HISTORY OF ANALYTICAL CHEMISTRY IN THE U.S.A.

H. A. LAITINEN
Department of Chemistry, University of Florida, Gainesville, FL 32611, U.S.A.

(*Received* 24 *February* 1988. *Accepted* 12 *April* 1988)

The development of analytical chemistry in the U.S.A. is logically described in four time periods, namely (*a*) the nineteenth century, (*b*) 1900–1939, (*c*) the decade of the 1940s, and (*d*) from 1950 to the present day. During the nineteenth century, American analytical chemistry, like chemistry as a whole, tended to lag behind European practice. The first four decades of the twentieth century saw an emergence of analytical chemistry as a scientific discipline in addition to its time-honored role as an empirical set of procedures for characterization of matter. The decade of the 1940s represents a special period, because during the first half of this decade, World War II created an enormous stimulus for the solution of new and difficult problems, but at the same time imposed severe limitations on communication, both within the U.S.A. and with scientists in other countries. The second half of the decade was a period in which pent-up wartime developments were published, and also new cross-disciplinary stimuli came into play to bring about rapid advances in all branches of analytical chemistry. The most recent period, since 1950, represents the modern era of broadening and deepening the subject by taking advantage of theoretical and experimental advances in various branches of science.

THE NINETEENTH CENTURY

The chemical historian Aaron J. Ihde[1] remarks: "American chemistry was hardly a mature science as the twentieth century began, but here and there a center of activity was beginning to attract attention. During the previous century chemistry was part of the usual college curriculum but seldom received significant emphasis before the last quarter of the century.... Whatever chemical activity existed in the United States was generally to be found in educational institutions, or to a lesser extent, in government." Of the five outstanding American chemists of the period he describes, four made substantial contributions to analytical chemistry.

Stephen M. Babcock (1843–1931) was primarily an agricultural chemist best known for a simple test for butterfat in milk. Harvey W. Wiley (1844–1930) was primarily a food chemist in the U.S. Department of Agriculture. He was instrumental in founding the Association of Official Agricultural Chemists in 1884. This organization, now known as the Association of Official Analytical Chemists, is noted for publishing the "Official and Tentative Methods of Analysis" of the A.O.A.C., which serve as the basis for commerce and the enforcement of pure food and drug legislation. Theodore William Richards (1868–1928) was a teacher of analytical and physical chemistry noted primarily for his work on atomic weights, for which he received the Nobel Prize (the first awarded to an American chemist) in 1915. He had many notable students, including G. N. Lewis, Roger Adams, Otto Honigschmidt, his successor Gregory Baxter, and the well known analytical chemist Hobart H. Willard. Edgar Fahs Smith (1854–1928) was primarily known for his work at the University of Pennsylvania on electrolytic methods of analysis. He also had many noted students, including Joel H. Hildebrand and Herbert S. Harned. The fifth chemist mentioned by Ihde was Ira Remsen, a renowned organic chemist.

Of special importance to early American analytical chemistry was Edward Hart, Professor of Chemistry at Lafayette College in Easton, PA, who founded the *Journal of Analytical Chemistry* in 1887 and established the Chemical Publishing Company. In 1891 the name of the journal was changed to *Journal of Analytical and Applied Chemistry*. In 1893, Hart became editor of the *Journal of the American Chemical Society*, which had been established in 1879, and amalgamated his journal with it.[2]

Throughout the nineteenth century, the teaching of analytical chemistry was closely tied to agriculture, mineralogy and the analysis of ores, raw materials, alloys, foods and other materials. As organic and physical chemistry began to develop in Europe, the relative importance of analytical chemistry dwindled. Until at least the outbreak of World War I in 1914, most American research chemists received at least a part of their education in European centers, and it is logical that the influence of European physical chemists such as Ostwald, Arrhenius, van't Hoff, and Nernst near the turn of the century began to be felt in the teaching and practice of American analytical chemistry.

THE PERIOD 1900–1939

It was not until the outbreak of World War I that American chemistry had to break away from Euro-

pean, and especially German, dominance. Industry had to develop capabilities in the manufacture of fertilizers, explosives, dyes and drugs, while academic chemists could no longer depend upon advanced training in Europe. In analytical chemistry, several academic centers emerged by the mid-1920s, notably Caltech (E. H. Swift), Cornell (E. M. Chamot), Harvard (G. P. Baxter), Illinois (G. F. Smith), Michigan (H. H. Willard), Ohio State (C. W. Foulk), Princeton (N. H. Furman), Purdue (M. G. Mellon), Virginia (J. H. Yoe), and Wisconsin (V. W. Meloche). In 1927 an important addition to this list occurred when I. M. Kolthoff came from Utrecht to the University of Minnesota. During the 1930s, the economic depression slowed down expansion so that few additions to this list could be made until 1939, when Harvey Diehl went to Iowa State and 1940 when P. W. West went to Louisiana State University.

In government laboratories, the National Bureau of Standards was outstanding, especially in traditional "wet" methods. The book *Applied Inorganic Analysis* (1929) by W. F. Hillebrand and G. E. F. Lundell was long a standard reference book. The NBS, beginning in 1905, has served an important need as the supplier of primary standard substances and certified standard reference materials. Other notable government laboratories of the era were at the U.S. Department of Agriculture, the U.S. Geological Survey and the US Bureau of Mines. Many industrial research laboratories were established in the 1920s, but the depression of the 1930s slowed their growth.

In analytical chemistry, the 1900–1939 period was marked by the gradual increase in emphasis on a scientific approach instead of a purely empirical one, and an increased emphasis on instrumental measurements to supplement the traditional chemical ones. To illustrate the scientific approach, consider the long series of papers by Kolthoff and his students on the formation and properties of precipitates. These papers were not directed primarily at improvements in specific analytical methods *per se* but to an understanding of the processes involved. Instruments themselves had little to do with the scientific approach, as illustrated by the long period during which atomic-emission spectroscopy was used in a purely empirical way for trace analysis without attention to the details of the processes involved. Polarography had been introduced as early as 1922 by Heyrovský, but until the late 1930s its use in the U.S.A. was largely empirical. In 1939, Kolthoff and Lingane[3] published a major article in *Chemical Reviews* on the fundamental aspects of the subject, which together with their book in 1941 stimulated a great deal of interest in the U.S.A. Ralph H. Müller, of New York University, published a paper in 1928 with H. M. Partridge, entitled "Applications of the Photo-Electric Cell to Automatic Titrations",[4] the forerunner of a great many contributions to analytical instrumentation for the next several decades.

After the amalgamation of the *Journal of Analytical and Applied Chemistry* with *J. Am. Chem. Soc.*, no American research journal devoted exclusively to analytical chemistry existed until the *Analytical Edition* of *Industrial and Engineering Chemistry* was established in 1929. The editorial policy was to emphasize papers devoted to analytical procedures and applications, while papers on the fundamentals continued to appear in *J. Am. Chem. Soc.* Instrumental papers were not excluded, as illustrated by the publication of a major paper on "Photoelectric Methods in Analytical Chemistry" by Ralph H. Müller in 1939.[5] The policy of excluding fundamental papers was to change by 1947, when the name of the journal was changed to *Analytical Chemistry*.

In the American Chemical Society analytical chemistry was represented by the Analytical Section of the Division of Physical and Inorganic Chemistry through the 1930s. In 1940 this Section was merged with the Division of Microchemistry, which had been established in 1938, to form the Division of Analytical and Microchemistry. In 1949 the name was changed again to its present name, the Division of Analytical Chemistry. The Division has had an active role in many professional activities, such as the co-sponsorship with the journal *Analytical Chemistry* of a summer symposium each year since 1948, the sponsorship of fellowships to support graduate study since 1966, the sponsorship of undergraduate awards in analytical chemistry since 1968, and since 1973 the sponsorship of a program of Summer Interns in which outstanding undergraduates are placed in summer jobs in industry. It also acts to select recipients of a number of Divisional awards which are funded by industry and presented at Divisional symposia at national ACS meetings. Divisional membership has steadily grown over the years until it has become the third largest in the ACS, exceeded only by that of the Organic and Polymer Divisions.

Pioneering work with the glass electrode by Haber and Klemensiewics dates back to the same year (1909) as the Sørensen definition of pH. Measurements with this electrode were hampered by the difficulties due to its high resistance, until the late 1920s, when several investigators, especially in the U.S.A., devised vacuum-tube potentiometers. The commercial availability of the Beckman pH meter in 1935 made such measurements a practical reality. The work of MacInnes and Dole, beginning in 1929, showing the effect of glass composition and the errors at each end of the pH scale, was also of great importance. Finally, the establishment of a functional pH scale through the establishment of a set of carefully measured pH standards came through the work of R. G. Bates and co-workers at the National Bureau of Standards, beginning in the late 1930s.

Electronic instrumentation has been an important contribution of American analytical chemistry for over sixty years. The photoelectric cell permitted a revolution in colorimetric analysis, the Dubosq colorimeter being replaced first by a photoelectric col-

orimeter, then by a filter photometer, and during the 1930s by the spectrophotometer. Atomic emission spectroscopy began to become quantitative during the 1920s, first by means of visual comparison of the intensities of photographic lines of pairs of elements, one being the unknown and the other an internal standard, often the main matrix element. Later, intricate methods of varying the exposure time, such as the rotating step or log sector permitted a calibration of the photographic plate, and finally the microphotometer provided a measurement of line intensities. The direct reading atomic emission spectrometer awaited the invention of the photomultiplier tube in the mid-1940s. The polarograph, invented in Czechoslovakia in 1925, was imported to the U.S.A. until the outbreak of World War II. Meanwhile, Heyrovský had signed an agreement with E. H. Sargent Co. to permit American manufacture of an instrument under the same name if the Nejedly company in Prague could not make deliveries. Accordingly, a series of Sargent Polarographs appeared in the 1940s. Competitors, mainly Leeds and Northrup, with their Electrochemograph and Fisher, with their Elecdropode, a manually operated instrument, appeared in the late 1930s. Ralph H. Müller *et al.* described a cathode-ray polarograph in 1938.[6] A few other electronic instruments were introduced, such as a fluorometer, a conductivity meter, and a gas analysis apparatus based on thermal conductivity. Two comprehensive review articles by Ralph H. Müller, in 1940 and 1941,[7] give an interesting account of the state of analytical instrumentation just before the American entry into World War II.

THE 1940s

The first half of the decade, the wartime years, represented the beginning of massive research support by the U.S. government. The nuclear research program brought several challenges to analytical chemistry. First of all, to prepare graphite of exceptional purity required trace analysis methods of unusual sensitivity. The characterization of transuranium elements required micro methods for handling small amounts of matter, and indeed learning entirely new chemistry. Characterization of fission products required rapid and quantitative separation of rare earth elements. To follow the course of isotope enrichment, improved methods of measurement of isotope ratios were needed. All of these had to be accomplished under strict secrecy conditions, so only personnel who had gone through clearance procedures could be consulted.

Other wartime programs also brought up new problems which to a lesser extent were sequestered from open publication. The synthetic rubber program involved analysis of complex organic systems such as the emulsions used in the synthesis, and the raw materials and products. A great deal of analytical work was involved with mechanistic studies of the polymerization process. The antimalarial drug program required sensitive methods for blood plasma analysis, with the demands for sensitivity increasing as the drugs were improved. The chemical warfare program involved tests for trace quantities of chemical agents and their degradation products. These and other programs resulted in a tremendous log-jam of unpublished developments in analytical methods and instrumentation, that eventually appeared in the literature during the second half of the decade.

Most of the developments were improvements on pre-war methods, but the changes were so dramatic that the antecedents were almost unrecognizable. As an example, neutron activation analysis was known in principle before the war, but the emergence of the nuclear reactor provided so much greater neutron fluxes that the method became practicable. Likewise, ion-exchange was known long before the war, and synthetic ion-exchange resins had been introduced, but rare-earth separations had still involved thousands of recrystallizations until the wartime program. Infrared and ultraviolet spectroscopy emerged as tools of the analytical laboratory rather than specialized research instruments. Mass spectrometry developed into a quantitative organic analytical method as well as an accurate method for measuring isotope ratios.

Developments in other sciences such as electronics and solid state physics also had an impact on analytical chemistry before the end of the decade. Radar research led to high-frequency titrimetry, and the invention of the thermistor rendered practicable the old concept of the thermometric titration. Invention of the transistor led to the development of solid state electronics. The digital computer went through several stages of development in the vacuum-tube mode during the 1940s before emerging later in solid state versions.

Beginning in 1943, Walter J. Murphy of ACS Publications began to lay plans for the creation of a new journal to replace the *Analytical Edition* of *Industrial and Engineering Chemistry*. He brought in for the first time an analytical chemist, Dr. Lawrence T. Hallet, and together with the editorial advisory board they created what in effect was a new journal, *Analytical Chemistry*, to carry feature articles and advertising matter as well as research papers. The magazine section, or A pages, proved to be very successful as a source of tutorial material and informative advertising matter, the income from which helped to keep the subscription price low and thereby to stimulate a large circulation. The new journal was prepared during the last half of the decade to handle the pent-up backlog of publications, and to modernize its definition of acceptable papers.

Beginning in 1946, academic research began to expand rapidly with governmental financial support of the return to school of former soldiers, coupled with the establishment of several research support agencies. The Office of Naval Research (ONR) was

the first of these agencies, established in 1945 and soon to be followed by others. From the beginning, the ONR supported pure research without regard to possible military applications, with the expectation that the National Science Foundation (NSF) would be established for the support of pure science. In 1950, the NSF was established, at first with quite a limited budget, but with a gradual growth over the years. The important principle was established that science was to be supported on the basis of research proposals submitted by individual investigators on a competetive basis and subjected to peer review. Essentially this same system is in operation today, supplemented by special institutional and project grants.

THE 1950s TO THE PRESENT

In a 1978 symposium on the occasion of the fiftieth anniversary of the journal *Analytical Chemistry*, several authors traced the development of the journal and the science decade by decade.[8] It is clear that several factors influenced this development, including the changing demands of government and industry for analytical information, progress in other branches of chemistry and other sciences, and the availability of skilled personnel and resources in universities and in governmental and industrial laboratories.

By 1950, a new generation of Ph.D.s was entering the academic scene, bringing in the experiences of the wartime research programs. Graduate enrollments increased greatly with governmental support. New faculty positions were added to existing institutions, and new Ph.D. programs were started. Students of the academic pioneers mentioned above were training students of their own. The enormous impact of Kolthoff on American analytical chemistry is demonstrated by the fact that a listing of his Ph.D. students and successive generations of his scientific progeny up to December, 1982 included 51 first generation Ph.D.s, 310 second generation, 497 third generation, 194 in the fourth generation, 10 in the fifth, and 11 in the sixth, for a total of 1073 Ph.D. descendents. Of course the list is still growing. Other notable contributors to the pool of analytical talent were N. H. Furman, H. H. Willard and others mentioned above as prewar academic pioneers. An important post-war contribution was made by H. V. Malmstadt, who trained 62 analytical Ph.D.s between 1951 and 1982 at the University of Illinois, about 20 of whom entered teaching careers and later greatly influenced the fields of spectroscopy and analytical instrumentation.

Greatly increased funding became available for equipment, and the supply of commercial instrumentation increased rapidly. Developments in other sciences were made available to analytical chemists. For example, high-frequency electronics was largely developed in the wartime radar program but was soon the subject of analytical applications. The invention of the transistor in the late 1940s soon was to revolutionize electronic instrumentation, not only directly through the replacement of vacuum-tube circuitry by solid state technology, but indirectly through the evolution of digital computers from large institutional facilities to mini- and micro-computers that could be dedicated to a single laboratory or instrument. This evolution took place during the 1950s and 60s, so that by the 1970s, analytical instruments with built-in computers began to emerge.

Demands for analytical information proved to be a stimulus for research and development throughout the postwar period. Solid state physics gained importance with the discovery of the transistor, and with it came unprecedented demands for accurate and sensitive trace analysis. Growth of the synthetic organic chemical industry brought demands for detailed characterization of raw materials, processes, and products. Applications of clinical methods expanded greatly. During the 1960s and 70s, the growing importance of environmental chemistry provided a new stimulus for analysis of increasing detail in a wide variety of samples. Analysis not just for elements and compounds, but for different species of the same element became important, and questions of spatial distribution began to assume importance. We shall now briefly examine several subspecialties over the past four decades.

The field of electronic instrumentation in analytical chemistry received enormous stimulus during the 1960s when H. V. Malmstadt and C. G. Enke devised a new approach to teaching and research in analytical instrumentation, based on individual experimentation in a modular mode. As computer technology improved, the approach was shifted from analog to digital electronics, made available at low cost to many educational institutions. Thus, a new generation of analytical chemists well versed in electronics and computer techniques began to emerge.

Despite the increasing emphasis being given to instrumentation in the post-war period, some notable advances in chemical methods were also being made. An example is complexometry, a field pioneered by Schwarzenbach in Switzerland during the late 1940s and soon exploited by many workers throughout the world. Early contributors in the U.S.A. include Harvey Diehl, H. A. Flaschka, and C. N. Reilley. Another notable area of chemical analysis is aquametry, based on the Karl Fischer reagent for water, used for a large variety of organic functional group analyses, especially by J. R. Mitchell at DuPont. Automated titrations, thermometric analysis, kinetic methods, and spectrophotometric titrations represented modernized adaptations of time-honored quantitative reactions.

During the 1950s electroanalytical chemistry began to broaden greatly as instrumentation permitted experimentation on shorter time scales. Stable DC coupled oscilloscopes were a rarity in 1950, but became commonplace by the end of the decade,

especially through the introduction by Tektronix of a wide variety of oscilloscopes with plug-in amplifiers. Pen and ink recorders improved greatly in sensitivity and response time. Coulometry, which dates back in principle to Michael Faraday, had seen only limited applications until the invention of the electronic potentiostat by Hickling in England in 1942. In the U.S.A., controlled potential coulometry was studied by Lingane, and coulometric titrations at constant current by Swift, Furman and their students in the 1940s. Diehl at Iowa State and Taylor at NBS carried out coulometric titrations of high accuracy. Modern work has emphasized measurements at short time intervals. C. G. Enke[9] in his 1959 thesis credited D. D. DeFord with the vacuum-tube operational amplifier circuitry used in the coulometry of fractional monolayer amounts of oxide. Later developments, such as chronocoulometry,[10] have been made possible by the use of solid state electronics.

Theoretical concepts such as an understanding of electrode kinetics and of mass transport at the rotating disk electrode (developed by Levich in the U.S.S.R.) led to a great expansion in the types of electrodes and the electrochemical techniques. In particular, the development of the theory of cyclic voltammetry by Nicholson and Shain in the 1950s proved to be a great stimulus. G. C. Barker, in England, had developed the theory of pulse polarography and a commercial instrument with complex vacuum tube circuitry had been introduced, but it was R. A. Osteryoung and E. P. Parry in the 1960s who introduced a much simpler solid state circuit which was commercialized by Princeton Applied Research Corp. (PARC) to make the method analytically practical. The modern era of ion-selective electrodes started with the work of Pungor in Hungary in the 1960s. Landmark discoveries in the U.S.A. were the lanthanum fluoride single crystal sensor for fluoride, and the liquid ion-exchange membranes by Frant and Ross in 1966. Other important innovations were the silver sulfide–metal sulfide sensors for metal ions, and the composite sensors based on a glass electrode and a diffusion membrane, for hydrogen ions or other species changing the pH at the glass surface. A pioneering paper[11] by Updike and Hicks in 1967 introduced the use of immobilized enzymes, a concept developed especially by Guilbault and by Rechnitz, beginning in 1970. Rechnitz has devised a wide variety of biochemical sensors, based not only on enzyme systems, but also on antigen–antibody interactions, and sensors based on plant or animal tissues and even living organisms. A different type of membrane sensor, based on amperometry, was introduced in 1956 by L. C. Clark, who used a diffusion membrane to obtain stable, diffusion-limited electrolysis currents at stationary electrodes. The first application, for monitoring dissolved oxygen, was soon commercialized but its obscure publication delayed further exploitation of this principle. Other important electroanalytical developments during the 1980s have included chemically modified surfaces and spectroelectrochemistry using transparent electrodes.

The development of gas chromatography (GC) in England in 1952 soon stimulated the manufacture of commercial instrumentation in the U.S.A. By 1955, several competing manufacturers had commercial instruments to offer. GC had an immediate impact on analytical chemistry, especially in industry. For example, in the petroleum industry, large distillation rooms had been devoted to the separation of crude oil fractions by use of the Podbelniak column, followed by measurement of the volumes of the fractions. The GC system soon replaced such distillation rooms. Likewise, organic mass spectrometry (MS), which had been introduced during the wartime rubber program, had a serious competitor in GC. Computer developments made GC–MS practicable for routine work by the late 1960s, and complete commercial systems were available by 1970. Liquid chromatography had been overshadowed by GC through the late 1950s and 60s, but began a resurgence in the 1970s with the development of HPLC (first used as an acronym for high pressure liquid chromatography and later for high *performance* LC), which could once more compete with GC in speed and resolution and which was applicable to nonvolatile compounds. An analytical system using HPLC and involving computerized electroanalytical measurements and flow injection analysis (to be discussed in further detail below) is BAS, or Bioanalytical Systems, introduced by Peter T. Kissinger of Purdue University in the 1970s.

Until the early 1940s, spectrophotometry was still in a primitive state. A few commercial spectrophotometers operating in the visible range were available, notably a recording instrument made by GE. Both UV and IR spectrometry were still in the hands of research specialists. A landmark was the introduction of the Beckman DU quartz prism instrument in 1942.[12] This manually operated instrument saw numerous analytical applications until its manufacture was halted in 1976. In the meantime, several automated instruments appeared, including the Beckman DR, which was briefly offered in 1953, and replaced by the DK-1 in 1954. These prism instruments were later supplanted by grating instruments, which are predominant today.

IR spectrophotometry was likewise primarily a research specialty until Norman Wright at Dow[13] showed its analytical applications, by the end of 1941. Other companies active in the field were Shell and American Cyanamid. Again, the government rubber program stimulated commercial development of analytical instruments, and by late 1942, Beckman delivered its first IR-1 instrument, based on a design by Robert Brattain of Shell Development. Perkin-Elmer produced a landmark instrument, the Model 12-A, based on a design by R. Bowling Barnes of Cyanamid, and originally built in 1936. This was soon replaced by the Model 12B, a recording instru-

ment. In the meantime, the Dow group had developed the first double-beam instrument, which appeared in commercial form in 1947 as the Baird Associates instrument. Perkin-Elmer, in 1949, introduced the Model 21, a double-beam recording instrument which did much to popularize IR spectrometry as an analytical method. Beckman also introduced a recording double-beam instrument in 1949, the Model IR-3, which was ahead of its time in using over 100 vacuum tubes but was subject to maintenance problems. Finally, in 1956, the IR-4 proved to be a commercially successful progenitor of a series of modern instruments. The Perkin-Elmer Model 137, which appeared in 1957, was a low cost, bench-top model that brought IR into everyday use in many laboratories.

Infrared spectrometry was to experience another important development, FT–IR, which represents an important example of the influence of computer developments on analytical chemistry. Although the Fourier transform had long been known as a mathematical device it was not until the development of the low cost digital computer and the Fast Fourier Transform algorithm that it became practicable to use this approach in analytical instrumentation. The first application in the form of commercial instrumentation was to IR and NMR in the late 1960s, but various other applications have since been made, for example in electrochemistry and mass spectrometry.

Atomic-absorption spectrometry came of age in the late 1950s and 60s. L'vov in the U.S.S.R. had pioneered in the technique, using a carbon furnace, but the introduction of the hollow cathode lamp by Walsh in Australia in 1955 greatly stimulated use of the technique in the U.S.A., where several instrument makers came out with commercial instruments to meet the demands for trace element determinations in environmental samples, foods, and other materials. Atomic-emission spectroscopy had long remained in a quiescent state until the development of the photomultiplier tube in the late 1940s. An application was made by Alcoa to aluminum analysis, with the "Quantometer", an early version of a direct reading spectrometer. The inductively coupled plasma, or ICP, was simultaneously introduced in 1964 by Greenfield in the U.K. and Fassel in the U.S., and subsequently investigated intensively by Fassel. Being commercially available and capable of multi-element determinations of great sensitivity, ICP spectroscopy is the most important of present-day emission spectrochemical methods. Atomic-fluorescence spectroscopy was pioneered by Winefordner, beginning in the late 1950s.

No other analytical technique can rival mass spectrometry in its wide variety of approaches to analysis. It has continued a long series of modifications since its early uses for isotope ratios and organic analyses.[2] Several of these modifications could produce such large amounts of data at high speed that it was necessary to wait for the development of inexpensive, high speed computers before they could become of great importance in analytical chemistry. For example, high-resolution MS began to be used as a structure tool in organic chemistry during the 1950s, but computers were still in a primitive state at that time. During the 1960s, development of minicomputers made it practicable to process the voluminous data generated in the analysis of GC effluents, so that by the end of the decade, commercial GC–MS units were available. For LC, interfacing with MS proved to be a more serious problem because of the need for disposing of the solvent, and it was not until the 1980s that commercial instruments became available. Various versions of MS differ in the manner of sample introduction, the production of ions, and their separation and detection.

The spark-source mass spectrometer (SS–MS) goes back to Dempster in 1934, and was used primarily by physicists in the immediate post-war period when solid state physics with its demands for ultrapure solids emerged. In 1954, Hannay and Ahearn showed its general utility for trace analysis, and in 1958 commercial instruments became available. Though SS–MS proved to be applicable to a large number of elements and extremely sensitive, its limited accuracy and the complexity of the spectra have led to a decrease in its utility as other techniques have come along. More recent techniques for solids analysis include such methods as secondary-ion MS and ion microprobe MS, which are primarily surface analysis techniques but permit depth profiling as well.

The time-of-flight MS was introduced as early as 1948 by Cameron and Eggers at Oak Ridge, and became commercially available from Bendix in 1955. It found analytical applications in situations requiring rapid response, as in shock-wave research. The quadrupole MS originated from high-energy particle accelerators and was introduced as a mass spectrometer in Germany in 1955 and commercialized in the U.S.A. in the late 1950s. The compact size lent itself to many analytical applications, culminating in the "triple quad" or tandem MS/MS/MS system in which a middle section permits reactions of selected ion fragments to be examined by the third MS. This system was originated by Enke and Yost in the late 1970s and quickly commercialized by Finnigan for analysis of complex mixtures. When coupled with GC or LC and operated under computer control, this system has emerged as a powerful technique for trace organic analysis. During the 1970s and 80s quadrupole MS has been coupled with a large variety of ultrahigh vacuum spectroscopy techniques for the examination of species emitted from surfaces upon exposure to beams of electrons, photons, ions or molecules.

Ion cyclotron resonance mass spectrometry or ICR–MS was described as early as 1965, but analytical applications did not appear until the fundamental chemical studies of Baldeschwieler led to commercial instruments in the 1970s. This is another

example of the importance of the microcomputer, because with the introduction of the FT version by Nicolet the method finally assumed analytical importance.

X-Ray emission spectroscopy can be traced back to Moseley in England in 1913, and to de Broglie in France, who in 1914 observed the phenomenon of X-ray fluorescence from samples outside the X-ray tube, but it did not emerge as an important analytical technique until 1948, when H. Friedman and L. S. Birks at the U.S. Naval Research Laboratory used it for trace analysis.[2] Commercial instrumentation soon followed. The electron microprobe was devised in the late 1940s independently in the U.S.A., France, and the U.S.S.R. A landmark was the publication of the Ph.D. thesis of Castaing from the University of Paris in 1951, but it was not until the middle 1950s that improved instruments were developed in several countries. An important advance came in the middle 1960s when energy-dispersive X-ray spectroscopy with the use of a silicon crystal, and later, of the Li-drifted Si detector, was introduced by F. S. Goulding and co-workers at Berkeley. This detector rendered possible the use of the scanning electron microscope to determine surface elemental distribution for a wide variety of samples.

Photoelectron spectroscopy originated as a surface analytical technique in Sweden in the late 1960s. The monograph of Siegbahn in 1967 stimulated world-wide interest in X-ray photoelectron spectroscopy (XPS or ESCA). An early American investigator in the field was David M. Hercules. After the introduction of commercial instrumentation in 1970 many investigators entered the field. The current trend has been to incorporate a number of high-vacuum spectroscopy techniques into a single instrument to permit excitation by photons, electrons, or ion beams, and observation of various types of output signals (photons, ions, or electrons). From the analytical viewpoint, single-purpose instruments continue to thrive because they can be designed for multiple sample handling and quicker throughput.

Development of the laser in the 1960s has led to a wide variety of analytical applications. The early application to the laser microprobe as a sampling device for atomic emission was soon supplanted by other probe methods. Later applications have been made to virtually all forms of spectrochemical analysis from atomic absorption, emission and fluorescence to molecular absorption, fluorescence, and phosphorescence. Perhaps the ultimate in detection limits was reached in 1976 when J. P. Young and co-workers at Oak Ridge National Laboratory used resonance ionization spectroscopy for the detection of a single atom.[14]

A good example of the impact of lasers is in Raman spectroscopy, which had been discovered in 1928 but had not received appreciable analytical application even though R. F. Stamm of Cyanamid had described an instrument and discussed possible analytical applications in 1945. After S. P. S. Porto and D. L. Wood reported on the use of the pulsed ruby laser in 1962, commercial instrumentation soon became available. By 1964, the double monochromator was used to enhance sensitivity by elimination of stray light. More recent advances have further improved sensitivity by using multichannel detectors to provide time-resolved spectra. In 1984, Asher pioneered in the application of resonance Raman spectrometry in trace analysis for individual polynuclear aromatic hydrocarbons in mixtures down to levels of 20 ng/g. Another enhancement technique is SERS, or surface-enhanced Raman spectroscopy. In 1974, Fleischmann *et al.* in England[15] had observed unexpectedly intense Raman bands for pyridine at a silver electrode and had attributed the effect to surface roughness. Van Duyne *et al.* at Northwestern University[16] found in 1977 that the effect increased with smoother electrodes and introduced the term SERS to describe the huge increase (by a factor of the order of 10^6) for adsorbed species. The large enhancement was independently observed by Albrecht and Creighton in the U.K.[17] A great many publications on the subject have since appeared.

RECENT TRENDS

Chemometrics involves the use of mathematical and statistical techniques in data acquisition, storage, and interpretation. The term was introduced by Bruce R. Kowalski[18] to embody the growing body of mathematical techniques that with the development of inexpensive high-speed computers have become practical to employ in the various stages of the analytical process. Mention has been made above of Fourier transform techniques in various forms of instrumental analysis. However, regardless of the measurement technique, chemometrics is concerned with the statistics of sampling, experimental design, optimization, pattern recognition, correlation of information and the like. It is clear that this field is in its infancy and will influence all aspects of analysis from pure research to routine applications. It may be safely projected that the use of chemometric techniques such as pattern recognition will be increasingly used with automated analytical systems for diagnostic purposes in the medical field.

Automation of analytical methods has been advancing in several directions, beginning in the late 1940s. Elemental organic microanalysis has been automated, primarily through pioneering work by W. Merz in Germany, and others. Commercial instrument development in the USA as well as in other countries was well developed by the 1960s.

The large sample throughput demanded in hospitals and clinical laboratories provided the impetus for development of an automated system for the analysis of solutions. L. T. Skeggs[19] of the Veterans's Administration Hospital in Cleveland applied a system of segmented flow in plastic tubes to perform many

routine operations of sample preparation and measurement, culminating in 1957 with the introduction of the AutoAnalyzer® by Technicon. This system has since been gradually extended and refined with the incorporation of computer control and data output. A different system, based on the use of centrifugation, was developed by Norman Anderson of Oak Ridge National Laboratory during the 1960s. Since the introduction of these pioneer instruments, versatile discrete (batch) analyzers have been developed with random access capabilities to permit the operator to select the analyte(s) to be measured.

Another important clinical analysis technique is immunoassay, using specific antigen–antibody interactions for measuring antigens. This approach, which involves the use of a tagged antigen to compete with analyte antigen for binding sites on the antibody, was originated in 1962 by Berson and Yalow,[20] who used radioimmunoassay to determine small quantities of insulin. In 1977, after Berson's death, Rose Yalow was awarded the Nobel prize in physiology for this development. Tagging agents other than radioisotopes, such as fluorophores or enzymes, were later introduced. By the late 1960s and early 1970s the immunoassay technique had emerged as a significant and growing approach to clinical analysis.

Another approach to automatic analysis is to use a continuous rather than segmented flow of liquid and to inject a series of samples, which are analyzed downstream. HPLC of course uses a continuous stream, but the emphasis is on separation of a mixture into its components. In flow injection analysis, or FIA, the objective is to determine a single component in a series of injected samples. The origins of the approach are somewhat controversial, depending on the emphasis given to its various aspects. The earliest report of the use of an injected sample followed by downstream detection seems to be that of Pungor *et al.* in Hungary in 1970;[21] a voltammetric detector was used. The most detailed and systematic studies are those of Růžička and Hansen in Denmark. A patent application was filed in 1974,[22] followed by a classic series of papers beginning in 1975,[23] in which the term "flow injection analysis" was introduced. In the meantime, Bergmeyer and Hagen in Germany[24] had described a system of enzymatic analysis based on an immobilized enzyme and a continuously flowing buffer solution into which samples were introduced. American contributions began in 1972 when White and Fitzgerald[25] used a continuously flowing solution with an injected sample, to determine ascorbic acid. In 1973, Frantz and Hare[26] described in an internal report a system in which a sample was inserted into an unsegmented stream by breakage of a capillary of defined volume. Stewart, Beecher and Hare presented papers at national meetings in 1974[27] describing the automated analysis of discrete samples in unsegmented continuously flowing streams.

Process stream analysis, the on-line monitoring of the quality of industrial streams, has existed in primitive forms for a long time, but starting in the late 1950s with the development of minicomputers, and especially in the 1970s with the advent of the microprocessor, it has rapidly increased in importance. Today, an extensive array of digital analysis systems and programmable controllers is available.[28] Many of the modern analytical methods are being used for on-line analysis, including GC, LC, MS, absorption and emission spectrometry, electrochemical detection systems, and even techniques such as X-ray emission. The microprocessor has enabled the introduction of chemometric techniques such as internal self-diagnostics and multi-analyzer comparisons. It may be safely predicted that process analyzer technology will continue to develop in importance and complexity.

Robotics is another product of the computer age that is beginning to spread from the factory to the laboratory. It is interesting that many of the operations of classical analysis, such as sample dissolution, chemical pretreatment, extraction, and titration lend themselves to robotics, so many of the time-honored chemical methods may survive for a long time in competition with the purely instrumental approaches.

TEACHING OF ANALYTICAL CHEMISTRY IN THE U.S.

ROYCE W. MURRAY
Kenan Laboratories of Chemistry, University of North Carolina, Chapel Hill, NC 27599-3290, U.S.A.

(*Received* 4 *May* 1988. *Accepted* 28 *July* 1988)

Analytical chemistry has long been, and continues to be, an important component of the undergraduate Bachelor of Science Chemistry degree in most colleges and universities in the U.S. It typically occupies the position in the curriculum where the student first encounters lecture and laboratory instruction in quantitative measurements of chemical materials, and sometimes is the student's first quantitative experimentation of any form. The skills and attitudes developed in this course in quantitative measurements are underpinnings of subsequent stages of the curriculum, including experimental physical chemistry.

Analytical chemistry plays a second important role by introducing the undergraduate student to the principles and applications of chemical transducers. I will refer to chemical transducers in this article in the sense of devices and means by which chemists convert chemical structural and compositional information into recordable electrical and optical phenomena, *e.g.*, a molecular absorption spectrum, a mass spectrum, a cyclic voltammogram, a chromatogram, a pH reading, or a change in molecular conductivity. The chemist's transducer is in many ways an interface between chemistry and physics in the student's training, albeit not often mentioned as such by the professor (I use "professor" in the U.S. sense: a teacher). Chemical transducers are pervasive in instruments found in undergraduate organic and physical chemistry and biochemistry laboratory courses. These instruments are often used on an empirical basis, preceding explanation of their principles in an analytical course in the terminal year of the curriculum. Chemical transducers are employed by nearly all chemists who continue further study and/or pursue a professional career in science. Hence, an appreciation of chemical transducers is perhaps the broadest and most lasting contribution that analytical chemistry plays in undergraduate education in the U.S.

Analytical chemistry also plays an important role in Bachelor of Science and Bachelor of Arts undergraduate degree programs undertaken by students aiming at careers in the health sciences (medicine, dentistry, pharmacy, nursing, public health). Individuals in health science and health care professions frequently need to seek or use research or clinical diagnostic information derived from analytical chemical experiments and tests. An appreciation, even if only in general terms, of the basis and limitations of such tests, is critical in the use of the scientific approach needed in many elements of the health science and health care professions. An understanding of chemical transducers, and particularly of their limitations, could plausibly be a component of Bachelor of Engineering curricula, but with the exception of Chemical Engineering this is seldom the case.

The principal thrust of this article will be the history of the analytical chemisty component of the modern B.S. chemistry curriculum offered in the U.S. to those students planning professional careers in chemistry. A historical perspective often yields a better understanding of the present; since the elements of older approaches to chemical education are usually strongly filtered by events of subsequent years, the most essential tenets are those that survive. I will begin my "history" in the 1950s, since this was the beginning both of a period of great change in analytical chemistry, and of my own professional exposure to analytical chemistry.

Any article on chemical education, especially one with a historical intent, must come with caveats. The most important here is that there is considerable (for better or worse) diversity in the U.S. undergraduate educational system. B.S. chemistry degrees are offered by four-year colleges where the faculty, and hence also the students, often have little if any research involvement, and by large universities where the faculty are deeply committed to chemical research and where undergraduates meet graduate students who serve as teachers as well as role models. There is a continuum of institutions between these extreme types. Because of this diversity, I will inevitably but unintentionally miss elements of analytical chemistry as taught in some institutions. My second caveat is that, to avoid an entirely anecdotal approach, I will engage in a "textbook archaeology", using the contents of textbooks in analytical chemistry published at different points in time, to document various points of emphasis in analytical chemistry as they were taught on a national scale. Of course many professors, including probably the pioneer teachers, choose to use their own notes for their lectures rather

Table 1. Synopsis of contents of selected analytical chemistry textbooks for beginning courses

I. M. Kolthoff and E. B. Sandell, *Quantitative Inorganic Analysis*,[2] 3rd Ed.
- Gravimetric analysis (392 pp): mass action laws, solubility, separations, formation of precipitates, theory of electroanalysis, detailed examples
- Volumetric analysis (197 pp): principles and applications of acid–base, precipitation, complexation, and reduction-oxidation reactions and titrations, electrometric titrations
- Physicochemical methods (54 pp): colorimetry, spectrophotometry

R. B. Fischer and D. G. Peters, *Quantitative Chemical Analysis*[3]
- Analytical data (38 pp): precision, accuracy, statistics
- Chemical equilibria (59 pp): kinetic and thermodynamic concepts, calculations
- Precipitation analysis (51 pp): nucleation, growth, purity, homogeneous solution precipitation
- Separations (44 pp): extraction, chromatography
- Titrations (201 pp): acid–base, precipitation, complexation
- Redox principles (161 pp): electrochemical cells, redox reactions and titrations, indicators
- Radiant energy methods (81 pp): electromagnetic radiation, absorption and its laws, instruments
- Electrochemical methods (137 pp): potentiometry, pH, potentiometric titrations, conductometry, electrolysis cells, coulometry, polarography

D. A. Skoog and D. M. West, *Fundamentals of Analytical Chemistry*,[4] 4th Ed.
- Analytical data (51 pp): precision, accuracy, errors
- Gravimetric analysis (65 pp): properties of precipitates, solubility, separations
- Titrimetric analysis (198 pp): precipitation, acid–base, complexometric, redox reactions, equilibria, and titrations
- Potentiometric methods (80 pp): electrochemical cells, titrations, reference and indicator electrodes
- Other electroanalytical methods (44 pp): current flow, electrogravimetry, coulometry, polarography
- Spectroscopy (119 pp): electromagnetic radiation, absorption laws and instruments, atomic absorption and emission, molecular absorption
- Separations (61 pp): precipitation, extraction, distillation, chromatography

than the available textbooks, and in any case, most would teach selected sections, not the whole, of any given textbook in a course. However, I have found little discord between my own recollections and impressions of what analytical chemistry was generally taught in the past and my excursion into textbook archaeology.

Stating what analytical chemistry was (and is) taught to the chemistry undergraduate would be incomplete without an understanding of the forces and events shaping the curricular content. A second element of this article will thus be to consider some of these influential factors and their action on the past, present and future of analytical chemistry teaching in the U.S.

HISTORICAL CONTENT OF UNDERGRADUATE ANALYTICAL CHEMISTRY COURSES, FROM THE 1950s

The typical chemistry curriculum, from the 1950s to today, has contained an "introductory" and an "advanced" course.* In the early 1950s these two courses were commonly presented in sequence, in the sophomore (second) year. As more (and more sophisticated) chemical phenomena came to be exploited as chemical transducers in instruments, the advanced course was moved to the senior (fourth) year to be taught (at first, in the 1960s) in parallel with or (more commonly today) following physical chemistry. The more advanced material was at first termed "physicochemical analysis", and later "instrumental analysis"; the latter name continues to be common today.

Many variations of this two-course pattern have been offered. Examples include a sophomore level intermediate course with an advanced course in the senior year (common in the 1950s and 1960s), an introductory course as the laboratory (practical course) for freshman (general, first year) chemistry, combination of advanced analytical chemistry with physical chemistry courses (especially in the laboratories), and presenting the introductory and advanced courses as elementary instrumental analysis in the sophomore year (done at my institution through the 1970s and early 1980s). The diversity of educational approaches that can be found includes important innovations in teaching analytical chemistry, but regrettably sometimes simply reflects a particular institution's faculty disinterest in analytical chemistry.

The content of "introductory analytical chemistry" courses in the 1950s, 1960s, and 1980s is exemplified by summaries (Table 1) of the contents of textbooks of those vintages. The textbook by Kolthoff and Sandell is notable on account of the dedication of the Honor Issue of Talanta and for its widespread use before instrumental methods came into great importance. The Kolthoff and Sandell texts were influential in the 1930–1950 period by presenting the basic chemical reactivity and physical aspects underlying titrimetric and gravimetric analysis, instead of empirically discussing the technique and procedures

*In U.S. colleges and universities, there is no universal standard for the duration of a "course". A typical undergraduate year would be two semesters of instruction, starting in September and ending in May, with 30–36 credit hours of courses distributed among the chemistry, mathematics, english, history, etc., requirements for the degree sought. A typical 4–5 credit hour analytical chemistry semester course would include 13 weeks of instruction (three 1-hour lectures and 4–6 hours in the laboratory) and a 2-week final examination period.

for quantitative analysis. Gravimetric and titrimetric analyses were the dominant topics of both beginning and advanced courses before the 1950–1960 period.

The two post-1960s texts in Table 1 show that elementary aspects of spectrophotometry, separations, and electrochemistry became incorporated into teaching materials used for beginning courses in analytical chemistry, mainly at the expense of time devoted to gravimetric analysis. From the text pagination it would appear that the emphasis on titrimetric topics has remained relatively unchanged over a 40-year time span, but this is misleading since the more modern texts have increasingly incorporated basic explanatory material into the titrimetric sections, including quantitative treatments of chemical equilibria, modern chemical viewpoints of reactivity (particularly co-ordination chemistry and nonaqueous acid–base chemistry), and use of electrode potentials (redox potentiometry, glass electrodes) as transducers to detect titration end-points. In fact, I see the emphasis on titrimetric material in modern introductory texts as having shifted from the use of titration as a means of chemical analysis to use of titration reactions and end-point detection to illustrate the fundamentals of phenomena and transducers such as equilibria, spectrophotometry, coordination chemistry and electrochemistry.

The really big change in undergraduate analytical chemistry occurred in the 1950s and early 1960s (depending on the institution), with the appearance of a wave of new chemical transducers and the instruments into which they were incorporated. Some new textbooks appearing in this period continued the trend of the Kolthoff and Sandell texts by adopting a very basic physicochemical approach to gravimetric and titrimetric analysis, as in the Laitinen text (Table 2). Others, such as the Delahay and Ewing texts (Table 2) and that by Willard, Merritt and Dean,[1] focused on the wave of chemical transducers and adopted a course plan for the advanced course that contained no further gravimetric or titrimetric material but was entirely devoted to instrumental forms of analysis. The latter format for the advanced course has become the more widely adopted, and has in my opinion both reflected and promulgated the enormous transformation in analytical chemistry in the U.S. that continues today. I refer to the attention, both in the frontiers of research in analytical chemistry and in the typical senior level instrumental analysis course, to understanding and teaching the fundamental principles behind chemical transducers and not just their exploitation to produce a chemical measurement. This has been a characteristic that, I believe, has given teaching and research in analytical chemistry in the U.S. its leadership role in the world.

Study of the textbooks in Table 2 reveals useful insights into how the advanced course in analytical chemistry has changed since the emphasis on instrumental analysis began in the 1950s. The material devoted to spectroscopy of various kinds has expanded at a steady pace, not surprisingly in view of the considerable advances that have been made in the electronic absorption and emission phenomena, both molecular and atomic, that can be related to quantities of chemical materials. Structurally sensitive techniques such as NMR, ESR, infrared and Raman spectrometry are also represented in the advanced teaching materials but the emphasis, in analytical chemistry textbooks, on determining chemical structures has been much less than that on determining chemical quantities. Chemical structure determination has not been wholeheartedly adopted by U.S. analytical chemists as a province of analytical chemical education, partly of course because it is also a significant part and need of organic and inorganic chemistry. In fact, where in the chemistry curriculum, and to what depth, methods for chemical structure determination are taught, varies a great deal among U.S. colleges and universities today.

