–water mixture, and diluting to known volume with the solvent mixture. Portions of these solutions were diluted with the solvent mixture to give the test samples. The ethanol–water mixture was prepared by diluting 400 ml of absolute ethanol to 1 litre with distilled water.

Procedure

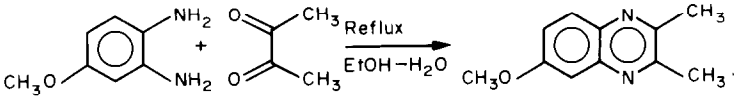
In a 50-ml round-bottomed flask place 2.5 ml of sample, containing 0.3–1.9 μg of biacetyl, and add 1 ml of DA solution and 10 ml of absolute ethanol. Fit a condenser and reflux the mixture for 40 min, cool, then transfer the contents of the flask quantitatively to a 25-ml standard flask and dilute to the mark with ethanol–water mixture. Measure the fluorescence at 395 nm, using an excitation wavelength of 345 nm. Prepare a blank in the same way and measure its fluorescence.

Apply the procedure to three more 2.5-ml portions of the sample, to which have been added two, four and six times the amount of biacetyl in the initial sample (estimated by a calibration graph procedure). Use a plot of fluorescence intensity *vs.* added amount to compute the initial concentration.

RESULTS AND DISCUSSION

Characteristics of the fluorophore and the reagent

DMQ (**III**) is the product of the condensation reaction between DA (**I**) and biacetyl (**II**):



I II III

*Author for correspondence.

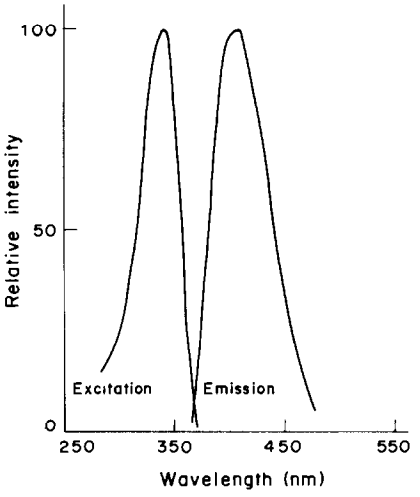


Fig. 1. Corrected excitation and emission spectra of 2,3-dimethyl-6-methoxyquinoxaline in ethanol–water solution. Excitation wavelength 345 nm. Emission wavelength 400 nm.

DMQ exhibits strong fluorescence not only in the ethanol–water solvent system used but also in pure ethanol, benzene and cyclohexane. Changing from the most to the least polar solvent shifts the λ_{max} of emission to longer wavelengths, with a concomitant decrease in fluorescence intensity.

The increased fluorescence observed in the hydroxylic solvents may be due to interchange of the lowest n, π^* and π, π^* excited singlet states in going from the hydrocarbon to the hydroxylic solvents.[18]

At this point it is worth mentioning that the presence of an electron-donating substituent such as the methoxy group in the 6-position of the quinoxaline ring is absolutely necessary, since the 2,3-dimethyl, 2,3,6-trimethyl and 2,3,6,7-tetramethyl quinoxalines (which we have also synthesized for this work) do not display significant fluorescence.

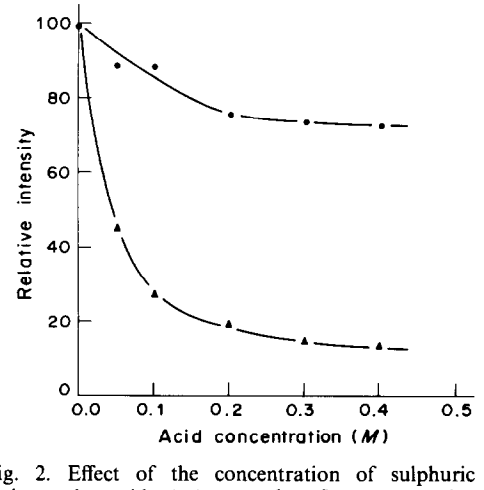

Fig. 2. Effect of the concentration of sulphuric (▲) and acetic acid (●) on the fluorescence intensity of 2,3-dimethyl 6-methoxyquinoxaline in ethanol–water solutions.

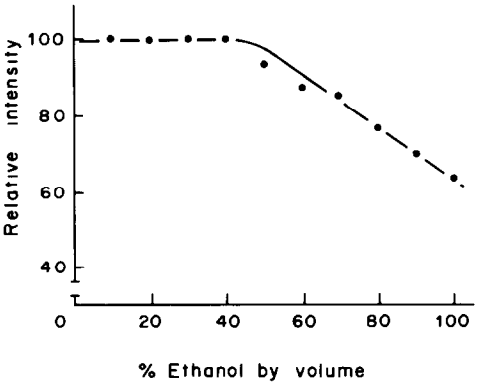

Fig. 3. Effect of solvent composition on the fluorescence intensity of 2,3-dimethyl-6-methoxyquinoxaline in ethanol–water solutions.

The corrected excitation and emission spectra of DMQ are shown in Fig. 1.

Our reagent (DA) does not fluoresce when excited at 395 nm in ethanol–water medium and therefore does not interfere. It does fluoresce, however, when excited at a shorter (*i.e.*, 304 nm) wavelength, displaying a maximum at *ca.* 360 nm.

Effect of added acid or base

Addition of various amounts of sulphuric or acetic acid to a solution of DMQ ($0.11 \times 10^{-5}\,M$) resulted in a decrease in fluorescence intensity (Fig. 2). Since addition of sodium hydroxide did not affect the fluorescence intensity we decided to use an alkaline medium to avoid the need for accurate pH control. There was no adverse effect on the rate or equilibrium of the condensation reaction.

Effect of solvent composition

As can be seen in Fig. 3, ethanol exerts a quenching effect which (fortunately) reaches a plateau when the ethanol concentration is larger than 40% v/v. We chose this particular solvent system so that determination of biacetyl in wine distillates would require minimum adjustment of the method.

Effect of reflux time

Prolonging the reflux time from 40 min to 5 hr did not affect the fluorescence development.

Stability of DMQ in solution

We submitted an analysis sample to extreme conditions (fully open excitation monochromator shutter

Table 1. Determination of biacetyl by standard-addition in ethanol–water solution

[Biacetyl], M		
Taken	Found	Std. devn., M
1.01×10^{-6}	1.10×10^{-6}	0.04×10^{-6}
1.0×10^{-7}	1.05×10^{-7}	0.04×10^{-7}

Table 2. Fluorescence excitation and emission maxima for carbonyl compounds subjected to the procedure

Compound	Excitation maximum*, nm	Emission maximum*, nm
Biacetyl	345	395
Glyoxal	345	422
Benzil	433	547
Acetone	432	544
Benzophenone	440	545

*Taken from the uncorrected spectra, for ethanol–water solution, ketone concentration *ca.* 1×10^{-5} *M*.

and longer exposure times than required for the actual measurement), but no photodecomposition occurred.

Precision of the determination

The precision was estimated by preparing two sets of solutions, each containing five identical samples and a blank.

The fluorescence intensity was measured twice in each determination. The results in Table 1 show that biacetyl was determined with fair precision.

A calibration graph can also be used. In preliminary experiments we found that the response was linear over the concentration range from 1×10^{-8} to 1×10^{-5} *M*.

Fluorescence from other carbonyl compounds

Other α-dicarbonyl compounds such as glyoxal and benzil also exhibit fluorescence under the conditions employed, presumably because the corresponding 6-methoxy- and 2,3-diphenyl-6-methoxyquinoxalines are formed. Fluorescence is also observed when monocarbonyl compounds such as benzophenone and acetone are treated with DA according to our procedure. However, with the exception of glyoxal, these compounds (Table 2) have different fluorescence characteristics and thus do not interfere in the determination of biacetyl when excitation at 345 nm is used.

Since glyoxal can easily be oxidized to oxalic acid, the proposed method can readily be adapted for determination of biacetyl and glyoxal in samples containing both substances. Moreover, it can be used for the determination of acetoin, since this yields biacetyl on oxidation.

Glucose, fructose and sucrose give no fluorescence in the procedure and do not quench that due to 2,3-dimethyl-6-methoxyquinoxaline.

STUDY OF THE TITANIUM–PHENYLFLUORONE COMPLEX FORMED IN THE PRESENCE OF TRITON X-305 AND EMULSIFIER OP

WU QUIANFENG
Shaanxi Research Institute of Environment Protection, 25 Chang An Road (N.), Xian, People's Republic of China

(*Received* 23 *May* 1984. *Revised* 19 *July* 1984. *Accepted* 11 *January* 1985)

Summary—A highly sensitive method for the spectrophotometric determination of titanium with phenylfluorone (PF) in the presence of Triton X-305 and emulsifier OP has been developed. In acid medium (pH 1.4–2.2) Ti(IV) forms red-violet complexes with PF, Triton X-305 and OP. The complex exhibits maximum absorption at 540 nm. The molar absorptivity is 1.63×10^5 l.mole^{-1}.cm^{-1}. The Ti:PF ratio in the complex is 1:2. Beer's law is obeyed in the titanium concentration range 0–0.2 μg/ml in the final solution. Fluoride and EDTA interfere. The method has been used for the rapid direct determination of microamounts of Ti(IV) in soils and cereals with satisfactory results.

Hydrogen peroxide[1] and diantipyrylmethane (DAM)[2] have long been used for spectrophotometric determination of microamounts of titanium. These methods have low sensitivity but high selectivity. Attempts have been made to enhance the sensitivity by addition of thiocyanate and use of solvent extraction,[3] but the methods are laborious and the sensitivity still not high.

Phenylfluorone (9-phenyl-2,3,7-trihydroxy-6-fluorone) (PF) yields intensely coloured complexes with a number of metals and has frequently been used for their spectrophotometric determination.[4–13] Many of these determinations also utilize cationic surfactants such as cetyltrimethylammonium bromide (CTAB),[4,7,8,12] cetylpyridinium bromide (CPB),[9,10,13] tetradecylbenzyldimethylammonium chloride (Zeph)[6] and so on. The molar absorptivity of the products obtained may exceed 10^5 l.mole^{-1}.cm^{-1}.

We have discovered that some non-ionic surfactants such as Triton X-305 or the emulsifier "OP"* may be used as solubilizing agents for the Ti–PF binary complex. It is of interest to note that a combination of Triton X-305 and OP has a very strong solubilizing effect. This paper reports an investigation of the conditions for formation of the Ti–PF–Triton X-305–OP complex in aqueous solution and the application of the system to direct determination of trace amounts of titanium in soils and cereals.

EXPERIMENTAL

Reagents

All chemicals were of analytical reagent grade.

Standard titanium solution. Prepared by dissolving 0.1668 g of high-purity titanium dioxide with 20 ml of concentrated sulphuric acid and 10 g of ammonium sulphate, heating till fuming, cooling and diluting accurately to 1 litre with demineralized water. Working solutions are prepared by accurate dilution of the stock solution.

PF solution, 0.03%. Prepared by dissolving 0.3 g of PF in absolute ethanol and 50 ml of sulphuric acid (1 + 1) and diluting to 1 litre with absolute ethanol. The working solution (0.01%) is prepared by mixing 150 ml of stock solution with 300 ml of absolute ethanol and adding 3 ml of concentrated sulphuric acid. It is stored in a brown bottle.

Mixed surfactant solution. Add 5 g of Triton X-305 to 2 ml of OP dissolved in 100 ml of water, and heat until it is completely dissolved.

Procedure

Transfer a portion of standard solution containing 5 μg of titanium into a 25-ml standard flask, add 5 ml of 0.025*M* hydrochloric acid, 4 ml of 0.01% PF solution and 3 ml of mixed surfactant solution. Dilute to volume with demineralized water. After 7 min measure the absorbance at 540 nm in a 1-cm cell against a reagent blank.

RESULTS AND DISCUSSION

Absorption spectra and effect of pH

Figure 1 shows that the Ti–PF complexes have maximum absorption at 540 nm, and the PF blanks at 470 nm, irrespective of the presence or absence of the surfactants. The absorbance is maximal and practically independent of pH in the range 1.4–2.2. A pH of 1.6 was selected for use.

Effect of PF concentration

The absorbance at 540 nm is constant when the volume of 0.01% PF used is varied between 3.8 and 4.2 ml, and decreases with higher or lower volumes. Hence 4 ml of 0.01% reagent solution was chosen for use.

Choice of non-ionic surfactants

Triton X-305, OP, Triton X-100, gelatin and poly-

*OP is $(CH_3)_3C.CH_2.C(CH_2)_2.C_6H_4(OCH_2.CH_2)_{10}OH$.

Table 1. Influence of non-ionic surfactants on Ti–PF complex colour reaction (pH 1.6)

Reaction system	ε, 10^4 *l.mole*$^{-1}$.*cm*$^{-1}$
Ti–PF	3.4
Ti–PF–OP	10.8
Ti–PF–Triton X-305	12 9
Ti–PF–Triton X-305–OP	16.3

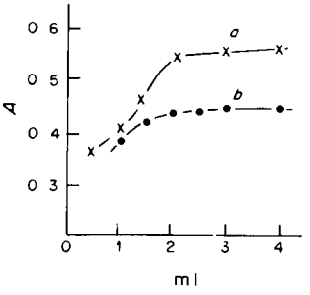

Fig. 2. Effect of non-ionic surfactant concentration: *a*, 5% Triton X-305; *b*, 2% OP.

(vinyl alcohol) were tested but only the first two showed any strong effect on the solubilization or sensitivity. Triton X-305 was better than OP, but a synergic effect was observed when both were used together (Table 1).

The effect of changing the concentration of Triton X-305 or OP is shown in Fig. 2. Maximum and constant intensity can be obtained with 2–4 ml of 5% Triton X-305 or 2% OP. Thus all further measurements were made with 3 ml of Triton X-305–OP mixture in the final solution.

Composition of the complex

The concentration of the Triton X-305–OP mixture was kept constant and a large excess was used, and the ratio of Ti(IV) to PF in the complex was determined by Job's method and found to be 1:2. Similar results were obtained from a molar ratio plot.

Calibration, sensitivity and precision

Beer's law is obeyed over the titanium concentration range 0–0.2 μg/ml in the final solution. The molar absorptivity is 1.63×10^5 l.mole^{-1}.cm^{-1}. The complex is formed quickly and its absorbance at 540 nm remains stable for at least 40 min for determination of 3 μg of Ti(IV). The standard deviation is 0.021 μg and the coefficient of variation 0.7%.

The method is much more sensitive than any of the methods using cationic surfactants, but similar in sensitivity to other methods based on fluorones (as shown in Table 2).

Effect of foreign ions

The effect of the most commonly encountered cations and anions was investigated. The tolerance limit was taken as the concentration of a foreign ion which caused an error of not more than 3% in the determination of 3 μg of Ti(IV). Up to at least 0.5 mg of the following did not interfere: zinc, nickel, copper, cadmium, cobalt(III), aluminium, lead. Manganese(VII), chromium(VI), vanadium(V), iron(III), zirconium(IV) and molybdenum(VI) interfere, but the interference of Fe(III), V(V), Cr(VI) and Mn(VII) can be eliminated by reduction with ascorbic acid, and their tolerance levels are then 10.0, 0.03, 0.5 and 0.5 mg respectively. Up to 0.3 mg of zirconium does not interfere if masked with EDTA. Up to 25 μg of Mo(VI) will not interfere if reduced with hydroxylammonium chloride and then masked with EDTA.

Table 2. Comparison of micellar solubilization spectrophotometric reagents for Ti(IV)

Colour system*	Acidity range	λ_{max}, nm	ε, 10^4 *l.mole*$^{-1}$.*cm*$^{-1}$	Ref.
Ti–PF–Triton X-305–OP	pH 1 4–2 2	540	16.3	This paper

*SAF = salicylfluorone; SPF = sulphenylfluorone.