Chemical separations are another area where great changes have occurred in methodology, in transducers available as detectors, and in the chemical materials that have been devised for the differential chemical and physical interactions that produce separations. The texts in Table 2 show a corresponding increase in the amount of descriptive material dealing with separations, especially the chromatographic methods. Certainly the chemical basis of partition and adsorption chromatography has become quite broad, and the power of chromatographic separations has had an enormous impact on chemistry as a whole. If anything, then, it is surprising that the attention given to separation chemistry and methods in modern texts has not grown more than it has.

Electrochemical topics, in terms of the basic concepts of electrode potentials and the time-dependence of electrolysis currents, were already well established by the mid-1960s, so the principles presented in modern texts, with the addition of those of the pulse polarography methods, are not greatly different from those found in the 1960 Delahay text. The number of pages typically devoted to electrochemical topics likewise has not changed greatly since then. The areas of great recent growth in electrochemistry, including exploration of electron-transfer reactions, the chemical modification of surfaces, electrocatalysis, and applications to bioanalytical chemistry, have not yet found their way into the instrumental analysis texts, but undoubtedly will over time.

The Ewing text (Table 2) represents the introduction of elementary electronics into undergraduate chemistry material, which has now become an important part of many advanced courses in analytical chemistry. The more recent texts furthermore contain sections dealing with automation in chemical analysis. These items in the texts reflect the realization, or more properly the opinion, that the analytical chemists of tomorrow will play a role in the design of

chemical instruments for analysis, and that the undergraduate should appreciate the electronics principles behind the control of a chemical transducer and the readout of chemical information from it. This has been a very difficult goal to achieve for our students, because of the great speed with which analog electronics changed in the 1950s and 1960s and digital electronics in the 1970s and 1980s. An unresolved issue among analytical chemists is whether it is any longer practical to attempt to educate chemistry students in the electronics of chemical instrumentation, given the need for lecture time devoted to understanding the basics of how chemical transducers work to reveal chemical quantity and structure.

It is apparent, in comparing instrumental analysis textbooks of today with the earlier ones, that both the level of sophistication and the quantity (in pagination) of material available to the teacher of an advanced analytical chemistry course has grown enormously. It is not clear to me whether this

Table 2. Synopsis of contents of selected analytical chemistry textbooks for advanced courses

P. Delahay, *Instrumental Analysis*[5]
- Electrochemical potentials (53 pp): cells, Nernst equation, reduction–oxidation reactions, reference electrodes, voltage measurements, potentiometry, pH, titrations using acid–base, precipitation, complexometric, redox reactions
- Polarography, voltammetry, electrolysis (79 pp): mass transfer, reversible and irreversible reactions, dropping mercury and rotated electrodes, voltammetric titrations, electrogravimetry, electrolysis at controlled potential, coulometry
- Conductometry and high frequency methods (18 pp)
- Emission spectroscopy (34 pp): spectrographs, sources, flames, qualitative and quantitative analysis
- Spectrometry (55 pp): absorption and laws, spectrophotometers, fluorometers, infrared, fluorescence, turbidimetry
- Raman spectroscopy (10 pp)
- X-Ray methods (21 pp): emission and absorption
- Mass spectrometry (15 pp)
- Nuclear methods (31 pp): decay counting, activation analysis

G. W. Ewing, *Instrumental Methods of Chemical Analysis*,[6] 2nd Ed.
- Spectroscopy (228 pp): UV, visible, and IR absorption, fluorescence, emission, and flame spectroscopy, X-rays, polarimetry, refractivity
- Electrochemistry (120 pp): potentiometry, polarography, voltammetry, electrodeposition, coulometry, conductivity
- Radioactivity (26 pp)
- Mass spectrometry (24 pp)
- NMR (16 pp)
- Separations (77 pp): extraction, chromatography
- Thermal methods (16 pp)
- Electronic circuitry (44 pp)

H. A. Laitinen, *Chemical Analysis*,[7]
- Chemical equilibria (17 pp): activity, Debye–Hückel
- Acids and bases (85 pp): aqueous reactions, pH, equilibria calculations, buffers, indicators, non-aqueous reactions, titrations
- Precipitation (111 pp): solubility, complexing agents, formation, nucleation, growth, aging, colloids, electrical double layer, contamination, thermal decomposition, titrations
- Complex formation titrations (26 pp)
- Organic reagents for precipitation, extraction (29 pp)
- Electrochemical potentials, separations (50 pp): cells, Nernst equation, equilibrium constants, complexation, irreversible reactions, electrolysis
- Oxidation–reduction reactions (126 pp): titration curve theory, indicators, reagents—permanganate, cerium (IV), iodine, oxyhalogen compounds
- Reaction rates in chemical analysis (20 pp)
- Separation methods (65 pp): distillation, extraction, chromatography
- Statistics in analysis (42 pp): errors, normal law of error, tests, regression analysis

D. A. Skoog, *Principles of Instrumental Analysis*,[8] 3rd Ed.
- Electronic circuitry (60 pp): semiconductors, operational amplifiers, microcomputers, microprocessors
- Spectroscopy (412 pp): instrumentation, molecular and atomic absorption and emission spectroscopy, IR and Raman, NMR, X-ray and electron spectroscopy
- Electrochemistry (146 pp): potentiometry, coulometry, voltammetry, polarography, conductance
- Radiochemical methods (21 pp)
- Mass spectrometry (44 pp)
- Thermal methods (14 pp)
- Separations (124 pp): principles of, gas, liquid, planar chromatography
- Automated analysis (29 pp)

G. D. Christian and J. E. O'Reilly (eds.), *Instrumental Analysis*,[10] 2nd Ed.
- Electrochemistry (144 pp): potentiometry, voltammetry, polarography, coulometry, conductance
- Spectroscopy (332 pp): molecular UV, visible, IR, Raman, fluorescence, phosphorescence spectroscopy, atomic absorption, emission, fluorescence spectrometry, NMR, ESR, X-ray and electron spectroscopy
- Mass spectrometry (47 pp)
- Thermal methods (37 pp)
- Kinetic methods (34 pp)
- Separations (127 pp): extraction, liquid and gas chromatography
- Electronics (88 pp): analog circuitry, digital electronics, microcomputers
- Automated analysis (41 pp)

broadening scope of topics in senior level instrumental analysis courses is uniformly utilized by those who teach such courses; probably it is not. It is, of course, an advantage for the teacher to have ample material to choose from. At the same time, the increase in the length of instrumental analysis textbooks is not as unrealistic as it might at first seem, since as our understanding of various spectroscopic, separational, and electrochemical topics improves through research in these fields, our ability to explain the basics of these subjects in texts to student neophytes in a pedagogically effective way also improves. This pedagogical improvement is in fact reflected in most modern textbooks in instrumental analysis, and we can teach our students more per unit time as a result. Nonetheless, I believe most analytical chemistry professors would agree that the present undergraduate instrumental analysis courses are bursting at the seams with information about an expanded world of chemical transducers and the instruments within which they function.

FACTORS INFLUENTIAL IN ANALYTICAL TEACHING

What are the factors and forces that mold an educational curriculum over time? A historical review of the teaching of analytical chemistry is incomplete without considering what these have been, and are. Certainly the most influential factors are (*a*) the analytical chemistry professors, especially their previous training, and attitude toward research, and (*b*) the existence of a vigorous research community in analytical chemistry that enhances the intellectual content of the discipline by inquiring into new means of chemical measurement and the fundamentals on which such measurements can be based. In the 1950s, a vigorous research community did exist in analytical chemistry, and indeed its frontiers were in a ferment of change. In a companion article in this issue, Herbert Laitinen describes the course of analytical chemistry research, especially the surge of new work published after the second World War. Many of these new developments involved chemical transducers (in the sense used here) and formed the basis for what we now call "instrumental analysis". It remained then for the professors of the 1950s and 1960s to distill such research developments and teach them to undergraduate students, and this process resulted in the advanced course in instrumental analysis discussed above.

In a lecture at the 1965 National American Chemical Society meeting, on the occasion of his receiving the Division of Analytical Chemistry Fisher Award, my late colleague Charles N. Reilley observed that analytical chemistry professors should teach their students about the areas of current research in analytical chemistry. ("Analytical chemistry is what analytical chemists do.") Some of today's students will be tomorrow's scholars of our discipline, and they should have the benefits of the current scholars' thinking about emerging fundamentals and the opportunities for new chemical measurements. Many other professors shared this outlook on analytical chemistry education with Professor Reilley, and this attitude on the part of the publishing scholars of analytical chemistry in the 1950s and 1960s played an important role in creating and sustaining the instrumental analysis course. The emerging results of current research continue to be reflected in the content of instrumental analysis courses, through choices by individual professors and eventually by authors in their textbooks as shown by the samples in Table 2. This combined effect, the willingness of analytical chemistry professors to incorporate new topics into analytical chemistry as they are created by research, and the existence of a fundamentally oriented, vigorous research community in analytical chemistry, was undoubtedly the most important factor in the evolution of the instrumental analysis course from an advanced gravimetric–titrimetric analysis course. Indeed, this is a process that is fundamental in the evolution of chemistry as a whole.

The authors of textbooks, by their choice of topics and especially by the blend of basic and applied material chosen for presentation, also have a great influence in analytical teaching, particularly outside the research centers of analytical chemistry. Sometimes the time lapse between the appearance of new chemical transducer concepts in the research literature and their appearance in textbooks seems too long. For example, many new analytical methods such as microprobe analysis by electron and particle spectroscopy, chemically modified electrodes, single atom or molecular characterization by scanning tunnelling microscopy, and fiber optic formats for analytical spectroscopy, are not adequately represented in texts today, and it is time that authors should decide to include them. On the whole, however, the discipline of analytical chemistry has been well served by those who prepare texts for instrumental analysis courses.

Teaching of the elementary aspects of spectrophotometry, electrochemistry, and separation methods, as noted above, shifted fairly rapidly into the introductory level analytical chemistry course as the advanced course took on an instrumental analysis orientation. Though this occurred as early as the 1960s, there has since been only slow change in the amount of such modern material taught in the introductory course. This is in contrast to the enormous changes and advances that have been introduced by research in chemical transducers, and consequently in the instrumental analysis course itself. This naturally evokes the question: is the content of the current introductory analytical course "optimum" with respect both to pedagogy and to other elements of the chemistry curriculum, or is it in fact "non-optimum", with desired changes impeded by competing or conflicting factors? I believe it likely that the latter has been the case for some time. I believe it is a

pedagogically correct step, and one consistent with the real needs of the student of chemistry, to further enhance the emphasis on instrumental analysis in the introductory level analytical course. Certainly we understand enough about chemical transducers to teach the basic features and uses of many more of them than are discussed in most current introductory courses and texts. Certainly the ensuing laboratory courses (practical courses) in organic, inorganic, and physical chemistry would profit from greater familiarity of their students with chemical measurement science. And certainly the level of sophistication possible in the advanced analytical chemistry course could be enhanced. I am admittedly influenced in this point of view by the demonstrated success of our program at the University of North Carolina in teaching an introductory level instrumental analysis course in the second year of the curriculum, following some titrimetric analysis experiences in the general chemistry laboratory.

Three factors seem obvious retardants to a move of more chemical transducer teaching materials to the sophomore level introductory course. They are the equipment needs of the associated laboratory course, the content of the preceding course in general chemistry, and the problem of what to remove from the introductory course to make room for more serious attention to chemical transducers. None of these factors is trivial.

The cost, complexity, and reliability of the equipment required for analytical chemistry laboratory courses that deal with the applications of chemical transducers are important practical factors that affects what analytical chemistry is taught to the undergraduate chemistry student in both lecture and laboratory. Typically the institutional budget for equipment for undergraduate laboratory courses is meager (albeit highly variable from institution to institution), and also has to satisfy the competing needs of other laboratory courses in the curriculum. Because the introductory analytical course usually has a large student population and the young students are less able to effectively use (and not abuse) complex instruments, the content of this course is quite sensitive to the cost and complexity of available instruments. I believe this is a major reason why progress in introducing into the introductory course laboratory analytical experiments that are based on electronic instruments has been relatively slow over the years. The progress that has been made may have depended as much on the availability of inexpensive "teaching equipment" as on institutional choices. The emergence of commercial vendors who aim at this market has had a salutary effect in many instances and probably on chemical education in general. Readable textbooks on electronics for chemists[11] and modular laboratory instruments such as those designed at the University of Illinois by Malmstadt and co-workers played significant roles in early commercialization of "teaching equipment". Also, advances in materials have been important; the capacity to fabricate, at lower cost, diode-array detectors, replica gratings for spectrometers, polymers for ion-exchange and gel-permeation chromatography, finely divided particles for high-resolution liquid chromatography, and glassy carbon and special glasses for electrodes has served to make many analytical instruments of moderate cost and complexity available for undergraduate instruction. Nonetheless, if the content of an introductory level analytical course is dictated by financial considerations, then further evolution of the course may rest as much on the priorities of the college or university faculty in expenditure as on the intellectual progress in the field or the contents of textbooks.

The general chemistry course content should, in principle, introduce the student to the basic ideas of chemistry and provide a foundation for subsequent courses in chemistry. The typical general chemistry course of today gives the student a good education in the important physical principles of chemistry, but all too often a course is less effective in introducing the student to chemical reactivity, equilibrium, and structure. Students can leave a general chemistry course without knowing the structure of a sulfate ion and why that ion is a weaker base than, say, acetate. In this context it has to be recognized that the introductory level analytical chemistry course must teach its students, at least to some extent, the essential background chemistry of many chemicals that appear as reagents, components of illustrative chemical equilibria, spectrophotometric chromophores, redox ions in electrochemical cells, liquid phases in gas chromatographic columns, *etc.* This is necessarily done empirically rather than by systematic development of a chemical background, and even then requires a significant portion of the course's lecture time. Thus, changes in the content of the introductory analytical course require careful consideration of the consequences of developing the necessary chemical background to discussion of a newly introduced chemical transducer. The message here is clearly that enhancing the chemical content of general chemistry enhances the use of chemical transducer material in the subsequent analytical course.

Finally, increasing the chemical transducer component of the introductory level analytical course obviously changes the extent to which other material is taught. I believe this is a less serious problem than it might at first seem. Aspects of titrimetric reactions in chemistry continue to be important elements of a chemist's education, but as the trend has been to teach these as a vehicle for instruction in other basic concepts, they can obviously include the use of additional chemical transducers for equivalence-point detection.

I should not end this discussion of influential factors without mentioning the important role of the American Chemical Society in chemical education in the U.S. Through the Committee on Professional

Training (CPT), the ACS establishes requirements for the components of a professional degree program in chemistry. This committee consists of chemical educators from all branches of chemistry, and as such serves also to ensure that undergraduate chemists are educated broadly and that attention is given to emerging aspects of chemistry. The national move toward establishment of the instrumental analysis course as an upper level course (with adequate physical chemistry courses as support) was greatly aided by inclusion of the course in the CPT guidelines in the 1960s. Today, chemistry as a discipline is changing in ways that make inclusion of more biological chemistry and materials chemistry a probable component of CPT guidelines of the future. Those who believe in the importance of the introductory and instrumental analysis courses in analytical chemistry in an undergraduate chemist's education must be prepared to both defend and mold these courses in the future, to accommodate the needs of teaching our students about other important new directions of chemical science.

(*Received* 4 *May* 1988. *Accepted* 14 *September* 1988)

Summary—The theory of nonlinear chromatography has been advanced by the incorporation of recent results obtained by the theory of partial differential equations. The system of equations of the ideal model has been solved analytically in the case of a single component for which the equilibrium isotherm between the mobile and the stationary phases is given by a Langmuir equation. A series of computer programs has been written which permits the calculation of numerical solutions of the semi-ideal model. The properties of the solutions obtained are described and discussed for a one-component system (profile of high concentration bands of a pure compound eluted by a pure solvent), several two-component systems (elution of a pure compound band by a binary mobile phase, separation of a binary mixture eluted by a pure mobile phase), and three-component systems (separation of a binary mixture eluted by a binary solvent, displacement and separation of a binary mixture). Experimental results are reported which validate the conclusions derived from the numerical integration of the model. The conclusions of the work apply to all high-performance chromatographic procedures, *i.e.*, to those where the kinetics of mass transfer are fast enough for the mobile and stationary phases always to be near equilibrium. More specifically, the contribution from the kinetics of the retention mechanism to the mass transfer resistance must itself be negligible. This clearly excludes affinity chromatography.

The rapid development of preparative liquid chromatography during recent years has been spurred by the needs of the pharmaceutical and biotechnological industries, which require powerful separation processes for the extraction and purification of the drug intermediates prepared by organic synthesis and the products generated by cloned microorganisms. Compared to classical procedures for the development of analytical methods in chromatography, preparative chromatographic procedures require a completely different approach, and considerable changes in implementation. Analytical chromatography aims at collecting information regarding the composition of a mixture. The goal of preparative chromatography is the production of significant amounts of pure compounds. The ways of handling material and information differ greatly.

A minimum degree of resolution between two bands is required in order for the analyst to be able to collect the information desired regarding the peaks of the components of the analyte (peak retention times and areas). The deconvolution of complex chromatograms has never been very successful in quantitative chromatography.[1] In contrast, it is possible to collect large amounts of highly pure compounds from poorly resolved band systems, and to do so with a good yield. It suffices to discard the intermediate fractions which contain undesired mixtures.

While in analytical applications of chromatography the emphasis is on analysis time and resolution, in preparative applications it should be on production rate and purity of the collected fractions. Throughput is a means to achieve a high production rate but should not serve as a basis for comparison between procedures or separation schemes. The production rate is maximum for some intermediate value of the throughput. At larger throughputs, the production rate decreases because the degree of separation between the bands becomes poor and the yield drops faster than the throughput increases. On the other hand, at low values of the throughput, the resolution between bands and the yield are good, and the yield decreases slowly with increasing throughputs.

Optimization of the experimental conditions under which a separation or purification is performed cannot be made without a clear understanding of the phenomena which take place during the migration of a high concentration band in a chromatographic column. The mechanisms of band broadening and band separation must be elucidated. The knowledge gained through years of research and development of analytical chromatography cannot be extrapolated, because of a major difference: while analyses are done with small sample sizes, with which the retention times and band profiles are independent of the

*Author to whom correspondence should be addressed.
†Department of Chemical Engineering.

composition of the sample, preparative separations must be run with large sample sizes, for which this is no longer true. Extremely sensitive detectors are available which in most cases give all the information required about the sample composition without requiring the use of large sample sizes. Thus, the concentration of all the sample components can be kept low enough for their retention times to depend only on the slope of their equilibrium isotherms between the mobile and stationary phases, and be independent of the composition of the sample.

These conditions are not valid in the case of preparative chromatography, where large sample sizes are employed, the bands become unsymmetrical, the retention times at the band concentration maximum and the band widths depend on the amount of sample, on the concentration of the corresponding compound in the mixture and on the concentration of the compounds eluted in bands adjacent to the band under study. Chromatography has become nonlinear and the influence of thermodynamics and kinetics on the band position and width can no longer be studied separately.

Besides the elution profiles of high concentration bands and their progressive separation during their migration along the column, the theory of nonlinear chromatography should explain a number of phenomena which are all related to the nonproportionality between the concentrations of each solute at equilibrium in the stationary and the mobile phases, for example, the influence of the concentration of a strong solvent (*i.e.*, the "organic modifier") on the elution profiles of large bands, the behavior of high concentration bands in gradient elution, or the chromatograms obtained in frontal analysis or in displacement chromatography.

The aim of this paper is to summarize the results of our recent work on the mechanism of band spreading and band separation under conditions where the concentrations are high, the molecules of several compounds compete for sorption by the stationary phase, and the equilibrium isotherms are not linear. The proper adjustment of the transient conditions at the column inlet permits the study of all the methods and phenomena just described.

THEORY

The fundamental problem of nonlinear chromatography has been formulated by Wilson[2] who also suggested the use of the ideal model, assuming that the column efficiency is infinite, as a first approach to its solution. Shortly thereafter, some of the most important consequences of the ideal model, *i.e.*, the eventual appearance of concentration discontinuities in the elution profile of a band, no matter how smooth the injection profile is, were pointed out by DeVault[3] and Glueckauf,[4,5] and later Guiochon and Jacob,[6] Purnell and Conder,[7] Valentin *et al.*,[8] and Rhee *et al.*[9,10] studied the properties of the equation resulting from the ideal model, while Lapidus and Amundson[11] formulated the most general model for chromatography.

The mass-balance equations of chromatography

The mass balance of a compound in a slice of the chromatographic column may be written:

$$\frac{dC_m}{dt} + F\frac{dC_s}{dt} + \frac{d(uC_m)}{dz} = D\frac{d^2C_m}{dz^2} \qquad (1)$$

where C_m and C_s are the concentrations of the studied compound at time t and abscissa z, in the mobile and stationary phase respectively, u is the mobile phase velocity, F is the phase ratio, $(1-\epsilon)/\epsilon$, where ϵ is the total column porosity, and D is the coefficient of axial dispersion, *i.e.*, D accounts for band spreading by axial molecular diffusion in the tortuous packing and by eddy diffusion (lack of radial homogeneity of the mobile-phase flow pattern).

In liquid chromatography the mobile phase density is constant along the column, as the compressibility is negligible,[12] and the partial molar volumes of the solute in the mobile and stationary phases are nearly the same. There is no sorption effect. The mobile phase velocity may be regarded as constant in equation (1) and there is no need for a mobile phase mass-balance equation, as long as the mobile phase is pure and we can assume that it is not adsorbed.[13]

An equation such as equation (1) must be written for each system component, *i.e.*, for each component of the sample and of the mobile phase (if that is not a pure solvent). In many cases, the mobile phase in liquid chromatography is a mixture of a "weak" solvent (*e.g.*, water in H_2O/CH_3OH or H_2O/CH_3CN mixtures used in reversed-phase or ion-pair HPLC, dichloromethane in a CH_2Cl_2/CH_3OH mixture used in normal phase HPLC), a "strong" solvent or organic modifier (*e.g.*, CH_3OH or CH_3CN in the previous examples) and additives (*e.g.*, sodium and alkylsulfate, or chloride and tetraalkylammonium, ions in ion-pair HPLC, or the buffer ions in reversed phase or ion-exchange HPLC). A mass-balance equation for all these compounds is required if we want an accurate solution. There are two exceptions. First, the mass-balance equation for the weak solvent may be omitted, which in the definition of the adsorption isotherms forces adoption of the convention that the solvent is not adsorbed.[13] Second, if the organic modifier or some additives are much less strongly retained than the components of interest, when in solution in the pure weak solvent, their mass-balance equation may also be omitted.[14]

The system of non-linear partial differential equations consisting of a mass-balance equation for each component of the sample and of the mobile phase (minus the weak solvent) and of the appropriate relationships between the concentrations $C_{m,i}$ of the components in the mobile phase and their concentrations in the stationary phase, $C_{s,i}$, constitutes the fundamental system of equations of chro-

matography. There are two approaches to the solution of this system, either the use of the relevant kinetics equations, or the assumption that the compositions of the stationary phase and the mobile phase are such that they are always very close to equilibrium.

Relationship between the concentrations of a species in the two phases of a chromatographic system

The exact general solution of the chromatographic problem would require that the system of mass-balance equations just discussed be completed by a set of equations describing the kinetics of mass transfer between the phases, *i.e.*, relating the rate of change of the concentration in the stationary phase to the values of the actual concentrations in the mobile and stationary phases. The first attempt at solving this problem was made by Lapidus and Amundson[11] who wrote, for one component, *i*:

$$\frac{dC_{s,i}}{dt} = K_i(C^*_{s,i} - C_{s,i}) \qquad (2)$$

where K_i is a kinetic constant, and $C^*_{s,i}$ is the equilibrium concentration of the compound *i*.

In the case of a single component, eluted by a pure mobile phase, an analytical solution of a system of partial differential equations made from equation (1) (with $D = 0$) and a kinetic equation similar to (2) has been derived by Thomas[15] for the Riemann problem (frontal analysis). This solution has been recently improved by Wade *et al.*[16] and extended to the solution of the impulse problem (elution). The solution is very complex to derive, however, and necessitates the use of the Thomas transform and of a two-dimensional Laplace transform. It does not seem possible to extend it to a multicomponent system. Furthermore, its practical use for the optimization of experimental conditions in preparative liquid chromatography would require prior knowledge or determination of the rate constants, a rather impractical requirement.

Accordingly, we have preferred the alternative approach, which assumes that the two phases of the chromatographic system are always very close to thermodynamic equilibrium. Thus, there is a relationship between the concentrations, in both phases, of each component of the system. This relationship, given by solution thermodynamics, is the equilibrium isotherm:

$$C_{s,i} = f(C_{m,i}, C_{m,j}) \qquad (3)$$

Giddings[17] and later Haarhoff and van der Linde[18] have shown that if the column is efficient enough (in practice, if its efficiency is more than a few hundred plates, which is low by current standards), and if the mass transfer follows first-order kinetics, it is possible to simplify greatly the fundamental system of equations of chromatography [equations (1) and (2)]. They have shown that under those conditions, the solution of this system is the same as the solution of a system of equations made from equation (3) (the isotherm) and a mass-balance equation similar to equation (1), but where the axial diffusion coefficient is replaced by an apparent diffusion coefficient related to the column HETP, *H*:

$$\frac{dC_m}{dt} + F\frac{dC_s}{dt} + \frac{d(uC_m)}{dz} = D_a\frac{d^2C_m}{dz^2} \qquad (4)$$

where

$$D_a = \frac{HL}{2t_0} \qquad (5)$$

L being the column length, and t_0 the dead time of the column.

Unfortunately, it is not possible to derive an analytical solution of this new system, and a computer program which would permit the direct calculation of numerical solutions has not been written yet. The theory of nonlinear partial differential equations offers very little help in this matter. Most theoretical work during the last forty years has concentrated on the simpler ideal model, which assumes constant equilibrium between both phases, and that axial diffusion is negligible, *i.e.*, that the column efficiency is infinite. Equation (1) then becomes

$$\frac{dC_m}{dt}(1 + Fk') + u_0\frac{dC_m}{dz} = 0 \qquad (6)$$

where k' is the differential, $dC_{s,i}/dC_{m,i}$ of the isotherm [see equation (3)] and u_0 is the linear mobile-phase velocity.

One of the important features of equation (6) is that a velocity u_z is associated with each value of the concentration. This velocity is given by

$$u_z = \frac{u_0}{1 + Fk'} \qquad (7)$$

where k' is the value of the differential of the isotherm at the corresponding concentration, *C*.

It should be re-emphasized at this stage that the equilibrium concentration of a compound *i* in the stationary phase is a function of the concentrations of *all* the components of the mobile phase. There are, unfortunately, few good theoretical models to relate these concentrations, whatever the mode of chromatography used. The most popular, in adsorption chromatography, is the classical competitive Langmuir isotherm, which is a good first approximation for single compound adsorption but does not represent accurately the experimental data in many cases, especially for the competitive adsorption of multicomponent systems.[19]

Analytical solution of the ideal model

An exact solution of the ideal model of chromatography has been derived in the particular case where the equilibrium isotherm can be represented by

a Langmuir equation:

$$Q = \frac{aC}{1 + bc} \tag{8}$$

where Q is the concentration of solute in the stationary phase at equilibrium, and a and b are numerical coefficients. The product aF is equal to the limit column capacity factor at zero sample size, k'. The ratio a/b is the saturation capacity of the column.

In principle, Q would be better expressed as a surface excess concentration, but it is practical in chromatography to express it as a bulk concentration, which avoids difficulties in defining or measuring the adsorbent surface.

In the present case, of an infinite column efficiency and a Langmuir isotherm, the elution profile has two parts,[14] a vertical front, at a retention time, t_f, given by:

$$t_f = t_0 + t_p + (t_{R,0} - t_0)(1 - \sqrt{L_f})^2 \tag{9}$$

and a smooth tail, described by the equation (with $t_f < t < t_{R,0}$):

$$C = \frac{1}{b}\left(\sqrt{\frac{t_{R,0} - t_0}{t - t_p - t_0}} - 1\right) \tag{10}$$

where t_0 is the dead time of the column, t_p is the time width of the rectangular injection, $t_{R,0}$ is the limit retention time of the corresponding compound at zero sample size, L_f is the loading ratio (the ratio of the sample size to the column saturation capacity).

The band maximum is given by:

$$C_M = \frac{\sqrt{L_f}}{b(1 - \sqrt{L_f})}. \tag{11}$$

and the band-width at the baseline is:

$$W = (t_{R,0} - t_0)(2\sqrt{L_f} - L_f) \tag{12}$$

The ideal model corresponds to a column of infinite efficiency. In practice a vertical front cannot exist, because an infinite concentration gradient would generate an infinite diffusive mass flux. Nevertheless, extremely steep band fronts are observed, and for typical HPLC columns, with HETP below 20 μm and efficiencies above 5000 theoretical plates, the band profiles differ very little from those predicted by the model (see Fig. 1). Thus a small correction can be derived easily, and this result can be used to represent all overloaded band profiles under reduced coordinates. This makes it extremely easy either to predict the band profiles when the isotherm is known, or, conversely, to derive the parameters of the Langmuir isotherm which best fits the experimental profiles.[14] When the adsorption behavior cannot be accounted for by a Langmuir equation, systematic deviation between experimental and predicted band profiles takes place.

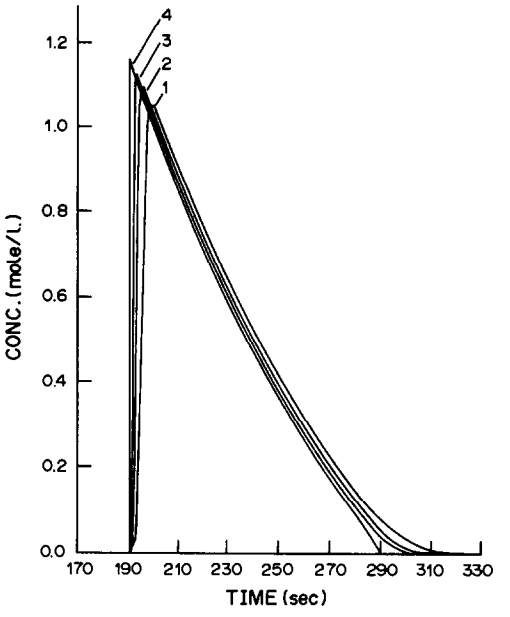

Fig. 1. Comparison between the analytical solution of the ideal model (infinite efficiency column) and the numerical solutions of the semi-ideal model, for different values of the column efficiency. Loading factor, 0.05. 1, Ideal model band profile; 2, 4000 plate column; 3, 2000 plate column; 4, 1000 plate column.

Numerical solutions of the semi-ideal model

Since it is not possible to derive exactly the analytical solutions to equations (1) or (4), but only to the simpler equation (6), we may attempt to calculate numerical solutions of equation (4). Unfortunately, an exact solution to equation (4) is not possible.[20] However, it is possible to employ an algorithm developed within the framework of the finite difference method to calculate numerical solutions of the system of equations (3) and (6). Excellent results are obtained, as discussed in the next section.

The numerical integration of a partial differential equation introduces errors, much in the same way as does the numerical calculation of a finite integral. These errors apply to the whole profile, so the profile obtained is different from the exact solution. We have shown[20,21] that if we write a program which calculates a numerical solution of equation (6) (*i.e.*, we assume an infinite column efficiency), we obtain instead a numerical solution of equation (4) (corresponding to the exact value of the finite column efficiency), provided the values of the time and length increments in the calculation are properly chosen. The difference between the profile obtained and the true solution of equation (6) results from the errors made in replacing the partial differential equation (6) by a finite difference equation. It can be shown that these errors act in exactly the same way as an apparent diffusion coefficient.[21]

The numerical procedure used for calculating integrals of equation (6) is designed to cancel the

first-order errors. We have been able to show that the second-order errors are proportional to the second differential, d^2C/dx^2.[21] The proportionality coefficient turns out to be equal to the apparent diffusion coefficient, provided the differential elements, dz and dt of the numerical integration are chosen as:

$$dz = H; \quad dt = \frac{2H}{u_z} \tag{13}$$

where H is the height equivalent to a theoretical plate of the column studied, and u_z is the maximum velocity of the band studied [*i.e.*, $u/(1 + k'_0)$].

Thus, the "numerical diffusion" can replace exactly the effects of the axial dispersion and the resistances to radial mass transfer which cause band broadening. While we are trying to calculate a numerical solution of the ideal model, we obtain instead a numerical solution of the more exact equation (4), which takes into account the actual column efficiency, as an overall coefficient, in which all the experimental contributions are lumped together. This method is valid if the kinetics of mass transfer do not change much during the migration of the band, which will be the case in most of the applications in high-performance liquid chromatography, but it is not valid either with high concentration bands of polymers, especially proteins, which are very viscous, or in affinity chromatography. A number of examples are reported and discussed in the next section.

The method can be extended readily to the calculation of solutions of multicomponent problems, involving the system of partial differential equations accounting for the mass balance of several compounds. Several new difficulties arise, however. The most important one is in the selection of the time and space increments of the integration. On the one hand, the values of these increments must be the same for the derivation of the whole chromatogram. On the other hand, equations (13) give different results when applied to different components of a sample. The theoretical results available, which support equations (13), have been obtained for a single partial differential equation, and the method described above in this section for the selection of the increments is difficult to extend straightforwardly to a multicomponent system. Which component should be used for the derivation of dt? The theory of systems of partial differential equations is still much less developed than that of single equations. It is not possible to derive stability conditions for the selection of proper sets of values of the integration increments. In calculations for single-component bands eluted by a binary solvent or for the separation of a mixture of closely eluted components, the difficulty is mainly theoretical. It may become real for the prediction of the profiles in gradient elution or in displacement chromatography.

For the present, we can consider that when the efficiency of the column has been chosen for a certain compound, *i.e.*, a certain value of k', the efficiency of the simulated column is defined for all other compounds, *i.e.*, the column HETP is a well defined function of k', as it is, for example, with open tubular columns in chromatography.[22] H is not constant, as it is approximately with packed HPLC columns, but varies rapidly with k'_0. The solution of multicomponent problems then requires some compromise in the selection of the integration increments. This does not much affect either the validity of the results obtained in the study of band profiles in nonlinear chromatography or the nature of the conclusions derived in the optimization of experimental conditions for preparative applications, because of the rather moderate effect of the efficiency. This effect appears in most cases as a correction to the results derived from the ideal model.

RESULTS AND DISCUSSION

The following problems have been studied: the profile for elution of a high concentration band with either a pure eluent or a mixture of a strong and a weak solvent; the elution profiles of the two components of a binary mixture, eluted with a pure solvent, and their progressive separation; the displacement and separation of a binary mixture. The results of these simulations have been compared with experimental results. The agreement observed is as good as the accuracy of the experimental results permits.

In the following discussion, the sample size is given in dimensionless units. It is defined as the ratio between the actual sample size injected and that corresponding to the column saturation limit. In the case of an absorbent, the latter is the amount which would form a monolayer on the surface.

The elution profile of a single compound in ideal nonlinear chromatography: the case of a Langmuir isotherm

For a single component, it is possible to derive an analytical solution of the ideal model of chromatography under overloaded conditions (see the theoretical section, above). This solution is the elution profile which would be obtained with a column of infinite efficiency. In practice, elution profiles obtained with columns having more than 5000 plates cannot be distinguished from those predicted by the ideal model, when the loading factor exceeds 0.02 (see Fig. 1).

This property can be used to predict the elution profile of any pure-component sample when the equilibrium isotherm is represented by a Langmuir equation and the coefficients are known.[14] Conversely, it can also be used to determine the best values of the parameters of a Langmuir equation representing the absorption behavior of a compound when the elution profile of a high concentration band is known.[14]

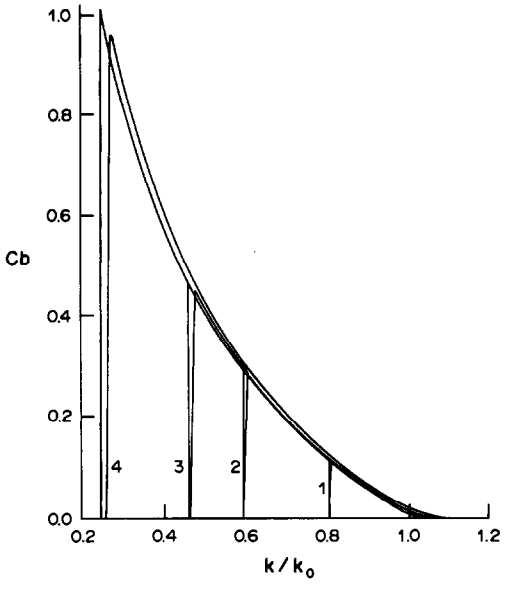

Fig. 2. Influence of the loading factor on the band profile, and the sensitivity of the profile to the column efficiency. For each value of the loading factor, the figure shows two profiles, one derived from the ideal model, and one calculated by using a semi-ideal model, with a different column efficiency. 1, Loading factor, 0.01; efficiency, 10000 plates. 2, Loading factor, 0.05; efficiency, 5000 plates. 3, Loading factor, 0.10; efficiency, 2000 plates. 4, Loading factor, 0.25; efficiency, 1000 plates.

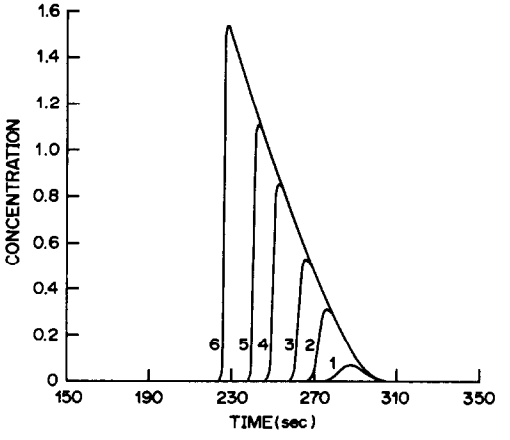

Fig. 3. Band profiles generated by computer calculations, using the semi-ideal model. Langmuir isotherm, with $a = 25$, $b = 0.10$. Phase ratio, $F = 0.25$. Column, 25 cm long, 2500 theoretical plates. Flow-rate, 5 ml/min. 1, Loading factor, 0.0004; 2, loading factor, 0.002; 3, loading factor, 0.0040; 4, loading factor, 0.0080; 5, loading factor, 0.012; 6, loading factor, 0.020.

These operations are performed with reduced coordinates. The reduced ordinate is the product of the concentration and the second coefficient [b, see equation (8)] of the Langmuir isotherm. The reduced abscissa is the ratio, k'/k'_0, of the column capacity factor, k', associated with a given concentration and the limit column capacity factor for a zero sample size, k'_0. The profiles obtained depend only on the loading factor. Figure 2 shows a series of profiles, corresponding to different values of the loading factor. Each profile can be compared with the band profile generated by the semi-ideal model, for columns of different efficiencies. Figure 2 illustrates also the decreasing influence of the column efficiency on the elution profile of a large high concentration band, with increasing loading factor.

The elution profile of a single compound in semi-ideal nonlinear chromatography: numerical solution

We have used the program described in the theoretical section above to generate a series of elution profiles under a variety of experimental conditions.[23] Figures 3 and 4 show a series of profiles corresponding to a Langmuir isotherm and an S-shaped isotherm, respectively. The differences are striking.

In the case of the Langmuir isotherm, the velocity associated with a concentration within the framework of the ideal model increases monotonically with the concentration, since the derivative of the isotherm decreases monotonically with increasing concentration in the mobile phase [see equations (7) and (8)]. Thus, the higher concentrations move faster than the lower ones and try to pass them. They cannot do so, however, because, at any given time, the concentration of a compound cannot have several values at any given point. Mathematically, this means that the band profile cannot remain continuous when a high concentration tries to pass a lower one, but a generalized, so-called "weak", solution must be considered instead.[14,20-22] The tangent to the profile becomes

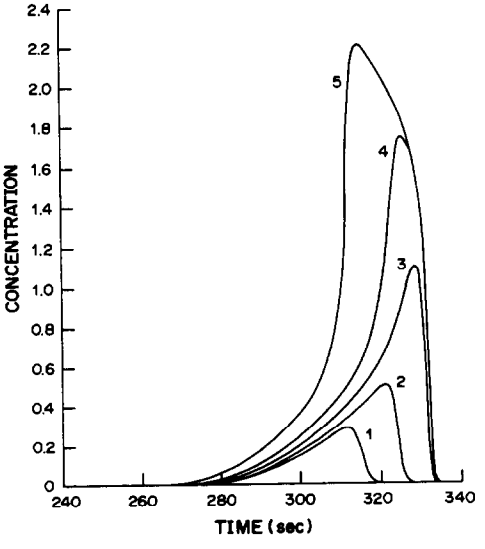

Fig. 4. Band profiles generated by computer calculations, using the semi-ideal model. S-shaped isotherm. Column, 25 cm long, 2500 theoretical plates. Flow-rate, 5 ml/min. 1, loading factor, 0.0020; 2, loading factor, 0.0040; 3, loading factor, 0.0120; 4, loading factor, 0.020; 5, loading factor, 0.040.

vertical and remains so as long as necessary. The profile acquires a discontinuous part (see Fig. 3). When the sample size increases, the discontinuity, also called the "concentration shock," becomes greater, and the retention time decreases. The band profiles in the ideal case are given by equations (9)–(12). They are illustrated in Figs. 1 and 2.

Figure 4 shows the band profiles obtained with an S-shaped isotherm. In this case, initially, the curvature of the isotherm at low concentrations is in the opposite direction to that of the Langmuir isotherm. When the solute concentration in the mobile phase increases, the concentration sorbed at equilibrium increases faster. Accordingly, the slope of the isotherm (*i.e.*, k') increases with increasing concentration and the velocity associated with a concentration decreases at first with increasing concentration [see equation (7)]. The phenomenon which takes place is the reverse of what happens with a Langmuir isotherm: the band has a slowly rising elution profile followed by a sharp drop, the rear shock layer which replaces the discontinuity predicted by the ideal model. Eventually, the inflection point of the isotherm is reached, the curvature changes sign, and the velocity associated with a concentration [see equation (7)] now decreases with increasing concentration. A new discontinuity appears and grows on the front of the peak. The profile illustrated in Fig. 4 is characteristic.

Figure 5 shows the comparison between the profile recorded experimentally for elution of a high concentration band of benzyl alcohol on a silica column, and the predicted profile by using the semi-ideal model, for the same experimental conditions. The equilibrium isotherm has been determined by combining the results of measurements made by frontal analysis, with those derived from characteristic points of the elution and the frontal analysis.[24] The agreement between the predicted profile (solid line) and the experimental points is striking. The slight difference in curvature between the two profiles results from an approximation made in the model. The eluent used in this determination is a mixture of a strong and a weak solvent (*n*-heptane and tetrahydrofuran). Though the weak solvent can be considered as nonadsorbed, the strong solvent can not. As discussed in the next section, we have shown that if the ratio, a_j/a_i, of the first coefficients of the Langmuir isotherms describing the adsorption behavior of the strong solvent, a_j, (organic modifier) and the solute, a_i, is of the order of 0.1–0.2, the difference between the profiles predicted (simulated) by using a single-component and a two-component model is very similar to the one observed here.[23] A large number of similar results, obtained with various sample sizes of different compounds, and several chromatographic systems, have been obtained.[23] In all cases, the same excellent agreement between experimental chromatograms and simulated band profiles has been achieved.

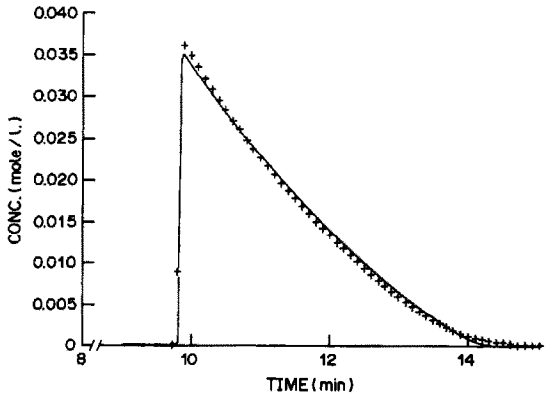

Fig. 5. Comparison between an experimental band profile (points) and the profile predicted by our numerical solution of the semi-ideal model, using the same experimental conditions, including the column efficiency, and the equilibrium determined by a combination of methods. Stationary phase: silica gel, 10 μm. Mobile phase: n-heptane/THF (85/15, v/v). Flow-rate: 1 ml/min. Solute: benzyl alcohol. Ambient temperature.

The elution profile of a single-component high concentration band, with a binary mixture as a mobile phase

When the mobile phase is a mixture, we should use a mass-balance equation for each of its components, except for the weak solvent, since any additive to the weak solvent is, by definition, positively adsorbed.[13] This means that the problem of the prediction of the elution band of a single component eluted with a binary mixture as mobile phase is a two-component problem, as is the problem of the separation of a binary mixture by use of a pure solvent as mobile phase, or the problem of the high concentration band profile in gradient elution. Accordingly, the separation of a two-component mixture with a binary solvent is a three-component problem.

The theory of systems of partial differential equations is not yet very advanced, and there are few general theorems which can be of any help in the present study.[20,21] For example, there is no general result describing the stability condition for a numerical solution. There are no general procedures available for the derivation of a suitable algorithm. We have extended the algorithm used for the prediction of band profiles for the one-component problem, to the calculation of solutions of the two-, three- and four-component problems. This merely requires the introduction of a mass-balance equation and a competitive isotherm [equation (3)] for each new species involved. In fact, the program can be extended easily to any number of components. The practical difficulties are that we now have no stability condition and no method to calculate the proper values of the integration increments (see theoretical section). We have selected the same increment values as for the single-component integration and have obtained satisfactory results, with no numerical instability and with excellent agreement with the available experimental results, with the single exception that the

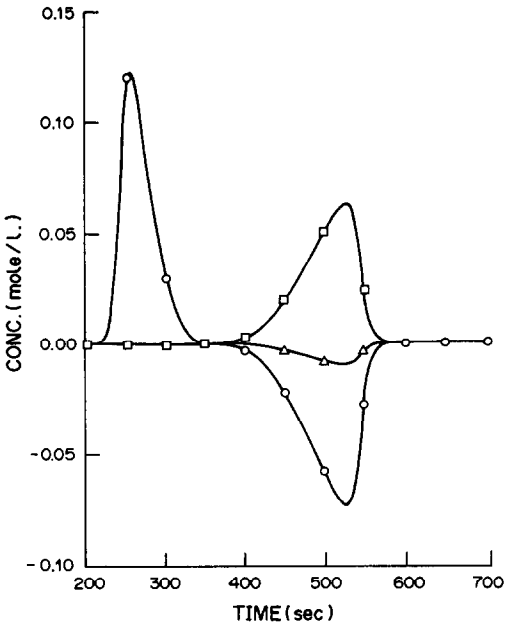

Fig. 6. Simulation of system peaks. Injection of a large sample of solute with a binary mixture mobile phase. Circles, signal obtained with a detector selective for the solvent. Squares, signal obtained with a detector selective for the single solute. Triangles, signal observed with a non-selective detector.

chromatogram predicted for a zero sample size of a mixture of several compounds exhibits a particular relationship between HETP and k'_0 which is a property of the program.[25] It is easy to adjust the HETP of one compound to the desired value, but that of all other compounds is then defined.

So far, we have investigated in detail only the elution of a single-component band with a binary mixture. The separation of a binary mixture is under current investigation. We have studied the influence of the concentration of the strong solvent and of the relative strength of the adsorption of the strong solvent (organic modifier) and the solute.

Figure 6 shows the concentration signals obtained at the column outlet for a high concentration band injected into a column, and elution with a binary mobile phase. The profiles of the solvent and the solute are indicated separately. It is apparent how different the situation of the analyst can be, depending on whether he is using a solute-selective detector or a nonselective detector. In the former case, there is a single peak, with area proportional to the sample size. In the latter case, there are two peaks, and the second one is the result of an interference between a band of pure strong solvent and the band of solute. The band which appears on the trace from a real non-selective detector would be a composite of these two bands, different from any of the concentration profiles shown in Fig. 6, because there is no reason why the response factors for the strong solvent and the solute should be identical. It would be very difficult to use the band profile in quantitative analysis. Even with an ultraviolet detector and a component absorbing at the detector wavelength, strong band distortion may take place if ultraviolet absorption by the solvent is not negligible.

The effect of the relative strengths of adsorption of the solute and the strong solvent is illustrated in Fig. 7. The elution band profile for a constant size injection of a pure solute is simulated, for a series of strong solvents (organic modifiers) having various ratios of their retention relative to that of the solute. For very weak organic modifiers, the profile remains similar to that observed with the pure weak solvent, but the retention time decreases, which is the effect normally expected from the addition of a strong solvent to the mobile phase. When the solute and the strong solvent have the same retention, a Gaussian peak is observed at all concentrations. With a strong solvent, one which is more strongly adsorbed than the solute, the retention becomes small (but not necessarily negligible), the peak is skewed in the opposite direction, with a smooth front and a steep rear, and may exhibit very complex, strange shapes before becoming Gaussian again and unretained.[26]

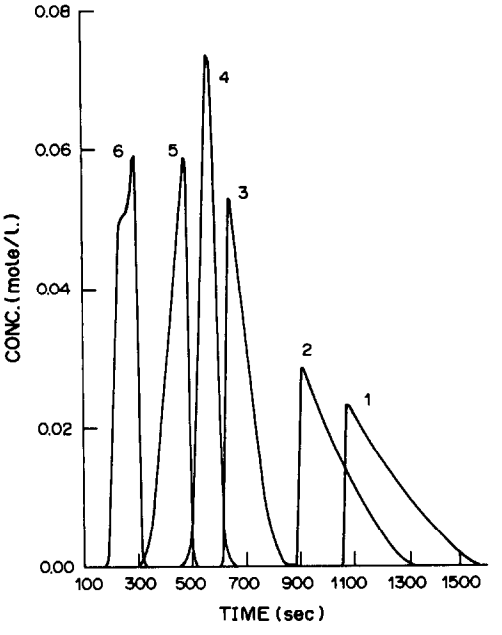

Fig. 7. Series of band profiles recorded with a solute-selective detector, as response to the injection of identical amounts of solute in a chromatographic system using a binary solvent as mobile phase. Effect of the strength of the organic modifier. The parameter used is the ratio, $R = a_j/a_i$, of the first coefficients of the Langmuir isotherms of the strong solvent (a_j) and of the solute (a_i). The concentration of strong solvent is 0.25M. 1, The modifier is not adsorbed, $R = 0$. 2, $R = 0.1$. 3, $R = 0.5$. 4, $R = 1.0$. 5, $R = 2$. 6, $R = 10$.

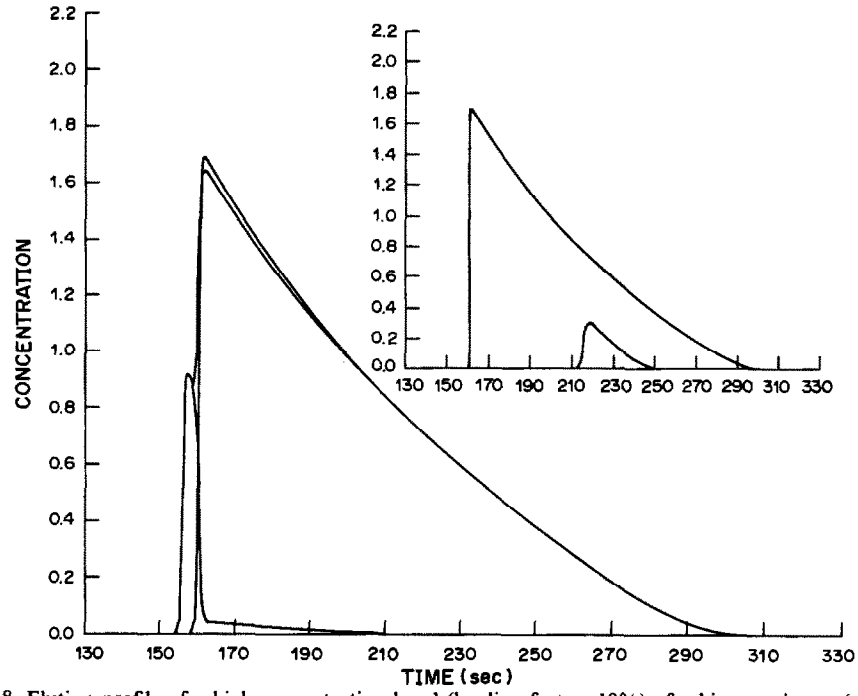

Fig. 8. Elution profile of a high concentration band (loading factor, 10%) of a binary mixture (relative retention at zero sample size, 1.09; same column capacity). Value of k_0' for the second compound, 6.25. Limit retention times of the two compounds, 290 and 270 sec, respectively. t_0 = 40 sec. Relative concentration of the two compounds, 1/19. Insert: chromatograms obtained for the same amounts of each component injected singly.

The elution profile of a multicomponent high concentration band: separation of a binary mixture with a pure eluent

We have generated band profiles of samples of binary mixtures, by using a program similar to the one used for a single component and described above. This program calculates the elution profile of each component of the mixture as it would be obtained by using a detector selective for that compound, and also the sum of the two profiles, which would be the response of a non-selective detector. Figures 8–11 are examples corresponding to different compositions of the binary mixture used (1:19, Fig. 8, 1:2, Fig. 9; 2:1,

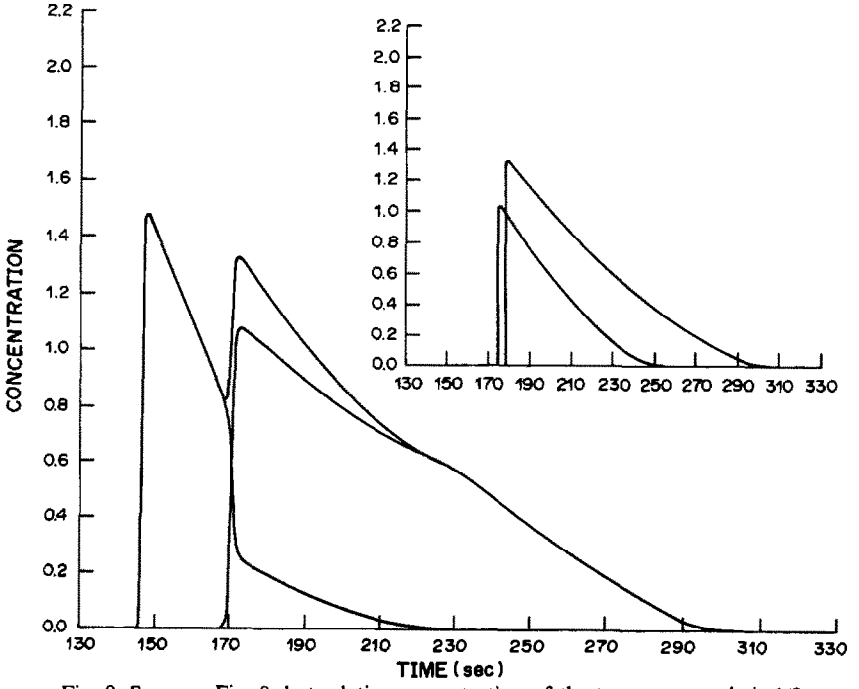

Fig. 9. Same as Fig. 8, but relative concentration of the two compounds is 1/2.

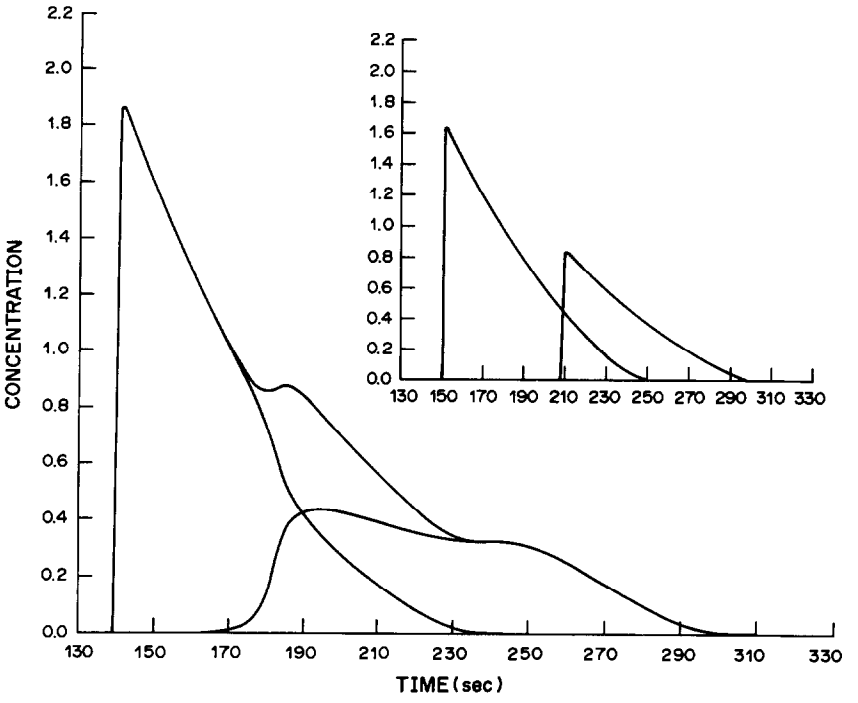

Fig. 10. Same as Fig. 8, but relative concentration of the two compounds is 2/1.

Fig. 10; 19:1, Fig. 11) but the same loading factor, 10%, and the same other experimental conditions (equilibrium isotherm, column efficiency, 3000 theoretical plates). Similar figures illustrating the discussions of various aspects of the separation process of a binary band, the optimization of experimental conditions, the yield and production rates achieved, have been published.[27-30] It is important to stress that, for the sake of simplicity, similar isotherms have been used for the two components. The model used to account for the competitive adsorption behavior of the two compounds [see equation (3)] is the simple competitive Langmuir isotherm:

$$C_i = \frac{a_i C_i}{1 + b_i C_i + b_j C_j} \tag{14}$$

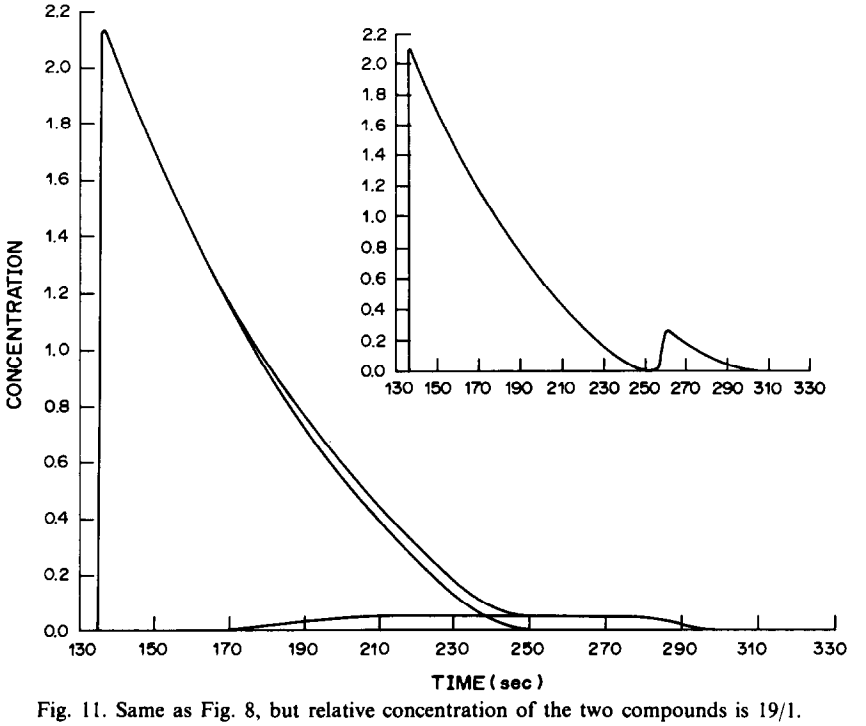

Fig. 11. Same as Fig. 8, but relative concentration of the two compounds is 19/1.

where the subscripts i and j stand for the two components of the binary mixture. The two single-component isotherms ($C_j = 0$ and $C_i = 0$, respectively) diverge progressively from each other, so there cannot be an inversion in the elution order. More complex situations are possible,[19] and it becomes very difficult to account for the results.[31]

Two important phenomena are observed in these figures. First (see Figs. 8, 9 and to a lesser extent 10), two diffusion-relaxed concentration discontinuities, or shock layers (see above), are observed on the profile of each band system, as demonstrated by Guiochon and Jacob.[6] One shock layer occurs between one of the two components and the mobile phase, the other between the two components. If the isotherms are of the Langmuir type, the external discontinuity appears before the band, as shown here. If the isotherm were S-shaped the discontinuity would appear on the back of the band (see Figs. 12 and 13). These two discontinuities are somewhat relaxed by axial diffusion and the resistance to radial mass transfer, and become shock layers. The fundamental property of these shock layers, as shown by the theory of weak solutions of hyperbolic partial differential equations,[14] is that they move at the same velocity as the corresponding discontinuity. The first shock layer is steeper than the second, and the slopes of the two component profiles in the second shock layer depend rather strongly on the column efficiency, which explains the better performance of the more efficient column under overloaded conditions.[28]

Secondly, there is a strong interaction between the two bands, as long as the two components spend a large fraction of their retention time in unresolved or partially resolved bands. This strong interaction is illustrated by a comparison between Figs. 8–11 and the inserts in each one of them. In each case, the difference between the profiles obtained for the binary mixture (Figure) and the profiles obtained for the same amounts of each component injected singly (insert) is striking. The qualitative result of this interaction, *i.e.*, the shape of the two elution bands, depends on the relative composition of the mixture; the intensity of the effects depends on the absolute concentrations. With two compounds having a limit relative retention of 1.25 for zero sample size, it takes a certain amount of column overload to achieve significant interference between their elution bands. Figures 8–11 correspond to a loading factor of 0.10, *i.e.*, the sample size is 10% of the amount required to saturate the column at equilibrium. For smaller values of the relative retention the same degree of band interference would be obtained with smaller loading ratios.

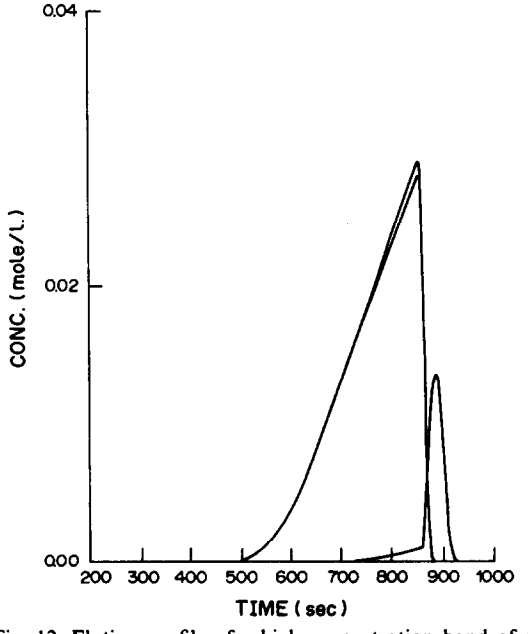

Fig. 12. Elution profile of a high concentration band of a binary mixture eluted with a binary solvent. Concentration of strong solvent: 0.1M. Ratios of first Langmuir isotherm coefficients: solute 2/solute 1, 1.2; strong solvent/solute 1, 1.5. Relative concentration of two compounds, 9/1.

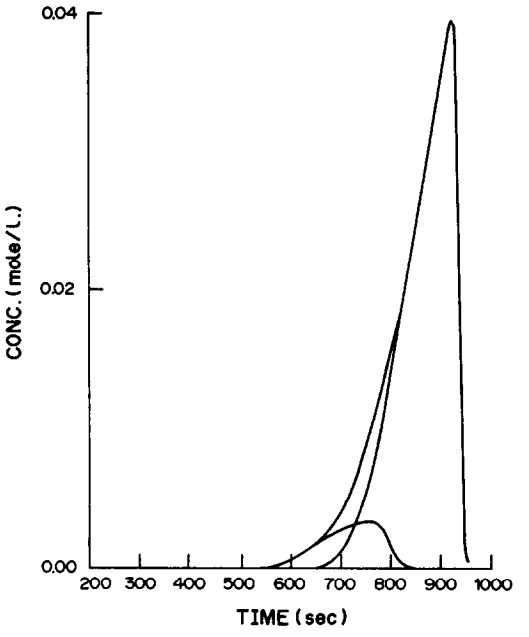

Fig. 13. Same as Fig. 12, but relative concentration of the two compounds is 1/9.

When the second component is at much the higher concentration, it tends to displace the first component (Fig. 8). The first component band is considerably pushed forward and its elution profile takes a characteristic L-shape, with a narrow front part containing a large fraction of the compound, followed by a shallow tail. This tail ends somewhat before the limit retention time of the first component. The elbow of the tail occurs at the same time as the maximum of the band of the second component. The relative importance of the tail depends on the relative concentrations and retentions of the two components. When the relative concentration of the second component

decreases, the displacement effect decreases and becomes very weak (Fig. 10) or nonexistent (Fig. 11). The relative importance of the tail of component 1 increases. The front of compound 1 moves forward (the degree of column overload by component 1 increases) and its rear recedes and straightens up. In all cases, however, the front of the band of component 2 is eluted earlier when it is mixed with component 1 than when the same amount of 2 is injected alone, even if the effect is hard to notice, such as in Fig. 8 (compare inserts and Figures).

At the same time as component 2 displaces component 1, it tends to tag along with it. The effect increases when the displacement effect decreases. It is very important in Fig. 11, moderate in Fig. 10, and barely noticeable in Fig. 8, where the nearly vertical front of component 2 is eluted a few seconds later when it is pure than when it is mixed with 5% of component 1. Both effects are explained by the mutual interaction of the two components.

When two compounds have a relative retention of 1.25, it means that, at equilibrium with a dilute, equimolar solution, the concentrations of the two compounds in the stationary phase are in the ratio 1/1.25. At high concentration the ratio is still close to 1 [see equation (14)]. As a consequence, a large fraction of the molecules of component 1 is sorbed, even in the presence of a high concentration of component 2. The very high resolution power of chromatography should not let us forget that when separating compounds by chromatography, we are usually dealing with compounds which have very close values of their Gibbs free energies of adsorption. This means that the molecules of component 2 cannot completely force those of component 1 out of the stationary phase, even when the relative concentration of component 2 is large (Fig. 8). Hence the tail observed for the band of 1 in Figs. 8 and 9. On the other hand, when component 1 is in large excess, its molecules occupy a large fraction of the sites available on the surface and crowd the molecules of 2 out of the stationary phase. Hence we see the second component being pulled along by the first one (tag-along effect) and the spreading of the band of component 2 over a long time.

The tag-along effect, which has not been described in the literature, has undesirable consequences in preparative chromatography, since the yield of both components at high purity will be very low in the case illustrated in Fig. 11. The profiles generated can be used to derive the yield and rate of production for both components at any stated degree of purity, by a simple integration of the band areas.[27] There is an optimum in the column loading, which depends on the column characteristics as well as on the nature of the separation problem studied.[28,29] In general, it seems it is much easier to extract small amounts of an impurity if it is eluted first (Fig. 8). Similarly, the yield for purification of a major component is higher if the impurity is eluted last (compare Figs. 8 and 11).

The elution profile of a multicomponent high concentration band: separation of a binary mixture by a binary mobile phase

Figures 12 and 13 show simulated chromatograms for the injection of a large band of a binary sample, and elution with a mixture of two solvents as mobile phase. The competitive adsorption isotherms [see equation (3)] of the three adsorbed species, the two solutes and the strong solvent, are Langmuir isotherms [equation (14) holds, but is written for three solutes instead of two]. The relative retention of the two sample solutes is 1.2. The strong solvent is more strongly adsorbed than the first solute, and its limit relative retention is 1.5 (see Fig. 7).

In this case, the band profile becomes skewed in a direction which is the reverse of the one normally observed with Langmuir isotherms. The band profiles exhibit shapes which are very similar to those observed with the Langmuir isotherms, as seen if Figs. 8 and 12 on the one hand, and Figs. 11 and 13 on the other, are compared. The equivalent of a displacement effect is observed in Fig. 12, but it is not the result of faster migration of the band of the second component forcing the band of the first one out of the column. It is the increasingly sluggish pace of the first component which delays the migration of the second one, because the equilibrium concentrations of both components in the stationary phase increase faster than their concentrations in the mobile phase. The comparison with displacement would be incorrect here. Similarly, in Fig. 13 it is the first component which experiences difficulties in separating itself from the second one, during a slow process which leaves its band considerably spread. This happens because the equilibrium concentration of component 1 in the stationary phase increases faster than the concentrations of either component 1 or component 2 in the mobile phase.

Nevertheless, the practical results, *i.e.*, the conclusions drawn regarding the yields and production rates observed in preparative HPLC, are the reverse of those derived in the case of classical Langmuir isotherms. This is quite paradoxical, since we still have Langmuir adsorption isotherms in this case. This suggests that the introduction of some additive or strong solvent into the mobile phase used in preparative liquid chromatography may facilitate the solution of some difficult separation problem and offer a practical way to increase yields and production rates.

Displacement chromatography

The last problem we have studied systematically is the progressive build-up of displacement profiles. It is known that after a certain period of time, during which steady-state conditions slowly prevail, an isotachic train is formed and propagates. Helfferich and Klein[32] have derived a method permitting the calculation of an approximate profile of the isotachic train. The result does not permit, however, an accurate

prediction of the yield and production rate of each compound at a certain degree of purity. Furthermore, one of the goals of preparative chromatography is to find conditions for optimum production rate. It is clear that the maximum production rate occurs before the formation of an isotachic train. The increase in the production rate, as a result of the time saved, will be much larger than the loss due to the yield drop. Displacement chromatography has been little used so far for preparative applications, owing to the lack of experience and the need for on-line analysis for the determination of the individual component profiles. Simulation of the transient conditions and an understanding of the competitive process is a first step to introducing displacement separation at the process level.

In the simplest general case, where a pure carrier impregnates the column before injection of a binary mixture, followed by continuous introduction of the displacer solution, we have a three-component problem which can be studied by the same approach as that described above. Some results of the simulation are shown in Figs. 14 and 15. The same amount of sample is injected in both experiments.

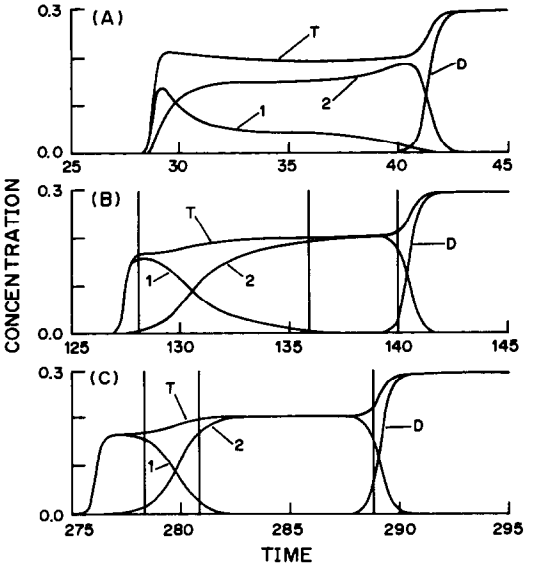

Fig. 14. Simulation of displacement profiles, as recorded at the outlet of various columns. Same experimental conditions, including isotherms, as for Fig. 8. Loading factor, 2.5% of column saturation capacity. Dirac injection. 1, Profile of the first component of a binary mixture. 2, Profile of the second component. D, Profile of the displacer. T, Total profile, as recorded by a nonselective detector, with the same response factor for all three compounds. (A), (B) and (C) show the displacement profiles at the exit of three different columns, 5, 17 and 35 cm long, respectively. The cut points for 98% purity are shown for components 1 and 2. For component 2 the determination of the cut points allows for 1% impurity of component 1 and 1% impurity of the displacer. The yields obtained with the three columns are 0 (A), 0.18 (B) and 0.60 (C) for the first component, respectively. For the second component, they are 0 (A), 0.44 (B) and 0.85 (C), respectively.

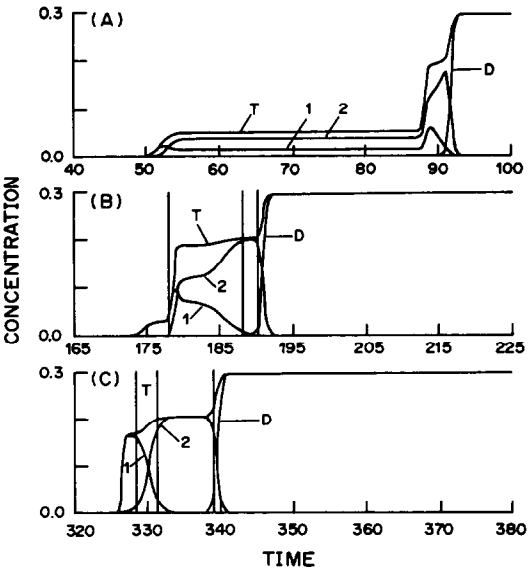

Fig. 15. Same as Fig. 14, but 5-ml injection. The yields obtained with the three columns are 0 (A), 0.15 (B) and 0.53 (C) for the first component, respectively. For the second component, they are 0 (A), 0.23 (B) and 0.83 (C) respectively.

In the first case (Fig. 14), a narrow plug is injected. Figure 14 shows the profiles of each component of a binary mixture and of the displacer at the exit of (A) a 5-, (B) a 17- and (C) a 35-cm long column. The concentration of each component of the injected sample is larger than the steady-state concentration in the isotachic train, so the band becomes more dilute and broadens. The two components segregate progressively, one at each end of the sample band, pushed by the displacer front. The interaction between the two components causes the progressive separation of their bands, but a significant intermediate zone remains between them. The vertical lines in Figs. 14A–C show the cut points for the collection of 98% pure fractions. The intermediate part of the feed must be rejected (wasted) or recycled, but should not be collected. The width of this intermediate zone, and hence the yields for the two components (which increase with increasing column length as long as the isotachic train builds up, see Figure caption), will depend on the column efficiency.

In the second case (see Fig. 15), the same amount of material as for Fig. 14 is injected, but as a large volume of dilute sample. Figure 15 shows the simulated profiles at the exit of columns of lengths (A) 5, (B) 17 and (C) 35 cm. A certain degree of separation takes place at the front of the band in the column (frontal analysis). When the displacer is introduced, it produces two effects. First it pushes the whole band further down the column, at a velocity faster than the velocity associated with the concentration of the injected band. The frontal separation increases at the downstream end of the sample zone. On the other hand, the displacer concentrates the band and produces some separation between the two compounds,

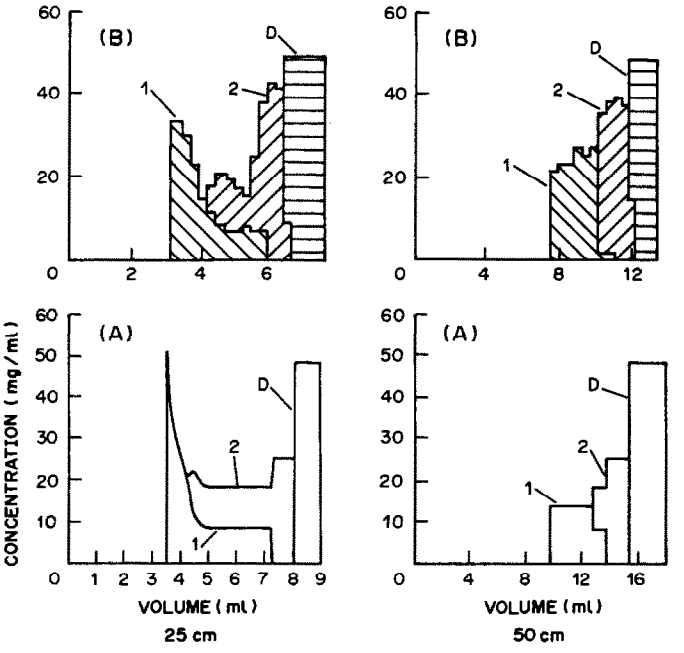

Fig. 16. Comparison between our simulated profiles (bottom) and the experimental results (top) previously published by Frenz.[34] Displacement of a resorcinol/catechol mixture on two columns, one 25 cm long (left-hand two diagrams), the other 50 cm long (right-hand two diagrams), see text.

which segregate, one at each end of the displaced sample zone [see Fig. 15(A)]. The separation builds up at both ends of the sample zone and eventually the two zones that are rich in component 1 meet and the isotachic train is formed [see Fig. 15(B)]. In this case, the fractions collected are more concentrated than the injected sample. The effect of frontal analysis on displacement development is seen in the variation of the yield with increasing column length. Unlike the case of a Dirac pulse injection, where the yield increases monotonically with increasing column length, for a large-volume injection the yield increases, then falls rapidly to a very small minimum [at 17 cm, the length corresponding to Fig. 15(B)], when the two concentration maxima of the first component merge.[33] Finally, the yield increases and reaches its limit value when the isotachic train forms. The value of the maximum yield is exactly the same as that observed under the conditions of Fig. 14. The same isotachic train forms in both cases.

Finally, Fig. 16 shows a comparison between experimental results,[34] shown on the two top diagrams, and simulated displacement profiles (bottom diagrams), under experimental conditions such that the isotachic train is not yet fully developed. The band profiles at 25 cm (left-hand two diagrams) and 50 cm (right-hand diagrams), were predicted for the separation of resorcinol from catechol. Single-component Langmuir isotherm parameters were employed in a competitive Langmuir model for the solutes. The competitive isotherms for the displacer and the second component had been estimated from the limited data available. A porosity of 0.8 was assumed. Otherwise, all the experimental conditions were used, *i.e.*, HETP, mobile phase flow-rate, column length. The breakthrough (left-hand two diagrams) was at just over 3 ml while the predicted value was 3.4 ml. The plateau concentration of the tail of the first component was experimentally determined as 10 mg/ml, the same as predicted. The peak maximum of the first component is predicted to be 50 mg/ml, and the maximum measured was 35 mg/ml. Published experimental data[34] showed that the second component displayed two maxima, as also predicted. With the same data, the profile was also determined at 50 cm (right-hand two diagrams). A nearly isotachic train was observed and also predicted. The heights of the bands were not exactly the same, indicating the errors made in the approximation of the displacer isotherm.

The agreement is excellent, considering the assumptions made in the Langmuir model. Quantitative agreement can be expected only if the competitive isotherms of all the compounds involved have been determined on the column actually used for the separation. The band profiles obtained during displacement development depend on the exact value of the competitive isotherms in the whole concentration range scanned during the experiment. On the other hand, less information is required in order to predict the band profiles in the isotachic train.

CONCLUSION

The theory of nonlinear chromatography now permits a useful discussion of the phenomena re-

sponsible for the broadening of elution bands at high concentration, for the progressive separation of these bands, and for the formation of an isotachic displacement train. It makes possible the calculation of the yields and production rates under any set of experimental conditions. The combination of our program with an optimization program, such as SIMPLEX, permits the rapid determination of the optimum conditions for maximum production, in preparative chromatography.[35]

The results discussed here are from numerical integration of the semi-ideal model. This model assumes that the kinetics of mass transfer in the column are fast and that the compositions of the mobile phase and the stationary phase are always very near to equilibrium. It is very important that the kinetics of the retention mechanism involved (sorption/desorption, whether in normal-phase, reversed-phase or ion-exchange chromatography, or complexation/dissociation, *etc.*) be fast compared to that of the other processes contributing to band broadening, such as diffusion in the mobile solvent. Thus, our results apply to all high-performance modes of chromatography.

These results cannot be used in some important applications, however, such as affinity chromatography, or when the viscosity of highly concentrated sample solutions in the mobile phase is much larger than that of the pure solvent, as may occur in the preparative separations of polymers and particularly proteins. In these cases, it is necessary to solve the general model [see equations (1) and (2)] incorporating an appropriate equation for the mass transfer kinetics. Analytical solutions have been proposed for some special cases.[15,16] A numerical solution valid for any kinetic equation is currently under development.[36]

MOLECULAR MODELLING OF STRUCTURAL CHANGES WHICH AFFECT CHROMATOGRAPHIC SELECTIVITY IN CHIRAL SEPARATIONS

MIRON G. STILL and L. B. ROGERS
Department of Chemistry, University of Georgia, Athens, GA 30602, U.S.A.

(*Received* 22 *April* 1988. *Accepted* 14 *August* 1988)

Summary—A molecular mechanics program, MM2, was utilized to model two chromatographic systems. It was first used to locate the most stable conformers of homologs of two derivatized silica stationary phases, *N-tert*-butyloxycarbonyl-D-valine-*N'*-n-butylamide and *N-tert*-butyloxycarbonyl-D-alanine-*N'*-n-butylamide, and also of the enantiomers of 2,2,2-trifluoroanthrylethanol (TFAE). The most stable (R) and (S) conformers of TFAE were then docked with those of the amino-acid derivatives. The calculations correctly predicted the elution order as well as the relative resolving powers of the two bonded phases. Replacing the n-butyl "spacer" chain with a methyl, ethyl, or n-propyl group confirmed the importance of chain length. Calculations involving the n-propyl spacer correctly predicted the elution order of enantiomers of TFAE on both phases as well as the relative enantiomeric resolving power of the two stationary phases. Similar calculations involving either ethyl or methyl spacers on the alanine derivative did not make correct predictions, thereby confirming the important influence of the spacer on fractionation of enantiomers.

Many chromatographic chiral phases have been synthesized and evaluated experimentally. Some of these phases were synthesized from species having many chiral centers. For example, silica phases bonded with bovine serum albumin[1] and α-acid glycoprotein[2] have been used to resolve chiral pairs. Enantiomeric pairs have also been separated on bonded phases which incorporate small molecules. Phases of this type include those which were originally created by Pirkle from dinitrobenzoyl derivatives of amino-acids.[3] Other derivatives of amino-acids which have been evaluated include formyl,[4] acyl,[5] and carbobenzoxy derivatives.[6] Lipkowitz *et al.* have used the molecular mechanics program MM2 to predict and confirm the elution order of TFAE enantiomers on dinitrobenzoylphenylglycine.[7–10] Armstrong *et al.* have also used computer modeling for studying the mechanisms of retention on cyclodextrin columns.[11] However, neither group has exploited molecular mechanics to its full capabilities. For instance, energies of interaction between individual atoms or groups can be obtained and often provide useful insight into the molecular interactions. Thus, the role and the relative importance of different groups can be determined. Examples will be given later.

The present report represents an independent study of the applicability of MM2 to chiral systems. After starting our work on a Pirkle-type phase, we learned that Lipkowitz was studying these phases, so we changed to a chiral chromatographic phase that had been synthesized and characterized chromatographically in our laboratory. Furthermore, examination of a second system seemed desirable as a test of the reliability of this computational method because many experimentalists are dubious of MM2 calculations for reasons such as "inadequate" handling of hydrogen bonding and general uneasiness about the absolute values of the calculated numbers. However, in the present case, we are interested not in the absolute values but in the differences for two very similar species.

In addition, our calculations explored the effects of two other variables: a change in the amino-acid side-chain and a change in the length of the spacer chain used to attach the amino-acid derivative to the surface of the silica.[12,13] Our calculations ignored the contributions of the surface, not because they are unimportant but because the MM2 parameters were not available. The surface effect, which is hoped will balance out in calculating a difference between two enantiomeric complexes, will be discussed later.

The chiral phases we used were synthesized by Hsu *et al.*[12] by bonding *tert*-butyloxycarbonyl (BOC) derivatives of amino-acids to a butyl spacer on silica in order to estimate the relative contributions of individual chiral centers to the overall chiral recognition exhibited by a tripeptide-derivatized phase. Hsu *et al.* evaluated their phases chromatographically with trifluoroanthrylethanol as a test solute in organic mobile phases. The chromatographic α-values found ranged from 1.02 for BOC–D-alanine to 1.10 for BOC-D-valine. On all the D-amino-acid phases, (R)-TFAE was the last to elute.

Therefore, the purpose of the present study was to use MM2 to make predictions and test their qualitative agreement with the chromatographic results for the separation of (R)- and (S)-TFAE on valine and alanine derivatives. If successful, the calculations should predict (*a*) the elution order of the TFAE enantiomers, (*b*) an effect of chain-length of the

spacer on α, and (*c*) a larger α-value [as reflected in the difference in energy between the (R) and (S) complexes] for valine complexes than for those of alanine. However, the calculated values would be expected to be larger than the experimental ones, since the MM2 calculations do not consider interactions which result in retention of both enantiomers but do necessarily differentiate them. The more prominent examples are the hydrophobic interactions between the solute and the unreacted spacer bonded to the silica, the hydrogen bonding between the solutes and the silanols on the surface of the column packing, and the effects of solvent interactions with both the solute and the stationary phase.

EXPERIMENTAL

All calculations were performed on a VAX 11/750 or a MicroVax II with version '87 of MM2 by Allinger.[15] This version incorporated improved hydrogen-bonding parameters, peptide parameters, and a simplex optimization routine for docking. These recent improvements were not available for use in previously reported work.[7-10] All calculations were performed with use of a dielectric constant of 4.4 to approximate the mobile phase of 60% hexane/40% methylene chloride used in the chromatographic study. However, specific solvent interactions were not included.

Figures 1a and 1b show the numbering for the species for which the energies were first minimized and then used for docking. This basic numbering system in Fig. 1a was maintained throughout the study. For example, when a methyl group was substituted for the n-propyl spacer, C-14 was deleted and C-13 was replaced by a hydrogen atom.

The following dihedral angles were examined. For the amino-acid species, the assignments made in Fig. 1a were: angle 1 = atoms 1,2,3,4; angle 2 = atoms 3,5,6,7; angle 3 = atoms 5,6,8,9; angle 4 = 7,6,15,16; angle 5 = 10,11,12,13; and angle 6 = atoms 11,12,13,14. For TFAE, shown in Fig. 1b, angle 7 = atoms B,C,D,E and angle 8 = atoms A,B,C,D. In all cases it is assumed that the system is viewed through the second of the four atoms listed, along the bond joining it to the third atom listed. A positive angle indicates that the fourth atom is clockwise relative to the first one listed, and a negative angle indicates that the fourth atom is counter clockwise to the first.

§Definition of atom types from MM2.

Four torsional parameters for the stationary phase and one for the solute were not available. Table 1 lists these parameters and the substitutions used. MM2 did not contain silanol parameters; therefore, BOC-D-valine-*N'*-alkylamide and BOD-D-alanine-*N'*-alkylamide were used as models of the stationary phases. It should be noted that n-propyl derivatives were emphasized in our calculations because they closely resembled the butyl species but required *many* fewer calculations for optimization. The effects of using methyl and ethyl spacers were also investigated.

Four strategies of docking were used, each designed to maximize certain interactions. Figures 2a–h illustrate these strategies, using both enantiomers of TFAE with BOC-D-valine-*N'*-n-propylamide as examples. The same strate-

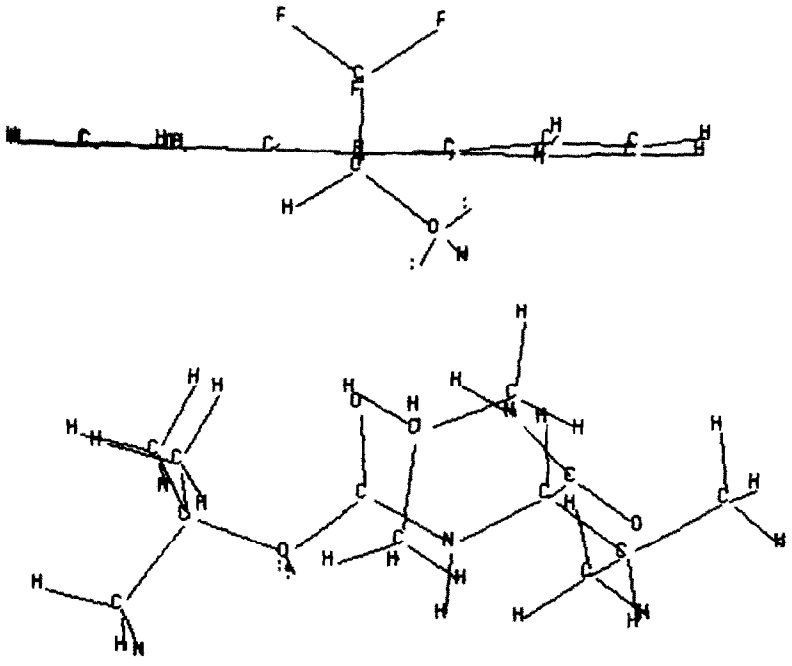
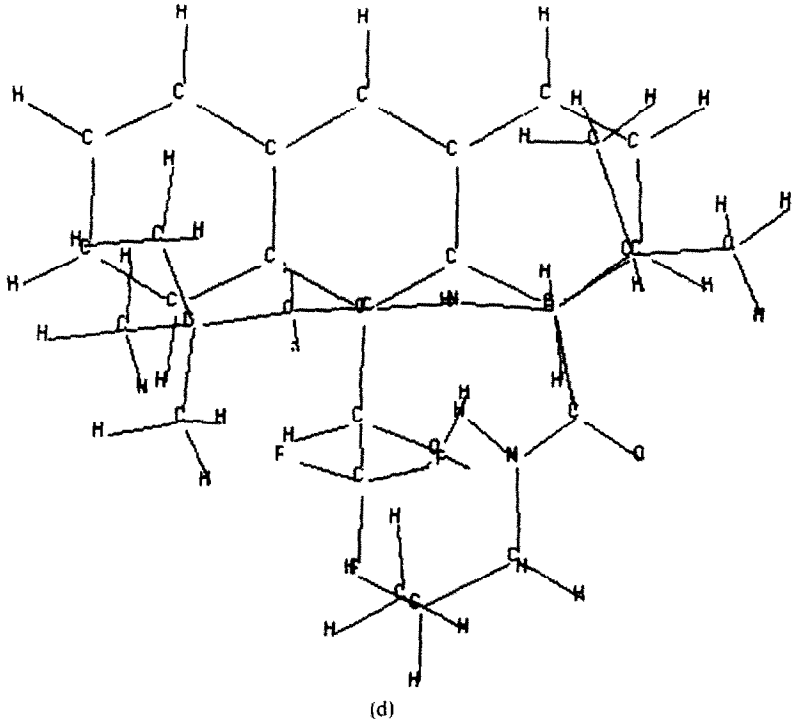
gies were used for species having the methyl, ethyl, and propyl spacers bonded to the BOC-D-valine and BOC-D-alanine derivatives. Only the most stable conformers were used for docking except in the case of BOC-D-valine-N'-n-propylamide, where two conformers were used because there was only a small energy difference between them.

The first docking strategy, shown in Figs. 2a and 2b, was based on observed NMR shifts.[12] It was designed to maximize both the interaction between the carbonyl oxygen atom of the BOC group and the hydrogen atom of the hydroxyl group of TFAE, and also the interaction between the hydrogen atom of the protected amine group and the anthryl ring. Different orientations were calculated in which



(c)



(d)

the TFAE was rotated in 30° increments about the carbonyl carbon atom of the BOC group, and the chiral carbon atom of TFAE was kept fixed on the z-axis. Many of the final minimized structures did not have large interaction energies for either of the assumed points of interaction, and the final orientations were extremely different from the initial ones. Therefore, other strategies were tried.

The orientations for the second docking strategy are shown in Figs. 2c and d. The points of interactions which were maximized were that of the carbonyl oxgyen atom of

the BOC with the hydrogen atom of the hydroxyl group of TFAE and also that of the hydrogen atom of the amino group of the spacer with the anthryl ring. The anthryl ring in Fig. 2d was rotated in 45° increments with respect to the carbonyl bond of the BOC group, with the chiral carbon atom of TFAE kept on the z-axis.