Table 3. Results for determination of Ti(IV) by the proposed and DAM methods

Samples	Proposed method,* %	Relative standard, deviation, %	DAM method, %
Red soil	0.343	0.34	0.349
Black soil	0.316	0.55	0.324
Yellow soil	0.323	0.36	0.337
Alluvial soil 1	0.217	0	0.218
Alluvial soil 2	0.294	0.72	0.310
Violet soil	0.238	1.75	0.239
Rice	2.2×10^{-4}	2.62	2.4×10^{-4}
Wheat	2.4×10^{-4}	2.41	2.5×10^{-4}

*Average of three determinations.

Chloride, nitrate, sulphate, oxalate, phosphate, tartrate, ascorbic acid and hydroxylammonium chloride do not interfere, even in large amounts. Fluoride interferes but can easily be removed by fuming with concentrated sulphuric acid. Up to 2 mg of EDTA can be tolerated. The amount of chloride added in the procedure is enough to mask up to 20 μg bismuth.

Application of method

The method was applied to the determination of Ti(IV) in soil and cereal samples. The samples were freeze dried and ground (soil to 100 μm, cereal to 40 μm particle size) before analysis.

A 0.100-g soil sample was placed in a 100-ml conical beaker, 8 ml of concentrated sulphuric–phosphoric acid mixture (1 + 1) were added, and the beaker was heated on a hot-plate until the evolution of white fumes ceased. The beaker was cooled, 2 ml of concentrated nitric acid were added and heating was continued until the soil digest solution became colourless and dense fumes of sulphur trioxide appeared. After cooling, the residue was taken up with water and transferred into a 100-ml standard flask and the solution made up to volume. Some of the solution was filtered through a dry paper and 1 ml of filtrate was pipetted into a 25-ml standard flask. One drop of 0.1% *p*-nitrophenol solution and 2.2 ml of 4 g of sodium hydroxide and 4 g of sodium chloride in 100 ml of water were added, followed by 1*M* hydrochloric acid until the solution just became colourless. Five drops more of the acid were added, and 2 ml of 5% ascorbic acid solution, followed by 4 ml of 0.01% PF solution and 3 ml of mixed surfactant solution. The mixture was diluted to volume with water and after 7 min the absorbance was measured at 540 nm in a 1-cm cell against a reagent blank.

For analysis of cereals, a 2.0-g sample was placed in a 100-ml conical beaker, 10 ml of nitric–sulphuric–perchloric acid mixture (8:1:1 v/v) were added and the mixture was allowed to stand for at least 12 hr at room temperature (to avoid foaming on subsequent heating). The procedure for the soil digestion method was then applied.

Table 3 gives the results obtained for Ti(IV) in the samples tested. The results are in good agreement with those obtained by the DAM method. The results for the recovery tests were 82–94% for soil and 91–92% for cereal.

ANNOTATIONS

A NOTE ON THE APPLICATION OF SIGNIFICANCE TESTS BASED ON THE *R*-FACTOR RATIO TO THE SELECTION OF SPECIES IN COMPLEX-FORMATION EQUILIBRIA

MARIUSZ JASKÓLSKI and LECHOSŁAW ŁOMOZIK
Faculty of Chemistry, A. Mickiewicz University, ul. Grunwaldzka 6, 60-780 Poznań, Poland

(*Received* 15 *November* 1984. *Accepted* 24 *January* 1985)

Summary—The use of the significance test based on the *R*-factor ratio for the selection of species in complex formation equilibria studied by least-squares analysis of potentiometric titration data is discussed.

The significance test based on the *R*-factor ratio originally developed for crystallographic applications by Hamilton[1] was first applied to the selection of species in complex-formation equilibria by Vacca, Sabatini and Gristina[2] (hereafter VSG). However, in practical applications, VSG seem to have used the test incorrectly, and this weakened the power of the test and led in certain situations to wrong conclusions. Therefore, we decided to demonstrate the correct method of use of this test and to illustrate its application with a practical example.

The *R*-factor ratio test allows a decision to be made about whether the extension of a model to include additional parameters results in a *significant* improvement in the agreement between the observed and calculated quantities.

When complex-formation equilibria are investigated by least-squares analysis of potentiometric titration data, it is common practice to try various models and to compare the agreements between the experimental observations and the quantities calculated from the various models. A convenient measure of the agreement between the observed data and the values calculated by the least-squares fit is the generalized *R*-factor.[1] If there is no correlation between the data the *R*-factor has the form: $R = [\Sigma w_i(F_i^{obs} - F_i^{calc})^2/\Sigma w_i(F_i^{obs})^2]^{1/2}$, where F stands for the quantities to be compared and w_i is the weight associated with each observation (and equal to the inverse of the variance of the observation). Usually, the model that gives the best fit with the observations (lowest R value) is considered to be correct. However, as pointed out by Hamilton,[1] it is always possible to improve the agreement by including extra parameters in the model. Here, we describe the use of the *R*-factor ratio test to decide whether the inclusion of extra complex species in a model results in *significantly* better agreement between the values calculated from the model and the observations.

Suppose that a complex formation equilibrium can be described by two models: A and B. Let model A consist of m_A and model B of m_B complex species. Let the corresponding generalized *R*-factors be R_A and R_B and the number of observations (titration points) n. Let A be a subset of B, and $m_A < m_B$.

Model A can therefore be said to be *restrained* with respect to model B since some of its formation constants have been set to zero (non-existent species). We want to test the following hypothesis:

H_0: model A is correct.

The hypothesis is linear since it imposes linear relationships on the parameters of the model. The relationships are of the form

$$\beta_k = 0; \quad k = 1,\ldots b \tag{1}$$

with

$$b = m_B - m_A$$

Since the equations (1) are linearly independent, *the dimension of the hypothesis is b*. In practice, b will usually be a small integer. The approach adopted by VSG was incorrect in assuming that $b = m_B$. Moreover, their m_B included the free metal and free ligand concentrations at each titration point, which led to unrealistically large dimensions of the hypotheses.

We want to compare the R factors for the restrained model A, corresponding to the hypothesis, and the unrestrained model B, by calculating

$$\mathscr{R} = R_A/R_B$$

From the table of significance points for the *R*-factor ratio[3] we find a value $\mathscr{R}_{b,(n-m_B),p}$, where p is the level of significance and $(n - m_B)$ is the number of degrees of freedom calculated as (number of observations) – (number of parameters in the unrestrained model B). If

$$\mathscr{R} > \mathscr{R}_{b,(n-m_B),p} \tag{2}$$

we can reject the hypothesis at the p level. This is equivalent to saying that the probability of error if the hypothesis is rejected is less than p. Therefore, p should be as low as possible. In practice, one will *not* reject the H_0 hypothesis if the p level for which (2) is fulfilled is greater than 5%.

The practical example discussed is taken from VSG. For the system copper(II) + *N,N,N′,N′*-tetramethylethylenediamine, six different models were tried. The lowest R factor ($R_0 = 0.00141$) was obtained for a model comprising six complex species. The other models yielded: $R_1 = 0.00242$, $R_2 = 0.00184$, $R_3 = 00200$, $R_4 = 0.00194$, $R_5 = 0.00159$. The corresponding $\mathscr{R}$ values are: $\mathscr{R}_1 = 1.716$, $\mathscr{R}_2 = 1.305$, $\mathscr{R}_3 = 1.418$, $\mathscr{R}_4 = 1.376$, $\mathscr{R}_5 = 1.128$. VSG do not give the compositions of the systems 1–5 explicitly, but we can assume that they were obtained by excluding one or two species from model 0. The number of degrees of freedom given by VSG is 145. If we pessimistically assume that models 1–5 included only one species then the dimension of each of the five hypotheses (H_0: model i is correct; $i = 1,\ldots 5$) is 5. From the R-factor ratio tables we find $\mathscr{R}_{5,145,0\,005} = 1.059$. Therefore, by comparison of the models 1–5 with the unrestrained model 0 we can reject the hypotheses that any of the models 1–5 is correct, at the 0.5% level. Consequently, we are justified in accepting model 0 as correct.

In the example above, VSG used $b = 308$ which resulted in $\mathscr{R}_{308,145,0\,05} = 1.848$ for p as high as 5% and led to the wrong conclusion that there is no significant difference between the six models.

A word of caution may be appropriate. We strongly recommend that model selection should not be based on a single criterion only. In particular, it might be dangerous to try to reach conclusions about the chemical model from the R-factor alone. The R-factor ratio test can be, as illustrated in the example above, a very useful aid in making a decision in ambiguous situations. However, it should always be regarded as an auxiliary tool and used in connection with other tests. We shall discuss the problem of the various possible criteria for model selection in a forthcoming paper.

EFFECT OF ACIDITY ON THE EXTRACTION AND KINETIC STABILITY OF THE COPPER(II)/APCD/IBMK SYSTEM IN STRONGLY ACIDIC MEDIA

MASAHIKO MURAKAMI and TAKEO TAKADA
Department of Chemistry, College of Science, Rikkyo (St. Paul's) University, Nishi-Ikebukuro, Toshima-ku, Tokyo 171, Japan

(*Received* 11 *September* 1984. *Accepted* 11 *January* 1985)

Summary—The extraction of copper(II) from strongly acidic solution (0.01–8*M* hydrochloric acid) with ammonium 1-pyrrolidinecarbodithioate in isobutyl methyl ketone has been investigated. The shaking time needed for quantitative extraction decreases as the acidity is increased. The effect of the mutual solubility of the organic solvent and the aqueous phase is significant when the acidity of the aqueous phase is increased. The acidity of the aqueous phase mainly affects the kinetic stability of the chelate during the shaking period, rather than the decomposition of the chelating agent. The kinetic stability of the chelate apparently depends on the mole ratio of reagent to copper, the half-lives for the chelate extracted from 4*M* hydrochloric acid being 29.0, 40.0 and 85.0 min for reagent: metal mole ratios of 10, 100 and 1000, respectively.

Generally, solvent extraction of metal chelates requires pH adjustment and does not work at very low pH (< 1), because the complexation is largely affected by the hydrogen-ion concentration of the aqueous phase. However, it has been reported[1,2] that Cd, Pb, Ni and Co(II) can be extracted at low pH (< 1) with ammonium 1-pyrrolidinecarbodithioate (APCD) into isobutyl methyl ketone (IBMK). Moreover, the hydrogen-ion concentration was said to affect the decomposition of the chelating agent rather than the formation of the metal chelate. It was also reported that the kinetic stability of the extracts in IBMK decreases as the pH is decreased.

In the preceding paper,[3] we reported on the extraction of Cu(II) from strongly acidic solution (0.01–6*M* hydrochloric acid) into IBMK with APCD. We found that the copper chelate can be extracted quantitatively even from the 6*M* acid if the extraction is done rapidly and the extract is stabilized by washing with water. Although several reports[4–9] have commented on the kinetic stability of metal–APCD chelates in IBMK, they have merely discussed, from a practical point of view, the effect of pH in the stability.

Therefore, we have systematically investigated the kinetic stability of the extracts and determined the optimum conditions for the extraction.

EXPERIMENTAL

Reagents

All chemicals used were of reagent grade. Water was redistilled from all-glass apparatus. Stock 1000-μg/ml copper solution was prepared from 99.99% pure copper metal, then adjusted in acidity to 0.01*M* hydrochloric acid, and diluted 100-fold with water to give the 10-μg/ml working solution.

APCD solution ($1.6 \times 10^{-2}M$) was prepared by dissolving 0.13 g of ammonium 1-pyrrolidinecarbodithioate in 50 ml of water containing 0.5 ml of 0.1*M* ammonia solution, and stored in a refrigerator; it was stable for at least 1 month. All solvents were used without further purification.

Procedure

Transfer 40 ml of hydrochloric acid of the desired concentration, and 5 ml of 10-μg/ml copper solution, to a 100-ml separatory funnel, add 25 ml of IBMK and 5 ml of APCD solution, and mechanically shake the mixture vigorously.

Measure the absorbance of the IBMK phase at 435 nm, in a 10-mm silica cell against IBMK as reference.

RESULTS AND DISCUSSION

Effect of shaking time

The effect of shaking time on the degree of extraction with a 100-fold reagent:copper molar ratio was studied at various acidities. After its separation, the organic phase was washed by shaking for 300 sec with 50 ml of water, then its absorbance was measured at 435 nm. The amount of copper left in the aqueous phase was checked by flame atomic-absorption spectrometry, but none was found.

Figure 1 shows that for each acidity there is an optimum shaking time (all curves have been normalized to make the maximum absorbance 1.0). The small variation between the maximum absorbances is attributed to the effect of increasing acidity on the mutual solubility of the two phases.

The minimum shaking time for quantitative extraction decreases as the acidity is increased: 300 sec for pH 7.5, 120 sec for 0.01*M* acid, 60 sec for 0.1*M* acid and 30 sec for 4*M* acid. These findings disagree with these reported by Irving and Williams,[10] who stated that the rate at which the metal chelates are formed and extracted decreases as the pH is reduced.

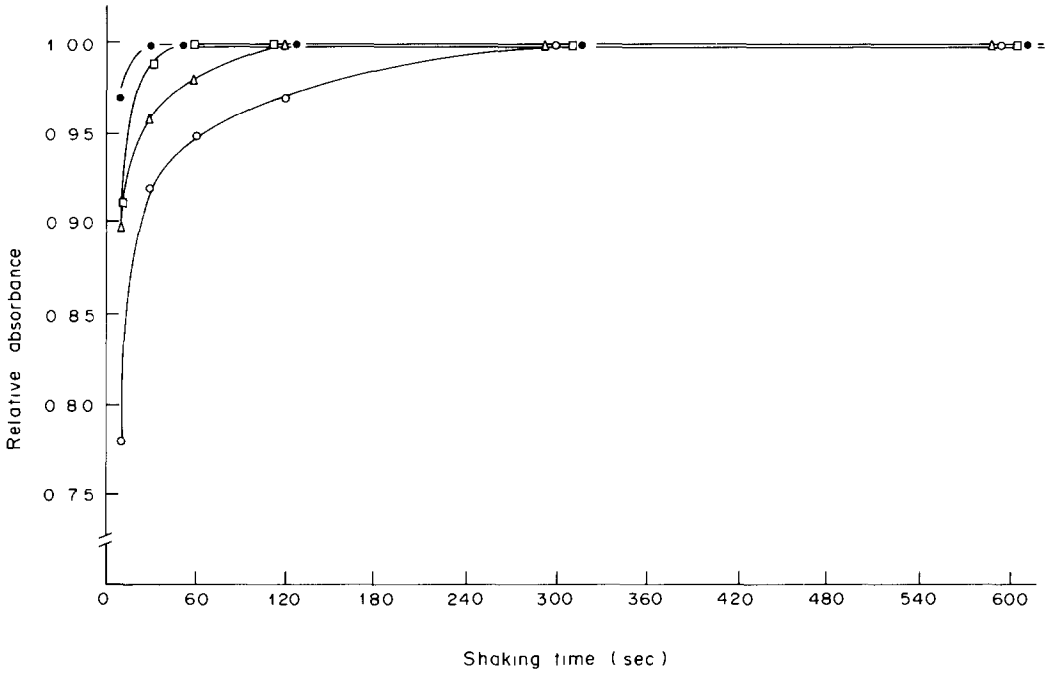

Fig. 1. Effect of shaking time on the extraction of Cu(II) with APCD: pH 7.5 (○), 0.01*M* HCl (△), 0.1 *M* HCl (□), 4*M* HCl (●); aqueous phase 50 ml; organic phase 25 ml; [Cu(II)] $1.5 \times 10^{-5}M$; [APCD] $1.5 \times 10^{-3}M$.

The absorbance was found not to decrease even with a 20-min shaking period under the proposed conditions. Hence a 300-sec shaking period is selected as optimum for extraction from 0.01–4*M* hydrochloric acid.

Effect of APCD concentration

The effect of acidity on the concentration of APCD needed for quantitative extraction was studied. First we studied the decomposition rate of free APCD in 0.01 and 4*M* hydrochloric acid, and found no difference in the half-life for decomposition (26.9 and 25.6 min for 0.01 and 4*M* acid respectively). This agrees with the report by Aspila *et al.*[11] that the decomposition rate of dithiocarbamic acid is not dependent on pH when this is less than 2.

The effect of APCD concentration on the degree of extraction under acidic conditions was then studied. Figure 2 shows the results. If the metal chelate is practically undissociated, the absorbance will increase linearly with APCD concentration until the ligand is just in excess, and then abruptly become constant. This is the case for 0.01*M* hydrochloric medium (Fig. 2a), even though free APCD slowly decomposes at this acidity. Extrapolation of the linear portions of the plot gives an intersection at [APCD]:[Cu] = 2:1, indicating that the predominant complex is $Cu(PCD)_2$.

For 4*M* hydrochloric acid medium, however, the curve is much more rounded in the region of the intersection (Fig. 2b) indicating that there is appre-

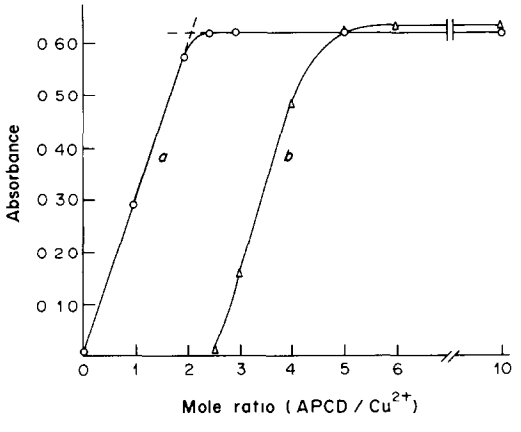

Fig. 2. Effect of APCD concentration on the extraction of Cu(II): (*a*) 0.01*M* HCl, (*b*) 4*M* HCl; aqueous phase 50 ml; organic phase 25 ml; [Cu(II)] $1.5 \times 10^{-5}M$; shaking time 300 sec.

Table 1. APCD/IBMK extraction of Cu(II) from 8*M* HCl

60	0.264
30	0.721
10	1.124

$[Cu^{2+}]$ $1.5 \times 10^{-5}M$, [APCD] $1.5 \times 10^{-2}M$.

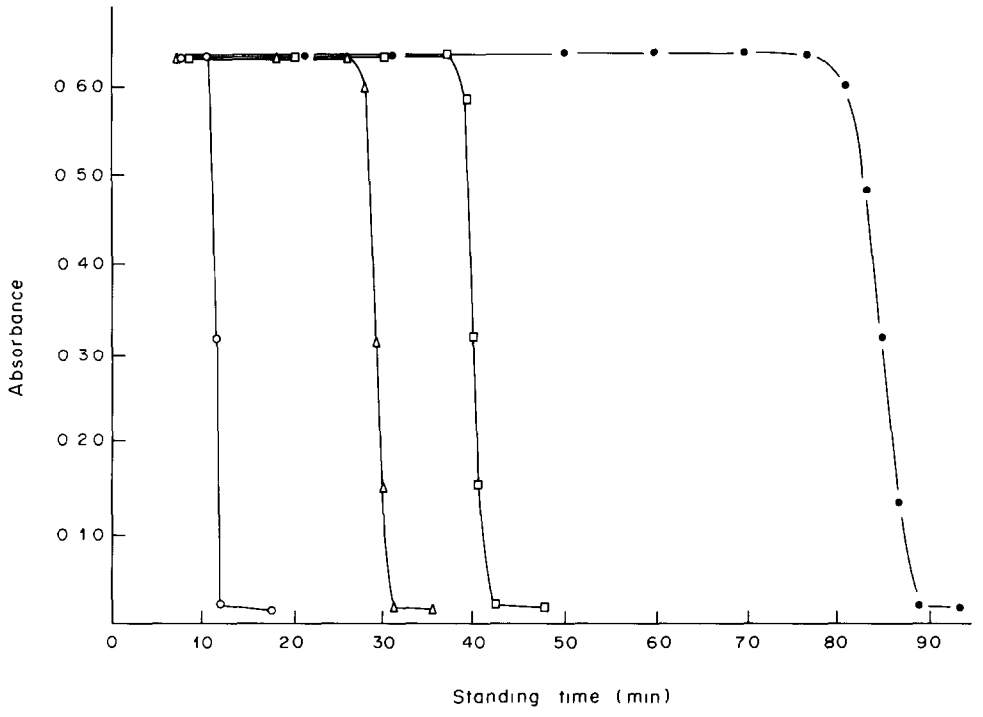

Fig. 3. Kinetic stability of Cu(II)–PCD chelate extracted from 4*M* HCl: [APCD] $7.5 \times 10^{-5}M$ (○), $1.5 \times 10^{-4}M$ (△), $1.5 \times 10^{-3}M$ (□), $1.5 \times 10^{-2}M$ (●); [Cu(II)] $1.5 \times 10^{-5}M$; shaking time 300 sec.

ciable decomposition of the complex during the shaking period. However, extraction is complete at mole ratios of ligand to metal 6:1, presumably because the excess of ligand is large enough to restore the complexation equilibrium in spite of the decomposition of APCD in the complex.

In the earlier work,[3] we observed that the copper chelate was not extracted from 8*M* hydrochloric acid even with 10 times as much APCD as copper, because of decomposition of the chelate during the 60-sec shaking period. We have therefore attempted to extract the copper chelate from 8*M* hydrochloric acid with a very large excess of reagent (1000-fold ratio to copper). The shaking time was varied from 10 to 300 sec, and the copper remaining in the aqueous phase was determined by flame atomic-absorption spectrophotometry. Table 1 shows that the absorbance decreases with increase in shaking time, which suggests that the decomposition of the chelate occurs during the shaking period. Moreover, although extraction of the chelate from 8*M* hydrochloric acid is incomplete (considerable amounts of copper are found in the aqueous phase), the absorbance of the organic phase is much higher (1.124) than that for extraction from 4*M* hydrochloric acid (0.635) for the same amount of copper. This is due to the remarkable decrease in volume of the organic phase. Irving and Rossotti[12] reported that the solubility of IBMK in hydrochloric acid increases considerably as the acidity is increased.

Hence IBMK is unsuitable for extraction from strongly acidic media, such as 8*M* hydrochloric acid.

Table 2. Half-life ($t_{1/2}$) for Cu(II)–PCD chelate extracted from 4*M* HCl

[APCD] *M*	$t_{1/2}$		
	Untreated	With wash	With filtration
7.5×10^{-5}	11.5 min	—	—
1.5×10^{-4}	29.0 min	88.0 min	44.0 min
1.5×10^{-3}	40.0 min	>24 hr	>24 hr
1.5×10^{-2}	85.0 min	—	—

[Cu^{2+}] $1.5 \times 10^{-5}M$, shaking time 300 sec.

Kinetic stability of extract

The kinetic stability of the chelate extracted from 4*M* hydrochloric acid into IBMK was studied as a function of reagent concentration, with various treatments of the extract, *viz.* with or without washing with water, and filtration of the organic phase through a dry filter paper after the extraction. The stability was determined by measuring the change of absorbance at 435 nm with time, the samples being kept in the spectrophotometer throughout. The timing was started when the reagent was added to the aqueous phase.

The variation of absorbance with time, when the extract is not washed with water, is shown in Fig. 3. Characteristically the absorbance is constant for a certain time, and then suddenly drops. Table 2 gives the time ($t_{1/2}$) needed for the absorbance of the extract

to decrease to half its original value, under various conditions; $t_{1/2}$ was found to depend on the concentration of the reagent added and on the treatment of the extract. Like washing,[3] filtration stabilizes the extract. When $1.5 \times 10^{-3}M$ APCD (100-fold ratio to copper) was used, the extract exhibited excellent stability (Table 2).

It is considered that decomposition of the extract is suppressed by removal of the free acid remaining in the separated IBMK, by means of washing or filtration (the separated IBMK phase tends to be turbid, containing fine droplets of the aqueous phase).

When the copper(II)–APCD chelate is extracted from strongly acidic solution, the kinetic stability of the chelate is a most important factor, and several of the conditions to be used should be selected according to their influence on the stability. The following conditions are recommended for extraction of the copper chelate from 0.01–4*M* hydrochloric acid: a large excess of reagent (>100-fold molar ratio to copper), 180–300 sec shaking time, rapid phase separation, and washing of the organic phase with water.

The kinetic stability of the copper chelate in IBMK after extraction from a strongly acidic aqueous phase is highly dependent on the concentration of APCD added, so a direct comparison of results reported by various authors is useless unless the concentrations of chelating agent and copper used are the same for the methods compared.

BORATE–POLYOL COMPLEXES IN AQUEOUS SOLUTION

DETERMINATION OF ENTHALPIES BY THERMOMETRIC TITRIMETRY

ROBERTO ARUGA
Institute of Analytical Chemistry, University of Turin, via Giuria 5, 10125 Turin, Italy

(*Received* 19 *December* 1984. *Accepted* 5 *February* 1985)

Summary—Enthalpies for the reaction of borate with 1,2-ethanediol, 1,2-propanediol, 1,2,3-propanetriol and D-mannitol have been determined by thermometric titrimetry. From these enthalpies and equilibrium constants taken from the literature, corresponding entropies have been calculated. The data refer to aqueous solutions at 25° and $I = 1.0M$ ($NaNO_3$). The results indicate reasons for the differences in the stabilities of the complexes.

The remarkable complex-forming ability of the borate ion with polyhydroxy compounds (polyols) in aqueous solution is well known. Biot,[1] as early as 1842, reported that a solution of boric acid became acid to litmus upon addition of sugars. Thomson[2] found that boric acid could be determined by titration in the presence of various polyhydroxy compounds, with phenolphthalein as indicator. More recently, these reactions have been shown to be not only of analytical but also of biological interest, as several compounds of biological importance, such as vitamins and coenzymes, can react with borate in the same manner.

The stoichiometry and stability of these complexes have been studied by various workers,[3–7] but values for the enthalpies and entropies of formation are both scarce and inconsistent. In fact only one calorimetric enthalpy value is available, which refers to the borate complex with mannitol.[7] It must be noted, in this connection, that there is serious disagreement between the -18.62 kJ/mole for the first step of reaction with mannitol, obtained by calorimetry, and the -33.68 kJ/mole obtained from values of the equilibrium constant at different temperatures.[5] The two methods give such inconsistent values for the entropy that these differ even in sign: $\Delta S_2^\circ = -27.2$ J . mole^{-1} . K^{-1} (ref. 7) and $+36.0$ J . mole^{-1} . K^{-1} (ref. 5).

Taking into account these observations, and also considering the value of thermodynamic quantities in elucidating the structures of the complexes formed, it was thought of interest in the present work to determine by thermometric titrimetry the enthalpies, and hence entropies, of the reaction of borate with 1,2-ethanediol (ethylene glycol), 1,2-propanediol (1,2-propylene glycol), 1,2,3-propanetriol (glycerol) and D-mannitol.

EXPERIMENTAL

Reagents

Analytical grade reagents were always used (Erba RPE), *viz.* boric acid (>99.8% pure); ethylene glycol and 1,2-propylene glycol (>99.5%); glycerol and D-mannitol (>99%). All solutions were prepared immediately before use. The background electrolyte was sodium nitrate.

Equipment

Calorimetric measurements were made at 25° with an LKB 8700-2 Precision Calorimetry System and an LKB 8726-1 100-ml titration vessel, provided with a standard resistor (50 Ω) and a thermistor (2000 Ω). The accuracy of the instrument was checked by measuring the molar enthalpy change of the reaction between tris(hydroxymethyl)methylamine and hydrochloric acid in aqueous solution. Fuller details of the instrument calibration have been reported.[8] The temperature of the titrant was kept at that of the calorimeter by immersing (for at least 12 hr before the measurement) the Teflon titrant reservoir in the thermostatic bath containing the calorimetric cell. The calorimeter was also equipped with a Radiometer ABU 12b autoburette for the addition of titrant. The calorimetric experiments were performed in a room kept at a temperature constant within ±0.3%.

Procedure

At least three series of measurements were made for each polyol–borate system, each series being performed in the following manner. Successive portions of 2.507 ± 0.002 ml of sodium borate solution were added to 88.00 ml of polyol solution in the calorimetric cell, and the heat liberated on each addition was measured (for the borate and polyol concentrations, see Table 1). The pH of all solutions was brought to 11.0 ± 0.2 by addition of sodium hydroxide before each measurement, and the ionic strength adjusted to $1.0M$ by addition of sodium nitrate. The corresponding heat of dilution was measured by adding the same amounts of the sodium borate solution to 88.00 ml of $1.0M$ sodium nitrate at pH 11.0, without any polyol. From these experiments the following conclusions can be drawn. (*a*) There is negligible association between the $B(OH)_4^-$ ion (which is the reacting species) and the proton, since the pK_a of boric acid is so high (8.69 at $I = 1.0M$).[9] (*b*) There is negligible dissociation of the polyols, since the pK_a values are all above 14.[10] (*c*) Complex species containing more than two molecules of polyol per borate ion are not present: their absence has been demonstrated[6] for polyol:borate ratios up to 200:1. (*d*) The contribution to the measured enthalpies from dissociation of polyborate species was negligible: since the borate concentration was lower than $0.025M$ at the end of the mixing process, it must have reacted[5] in the monomeric form and,

moreover, the heat of dissociation of any polyborates which may be present in the initial solution is counterbalanced by an equal heat effect during the dilution experiment, so that it is eliminated in the calculation of the corrected heat (see below). (*e*) Thermal effects from the neutralization reaction between H^+ and OH^- and for changes in the optical rotatory properties of certain polyols in the presence of borate are negligible; in particular the latter process is extremely slow if compared with the time required for a calorimetric measurement.[7,11,12]

Treatment of the experimental data

Some experimental data are collected, as an example, in Table 1: the initial concentration of polyol in the calorimetric vessel (C_L); the cumulative volume of titrant added to the calorimetric vessel (ΣV_T); the concentrations of the complex species and of free polyol ($[BL^-]$, $[BL_2^-]$, [L]) after each addition of titrant; the mean cumulative heat, corrected for dilution (ΣQ_c).

Molar enthalpies of association were determined from the experimental heats (ΣQ_c) and the concentrations of the complex species: the latter were calculated from values of the corresponding stability constants determined potentiometrically by Paàl[6] (see Table 2) under the conditions of temperature and ionic strength used in the present work. No contraction in volume was found (in the limits of the instrumentation used) on mixing the reagents. The ΔH° values, with the corresponding standard deviations, were calculated by two different methods: (*a*) the numerical method of minimizing the sum of the squares of the deviations for each measurement;[13] (*b*) a graphical method derived from the equations of Leden and Fronaeus.[14] These two methods gave results in good accordance. In order to check the enthalpy values, the experimental heats were recalculated by using the ΔH° values obtained. Entropy values were calculated by means of the equation $\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ$.

RESULTS AND DISCUSSION

The molar thermodynamic quantities for the first two steps of complex formation of borate with polyols are collected in Table 2. For ethylene glycol, values for only the first step are listed. In this case, in spite of the excess of polyol, the concentration of the BL_2^- species was too low to give reliable ΔH° values for the second step.