Next, Figs. 2e and f show the orientations for the third docking strategy. The points of interaction which were

maximized were that between the carbonyl group bound to the spacer and the hydroxyl hydrogen atom, and also that between the hydrogen atom of the amino group of the spacer and the anthryl group. The anthryl group was maintained above the carbonyl bond. Locations of the solute were changed by 1-Å increments first in the x and then the y direction.

Finally, Figs. 2g and h display the orientations for the fourth docking strategy. Here, interactions were maximized between the carbonyl oxygen atom bound to the spacer and the hydroxyl hydrogen atom as well as between the hydrogen atom of the protected amine and the anthryl ring. The anthryl ring was again above the carbonyl bond, and the solute was moved in 1-Å increments, first in the x and then in the y direction. This fourth docking strategy led to the most stable complexes.

RESULTS AND DISCUSSION

Individual species

As stated earlier, the emphasis in this work centered around calculations involving the n-propyl derivatives; however, it was possible to save computer time in the chain-length study because several angles were common to the methyl and ethyl derivatives which were examined first. Tables 2 and 3a show the most stable conformers of angles 2 and 3 for *N*-BOC-D-valine-*N'*-methylamide, and BOC-D-alanine-*N'*-methylamide. In both cases, the most stable conformer had angle 2 equal to approximately $-30°$ and angle 3, 120°; that conformer represented more than 90% of the population. Then, angle 1 was minimized for the BOC-D-alanine-*N*-methylamide, with angles 2 and 3 at the most stable values. Two conformers were found, at 0° and 180°, with the conformer at 0° more stable by 1.75 kcal/mole. With angles 1, 2 and 3 set at the most stable values, angle 4 of BOC-D-valine-*N'*-methylamide was examined. The most stable conformer had a value of 65% for angle 4 and represented 60% of the population. Table 3b lists the angles and energies of the other 3 conformers.

The ethyl derivatives of both BOC-D-amino-acids were also examined. The values of the most stable conformers for angles 1, 2 and 3 for BOC-D-alanine-*N*-methylamide were used to examine values for angle 5. Tables 4a and b show that the most stable conformer was found to have angle 5 equal to 68° for the valine-derivative and 61° for the alanine.

The propyl derivatives of the BOC-D-amino-acids have seven times as many conformers as the methyl derivatives, owing to the added dihedral angles, 5 and 6 (see Tables 5a and 6). For both the valine and alanine species, the most stable conformer had values of 60% for both angles 5 and 6. This conformer represented approximately 40% of the population for each species. Table 5b shows that, for BOD-D-valine-*N*-propylamide with its angles 5 and 6 equal to 60°, two conformers existed which were degenerate in energy when angle 4 was equal to 60° and 180°. Therefore, both of these were used for docking.

Locating stable conformers of TFAE was simpler. Figure 1b shows the two angles of interest for TFAE, 7 and 8. The conformer with angle 7 equal to $-10°$ and 8 to 139° represented 95% of the total population.

Docked pairs

Only the most stable (R) and (S) conformers for each species were used for docking, except for the

complexes of BOC-D-valine-*N'*-propylamide where the two conformers were docked. For each pair, only the most stable (R) and (S) complexes were compared.

For TFAE docked with BOC-D-alanine-*N'*-propylamide, the energy difference between the (R) (−29.23 kcal/mole) and (S) (−29.28 kcal/mole), complexes was 0.05 kcal/mole, which is within the uncertainty of the program. Top and side views of the most stable orientations for these complexes, obtained by using the fourth docking strategy, are shown in Figs. 3a–d. The α-value calculated for TFAE on the alanine phase was 1.00, which is within experimental error of the chromatographic value, 1.02.

*Relative energy difference.

When the same docking strategy was used for the BOC-D-valine-*N'*-propylamide, the energy difference shown in Table 7 between the (R) and (S) complexes (Figs. 4a–d) was 0.52 kcal/mole when the conformer with angle 4 equal to 180° was examined. With the conformer with angle 4 equal to 60°, the difference (between the most stable complexes) was 0.18 kcal/mole. In both cases, the (R) complex was the more stable; therefore, the (R) enantiomer should be retained longer than the (S), a prediction which agrees with experiment.

On the basis of the calculations it can be concluded that the valine phase would be more effective than the alanine, and that (R) TFAE would be eluted later than (S) TFAE from the valine phase. Both predictions are indeed in agreement with experimental data.

For the most stable pair of complexes involving BOC-D-valine-*N'*-propylamide, the contributions of several types of energies to the total calculated by MM2 are given in Table 7. The largest overall difference was for the non 1,4 van der Waals energy, which favored stability of the (R) complex by 0.66 kcal/mole. The compression energy also favored the stability of the (R) complex, but only by 0.08 kcal/mole. The other energy types slightly favored stability of the (S) complex; the largest effect was from the bending energy, but even that differed by merely 0.10 kcal/mole.

Examining the energy of interaction between parts of TFAE with all of the BOC-D-valine-*N*-propylamide was informative. Table 8 shows that the largest differences of interaction were for the anthryl ring and the oxygen atom, which favored retention of the (R) enantiomer by 0.24 and 0.20 kcal/mole, respectively. The largest of the other differences was for the trifluoromethyl group, 0.06 kcal/mole, which also favored retention of the (R) enantiomer. The two largest interactions for both the (R) and (S) com-

plexes were that for the anthryl ring and that for the hydrogen atom of the hydroxyl group, each of them with the entire species. Note, however, that the anthryl interaction differentiated ($\Delta E = 0.24$ kcal/mole) between the (R) and (S) species, whereas the hydroxyl hydrogen interaction did not ($\Delta E = 0.03$ kcal/mole).

Similarly, Table 9 shows the parts of BOC-D-valine-*N'*-propylamide which interacted with TFAE in both the (R) and (S) complexes. The largest

two interactions which favored retention of (R) TFAE more than (S) TFAE were for the isopropyl group and the carbonyl oxygen atom bonded to the spacer. These stabilized the (R) complex more than the (S) complex by 1.05 and 0.18 kcal/mole, respectively. The largest interaction which favored retention of (S) TFAE was that with the n-propyl group of the spacer. The (S) complex was favored by 0.96 kcal/mole.

Two other points, which interacted strongly with

both (R) and (S) TFAE but did not differentiate between them, were the hydrogen atom of the protected amine and the *tert*-butyl group. In fact, the hydrogen atom of the protected amine showed the strongest interaction for both the (R) and (S) complexes, −5.24 and −5.16 kcal/mole, respectively. However, these two functions did not significantly differentiate between the two mirror images, and simply stabilized the diastereomeric complexes while other functionals differentiated between them.

It should be noted that the energy values calculated from MM2 for the propyl derivative of valine predict a larger α-value than that found experimentally. This should indeed be the case, since MM2 ignores factors which increase the retention times of both enantiomers but do not differentiate them, such as residual surface silanols and hydrophobic interactions with unreacted spacer. However, the MM2 calculations involving the n-propyl derivatives agreed quite closely with the chromatographic data for the n-butyl spacer. For the BOC-D-valine-*N'*-ethylamide and -*N'*-methylamide derivatives, the (R) complexes

were calculated to be more stable than the (S) complexes by 0.49 and 0.40 kcal/mole respectively.

Calculations for the ethyl and methyl derivatives of alanine differed in major ways from those for the propyl derivative (Table 10) and thus from the experimental data for the butyl spacer. For the ethyl derivatives of alanine, the energy difference was calculated to be 0.50 kcal/mole, favoring greater retention of the (R) isomer; for the methyl derivatives the difference of 1.53 kcal/mole favored longer retention of the (S) enantiomer than of the (R). Furthermore, for either the methyl or ethyl derivatives, the alanine stationary phase was predicted to give a larger α-value than the valine phase. Thus, using the methyl or ethyl derivatives as an approximation yielded results which radically disagreed with the experimental data for the butyl spacer.

Table 10. Calculated energy difference (*kcal/mole*) as a function of spacer length

	Valine species		Alanine species	
Spacer	E*	α†	E*	α†
Methyl	0.40	1.97	−1.53	0.08
Ethyl	0.49	2.29	0.50	2.33
n-Propyl	0.52	2.41	−0.05	0.99

*Value calculated from ln $K = E/RT$.
†Value less than 1 indicates the (S) complex was calculated to be more stable than the (R) complex.

MM2 shows promise for examining the effects of structural changes of other chiral phases. Computational techniques can be extremely useful for design of stationary phases and finding the columns most suitable for resolving enantiomeric pairs. Further evidence for this has been found in our laboratory with preliminary calculations involving nonbonded interactions for three other enantiomeric systems. In each case, the calculations agreed with the experimentally determined elution order. Moreover, the relative α-values were correctly predicted by these calculations.[16] Hence in all five cases examined by our group, the calculations have agreed qualitatively with experimental data.

CONCLUSION

Our MM2 calculations have shown good qualitative agreement with experimental results when they were based on use of a propyl group instead of the corresponding butyl spacer. In these calculations, the elution order was correctly predicted, and the selectivity of each stationary phase was predicted. Hence, there was good qualitative agreement between experiments and the values calculated by MM2 for the interactions of TFAE with BOC-D-amino-acid stationary phases. In contrast, calculations based on methyl or ethyl as spacer group incorrectly predicted

the elution order in all but one case, and also the relative sizes of the α-values, thereby confirming the important role of the spacer in influencing the α-value for a fractionation.

AN AIR-CARRIER CONTINUOUS ANALYSIS SYSTEM

KAJ PETERSEN and PURNENDU K. DASGUPTA*
Department of Chemistry and Biochemistry, Texas Tech University, Lubbock, TX 79409-1061, U.S.A.

(*Received* 6 *May* 1988. *Accepted* 23 *August* 1988)

Summary—An air-carrier continuous analysis system (ACCAS) is introduced that permits the reaction of a fixed volume of a sample with fixed volumes of one or more reagents, either simultaneously or sequentially. ACCAS is envisioned as a complement to segmented continuous-flow analysis (SCFA) and flow-injection analysis (FIA). ACCAS is capable of high throughput rates (~3600 samples/hr) and low waste generation.

Automation of liquid sample and reagent processing was revolutionized by Skeggs[1] in 1957 with the invention of segmented continuous-flow analysis (SCFA). The commercial instrumentation introduced by the Technicon Corporation proved so successful that for years SCFA was identified with the trade name of the Technicon instrument, the Auto-Analyzer. Though the equipment for SCFA has undergone considerable development, the principle remains essentially the same, with the sample, gas for segmentation, and the reagents introduced into the flow system by peristaltic pumping at fixed rates, followed by signal detection. Although removal of the segmenting air by a debubbler prior to measurement dominated early practice, electronic gating of the detector output is now well-established and easily practiced.[2–7]

Flow-injection analysis (FIA) involves introduction of a fixed volume of sample as a segment into an unsegmented reagent-bearing carrier stream flowing at a fixed flow-rate. The sample and the carrier are completely miscible, and the reaction product formed as the sample and reagent diffuse into one another, is measured in a flow-through detector after a preselected reaction time.

Mottola[8] has attempted to trace the conceptual origin of unsegmented continuous-flow analysis, as in FIA. Enough evidence was presented to make readers wonder precisely where and when the technique was first invented. If the conceptual boundaries are further extended, it might be asked whether measurement of channel flow by multipoint downstream measurements following upstream injection of a concentrated dye is also a form of unsegmented continuous-flow analysis, albeit for determining a nonchemical parameter.[9] We believe it to be unquestionable, however, that a scheme for automated unsegmented continuous-flow wet chemical analysis first entered as a formal contender to SCFA only little more than a decade ago, in the papers by Růžička and Hansen[10] and Stewart, Beecher and Hare.[11] As the present decade draws to a close, we believe it fair to state that no two people have contributed more to make FIA what it is today than Růžička and Hansen,[12,13] although it clearly extends far past the confines of their contributions alone. The credit due them must extend considerably beyond that for coining the term flow-injection analysis; without their early determined pursuit, FIA would not have risen to its present status, that of a formidable competitor to SCFA, despite early predictions that it would consume too much reagent or require too high a pumping pressure to be practical.[14] Perusal of the resulting polemic[15–21] will disillusion anyone who believes that analytical chemistry is a dispassionate science. The intervening years have proven the validity of Haldane's concept[22] of the four sequential stages of acceptance.

Comparisons of FIA and SCFA are meaningful only when single-point (*e.g.*, peak height) measurements are made. FIA offers reproducible controlled dispersion, unattainable in SCFA, and thereby permits a variety of reproducible multipoint measurements (generally classed under the term gradient FIA) for which no parallel exists in SCFA. While the most fertile and novel uses of FIA lie in gradient applications, the vast majority of FIA publications (and likely an even larger majority of determinations performed) involve single-point measurements. Is FIA better than SCFA for such applications? With respect to some of the parameters important to the practicing analyst, *e.g.*, sample throughput rate, reagent consumption, *etc.*, Snyder[23] theoretically predicted that SCFA should be superior for all but those reactions requiring only a few seconds. The diametrically opposite conclusion was reached by Rocks and Riley,[24] based on literature reports of comparable determinations performed by the two techniques. In a study deliberately designed

*Author for correspondence.

to compare the two techniques, Patton and Crouch[25] found that for equilibrium-based spectrophotometric determinations, SCFA competes favorably with FIA, even for fast reactions, but noted that FIA is by far the simpler alternative in the limit. We believe that it is indeed simplicity and lower cost that allowed FIA such a wide entry to the average analytical laboratory and remain the leading reasons why there has been exponential growth of FIA-related publications for some time[26] and the present annual publication rate of papers utilizing FIA is far higher than that of those utilizing SCFA. This is despite the fact that the ratio of the number of actual determinations made by FIA to that made by SCFA (for any kind of end-use except publication) appears to be far more modest.

Dispersion, controlled and reproducible as it may be, is both the Samsonian mane and the Achillean heel of FIA. Unless techniques such as stopped-flow analysis or storage in a multiple-loop holding-valve system are used, sample dispersion plagues the utilization of FIA in situations that require long reaction times (minutes, rather than seconds). The means to limit sample dispersion as mentioned above are not without penalties: throughput rates and/or simplicity are sacrificed. Patton and Crouch [25] conclude that for reactions requiring multiple reagent addition and/or >0.5 min reaction time, the increased complexity of SCFA may be offset by its high mixing efficiency, low dispersion and sample/reagent conservation. However, they conclude that "the point at which this trade-off is reached is not clear-cut and the choice between the two complementary continuous flow techniques will be strongly influenced by the ingenuity of the operators and their predisposition [to FIA and SCFA]".

Attempts to incorporate the advantages of the one technique into the other are not new. Monosegmented flow analysis (MSFA) introduced by Pasquini and Oliveira,[27] for example, involves the use of a multiport multistack slider valve, essentially operated in a nested-loop configuration.[28] This system introduces an air segment on either side of the intercalated sample segment, to limit dispersion in FIA. The loop-type injection valve commonly used in FIA was incorporated into the carrier stream of an SCFA system by Gardner and Malczyk[29] to facilitate use of small sample volumes in SCFA. These systems show some dispersion, arrested by segmentation from progressing. It has been pointed out that similar systems in which one reactant is injected into another and allowed to disperse, or separately injected dispersing reactant zones are merged, in each case followed by segmentation, may be particularly facile for kinetic studies suitable to the permissible time-scale, especially with multi-wavelength detection.[30] Of particular relevance to the present paper is the work of Attiyat and Christian.[31] They used an immiscible fluid carrier, air, to transport a liquid sample to a detector; 100-μl samples of a zinc solution were transported to an atomic-absorption spectrometer. A comparable water carrier FIA system suffers from considerable sample dispersion, and gives only half the sensitivity (calibration slope). Throughput rates as high as 600/hr were possible. The authors were careful to point out that such systems can be used to carry out a reaction between a gaseous reagent and a liquid sample and may thus be of considerable value.

In the present paper, we introduce the air-carrier continuous-analysis system (ACCAS) in a form that allows the reaction of a fixed volume of a sample with fixed volumes of one or more reagents introduced either simultaneously or sequentially, in a number of different modes. The technique was developed primarily with the goal of reducing the total amount of liquid waste generated per sample. ACCAS falls in between FIA and SCFA in more senses than one, and borrows heavily from both techniques. Predictably, it has its own advantages and disadvantages. We envision ACCAS as a subclass of immiscible fluid-carrier continuous-analysis systems (IFCCAS). IFCCAS configurations, involving for example, injection of an aqueous sample into a carrier stream of methyl isobutyl ketone, have also been described by Attiyat and Christian.[32]

PRINCIPLES

Simultaneous introduction techiques

Split-loop injection. The simplest ACCAS mode involves the use of two 3-way valves V1 and V2 functioning as a loop injector[33] operated in a split-loop configuration[34] while a third 3-way valve V3 in concert controls the load/injection functions (Fig. 1). A suction pump P, *e.g.*, a peristaltic pump operated in the aspiration mode, is used and its effluent is directed to waste. All three valves are switched in tandem. [Throughout this paper, we indicate the common port of such a valve by a solid line; the port

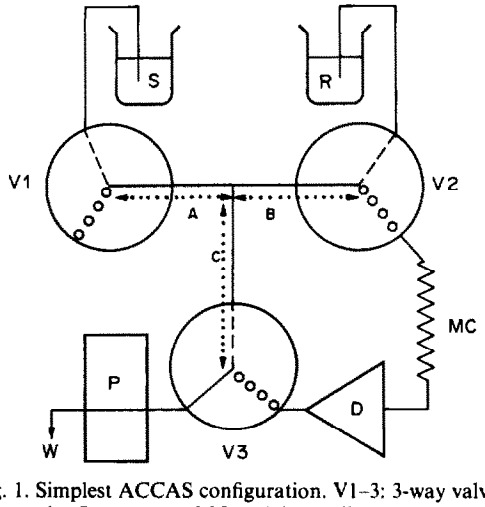

Fig. 1. Simplest ACCAS configuration. V1–3: 3-way valves; S: sample, R: reagent; MC: mixing coil, D: detector, P: pump, W: waste.

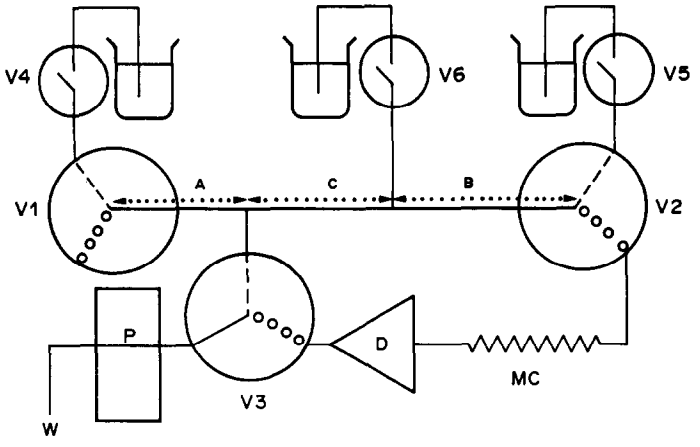

Fig. 2. Injecting multiple contiguous segments with a split loop. V4–V6 on/off valves; other symbols as in Fig. 1.

connected to the common line when the valve is energized is indicated by a dashed line (EC) and the port otherwise connected to the common line (CC) is shown by a line of open circles. The "normally open/normally closed" (NO/NC) nomenclature unfortunately has a diametrically opposite meaning in electronics to that in fluidics. Therefore, we use the terminology "commonly connected/energized connected" (CC/EC) to avoid confusion]. With the valves in the EC mode, the pump aspirates sample and reagent and fills the lengths A and B of the loop, respectively, with the two liquids, any excess being aspirated through C and V3. Length C is kept short so that it can be completely filled with liquid during each load cycle without wasting undue amounts of sample and reagent (partial filling of C during the load cycle may result in poor precision). When the valves are de-energized, the pump draws the contiguous sample/reagent segment through a mixing coil MC which is a knotted tubular conduit.[35] The length of MC and the valve cycling period may be adjusted so that one or more sample/reagent segments can be resident in MC at any particular instant, depending on the desired reaction time. Note that ACCAS does not *necessarily* involve continuous flow simultaneously in all parts of a system. In the system above, for example, the liquid segments in MC abruptly stop as the valves are switched to the load mode. The mixed liquid segments eventually pass through the detector, and thence to waste.

A minor modification of this system is necessary if there is a significant pressure difference between the reagent and sample. To avoid transfer of liquid from the higher to the lower pressure source during the time the two are in communication (all valves EC), two on/off valves V4 and V5 are incorporated in the lines leading to the sample and the reagent, respectively. Valves 1 and 2 are then no longer operated in tandem. The sample is loaded by turning on V1, V3 and V4 and then the reagent is loaded by having only V2, V3 and V5 on. In another modification, applicable to process-analysis, the sample can typically be made available from a regulated positive-pressure source. If the reagent is made available from a pneumatically pressurized source, the suction pump is no longer needed. The sample/reagent is moved by positive gas pressure from the CC port of V1. A fixed constant gas pressure is usually inadequate; it is necessary to use an on/off valve to admit the pressurizing driving gas in short bursts. Alternatively, a fixed pressure is used at the CC port of V1 but an on/off valve fitted after the detector is used to control the exit of the liquid.

A third modification of the system in Fig. 1 involves the use of an electropneumatically driven 6-port rotary loop valve with a split-loop in lieu of valves V1 and V2. Compared to the system in Fig. 1, a lower total injected segment volume is attainable in this configuration.

More extensive split looping is possible with a slightly more complex configuration. Figure 2 illustrates such a system. The 3-way valves V1, V2 and V3 serve the same functions as in Fig. 1; on/off valves V4, V5 and V6 are added to introduce three contiguous liquid segments of defined volume into one loop, regardless of any pressure difference between the sources of these liquids. With the system in the load position, V4, V5 and V6 are sequentially turned on (one at a time) and respectively fill the lengths A, B and C. This contiguous liquid segment is delivered to the sysem during the injection mode.

Fixed loop injection. The split-loop injection approach is simple but may lead to limited precision for very small injected volumes, because the interface zone between the two liquids, defined by the tee-port, may shift from run to run. A small-bore tee ameliorates, but does not eliminate, the problem. Further, if the measurement is at all sensitive to the total reaction time, loading cycles must also be strictly controlled because the interfacial reaction has already started during the load period. It is therefore desirable to confine the sample and the reagent in

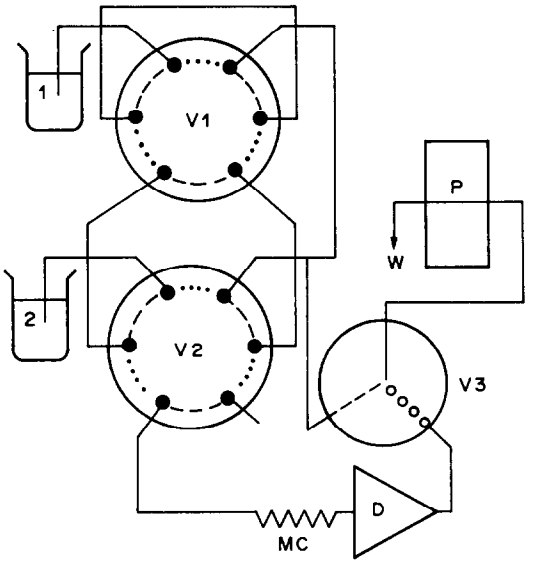

Fig. 3. A nested loop ACCAS system. V1, 2: PTFE rotary valves; V3: 3-way valve; other symbols as in Fig. 1.

individual fixed loops but still inject them as contiguous segments. This is easily possible with a 10-port rotary valve;[36] the ports (1–10) may, for example, be connected to: loop 1, liquid 1 inlet, liquid 1 waste, loop 1, loop 2, liquid 2 inlet, liquid 2 waste, loop 2, upstream components, downstream components. In general, for contiguous injection of n individual liquids contained in n individual loops, a $(4n + 2)$-port valve is needed. (It is, of course, possible to use all such valves in a split-loop configuration, effectively doubling the number of individual liquids a valve can handle, but with the attendant disadvantages of split-looping.)

An alternative plumbing scheme to accomplish the same ends may utilize two 6-port valves in a nested loop configuration.[28] An arrangement in which a 6-port rotary valve V1, nested within the sample loop of a similar outer valve V2, is used in tandem with a 3-way valve V3 to allow fully automated load/injection functions with a single aspiration channel, is shown in Fig. 3. Although the component 2/component 1/component 2 arrangement may appear redundant, the leading and trailing volumes of component 2 need not be identical. With long segment lengths and short mixing lengths, the mixed segment is spatially inhomogeneous but yields a reproducible mixing profile since all variables are well-controlled. This makes gradient ACCAS possible. In principle, the inner loop may also be an active-wall open tubular reactor, permitting differential analysis of the components of the sample loaded in V2, in much the same way that the original nested loop system was used for differential analysis in FIA with a discriminating packed-bed reactor.[28]

Principal variations of the nested loop approach include operating the inner valve in a split-loop configuration. The substitution of an 8-port valve for V1 leads to the functional equivalent of a 14-port valve and allows the contiguous injection of three individual liquids.

Sequential introduction techniques

Pulsed reagent introduction. We have previously described the use of membrane reactors in FIA, that are operated in an intermittent reagent-introduction mode.[37] The technique is functionally equivalent to reagent introduction at a tee by stop–go pumping but is simpler and typically leads to better precision. Briefly, the sample/carrier stream flows through a segment of a porous hydrophobic tubular membrane. The membrane is surrounded by a jacket tube and the annular volume within the jacket is in fluid communication with an on/off valve, connected in turn to a pressurized reagent bottle. Energization of the valve causes reagent to be introduced through the membrane pores into the principal flow stream. Operation in the reversed flow-injection analysis (r-FIA) configuration[38] is the simplest; however, reagent introduction timed in concert with sample injection permits the functional equivalent of merging zones. The membrane essentially provides a diffusion barrier between the reagent and the principal flow-stream in this scheme. This technique can be used in a simpler and more elegant fashion in ACCAS.

Because the fluid carrier, air, is immiscible with the sample, it is superfluous to incorporate membranes in the pulsed reagent-introduction scheme for ACCAS. It is sufficient to use a small-bore tee. Also, it is preferable to use active sensing of the presence of a liquid segment in the reagent-introduction tee to determine the appropriate time for reagent introduction, rather than to rely on timing. Although universally applicable optical schemes exist to detect the presence of an immiscible liquid segment by reflection at the interface, the simpler alternative of the measurement of electrical resistance provides very high reliability if the two immiscible fluids are air and a polar, relatively conductive, liquid.[33] Since most ACCAS applications are likely to fall in this category, a simple pulsed reagent-introduction arrangement for ACCAS is shown in Fig. 4. The sample is introduced into a flowing air stream by valve V1 (such as a six-port rotary loop injector or its functional equivalent). The injected liquid segment flows through a tee. Two platinum wire probes are sealed in, one in each long arm of the tee, and the electrical resistance between them is monitored. The short-arm of the tee is in fluid communication with a pressurized reagent reservoir via an on/off valve V2. When the injected liquid enters the tee and shorts the Pt-sensors, appropriate electronic circuitry energizes valve V2 for a preselected period of time and thus introduces the reagent into the injected liquid segment. Further, following the actuation of V2, the circuitry ignores the status of the resistance between the sensors for another preselected period of time. This latter period at least equals or exceeds the residence time of the

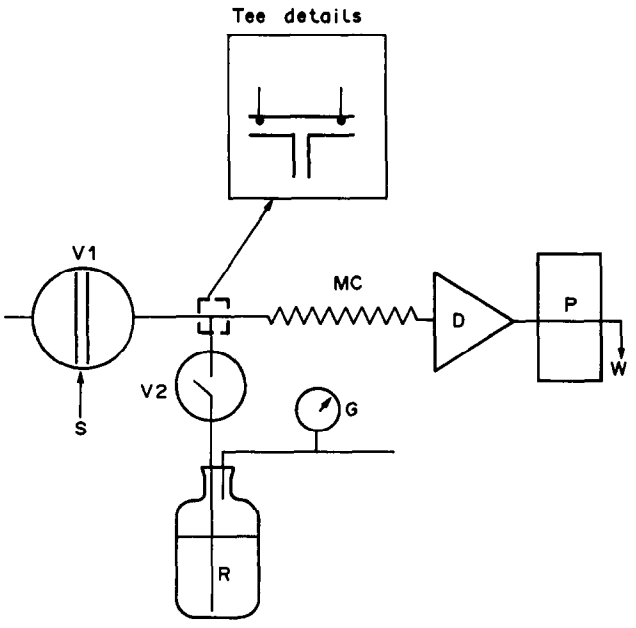

Fig. 4. A pulsed reagent-introduction system in ACCAS. Inset shows platinum resistance probes located in the tee. V1: six-port rotary loop injector; V2: on/off valve; G: pressure gauge; reagent bottle is pneumatically pressurized; other symbols as in Fig. 1.

injected liquid segment in the tee (whether the principal flow-stream is continuous as for the described arrangement, or intermittent, as would result from a single aspiration channel controlling both load and injection functions with the aid of an additional 3-way valve). Without this provision, reagent will continue to be introduced. The injected liquid segment containing the reagent introduced through the tee then flows through a mixing coil MC into the detector. The length of MC is adjusted according to the desired reaction time and thus may contain one or more segments at any given instant.

Many useful variations of the pulsed reagent-introduction system are possible. Valve V1 may be a more complex system, used to introduce the sample contiguous to one or more liquid segments. A mixing coil is placed between V1 and the tee, such that mixing (total or partial) is achieved between these components before the pulsed reagent-introduction occurs. One or more pulsed reagent-introduction systems may be sequentially linked by conduits representing the desired reaction time under the particular operating conditions, to perform sequential multistep reagent-introduction. Highly permeating reagents may be introduced through a nonporous permeable membrane,[39-41] rather than through a tee; electronic control may not even be necessary for these cases since the reagent can be removed from the membrane surface only by a liquid segment.

Valve-based sequential reagent introduction

ACCAS is heavily dependent on the present availability of relatively low-cost, low internal volume, fast-acting inert valves, and powerful microprocessors to govern their status. Incorporation of the ability to actively sense the presence of a liquid segment adds another dimension and makes possible sequential reagent-introduction by means other than pulsed introduction.

An example is shown in Fig. 5. Valve V1 is a electropneumatically actuated 6-port rotary loop valve operated in the split-loop configuration. V2 and V3 are on/off valves connected to the sample and reagent sources respectively and serve to prevent direct communication between them and allow reliable loop-filling despite pressure differences between the two sources. V4 is an on/off valve that allows air to enter valve V1. V5 is an on/off valve that allows fluid communication with a second reagent. Valves V6, V7 and V8 are 3-way valves; the first essentially governs load/injection functions; the latter two switch in tandem and are used to introduce the second reagent. A typical sequence of operation is depicted in Table 1. Steps 1 and 2 involve the loading of sample and reagent 1 respectively, each step occupying 4 sec. In step 3, the contiguous sample–reagent segment is drawn into mixing coil 1; the segment is mixed by this action. The step time (4.5 sec) is not long enough, however, for the segment to proceed beyond MC1, so it stops there. The status of V4 and V5 are now changed, so that during step 4 the pump draws reagent 2 through V8, the length V_{R2}, the short arm of the tee, and V6, V7. At the completion of step 4, the right-hand and the bottom arms of the tee (see inset) are full of reagent 2. In step 5, V4 and V5 are changed in status again. This causes the mixed segment in MC1 to start moving towards

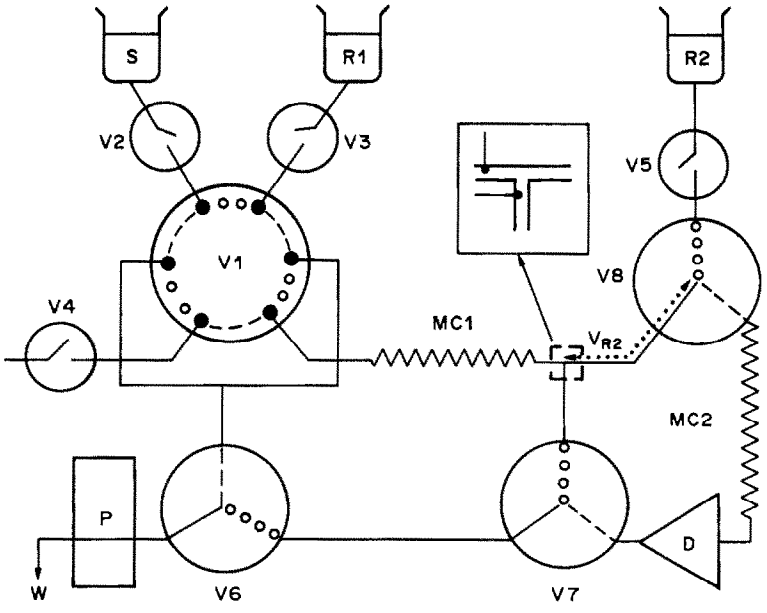

Fig. 5. ACCAS sequential reaction system. V1: 6-port rotary valve; V2–V5 on/off valves; V6–V8: 3-way valves; other symbols as in Fig. 1. Inset shows location of Pt-probes in the tee.

the tee. The leading air segment in front of the liquid segment moves any reagent 2 located in the short arm of the tee, so that the reagent 2 interface is essentially flush with the right side of the T-junction. As the segment continues to move in, it contacts reagent 2 and begins to move toward the bottom port. The platinum probes are shorted at this point and this initiates step 6, which lasts for 8 sec and causes the contiguous segment of (sample + reagent 1) and reagent 2 to be drawn into mixing coil MC2 and eventually into the detector D.

EXPERIMENTAL

Equipment

A single-channel Ismatec model Mini-S 860 (8 rollers, fixed 60 rpm speed, Cole-Parmer, Chicago, IL) pump was used for all applications. PVC pump tubing (Elkay Products, Shrewsburg, MA) was used for all pumping.

Six-port rotary PTFE valves were Rheodyne model 5020 equipped with model 5701 pneumatic actuators (Rheodyne Inc., Cotati, CA) and were actuated by 40 psig (2.8 kg/cm^2) in-house compressed air delivered through a pair of 3-way solenoid valves (Skinner Valve, Model MBD002, 12 V DC, New Britain, CT). The actuation times of these rotary valves were not explicitly measured but appeared to be substantially under 250 msec at the stated actuation pressure. On/off valves, as used in ACCAS applications, do not, in general, need to be of especially low internal volume. We have used either normally off 2-way valves (model LFAA 1201718H, fluid contact parts silicone rubber and PTFE-coated stainless steel) or a similar 3-way valve (model LFAA 1201618H) with the CC port closed off. These valves have a total internal volume of 99 μl and are actuated in under 15 msec at the rated voltage (12 V dc, 490 mW, The Lee Company, Westbrook, CT). The preferred 3-way valve for

Table 1. Temporal operation of the system in Fig. 5*

Step No.	Time, *sec*	Valve status								Function
		V1	V2	V3	V4	V5	V6	V7	V8	
1	0–4	EC	on	off	—	—	EC	—	—	V_S is loaded with sample

3	8–12.5	CC	off	off	on	off	CC	CC	CC	Sample and reagent 1 drawn from V1 and mixed in MC 1; stop in MC 1
4	12.5–15.5	CC	off	off	off	on	CC	CC	CC	Reagent 2 is loaded into V_{R2}, reaction continues in MC 1
5	15.5–18.0	CC	off	off	on	off	CC	CC	CC	First mixed segment enters tee and contacts V_{R2}
6†	18.0–26.0	CC	off	off	on	off	CC	EC	EC	First mixed segment and reagent 2 enter MC 2 contiguously, en route to the detector

*Absence of a specific status indication connotes that this valve status is not important for this step. The dotted line in the figure depicts the CC port, the dashed line the EC port. Off status for 2-way valves connotes no connection.
†This step is initiated by active sensing rather than by time, see text.

low internal volume applications was also a Lee valve (LFYA 1203032H, all-fluorocarbon contact parts, 15 μl internal volume, rated pressure 60 psig, actuation time under 25 msec at rated power: 12 V dc, 2 W). The mean time before failure for the Lee valves is rated at between 10^7 and 2×10^8 switching cycles, depending on the valve type. In some applications it was possible to substitute less expensive all-PTFE 3-way valves of somewhat greater internal volume (30 μl) and lower pressure rating (20 psig) from a different manufacturer (model 075T3WMP, actuation time 15 msec at rated power: 12 V dc, 2.6 W; Bio-Chem Valve Corporation, East Hanover, NJ). The cost of the valves ranged from $35 for the on/off valves to $400 for the complete electropneumatically actuated 6-port rotary valve assembly.

System control was accomplished with a programmable electronic timer (Micromaster LS, Minarik Electric, Los Angeles, CA). The timer provides control of eight independent contact closure switches and can monitor the logic status of sixteen different input channels and perform any common logical operation based on these inputs. It contains four independent sequential process controllers, each providing 100 msec resolution, and one high-speed counter providing 10 msec resolution. The programming capacity is 9999 steps and instructions can be stored on and downloaded from magnetic media. Light-emitting diodes indicate the status of all input/output channels. Though programming the timer is relatively complicated, the device offers remarkable capabilities for its cost ($570).

In this work, we have exclusively used home-built photodetectors which utilize a short segment of a straight, 1.65 mm i.d. thin wall glass tube as the final conduit to the detector as well as the flow cell. The diameter of the tube serves as the optical path. This design is functionally identical to that described by Sly *et al.*[43] For many initial experiments, the previously described[44] filter photometer with this type of radial optical-path flow-cell was utilized. For the bulk of the experiments described here, however, an LED-based detector similar to the design of Sly *et al.*[43] was used; the design is shown in Fig. 6. The detector housing D is an opaque female coupler for $\frac{1}{4}$-28 threaded male nuts widely used in liquid chromatography and FIA. A hole of appropriate diameter is drilled through the middle of the coupler, perpendicular to the threaded aperture. The glass tube TT passes through this drilled hole; the detector housing can be moved along the tube. No. 004 O-rings (1/16 in. thick, 13/64 in. diameter, 5/64 in. aperture, Midcap Bearing, Lubbock, TX) were inserted, one from each threaded side of D, and defined the optical aperture. The light source was a high brightness GaAlAs light-emitting diode (660 nm, rated optical output 5 mW at 20 mA) molded in a transparent epoxy case with a 2 mm diameter hemispherical lens-end termination (Type SSL-LX20583SRC, Lumex, Inc., Palatine, IL). The LED was inserted from one threaded end of D and held in place by opaque epoxy adhesive. The LED was powered by a constant-current source[44] at 25 mA. Similarly, a photodiode (Type G1112, Hamamatsu Corp. Middlesex, NJ) was inserted at the other end of D and held in place by opaque epoxy adhesive. The photocurrent output was converted into a voltage output by a current–voltage converter and this circuitry also provided gain and offset controls before the final output.[44] The detector output was linear in transmittance; the data were manually converted into absorbance. Although the optical path-length attainable by this type of flow geometry is limited, it should be realized that a reduction in cell path-length does not cause a proportionate increase of the detection limit (in concentration units).[45] Detectors that utilize this flow geometry are commercially available (*e.g.*, from JASCO, Inc.). The output data were acquired by an Apple IIe microcomputer equipped with a 12-bit A/D board and/or a strip-chart recorder (Knauer, Model TY-2).

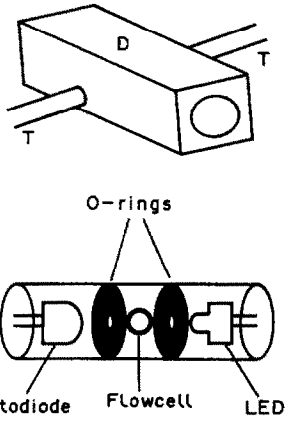

Fig. 6. LED-based, radial optical-path detector. The top portion shows the external appearance, a glass tube (flow-cell) TT passing through a $\frac{1}{4}$-28 female coupler D. The internal placement of components is shown in the lower portion.

Reagents

Unless otherwise stated, all solutions were prepared from analytical grade reagents in distilled demineralized water. Compositions are described under individual experiments.

Experimental configurations

All manifolds were made from PTFE tubing of various gages, and were of "standard" wall thickness (Zeus Industrial Products, Raritan, NJ); the stated diameters are the nominal values quoted by the manufacturer and were not explicitly measured. In making mixing coils, we briefly investigated the mixing efficiency of different geometries, given the same length and diameter of the conduit. Single-bead string reactors[46] or loosely filament-filled tubes led to extensive shattering of liquid segments. In open tubular mixers, tightly coiled helices produced much better mixing than straight tubes, and mixing produced by knotted conduits[35] was still more efficient. The knotted tubes involved closely spaced successive knots. Typical dimensions of the ellipsoid knots were 1–1.5 cm in the major axis and 0.8–1 cm in the minor axis. Frequent shattering of segments also resulted from abrupt diameter mismatches if different tubing diameters were used in the flow system. Tapering the larger bore tubing to match the bore of the smaller one is necessary for successful coupling. (Tapering to match the bores of two different diameter conduits was also found necessary to improve reproducibilities in FIA based on peak width measurement.[46]) Individual experimental systems are described below.

Experimental systems

Experimental system 1 utilized the configuration of Fig. 1. Loop lengths A and B were 6.2 cm long, 0.56 mm i.d. tubes, so, including the internal volumes of V1 and V2 (7.4 μl per passage) the sample and reagent volumes were ~23 μl each. The pump aspiration rate was 1.75 ml/min. The mixing coil was 40 cm of 1.1 mm i.d. knotted conduit (380 μl residence volume). Two different experiments were conducted: 0.1–0.75mM ferric nitrate slightly acidified with dilute nitric acid was used as the sample and 0.5mM Methylthymol Blue (MTB) containing 80mM acetic acid and 20% v/v 2-propanol (as wetting agent) was used as the reagent. Both ML and M_2L are formed under these conditions and the reaction is far from instantaneous. Although the mixing coil was long enough to accommodate up to 8 sample/reagent mixed segments, the system was operated with a load period of 2 sec and an injection period of 13 sec, resulting in only one segment being resident in the mixing

coil at any given time, and a throughput rate of 240 samples/hr (experiment 1a).

In the second experiment utilizing the same configuration, the lengths A and B were reduced to 3.6 cm each of 0.3 mm i.d. tubing (resulting in sample/reagent volumes of 10 μl each) and the mixing coil was reduced to 8 cm of a 0.8 mm i.d. knotted tube (2 knots, residence volume $\sim$40 μl). The chemical system involved a fast reaction, 0–0.20M cupric sulphate containing 0.10M sulphuric acid as sample, and 2M ammonia solution as reagent. The load and injection periods were 1.0 and 1.0 sec respectively, resulting in a throughput rate of 1800 samples/hr (experiment 1b).

The second experimental configuration utilized a six-port rotary valve to substitute for valves V1 and V2 in a split-loop configuration. The sample and reagent volumes were 8.6 μl each (3.5 cm long, 0.56 mm i.d. tubing) with a mixing coil of 40 μl residence volume (8 cm, 0.8 mm i.d. tubing) and a pump aspiration rate of 2 ml/min. Load and injection cycles were 1 sec each, resulting in a sample throughput rate of 1800/hr. The cupric sulphate–ammonia reaction was studied (experiment 2).

The third experimental configuration involved a nested loop with two rotary valves (Fig. 3, but without V3, and load/injection operation was not automated). The inner loop was 19 μl in volume and each of the outer loops was also 19 μl in volume (0.56 mm i.d. tubing, includes valve port internal volumes). Cupric sulphate and ammonia solutions were utilized as the sample and reagent; loading and injection were manual. The pump was operated in a positive-pressure pumping mode (air 3 ml/min). The mixing coil was 40 μl in volume (0.8 mm i.d., 8 cm). Manual operation precluded high throughput rates; a nominal throughput rate of $\sim$100/hr was studied (experiment 3a).

The nested loop configuration was also studied for the applicability of gradient ACCAS, with long loops. The inner loop volume for this application was 40 μl, the leading outer loop 75 μl and the trailing outer loop 150 μl, all made from 0.8 mm i.d. tubing. The mixing coil for this application was 280 μl in volume (1.0 mm i.d. tube, 36 cm long, 5 or 6 knots) with the air carrier flowing at 1.76 ml/min. The sample, loaded into the inner loop, was a solution of Methylene Blue (10^{-3}–2×10^{-3} w/v %, in water) and it was allowed to disperse into leading and trailing segments of water (experiment 3b).

Pulsed reagent-introduction was studied in a number of different configurations; essentially the same reproducibility was observed in the different modes. Results are described for the system shown in Fig. 4, operated at a throughput rate of 3520/hr for the Fe^{3+}–MTB reaction system; the reaction was incomplete at the time of measurement. The sample (Fe^{3+}) volume was 27 μl, including valve internal volume. The mixing coil was 280 μl (36 cm, 1.0 mm i.d.). The pump aspiration rate was 3 ml/min. 2-Propanol and/or zonyl FSN (a fluorocarbon surfactant, Dupont, 1 μl/ml) was necessary in the reagent formulation (see experiment 1a) for better wettability. The reagent was pressurized under 10 psig pneumatic pressure and sufficient 0.3 mm i.d. restriction tubing was added between the outlet of valve V2 and the tee to obtain reagent addition in $\sim$3-μl increments for 100 msec actuation time of the valve (experiment 4).

Results for valve-based sequential reagent-introduction are described for the experimental system shown in Fig. 5; the timing sequence described in Table 1 was used. The chemical system involved the determination of salicylic acid by the Berthelot reaction. The ternary reaction between a phenol, an amine (ammonia) and a suitable oxidant (hypochlorite) best proceeds if the amine is first added to the phenol.[47] The split-loop of V1 (0.8 mm i.d. tubing) was asymmetric; 123 μl of sample and 17 μl of reagent 1 (0.1M ammonium chloride, 4% w/v Na_2EDTA, 0.50M sodium hydroxide and 1% w/v sodium nitroprusside, the last functioning as a catalyst; prepared fresh daily) are delivered by this valve to MC1 (8 cm of 0.8 mm i.d. tube + 30 cm of 1.1 mm i.d. tube, total residence volume 325 μl). The length V_{R2} was 14 cm of 0.8 mm i.d. tube (70 μl) and reagent 2 was a 4.5% v/v solution of the commercial bleach Clorox (5.25% w/v NaOCl). The second mixing coil was 191 cm of 1.1 mm i.d. tubing in addition to a 31-cm 0.8 mm i.d. tube (total residence volume 1970 μl). With a pump aspiration rate of 3 ml/min, the particular timing sequence described in Table 1 resulted in a first step reaction time of $\sim$10 sec and a second step reaction time of $\sim$130 sec, with a throughput rate of 135 samples/hr. Salicylic acid solutions (0.001–0.004% w/v) were used as the sample (experiment 5).