The present enthalpy and entropy values are in only partial agreement with those reported previously.[5] For mannitol, the entropies are in complete disagreement: -54 and $+36$ J.mole^{-1} K^{-1} in the cited paper,[5] and -7.9 and -50 from the present work, for the first and second steps, respectively. In any case, poor agreement between calorimetric values and those obtained from variation of an equilibrium constant with temperature[5] is fairly frequent. In general, calorimetric values are considered more reliable.[15] However, the present enthalpy data for mannitol are in fairly good accordance with those

obtained by Evans *et al.* calorimetrically:[7] -18.62 ± 0.25 and -19.9 ± 0.5 kJ/mole for ΔH_1° and ΔH_2° respectively, in comparison with -19.75 ± 0.25 and -23.4 ± 0.5 (Table 2). It is interesting to note that the standard deviations indicate that the data obtained by the two different calorimetric methods (*i.e.*, thermometric titrimetry in the present case, and continuous flow calorimetry[7]), have similar reproducibilities.

Examination of the results in Table 2 for the first step of reaction shows that the ΔG_1° values, in both sign and relative magnitude, are determined by ΔH_1°. The ΔS_1° values, on the other hand, are unfavourable to the complexation process, and are not very different from zero. These facts seem to indicate a greater influence of direct solute–solute interactions rather than external factors on the formation of the 1:1 complexes. In order to verify this conclusion, and for a better interpretation of the enthalpy values, the latter have been divided into electrostatic ($\Delta H_{(el)}$) and non-electrostatic ($\Delta H_{(non)}$) parts, following the calculation method proposed previously.[16,17] The electrostatic contribution to the enthalpy is a measure of long-range electrostatic interactions, depending on the dielectric constant of the medium; the non-electrostatic part is a measure of covalent, short-range interactions. The values obtained for $\Delta H_{(non)}$ and $\Delta H_{(el)}$ are listed in Table 2. They confirm that electrostatic contributions are almost non-existent, and that the direct covalent borate–polyol interactions are the controlling factors affecting ΔH°, and consequently ΔG°. Moreover, ΔH_1° and $\Delta H_{1(non)}$ become more favourable from ethylene glycol to mannitol; this seems to indicate the presence of progressively stronger solute–solute bonds. In fact, in propylene glycol, besides the two hydroxy-groups of ethylene glycol, a methyl group is present, which enhances the bond-forming properties with borate by inductive effects. In glycerol a third hydroxy-group is present, which can form hydrogen bonds with borate. Finally, the possible formation of a third C—O—B bond has been suggested for mannitol.[6]

The thermodynamic parameters for the second reaction step are remarkably different from those of the first step. ΔH_2° (again mainly due to $\Delta H_{(non)}$) is more favourable than ΔH_1°; ΔS_2°, on the other hand, is strongly negative. These values confirm, at least partially, the hypothesis of Paàl,[6] who suggested a much lower degree of hydration of borate in the 1:1 glycol–borate complex than in the uncomplexed form. Consequently, fewer borate–solvent bond ruptures would take place when the second molecule of polyol enters the complex. More particularly, the smallest difference between $\log K_1$ and $\log K_2$ is found for propylene glycol, together with the greatest difference between ΔH_1° and ΔH_2° and between ΔS_1° and ΔS_2°. This seems to confirm the hypothesis that the greatest desolvation of borate is caused by the methyl group of propylene glycol, as a consequence of its strong shielding properties.[6] In contrast, the greatest difference between $\log K_1$ and $\log K_2$ is found for mannitol, for which ΔH_2° is also the most unfavourable and very similar to ΔH_1°. This is in accordance with a possible formation, by the first polyol molecule, of a third C—O—B bond, which would hinder the binding with the second molecule of mannitol. It must be noted, in this connection, that in the previously mentioned calorimetric work on mannitol–borate complexation[7] the constancy of the corresponding ΔH_1° and ΔH_2° values was discussed. This constancy was justified by means of the general hypothesis of Poulsen and Bjerrum, according to which, for reactions with electrically neutral ligands, heats of successive steps will be approximately constant, variation in stability being mainly determined by the entropy changes. The data in Table 2, on the contrary, indicate that constancy of the ΔH° values for mannitol is peculiar to this compound and is not typical of the enthalpy data for the other polyols.

DETERMINATION OF BERYLLIUM IN Pt–Be ALLOY BY ATOMIC-ABSORPTION SPECTROMETRY AFTER ION-EXCHANGE SEPARATION

KRYSTYNA BRAJTER and KRZYSZTOF KLEJNY
Department of Chemistry, University of Warsaw, 02093 Warsaw, Poland

(*Received* 17 *January* 1984. *Revised* 21 *January* 1985. *Accepted* 9 *February* 1985)

Summary—Traces of beryllium in platinum have been determined by graphite-furnace atomic-absorption spectrometry, the graphite furnace being coated with lanthanum or titanium carbide. The coating improves the reproducibility, sensitivity and detection limit. Platinum interferes in the beryllium determination, and an ion-exchange separation is used in the determination of beryllium in Pt–Be alloy.

The determination of beryllium by atomic-absorption spectrometry (AAS) is difficult, whether flame or electrothermal atomization is used.[1–11] There are numerous interferences in the flame atomization methods, even when the high-temperature reducing nitrous oxide–acetylene flame is used,[4] and because of the formation of beryllium carbide the graphite furnace gives rather poor reproducibility and sensitivity.[7–11] According to the literature,[7,8,10,11] however, the reproducibility, sensitivity and determination limit may be considerably improved by coating the graphite furnace with a carbide or with pyrolytic graphite.

When we were asked to determine beryllium in Pt–Be alloy we decided to use AAS with electrothermal atomization (ETA) in graphite tubes coated with lanthanum or titanium carbide. We found there was spectral interference from platinum, and that the deuterium background corrector could not compensate for the high background absorption due to the platinum, so to avoid this matrix effect, we used ion-exchange to separate the beryllium.

EXPERIMENTAL

Instrumentation

Perkin-Elmer models 300 and 403 atomic-absorption spectrophotometers, equipped with the HGA model 72 and 74 graphite-furnace atomizers respectively, and a Beckman model 1272D atomic-absorption spectrophotometer equipped with a Unilam 1288 burner and a Pye-Unicam GRM 1268 graphite-furnace atomizer were used. The operating conditions are given in Tables 1 and 2. The Beckman instrument was also used for flame AAS determination of beryllium (wavelength 234 mm, band-pass 0.14 nm, lamp current 12 mA).

Carbide coating. A lanthanum chloride solution (La 1 mg/ml, 100 μl) or titanium sulphate solution (Ti 1 mg/ml, 200 μl) was injected into the tube and a heating programme was applied. The procedure was repeated two or three times, depending on the apparatus, for the lanthanum coating, and twice for titanium. For lanthanum the programme was heating at 100° for 100 sec, at 1100° for 30 sec and at maximum temperature for 10 sec. For titanium, the heating sequence was 100° for 120 sec, 1650° for 180 sec, 2850° for 20 sec.

Reagents

Standard beryllium solution. Beryllium (spectral grade, 0.5086 g) was dissolved in 2*M* hydrochloric acid and the solution was diluted to 250 ml. This solution was further diluted as required.

Standard platinum solution. Prepared by diluting a solution of H_2PtCl_6, standardized gravimetrically by precipitation of the ammonium salt.

Ion-exchange columns

The columns were made in tubes 25 cm long, 8 or 5 mm in bore, with a stopcock at the end. They were packed with Dowex 50W × 8, 20–50 mesh, sodium form.

Ion-exchange separation of platinum from beryllium

Static studies. Dowex 50W × 8 (sodium form, 400 mg) was mixed with 20 ml of beryllium solution containing 326 μg of Be(II) and the pH was adjusted with sodium hydroxide solution. The mixture was shaken for 8 hr, then the concentration of beryllium was measured by graphite-furnace AAS. The results are given in Table 3.

Column studies. To establish optimum conditions for the column separation of beryllium from platinum, an investigation was made of the effects of the amount of resin used. Recovery of 8 μg of Be was 99.2, 100.0, 99.9 and 93.5% complete, with use of 200, 400, 800 and 1200 mg of resin respectively. The efficiency of hydrochloric, nitric and citric acids as eluents was investigated, and 4–6*M* hydrochloric acid was chosen as the most efficient.

Procedure

A 5-ml portion of solution containing 2.5×10^{-4} mg of Be(II) and 7.14 mg of Pt(IV), adjusted to pH 3.5, was introduced into the Dowex column (bed height 3.5 cm, 400 mg of resin) and the platinum (as $PtCl_6^{2-}$) was washed through with 25 ml of water and collected in a 50-ml standard flask. The beryllium was eluted with 25 ml of 6*M* hydrochloric acid, into a 50-ml standard flask. Both eluates were diluted to the mark with water, and analysed by AAS according to the conditions given in Table 1. Blanks were run and appropriate corrections applied. The concentrations of Pt(IV) and Be(II) were obtained from calibration graphs.

Analysis of Pt–Be alloy. The alloy sample (0.741 g) was dissolved by heating with 20 ml of *aqua regia*. The solution was evaporated to dryness, a few ml of concentrated hydrochloric acid were added, and the evaporation was repeated, almost to dryness; this was repeated twice. The residue was dissolved in dilute hydrochloric acid and the solution was transferred into a 100-ml standard flask, and made up to volume. A 5-ml aliquot was adjusted to pH 3.5 and introduced into the Dowex column (sodium form).

Platinum was removed from the column by washing with 25 ml of water. Beryllium was eluted with 25 ml of 6*M* hydrochloric acid, the eluate being collected in a 50-ml standard flask and diluted to volume. The flow-rate was 0.5 ml/min. Beryllium was determined by AAS according to the conditions given in Table 1, by use of the graphite furnace coated with titanium carbide; the results were corrected for the blank.

RESULTS AND DISCUSSION

As shown in Fig. 1 the calibration graphs are linear only over a certain concentration range, and above a certain beryllium concentration there appears to be a memory effect when the lanthanum coating is used, but not with the titanium coating. The memory effect is due to incomplete volatilization of Be in the firing, as shown by an absorption peak appearing during the cleaning step. The titanium carbide coating enhanced the absorbance from 0.1 to 0.25 for 0.2 ng of beryllium when the Pye-Unicam GRM 1268 furnace was used. Use of more than 400 µg of titanium for the coating gave slightly lower results.

A char temperature of 1200° applied for 30 sec was chosen for use with the Perkin-Elmer spectrometers and 1100° for 30 sec for the Beckman instrument (Fig. 2). Lower[8] and higher[12] temperatures have been recommended in the literature.

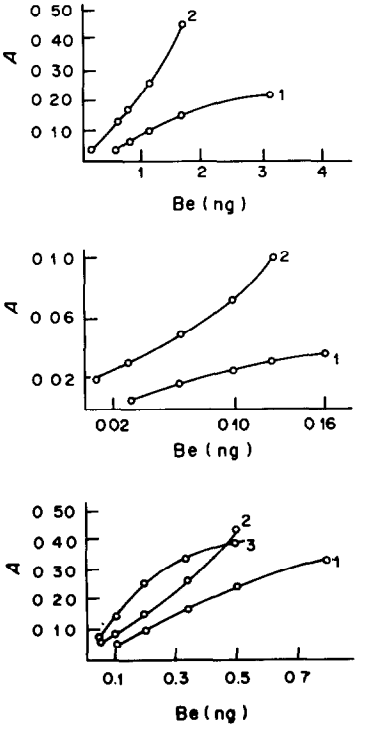

Fig. 1. Beryllium calibration graphs, with furnace (1) untreated, (2) coated with lanthanum carbide, (3) coated with titanium carbide; (a) HGA 72, 300 µg of La; (b) HGA 74, 200 µg of La; (c) Beckman spectrometer and GRM 1268, 300 µg of La or 400 µg of Ti.

With the Perkin-Elmer spectrometers the maximum attainable temperature was used as the atomization temperature, in agreement with the literature recommendations, but with the Beckman spectrometer an atomization temperature of 2750° (which is below the maximum) was chosen, since it gave a more linear calibration curve with the titanium coating (Fig. 3).

The conditions used for platinum determination were those established earlier.[12] Platinum was found to have a marked effect on the beryllium signal (Fig. 4), and this could not be eliminated by use of the deuterium-lamp background-compensator. It therefore seemed necessary to separate the traces of beryllium to avoid interference from the platinum matrix, and ion-exchange was chosen for the purpose.

The retention of beryllium on Dowex 50W × 8 was found to be maximal at pH ~ 3–4 (Table 3). The beryllium could be eluted from the column with 4–6*M* hydrochloric acid. Other eluents were also investigated; nitric acid interferes in the beryllium determination by AAS, and citric acid appears to be less efficient than hydrochloric.

To shorten the analysis time the conditions for column separation were investigated (as described above). As a result, a very short resin bed (3.5 cm long, 400 mg of resin) was used. The optimum flow-rate appears to be 0.5 ml/min. At higher flow-rates 25 ml of 4–6*M* hydrochloric acid will not be enough to elute the beryllium quantitatively. The optimum conditions for retention and elution of beryllium were adopted for the separation of platinum and beryllium and found to give good results (Table 4). The method was applied to the Be–Pt alloy which was the reason for the investigation and gave 0.0018 ± 0.00015% (mean and 95% confidence limits) for four AAS measurements in each of six separate determinations.

Our investigation confirmed that the sensitivity, reproducibility and detection limit of the beryllium

*Each result is the mean and range (95% confidence limits) of four determinations.

For the first group of experiments 20 ml of test solution were passed through 2.0 g of resin and the column was washed with 50 ml of water to elute Pt. The Pt eluate was diluted to 250 ml for analysis. Be was eluted with 25 ml of 4*M* HCl and the eluate diluted to 50 ml for analysis. For the second group, 5 ml of test solution was passed through 400 mg of resin, and the Pt was eluted with water (total volume of eluate 50 ml; subsequently diluted for analysis). Be was eluted with 25 ml of 6*M* HCl and the eluate diluted to 50 ml for analysis.

†±20.

determination are improved if the graphite furnace is provided with a carbide coating, but also showed that these quantities depend on the apparatus used (Table 5). The improvement seems to be greater with the titanium coating.

For comparison, flame AAS with a reducing nitrous oxide–acetylene flame was used (conditions in Table 2), but as expected, it gave higher detection limits and poorer sensitivity than the flameless AAS (Table 5).

Our results were similar to[10] or better than[13] those in the literature.

It seems that the optimum amount of carbide coating depends on the size of the furnace. The HGA 74 is smaller than the others.

FURTHER DEVELOPMENTS IN THE HIGH-PRECISION COULOMETRIC TITRATION OF URANIUM

TATSUHIKO TANAKA,* GEORGE MARINENKO† and WILLIAM F. KOCH
Center for Analytical Chemistry, National Bureau of Standards, Washington, D.C. 20234, U.S.A.

(*Received* 2 *August* 1984. *Revised* 16 *January* 1985. *Accepted* 8 *February* 1985)

Summary—An experimental study of the current efficiency in the coulometric generation of Ti(III), as a function of electrolyte composition, current density and electrode material, has been performed. The cathodes investigated include platinum, mercury and graphite. The first two are suitable for high-precision determination of uranium. The graphite surface is readily poisoned, rendering it useless for high-accuracy work. The use of mercury requires thorough removal of chloride from the system. The precision and error obtained are comparable for both the mercury and platinum cathodes, and are of the order of 50 ppm.

In aqueous solutions titanium(III) is a powerful reductant, and was first introduced as a coulometric titrant by Arthur and Donahue.[1] $E°$ for the Ti(IV)–Ti(III) couple, +0.1 V, is very nearly equal to that of hydrogen. Hence, in any coulometric experiment there is a possibility of co-reduction of hydrogen ion along with Ti(IV), resulting in a significant loss of current efficiency. A high current efficiency for the electrogeneration of titanium(III) can easily be obtained if mercury, which has a high hydrogen overpotential, is used as the cathode, and the hydrogen-ion concentration in the supporting electrolyte is low.