Segment-sensing an automated pulsed reagent-introduction

The sensing of a polar liquid segment is accomplished by the "bubble-gate" described in more detail elsewhere;[33] the sensor resistance is one arm of a bridge circuit, and an adjustable potentiometer is another arm and governs the tripping point. The bridge output is fed to a voltage comparator such that the comparator output goes high as the sensor resistance goes below the tripping point. This output can be directly used by the Micromaster LS to start its own ladder program, which for example, introduces a reagent for 200 msec by turning on a valve and then waits another 500 msec before returning to the principal program. It is also possible to use the sensor output to perform a similar function without relying on the logic capability of the timer; a simpler timer can be used, for example with the schematic shown in Fig. 7.

The resistance between the Pt-probes, shown in a fixed trip-point configuration, governs the output of the voltage comparator U1. As the sensor resistance goes low, Q1 conducts, K1 closes, and initiates the timing cycles of the 555-type timers U2 and U3. The on-period of U2, selected by the 91 kΩ resistor and the 1 μF capacitor, is 100 msec (1.1 RC) and relay K2 is energized for this period, delivering reagent through the valve. Relay K3 is also simultaneously energized by U3, its period (0.2–10 sec) being selected by the 1000 μF capacitor and the switch-selectable (SW1) resistor bank. This operation is depicted in Fig. 8.

RESULTS AND DISCUSSION

We would emphasize that the present paper is essentially a feasibility study of the ACCAS concept. None of the systems described was optimized with respect to sample/reagent volumes, reactor lengths/volumes or other physical/chemical configurational details.

Data discrimination

The conductivity-based "bubble-gate" was first used to control data acquisition[2] and the present version has also been used for a similar purpose.[33] During the present work, we found that a short piece of porous membrane tubing performs reliable desegmentation when positive pressure pumping is used (as opposed to aspiration). However, measurement without recourse to desegmentation was judged to be preferable. The periodicity of the liquid/air segments can be exploited for this purpose[7] and active sensing is no longer needed in this approach. However, reasonably precise timing is still required. These approaches were developed primarily to govern data output to a strip-chart recorder. With a continuous data-acquisition system having a reasonable computing speed, a more flexible approach is feasible. Referring, for example, to an experiment where the flow through the detector is continuous (*e.g.*, experi-

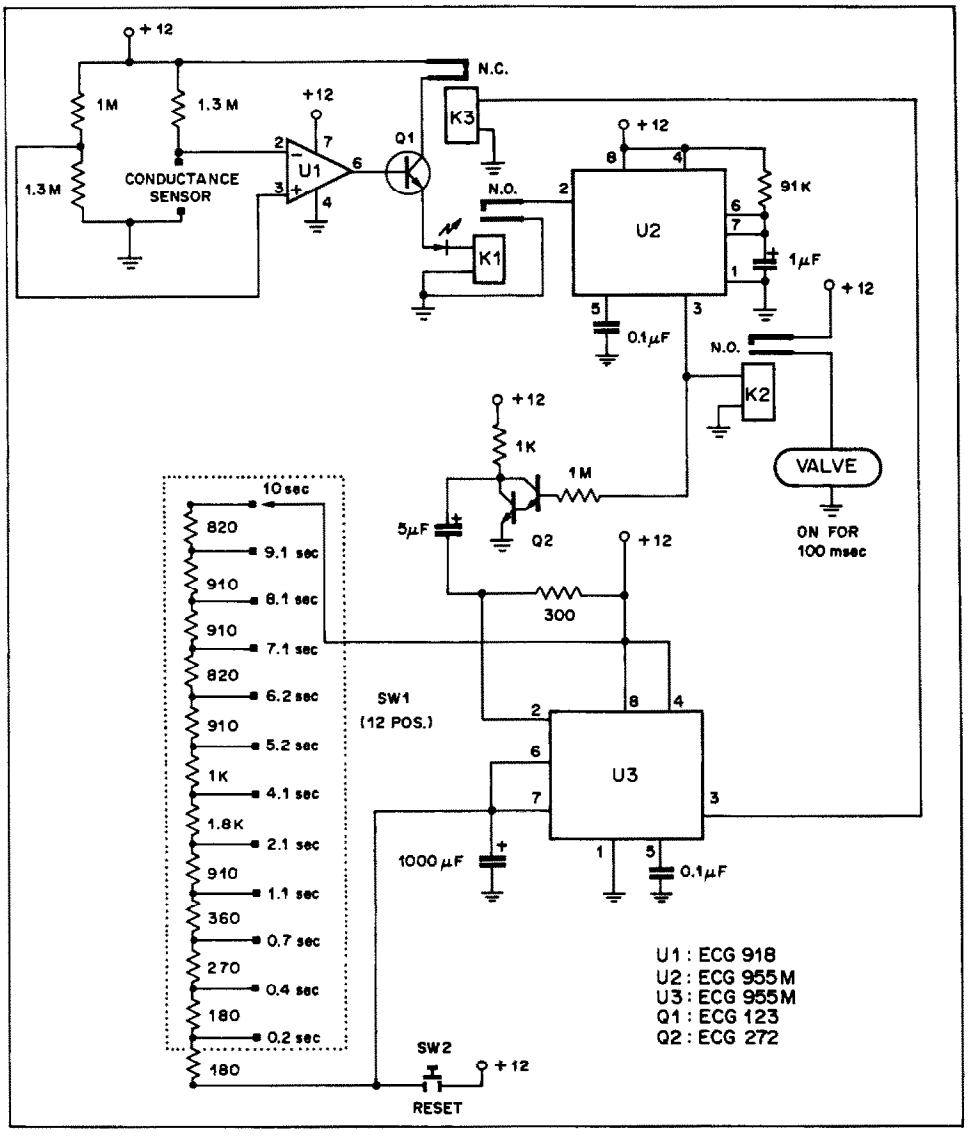

Fig. 7. Schematic of circuitry used for automated pulsed reagent-introduction.

ment 4), let us assume that the measurement occurs 10 sec after sample injection and that 2 sec are required for the liquid segment to pass through the detector. The data-acquisition system is triggered 9.5 sec after the sample injection and acquires data for 3.125 sec (50 points per set at a sampling rate of 16 points/sec). Software then sorts the data in order of their numerical values in each individual set and keeps only a few points in the middle for further consideration (*e.g.*, delete top 25, bottom 19 and keep 6) and calculates the mean and standard deviation for the remaining points. If replicate samples are analyzed, the software can be instructed to compute mean of means and the resulting standard deviation. An illustrative output is shown in Table 2. Such a system permits considerable leeway in the precision of sample arrival at a specific time. As long as the majority of the collected points represent readings on the liquid segment, rather than the air segment, the principle can be practiced.

Software-based postprocessing of data can also be used with uninterrupted continuous data-acquisition without any regard to periodicity. The air segments represent some finite constant absorbance (higher than a water blank), owing to reflection losses at the glass/air interfaces. It is trivial to distinguish between these absorbances and the absorbance of the sample, for all but those sample absorbances that are very close to the absorbance reading resulting from the air segments. Even in the latter case, we have observed that as long as the detector time constant is not prohibitively long, the detector clearly registers the passage of a liquid/gas interface as a "glitch", the interface reflecting light away from the photosensor, resulting in a transient absorbance higher than that of either of the pure segments (see for example, Fig.

9). Obviously, if each interface is recognized, it is simple to identify the sample readings properly.

There is, however, a basic difference in the way the segments are formed in SCFA and IFCCAS; segment identification can be much simpler in IFCCAS. Increasing the air flow-rate in SCFA primarily increases the segmentation frequency rather than the size of the air segment. In IFCCAS, the size of the immiscible fluid segment is dependent on system timing; each measurement segment (as opposed to the partioning segment) represents a sample in its entirety rather than a portion of a sample. In the preferred embodiment of ACCAS as shown, load and injection functions are controlled by a valve and a single aspiration channel. This results in intermittent, rather than continuous, flow through the detector. The detector has enough mobility for its precise location to be adjusted so that when the flow through the detector stops, a sample segment, rather than a partioning segment, will be resident therein. An appropriate timing sequence then ensures that the total time over which the sample is read is significantly different (typically longer) from the reading period for the partitioning fluid. The identification of the sample readings, whether visually on a strip chart or for software-based postprocessing, then becomes a simple task.

Performance parameters

In experiment 1a, the absorbances ($\pm$s.d., $n = 5$) measured for $Fe^{3+} = 0.1$, 0.25, 0.5 and 0.75mM were found to be 0.059 ± 0.001, 0.179 ± 0.06, 0.453 ± 0.010, 0.602 ± 0.005. The last three points have a good linear correlation (0.99) because the M_2L complex is predominantly formed; the most dilute sample allows significant formation of ML and its absorbance diverges substantially from this linearity.

In experiment 1b, 0.00, 0.05, 0.10 and 0.20M Cu^{2+} samples yielded absorbances ($\pm$s.d., $n \geqslant 20$) of 0.000 ± 0.000, 0.190 ± 0.005, 0.378 ± 0.008, 0.761 ± 0.021, resulting in a highly linear (correlation coefficient >0.999) response plot. Total liquid waste generated per sample was $\sim 20\,\mu$l. Figures 9 and 10 shows typical chart output at high and low chart speed.

In experiment 2, essentially the same performance as for experiment 1b was observed, except that the reproducibility appeared to be better [*e.g.*, 0.8% RSD for the 0.20M sample ($n = 78$) compared to 2.8% RSD for the corresponding sample in experiment 1b]. Waste generated per sample was also smaller.

Experiment 3a, involving the same chemical system, also showed excellent linearity (correlation coefficient >0.999), and consistently high precision (typically better than 1% RSD).

Experiment 3b, gradient ACCAS, produces a chart output illustrated in Fig. 11. The reproducibility of the temporal value of the sample absorbance ($t = 0$ means initiation of reading the liquid segment) was calculated for various time points. A typical set of absorbances for 0.002% Methylene Blue solution for $t = 0$, 2.5, 5.0, 7.5, 10.0 sec was 0.124 ± 0.002, 0.097 ± 0.002, 0.067 ± 0.003, 0.053 ± 0.003 and 0.050 ± 0.002 respectively. These time points correspond to dilution factors of 3.39, 4.33, 6.27, 7.92 and 8.40 respectively.

Precision for the results from experiment 4, the pulsed reagent-introduction system, averaged 3%

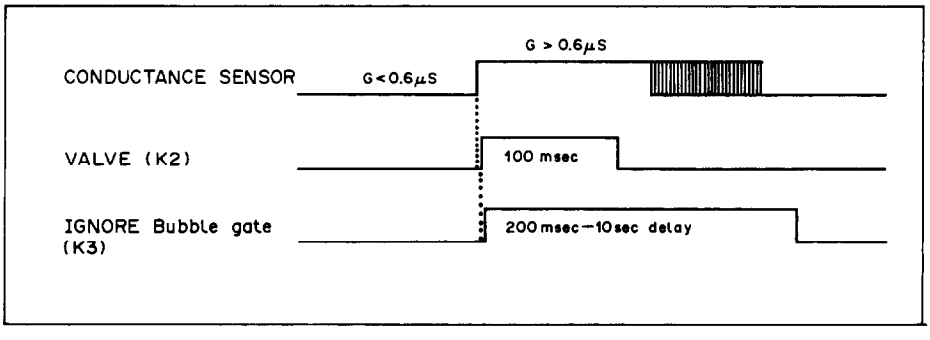

Fig. 8. Event diagram for pulsed reagent-introduction.

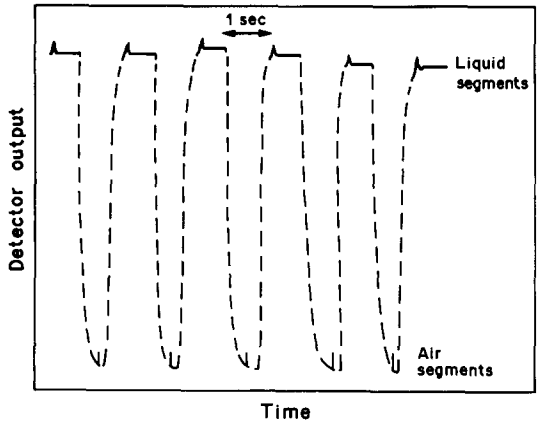

Fig. 9. High-speed chart record of an ACCAS output for 1800 samples/hr. The dashed lines indicate pen transitions from one segment to another; the speed of this transition is too high for a consistently legible record. Note that the passage of the interface through the detection zone results in a spike before either segment.

RSD over a large number of experiments. Operating the system at different sample throughput rates did not seem to affect the reproducibility much.

Experiment 5 was the only run described here in which the throughput rate was low enough for carry-over to be measured by manual transfer of the sample intake tube to a new sample container. No leading bubble was introduced at the sample inlet to minimize carry-over. Precision and carry-over under these conditions are exemplified by the following results for the experimental run of quadruplicate samples of 0.001, 0.002, 0.003 and 0.004% w/v salicylic acid, following initialization with water. The absorbances obtained were: 0.0256, 0.0309, 0.0309, 0.0309; 0.0715; 0.0745, 0.0745, 0.0745; 0.120, 0.123, 0.123, 0.123; 0.170, 0.174, 0.174, 0.174. The effect of carry-over is evident in the first sample in each set; equally evident is the excellent precision observed if the first point in each set is excluded. (Such exclusion also leads to a highly linear response plot, with a linear correlation coefficient better than 0.999).

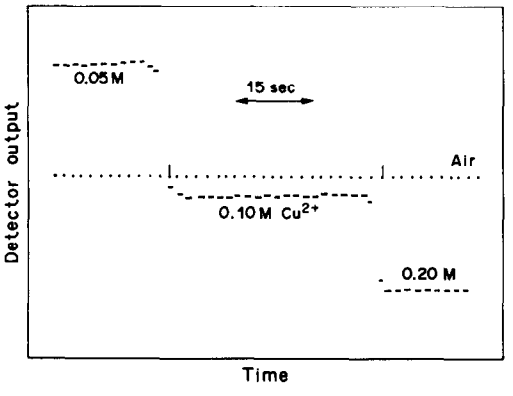

Fig. 10. ACCAS output at 1800 samples/hr; the sample was changed from 0.05 to 0.10 to 0.20*M* Cu^{2+} during the run.

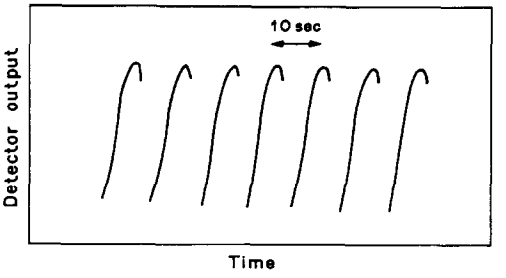

Fig. 11. Gradient ACCAS chart record, see text for details.

We are unable to provide carry-over data for most of the other systems at this time. True measurement of carry-over in a completely automated system is only possible with an autosampler and will include, probably as a significant portion, any contribution from the autosampler. It is also evident that some of the high analytical throughput rates cannot be meaningfully exploited without a device capable of supplying a new sample to the ACCAS unit at speeds considerably in excess of that attainable with any commercial autosampler now available. While it is presumably possible to perform analysis of a process stream by using the full throughput rate capability of ACCAS, we are unaware of any real process analysis needs that call for an analytical update every second. There are, however, situations where the high speed of ACCAS may be profitably utilized. Such examples may include profiling of mixing patterns in a mixing tank with a high-speed impeller, nutrient profiling of a large lake, and rapid identification of any unusual localized concentrations by an on-board instrument on a boat, tracking of a plume by means of an instrument (carried on an aircraft) utilizing gas-liquid reactions, *etc.*

Carry-over is also dependent on the concentration and nature of the wetting agents used, the total length and nature of construction of the conduit, and the individual segment volume. We believe that carry-over in ACCAS primarily results from adherence of microdroplets at all discontinuities (which are generally dependent on the construction details of the manifold) and since these droplets are incorporated in the next liquid segment, a smaller segment volume increases carry-over. Our experience indicates that when utilizing manifolds such as those described in these experiments, it will be difficult to reduce carry-over below 5% for most typical cases. Carryover will doubtless be affected by the use of conduits more wettable than PTFE, and special construction of uniform-bore manifolds. We suspect that a better solution is to use an alternative form of IFCCAS. One of the heavier liquid perfluorocarbons, for example, can be used as the segmenting fluid and since phase separation would automatically occur in the waste container, continuous recycling of the segmenting fluid should be possible. The use of a liquid, rather than a gas, should also improve pre-

cision of reaction times because of the far lower compressibility of a liquid.

Although it is possible to carry out gradient ACCAS, the reproducibility is relatively poor. Fairly large volumes are also involved. Reproducibility deteriorates with much smaller segment lengths; to perform a meaningful reduction in the volumes involved, the conduit bore (and cell path-length) may need to be reduced. It is doubtful whether ACCAS can compete favorably with FIA for such applications. Gradient IFCCAS may actually be of particular value in gas–liquid reactions as foreseen by Attiyat and Christian,[31] *e.g.*, for the analysis of gaseous process streams where analytes of interest often show a large temporal variability (*e.g.*, sulfur compounds in refinery sour gases). With a small gas segment and long liquid segment, the potential of a quasi-equivalent of a peak-width FIA system seems attractive.

At the present time, it is not clear how many of the more complex operations, *e.g.*, solvent extraction, dialysis, gas diffusion, ion-exchange, *etc.*, which are easily practiced by one or both of SCFA and FIA, can be incorporated into ACCAS/IFCCAS systems. For the simpler applications, ACCAS has the unique ability to deal with a multiplicity of individual liquids with a single pump channel; even an evacuated bottle with a vacuum regulator can be successfully used. The price of this simplicity is a heavier reliance on valves and microprocessor-based timing, albeit the cost of the additional valves is lower than that of an additional independently controlled pump channel. However, low internal-volume valves, while extremely rugged when properly operated, are particularly susceptible to fouling by particulate matter and in-line filtration may be necessary in some applications. For more complex reaction schemes such as that implemented in the system shown in Fig. 5, the complexity of the system configuration (and thus the probability of eventual failure, which must increase markedly when more than a certain number of individual electromechanical devices are used) can be substantially reduced by utilizing multiple pump-channels and/or a limited number of multiport valves. A single 2-position 20-port valve can, for example, be used to implement the scheme shown in Fig. 5.

At least in its present form, ACCAS suffers more from carry-over problems than does FIA or SCFA. Neither of the established techniques can compare with ACCAS in attainable throughput rates, however, and for most simple applications ACCAS compares favorably with these techniques in terms of the total volume of liquid waste generated.

Acknowledgements—This research would have been impossible without the electronic expertise of Jorge L. Lopez, who gladly performed endless modifications. We should also like to acknowledge valuable discussions with Steve Gluck and Timothy S. Stevens of the Dow Chemical Company. The work was sponsored by the Dow Chemical Company, Midland, MI, through a cooperative research agreement. Official endorsement of any statement in this paper by the Dow Chemical Company should not, however, be inferred.

(*Received* 28 *June* 1988. *Accepted* 13 *September* 1988)

Summary—Industrial analytical chemistry includes the measurement of the elemental composition and structure of molecules; the measurement of the concentration of specific molecules, atoms, and ions in contact with other molecules, atoms, and ions, the measurement of the energy and speed with which these reactions occur; and the separation of molecules, atoms, and ions specifically from other molecules, atoms and ions. It is also the measurement of the physical (interaction) and chemical (reaction) behavior of collections of molecules and how this behavior is controlled by the presence of other molecules and ions. Many excellent devices for separation and measurement have been developed to accomplish these tasks. Each of these attains a level of sensitivity and selectivity beyond which further improvement would be difficult. However, by coupling these techniques in various configurations, improved data can be generated in a short time span. Such techniques are often referred to as hyphenated, tandem, combined, or coupled. A more inclusive term is multidimensional techniques. In this paper, we briefly describe some of the most significant developments our laboratory has made in these and related techniques.

GAS AND LIQUID CHROMATOGRAPHY/ MASS SPECTROMETRY

Mass spectrometry has had a long and rich history within Dow research laboratories. Pioneering efforts at structure correlation by Fred McLafferty, at that time a Dow researcher, led to the discovery of the so-called McLafferty rearrangement.[1] Later, instrumental developments by Roland Gohlke resulted in possibly the earliest successful implementation of GC/MS (gas chromatography/mass spectrometry).[2] As environmental awareness increased, Dow became recognized as a leader in the development of ultratrace analytical methodology utilizing GC/MS for final detection.[3]

More recently, our laboratory has been conducting research in the area of combined high-performance liquid chromatography/mass spectrometry (HPLC/MS) in an effort to utilize state-of-the-art interface designs for problem-solving in an industrial environment. Within the past few years improvements in commercially available LC interfaces have contributed substantially toward making LC/MS a powerful analytical tool. We describe here some results obtained by using two different approaches, namely, the thermospray and moving belt interfaces.

The thermospray (TSP) technique was pioneered by Vestal and coworkers.[4,5] It offers the unique advantage of providing useful mass spectral data for many nonvolatile and thermally labile compounds with use of flow-rates and sample sizes similar to those commonly used in conventional HPLC. This allows direct implementation of many reversed-phase separation methods. Since TSP generates a high yield of pseudomolecular ions with little fragmentation, many of our early applications of TSP LC/MS were directed toward target compound analysis.

TSP LC/MS analysis was applied successfully in the assay of a heat-sensitive urinary metabolite (**I**) of MDL-257 (**II**) and its labeled analog in urine. The parent compound MDL-257, a bronchodilator currently under clinical trials, had been labeled in the piperidine ring (D_{10}) and used along with unlabeled material in a bioavailability study. The major metabolite (**I**) is thermally unstable and several attempts by conventional ionization methods caused decomposition to compound **III** (Scheme 1).

A typical LC/MS total ion chromatogram of a urine sample for the assay of the labeled and unlabeled metabolite (**I**) is shown in Fig. 1. The mass spectrum of peak A (Fig. 2) shows the mixture of unlabeled metabolite (**I**) at m/z 250 and its deuterated analogs at m/z 256, 257 and 258 without any significant decomposition at m/z 232. Peak B was an analog of (**I**) with an additional CH_2-group in the piperidine ring (m/z 264), that was used as an internal standard.

The TSP LC/MS technique was found to be superior to the moving-belt interface for the determination of acrylamide in sugar.[6] Acrylamide was derivatized to dibromopropionamide and separated by multidimensional reversed-phase liquid chromatography. It was then possible to provide quantitative information on this thermally labile compound by TSP LC/MS. Similarly, TSP ion-exchange LC/MS played a key role in the

Scheme 1

characterization of thermally labile acrylic acid oligomers.[7]

A disadvantage of the TSP technique for structure elucidation is that it yields mainly cationized molecular ions and only a few fragments. However, mass spectrometry/mass spectrometry (MS/MS) has been utilized extensively in conjunction with TSP to provide qualitative identification of unknown components. For example, an unknown additive was separated from a polymer sample and identified as didecyl phthalate (Fig. 3). The daughter ion mass spectrum (Fig. 4) of the protonated molecular ion (m/z 447) afforded adequate structural information for identification of this material. An alternative method for generating additional structural information was discovered at Dow while conducting research in the area of auxiliary ionization in TSP. Under certain conditions, application of electric fields in the skimmer cone region of a TSP source could cause fragmentation of otherwise stable pseudomolecular ions.[8] The electric field was applied by using an existing repeller electrode in a Finnigan TSP source (Fig. 5) and could produce an adjustable degree of fragmentation. At high potentials (>200

V/cm) extensive fragmentation of normally stable polycyclic aromatic compounds could be induced, as shown in Fig. 6. This methodology, however, appears limited to situations where nonbuffered eluents are employed, since the presence of appreciable levels of electrolytes in the LC eluent interferes with this process and prevents fragmentation.

Two types of moving belt interface have been used for most of our applications. Initially an interface to a Finnigan-MAT 4500 quadrupole MS was utilized and the solute was vaporized outside the ion source[9] and later the other interface was fitted to a VG-SE double-focusing instrument where the flash vaporization of the solute occurred inside the ion source.

The moving belt interface allows both electron impact(EI) and chemical ionization and is particularly well suited for normal phase separations. This methodology, though limited to compounds which can be vaporized thermally (MW < 1500) and subject to high background levels (m/z < 150), has demonstrated its usefulness time and again. An example of a normal phase LC/MS separation of a mixture of polymer additives is given in Fig. 7; here the total ion current was obtained by using EI ionization and the

GAS AND LIQUID FOURIER TRANSFORM INFRARED SPECTROMETRY

The potential of an FT-IR spectrometer interfaced to a gas chromatograph (GC/FT-IR) to separate components in a complex mixture and provide identifiable IR spectra of each component was recognized early within The Dow Chemical Company. In 1977, a GC/FT-IR instrument was constructed within Dow (V. J. Caldecourt, C. L. Putzig) based on the design of Azarraga and McCall.[10] This combination of a Digilab FTS-14 FT-IR spectrometer and

a Varian 1420 GC, interfaced by a 50 cm × 2 mm i.d. internally gold-coated glass lightpipe, possessed a modest (by today's standards) sensitivity of approximately 1 μg. Nevertheless, this instrument provided the solution to many complex problems involving chemical structure in the fields of environmental, agricultural, polymer, and toxicological chemistry.[11,12]

Commercial spectrometers purchased have included those based on Digilab's FTS-10, Nicolet's SX-60, and finally Mattson's Cryolect 4800 Matrix Isolation/GC/FT-IR. The problem-solving ability of this last instrument is demonstrated in Figs. 8 and 9. Figure 8 is the IR reconstructed chromatogram of the separation of a mixture of substituted pyridines. The separation was accomplished on a 30 m × 0.32 mm, 1 μm, DB-5 capillary column programmed from 120° (7 min hold) to 230° at 6°/min. In analysis by gas chromatography/mass spectrometry (GC/MS), peaks E–I (Fig. 8) give identical mass spectra [MW 263, dichloro(trichloromethylpyridines)] and are indistinguishable from one another. The corresponding IR spectra (2000–700 cm^{-1}) are given in Fig. 9(a–e). Each of the peaks E–I possesses a unique IR spectrum which can be assigned to a specific isomer. This separation was accomplished by employing state-of-the-art chromatography and at an identification level (potentially subnanogram) approaching that of GC/MS.

Examples of two recent significant applications

using the lightpipe interface are shown in Figs. 10–12. In 1987, Yurga reported that high molecular-weight polymer additives not normally analyzable by GC/FT-IR, could be analyzed by using very short thick-film capillary columns (1 m, 0.32 mm i.d., 1 μm film, phenylmethylsilicone) and high interface temperatures (300–320°). Figure 10 shows a Gram–Schmidt reconstructed chromatogram of a mixture of polymer additive standards at approximately the 500 ng level, for each, separated and identified by using this technique. Figure 11 presents spectra of two components from this analysis.

GC/FT-IR is finding applications, as is GC/MS, in taste and odor problem-solving for food packaging materials. In 1987, Yurga and Thompson applied cryogenic focusing techniques to GC/FT-IR to analyze residuals in the headspace from cellophane wrapper materials. Ten ml of the sample headspace gas were injected and cryogenically focused on the front 10 cm of the GC column by using nitrogen gas cooled with liquid nitrogen, and subsequently analyzed by GC/FT-IR. Representative reconstructed chromatograms are shown in Fig. 12. Identification of components (*e.g.*, styrene) at levels as low as 17 μl/l. in air can be accomplished with a lightpipe interface by using this technique.

The collection of standard infrared vapor-phase spectra introduced by Sadtler Research Laboratories, Inc., was an early aid to spectroscopists in identifying unknown compounds for which spectra had been recorded on GC/FT-IR instruments. The validity of the spectra in this reference library was reviewed by R. A. Nyquist of this laboratory. His interest in correlation of the infrared group frequencies derived from the reference library culminated in the publishing of his book "The Interpretation of Vapor-Phase Infrared Spectra—Group Frequency Data",[13] for which he was awarded the Williams–Wright Award in industrial infrared spectroscopy in 1985.

The interfacing of HPLC and FT-IR began with non-aqueous systems such as normal phase HPLC (NP-HPLC) because of the compatibility of normal phase eluents with direct interfacing to the infrared spectrometer. Other early experiments involved size exclusion chromatography (SEC) because of the large sample capacity of the column and the opportunity for a direct flow-cell interface. Factors limiting the sensitivity of the analysis include the absorption of mid-infrared radiation by common solvents used in NP-HPLC and SEC, most of which limit the useful range of the spectrum and exclude identification of unknown components. The development of microbore HPLC and micro flow-cells has allowed a reasonable flexibility in NP-HPLC/FT-IR for the identification of functional groups or determination of components in characterized systems.[14] Some groups at Dow are using SEC/FT-IR for the analysis of polymers to correlate functional group information with molecular weight distribution.

Of more interest to this laboratory was the interfacing of reverse phase (RP) HPLC and FT-IR spectroscopy since most of our problem-solving involves RP chromatography and the on-line combination of techniques is advantageous in terms of time,

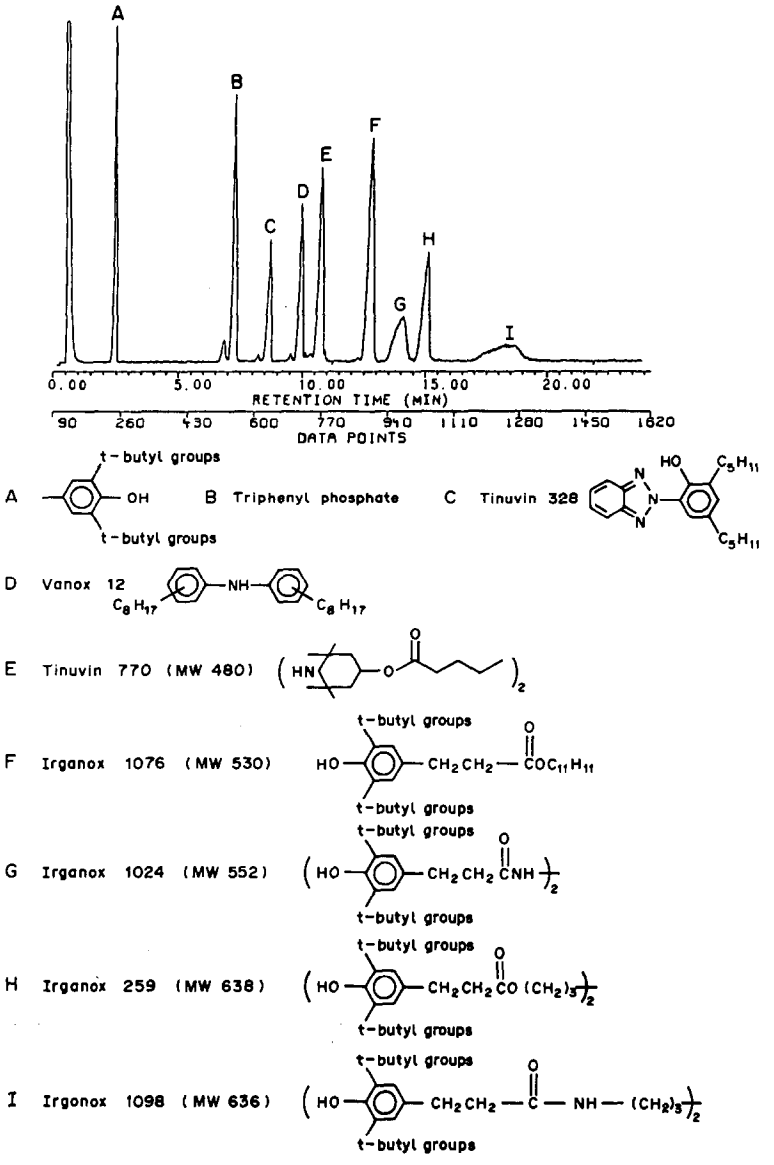

Fig. 10. Gram–Schmidt reconstructed chromatogram of high molecular-weight polymer additive standards analyzed by GC/FT-IR with a 1-m capillary column and high lightpipe interface temperatures.

efficiency, and certainty of identification, compared to the trapping of HPLC components. The major obstacle to the direct interfacing of RP-HPLC and FT-IR is the poor transmittance of water and other common RP-HPLC solvents in the mid-infrared region. Information is completely unobtainable over large regions of the spectrum and the signal-to-noise ratio is very poor in other regions, where a solvent or solvent system is also absorbing infrared radiation. Testimony to the difficulty of interfacing RP-HPLC and FT-IR spectroscopy is the fact that no commercially available interface has been developed, although some developments have recently been reported.[14,15] In general, researchers have taken two approaches to interfacing the techniques to circumvent this basic limitation: flow-cell methods or solvent-elimination methods. We have developed two interfaces using these two approaches, with the initial goal of using the conditions most commonly used for our customers' separations; analytical columns and flow-rates in the 1–2 ml range. In 1984, Yurga and Putzig began interface experiments with flow-cells and a commercially available membrane phase-separator used in our laboratory for flow-injection analysis. The membrane used in this phase-separator is not a selective membrane, but rather a hydrophobic membrane of 0.45 μm pore-size Teflon* resin tape. When the pores are first wetted with an organic phase, the surface interaction will prevent water from

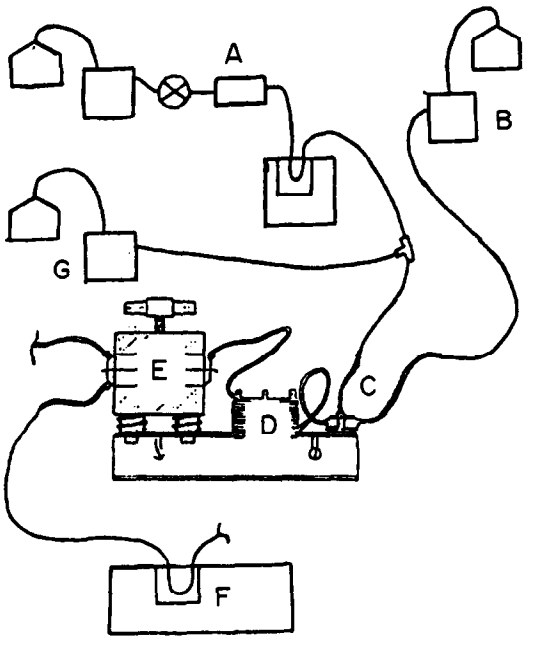

Fig. 13. Schematic representation of the RP-HPLC/FT-IR experiment with a membrane phase-separator and flow-cell interface.

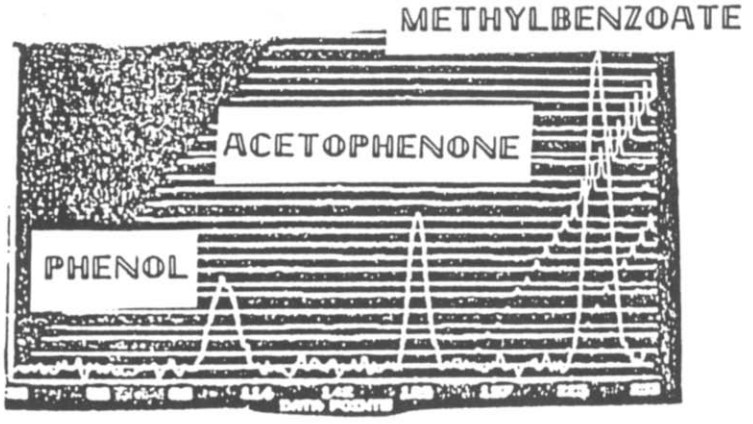
passing through the membrane. A schematic representation of the interface is presented in Fig. 13. The RP-HPLC set-up (A) contains the eluent(s), pump(s), injector, column, UV detector, and Teflon tubing leading from the UV detector to the segmentor (C). The use of 5–10 μm packed analytical columns permits a rapid response for existing separations used in the identification of unknown components. A second flowing stream (B) containing an organic IR-compatible solvent such as carbon tetrachloride or methylene chloride is introduced into the other port of the segmentor (C) where the aqueous and organic flowing streams are combined to produce a segmented two-phase flowing stream. This stream continues to a mixing coil (D) where the separated analytes are extracted into the organic phase. The aqueous phase is prevented from passing through the membrane (E), while the organic phase containing the analytes continues to the flow-cell (F) of the FT-IR spectrometer.

Typical parameters are a 0.1 mm pathlength cell of 0.25 μl volume or less, with barium fluoride, zinc selenide, or potassium bromide windows, and continuous scanning. A mercury-cadmium-telluride (MCT) detector is used. Flow-rates, tubing lengths,



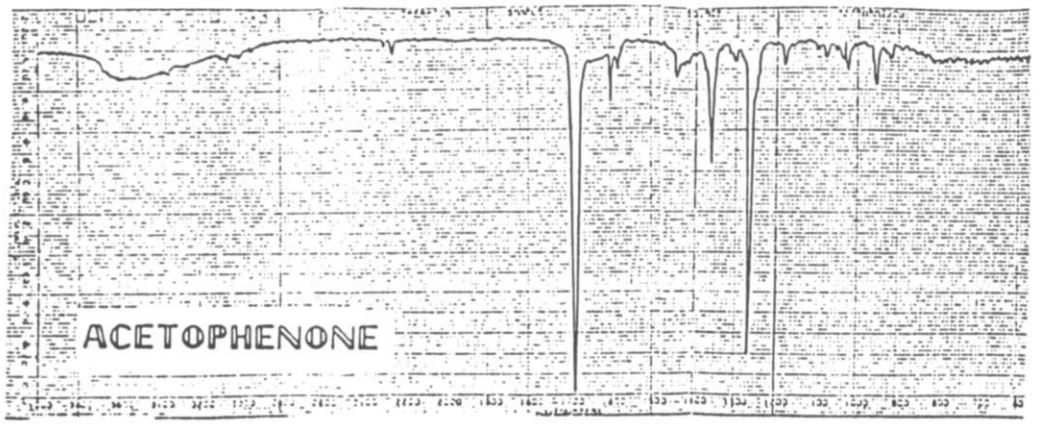


Fig. 14. Gram–Schmidt reconstructed chromatogram from the RP-HPLC/FT-IR analysis of a mixture containing phenol, acetophenone, and methyl benzoate, and the infrared spectrum of the second component, acetophenone.

and inner diameters (ranging from 0.3 to 0.7 mm) are optimized for specific applications to yield adequate extraction of analytes, separation of the phases, and optimum flow of the organic phase through the membrane. In addition, a T-connection (G) in the tubing downstream of the UV detector, but upstream of the segmentor, allows the addition of post-column experiments, such as ion-pairing or the addition of a salt, to improve or allow extraction for specific analytes. Information obtained includes a UV chromatogram of separated components, a Gram–Schmidt reconstructed chromatogram, and infrared spectra of separated components obtained by ratioing collected spectra against the solvent background, by use of GC/FT-IR software. Figure 14 shows the reconstructed chromatogram obtained for the separation of a mixture containing phenol, acetophenone, and methyl benzoate at the 1% level, and the infrared spectrum obtained for acetophenone. The limitations of this interface include the extraction coefficent, and the signal-to-noise limitation of detection with a solvent present. The major advantage of using a membrane phase extractor is the exclusion of the aqueous phase and polar modifiers, which are normally highly absorbing in the mid-infrared. The flow-cell interface is advantageous in terms of hardware and similarity to the usual HPLC set-up and finds applications in separations of components in the $\geq 0.5\%$ range. Development of a solvent-elimination approach for increased sensitivity, using this membrane phase separator interface, is continuing. The flow-cell interface approach is similar to work reported by Johnson *et al.* in 1985.[16]

USE OF A MEMBRANE AS AN INTERFACE IN MULTIDIMENSIONAL TECHNIQUES

When one side of a polymeric membrane is exposed to a chemical species (molecules, atoms, or ions) at a certain concentration, the chemical species will interact with the polymer molecules and then dissolve into the polymer matrix. This will create a concentration gradient across the membrane which provides a driving force for the chemical species to diffuse from one side of the membrane to the other. If the chemical species is not removed from the other side, the concentration there will gradually increase and finally become the same as that of the feed side. An equilibrium will be eventually established. In this case no net flow of the chemical species across the membrane will be observed. If the chemical species that has diffused to the other side of the membrane is continuously removed, a steady-state flow or permeation rate, of the chemical species across the membrane will be observed.

For chemical species in the gas phase, the permeation rate, J, measured in cm^3 (STP) per second per cm^2 of membrane area, can be expressed by the equation

$$J = \frac{DS\Delta P}{l} = \frac{P\Delta P}{l} \qquad (1)$$

where D is the diffusion coefficient (cm^2/sec), S the solubility [cm^3 (STP)/$cm^3 \cdot$cmHg), l the thickness of the membrane (cm), ΔP the pressure difference across the membrane (cmHg) and P the permeability of the gaseous molecule in the polymer [$cm \cdot cm^3$(STP)/$cm^2 \cdot$sec$\cdot$cmΔg].

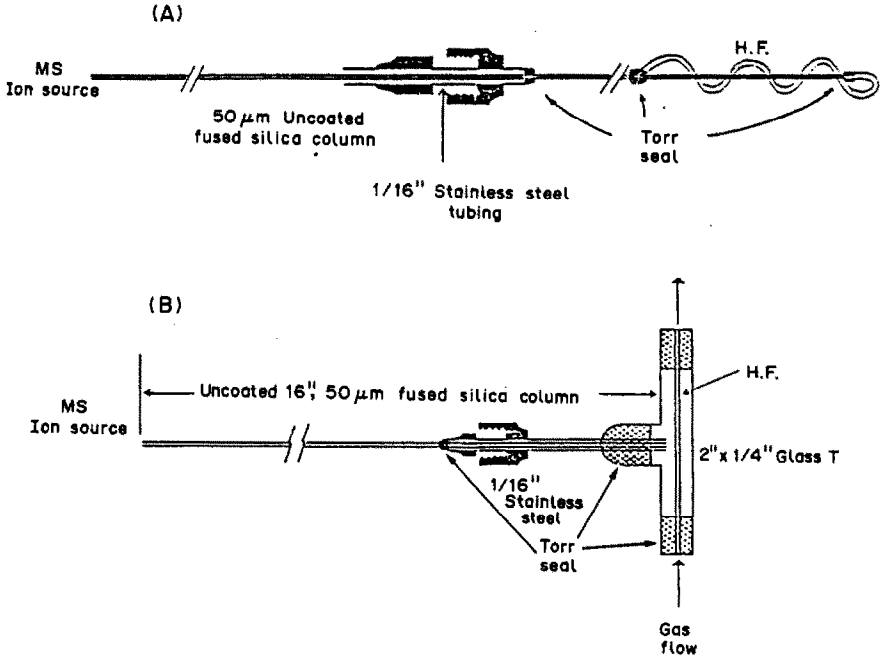

Fig. 15. Hollow-fiber membrane mass spectrometric interfaces: A, flow-over configuration; B, flow-through configuration (0.020 in. i.d., 0.037 in. o.d. Silastic medical grade tubing from Dow Corning).

Since permeability is a unique property of a molecule with respect to a polymer, each type of molecule will exhibit its own permeation rate across a polymeric membrane. This unique property makes polymeric membranes powerful separation media for molecules, atoms, and ions in many industrial applications.[17]

Analytical scientists have also utilized this unique property of polymeric membranes, for separating analytes or controlling diffusion of a chemical reagent into the analyte stream for reaction prior to reaching the analytical detector. The combination of a membrane system with an analytical device constitutes a new multi-dimensional technique with improved sensitivity and specificity. Dow analytical scientists have been contributing a great deal to the development of the technique.

There are two physical forms of membranes—flat films and hollow fibers. The former can be made in a laboratory and the latter are usually only commercially available.

In 1974, Westover *et al.*[18] devised a silicone-based polymer hollow-fiber probe for sampling organic molecules, from the gas phase or aqueous solution, into a mass spectrometer, as shown in Fig. 15A. The analyte permeates through the membrane and passes into a mass spectrometer. The membrane serves both as a pressure-reduction interface to a mass spectrometer and as an enrichment device for organic molecules. This allows analytical scientists to monitor parts per million (ppm) and parts per billion (ppb) of volatile organics in air and in aqueous solution respectively. By this technique, many otherwise difficult problems have been studied, such as the kinetic study of hydrolysis rates of chloromethyl methyl ether and bis(chloromethyl) ether in humid air[19] and in aqueous solution[20] and the *in vivo* mass spectrometric determination of organic compounds in blood.[21]

Recently, Bier and Cooks[22] have developed a direct-insertion hollow fiber probe for the selective introduction of organic molecules from aqueous solution into a mass spectrometer by allowing the aqueous solution to flow inside the hollow fiber. One version of this probe is shown in Fig. 15B. The sensitivity is 2–3 orders of magnitude greater than that with the flow-over hollow fiber probe shown in Fig. 15A for monitoring gaseous molecules and 2–3 times greater for monitoring volatile organics in aqueous solutions. The response signals and response curves at sub-ppm levels of methylene chloride and xylene are shown in Figs. 16 and 17, respectively.