For these reasons, Lingane and Iwamoto[2] coulometrically titrated uranium(VI) with titanium(III) electro-generated at a mercury-pool cathode in 0.2–1*M* citrate medium, containing 0.08*M* titanium tetrachloride, at pH 0.5–1.5 and 85°. The elevated temperature was required to increase the rate of reduction of U(V) with Ti(III), because at room temperature (25°) the rate is impracticably low. Later, Kennedy and Lingane successfully determined uranium(VI) by using a platinum cathode, which is more convenient to use than a mercury cathode. In their work, a medium of 6–9*M* sulphuric acid and 0.6*M* titanium(IV) was used as the supporting electrolyte. Under these conditions, titanium(III) can be generated with 100% efficiency for current densities as high as 3 mA/cm^2, but at elevated temperatures the efficiency decreases.[3] Kennedy and Lingane also found that iron(II) catalyses the reduction very effectively, eliminating the need for elevated temperatures.[3]

Takeuchi *et al.*[4] determined uranium(VI) in uranium(IV) oxide by use of Kennedy and Lingane's method. Marinenko *et al.*[5] improved the method and applied it to the analysis of Standard Reference Material (SRM) 960 Uranium Metal, issued by the National Bureau of Standards (NBS).

The generation of titanium(III) in a sulphuric acid medium, at a platinum cathode, is known to be less than 100% efficient.[5,6] Bishop and Hitchcock[7] investigated the electrode processes occurring at the platinum cathode during the reduction of titanium(IV) and found that trace impurities in the sulphuric acid can cause electrode poisoning, and emphasized the need not only to activate or condition the electrode, but also to purify the sulphuric acid. With 0.6*M* titanium(IV) sulphate/7*M* sulphuric acid purified by electrosorption, the loss of current efficiency is only 1 ppm at a current density of 59.2 mA/cm^2. However, according to Bishop and Hitchcock[7] it is difficult to purify sulphuric acid, and furthermore, after purification, the acid is soon recontaminated even when it is kept in an all-glass apparatus.

As mentioned above, the current efficiency for generation of titanium(III) has been extensively studied for the platinum cathode but not for other cathodes. Hence, systematic study of the efficiency of coulometric generation of titanium(III) at platinum, mercury and graphite electrodes was undertaken.

Coulometric generation efficiency for titanium(III)

The Ti(IV)–Ti(III) couple is reversible in 1–15*M* phosphoric acid,[8] but the Ti(IV) concentration cannot exceed 0.01*M* because of solution instability. Such a low concentration of Ti(IV) makes the system unusable for the coulometric generation of Ti(III) titrant. The titanium couple is also reversible in $\geq 4M$ sulphuric acid,[8] which is a preferred supporting electrolyte in cathodic titrations. Hydrochloric acid has also been employed as the medium for the generation of titanium(III), but the titanium couple is less reversible than in the same concentration of sulphuric acid.[8] Furthermore, both uranium(VI) and titanium(IV) are reduced by mercury in hydrochloric

acid.[9] In perchloric acid the titanium couple is irreversible[8] because titanium(III) immediately reduces perchlorate to chloride. Consequently, of all the common acids considered, only sulphuric acid is suitable for the investigation.

The coulometric titration cell used throughout this work has already been described in detail.[5,10,11] Platinum gauze, high-purity mercury and spectrographic grade graphite rod were employed as the cathode materials. The areas of these electrodes were 80, 12 and 1.5 cm^2, respectively. The graphite rod was polished with fine carborundum paper and then rubbed with filter paper before each use. The anode was a piece of platinum gauze. The potential of the cathode was measured with respect to a saturated calomel electrode (SCE). All the work was done with 100 ml of electrolyte solution, containing 100 mg of ferrous ammonium sulphate hexahydrate as catalyst for the uranium(VI) titration, and stirred at constant rate with a Teflon-coated magnetic bar. The electrode potentials for the three types of cathode in different electrolytes, at three levels of current density (10^{-4}, 10^{-1} and 10 mA/cm^2), are listed in Table 1.

The current density *vs.* working electrode potential diagrams obtained are shown in Figs. 1–3, and the current efficiency for the generation of Ti(III) from Ti(IV) can be readily estimated from them.

The current due to the reduction of other species in the supporting electrolyte (*e.g.*, of protons) is subtracted from the total current to compute the current efficiency. For example, consider the curves a and b in Fig. 2. At a current density of 20 mA/cm^2 the potential of the graphite cathode in 9*M* sulphuric acid/1*M* titanium(IV) is −0.05 V *vs.* SCE (point × on curve b). At the same potential the corresponding current density in the absence of titanium(IV) is 3×10^{-3} mA/cm^2 (point x' on curve a). Then

$$\text{current efficiency} = \frac{(20\ \text{mA/cm}^2) - (3.0 \times 10^{-3}\ \text{mA/cm}^2)}{20\ \text{mA/cm}^2} \times 100$$

$$= 99.985\%$$

Current efficiencies calculated for different electrodes, different current densities and various electrolyte compositions are summarized in Table 2.

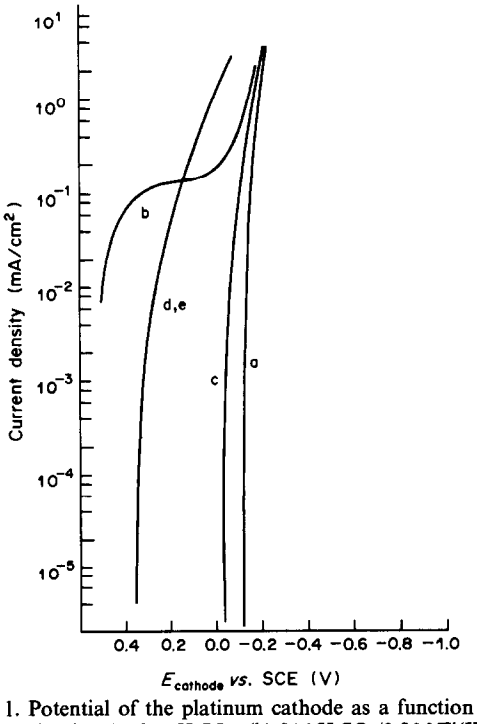

Fig. 1. Potential of the platinum cathode as a function of current density: (a) 2*M* H_2SO_4; (b) 2*M* H_2SO_4/0.2*M* Ti(IV); (c) 9*M* H_2SO_4; (d) 9*M* H_2SO_4/0.5*M* Ti(IV); (e) 9*M* H_2SO_4/1.0*M* Ti(IV).

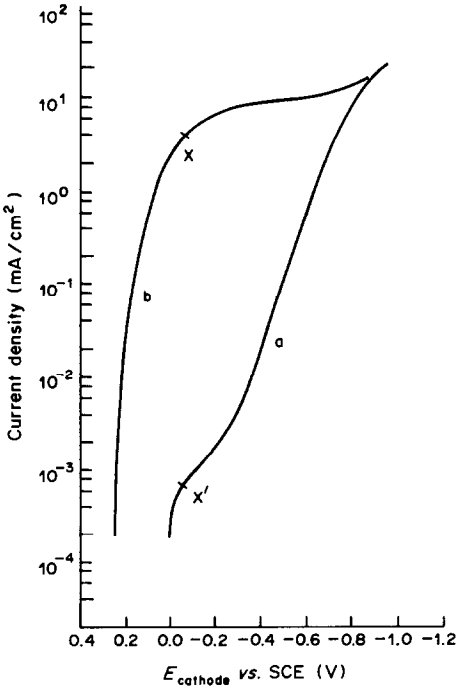

Fig. 2. Potential of the graphite cathode as a function of current density: (a) 9*M* H_2SO_4; (b) 9*M* H_2SO_4/1.0*M* Ti(IV).

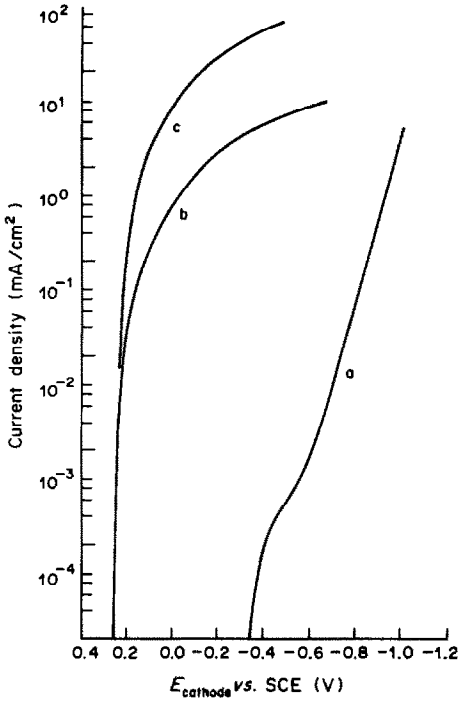

Fig. 3. Potential of the mercury cathode as a function of current density: (a) 2*M* or 9*M* H_2SO_4; (b) 2*M* H_2SO_4/0.2*M* Ti(IV); (c) 9*M* H_2SO_4/0.5*M* Ti(IV).

It is of interest to consider the potential of each of the cathodes investigated, at various current densities, for reactions in 9*M* sulphuric acid in the presence and absence of titanium(IV) (1*M*). In the latter case the primary potential-determining reaction is the reduction of protons to hydrogen gas (potential *E'*), and in the former it is the reduction of titanium(IV) (potential E''). A summary of the current-density/potential data is given in Table 1, and indicates that, between current densities of 10^{-4} and 10 mA/cm², $\Delta E = (E'' - E')$ increases dramatically for Hg and graphite cathodes (by 0.45 V). For platinum, under the same conditions, ΔE decreases by 0.27 V. The reason is evident from the values of *E'*. On both the mercury and graphite cathodes, the hydrogen overvoltage increases very markedly as a function of current density (0.55 V on mercury and 0.70 V on graphite), whereas on the platinum cathode the overvoltage increases by only 0.08 V over the same current-density range. The increase in overvoltage for the reduction of titanium(IV) on all three cathodes is comparable: 0.10 V for mercury, 0.25 V for graphite and 0.35 V for platinum over the 10^{-4}–10 mA/cm² current-density range. On the basis of only these data, mercury is the preferred cathode for 100% efficient generation of Ti(III) from titanium(IV) sulphate electrolyte, followed by graphite and platinum in order of decreasing efficiency. However, other considerations make platinum at least as attractive as the other two materials. As noted earlier, use of the mercury cathode results in significant titration errors when halides are present in the electrolyte. The addition of uranium(VI) chloride causes spontaneous oxidation of mercury to form mercurous chloride, in a reaction which is not reversible under these experimental conditions, so results for U(VI) are low. The graphite electrode used in our experiments became "poisoned" after a 30-min electrolysis and gave copious liberation of hydrogen with a concurrent loss of current efficiency. Thus, graphite was abandoned as cathode material for generation of Ti(III). For 1*M* titanium(IV) sulphate in 9*M* sulphuric acid the results obtained with the platinum cathode agree with those of Kennedy and Lingane.[3]

Kinetics of uranium reduction

It was found earlier by Kennedy and Lingane[3] that the slow reaction between U(VI) and Ti(III) at room temperature can be accelerated by the addition of small amounts of iron(II), but even then the reaction is quite slow as long as U(VI) is in excess. Only when excess of Ti(III) is present does the reaction proceed rapidly to completion.

This point is illustrated in Fig. 4 by three indicator-current curves measured in the equivalence-point region of the uranium titration. For each curve, 10 μeq of Ti(III) were coulometrically generated in the electrolyte [9*M* sulphuric acid/1*M* titanium(IV) sulphate containing 1 mg of ferrous ammonium sulphate hexahydrate per ml]. Curve 1 corresponds to

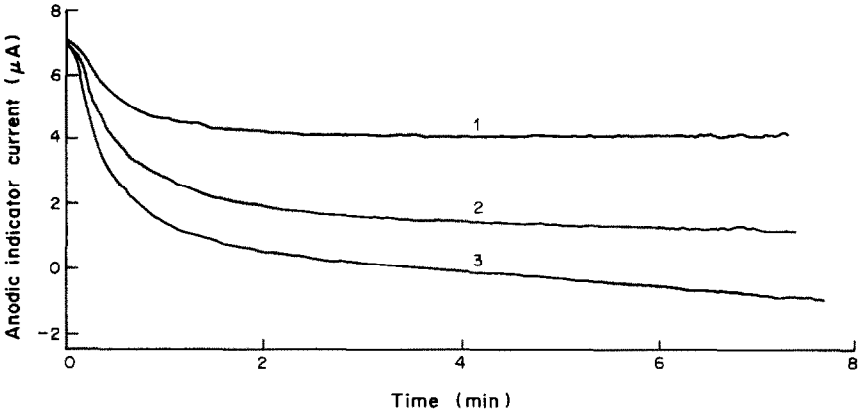

Fig. 4. Amperometric indicator current due to Ti(III), as a function of time. Electrolyte composition: 9*M* H_2SO_4/1*M* Ti(IV)/1-mg/ml $Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$, (1) 10 μeq Ti(III) + 5 μeq U(VI); (2) 10 μeq Ti(III) + 10 μeq U(VI); (3) 10 μeq Ti(III) + 15 μeq U(VI).

the region after the equivalence point. This curve was obtained by adding 5 μeq of U(VI) to the 10 μeq of Ti(III) generated. It can be seen that equilibrium is reached quite rapidly. The initial exponential decay of the indicator current reaches a constant value after $2\frac{1}{2}$ min. At the equivalence point (curve 2), the rate of reaction is significantly lower when 10 μeq of U(VI) are added to the generated 10 μeq of Ti(III), equilibrium being reached 7 min after addition of the U(VI) aliquot. Before the equivalence point (curve 3), the reaction rate when 15 μeq of U(VI) are added to the generated 10 μeq of Ti(III) is impracticably slow.

It is clear that, for stoichiometric reaction measurements, the system must be overtitrated to allow equilibration to take place at a reasonable rate and then the excess of titrant must be determined. On the basis of these studies the following experiments on the coulometric assay of uranium were performed.

EXPERIMENTAL

Coulometric assay of uranium metal

The instrumentation for coulometric generation of the titrant was similar to that described previously.[5,10,11] The electrolysis cell was also of the type described earlier,[5,10,11] with a few modifications. A silicic acid plug was cast in the bottom of the anode chamber to cover the glass frit. The remainder of the chamber was filled with 2*M* sulphuric acid and a glass tube with its bottom closed by a glass frit and a silicic acid plug, and filled with 2*M* sulphuric acid. The platinum anode and the SCE were immersed in the tube.

The end-point of the titration was determined amperometrically with a platinum foil indicator electrode (area approximately 1.2 cm^2) immersed in the cathode chamber. A polarograph was used to apply a constant potential between the indicator electrode and the SCE, and to record the indicator current. Argon, purified by passage through chromium(II) chloride and then 9*M* sulphuric acid, was used to purge oxygen from the cell and the electrolyte. The Faraday constant was taken as 96486.5 C/equivalent and the atomic weight of uranium as 238.0289.

Analytical-grade chemicals were used without further purification. Titanium(IV) sulphate solution was prepared by slowly adding 50% titanium tetrachloride solution to concentrated sulphuric acid, and removing all the hydrochloric acid by purging the solution overnight with argon. The final concentrations in the stock solution were 1*M* titanium(IV) and 9*M* sulphuric acid.