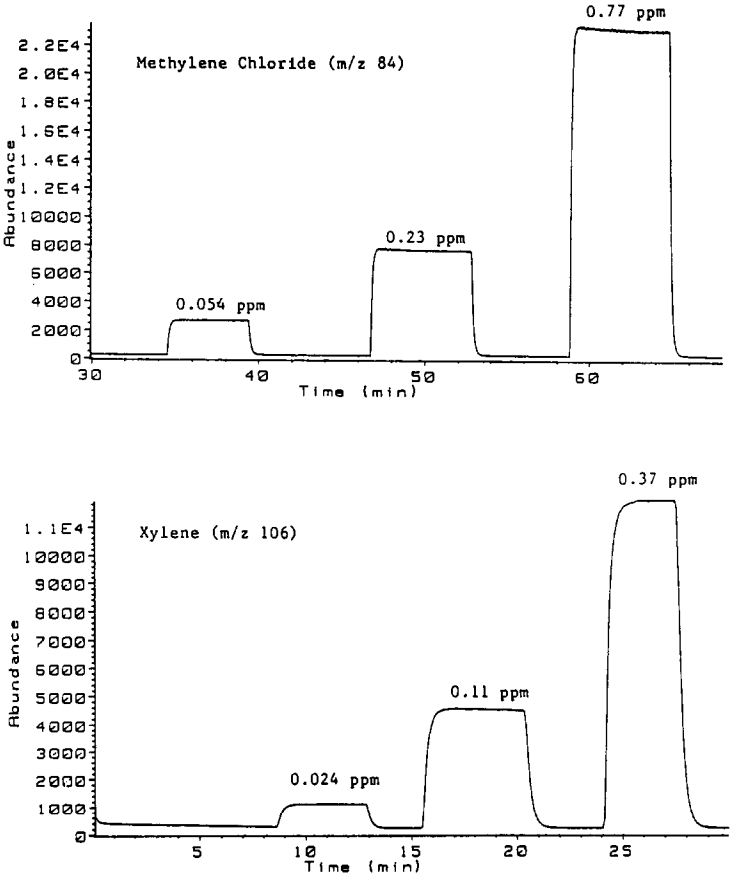

Fig. 16. Response signals for methylene chloride (m/z 84) and xylene (m/z 106) with interface B (Fig. 15) at 75°.

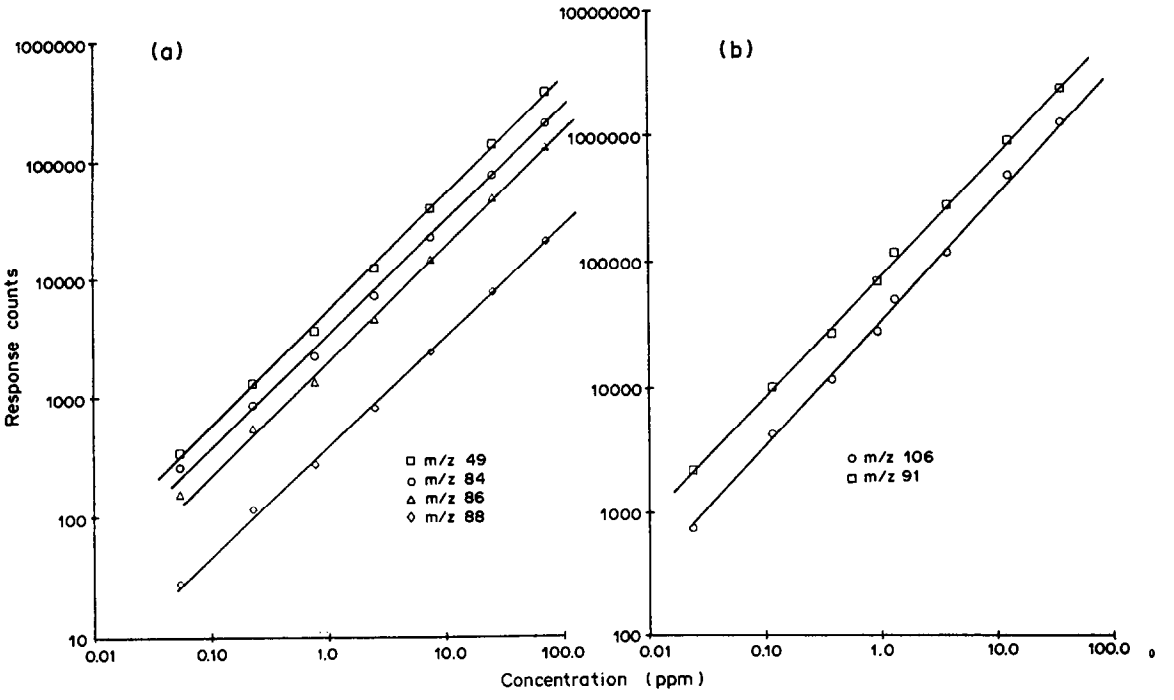

Fig. 17. Response curves of methylene chloride (a) and xylene (b) with interface B (Fig. 15).

These increases in sensitivity significantly broaden the range of applications of this technique to determination of ppb levels of organics in the gas phase and sub-ppb levels of organics in aqueous solution.[23]

Flat membranes were also utilized as a gas chromatography/mass spectrometry interface.[24] However, owing to the temperature-dependence of the transmission of organic molecules[25] and the advances in capillary-column gas chromatography, the interface is not widely used.

As shown in equation (1), the permeation rates are dependent on diffusivity and solubility. Diffusivity controls the time taken to reach a steady state from the start of the permeation process, or the response time of an analytical technique—the higher the temperature, the shorter the response time. Solubility determines the amount of organic molecules dissolving in the membrane and affects the amount permeating through the membrane. This influences directly the analytical sensitivity of the technique—the higher the temperature, the lower the solubility or the sensitivity. This is demonstrated in the signal or the response times *vs.* temperature curves of D-limonene, shown in Fig. 18. Different polymeric materials will show different degrees of dependence. The experimental conditions should be optimized for a specific application.

The flow-through hollow fiber interface has been utilized at Dow for rapid determination of volatile pollutants in aqueous matrices by flow-injection mass spectrometry.[26]

Instead of removing the permeating organic molecules by vacuum as in the case of mass spectrometers, Melcher *et al.*[27] of our laboratory removed the permeating molecules by a conversion into non-permeating

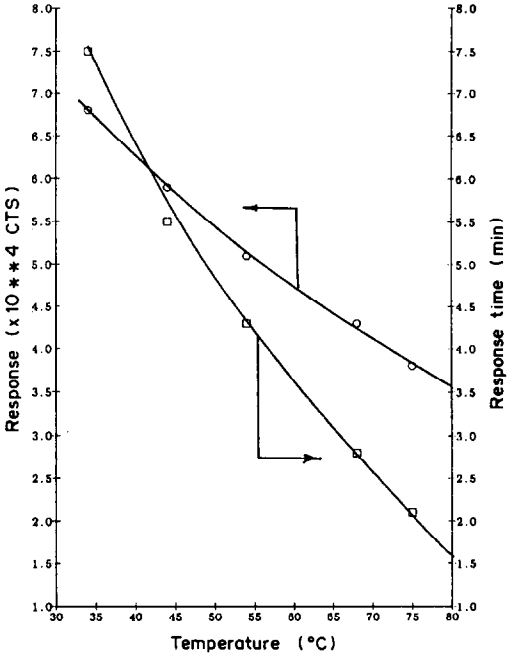

Fig. 18. The signal response and response time *vs.* temperature curves obtained with interface B (Fig. 15) for D-limonene in air.

species. The technique was designed for on-line monitoring of trace phenols in an aqueous waste stream. A dilute alkali is pumped through a hollow silicone fiber membrane placed in a cell and directed into the sample loop of a liquid chromatographic valve. When the acidified aqueous waste stream with high dissolved solids and particulate content is pumped through the cell containing the hollow fiber membrane, the phenol molecules permeating through the silicone membrane will react with the alkali inside the hollow fiber membrane to form sodium phenates, which do not permeate into the waste stream, because of the hydrophobic nature of the membrane. This unique extraction technique can be operated either in a continuous mode or in a stop–flow mode if higher sensitivity is desired.

Fossey and Cantwell[28] utilized a hydrophobic membrane of Teflon resin and a hydrophilic cellulose membrane for organic/aqueous phase separation. Combining this technique with flow-injection analysis allows simultaneous monitoring of both phases.

Considerable work in our laboratories has been done on development of the membrane techniques for controlled admission of reagents for post-column reactions in liquid chromatography and ion chromatography. Davis and Peterson[29] employed a hollow silicone polymer fiber for controlled admission of ammonia, fluorescamine and ninhydrin for post-column reactions with nitrophenols, amines, and amino-acids respectively. This technique enhances the sensitivity and reduces the chemical background. At the early stage of the development of ion chromatography, periodic replacements or regeneration of the suppressor column complicated the operation of an ion chromatograph.

Stevens *et al.*[30] developed a sulfonated polyethylene hollow fiber suppressor, which allows continuous operations without varying interference from baseline dips, ion-exclusion effects, or chemical reactions. The sulfonated polyethylene membrane allows sodium ions to permeate out and hydrogen ions to permeate in. However, the slow permeation rate across the membrane resulted in some band spreading and therefore poorer chromatographic resolution. A packed hollow fiber suppressor was then developed to minimize this effect.[31]

In conclusion, the selectivity of polymer membranes can significantly enhance the sensitivity and specificity of combinations of analytical techniques.

MULTIDIMENSIONAL CHROMATOGRAPHY BY ON-LINE COUPLING OF HPLC WITH CAPILLARY GC

The analysis of complex matrices, such as those encountered in environmental, medical, agricultural, fossil fuel and biotechnology systems, has become a very important area of separation science, motivating advances in theory and technique to the point where modern high-resolution chromatography operates at levels which are close to the theoretical limits.

Challenges still remain, however, with the continuing need to improve limits of detection and increase the information content of an analysis, since even with state of the art technology, there are limitations to the resolving power attainable with a single chromatographic system.[32]

One approach used to obtain greater resolution is multidimensional chromatography, in which two or more chromatographic techniques are combined. The power of a multidimensional system can be estimated by considering the peak capacity of a separation system,[33] defined as

$$n_1 = (N^{1/2}/4)\ln(V_{max}/V_{min}) \quad (2)$$

where n_1 is the peak capacity of a single separating system, N is the number of theoretical plates, and V_{max} and V_{min} are the maximum and minimum volumes respectively. For a multidimensional system, the maximum peak capacity becomes the product of the individual peak capacities of each separation system.

When a comparison of various multidimensional systems is made, the tremendous resolving power of this technology becomes evident. For example, the peak capacity of a liquid chromatographic system can be calculated to be about 70, whereas for a capillary GC system, the peak capacity can be as high as 300. The maximum peak capacity attainable by coupling these two systems is then around 21000. In addition, the coupling of a liquid chromatograph with a gas chromatograph in an on-line mode offers a different perspective of multidimensional separations, since selectivities that are difficult to obtain with coupled systems based on only one type of chromatography become possible when use is made of the wider range of variables available with two chromatographic techniques, *e.g.*, the choice of combinations of mobile and stationary phases, temperature profile and detector systems.

Although many attempts have been made to couple the two techniques,[34–36] the first successful application to quantitative analysis was only recently accomplished,[37] and utilized micro columns for LC and eluent introduction into a retention gap (uncoated inlet) at a temperature above the boiling point of the solvent.* Some examples of the multidimensional system utilizing micro columns for LC and capillary GC in an on-line mode are presented in Fig. 19 for the determination of trace chlorinated benzenes in fuel oil,[38] Fig. 20 for the determination of the herbicide Propachlor† (2-chloro-*N*-isopropylacetanilide) in soil,[39] and Fig. 21 for the determination of Chlorpyrifos [*O*,*O*-diethyl-*O*-(3,5,6-trichloro-2-pyridyl)phosphothioate] in rodent feed

*The method and apparatus described are the subject of pending patent applications.

used for toxicological studies.[40] Typical recovery data are presented in Table 1.

Some advantages of using a multidimensional system are speed of analysis, minimal sample preparation, sensitivity, automation, and reproducibility. The technology, however, is restricted to components which can be separated chromatographically in the gas phase, and the eluents used must be free of nonvolatile buffer salts.

The use of micro columns for LC offers a desirable approach, helping to overcome some of the problems associated with the introduction of large volumes into a capillary GC. Continued research in micro column technology and interface design may be expected to produce further improvements in this interesting area of chemical analysis.

ION CHROMATOGRAPHY

Ion chromatography (IC), originally developed in this laboratory, is now recognized as a "workhorse" technology for the determination of a number of ionic species in a great variety of sample matrices, and has been extensively employed in this laboratory over the past twelve years. In addition, it has been successfully transferred to on-site usage for process control, product development, quality control, and environmental and industrial hygiene monitoring. By incorporation into automated analyzers, it has also been implemented in on-line applications. This diverse usage of IC has been made possible by "re-shaping" the technology originally developed in the early 1970s, so as to expand its overall flexibility. This "re-shaping" has resulted in the scope of IC expanding beyond the analysis of common inorganic anions and cations, which was its initial focus on its introduction in 1975 by Small *et al.*,[41] to include organic acids, selected transition metals, carbohydrates, amino-acids, complexones, amines, aliphatic quaternary ammonium compounds, metal oxy-anions, polyphosphates and polythionates. A number of developments in various features of the original IC technology have contributed significantly to bringing about these expanded capabilities. Six of the key elements which have combined to make today's IC technology more versatile, and consequently, more effective in day-to-day problem-solving, are considered below.

Separation

While separation mechanisms such as ion-exclusion and ion-pairing are now also included in IC methodology, ion-exchange is still the predominant one. Most separations are carried out by using low capacity "pellicular" ion-exchange materials based on styrene/divinylbenzene (S/DVB) copolymers. Today's IC ion-exchangers are basically the same materials as those originally developed by Small *et al.*[41] However, their overall performance has been notably enhanced. Significant improvements in

component resolution, equilibration times, speed of analysis, exchange selectivities, column durability, and column reproducibility have been achieved. For cation analysis, surface-sulfonated S/DVB resins continue to be used effectively. Resins formed by electrostatically attaching a monolayer of a latex anion-exchanger to these same sulfonated resins are the workhorse materials for anion analysis. Both types of resin exhibit chemical stability throughout the pH range 0–14, resulting in a distinct advantage in the "practical" implementation of IC technology.

Eluent suppression

Since the sample species of interest in IC are predominantly ionic, electrolyte solutions are required to generate their ion-exchange separation. Sample ions are eluted, therefore, in this electrolyte background. IC, as originally developed, relied on conductivity detection. To overcome the problem of measuring sample ions in this highly conducting electrolyte (eluent) background, "eluent suppression" was devised. This technique dramatically reduced the background conductivity of the eluent, while also notably enhancing the sensitivity for the eluting sample ions. In the original instruments, the suppressor unit was a high-capacity ion-exchange column (*i.e.*, H^+-form cation-exchanger for anion analysis; OH^--form anion-exchanger for cation analysis) that had to be periodically regenerated. The interruptions for "packed bed" suppressor regeneration were eventually eliminated with the development of membrane units capable of continuous operation.[30] In addition to providing on-the-fly regeneration, the membrane devices significantly reduced the void volume contribution of the suppressor from approximately 1500 μl to less than 50 μl. This reduction improved overall IC system performance by improving component resolution. The latest version of the membrane suppressor has introduced eluent programming into conductivity-based IC systems. Since higher eluent concentrations can now be handled more effectively, the application of stepwise or continuous gradients to complex sample analysis is feasible. This capability permits the more effective elution of analytes having notably different retention characteristics.[42]

Detection

While conductivity is still the single most popular mode of detection for IC, several other detection schemes have been successfully introduced into routine use. Numbered among these are direct or indirect UV spectrometry, amperometry, visible region spectrometry, and fluorimetry. Judicious use of these additional modes of detection has resulted in enhanced specificity and sensitivity for the analysis of complex sample matrices, and a greater range of eluents, giving expanded separation capabilities. To date, the capabilities afforded by the use of these other detection schemes have been demonstrated in a number of applications. Direct UV detection introduced sodium perchlorate eluents into IC, with their ability to separate thiocyanate, thiosulfate, persulfate, and several polythionates. In addition, enhanced specificity was attained for the determination of a number of other UV-absorbing anions in complex matrices such as chloride or sulfate-based acids and brines.[43,44] The determination of non-chromophoric aliphatic quaternary ammonium compounds was achieved by using UV-absorbing aromatic quaternary ammonium salts in the eluent and indirect UV detection.[45] Amperometric detection enabled carbohydrates to be effectively monitored after ion-exchange separation as anions.[46,47] The IC determination of selected transition metals has been accomplished by coupling cation-exchange separations and visible detection by post-column reaction of the separated species with appropriate colorimetric complexing reagents.[48,49]

System design

Today's IC instrumentation is characterized by modular or component design, which provides the greatest versatility for ion analysis. Featuring access to a variety of separation/detection combinations, an appropriately designed modular system is actually multiple systems in one. On the one hand, it can be custom-made to meet specific routine analysis needs. On the other, it can be readily altered to accommodate changing analytical requirements. This latter capability allows a system to be conveniently combined with the separation/detection mode best suited for monitoring the ions of interest in any given sample matrix.

Data acquisition

Traditionally, recorders and computing integrators have been used for IC data acquisition and reduction. More recently, computer systems have been interfaced with IC systems to perform these functions as well as long-term data storage and extensive post-run data reprocessing. Significantly, the use of a computer has introduced total system control into IC. The full range of operating functions (*e.g.*, sample injection, eluent composition, analysis procedure, detector range, auto-zero, valve switching, *etc.*) can be controlled by the computer system. As a result, dramatic flexibility is available for either automating an analysis or carrying out method development.

Sample preparation

The broad range of sample matrices to which IC has been applied is evidence of its current versatility. To date, it has been used to determine species in simple as well as very complex aqueous samples, nonaqueous liquids, gases, and solids. A list of samples encountered in this laboratory includes such diverse types as waters, soil, air, acids, brines, alkalis, bromine, chlorine, detergents, fertilizers, complexones, biological fluids, paper pulping liquors,

herbicides, polymers, surfactants, foodstuffs, fire retardants, and pharmaceuticals.

In many instances, minimal sample preparation is required for IC analysis, that is, only dilution and/or filtration. Even for some very complex sample matrices, choice of the appropriate separation/detection scheme notably minimizes matrix interferences so that the "dilute and shoot" technique can still be employed. Where dilution is not applicable, alternative measures can be used to make the sample amenable to IC analysis. Sample pretreatment techniques that have been successfully applied to this end in this laboratory include evaporation, impinger scrubbing, use of solid sorbents, preconcentration, dissolution, extraction, precipitation, ion-exchange resin treatment, neutralization, complexation, and oxidation/reduction. Depending on the particular analysis required and the complexity of the sample, these techniques have been used singly or in combination in order to take full advantage of IC's multi-ion analysis capabilities wherever possible.[50]

Summary

Ion chromatography has proven itself to be a versatile, selective and sensitive method for ion analysis. The development of a broad range of separation and detection schemes over the past decade has dramatically and effectively broadened the utility of the original IC technology. With an expanded flexibility, today's IC technology is an indispensable tool for analytical problem-solving.

DSC/XRD/MS

Three powerful analytical techniques, differential scanning calorimetry (DSC), X-ray diffraction (XRD) and mass spectrometry (MS), have been combined so that materials can be completely characterized as they are heated in a controlled atmosphere. The DSC/XRD/MS instrument has been used to characterize the melting and crystallization behavior of SARAN* resin and polyethylene,[51,52] the mechanisms of oxidation and reduction in a variety of copper-based catalysts,[53–55] and the polymorphism and hydration chemistry of a number of commercial pharmaceuticals.[56,57]

All three techniques are used simultaneously to analyze a single sample. XRD continuously measures the structure of the material in the reaction chamber. The XRD data can also be used to measure crystallinity, crystallite sizes, reaction kinetics, thermal expansion or contraction, all as a function of temperature. MS is used to monitor and quantify volatiles. This can be of critical importance in the analysis of hydrated pharmaceuticals, the interpretation of reduction mechanisms in catalysts, or the analysis of decomposition phenomena in polymers. The DSC data are used to identify reaction types (endotherms and exotherms).

The simultaneous analysis allows the analyst to assign specific structural or chemical events directly to observed thermal events. Because the same environment and sample are used for all three analyses, instrumental and sample preparation conditions and the errors associated with them are kept constant. The instrument was invented and developed by a team of analytical scientists at the Dow Chemical Company. The critical design steps focused on retaining the integrity of the calorimeter while performing the diffraction and mass spectroscopic analyses. The invention also took advantage of current developments in high-speed multiposition X-ray detectors (PSDs) to collect X-ray diffraction data in the same time frame as the conventional calorimetry experiments. Materials were optimized so that the sample holder was essentially chemically inert and an insulator, but still allowed interaction with the XRD and MS probes. This combination of factors enabled us to use a relatively inexpensive, conventional X-ray source instead of a neutron, synchrotron or other high-flux source. A schematic of the instrument is shown in Fig. 22.

The strength of the instrument for solving problems in materials analysis is best demonstrated in the analysis of mixtures. Figure 23 shows three DSC scans which were taken on different lots of the same pharmaceutical as part of a quality control check. All three lots were shown to be pure by HPLC and researchers were immediately concerned that the chemistry of the pharmaceutical was changing from lot to lot. Figure 24 shows selected XRD data as a function of temperature, and also the DSC data for that sample. The mass spectrometer was not attached at the time of this experiment. The sample used in the DSC/XRD experiment was from the lot used for the bottom DSC scan in Fig. 23. Notice that the DSC scans from two samples of the same lot are dramatically different (four endotherms, against two endotherms and an exotherm). It would be difficult if not impossible to correlate the data from the DSC scan in Fig. 23 with the XRD data in Fig. 24 (*i.e.*, correlate data on the same lot by using two different instruments). The particular sample is a hydrate which is very sensitive to atmosphere and sample preparation, so for structural correlations the same sample must be analyzed in a controlled atmosphere by all three techniques.

The three lots of the pharmaceutical were all formulated as monohydrates, on the basis of weight loss and HPLC data. However, by use of a series of difference XRD plots, where adjacent XRD scans were subtracted, diffraction peaks could be cross-correlated and assigned to a particular structure. This eliminated the need for reference standards, which did not exist for these materials. These data were then combined with TGA (thermogravimetric analysis) data (alternatively, MS data could have been used) to

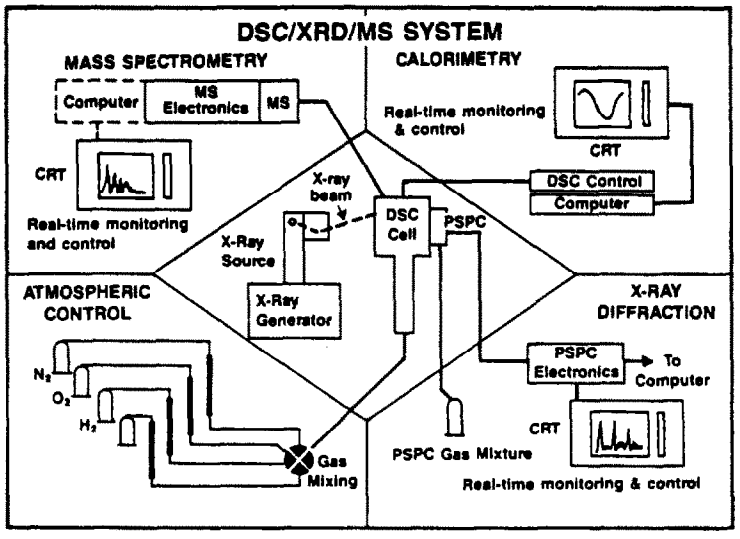

Fig. 22. Schematic diagram of the DSC/XRD/MS instrument. PSPC, position-sensitive proportional counter.

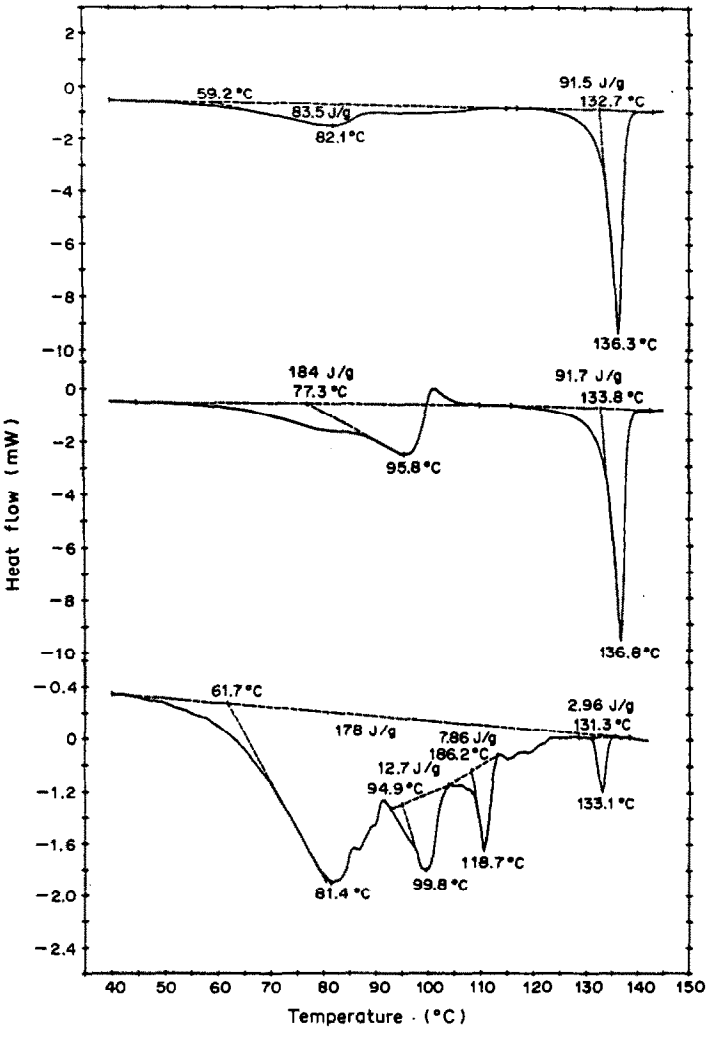

Fig. 23. Three DSC scans of different lots of the same pharmaceutical intermediate, taken on a commercial DSC.

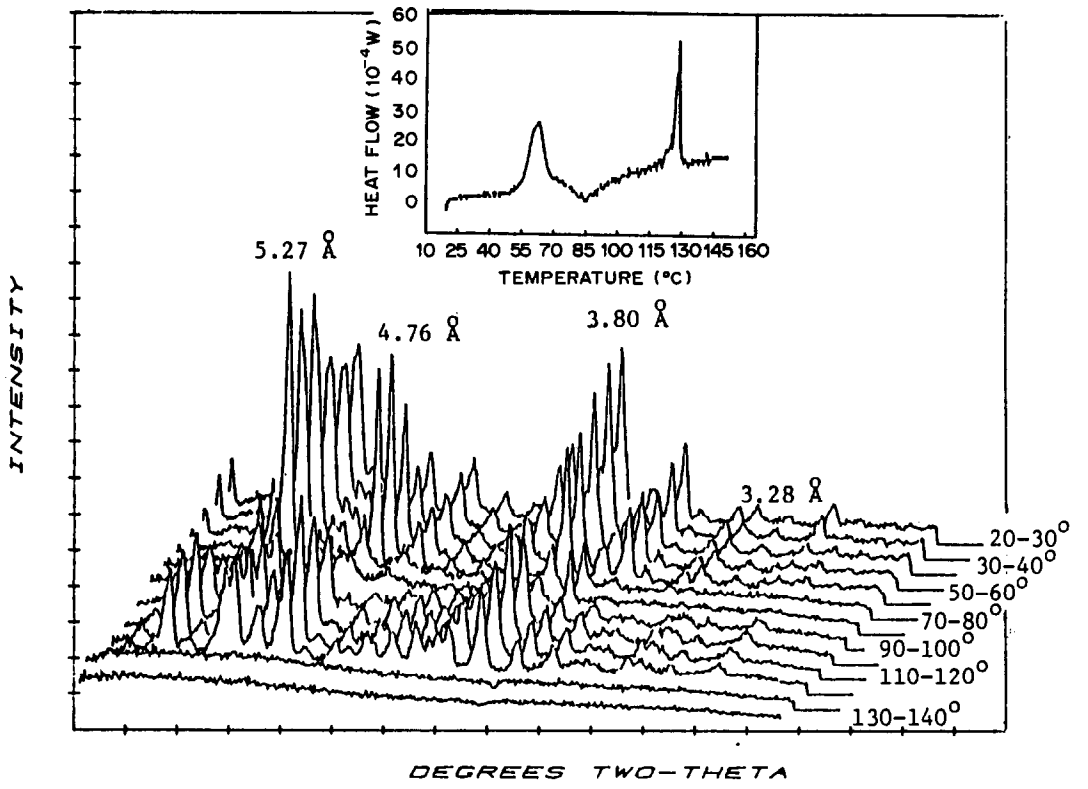

Fig. 24. DSC and XRD data for the pharmaceutical intermediate taken on the DSC/XRD instrument. In this DSC scan, endotherms point up. In Fig. 23, endotherms point down. The XRD plots are of intensity *vs.* 2θ at the temperatures shown at the right-hand end of each plot.

assign the hydration levels for each structure. Three different samples were analyzed in this manner by DSC/XRD to ensure consistency in the assignments. By this process, it was found that the pharmaceutical had stable 1.5, 0.5, 0.25 and 0.0 hydrates, each with a characteristic diffraction pattern. The 0.25 hydrate was an intermediate found only at elevated temperatures. Despite the fact that all three lots analyzed by DSC (Fig. 23) were formulated as monohydrates, in actuality, the DSC/XRD analyses showed them to be various mixtures of 1.5, 1.0 and 0.0 hydrates. Thus, the analyses explained both the lot to lot DSC variability of the samples and an observed difference in solubility among the lots (each hydrate had a different solubility).

The DSC/XRD data also showed that a controlled heating of the drug would result in the reproducible formation of a single anhydrous structure with known physical properties, which is of critical importance to the manufacturing of the pharmaceutical. Similar examples are shown for catalysts, polymers, and other pharmaceuticals in the references.

GEL-PERMEATION CHROMATOGRAPHY WITH MULTIPLE DETECTORS

The characterization of synthetic polymers is complicated by the heterogeneities which can exist simultaneously in composition, molecular weight, branching, and other microstructural features. Spectroscopic techniques applied to these complex mixtures yield only average quantities. Interpretation of one-dimensional separations is complicated by the dependence of solute retention on all structural features. For some polymer systems, the physical coupling of spectroscopy and chromatographic separations enables characterizations that are not possible by use of the techniques separately.

Gel-permeation chromatography (GPC) with multidetector or multiwavelength detection has been extensively applied to polymer characterization.[58] The average composition of co-eluted species is determined at each retention increment. Early at Dow, Runyon *et al.*[59] applied multiple-detector GPC to the characterization of styrene–butadiene copolymers. Subsequently, in our laboratory GPC has been physically coupled with combinations of UV–VIS absorption, fluorescence, differential refractive index (DRI), mass spectroscopic, infrared, and plasma emission detectors. Two recent applications from our laboratory of GPC with coupled UV absorption and DRI detection are given below.

A common problem in polymer science is determination of the molecular weight distributions of

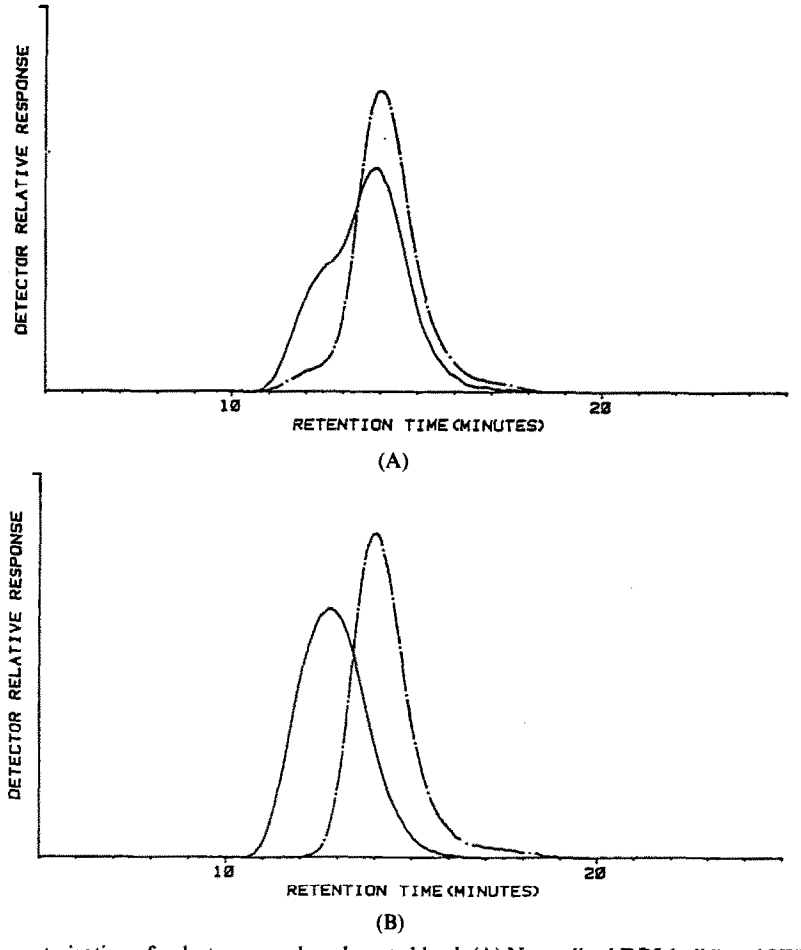

Fig. 25. Characterization of polystyrene–polycarbonate blend. (A) Normalized DRI (solid) and UV (dash) area-normalized gel-permeation chromatograms. (B) Calculated polystyrene (solid) and polycarbonate (dash) elution.

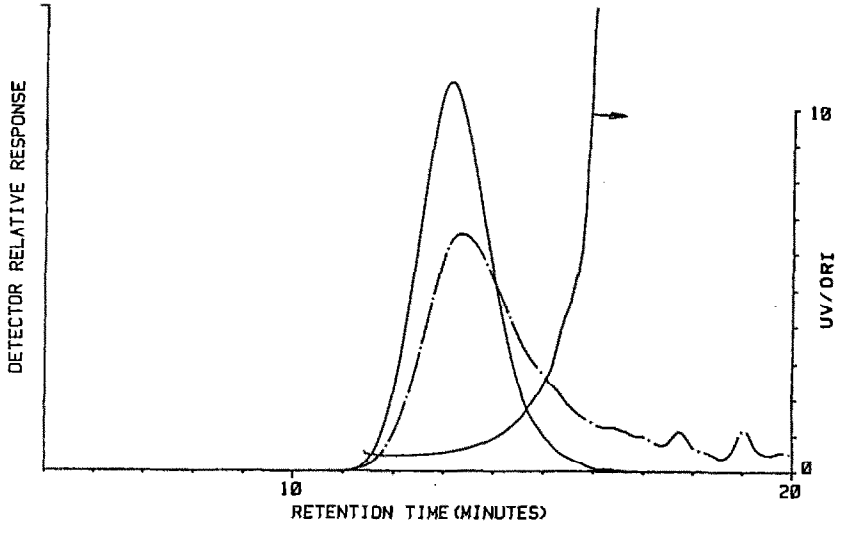

Fig. 26. Characterization of vinylidene chloride copolymer dehydrochlorination. Area normalized UV (dash) and DRI (solid) gel-permeation chromatograms, and dependence of UV/DRI response ratio on GPC retention index.

components in a polymer blend. Figure 25A illustrates the GPC chromatograms obtained with the UV and DRI detectors for a blend of polystyrene and polycarbonate. Molecular weight distributions cannot be calculated directly from the individual GPC chromatograms. In this case, the blend components have significantly different UV absorptivities, and the component molecular size distributions are easily calculated from the dual detector data (Fig. 25B) after standardization of the detector responses with homopolymers.

GPC with coupled UV absorption and DRI detectors has been applied in our laboratory to the elucidation of the mechanism for the dehydrochlorination of vinylidene chloride copolymers to give conjugated double bonds (Fig. 26). The UV absorption and DRI detector responses are proportional to the unsaturation and polymer concentrations, respectively. The ratio of UV to DRI response is proportional to the fraction of unsaturated species eluted at any particular retention increment. The coupled data demonstrate that the unsaturated species fraction is inversely proportional to molecular weight and suggest that the unsaturation is associated with polymer end-groups.

Light-scattering has been coupled with concentration detectors and GPC to determine absolute molecular weight distributions and to characterize branching.[60] Branching characterizations are based on the fact that the molecular weight–molecular size relationship is dependent on polymer topology. The GPC retention is a measure of the polymer size, and the molecular weights of each eluted component are determined with the coupled light-scattering and concentration detectors. Figure 27 illustrates data obtained for linear polystyrene and polystyrene crosslinked with divinylbenzene. At any particular molecular weight, the polymer chains become smaller (longer GPC retention) with increasing crosslink concentration.

ION TRANSPORT PROPERTIES OF CYCLIC AND ACYCLIC NEUTRAL CARRIER-CONTAINING MEMBRANES

MICHAEL L. IGLEHART and RICHARD P. BUCK
Department of Chemistry, University of North Carolina, Chapel Hill, NC 27599-3290, U.S.A.

(*Received* 18 *May* 1988. *Accepted* 13 *September* 1988)

Summary—The K^+–valinomycin permselective membrane provides a standard system for describing the normal current–voltage and current–time responses of the "closed circuit shuttle" carrier mechanism. The responses of a selection of cyclic and acyclic carrier-systems have been measured and compared with the standard system responses. Deviations from expected normal behavior suggest that failure of Donnan exclusion is caused by use of high-permittivity plasticizers and too few fixed sites in the membrane supports. The closed circuit shuttle model has been extended to allow for failure of Donnan exclusion, consumption of free carriers, and additional transport by extracted salts. The predicted limiting currents and current–time responses show many features of failure of Donnan exclusion.

Neutral carriers or neutral ionophores are uncharged hydrophobic complexing agents that selectively extract ions into inert, passive, fixed-site and mobile-site membranes, typically PVC, [poly(vinyl chloride)]. Preferred (w/w) compositions of "normal" membranes are 33% PVC, 66% plasticizer, and 1% neutral carrier, with a plasticizer which can have either low permittivity, *e.g.*, an oil-soluble ester such as DNA (dinonyl adipate), or high, *e.g.* a nitro-compound such as *o*-nitrophenyl octyl ether (*o*-NPOE). The extraction reaction can be of ion–dipole outer sphere or adduct formation inner sphere type. The literature is extensive and key papers on transport properties have been contributed by research groups at the University of Newcastle-upon-Tyne (Armstrong and Covington), ETH Zürich (Simon and Morf), the Technical University of Budapest (Pungor and Tóth), the State University at Leningrad (Materova), and the University of North Carolina (Buck). Extensive literature citations will be found in references 1–8. Interpretations of transport, consistent with this study, have recently been given by others.[9–11]

Studies of ion transport with or without carriers require perturbations of equilibrium or steady-state systems. The many earlier studies of potentiometric responses of carrier-based ion-selective electrodes are only indicative of possible transport mechanisms. The first studies of selective cation transport induced by a neutral carrier in an electric field used radio-labelled carriers and ions, and a macrotetralide mixture: 72% nonactin and 28% monactin for K^+.[12,13] Rozhdestvenskaya and Stefanova measured the a.c. conductivities of nonactin–PVC membranes,[14] and the work was extended to an acyclic carrier for Na^+,[15] but d.c. current–voltage curves were not studied. The first steady-state current–voltage curves studied for a plasticized PVC membrane were obtained with the acyclic ETH 1002 carrier for Ca^{2+}.[16,17] A more extensive series of papers used ingenious electrodialysis methods for several systems, of which valinomycin–K^+ is the most important.[18] More recently, the carrier ETH 149 for Li^+ transport has been investigated.[11]

In this paper, new results on carrier-induced ion transport, obtained by using steady-state current–voltage curves and transient current–time analyses, are reported for the acyclic carriers tridodecylamine and ETH 1001, and for the cyclic carrier nonactin. These results are compared with the older, established behavior for the cyclic carrier valinomycin. The behavior predicted by the closed-circuit shuttle mechanism accounts for all the electrochemical perturbation data for cyclic carriers in low-permittivity plasticizers, but ideal responses are not uniformly found for the acyclic carriers or for cyclic carriers in high-permittivity plasticizers. Although the results reported here are less complete than the corresponding K^+-valinomycin measurements, they include new transport characteristics for all the carriers, in high-permittivity solvents. Revision of the shuttle mechanism to include the failure of Donnan exclusion is the theoretical contribution of this paper.

CLOSED-CIRCUIT SHUTTLE CARRIER MECHANISM AND NORMAL BEHAVIOR

The model

An ideal, homogeneous membrane with singly-charged anionic fixed or mobile sites is assumed to contain a quantity of carrier that is at least equivalent to the number of sites. The carrier has a complex formation constant of about 10^6 for a singly charged cation, so nearly all the counter-ions will be of the type CM^+; M^+ is typically K^+ and C valinomycin

(val). The membrane is plasticized and the counterions are substantially present as carrier-complexed ions, and only partially ion-paired with the sites S^- (called S in Fig. 1a), so the current is carried by CM^+. Donnan exclusion holds and virtually no anions from the electrolyte are present in the membrane. The membranes are ideally permselective for cations, and the surface ion-exchange reactions are rapid and reversible. The potentiometric responses are Nernstian or, in the presence of interferences, expressed by the Nikolskii–Eisenman equation. This transport theory, in somewhat different terms, was originally developed by Morf *et al.*[17]

When an electrical perturbation is applied, current is carried by CM^+ moving from site to site without dissociation, and without transfer of free M^+ ions. Wipf *et al.*[19] have suggested that dissociation contributes some free M^+ that can also carry current. Our calculations suggest this is a very small effect and we find no experimental evidence for it in normal membranes. Carrier is released at the interface where M^+ leaves the membrane, but remains trapped in the membrane and is subject to back-diffusion across the membrane into its interior according to Fick's laws. The model system in Fig. 1 is basically a simple concentration polarization of the carrier, such that the carrier, under a d.c. current, has high concentration at the interface where M^+ leaves the membrane and a much lower concentration at the interface where M^+ enters it. For fixed-site membranes, the a.c. resistance is determined by the charge-carrier concentration (equal to the fixed-site concentration) and charge-carrier mobility. Under d.c. conditions there is a constant limiting current.

Electrochemical expectations from the model

The consequences of the theory for the impedance, steady-state current–voltage curves, current–time transients at constant applied voltage, and voltage–time transients at constant forced current can be summarized. Many of them are conclusions from theory and experiment.[1-8] Impedance plane plots (of imaginary *vs.* real parts of the impedance) are expected to be comprised of a single semicircle for fixed-site membranes and to have an additional finite Warburg impedance at lower frequencies when mobile sites are present. Current–voltage curves are expected to be ohmic at low applied voltages with resistances independent of the excess of carrier. At moderate voltages, the currents deviate negatively from ohmic response, and show a transition region followed by a limiting current at high applied voltages. The limiting currents should be independent of the electrolyte concentration in the solution bathing the membrane, by Donnan exclusion, since the ion-carrier complex concentration cannot exceed the site concentration. The limiting current should be dependent on the excess quantity of carrier, because it is determined by the concentration polarization of the carrier. Current–time transients depend on the applied voltage, but can be constant with respect to time (at low applied voltages in the ohmic range) or initially constant (at the ohmic value), followed by an exponential decay to the steady-state limiting current. At constant applied current,[20] the voltages can be constant (at currents well below the limiting current), or can look somewhat like those of a chronopotentiogram, with an initial voltage that increases to a new constant value (for intermediate currents) or becomes very large at currents equal to, or greater than, the limiting diffusion-controlled current.

The distribution of applied voltage across the membrane requires further comment. When a constant voltage is applied and the current decays to the steady-state value, the voltage appears in three clear-cut segments: two interfacial components and an internal or bulk-phase diffusion potential. At these high applied voltages, most of the potential drop is at the interface where cations enter, because of the low carrier concentration. The diffusion potential is simply IR_∞, where the resistance is calculated from the uniform site concentration and the mobility of CM^+. The IR_∞ value becomes constant at high applied voltages because the current reaches a limiting plateau. All of the excess applied voltage appears at the depletion interface according to this classical, reversible interface, diffusion-controlled model.

AN EXPERIMENTAL EXAMPLE SHOWING NEARLY IDEAL BEHAVIOR

K^+–valinomycin in plasticized, fixed-site membranes

The behavior of the K^+–valinomycin ($Kval^+$) system is remarkably close to the model described above, although there are noteworthy deviations. PVC is notoriously impure even after extraction and filtration;[2] it contains fixed sites, typically at 0.05–5m*M* concentration, as determined chemically,[6] and trace mobile sites that contribute a diffusional Warburg impedance.[2] The membranes are not uniformly plasticized and develop inhomogeneous regions, as may be deduced from measurements of the dielectric constant.[2] They are also susceptible to water uptake. Their resistances are nonlinear functions of the plasticizer content and carrier loading. Upon exposure to electrolytes, the membranes develop additional inhomogeneous high-resistance surface layers of exuded surfactant impurities and carrier.[3] Although the layers can be partially removed, inhomogeneous surface regions seem to remain, which have lower conductivities than those in the homogeneous bulk membrane. After subtraction of the surface film resistances, the bulk resistances of dummy membranes increase with exposure to aqueous solution. It is likely that some charge carriers and trace mobile sites are affected, perhaps being trapped or impeded by absorbed water. The effect is less pronounced for normal membranes with carriers,

because sequestered ions can reside stably in the plasticized regions.

Because of the naturally low concentration of sites, carrier membranes can be close to failure of Donnan exclusion, which means that bathing the membranes in a high concentration of the sensed ion M^+ will allow admission of salt into them. The membranes lose permselectivity, the potentiometric responses deviate negatively from Nernstian expectation, and the responses also become sensitive to the anion of the bathing electrolyte according to the Hofmeister hydrophobicity sequence.[4] Addition of mobile sites, such as TPB^- (tetraphenylborate), improves the Nernstian response. Inorganic TPB^- salts, *e.g.*, NaTPB, must not exceed the total carrier in concentration, otherwise the membrane loses specific carrier selectivity and acts as a simple mobile-site membrane with a general response to cations. Addition of TPB^- as the salt of a hydrophobic cation, *e.g.*, a tetraalkylammonium ion, avoids this interference.[21] The theory has been tested with independently determined extraction coefficients, and used to fit experimental data obtained for many potassium salts with valinomycin as carrier.[4]

Electrochemistry of $Kval^+$ in membranes

Current–voltage curves for the steady state have been extensively determined over a ± 55 V range.[1,5] Ohmic character is observed at low voltages and the values agree with independent determinations from impedance data. Likewise, the limiting currents obey the theory and give reproducible values for the carrier diffusion coefficient that agree with independent determinations. However, at high applied voltages, voltage-induced failure of Donnan exclusion occurs: the currents rise linearly with voltage to above the limiting value, to an extent dependent on the hydrophobicity of the anion of the bathing electrolyte. Normal behavior can be recovered by removing the offending anion and soaking the membrane in more dilute solutions of a chloride, fluoride or hydroxide. Because an excess of carrier is available, this behavior is ultimately limited by complete conversion of the membrane into the complex salt form. This carrier-assisted Donnan failure is a basic consequence of Morf's theory,[17] as elaborated by Buck *et al.*,[4] to explain responses in bathing solutions containing a low concentration of potassium tetraphenylborate.

Current–time curves, though mathematically difficult to express in closed form, predict ohmic initial values, as found experimentally for the $Kval^+$ system.[6] There is a characteristic transition time followed by an exponential current decay to the steady state value. The carrier diffusion coefficient can be determined experimentally from the transition time or from the decay time constant. Both of these give values which agree with that from the limiting current and provide an adequate test of normal behavior and of the approximate theory.[6]

ABNORMAL CHARACTERISTICS OF ION TRANSPORT AT CARRIER-LIMITED CURRENTS

Failure of Donnan exclusion

The possibility of extensive failure of Donnan exclusion as the activity of the bathing electrolyte is increased is built into the carrier transport theory. Salt extraction may then occur, with consumption of the excess of carrier, so that back-diffusion of the excess of carrier is affected. Instead of the limiting current being independent of the bathing electrolyte activity, it may rise or fall, depending on the relative mobilities of the carrier complex and the encroaching electrolyte anion, as more carrier is consumed by increasing concentrations of the bathing electrolyte. Decreasing limiting currents were observed for the Ca^{2+}–ETH 1002 carrier system.[17] This result is not surprising because the high-permittivity plasticizers required for bivalent systems encourage Donnan failure.

The conditions for failure of Donnan exclusion and for the extension of classical theory to neutral carrier systems were explained in detail earlier.[4] The main notion is based on the extraction equilibrium

$$K = \frac{[a_{(Kval^+)}a_{(X^-)}]_{membrane}}{[a_{(Kval^+)}a_{(X^-)}]_{bathing\ solution}} \tag{1}$$

This "constant" K is, in fact, dependent on the local concentration of carrier in the membrane surface because the species $Kval^+X^-$ does not exist in solution. Only K^+X^- has a significant concentration in solution, but the intuitive ideas are clearer when K is temporarily taken as being constant. The membrane is pretreated with $Kval^+$ so that at zero concentration of K^+X^- in the bathing solution the membrane contains $Kval^+S^-$, with site concentrations S about 0.1–1mM. The carrier concentration, $\bar{V}$, is taken to be about 10mM, *i.e.*, 10–100 times S.

Symmetric bathing of membrane, reversible ion-exchange

For all symmetric bathing concentrations of K^+X^-, there is a small amount of X^- in the membrane, and the $Kval^+$ concentration is greater than in S. According to classical theory,[4] the concentrations are:

for all x:

$$[X^-] = -S/2 + (S^2/4 + Q^2)^{1/2} \tag{2}$$

for all x:

$$[Kval^+] = S/2 + (S^2/4 + Q^2)^{1/2} = C_d \tag{3}$$

at $x = d$:

$$[val]_d = 0; \quad \text{at} \quad x = 0: \quad [val]_0 = 2\bar{V} - S - C_d \tag{4}$$

where

$$Q^2 = Ka^2/\gamma^2 \tag{5}$$

and γ is the mean solution ion-activity coefficient.

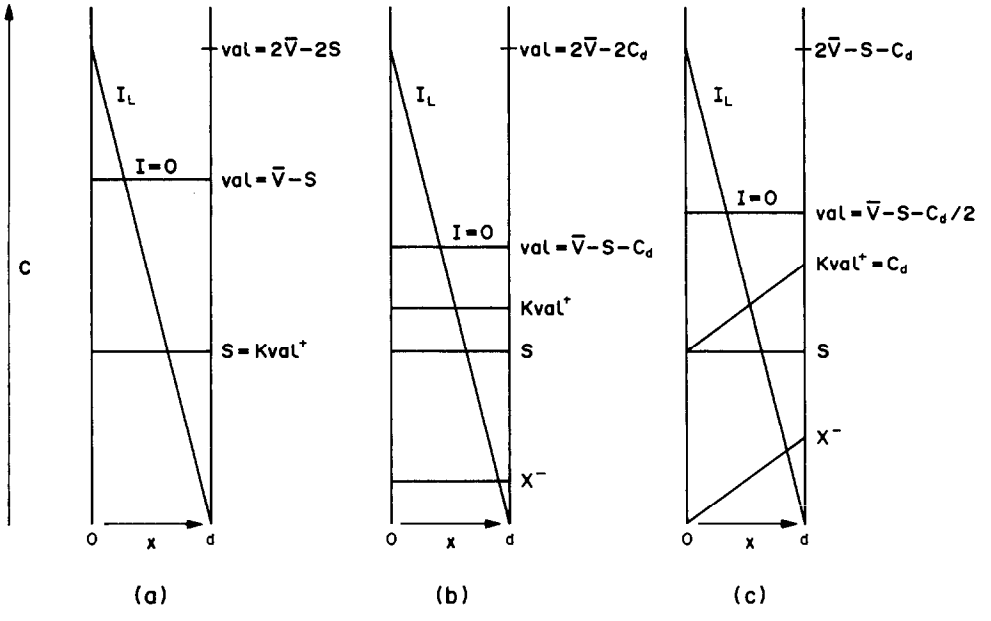

Fig. 1. (a) Schematic of concentration profiles of species in an ideal permselective carrier membrane at zero and at limiting current. (b) Schematic of concentration profiles of species in a symmetrically bathed, carrier membrane at failure of Donnan exclusion. (c) Schematic of concentration profiles of species in an asymmetrically bathed carrier membrane at zero and at limiting current, at failure of Donnan exclusion.

When K or the external activity of K^+X^-, a, is very large, K^+X^- is taken up until all of the carrier is consumed as complex and the membrane is flooded uniformly with $Kval^+X^-$. The concentration profiles before and after failure of Donnan exclusion are illustrated schematically in Fig. 1. Curiously, the partial limiting current carried by $Kval^+$ decreases and becomes zero when carrier is totally depleted, because this ion cannot move unless carrier is returned by diffusion across the membrane. During Donnan breakdown anions carry an increasing portion of the current, but cannot carry more current than is allowed by the diminishing internal diffusion–migration electric field. The latter is determined by the partial limiting current carried by $Kval^+$.

Nothing has been said concerning the role of free K^+, because its concentration is small when the membrane contains an excess of carrier, by virtue of the large complex formation constant for $Kval^+$. When all the carrier is converted into $Kval^+Cl^-$, and still higher bathing concentrations of potassium chloride are used, then even more potassium chloride is extracted into the membrane; the resistance drops further, and more current can cross the membrane. Since free K^+ is more mobile than $Kval^+$, the limiting current may continue to increase at all higher bathing electrolyte activities, even though the complexed species is not a significant current carrier, *i.e.*, the transference number of $Kval^+$ decreases while that of K^+ increases to the value for potassium chloride in the membrane. The flux of $Kval^+$ is determined by the flux of free carrier. Since there are no diffusion terms, ion fluxes are determined by the constant field term in the Nernst–Planck equation. Thus,

$$(Fd/RT)\partial\phi/\partial x = (D_{val}/D_{Kval})[val]_0/[Kval^+] \quad (6)$$

The partial currents are:

$$-I_{Kval}(d/FAD_{Kval}) = [2\bar{V} - S - C_d] \quad (7)$$

$$-I_X(d/FAD_X) = [X^-][val]_0/[Kval^+] \quad (8)$$

D is the diffusion coefficient of the species indicated, d is the membrane thickness, I is the current, and A the area of the membrane.

Asymmetric bathing of membrane

If Donnan exclusion fails at $x = d$, but not at $x = 0$, then

$$\text{at } x = d: \quad [X^-]_d = -S/2 + (S^2/4 + Q^2)^{1/2};$$

$$\text{at } x = 0: \quad [X^-]_0 = 0 \quad (9)$$

$$\text{at } x = d: \quad [Kval^+]_d = S/2 + (S^2/4 + Q^2)^{1/2} = C_d;$$

$$\text{at } x = 0: \quad [Kval^+] = S \quad (10)$$

$$\text{at } x = d: \quad [val]_d = 0;$$

$$\text{at } x = 0: \quad [val]_0 = 2\bar{V} - S - C_d \quad (11)$$

Use of normal Nernst–Planck transport equations for the carrier, $Kval^+$ and X^- fluxes,[5] and a linear approximation for the concentration profiles, gives

$$[Kval^+] = S + ([Kval^+]_d - S)x/d \quad (12)$$

$$[X^-] = [X^-]_d x/d \quad (13)$$

The internal field, $\partial\phi/\partial x$ falls according to

$$(Fd/2RT)\partial\phi/\partial x = (\bar{V} - C_d)/(S + [X^-]_d x/d) \quad (14)$$

The net diffusional potential difference is given by

$$(F/2RT)(\phi_d - \phi_0) = \{(\bar{V} - C_d)/[X^-]_d\} \ln([Kval^+]_d/S) \quad (15)$$

As $Q = 0$ for ideal Donnan exclusion, this equation is indeterminate. However, expansions give

$$(F/RT)(\phi_d - \phi_0) = (2\bar{V} - S)/S = -I_{Kval} d/AD_{Kval} FS \quad (16)$$

or

$$R_\infty = R_{dc} = (RT/F^2)d/AD_{Kval} S \quad (17)$$

This equation can also be obtained from equation (5), and applies to both symmetric and asymmetric bathing. The partial currents are approximately

$$-I_{Kval}(d/FAD_{Kval}) = 2(\bar{V} - S/2 - C_d/2) \quad (18)$$

$$-I_X(d/FAD_X) = [X^-]_d \quad (19)$$

To illustrate these cases very simply, S, K and the activity coefficients were all assigned a value of 1. External concentrations were varied from zero to 10 arbitrary units. Because small anions move faster than the bulky $Kval^+$, $D_X/D_{Kval} = 5$ was selected.

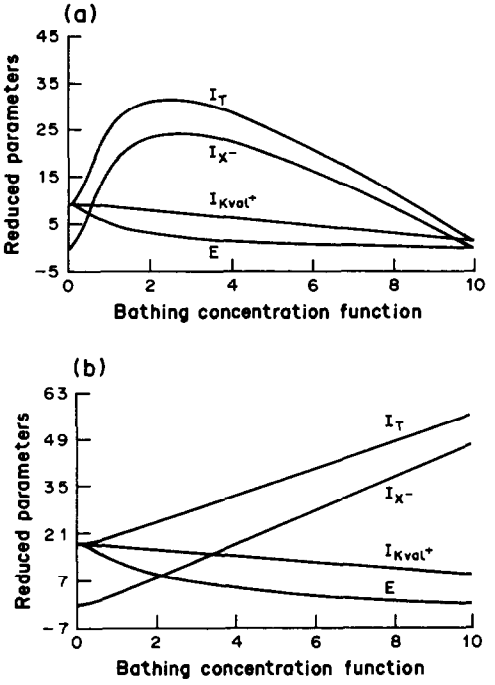

Fig. 2. Predicted behavior of limiting current *vs.* bathing electrolyte concentration: total current, anion current, cation current and electric field. (a) Symmetric bathing, flooded membrane; calculations with equations (6)–(8) with $S = 1$, $K = 1$, $\bar{V} = 10$, $D_X/D_{Kval} = 5$. (b) Asymmetric bathing; calculations with equations (14) (18) and (19) with the same parameters as for (a). I_T = total current; field $(-E)$ is $(Fd/RT)\partial\phi/\partial x$; reduced currents are $(-Id/FAD)$

Figure 2a shows the calculated total current, anion partial current and cation partial current for symmetric bathing. At low concentrations (below one unit), Donnan exclusion holds: the cation current remains constant and the anions contribute nothing initially. This calculation can be scaled along the bathing concentration axis by making K smaller.

For asymmetric bathing, the results are illustrated in Fig. 2b. Consequences of the failure of Donnan exclusion are as follows.

(1) When the co-ion (the anion in the following examples) diffusion coefficient is comparable to or larger than that of the counter-ion, limiting currents increase.

(2) Increasing limiting current occurs after onset of Donnan failure. The required bathing concentration is a complicated function of D_X, $D_{carrier}$, K and the bathing activities. For normal symmetric bathing, a maximum in the limiting current is expected.

(3) When the permittivity is large, K^+X^- can be extracted into the membrane without carrier. The limiting current may increase further because the decreasing transference number of the complex is replaced by a comparable transference number of the free cation.

(4) For symmetric bathing, concentration profiles should be uniform throughout the membrane. Current–voltage curves at increasing applied voltages should be linear, *i.e.*, ohmic.

The ionophores examined in this paper are nonactin (Non), tri-n-dodecylamine (TDA), and (−)-(R,R)-*N*,*N*′-bis[11-(ethoxycarbonyl)undecyl]-*N*,*N*′-4,5-tetramethyl-3,6-dioxaoctanediamide (ETH 1001).

EXPERIMENTAL

The cell, electrodes and associated experimental apparatus have been described elsewhere.[7] Nonactin was purchased from Sigma; ETH 1001 was obtained from Fluka and tri-n-dodecylamine from Alfa. The membranes were produced as described earlier.[2,3] Nonactin and TDA membranes were plasticized with dinonyl adipate (DNA). The ETH 1001 was plasticized with *o*-nitrophenyl octyl ether (*o*-NPOE).

RESULTS

Steady-state responses

Nonactin. The steady-state current–voltage curves reveal that the mode of cation transport is nearly the ideal neutral carrier mechanism found for valinomycin. This conclusion can be reached from, among other evidence, the proportionality of the limiting currents to the carrier concentration. Figure 3 shows the curves for two carrier concentrations, 14.8 and 2.79m*M*. This dependence on carrier concentration was derived earlier,[5] and is the direct result of carrier back-diffusion. The predicted form of the equation is:

$$I_L = 2AFD_{carrier}\bar{V}/d \quad (20)$$

Equation (20) differs from equation (7) in that the

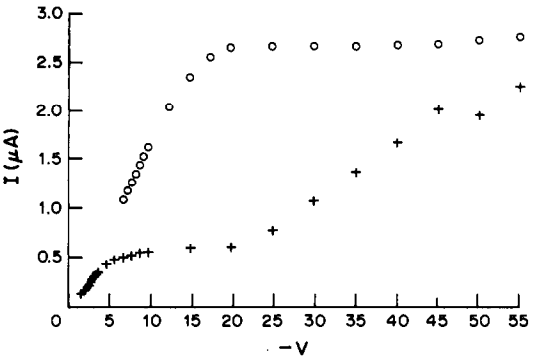

Fig. 3. Current–voltage curves for different nonactin concentrations in the membrane (sweep in the direction of increasing voltages): ○, 14.8mM nonactin; +, 2.79mM nonactin.

total carrier concentration replaces the free carrier concentration because only a small amount of carrier is bound in the complex. Table 1 gives the limiting currents from a number of measurements. The diffusion coefficient for nonactin is found to be 1.3×10^{-8} cm^2/sec. That the limiting current (for the same membrane) is the same when the membrane is bathed in 0.001 or 0.0001M ammonium chloride implies that carrier is not consumed by uptake of ions from the bathing solution nor lost to the solution.

It has also been shown that there is a 1:1 ratio between the cation and ionophore in the ammonium–nonactin complex.[22] The charge is presumably transferred by the NH_4Non^+ complex through the fixed sites. This conclusion is consistent with the equality of the high-frequency and d.c. resistivities (Table 2). This property of fixed-site membrane transport has been mentioned before.[23] The constancy of membrane resistivity at different bathing concentrations also indicates ideal behavior. On application of high voltages (and depending on the concentration of the bathing solution) the currents increase above the expected limiting values, because of failure of Donnan exclusion. This result is completely analogous to that for the valinomycin membrane. Further confirmation of ideal behavior is given by the transient behavior (see below).

Table 1. Steady-state limiting currents of nonactin membranes with different carrier concentrations

C_{Av}/d, mole/cm^4	I_L, μA
0.00125	2.67
0.00125	2.44
0.000232	0.56
0.000232	0.55
0.000232	0.59
0.000232	0.57
0.000232	0.55

Slope = 0.00196, y = intercept = 1.08×10^{-7}, correlation coefficient = 0.9976, $D_{Non} = 1.3 \times 10^{-8}$ cm^2/sec.

Table 2. Comparison of high-frequency and d.c. resistivities for a nonactin membrane with DNA plasticizer

ρ_∞, MΩ cm	$\rho_{d.c.}$, MΩ cm
203	202
489	481
404	373
147	147
190	189
237	232
674	661
674	700
164	171
975	903

Another similarity between nonactin and valinomycin is found in the impedance data (not shown). A 1% w/w nonactin membrane has a typical specific resistivity, ρ_∞, of 215 MΩ cm and a dielectric constant of 10. There is a second semicircle (which is time-dependent) in the complex impedance plane, and this can be removed by exposing the membrane surface to air. A membrane soaked for 12 hr in 0.001M ammonium chloride develops a low-frequency semicircle in the impedance plane, with a normalized resistance of 1.55 MΩ cm. The normalized capacitance is 0.155 μF/cm^2 and the time constant is 0.241 sec. The second semicircle is thought to be a film resistance arising from exuded plasticizer or surfactant impurity on the surface, analogous to the $Kval^+$ film.[2,3]

Tri-n-dodecylamine (TDA). The current–voltage curves for TDA membranes have limiting currents that depend on the bathing solution concentration as well as on the carrier loading. This is an illustration of the abnormal behavior expected theoretically when failure of Donnan exclusion occurs by virtue of the carrier hydrophobicity and a large ion–carrier complex formation constant. Figure 4 shows that a 5.39mM TDA membrane gave constant (within experimental error) limiting currents at the lowest bathing activities, followed by diminishing plateau

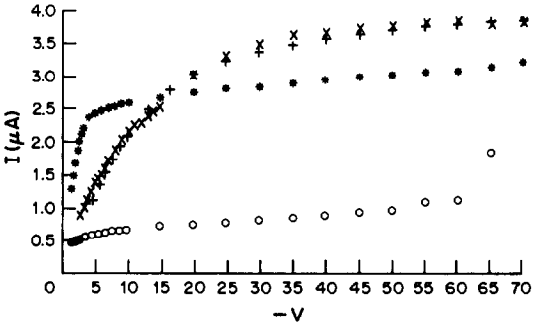

Fig. 4. Electrolyte concentration studies on the steady-state current–voltage properties of TDA membranes. Sweeps are in the direction of increasing voltages. ○, 0.1M HCl; •, 0.01M HCl; +, 0.001M HCl; ×, 0.0001M HCl.

currents at increasing hydrochloric acid concentrations. The limiting currents were 3.75 μA for 0.0001M, 3.78 μA for 0.001M, 2.98 μA for 0.01M and approximately 0.6 μA for 0.1M hydrochloric acid. This dependence is consistent with the simple theory in equations (7) and (8). At about 0.001M hydrochloric acid concentration, failure of Donnan exclusion has become significant. As the membrane extracts more protons, as HCl, more carrier is consumed. The amount of bound carrier is no longer negligible, and the cation limiting current decreases. This loss of permselectivity and the resultant carrier consumption may very well be the cause of this sensor's potentiometric failure at high acid concentrations.

When failure of Donnan exclusion occurs, the limiting currents are no longer proportional to total carrier content. The experimentally found limiting currents would be expected to increase with, but not necessarily be proportional to, carrier loading at fixed bathing solution activities above about 0.001M hydrochloric acid. The currents observed are not proportional when 22.6 and 5.39mM TDA membranes are compared. The limiting currents are 7.71 and 3.78 μA for the two carrier loadings, respectively, in 0.001M hydrochloric acid. Evidently these concentrations do not produce excessive amounts of salt extraction, as judged by the nearly equal limiting currents when the membranes are bathed in 0.001 and 0.0001M hydrochloric acid. However, it can be proved from bulk resistivity measurements (below) that the Donnan exclusion in this system is on the verge of failure. There seems to be sufficient excess current contribution from co-ions to cause high apparent diffusion coefficients of TDA, as judged from the values for the 22.6mM membrane (2.7×10^{-8} cm^2/sec) and the even greater valuc (5.6×10^{-8} cm^2/sec) for the 5.39mM membrane.

The initial d.c. resistances agree with the high-frequency resistances for membranes bathed in 0.001M (and lower concentration) hydrochloric acid. As failure of Donnan exclusion begins with $\geq$0.001M hydrochloric acid, we find that the bulk resistivities of TDA membranes decrease with increasing acid concentration: 314 MΩ cm in 0.001M, 54.5 MΩ cm in 0.01M and 41.6 MΩ cm in 0.1M hydrochloric acid for 5.39mM TDA membranes.

TDA membranes, dried in air after exposure to solutions, show an unusual growth of the surface film impedance, illustrated in Fig. 5. This behavior is unlike that found for valinomycin membranes. A 22.6mM TDA membrane soaked in 0.001M hydrochloric acid displays well-resolved bulk and surface semicircles in the impedance plane. When the membrane is exposed to air, the surface semicircle appears to grow, but merges into the bulk semicircle. Before the exposure of the membrane to air, the specific resistance for the bulk semicircle was 156 MΩ cm, with a time constant, τ_i, of 0.123 msec. The normalized resistance for the low-frequency semicircle

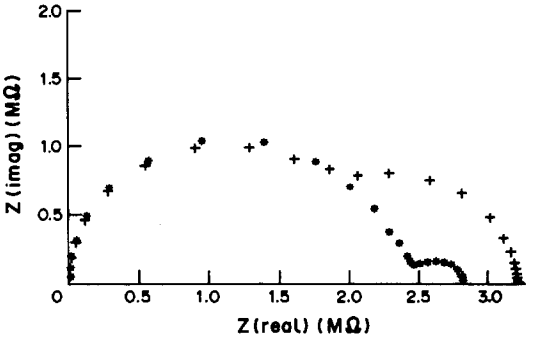

Fig. 5. Impedance plots of 22.6mM TDA membranes when bathed in 0.001M HCl; *, before membrane surface exposed to air; +, after membrane surface exposed to air.

was 0.286 MΩ cm and τ_i was 0.0454 msec. After exposure of the membrane to air, the bulk resistivity decreased by 10% to 133 MΩ cm, with time constant 0.111 msec. The resistance for the second semicircle grew to 1.26 MΩ cm, with time constant 1.75 msec. This behavior may be the result of the surfactant properties of TDA at high membrane loadings. The two semicircles do not merge when the membrane is bathed in 0.0001M hydrochloric acid. The behavior is normal, as judged from valinomycin-loaded membranes, and the second (low-frequency) semicircle disappears. This phenomenon is also dependent on the carrier concentration, and no merging of the two semicircles is observed for 5.39mM TDA membranes in 0.001M hydrochloric acid.

ETH 1001. Current–voltage curves for a wide range of calcium chloride concentrations in the bathing electrolyte were determined for a Ca^{2+}-selective PVC membrane, plasticized with *o*-NPOE and containing the ionophore ETH 1001. As carrier consumption occurs, beginning at about 0.001M calcium chloride, the limiting currents increase as expected from the simple theory. This result, shown in Fig. 6,

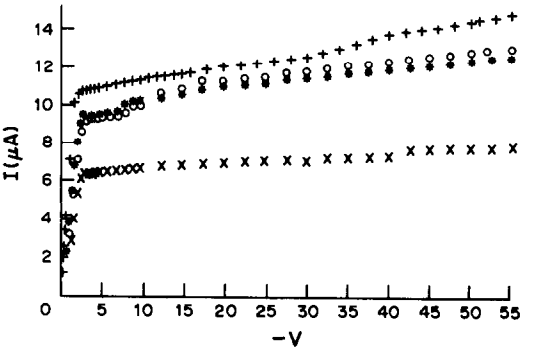

Fig. 6. Steady-state current–voltage curves for ETH 1001 membranes bathed in different concentrations of $CaCl_2$: +, 16.0mM ETH 1001 membrane in 0.1M $CaCl_2$; *, 16.0mM ETH 1001 membrane in 0.01M $CaCl_2$; ○, 16.0mM ETH 1001 membrane in 0.001M $CaCl_2$; ×, 10.1mM ETH 1001 membrane in 0.0001M $CaCl_2$.

Table 3. Bulk impedances for 1% ETH 1001 membranes plasticized with *o*-NPOE

$[CaCl_2]$, M	ρ_∞, $M\Omega$ cm	ϵ_g, pF/cm	τ_i, msec	ϵ
0.1	6.40	2.91	0.019	33
0.01	24.6	2.85	0.070	32
0.001	54.2	2.67	0.145	30
0.0001	46.9	2.57	0.120	29

is expected in view of the high-permittivity plasticizer. Only the lowest bathing concentration gives reliable data for pure CCa^{2+} transport. Data for 0.0001*M* calcium chloride were used to calculate the steady-state diffusion coefficient, 5.0×10^{-8} cm²/sec. Analogously rising limiting currents with increasing potassium chloride concentration were observed for the $Kval^+$ electrode when it was plasticized with *o*-NPOE.[5]

The current–voltage curves for ETH 1001 membranes are different from, but complementary to, those for a structurally similar ionophore, ETH 1002.[17] With ETH 1002 the current–voltage curves show decreasing limiting currents with increasing calcium chloride concentration in the bathing solutions, as a result of extensive carrier consumption. Our conclusion is that the earlier results[17] correspond to greater failure of Donnan exclusion, so that the limiting currents are on the high-concentration side of the response maximum. The structures are described by Morf[24] as ligands 8 (ETH 1001) and 15 (ETH 1002). ETH 1002 differs from ETH 1001 only in the lack of the two methyl groups in the 4- and 5-positions. The implication is that ETH 1002 forms a stronger complex.

Figure 6 is thought to be an accurate representation of the current–voltage curve for two reasons. First, voltage-induced membrane change was minimized by initially applying only small voltages. Voltage-assisted salt extraction occurs mainly at higher voltages. In this way, all points measured were subject to the lowest possible applied bias (*i.e.*, the least possible membrane change). Second, the steady-state data were measured at a constant current for 16 min.

The steady-state resistivities confirm that salt extraction is occurring. The d.c. resistivities for a 16m*M* ETH 1001 membrane were 10.7, 13.7, 16.5 and 29.6 MΩ cm for membranes bathed in 0.1, 0.01, 0.001 and 0.0001*M* calcium chloride, respectively. In all the solutions, the resistances decreased during current–voltage curve measurement and reached steady values after about 16 min. These resistivity drops are much more pronounced than the small drops found with low-permittivity DNA-plasticized membranes.[1] The great amount of voltage-assisted salt extraction required to reach a steady state is a consequence of the higher permittivity of *o*-NPOE.

The high-frequency bulk resistance is also dependent on the bathing electrolyte concentration and provides further confirmation of failure of Donnan exclusion. Tables 3 and 4 give impedance values for a 1% w/w loading membrane over a wide bathing concentration range. The bulk resistivities (Table 3) increase with decreasing solution concentration until the membrane is bathed in 0.0001*M* calcium chloride. Similar behavior is also found for the surface film resistances (Table 4). Tóth *et al.*, [3] have interpreted this behavior as concentration-dependent salt extraction into the exuded film. The properties of this film are similar to those of other plasticized PVC membranes, with the exception of TDA-based films (see above).

Table 4. Surface film impedances for 1% ETH 1001 membranes plasticized with *o*-NPOE

Current–time behavior

Nonactin. Fixed-site systems loaded with a large excess of neutral carrier should display current–time responses to a constant applied plateau voltage that have three characteristic regions: (1) the nearly constant initial current, (2) a monotonic exponential decay and (3) a steady-state current.[7] The current–time transient of a 2.79m*M* nonactin membrane is illustrated in Fig. 7. All three regions are observed. The initial current is exactly given by $-V_{appl}/R_\infty$ and a number of resistivity values are given in Table 2. The nearly constant initial current reflects transport

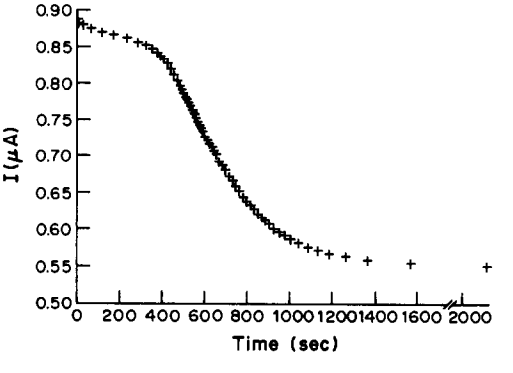

Fig. 7. Current–time transient of a 2.79m*M* nonactin membrane in 0.001*M* NH_4Cl. Bias is −2.33 V.

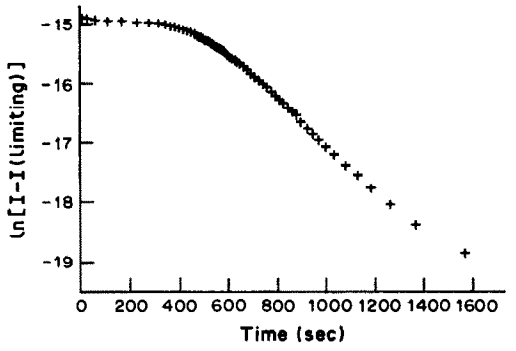

Fig. 8. Plot of $\ln[I - I_L]$ *vs.* time for the transient in Fig. 7. Slope = −0.00375, *y*-intercept = −13.28, square of the correlation coefficient = 0.9965, $D_{Non} = 1.4 \times 10^{-8}$ cm²/sec.

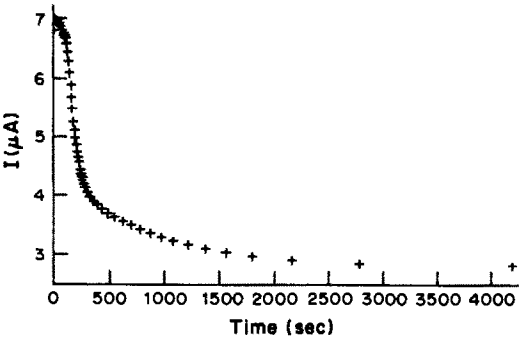

Fig. 9. Current–time decay of a 5.39m*M* TDA membrane. Bias is −18 V.

of NH_4Non^+ through fixed sites of the membrane. At the transition time, the surface concentration of the carrier is zero on the side of the membrane at which NH_4^+ enters, and $2\bar{V}$ on the side at which NH_4^+ leaves. The transition time can be used to calculate the diffusion coefficient of nonactin in the membrane. For 1% nonactin membranes, the calculated diffusion coefficient is 1.6×10^{-8} cm²/sec. Figure 8 is a semilogarithmic plot of Fig. 7, and the decay is seen to be exponential, as predicted.[7] The slope is −0.00375, which gives a diffusion coefficient of 1.4×10^{-8} cm²/sec. The intercept gives a diffusion coefficient of 1.6×10^{-8} cm²/sec.

The current–time transients in the high-voltage range, where Donnan exclusion may fail, differ from those described for valinomycin under the same conditions.[7] Valinomycin-loaded membranes show a monotonic current decay at high voltages when bathed in potassium chloride solutions. Nonactin-loaded membranes bathed in ammonium chloride solutions show a nonmonotonic transient after the transition time. The reason for this has not been established, but failure of Donnan exclusion is thought to be the cause. A similar curve was found for a normal valinomycin membrane, when bathed in potassium iodide rather than potassium chloride solution. Failure of Donnan exclusion was confirmed by the current–voltage curves for the iodide system. Nonmonotonic decay was found only at high voltages.

Tri-n-dodecylamine. Figure 9 shows the current decay for a 5.39m*M* TDA membrane bathed in 0.001*M* hydrochloric acid. The initial constant-current part of the decay corresponds to an apparent diffusion coefficient of 3.9×10^{-8} cm²/sec, compared with 5.6×10^{-8} cm²/sec for the steady-state calculated value. The initial constant current implies fixed sites, uniform concentration of protonated TDA and a uniform concentration of any encroaching anions. In the transient state the CM^+X^- concentration profile may range from high on the side from which CM^+ leaves, to low on the side at which it enters (Fig. 2). The theory has not been worked out for this complicated case. We surmise that the calculated diffusion coefficients should be more nearly correct from the $t = 0$ data than from steady-state data, because the contribution from anion transport should be least when the concentration profiles of charge carriers are constant. The semilog plot of the current, corrected for the steady-state value, gives a decay time constant of the order of −0.0015 sec, which is much too low.

ETH 1001. The initial part of the current decay for this neutral-carrier membrane differs from the transient for the valinomycin-loaded *o*-NPOE. The current first increases with time, then drops sharply and finally decays to a steady-state value, as shown in Fig. 10. Integrating the initial current up to the time of the sharp break, τ, which is analogous to the transition time in the normal case, gives Q_i, the number of coulombs passed, and τ. We have surmised that the polarized state depends on the boundary conditions and not on the integration pathway. Then from the integrated form of the Sand equation:

$$\tau^{1/2} = 2Q_i n / zFAD_{carrier}^{1/2} \pi^{1/2} C_{free} \qquad (21)$$

$D_{carrier}$ can be calculated; this gives $D_{ETH\,1001} = 5.0 \times 10^{-8}$ cm²/sec. The semilog plot in Fig. 11 reveals an exponential decay, with a time constant equivalent to $D_{ETH\,1001} = 4.7 \times 10^{-8}$ cm²/sec.

CONCLUSIONS

Normal permselective behavior of the current–voltage and current–time responses was previously

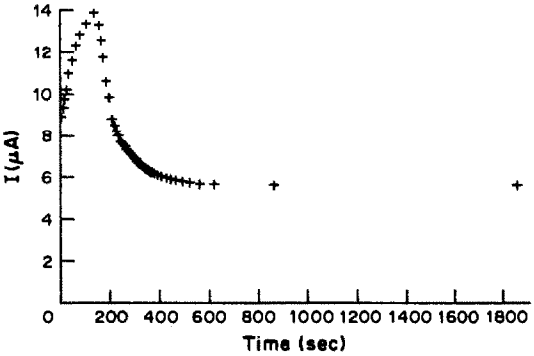

Fig. 10. Current–time decay of a 10.1m*M* ETH 1001 membrane in 0.001*M* $CaCl_2$. Bias is −8.73 V.

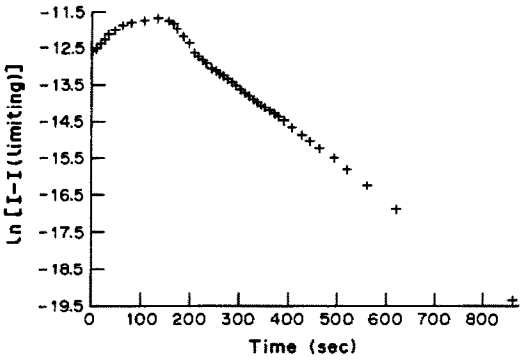

Fig. 11. Plot of $\ln[I - I_L]$ *vs.* time for the transient in Fig. 10. Slope = −10.8, *y*-intercept = −10.41, square correlation coefficient = 0.9977.

known only for K^+-valinomycin in low-permittivity plasticized membranes. Normal behavior has now also been found for nonactin in DNA. Typical low site-density PVC membranes with *o*-NPOE plasticizer are on the verge of failure of Donnan exclusion over some part of the practical bathing concentration range. New abnormal response characteristics are reported, *i.e.*, limiting currents, apparently in the plateau range of applied voltages, vary with bathing electrolyte concentrations; limiting currents are not exactly proportional to carrier concentration under constant bathing concentration conditions and current–time curves show maxima, or decrease without the expected initial constant-current region. Moreover, the apparent diffusion coefficients of carriers increase with increasing bathing electrolyte concentration. Bulk resistances, measured by the impedance method, decrease because of encroachment of salt at some point in the course of increasing the bathing electrolyte concentration. The theory should be modified to account for anion encroachment, consumption of free carrier and the linear increase of limiting current with high applied voltages beyond the normal plateau limiting current range.

The theory has been amended in two ways: for uniform and nonuniform encroachment of bathing electrolyte into the membranes from symmetric or asymmetric bathing, but only for steady-state responses. For normal symmetric bathing, limiting currents can increase and pass through a maximum. Experimentally, one or both of the effects can be found for all the carriers studied in membranes plasticized with *o*-NPOE (including valinomycin, as reported elsewhere) and for TDA in DNA-plasticized membranes.

The mobilities of the acyclic carriers are generally larger than those of the cyclic carriers studied. The diffusion coefficient of TDA is at least twice that for the cyclic carriers. This may be explained, in part, by the smaller size or different shapes of the ion/carrier complexes compared with the bulky, spherical, cyclic carrier complexes. Similar conclusions have been reported for other systems.[9,25]

THEORETICAL AND EXPERIMENTAL STUDIES OF ELECTROSTATIC EFFECTS IN REVERSED-PHASE LIQUID CHROMATOGRAPHY

STEPHEN G. WEBER
Department of Chemistry, University of Pittsburgh, Pittsburgh, PA 15260, U.S.A.

(*Received* 24 *May* 1988. *Accepted* 8 *September* 1988)

Summary—Electrostatic effects are important in many reversed-phase liquid chromatographic separations involving surfactants and ion-pair reagents. To give better understanding of such systems the Poisson–Boltzmann equation has been solved for two cases. The first is that of an infinitely long cylinder with charge density on the inner wall, and two phases in the interior, one in the center and the other around it. Salts with ions of various solubilities in each phase may be present. The solution is obtained for the low-potential case ($\Delta\psi e/kT \ll 1$). The second case is that of a planar sandwich, wall/phase 1/phase 2/phase 1/wall, with the same chemistry as case 1 but without the low-potential restriction. In case 2, there is also a Langmuir adsorption isotherm for each ion. The theory shows that the information gained from the Stern–Gouy–Chapman theory, which is mathematically semi-infinite, only applies when the diffuse layer thickness is much smaller than the pore radius, an unlikely circumstance in chromatography. The volume-averaged electrostatic potential difference can be measured experimentally with the solutes ϕ_4Si, ϕ_4As^+, ϕ_4B^- (ϕ = phenyl). The results are in agreement with theory. They show that the electrostatics of the system is dominated by fixed charges on the silica when the salt present is insoluble in the stationary phase, but when ions with some solubility in the stationary phase are used, mixed effects are obtained.

The interactions between ions and between ions and surfaces have been employed to great advantage in reversed-phase liquid chromatography.[1] Many careful studies have been made in which retentions of charged solutes have been determined as a function of solution conditions.[2–7] The models used to describe these events were primarily chemical in nature. Various equilibria, erroneously referred to as "mechanisms", were called on to explain the solute behavior, such as ion-pairing, surfactant adsorption and ion-exchange.

Later, more general electrostatic models emerged[8–13] in which the primary influences on retention were the surface charge density on the stationary phase, and the ionic strength of the mobile phase. These models are generally successful. The most detailed of the models is that of Cantwell[8,11–14] who employed the Stern–Gouy–Chapman theory of the electric double-layer to find the chromatographic properties of an ionically buffered surfactant-containing system. In this theory,[14–18] the simultaneous solution of the Poisson equation of electrostatics and the Boltzmann equation of statistical mechanics is obtained to relate surface charge density, ionic strength and potential–distance profile.

The work of Knox and Hartwick[9] in clarifying the relationships among the various equilibria in these sytems, and of Cantwell[13] in relating the chromatographic phenomena to an established paradigm for the liquid–solid interface, together provide a solid foundation for a rather complete appreciation of ionic effects in chromatography. There do remain, however, some areas for continuing investigation. What, for example, is the influence of a rather thick stationary phase on the electrostatics? Can the influence of adventitious ion-exchange sites on the stationary support[19] be included in electrostatic models that have a stationary phase overlayer? What is the influence of the pore size on the system? What is the influence of non-surface-active ions?

We seek answers to these questions. Because of the remarkable sensitivity of chromatography, small energetic effects are visible as changes in the capacity factor k'. Also, the potential gradient at the interface may have an influence in separation of large molecules (*e.g.*, proteins), since the dipole moment of such molecules can be large. Thus, the effects described, although couched in a theoretical framework, are of practical importance in separation. Regardless of its chromatographic relevance, the physical problem of the electrostatics in a cylinder is a current research problem,[20,21] *e.g.*, for understanding flow in capillary zone electrophoresis.[20]

THEORY

Symbols

a	radius of inner cylinder (stagnant mobile phase)
C_{ij}	a coefficient
e	charge on the electron
I	ionic strength

I_0	modified Bessel function of the first kind, of order zero
I_1	modified Bessel function of the first kind, of order one
k	Boltzmann's constant
K_0	modified Bessel function of the second kind, of order zero
K_1	modified Bessel function of the second kind, of order one
n_i°	concentration of ion i in bulk solution (outside the porous particle)
r	radial dimension
R	radius of pore
T	temperature
z	charge of ion, including sign
α_i	molecular volume or area of species i
$\alpha_{\phi_4\mathrm{M}}$	$k'_{\phi_4\mathrm{M}}/k'_{\phi_4\mathrm{Si}}$; M = As, B; ϕ = phenyl
β	$\epsilon_2\kappa_2/\epsilon_1\kappa_1$
γ_i	transfer activity coefficient for ion i (mobile phase to stationary phase)
ϵ_i	permittivity of medium i
κ	inverse Debye length
$\Delta\mu^\circ_{+,-}$	free energy of transfer of an ion from stagnant mobile phase to stationary phase.
$\psi(r)$	electrostatic potential at point r
σ	surface charge density*

Two theoretical descriptions will be given for the problem of understanding electrostatics in chromatography. These will be related to the treatment of Cantwell in the discussion section. The two theoretical treatments are: the analytical solution of the linearized Poisson–Boltzmann equation for a cylindrical pore that has two phases (the stationary phase and the stagnant mobile phase); the numerical solution of the Poisson–Boltzmann equation for a saturable surface (the Stern model[22]), and a surface charge density in a thin "sandwich" (surface/phase 1/phase 2/phase 1/surface). The first case has limited applicability in most chromatographic circumstances, but it is easy to program (the solution is in terms of Bessel functions) and allows appreciation of the effect of various ions and solvents and the dimensions of the system. The second must be solved numerically, but it is quite comprehensive in allowing any number of ions and permanent ion-exchange sites for arbitrary concentration and solubility.

Derivation 1

The pore of a stationary particle is modeled as an infinitely long cylinder with radius R. The stagnant mobile phase occupies the central region, of radius a. The differential equation governing the system is

$$\nabla^2\psi(r) = \frac{d^2\psi}{dr^2} + \frac{1}{r}\frac{d\psi}{dr}$$

$$= \begin{cases} -\dfrac{4\pi}{\epsilon_1}\sum_i z_i e n_i^\circ \exp\{-z_i e\psi(r)/kT\}; \\ \quad (0 \leqslant r \leqslant a) \end{cases} \quad (1a)$$

$$\begin{cases} -\dfrac{4\pi}{\epsilon_2}\sum_i z_i e n_i^\circ \gamma_i \exp\{-z_i e\psi(r)/kT\}; \\ \quad (a \leqslant r \leqslant R) \end{cases} \quad (1b)$$

For potentials that obey the relationship shown in equation (2)

$$|\psi(R)| \ll \frac{kT}{|z|e} \quad (2)$$

we can linearize equation (1) to yield equation (3):

$$\frac{d^2\psi}{dr^2} + \frac{1}{r}\frac{d\psi}{dr} + a_j - b_j\psi = 0;$$

$$(j = 1, 0 \leqslant r \leqslant a; \quad j = 2, a \leqslant r \leqslant R) \quad (3)$$

$$a_1 = \frac{4\pi}{\epsilon_1}\sum_i z_i e n_i^\circ \quad (4)$$

$$b_1 = \frac{4\pi}{\epsilon_1}\sum_i \frac{z_i^2 e^2 n_i^\circ}{kT} = \kappa_1^2 \quad (5)$$

$$a_2 = \frac{4\pi}{\epsilon_2}\sum_i z_i e n_i^\circ \gamma_i \quad (6)$$

$$b_2 = \frac{4\pi}{\epsilon_2}\sum_i \frac{z_i^2 e^2}{kT} n_i^\circ \gamma_i = \kappa_2^2 \quad (7)$$

This leads to the solution

$$\psi_j - \frac{a_j}{b_j} = C_{1j}I_0(x) + C_{2j}K_0(x) \quad (j = 1, 2) \quad (8)$$

where

$$x = \kappa_j r \quad (9)$$

The four coefficients are calculated with the following four boundary conditions:

$$(i) \quad r = 0 \quad \partial\psi/\partial r = 0 \quad \text{(symmetry)} \quad (10)$$

$$(ii) \quad r = R \quad \frac{\partial\psi}{\partial r} = \frac{4\pi}{\epsilon_2}\sigma \quad (11)$$

$$(iii) \quad r = a \quad \epsilon_1\frac{\partial\psi_1}{\partial r} = \epsilon_2\frac{\partial\psi_2}{\partial r} \quad (12)$$

$$(iv) \quad r = a \quad \psi_1 = \psi_2 \quad (13)$$

yielding

$$C_{11} = \frac{\epsilon_2}{\epsilon_1}\frac{I_1(\kappa_2 a)}{I_1(\kappa_1 a)}C_{12} - \frac{\epsilon_2}{\epsilon_1}\frac{K_1(\kappa_2 a)}{I_1(\kappa_1 a)}C_{22} \quad (14)$$

$$C_{12} = \frac{(a_2/\kappa^2)I_1(\kappa_1 a)K_1(\kappa_2 R) + \dfrac{4\pi\sigma}{\epsilon_2\kappa_2}[\beta I_0(\kappa_1 a)K_1(\kappa_2 R) + K_0(\kappa_2 a)I_1(\kappa_1 a)]}{\text{denominator}} \quad (15)$$

$$\text{denominator} = \beta I_0(\kappa_1 a)[I_1(\kappa_2 a)K_1(\kappa_2 R) - K_1(\kappa_2 a)I_1(\kappa_2 R)] - I_0(\kappa_2 a)I_1(\kappa_1 a)K_1(\kappa_2 a) - K_0(\kappa_2 a)I_1(\kappa_1 a)I_1(\kappa_2 R)$$

*The charge is negative and related to the number of anionic sites per unit surface area, and for convenience is expressed in units of -10^{-12} mole/cm^2.

$$C_{21} = 0 \tag{16}$$

$$C_{22} = \frac{4\pi\sigma}{\epsilon_2\kappa_2 K_1(\kappa_2 R)} + C_{12}\frac{I_1(\kappa_2 R)}{K_1(\kappa_2 R)} \tag{17}$$

In the expressions above, I_0 and I_1 are modified Bessel functions of the first kind, of order zero and one, respectively. K_0 and K_1 are modified Bessel functions of the second kind, of order zero and one, respectively. The abbreviation β is used for $\epsilon_2\kappa_2/\epsilon_1\kappa_1$.