Uranium sample solution was prepared from uranium metal (NBS SRM 960) cut into approximately 1-g pieces. Immediately before the sample was weighed, the surface oxide was removed[12] by dipping the pieces in warm nitric acid (1 + 1) for 10 min, rinsing with distilled water, etching in hydrochloric acid (1 + 3) for 5 min, rinsing with distilled water again, immersing in acetone, air-drying for a few minutes, then placing them in a vacuum desiccator. The sample was weighed to the nearest microgram before any significant amount of surface oxide could form (*i.e.*, within 30 min), and the weight was corrected for air buoyancy. The sample was then dissolved in hydrochloric acid (1 + 1) in an inclined 125-ml Erlenmeyer flask (10 ml of acid per g of sample). After dissolution was complete, 0.5–1 ml of 30% hydrogen peroxide was added slowly to ensure that all uranium was in the hexavalent state and to dissolve any traces of black residue (ostensibly U_3O_8). The solution was then evaporated nearly to dryness under infrared lamps, the residue was taken up with water and the evaporation was repeated, to destroy the excess of hydrogen peroxide. Five ml of concentrated sulphuric acid were then pipetted slowly down the wall of the flask and the solution was evaporated till fuming. Finally the solution was diluted to about 15 ml with distilled water and then titrated. Reagent blank samples were prepared by the same procedure.

Titration procedure

The procedure was similar to that developed for the assay of NBS SRM 960 Uranium Metal by Marinenko *et al.*[5]

About 75 ml of titanium(IV) sulphate catholyte and 100 mg of ferrous ammonium sulphate hexahydrate were placed in the cathode chamber of the cell. Argon, purified from traces of oxygen by passage through chromous chloride solution, was passed through the contents of the cell for about 30 min, the solution being vigorously stirred with the magnetic stirrer. After purging, the catholyte was permitted to flow into the intermediate compartments of the coulometric cell until it just covered the bottom of each compartment. A current–voltage curve was run before each titration to determine the optimum potential for the indicator system.

For pretitration, *ca.* 10 μeq of uranium(VI) were added to the cathode chamber and titrated at 3.22 mA by passage of small increments of charge, each corresponding to 1 μeq. After a slight excess of titanium(III) had been generated, as evidenced by the indicator-current increase, the solution was allowed to equilibrate for 30 min. Additional amounts of titanium(III) were then generated and the indicator current

was measured after each charge increment. The linear portion of the indicator-current curve was extrapolated graphically, and its intersection with the zero-current line taken as the end-point.

After the pretitration, the intermediate cell compartments were rinsed by repeated emptying and filling with catholyte, by suction or argon pressure. The final reading of the indicator current was used to establish the amount of overtitration.

Next the intermediate compartments were filled with catholyte and the sample was transferred from the Erlenmeyer flask to the cathode chamber. The major part of the titration was then done at a constant current of about 102 mA for a precalculated time corresponding to a few μeq in excess of the theoretical amount. The intermediate compartment and the sample flask were then rinsed three times with the titrated solution, by suction or argon pressure. After equilibration of the solution for 30 min, the end-point was located by the procedure used for the pretitration.

ANALYTICAL RESULTS AND DISCUSSION

In view of the studies of the efficiency of generation of Ti(III) at different types of cathode it was of interest to verify independently the performance of the various cathodes in coulometric titrations. Hence, NBS SRM 960 Uranium Metal was analysed by the procedure of Marinenko *et al.*[5]

As mentioned earlier, work with the graphite cathode was abandoned because hydrogen was liberated and the current efficiency decreased. The results of analyses with the platinum cathode are shown in Table 3. The oxidimetric assay value is 99.981% ($s = 0.0048$). When this value is corrected for the iron and vanadium present, which are titrated along with uranium, the assay becomes 99.970% U, which is in excellent agreement with the certified value of 99.975%. It should be noted here that though the titration procedure was the same in this work as for the certification, the current densities were different (2.5 mA/cm^2 for certification, 1.27 mA/cm^2 in this work). The agreement of the results obtained at current densities differing by a factor of 2 is further evidence of the consistency of the titration process under selected conditions. Both current densities should provide 100% efficient generation of Ti(III) according to the data in Table 1.

Table 3. Coulometric assay of NBS SRM 960 Uranium Metal at a platinum cathode (supporting electrolyte 1*M* titanium(IV) sulphate/9*M* sulphuric acid; current density 1.27 mA/cm^2)

U metal, *mg*		
Taken	Found	Assay, % *w/w*
865.38_4	865.22_2	99.981
1033.58_0	1033.42_0	99.984
1028.65_6	1028.49_1	99.984
1075.75_7	1075.60_7	99.986
990.34_0	990.10_8	99.977

	Average	99.981
	Std. dev.	0.004_8

As a further test of the accuracy of the current efficiencies predicted from the current density/potential diagrams, uranium metal SRM 960 was coulometrically titrated with Ti(III) electrogenerated at the mercury cathode at a current density of 8.3 mA/cm^2. The electrolyte was 0.1*M* titanium(IV) sulphate/9*M* sulphuric acid. At a current density of 8.3 mA/cm^2, the predicted current efficiency is 99.96%. The assay of the uranium metal was 99.999%, which is 0.01% higher than the value obtained under 100% efficient generation conditions with a platinum cathode. The uranium assay expected from the current density data alone should be 100.029%. However, the titration "efficiency" should be higher than the current efficiency because uranium is directly reduced in the initial stages of the titration.

When the Ti(IV) concentration in the electrolyte was increased to 0.5*M*, the uranium assay was 99.987% ($n = 3$, $s = 0.0087\%$). The current-density studies indicate that this electrolyte should provide 100% efficient generation of Ti(III), which is borne out by the uranium assay.

A set of uranium metal samples, ranging in weight from 30 mg to 1.2 g, was analysed with the mercury cathode system with 0.2*M* titanium(IV) sulphate/9*M* sulphuric acid electrolyte. The results are presented in Table 4. The assay value for Uranium SRM 960 obtained with the platinum cathode system (99.981%) is in excellent agreement with the value obtained with the mercury cathode system (99.982%), under experimental conditions which are significantly different with respect to not only the nature of the cathode material but also the electrolyte composition and current density.

A word of caution is in order regarding the use of the mercury cathode for uranium determination. The use of the mercury cathode requires that great care be taken in preparing the supporting electrolyte. The absence of chloride is essential. When the 9*M* sulphuric acid supporting electrolyte contains chloride,

the introduction of uranium(VI) causes the spontaneous oxidation of mercury to form mercurous chloride on the surface of the cathode. In principle this is reversible, *i.e.*, Hg(I) is reduced back to metallic mercury, and should not cause any loss of generation efficiency as far as charge balance is concerned, but in practice complete electrochemical reduction of the calomel is not feasible. Thus, in the presence of chloride, the uranium assay is low.

The values of the reductometric assay of uranium metal reported in Tables 3 and 4 include all impurities which would oxidize Ti(III). In SRM 960 Uranium Metal two principal electroactive impurities are present: 42.1 ppm of iron and 4 ppm of vanadium, which are equivalent to 109 ppm of uranium. Therefore, to establish the uranium assay of SRM 960, a correction of 109 ppm must be applied to the reductometric assay. Thus, the corrected coulometric assay of SRM 960 is 99.970% ($s = 0.0048$) with the platinum cathode and 99.971% ($s = 0.0030$) with the mercury cathode. The two values, for all practical purposes, are identical. This uranium assay is in excellent agreement with the certified value of 99.975%.

ANIONIC INTERFERENCES WITH COPPER ION-SELECTIVE ELECTRODES

CHLORIDE AND BROMIDE INTERFERENCES

A. LEWENSTAM, T. SOKALSKI and A. HULANICKI
Department of Chemistry, University of Warsaw, Warsaw, Poland

(*Received* 14 *June* 1984. *Revised* 10 *January* 1985. *Accepted* 1 *February* 1985)

Summary—The effect of halide ions on copper ion-selective electrodes is connected with complexation and redox reactions, with the formation of amorphous sulphur, which by blocking the surface causes instability of potential response. It may be eliminated by addition of sodium thiosulphate solution. The electrode behaviour has been explained on the basis of the diffusion model. An equation is proposed for linearization of the calibration curve. The parameters of the semiempirical model which describes the electrode behaviour agree well with the physical meaning presented by the diffusion model. The treatment given enables analytical measurements of copper concentration to be made even in the presence of significant concentrations of chloride or bromide.

Copper-selective electrodes with membranes composed of copper(II) sulphide mixed with silver sulphide or of pure copper(I) sulphide show a rapid and Nernstian response (*i.e.*, 29.6 mV/decade at 25°) over a broad range of copper(II) concentration, but applications of these electrodes to real analytical samples often reveal non-Nernstian behaviour.[1] Such effects were observed when the Orion 94-29 electrode was used for measurements of copper concentrations in sea-water[2] or lake water.[3] Such facts have diminished the attraction of copper-selective electrodes as analytical tools, but at the same time have attracted the attention of scientists interested in electrode-response mechanisms, as the electrode behaviour could not be explained by existing theories.[4] Attempts to elucidate the super-Nernstian electrode slope, attributed to the presence of chloride ions, have been made in a number of papers. In some of them the source of anomalous electrode behaviour was considered to be exchange reactions occurring at the electrode surface:[4–8]

$$Ag_2S + 2Cu^{2+} + 2nCl^- \rightleftharpoons CuS + 2AgCl_n^{1-n} \quad (1)$$

$$Cu_2S + Cu^{2+} + 2nCl^- \rightleftharpoons CuS + 2CuCl_n^{1-n} \quad (2)$$

Others[9–11] have attributed the behaviour to redox reactions with participation of the membrane material:

$$Ag_2S + 2Cu^{2+} + 4nCl^- \rightleftharpoons 2CuCl_n^{1-n} + 2AgCl_n^{1-n} + S \quad (3)$$

$$Cu_2S + 2Cu^{2+} + 4nCl^- \rightleftharpoons 4CuCl_n^{1-n} + S \quad (4)$$

$$CuS + Cu^{2+} + 2nCl^- \rightleftharpoons 2CuCl_n^{1-n} + S \quad (5)$$

However, most papers do not offer a detailed explanation of the electrode response. Ross's interpretation[4] does not assume the occurrence of super-Nernstian slope, but indicates only that silver chloride is formed in the case of the CuS/Ag_2S membrane [reaction(1)]. The formation of electroactive AgCl has been experimentally confirmed by Moody and co-workers.[5,12] Lanza[7] suggests that the electrode interference is connected with the presence of Ag_2S and is due to reaction (1). His conclusions are not unequivocally confirmed by his own experimental data. There is also no explanation for super-Nernstian slope in the absence of chloride, and for electrodes which do not contain Ag_2S. Hepel,[8] extending the views of other authors, assumes reaction (2) to be the main reason for the interference. In his considerations, based only on potentiometric data, he neglects the role of redox processes in spite of some earlier remarks[9,13–15] about their importance. The influence of the redox reaction (5) has been discussed by Westall *et al.*[9] Their theoretical considerations were well supported by experiments, but these covered only a relatively narrow concentration range, namely pCu from 3.5 to 5.0, because according to the authors' statement this reaction is hindered by formation of AgCl at the membrane surface. They did not confirm the presence of sulphur at the membrane surface, but this has been reported independently.[10,11]

No complete explanation has so far been given, then, for the non-Nernstian electrode behaviour, especially the variation of slope between 0 and 120 mV/pCu in the pCu range from 2 to 5. In this paper we attempt to give a more general description of the interferences with copper electrodes in solutions containing copper-complexing anions, and propose a method for elimination of this interference and for practical utilization of the super-Nernstian slope.

EXPERIMENTAL

Measurements of the e.m.f. were made with Radiometer pHM 64 and Radelkis OP-206 instruments, with a Radio-

meter K-401 saturated calomel electrode as reference. All solutions were kept at $25 \pm 1°$. The indicator electrodes tested were an Orion 94-29A (CuS/Ag_2S), a CuS membrane electrode prepared as described earlier[10] and a Cu_2S single-crystal electrode prepared according to Hepel.[8]

All reagents were of analytical grade and doubly quartz-distilled water was used throughout.

RESULTS AND DISCUSSION

Electrode response in presence of chloride and bromide ions

Although the behaviour of several electrodes has been well documented, the response of the CuS/Ag_2S, CuS and Cu_2S electrodes was retested under comparable conditions. All measurements were performed in acetate buffers at pH 4.5. The solutions were not stirred during measurements, to ensure predominence of diffusion to and from the electrodes. The e.m.f. was recorded until its drift was less than 1 mV/hr. The results obtained (Figs. 1 and 2) indicated differences in the behaviour of various electrodes. A stable e.m.f. was reached first with the CuS/Ag_2S electrode (approx. 10 min), whereas for the two other electrodes stable e.m.f. values were obtained only after much longer times, even up to several tens of hours. The electrode potential drifted towards more positive values. Its reproducibility for the Orion electrode was better than 5 mV. The slope of the electrode response was found to be dependent on the concentrations of copper ion and interferent. The slope was constant only for the Orion electrode in the range pCu 3.5–5.0, which is in agreement with the findings of Westall *et al.*[9]

To obtain information on the state of the electrode surface, the dependence of the potential on pCl or pBr was investigated after each series of measurements. After treatment of the membrane with 1–3*M* potassium chloride or 1*M* potassium bromide,

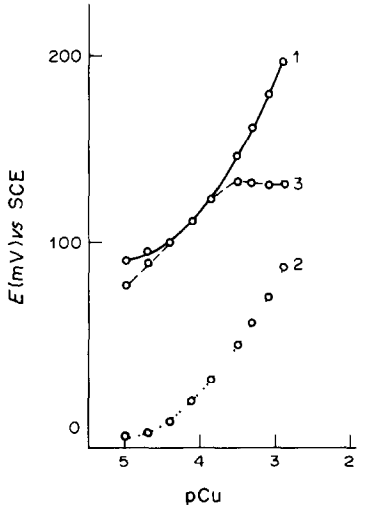

Fig. 1. Calibration graphs for copper electrodes in 1*M* potassium chloride. Curve 1—CuS membrane, curve 2—Cu_2S membrane, curve 3—Orion 94-29 electrode.

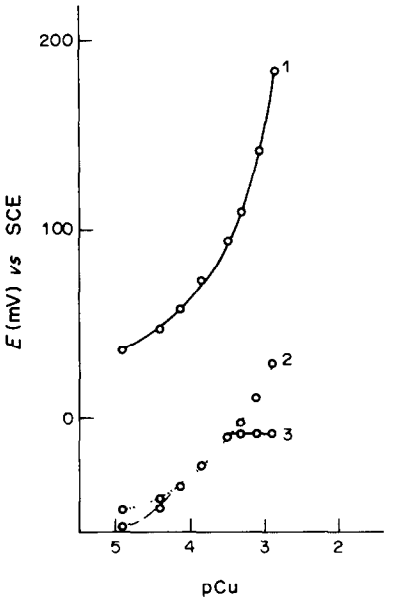

Fig. 2. Calibration graphs for copper electrodes in 1*M* potassium bromide. Curve 1—CuS membrane, curve 2—Cu_2S membrane, curve 3—Orion 94-29 electrode.

this function was linear only for the Orion electrode. For the other two electrodes (and also for the Orion electrode after previous exposure to 2 or 3*M* potassium bromide) such linearity was not observed. This indicates that in most cases no electroactive substances with composition different from that of the membrane are precipitated on the membrane surface. It may also suggest formation of soluble copper or silver complexes. The exceptional behaviour of the Orion electrode in the above-mentioned solutions indicates that in this case solid AgCl (or AgBr) has been formed. This process also seems to be responsible for the plateau of curve 3 in Figs. 1 and 2 for concentrations above pCu 3.5.

On the basis of previous data[5] and the results of this study the following interference mechanisms may be proposed for the various types of electrode:

$$Ag_2S + 2Cu^{2+} + 4nX^- \rightleftharpoons 2AgX_n^{1-n} + 2CuX_n^{1-n} + S \quad (6)$$

$$CuS + Cu^{2+} + 2nX^- \rightleftharpoons 2CuX_n^{1-n} + S \quad (7)$$

$$Cu_2S + 2Cu^{2+} + 4nX^- \rightleftharpoons 4CuX_n^{1-n} + S \quad (8)$$

These reactions explain the interference processes on the membrane surface, and the poor reproducibility and the instability of potential response are due to the formation of elemental sulphur. Considering the empirically established fact that electrochemical corrosion is stimulated by chloride and bromide ions[16] it seems reasonable to suppose that the rapidly formed amorphous sulphur mechanically blocks the electrode surface[10] and causes the irreversibility of reactions (6), (7) or (8). It becomes obvious that direct determination of copper in the presence of high

concentrations of chloride or bromide ions is impossible.

Optimization of conditions for potentiometric determination of copper

It may be expected that addition of a reagent which binds copper(II), copper(I) and silver(I) more strongly than chloride or bromide does may act advantageously in the determination of copper(II). Thiosulphate was chosen as such a reagent, since it is known to diminish the strongly corrosive action of halide ions on copper and silver. The stability of the relevant thiosulphate complexes is greater than that of the halide complexes (Table 1). The reducing properties of thiosulphate ($E^0_{S_4O_6^{2-}/S_2O_3^{2-}} = 0.15$ V) are also advantageous. Those properties suggest that the halide ions will not participate in the redox reactions, and that these will proceed at lower rate. Therefore formation of crystalline sulphur instead of amorphous[17] is more probable, and the whole process becomes more reversible. In these experiments the Orion 94-29 electrode was used because its properties are well known and the response in halide solutions is the most reproducible.

The potential of the copper electrode in solutions containing thiosulphate depends significantly on the thiosulphate concentration (Fig. 3). Below a certain thiosulphate concentration the electrode potential is practically constant, but decreases linearly with higher thiosulphate concentrations. It also depends on the copper concentration. A thiosulphate concentration of 0.04M, in the middle of the linear decrease range, was used for further studies. Such a concentration is sufficient to mask the halide effect but is not large enough to cause rapid membrane dissolution.

For all the solutions containing both halide and thiosulphate ions the copper calibration curves are well reproducible, and so are the potential values. Measurement in 0.04M thiosulphate solution gave better results than that in 0.4M thiosulphate medium because with the latter the slope of the electrode response is lower for smaller copper concentrations (Fig. 4). The tangent to the calibration curve always has super-Nernstian slope, but the curves are not linear in any range. This behaviour can be explained by considering linearization of the standard curve.

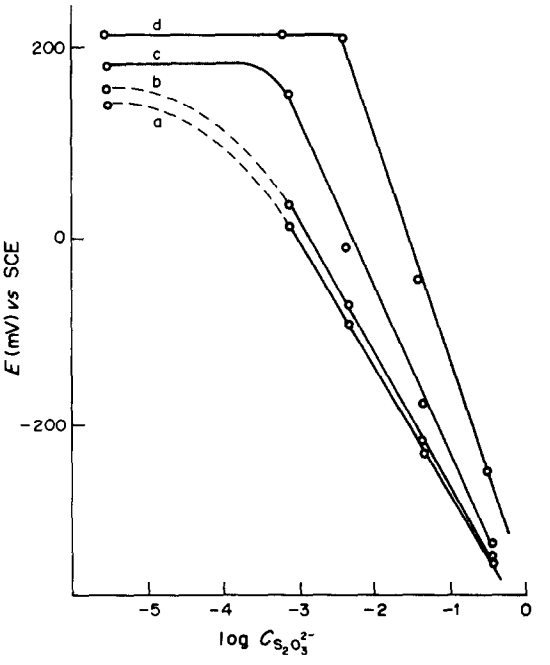

Fig. 3. Dependence of potential response of the Orion 94-29 electrode on thiosulphate concentration at various total copper concentrations in 2M KNO_3. Curve a—$10^{-4.7}M$ Cu^{2+}, curve b—$10^{-4.2}M$ Cu^{2+}, curve c—$10^{-3.3}M$ Cu^{2+}, curve d—$10^{-2.2}M$ Cu^{2+}.

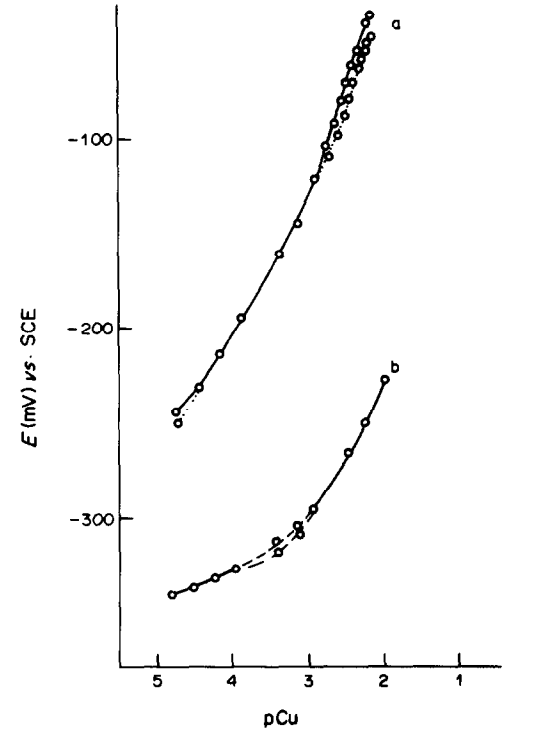

Fig. 4. Calibration graphs for Orion 94-29 electrode in solutions containing halide and thiosulphate ions. Curve a—0.04M sodium thiosulphate, curve b—0.4M sodium thiosulphate. Solid lines for 1M potassium chloride, dashed lines for 1M potassium bromide.

Linearization of the calibration graph

The linearization function is based on the diffusion model[6] with the following assumptions: (*a*) the electrode potential depends on the main-ion concentration at the membrane surface; (*b*) the concentrations of various species are different at the membrane surface and in the bulk solution; (*c*) concentrations at the membrane surface are controlled by rapid and reversible reactions at the membrane-solution interface; (*d*) these reactions do not change the bulk composition of the solution.

Because the electrode potential may be governed by the reactions of both components of the electrode the processes pertaining to each of them have been considered separately.

When CuS is the potential-defining species, then for the potential given by the equation

$$E = E^0_{ISE} + \frac{RT}{2F} \ln [Cu^{2+}]_0 \quad (9)$$

the concentration of copper ions at the membrane surface ($[Cu^{2+}]_0$) in the presence of thiosulphate is controlled by the redox reaction

$$Cu(S_2O_3)_2^{2-} + CuS + 2S_2O_3^{2-} = 2Cu(S_2O_3)_2^{3-} + S \quad (10)$$

Taking into account the stability constants of the thiosulphate complexes (Table 1) it is not a bad approximation to consider that at a total thiosulphate concentration of 0.04*M* the predominant species are the bis-complexes.

The equilibrium constant of reaction (10) is:

$$K_1 = \frac{[Cu(S_2O_3)_2^{3-}]_0^2}{[Cu(S_2O_3)_2^{2-}]_0 [S_2O_3^{2-}]_0^2} = \frac{\beta^2_{2,[Cu(S_2O_3)_2^{3-}]} K_{s0(Cu_2S)}}{\beta_{2,[Cu(S_2O_3)_2^{2-}]} K_{s0(CuS)}} = 10^{1.8} \quad (11)$$

where the subscript 0 refers to concentrations at the membrane surface.

In the bulk of the solution thiosulphate is present as free ions and as copper(II) complexes whereas at the membrane surface where copper(I) is formed, the copper(I) complexes must also be taken into account. For the bulk solution concentration the mass balance is given by the equation:

$$C_{S_2O_3^{2-}} = [S_2O_3^{2-}] + 2[Cu(S_2O_3)_2^{2-}] \quad (12)$$

whereas at the membrane surface

$$C_{S_2O_3^{2-}} = [S_2O_3^{2-}]_0 + 2[Cu(S_2O_3)_2^{3-}]_0 + 2[Cu(S_2O_3)_2^{2-}]_0 \quad (13)$$

but at equilibrium the last term is negligible compared to the others, so

$$C_{S_2O_3^{2-}} = [S_2O_3^{2-}]_0 + 2[Cu(S_2O_3)_2^{3-}]_0 \quad (14)$$

Assuming the fluxes of both thiosulphate complexes to be equal, than from equation (10):

$$2D''([Cu(S_2O_3)_2^{2-}] - [Cu(S_2O_3)_2^{2-}]_0) = D'([Cu(S_2O_3)_2^{3-}]_0 - [Cu(S_2O_3)_2^{3-}]) \quad (15)$$

where D' and D'' represent the diffusion coefficients of the copper(I) and copper(II) complexes, respectively, and if $[Cu(S_2O_3)_2^{3-}] = 0$, the concentration of copper(I) at the membrane surface is given by

$$[Cu(S_2O_3)_2^{3-}]_0 = \frac{D''}{D'}([Cu(S_2O_3)_2^{2-}] - [Cu(S_2O_3)_2^{2-}]_0) \quad (16)$$

It is also reasonable to accept that the surface concentration of $Cu(S_2O_3)_2^{2-}$ is negligible compared to the bulk concentration, so

$$[Cu(S_2O_3)_2^{3-}]_0 = 2\frac{D''}{D'}[Cu(S_2O_3)_2^{2-}] \quad (17)$$

By substitution of this expression into equation (14) and setting $D''/D' = B$, the surface concentration of the ligand can be evaluated:

$$[S_2O_3^{2-}]_0 = C_{S_2O_3^{2-}} - 4B[Cu(S_2O_3)_2^{2-}] \quad (18)$$

or, assuming that the predominant form of copper(II) in the solution is its complex:

$$[S_2O_3^{2-}]_0 = C_{S_2O_3^{2-}} - 4BC_{Cu^{2+}} \quad (19)$$

The surface concentration of the ligand (19) and the concentration of $Cu(S_2O_3)_2^{2-}$ expressed in terms of the stability constant β_2 and equation (11) can be used to calculate the potential-governing concentration of copper(II):

$$[Cu^{2+}]_0 = \frac{4B^2C^2_{Cu^{2+}}}{K_1\beta_2(C_{S_2O_3^{2-}} - 4BC_{Cu^{2+}})^2} \quad (20)$$

Thus the equation for the electrode potential (9) may be written in more extended form:

$$E = E^{0\prime} + \frac{RT}{F} \ln \frac{C_{Cu^{2+}}}{(C_{S_2O_3^{2-}} - 4BC_{Cu^{2+}})^2} \quad (21)$$

where

$$E^{0\prime} = E^0_{ISE} + \frac{RT}{F} \ln \frac{2B}{\sqrt{\beta_2 K_1}} \quad (22)$$

When Ag_2S is the potential-governing electrode component, the concentration of copper(II) ions is controlled by the reaction

$$2Cu(S_2O_3)_2^{2-} + Ag_2S + 4S_2O_3^{2-} \rightleftharpoons 2Cu(S_2O_3)_2^{3-} + 2Ag(S_2O_3)_2^{3-} + S \quad (23)$$

occurring at the membrane surface, for which the equilibrium constant is

$$K_2 = \frac{[Cu(S_2O_3)_2^{3-}]_0 [Ag(S_2O_3)_2^{3-}]_0}{[Cu(S_2O_3)_2^{2-}]_0 [S_2O_3^{2-}]_0^2} = 10^{2.8} \quad (24)$$

The mass balance for the ligand is expressed as

$$C_{S_2O_3^{2-}} = [S_2O_3^{2-}]_0 + 2[Cu(S_2O_3)_2^{2-}]_0 + 2[Cu(S_2O_3)_2^{3-}]_0 + 2[Ag(S_2O_3)_2^{3-}]_0 \quad (25)$$

and the stationary state is described by equality of the corresponding fluxes

$$D''([Cu(S_2O_3)_2^{2-}] - [Cu(S_2O_3)_2^{2-}]_0) = D'([Cu(S_2O_3)_2^{3-}]_0 - [Cu(S_2O_3)_2^{3-}]) \quad (26)$$

and

$$D''([Cu(S_2O_3)_2^{2-}] - [Cu(S_2O_3)_2^{2-}]_0) = D^{Ag}([Ag(S_2O_3)_2^{3-}]_0 - [Ag(S_2O_3)_2^{3-}]) \quad (27)$$

When $[Cu(S_2O_3)_2^{2-}]_0$, $[Cu(S_2O_3)_2^{3-}]$ and $[Ag(S_2O_3)_2^{3-}]$ are negligible in comparison with the respective concentrations in the equations above, then the concentrations in equation (24) may be expressed as

$$[Cu(S_2O_3)_2^{3-}]_0 = BC_{Cu^{2+}} \quad (28)$$

$$[Ag(S_2O_3)_2^{3-}]_0 = GC_{Cu^{2+}} \quad (29)$$

and

$$[S_2O_3^{2-}]_0 = C_{S_2O_3^{2-}} - 2(B+G)C_{Cu^{2+}} \quad (30)$$

where G represents D''/D^{Ag}.

Substitution into equation (24) gives the following expression for the potential of the copper ion-selective electrode:

$$E = E^0 + \frac{RT}{F} \ln \frac{C_{Cu^{2+}}}{(C_{S_2O_3^{2-}} - 2(B+G)C_{Cu^{2+}})^2} \quad (31)$$

where

$$E^0 = E^0_{ISE} + \frac{RT}{F} \ln \frac{\sqrt{BG}}{\sqrt{\beta_2 K_2}} \quad (32)$$

Some doubts may arise about the degree of reduction of copper in the bulk of the solution. The equilibrium constant of this reaction is probably not larger than 5×10^2, as can be evaluated on the basis of known redox potentials. This reaction has a large activation energy, however, and also the copper(I) complexes can be oxidized in the presence of oxygen.[22] To obtain experimental evidence on this, the copper(II) solutions were titrated with thiosulphate. When the reduction and complexation occur in the bulk, the consumption of titrant should be 3 moles of thiosulphate for 1 mole of copper(II);

$$2Cu^{2+} + 6S_2O_3^{2-} \rightleftharpoons 2Cu(S_2O_3)_2^{3-} + S_4O_6^{2-}; \quad (33)$$

otherwise only 2 moles of thiosulphate should be consumed in the complexation reaction:

$$Cu^{2+} + 2S_2O_3^{2-} \rightleftharpoons Cu(S_2O_3)_2^{2-} \quad (34)$$

In the experiment, about 2.2 moles were found to be consumed, which indicates that a small amount of reduction proceeds in the solution.

If the reduction is assumed to be complete, then $[Cu(S_2O_3)_2^{3-}]$ equals the total copper concentration and the potential should be interpreted only on the basis of the reaction stoichiometry. In such a case the final equation would have the form:

$$E = E^0 + \frac{RT}{F} \ln \frac{C_{Cu^{2+}}}{(C_{S_2O_3^{2-}} - ZC_{Cu^{2+}})^2} \quad (35)$$

where from the stoichiometry $Z = 3$, which is close to $2(B+G) = 3.5$, found experimentally as a best fit for the Orion-type electrode.

In order to check the agreement of the proposed model with the experimental data, equations (21) and (31) were written in the semi-empirical form with "constant", S and A_e as the equation parameters:

$$E = \text{constant} + S \log \frac{C_{Cu^{2+}}}{(C_{S_2O_3^{2-}} - A_e C_{Cu^{2+}})^2} \quad (36)$$

The "constant", S and A_e were calculated by the following numerical linearization procedure.

(*a*) For the set of $(pC_{Cu^{2+}})_i$ values corresponding to the set of E_i values for a fixed A_e value, the values n_i for

$$n_i = \log \frac{(C_{Cu^{2+}})_i}{[C_{S_2O_3^{2-}} - A_e(C_{Cu^{2+}})_i]^2} \quad (37)$$

were calculated.

(*b*) The E_i and n_i values were correlated by the least-squares method and the values of the "constant," S and r^2 were obtained (r is the correlation coefficient).

(*c*) The A_e value was changed by steps of $\Delta A_e = 0.1$, starting from $A_e = 0$, and the calculations were repeated until the best correlation coefficient was obtained (Table 2).

When the thiosulphate concentration was 0.4*M*, only potential values for total copper concentrations larger than $10^{-3}M$ were taken into account, whereas for 0.04*M* thiosulphate concentration only potential values for total copper concentrations less than $2 \times 10^{-3}M$ were used. This was done to avoid excessive membrane corrosion in the first case and incomplete conversion of Cu(II) into Cu(I) in the second. Neither of the linearized calibration curves for 0.04*M* and 0.4*M* thiosulphate media covers the whole analytical range (Fig. 5), but the linear parts are complementary and together cover the pCu range from 2 to 5. Two scales are shown on the abscissa, the linear scale n and the non-linear scale pCu. Their interrelation changes according to the thiosulphate concentration.

The experimentally found parameters of equation (36) should have a physical meaning which follows from the model presented for the interference mech-

anism. The parameter $A_e = 4D''/D'$ cannot be exactly calculated, because of lack of precise values for the diffusion coefficients. However, they may be evaluated by taking into account that in the absence of complexing ligands the ratio of the diffusion coefficients for copper(II) and copper(I) species is 0.45.[23] It is known that complexation increases this value[24,25] and it may be assumed that it approaches unity.[26] Therefore the value of A_e should fit in the range 1.8–4 for linear diffusion transport, or even in the narrower range 2.5–4 when convection is taken into account.[27] The experimentally found value of 3.5 fits well in this range.

The constant corresponding to the standard potential E^0 can be calculated on the basis of equations (21) and (31), with the parameter B calculated from the experimentally found value of A_e. Assuming the activity of sulphur in the membrane to be unity (sulphur-rich electrode), the expected E^0 should be -57 mV *vs.* SCE. Assuming the activity of silver to be unity (silver-rich electrode), then $E^0 = -192$ mV *vs.* SCE. The values of the "constant," given in Table 2, are nearly bracketed by these two values, so they seem to be physically sound.

The slope of the linearized curve should be Nernstian, and the values in Table 2 are all, except for the 3*M* potassium bromide system, within the reasonable limits of 55.0–59.5 mV/pCu.

CONCLUSIONS

The interferences caused by the presence of chloride and bromide ions in the response of copper ion-selective electrodes are manifested by insufficient reproducibility, long response time, narrow range of linearity of electrode response and variable slope in the pCu range from 2 to 5. Such effects may be effectively counteracted by the addition of a proper concentration of thiosulphate, the strongly complexing and reducing properties of which can eliminate the membrane corrosion caused by halides and prevent precipitation of the slightly soluble silver halides. The exchange reactions at the membrane/solution interface are also stabilized, which permits the analytical utilization of the super-Nernstian electrode slope.

It may be suggested that a similar procedure may be applied for elimination of interferences with other solid-state ion-selective electrodes.

(*Received* 6 *December* 1984. *Accepted* 31 *January* 1985)

Summary—The simultaneous determination of tin(II) and lead(II) as well as of indium(III) and cadmium(II) by second-harmonic a.c. voltammetry using a semi-stationary mercury electrode with a drop-time of 240–300 sec (the long-lasting sessile-drop mercury electrode) has been investigated. Under the best experimental conditions, concentration ratios in the ranges $1:12 \leqslant c_{Sn}:c_{Pb} \leqslant 15:1$ and $1:15 \leqslant c_{In}:c_{Cd} \leqslant 15:1$ can be determined.

The half-wave potentials for the reduction of tin(II) and lead(II), and of indium(III) and cadmium(II), in the commonly used electrolytes, are very close and thus simultaneous polarographic determination of these pairs of elements is hindered. Various organic complexing agents or special solutions have been suggested as the supporting electrolytes for the determination of these elements. Kasagi and Banks[1] investigated the polarographic determination of small amounts of indium(III) in the presence of large amounts of cadmium(II), lead(II) and tin(II), using a solution of potassium iodide as the supporting electrolyte.

Metzger *et al.*[2–4] determined tin(II) and lead(II) by employing a mixture of hydrochloric acid and an alcohol (from C_1 to C_5) as solvent. In these supporting electrolytes the half-wave potentials of tin(II) and lead(II) are better separated and so the simultaneous determination of these ions is possible. Cinquantini *et al.*[5] determined tin(II) and lead(II) in 1*M* triammonium citrate medium at pH 4–7. Jacobsen and Tandberg[6] determined indium(III) and cadmium(II) in citrate buffer at pH 3.5 by d.c. and a.c. polarography. Perone and co-workers[7,8] and Bond and Grabaric[9] used microprocessor-controlled polarographs for the simultaneous determination of two species with overlapping polarographic waves. Fagioli *et al.*[10] employed second-harmonic a.c. polarography for the simultaneous determination of indium(III) and cadmium(II) in 1*M* hydrochloric acid with a conventional dropping mercury electrode. This work has now been extended to the simultaneous determination of tin(II) and lead(II) and of indium(III) and cadmium(II) by second-harmonic a.c. voltammetry by use of a semi-stationary mercury electrode with a drop-time of 240–300 sec.[11] This technique makes it possible to shorten the analysis time and gives lower detection limits than those attained by conventional a.c. polarography.

EXPERIMENTAL

Apparatus

Current *vs.* potential curves were recorded with an AMEL model 471 Multipolarograph equipped with a 291/LF stirrer and a 452/T timer. The three-electrode system consisted of a long-lasting sessile-drop mercury electrode as the working electrode, a saturated calomel reference electrode (SCE) and a platinum auxiliary electrode. The voltammetric cell was kept at 25.0 ± 0.5°. The solutions were deaerated by passage of pure nitrogen before analysis, and during the polarography a nitrogen atmosphere was maintained above the solution, and the solution was stirred with a magnetic stirrer.

Reagents and reference solutions

Hydrochloric acid and all other chemicals were Merck "Suprapur" grade. Intermediate reference solutions of various concentrations were prepared from BDH 1000-mg/l. stock solutions of Sn, Pb, In and Cd. The water used was demineralized and then twice distilled from potassium permanganate. The Teflon cell was periodically rinsed with concentrated nitric acid to eliminate contamination. Standard additions were made with Eppendorf micropipettes with disposable plastic tips.

RESULTS AND DISCUSSION

The voltammetric behaviour of the tin(II)–lead(II) and indium(III)–cadmium(II) pairs was studied by first and second harmonic a.c. polarography.

Calibration curves for tin(II) and lead(II)

Hydrochloric acid (1*M*) was chosen as supporting electrolyte. The measurement conditions used are

Table 1. Experimental conditions for the determination of tin(II) and lead(II) by a.c. voltammetry

Parameter*		Sn(II)	Pb(II)

f	*Hz*	100	100
ΔE	*mV*	10	10
$\phi_{\text{first harmonic}}$	*degrees*	270 + 80	270 + 89
$\phi_{\text{second harmonic}}$	*degrees*	270 + 67	270 + 72

*E_i = initial potential; t_d = delay time for growth of drop before recording; dE/dt = potential scan-rate; f = frequency; ΔE = amplitude of a.c. voltage; ϕ = demodulation phase angle.

listed in Table 1. The demodulation phase angle ϕ was carefully set, since if properly chosen it can almost completely eliminate the capacitive current.

The polarographic wave parameters are reported in Table 2. The peak-width measured at half-height of the fundamental harmonic polarographic curve is $W_{1/2} = 90/n$ mV where n is the number of electrons involved in the electrode process. This relationship together with the equation $p\text{–}p = 68/n$ mV, where $p\text{–}p$ is the peak-to-peak separation of the potentials of the second harmonic a.c. polarographic curve,[12] are the simplest tests for the polarographic reversibility of an electrode reaction. The experimental half-peak widths and peak-to-peak separations of potential indicate that the polarographic reactions for both electroactive species are reversible. The half-wave potentials are also in excellent agreement with the literature values reported in the same Table.

The calibration curves for the determination of tin(II) and lead(II) were prepared for both first and second harmonic a.c. voltammetry. In all cases the standard addition method was used and each point was the mean of five readings. The second harmonic a.c. calibration curves were plotted on the basis of the cathodic peak current for tin(II) and the anodic peak current for lead(II).[13] The correlation coefficient is very satisfactory for all the regression functions reported in Table 3, while the relative standard deviation s_r is reasonably low. The corresponding detection limit is also reported for each calibration curve.

Simultaneous determination of tin(II) and lead(II)

The simultaneous determination of tin(II) and lead(II) was studied over the concentration ranges covered by the individual calibration curves. The voltamperograms were recorded under the experimental conditions reported in Table 1. The second (curve *a*) and the fundamental (curve *b*) harmonic a.c. voltamperograms of mixtures of tin(II) and lead(II) are shown in Fig. 1. The second harmonic a.c. voltamperogram indicates good resolution of the two electroactive species, whereas in the first harmonic a.c. voltamperogram the peaks for the two elements are not separated, and the combined peak has a half-width $>90/n$ mV.

Under the experimental conditions reported in Table 1, the simultaneous determination of tin(II) and lead(II) is possible in the range of concentration ratios $1{:}12 \leqslant c_{Sn}{:}c_{Pb} \leqslant 15{:}1$. The data were processed by univariate and bivariate analysis. The regression

Range of concentrations $0\text{–}5 \times 10^{-5} M$	Range of concentrations $0\text{–}3 \times 10^{-5} M$

*The limit of detection, D.L., is expressed according to the IUPAC recommendation[15] (99% probability). The units are μA for i_p and M for c.

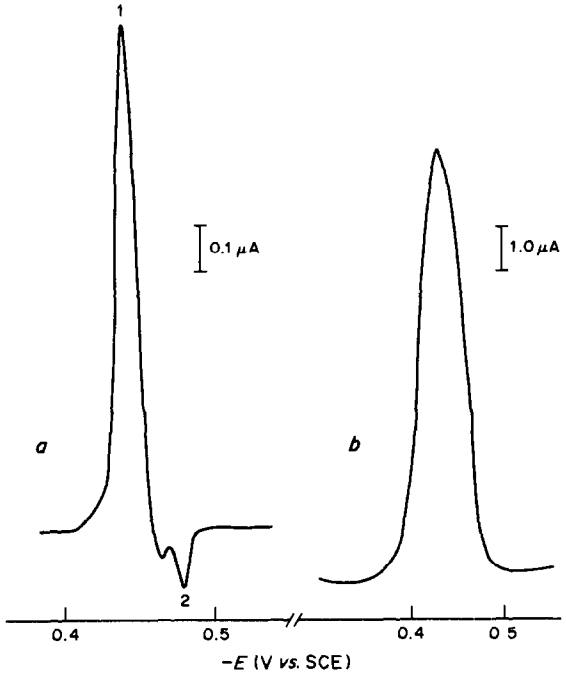

Fig. 1. Alternating current voltamperograms of tin(II) and lead(II): $c_{Pb} = 5.85 \times 10^{-5} M$; $c_{Sn} = 8.33 \times 10^{-6} M$. Curve *a*: second harmonic a.c. voltamperogram [Pb(II): peak 1, Sn(II): peak 2]. Curve *b*: first harmonic a.c. voltamperogram. Experimental conditions: Table 1.

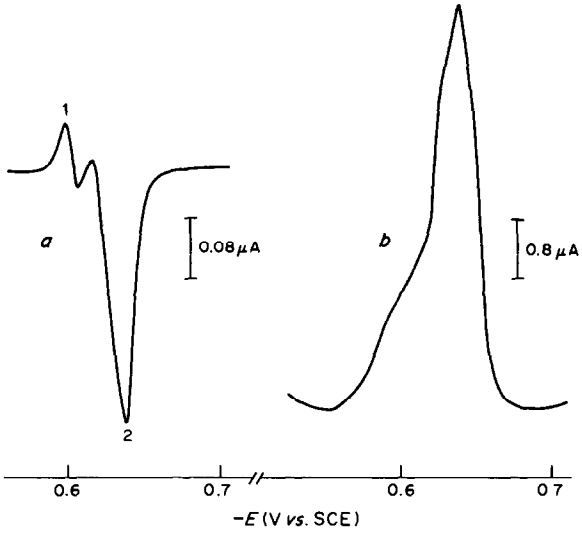

Fig. 2. Alternating current voltamperograms of indium(III) and cadmium(II): $c_{In} = 3.15 \times 10^{-6} M$; $c_{Cd} = 1.54 \times 10^{-5} M$. Curve *a*: second harmonic a.c. voltamperogram [In(III): peak 1, Cd(II): peak 2]. Curve *b*: first harmonic a.c. voltamperogram. Experimental conditions: Table 5.

functions calculated on the basis of the respective peak current values for tin(II) and lead(II) in mixtures are reported in Table 4. The univariate analysis neglects the presence of the interfering element, while the bivariate analysis takes into account the contribution of the interfering element as well. It is noteworthy that the slopes of the bivariate regression equations for both elements are practically equal to those of the individual calibration curves (*cf.* Table 3) and the univariate regression line. This proves that in the range of concentration ratios considered, the mutual interferences of tin(II) and lead(II) are negligible. The precision of the method, expressed as the relative standard deviation s_r, is 2–3% and the accuracy, expressed as relative error e, is 1–2%.

Calibration curves for indium(III) and cadmium(II)

The technique used for tin(II) and lead(II) determination was also employed for the a.c. voltammetric determination of indium(III) and cadmium(II). The

experimental conditions are reported in Table 5 and the polarographic wave parameters in Table 6.

It is apparent that the literature and experimental data are in excellent agreement. The calibration curves and other statistical parameters for indium(III) and cadmium(II) are given in Table 7.

For the second harmonic a.c. calibration curves the cathodic peak current of cadmium(II) and the anodic current of indium(III)[13] were measured. The relative standard deviation (1–2%) is again low.

Simultaneous determination of indium(III) and cadmium(II)

Indium(III) and cadmium(II) were simultaneously determined in the concentration ranges covered by the individual calibration curves. One example of the second and first harmonic a.c. voltamperograms of indium(III) and cadmium(II) mixtures in 1*M* hydrochloric acid is shown in Fig. 2. In the second harmonic a.c. voltamperogram (curve *a*), the peaks for the species are separated, but in the first harmonic a.c. voltamperogram (curve *b*), they are not. Under the experimental conditions in Table 5, the determination of indium(III) and cadmium(II) is possible in the range of concentration ratios between 15:1 and 1:15. The regression functions relating to indium(III) and cadmium(II) mixtures are summarized in Table 8. The slopes of the bivariate functions for both elements are practically equal to the slopes of the individual calibration curves and of the univariate analysis, showing that the mutual interference is negligible. The relative standard deviation and the relative error are both 2–3%.

*D.L. and units are defined in the footnote to Table 3.

Both the selectivity and the sensitivity of the measurements with the semi-stationary electrode showed a definite improvement over those obtained with the conventional dropping mercury electrode. This is due to the larger surface area of the semi-stationary electrode and to the elimination of the noise of the dropping mercury electrode capillary at low concentrations.

DETERMINATION OF NEODYMIUM AND BORON IN IRON–NEODYMIUM–BORON ALLOYS BY DIRECT-CURRENT PLASMA ATOMIC-EMISSION SPECTROMETRY

NOEL M. POTTER and HARRY E. VERGOSEN, III
Analytical Chemistry Department, General Motors Research Laboratories, Warren, Michigan 48090, U.S.A.

(*Received* 20 *September* 1984. *Revised* 30 *November* 1984. *Accepted* 31 *January* 1985)

Summary—Rapid, accurate methods for the determination of neodymium and boron in iron–neodymium–boron alloys are presented. The procedure involves dissolution of the alloy with nitric acid and measurement of the elemental concentrations by direct-current plasma atomic-emission spectrometry. Lithium is added in the determination of neodymium, to control interferences. The relative standard deviations are approximately 1%, and the accuracies comparable to those obtained by classical chemical methods.