Derivation 2

Equation (1) is modified to allow for saturation of the stationary phase by ions with a large positive transfer activity-coefficient γ_i. This was done by Stern[22] in 1924 to allow the Poisson–Boltzmann equation to be used in cases where there was strong attraction of ions to the surface. If this consideration is not included, the Boltzmann factor, $\exp(-ze\psi/kT)$, for cases in which z and ψ have opposite sign, leads to unrealistically high concentrations. Equation (1a) remains the same, while equation (1b) becomes

$$\nabla^2\psi(r) = -\frac{4\pi}{\epsilon_2}\frac{\sum_i z_i e n_i^\circ \gamma_i \exp\{-z_i e\psi(r)/kT\}}{1+\sum_i z_i e n_i^\circ \alpha_i \gamma_i \exp\{-z_i e\psi(r)/kT\}} \tag{18}$$

The new term that has been added to the denominator is identical to the term in the numerator except for the factor α_i, which is the molecular volume or molecular area, depending on the units of n_i°. This equation has been simplified, for practical reasons, to cover only the case of planar (sandwich) geometry.

The boundary conditions for equations (1a) and (18) are given by equations (10)–(13). There is only one difference in the treatment of the two derivations in practice. The surface charge is accompanied by counter-ions that must be specified. Charge neutrality requires that the number of counter-ions should equal the number of fixed charges. The concentration of counter-ions in the cylinder is given by equation (19) and for the rectangular space by (20). In the latter case R is the half-width of the space.

$$n_{cyl} = \frac{2\sigma}{R} \tag{19}$$

$$n_{rect} = \frac{\sigma}{R} \tag{20}$$

Control of interfacial potential

The value of σ is usually fixed by material and preparation considerations. Thus, it is not an experimental variable that can be chosen at will to alter the potential difference between phases. The number and type of ions, however, are very much under the chromatographer's control. For purely chemical reasons, the solubilities of the anion and cation of a salt in a solvent are probably different from one another. The same can be said for a second solvent. Thus, the transfer activity-coefficients (partition coefficients) of the two ions differ. In a salt-containing two-phase system at equilibrium, a potential difference arises between the two phases that balances the solvation and electrostatic parts of the electrochemical potential so that the electrochemical potentials of the ions are equal in the two phases. Several reviews and compilations of data on this topic have been published.[24–30] The practical result of this effect is that *any salt in a chromatographic system contributes to the interfacial potential difference.*

Of course, some experimental determination of the electrostatics at the chromatographic interface is needed. We recently introduced a method for doing this.[31] It relies on the use of the assumption[32] that the solubilities of the tetraphenylarsonium and tetraphenylborate ions are the same. This assumption has been critically discussed.[25,33–35] A consequence of this assumption is that the k' values for the solutes ϕ_4As^+ and ϕ_4B^- are expected to be the same in the absence of electrostatic effects. In the presence of such influences, however, the retention times of the charged species reflect the volume-weighted average of the potential in the two chromatographic phases. This may be experimentally determined by using the α values of the solutes, where the reference solute is the neutral ϕ_4Si [note: the following equation is correct—there is an error in equation (8) of reference 31].

$$\frac{ze\Delta\psi}{kT} = \frac{1}{2}\ln\frac{\alpha_{\phi_4B^-}}{\alpha_{\phi_4As^+}} \tag{21}$$

Furthermore, independent of the electrostatic effects, the retention of a charged species in reversed-phase liquid chromatography is reduced, compared to an otherwise identical neutral species, because of the lower dielectric constant of the stationary phase.[33,34] This effect is independent of the charge sign of the ion. It can be shown[31] that the experimental quantity

$$\tfrac{1}{2}kT\ln\{(\alpha_{\phi_4As^+})(\alpha_{\phi_4B^-})\}$$

(where the α values are referred to k' for ϕ_4Si) is equal to the free energy required to transfer an ion of this size from the mobile phase into the stationary phase.

In summary, since each kind of ion differs from all the others, it is expected that the transfer free energy γ_i of each kind will also be different from the others. Consequently, through the action of the salts in the system, the chemical nature of the stationary phase and the bound ion-exchange sites, an electrostatic potential is created in the pores of the support. The potential is a function of distance from the wall of the pore. The volume-weighted average of the electrostatic potential difference between the mobile phase and the stationary phase can be experimentally determined by using well chosen solutes.

EXPERIMENTAL

Laboratory work

Experimental details can be found in reference 31. The column (10 μm Spherisorb ODS, HPLC Technology) was

equilibrated with many column-volumes (typically 150 ml) of solvent/electrolyte before experiments were undertaken. Injections of the probe solutes, ϕ_4AsCl, Kϕ_4B and ϕ_4Si were done in triplicate. The electrolytes used were KCl, $KClO_4$, $(n\text{-}C_4H_9)_4NCl$, $(n\text{-}C_4H_9)_4NClO_4$ at 5.0, 10 and 15mM concentration in 50/50 v/v acetonitrile/water mixture.

Computation

The solution of equations (1a) and (18) subject to the boundary conditions in equations (10)–(13) was accomplished by using the "shooting" method.[35] In the problem at hand, the two boundary conditions are $r = 0$ and $r = R$. Initial-value problems are fairly straightforward to solve since it is known where to begin integrating. The shooting method allows the use of initial-value solvers for boundary value problems. One boundary condition is known at $r = 0$, *viz.* the potential gradient [equation (11)]. A guess is made at $\psi(0)$, followed by integration over r. At $r = R$ the potential gradient should be zero. If it is not, the guess for $\psi(0)$ is adjusted and another try made. A root-finding algorithm was used to adjust $\psi(0)$ automatically. For large pore-radii or high concentration of salts, corresponding to the approach to bulk conditions, the method is extraordinarily sensitive. For example, the guess at $\psi(0)$ was needed to ten significant figures before the root-finding routine could converge for a computation involving 5-μm pores and 10mM Bu_4NCl.

RESULTS AND DISCUSSION

Approximate solutions for low potentials

The overall qualitative understanding of the electrostatic events is based on investigation of the low-potential case given by equation (8). Figure 1 shows how the potential varies with distance inside a cylinder that represents a model pore in a reversed-phase chromatographic particle. Note that at a salt concentration of 1M the potential change is clearly associated with the interfacial region. In the case illustrated, the cation is more soluble in the stationary phase, so there is a slight charge separation at the interface. The difference between the potentials of the stationary phase and the stagnant mobile phase (stationary minus mobile) agrees with that calculated by assuming that the pore is of macroscopic dimensions; *i.e.*, equation (22)

$$[1/\kappa_2 \ll (r_0 - a);\ 1/\kappa_1 \ll a] \tag{22}$$

holds, as shown in equation (23):

$$\Delta\psi = \frac{kT(\ln \gamma_-/\gamma_+)}{(z_- - z_+)e} = \frac{\Delta\mu^\circ_+ - \Delta\mu^\circ_-}{(z_- - z_+)e} \tag{23}$$

(All potential and free energies are for the process of transfer from the central zone (stagnant mobile phase) to the outer zone (stationary phase).) The value of kT/e is 0.0257 V at $T = 298$ K. For a difference of -300 cal/mole in free energy of transfer which is equivalent to about $kT/2$, and for $z_- - z_+ = -2$, a $\Delta\psi$ of about $kT/4e$ is expected. That it is obtained is readily verified by inspection of Fig. 1. As the concentration of added salt decreases, the geometry begins to play a role. At 10mM concentration of salt, the entire pore is charged, and ion-exclusion of cations results.

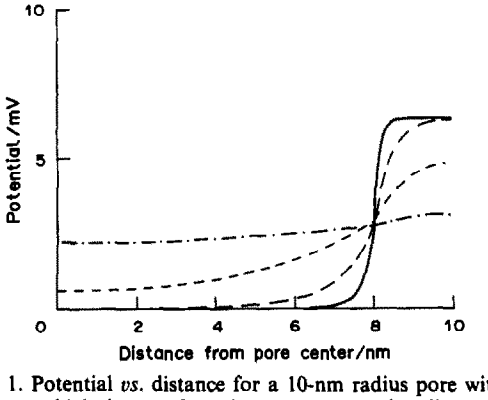

Fig. 1. Potential *vs.* distance for a 10-nm radius pore with a 2-nm thick layer of stationary phase. The dielectric constant of the central region is 60 (corresponding roughly to 50/50 v/v acetonitrile–water) and that of the edge region is 22.[31] The temperature is 298 K. The salt is composed of a univalent cation with a free energy of transfer (mobile phase → stationary phase) of -300 cal/mol and a univalent anion with zero free energy of transfer. Identification of lines: —·—·— salt concentration is $10^{-3}M$; ----- $10^{-2}M$, ——— $10^{-1}M$, —— $1M$.

A solute will be influenced by the potential according to the Boltzmann equation. This effect for the stagnant mobile phase and the stationary phase is calculated by integrating the Boltzmann factor over the relevant volumes. Since it is only the radial direction that matters, integration over the radius is adequate. For the stagnant mobile phase, we have (n = number of molecules, subscripts, sm = stagnant mobile phase, s = stationary phase, fm = flowing mobile phase)

$$n_{sm} = C^\circ \int_0^a r \exp[-ez\psi(r)/kT]dr \tag{24}$$

and for the stationary phase

$$n_s = \gamma C^\circ \int_a^R r \exp[-ez\psi(r)/kT]dr \tag{25}$$

In these equations C° is the concentration of solute in the flowing mobile phase, where it is assumed, reasonably, that there are no significant potential gradients. The potential in the flowing mobile phase is taken to be zero, without loss of generality. The partition coefficient for the probe solute in the presence of electrostatic effects is γ. To calculate k' we need to know n_{fm}. That can be done in the following way. When the potential in the pore is zero, then the ratio n_{sm}/n_{fm} is just the porosity ratio ϵ_p/ϵ_z. A value of 0.6 has been found[36] for the material we use. Then,

$$n_{fm} = \frac{C^\circ}{0.6}\int_0^a r dr = \frac{C^\circ a^2}{1.2} \tag{26}$$

There is an apparent discrepancy in units in equations (24)–(26) that is clarified if we recall that we have ignored the pore length, which can be taken as unity. By calculating values of k' for an anion and a cation, both of which have the same k' in a zero-potential system, we can determine an "effective" potential difference (between stationary and mobile phases)

*Free energy of transfer of ion from mobile phase to stationary phase, in cal/mole.

†In lines 5, 9, 13 and 17 there is only counter-ion for the fixed charges present.

that the solute experiences,[31] see equation (21). Values of the effective potential for the cases plotted in Fig. 1 can be found as entries 1–4 in Table 1. Note that, for high concentrations of salt, the value of the chromatographically determined effective potential approaches the theoretical bulk value (about +6.5 mV). When equation (22) does not apply, the effective potential is lower in magnitude than the bulk value.

Figures 2–5 show the influence of anion-exchange sites (-1×10^{-12} mole/cm^2, a reasonable value[19]) on the potential. The associated effective potentials are shown in Table 1.

Consider first lines 5, 9, 13, and 17 (solid lines in Figs, 2–5; note the difference in scales). In these cases, only the anionic sites on the surface, and their counter-ions, are present. In all cases the effective potential is negative. This is due to the sign of the fixed charges. The effect of the solubility of the counter-ion in the stationary phase is easily seen from the figures and the effective potentials. The poorly

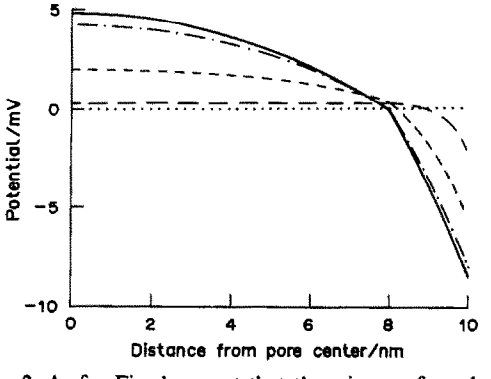

Fig. 2. As for Fig. 1, except that there is a surface charge density of -1.0×10^{-12} mole/cm^2 on the edge of the pore. The salt is equally soluble in the stationary phase and the mobile phase. The concentration of *added* salt (that is, not including the counter-ion to the fixed charges) is 0M ——; $10^{-3}M$ —·—·—·—; $10^{-2}M$ - - - - -; $10^{-1}M$ ———; .... zero reference.

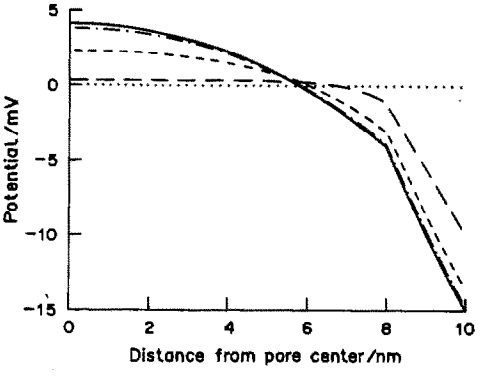

Fig. 3. Same as Fig. 2, except that the free energy of transfer of both the anion and cation is +2000 cal/mole.

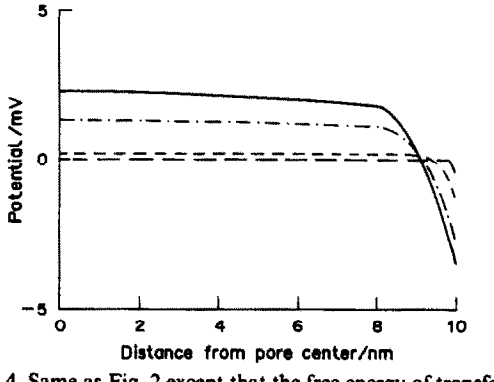

Fig. 4. Same as Fig. 2 except that the free energy of transfer of both the anion and the cation is −2000 cal/mole. (N.B. zero reference is coincident with line for 1M added salt).

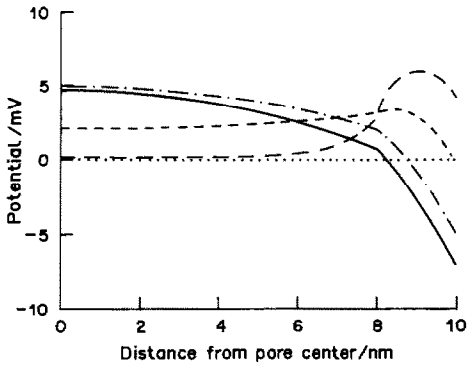

Fig. 5. Same as Fig. 2, except that the free energy of transfer of the cation is −300 cal/mole, anion 0 cal/mole.

soluble (in the stationary phase) counter-ion (Fig. 3) does not effectively screen the fixed charges, whereas the more soluble counter-ions (Fig. 5, the most obviously Fig. 4) do.

As the concentrations of the salts that are "electroneutral" (lines 5–16 in Table 1, Figs. 2–4) is increased, the effective potential decreases. The salt that is soluble in the stationary phase is more effective than the others, primarily because the number of counter-ions close to the fixed charges is larger than in the other cases. Reducing the distance between the fixed charges and the counter-ions by chemically attracting the latter ($\Delta\mu_+^\circ < 0$) to the interface is very effective in reducing the influence of the fixed charges.

When the salt is not electroneutral, there can be a sign-change in the effective potential (lines 17–20 in Table 1, Fig. 5). When the charge separation induced by the differing solubilities of the anion and cation exceeds the naturally occurring charge separation of opposite sign, then the stationary phase takes on a positive potential, as shown in lines 19 and 20 of Table 1.

All of the ion-associated phenomena typically observed in reversed-phase liquid chromatography are represented by the simple electrostatic picture presented. While formulas for retention based on models of equilibria[2-9] are undoubtedly more useful to the practicing chromatographer as a means of predicting retention behavior in the laboratory, the more general model provided herein is conceptually more appealing, owing to its generality, if for no other reason. The application of Stern–Gouy–Chapman theory to chromatography on polysytrene–divinyl benzene by Cantwell is very similar to the electrochemical theory presented here. Cantwell has applied the theory for a semi-infinite system (bounded at one end by a surface and unbounded at the other) to chromatographic particles. This cannot be quantitatively applicable if the dimensions of the porous space, or indeed, of the insulating chromatographic support that separates liquid spaces, are of the same order of magnitude as the Debye length, as has been shown for a thin organic film sandwiched between water layers.[40] Only if the concentrations of salt are greater than about 100mM (in typical chromatographic systems) will theory for semi-infinite systems apply.

This is demonstrated in Fig. 6. The potential at the edge of the pore is plotted as a function of the inverse of the square root of the ionic strength. Cantwell has used the result of Stern–Gouy–Chapman theory for semi-infinite systems to describe the effect of concentration on the potential at the interface between the support and the stagnant mobile phase.[11] The theory, as it applies to the case in hand, is simply stated as equation (27):

$$\psi(R) = \text{constant} \times \frac{\sigma}{I^{1/2}} \tag{27}$$

where I is the ionic strength. A plot of log $[\psi(R)]$ *vs.* log$[1/I^{1/2}]$ should yield a straight line of slope 1. It can be seen that only for large pores (100 nm radius) is the theoretical slope obtained for any significant fraction of the range of concentrations plotted. For the case of smaller pores of relevance to chromatography, the potential developed is smaller and relatively insensitive to concentration of ions. When there is extraction of the added salt into the stationary phase, the dependence of the potential at R_0 on concentration is weak and more complex. The limiting slope of the line still obeys theory, but the line is displaced because of the effect of the transfer activity coefficient on the concentration of ions near the fixed charges.

Numerical solution for arbitrarily high potentials

Qualitatively, the results of computations using equations (1a) and (18) appear the same as those

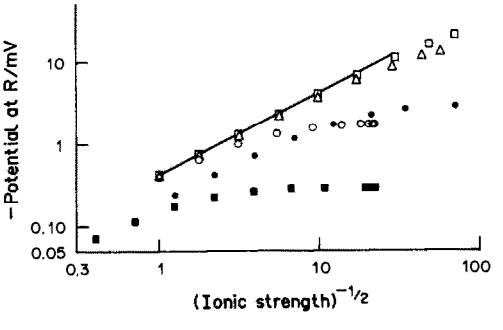

Fig. 6. Potential at the pore edge, $\psi(R)$, as a function of $(\frac{1}{2}\Sigma\, c_i z_i^2)^{-1/2}$. The surface charge density is -1×10^{-12} mole/cm^2. The open symbols are for a pore consisting of a single phase with a dielectric constant of 78 and diameters of 10 nm; ○; 100 nm, △; 200 nm, □. The darkened symbols are for a two-phase cylinder with each phase having the same dielectric constant (78) and the anion and cation both having a transfer free energy of −2 kcal/mole (from stagnant mobile phase to stationary phase). The pore diameters are 10 nm, ■; 100 nm, ●. In each case, the radius of inner cylinder is 90% of the radius of the outer cylinder. The solid line is the Cantwell theoretical prediction for a semi-infinite planar one-phase system.

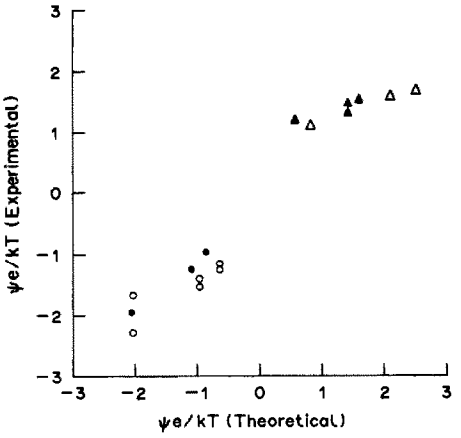

Fig. 7. Theoretical *vs.* experimental potential. Parameters for theory: $T = 298$ K; $\epsilon_1 = 60$; $\epsilon_2 = 22$; $R = 5$ nm, $R - a = 2$ nm; $\sigma = -2 \times 10^{-12}$ mole/cm^2; it has been assumed that only one monolayer of any species will "fit" on the stationary phase, even though this phase is several atoms thick. The apparent molar volume, α, was then taken as (10^{10} cm^2/mole) ($R - a$) for all ions. Added salt: KCl, ○; $KClO_4$, ●; $(n\text{-}C_4H_9)_4NCl$, △; $(n\text{-}C_4H_9)_4NClO_4$, ▲. In each case, the concentrations are 5m*M* (left-hand point or points in each triad), 10m*M* (center) and 15m*M* (right).

pictured in Figs. 1–5. The electrostatic potential created by the fixed charges on the silica in combination with various ions in the solution has been experimentally investigated. The ions were chosen to span a range of solubilities. The ions and their free energies of transfer (water to acetonitrile, kJ/mole at 25°) are: Cl^-, 42.1; ClO_4^-, 2; K^+, 8.1; $(n\text{-}C_4H_9)_4N^+$, −31.[29] Figure 7 shows the agreement between the chromatographically measured potential and the theoretical potential. Regarding the latter, there are many parameters that can be adjusted to obtain a fit. We have chosen reasonable values for the physical and chemical parameters, and found a good correlation between the theory and experiment. No attempt has been made to find a best fit. The most arbitrary parameter is the free energy of transfer for the ions. The values for transfer from water to acetonitrile are well established. However, these cannot be used for the experimental system, which consisted of a 50/50 v/v acetonitrile–water mobile phase and a reversed stationary phase. We have assumed that the free energies would simply be decreased by a fixed factor, in this case 1/3. This is a weak assumption in a quantitative sense. Judging from the limited data available,[41] this assumption is worst for the most indifferent ions, *viz.* K^+ and ClO_4^-. This is fortunate, since a significant relative error (*e.g.*, a factor of two) in free energy of transfer of either of these ions will influence the computations very little.

An implicit assumption in our treatment is that the free energy of partitioning adds to the electrostatic free energy for solutes. The chemical reasoning behind this is that the solute experiences both energies simultaneously. This makes physical sense for reversed phases. Cantwell has assumed that the electrostatic contribution and the adsorption (chemical) contributions to k' are *additive*. This is a tenable model if the fixed charges are widely spaced, so that a solute either adsorbs on a neutral portion of the interface or it interacts with the charge. This seems less likely for reversed-phase chromatography since in order to get near the fixed charges the solute must be in the stationary phase.

CONCLUSIONS

Several important points have been made. A stationary phase influences the electrostatics of the system by virtue of its dielectric constant, and its ability to solvate ions differentially in the eluting mobile phase. The influence of fixed charges on the electrostatics is significant (Table 1), but not as large as would be predicted from considering the system to be semi-infinite (Fig. 6). For large pores, the influence of non-surface-active ions is that predicted by Cantwell. For smaller pores, or for salts that are extracted into the stationary phase, the simple result does not apply. Experimental measurements of the volume-average electrostatic potential difference between the mobile and stationary phases are in good agreement with the theory.

(*Received* 4 *July* 1988. *Accepted* 13 *July* 1988)

Summary—A pattern-recognition/artificial-intelligence program, referred to as MAPS (Method for Analyzing Patterns in Spectra), was recently developed to identify the relationships that exist between substructures and the characteristic features they produce in the spectra from mass spectrometry (MS) and successive mass spectrometry (MS/MS). MAPS has been extended to utilize these relationships to formulate exclusion rules as well as inclusion rules, so that the absence of recognized substructures can be predicted as well as their presence. The potential usefulness of each MS and MS/MS spectral feature in such rule formulation is characterized by correlation and uniqueness factors. The correlation factor expresses the degree of correlation between a feature and a specific substructure; the uniqueness factor expresses the uniqueness of a feature with respect to that substructure. Features with high correlation factors are of most use for predicting the absence of substructures, whereas features with high uniqueness factors are most useful for predicting their presence. Feature intensity-data have been found to improve the inclusion-rule performance and degrade the exclusion-rule performance. Criteria for optimizing the predictive abilities of both rule types are discussed.

Successive mass spectrometry (MS/MS) can be performed with a variety of mass spectrometric instruments, including Fourier-transform (FTMS), tandem quadrupole (TQMS), and double-focusing mass spectrometers (MIKES or linked scan). Ions selected in the first stage of mass analysis undergo collisionally activated dissociation (CAD). The second stage of mass analysis provides a mass spectrum of the ionic CAD products (daughter ions) of the selected parent ion. Daughter spectra can provide direct information on the structure of the corresponding parent ion and thus, indirectly, on the structure of the portion of the molecule from which the parent ion was derived in the ion-source.

A library of the daughter spectra of known ions would be of great utility for structure elucidation. Specific parent-ion structures can be identified by comparing the daughter spectra with the daughter spectra of known ion structures. This idea was originally proposed by Beynon and co-workers in 1978.[1] Although databases of reference daughter spectra have been created by various groups[2–4] they have not been widely applied in molecular structure elucidation. There are two major reasons for this. One is that identifying an ion structure does not directly identify the structure of the molecule from which the ion was derived. The other is that the relative abundances of ions in daughter spectra are highly dependent on instrument type and experimental operating conditions; current MS matching routines depend on intensity matches at each mass value. Dawson's round-robin reproducibility study showed that widely different daughter spectra were observed for specific parent ions when standardized operating conditions were used with different TQMS instruments.[5] Comparisons of daughter spectra from TQMS, MIKES and FTMS instruments show still greater disparities. Although the mass spectrometry community has not yet reached a consensus on the criteria for collecting instrument-independent daughter spectra,[6] several prerequisites have recently been identified.[7,8]

Even without instrument-independent spectra, MS/MS has been used very successfully for the determination of ion structures. However, daughter-spectra/ion-structure relationships are not easily come by; each one is generally the result of an intensive study. For molecular identification by this route, it would be necessary to identify the ion structures corresponding to each daughter spectrum. Even then, certain ion structures may be products of rearrangements and thus may not represent the structure of the part of the molecule from which they were

*Author for correspondence.

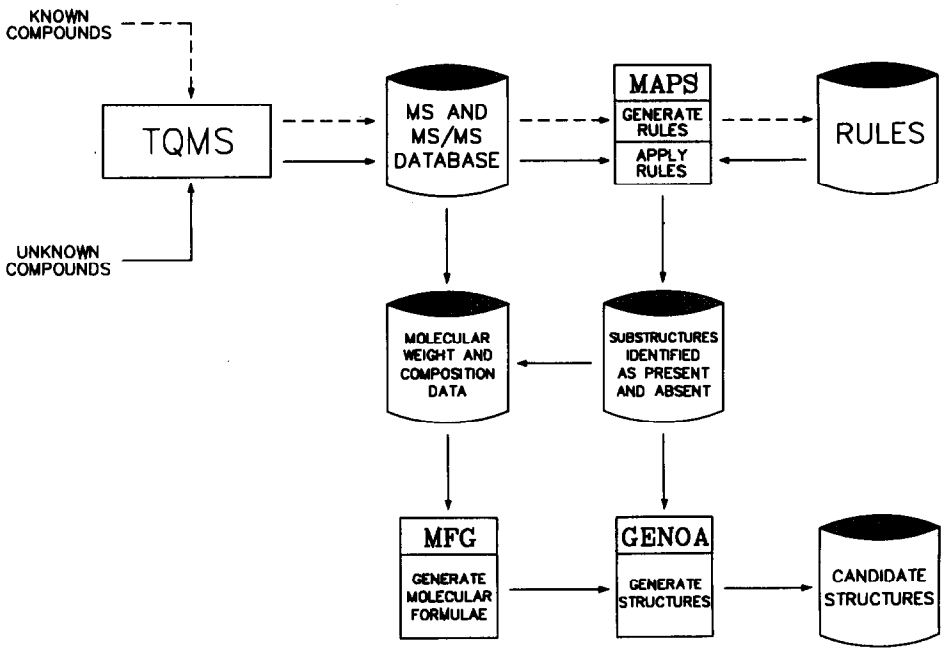

Fig. 1. Schematic of ACES.

derived. Molecular substructure rather than ion-fragment information is certainly more useful in the structure elucidation of unknowns.

Another significant disadvantage of the daughter-spectrum matching approach is that using only daughter spectra does not take full advantage of the extra information that MS/MS affords. Daughter-spectrum matching routines use the patterns in only one of the several types of data available from MS/MS. Information characteristic of a given substructure is not limited to the daughter spectrum of its closely related ion structure; it can also be obtained from neutral losses and daughter ions in the daughter spectra of other ion structures which contain part or all of that substructure or for which ion formation is influenced by the presence of that substructure.

Recently, we reported on the development of an algorithm for elucidation of the relationships between substructures and the characteristic features they produce in MS and MS/MS spectra.[9] This program, referred to as MAPS (Method for Analyzing Patterns in Spectra), discovers these relationships by automated intelligent analysis of a database of the MS and MS/MS spectra of known compounds. No assumptions about the fragmentation processes or ion rearrangements are made within MAPS; spectral features are empirically correlated with molecular substructures rather than with ion structures, and chemical heurism is then applied to remove false correlations. MAPS takes full advantage of the extra information that MS/MS affords, by extracting several types of features from MS and MS/MS spectra.

MAPS is one component of an integrated system developed in this laboratory for structure elucidation from MS and MS/MS data.[10] This system, referred to as ACES (Automated Chemical structure Elucidation System), is shown schematically in Fig. 1. A TQMS instrument is currently used as the source of the MS and MS/MS data. The MAPS software operates in two modes. In the identification mode, MAPS uses substructural MS, and MS/MS data from known compounds to formulate rules for predicting the presence and absence of substructures. In the application mode, these rules may be applied to MS and MS/MS data from an unknown to identify the substructures likely to be present or absent. A vital part of this system is GENOA, a constrained structure generator originally developed as part of the DENDRAL project.[11] Given substructural constraints and a molecular formula, GENOA generates all structures consistent with the constraints provided. In ACES, molecular formula determination is performed by the MFG (Molecular Formula Generator) program,[12] and substructural constraints are provided by MAPS. Negative information (substructures known to be absent) can also be used by GENOA to constrain the structure generation.

This paper reports several modifications to the MAPS program which have improved the quality and predictive abilities of the rules. In the previous version of MAPS, MS and MS/MS spectral-feature/substructure relationships were used to generate rules for predicting the *presence* of substructures. The MAPS code has been modified to use these relationships to generate rules for predicting the *absence* of substructures as well. As will be shown

here, the criteria for selecting data which aid in predicting the presence of a substructure differ from those for choosing data useful in predicting its absence. Therefore, an *exclusion rule used to predict a substructure's absence* is not the simple complement of the *inclusion rule used to predict its presence*, but is a separate type of rule. Also, intensity data have been incorporated into the rule-generation process by the use of four intensity classes (strong, medium, weak and absent). In this paper, these recent modifications to the MAPS program are described and the effects, on rule performance, of the various parameters associated with rule generation and application are evaluated and discussed. The results have been used to optimize the predictive abilities of both types of rule.

EXPERIMENTAL

The MAPS software is written in InterLISP-D, a version of the LISP programming language, and runs on a Xerox 1108 AI workstation. The compounds, instrumentation, and methodologies used for acquisition and processing of the MS and MS/MS data, and the extent and construction of the training set used in this work, have been described in a previous paper.[9] The training set includes MS and MS/MS data for 76 compounds. These data comprise 2526 spectral features and 67 different recognized substructures.

Rule generation with maps

The rule-generation process, which is described in greater detail elsewhere,[9] is briefly reviewed here. MAPS extracts several types of features from the normal mass spectra and the daughter spectra of known compounds, for use in rule generation. These include the m/z values seen in conventional and daughter spectra, neutral losses derived from daughter spectra, and parent-to-daughter transitions. The availability of unequivocal neutral-loss data from daughter spectra is particularly valuable in rule generation. The list of derived spectral features along with a list of substructures contained in each known compound comprises the training set. Correlation and uniqueness factors, which are described in further detail below, are calculated for each spectral-feature/substructure combination and are used to determine whether or not that feature should be included in the rule for that substructure. Rules are further refined by using the elemental composition of each substructure to define "legal" fragment masses which are then used to remove features which cannot be attributed to that substructure.

The features for use in the inclusion and exclusion rules are selected by applying two different sets of criteria obtained from the feature/substructure correlation process. The correspondence between a given feature f_i and substructure ss_j can be described by correlation and uniqueness factors defined as:

$$\text{Correlation factor } (f_i, ss_j) = \frac{\text{number of occurrences of } f_i \text{ when } ss_j \text{ is present}}{\text{number of occurrences of } ss_j} \times 100\%$$

$$\text{Uniqueness factor } (f_i, ss_j) = \frac{\text{number of occurrences of } f_i \text{ when } ss_j \text{ is present}}{\text{number of occurrences of } f_i} \times 100\%$$

These factors are obtained from training-set statistics. Under similar instrumental conditions, certain spectral features appear whenever a specific substructure is present. The absence of such a feature suggests the absence of the corresponding substructure. Thus, common sense suggests that *each exclusion rule should contain features which have high correlation factors* with respect to that substructure. However, these same features may not be useful for predicting the presence of that substructure if they have moderate to high correlation factors with other substructures as well, since this may lead to false positives. Thus, *each inclusion rule should contain features which have high uniqueness factors* with respect to that substructure. The MAPS code has been modified to exploit these criteria for the generation of both rule types.

One of two filters may be applied to select features for rule generation; a correlation filter or a uniqueness filter. If the correlation filter is used, the user must specify the value of C, which represents the *minimum correlation factor* necessary for a feature to be included in a rule. Likewise, if the uniqueness filter is used, the user must specify the value of U, which represents the *minimum uniqueness factor* necessary for a feature to be included in a rule. A rule is simply a list of clauses obtained from the features having correlation or uniqueness factors which exceed the preset values of C or U for a given substructure. Table 1 shows inclusion rules for the ethyl substructure generated at three different values of C and U. Correlation or uniqueness factors for each clause in the rules are designated by the letters CF or UF, respectively. Fragment formulae are shown in the last column for each rule clause and include multiple neutral losses where appropriate. These formulae are automatically postulated by MAPS, on the basis of the valence rules and the elemental composition of each substructure. Rule length (number of clauses) increases as C or U decreases, because that generally increases the number of features that have the necessary degree of correlation or uniqueness.

The rule-generation process results in a set of rules which characterize each substructure. Ideally, there would be an inclusion and exclusion rule for each substructure that is adequately represented in the training set. The content and performance of rules are seen to depend on the values of C and U used for rule generation.

The previous version of MAPS did not use intensity data from normal spectra or daughter spectra. These intensities are known to depend on a large number of instrumental parameters. In addition, we have observed that for MS/MS data, relative intensity is not as significant as the presence or absence of a particular feature, for identifying the presence and absence of substructures. A compromise between ignoring intensity data and using the common intensity-based matching is to use crude intensity classes. In MAPS, a given intensity I_x which has been normalized to the base peak (100%) is categorized into one of four defined intensity classes according to the ranges shown below.

strong:	$I_x \geq 10\%$
medium:	$1\% \leq I_x < 10\%$
weak:	$I_x < 1\%$
absent:	$I_x <$ detection level threshold

When intensity data are used in the rule generation, the intensity of each feature is assigned to an intensity class and associated with that feature. Intensity data can be used or omitted in the rule-generation process; their effects on rule performance will be demonstrated below.

Evaluation of unknowns by maps

The rules generated by MAPS may be applied to unknowns to obtain an "expert" evaluation of the substructures present and absent. Normal MS spectra and the related daughter spectra of an unknown are entered into an "unknowns database". MAPS extracts from these data the same types of features that were used for rule generation, namely lines present in conventional mass spectra and daughter spectra, neutral losses from daughter spectra, and parent-to-daughter transitions. The rules for each substructure are applied to the set of features derived from the unknown's spectra to identify the substructures which are

present in and absent from the unknown. GENOA may then be invoked to generate all possible structures consistent with a given molecular formula and the substructural constraints identified by MAPS.

Rule performance is affected by the choice of the variable M which specifies the degree of match between the features in a rule and the set of features from an unknown that is necessary for a prediction to be made. In the absence of any special weighting of the clauses, the degree of match is simply the number of features in the unknown in common with the clauses in the rule, divided by the number of clauses in the rule. For exclusion, a substructure is predicted to be absent when the degree of match is *less than or equal to* the specified value of M. For inclusion, a substructure is predicted to be present if the degree of overlap is *greater than or equal to* the specified value of M. Spurious m/z values in the unknown's spectra as a result of contaminants or artifacts may mislead conventional spectral-matching algorithms, but will affect MAPS much less since, in general, they will not correlate with particular substructures.

The predictive abilities of the rules have been assessed by applying them to all 76 training set compounds. The results are tabulated into four categories: correct and incorrect predictions of the presence and absence of substructures. This process is shown in Fig. 2. A rule represents a composite of the features characteristic of a substructure. As the number and variety of training-set compounds containing a given substructure increases, its inclusion and exclusion rules should become more reliable. Individual training-set compounds containing a specified substructure may exhibit any number of the clauses in the corresponding rule and any combination of other substructures. Thus, a useful evaluation of the predictive abilities of the rules can be obtained by applying them to training-set data.

Rule performance can be described by three quantities (recall, false positives and a reliability factor) as shown below.

$$\text{Recall} = \frac{\text{number of correct predictions}}{\text{total number possible}} \times 100\%$$

$$\text{False positives} = \frac{\text{number of incorrect predictions}}{\text{total number possible}} \times 100\%$$

$$\text{Reliability factor} = \frac{\text{number of correct predictions}}{\text{total number of predictions}} \times 100\%$$

These are calculated for rules generated at given values of C or U and applied to the spectra of training-set compounds at a given value of M. A *false positive* resulting from the application of either an inclusion or exclusion rule *guarantees that the set of candidate structures from GENOA will not contain the correct structure*. Therefore, only predictions of the greatest certainty should be transmitted to GENOA for structure generation. Thus, in optimizing rule performance, *the major objective is maintaining an adequate recall while minimizing false positives.*

RESULTS AND DISCUSSION

The effects of a variety of factors were tested with respect to the content of the resulting rules and their effectiveness in application. These factors include feature intensities and the C, U and M variables. Several different weighting schemes which exploit the relative correlation and uniqueness factors of individual rule clauses were developed in an attempt to improve rule performance. These weighting schemes, however, resulted in only a marginal improvement in rule performance at values of C and $U < 100\%$ and have no effect at all at C and U values of 100%. Their use has been abandoned since optimal rule performance is achieved when C and $U = 100\%$, as demonstrated in this section. The effects of intensity data on rule content and the optimization of both rule types is now described.

Effects of intensity data on rule content

When a rule is generated with clauses that include intensity data, it may contain multiple clauses for the same feature, with different intensity classes. This only occurs for neutral losses and daughter ions, since these features may appear in several daughter spectra, with different intensities. For example, the ethyl rule with intensities generated at $C = 50\%$ (shown in Table 1) contains clauses with associated intensity classes of medium and strong for a daughter ion at m/z 29 and neutral losses of 26 and 28 amu.

Correlation and uniqueness factors for features with intensity data are *not* the same as those for equivalent features without intensity data, since the use of intensity data decreases both the number of occurrences of f_i and the number of occurrences of

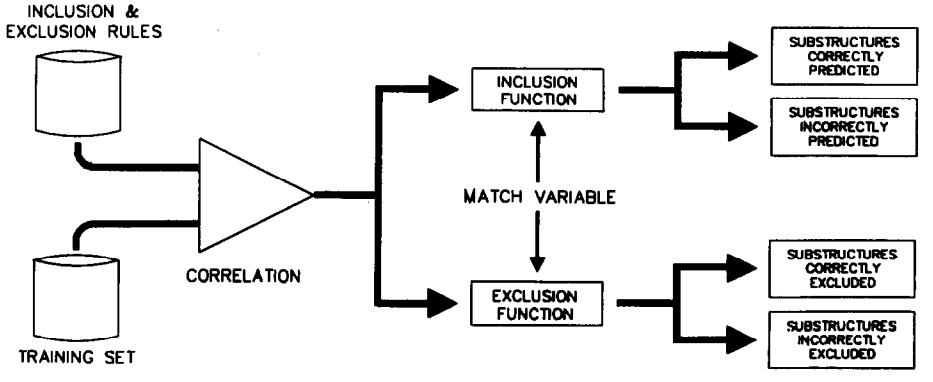

Fig. 2. Schematic of the rule-validation process. Inclusion and exclusion rules are correlated against each compound in the training set and the resulting predictions are categorized as correct or incorrect at various values of M.

Table 1. Inclusion rule for the ethyl substructure generated at three different C and U values

$C = 100\%$	no features correlate	
$C = 75\%$	IF [CF = 93%] strong intensity neutral loss of 28 amu	C_2H_4
	THEN the ETHYL substructure is present	
$C = 50\%$	IF [CF = 59%] medium intensity neutral loss of 2 amu	H_2
	AND [CF = 56%] strong intensity neutral loss of 15 amu	CH_3
	AND [CF = 56%] medium intensity neutral loss of 16 amu	CH_4
	AND [CF = 52%] medium intensity neutral loss of 26 amu	C_2H_2
	AND [CF = 63%] strong intensity neutral loss of 26 amu	C_2H_2
	AND [CF = 74%] medium intensity neutral loss of 28 amu	C_2H_4
	AND [CF = 93%] strong intensity neutral loss of 28 amu	C_2H_4
	AND [CF = 52%] medium intensity daughter ion at m/z 29	C_2H_5
	AND [CF = 55%] strong intensity daughter ion at m/z 29	C_2H_5
	THEN the ETHYL substructure is present	
$U = 100\%$	no features correlate	
$U = 75\%$	IF [UF = 75%] weak intensity neutral loss of 27 amu	C_2H_3
	THEN the ETHYL substructure is present	
$U = 50\%$	IF [UF = 50%] weak intensity neutral loss of 2 amu	H_2
	AND [UF = 67%] medium intensity neutral loss of 4 amu	$H_2 + H_2$
	AND [UF = 54%] strong intensity neutral loss of 16 amu	CH_4
	AND [UF = 53%] weak intensity neutral loss of 27 amu	C_2H_3
	AND [UF = 55%] medium intensity neutral loss of 27 amu	C_2H_3
	AND [UF = 75%] strong intensity neutral loss of 27 amu	C_2H_3
	AND [UF = 53%] strong intensity neutral loss of 29 amu	C_2H_5
	AND [UF = 62%] weak intensity daughter ion at m/z 15	CH_3
	AND [UF = 57%] weak intensity daughter ion at m/z 28	C_2H_4
	AND [UF = 54%] medium intensity daughter ion at m/z 29	C_2H_5
	AND [UF = 54%] strong intensity daughter ion at m/z 29	C_2H_5
	THEN the ETHYL substructure is present	

a given feature f_i when substructure ss_j is present. Thus, intensity data affect rule content.

When intensity classes are associated with a feature, the correlation factor of that feature without intensity data is divided among three equivalent features with intensity classes of strong, medium and weak. Thus, features incorporating intensity data have lower correlation factors. Because of this, rules containing intensities generated at a given C value usually have fewer clauses. This is demonstrated in Table 2, which shows exclusion rules for the ethoxy substructure generated at $C = 100\%$. Note that two clauses in the rule without intensity data, namely parent ions at m/z values of 43 and 45, do not appear in the rule with intensities, since they do not possess the required correlation factors.

Since the compounds which contain a given feature f_i are divided among three equivalent features with intensity classes of strong, medium and weak when intensity classes are associated with that feature, the uniqueness factors for features with intensities may be greater than, less than, or equal to the uniqueness factor of the same feature without intensity data. Usually, at least one of the features with an associated intensity class has a higher uniqueness factor. Thus, at a given value of U, inclusion rules with intensity data will have more clauses than those without intensity data. This is demonstrated in Table 3, which shows inclusion rules for the benzyl substructure generated at $U = 100\%$. Note that several clauses in the rule with intensity data (neutral losses of 75 and 78, line in primary scan at m/z 90, daughter of m/z 29 from m/z 69, and daughter of m/z 51 from m/z 91) do not appear in the rule without intensities, since the corresponding features do not possess the required uniqueness factors.

Exclusion rule optimization

Intensity information is not usually considered for excluding substructures since it is the absence of certain characteristic features which indicates the absence of the corresponding substructure. In an attempt to verify this, exclusion-rule performance was evaluated with and without the use of intensities. In Fig. 3, recall is plotted as a function of the M value when all exclusion rules (generated at $C = 100\%$) are

Table 2. Exclusion rule for the ethoxy substructure generated at $C = 100\%$, (a) with and (b) without intensity data

(a)	IF NO strong intensity neutral loss of 28 amu	CO, C_2H_4
	THEN the ETHOXY substructure is ABSENT	
(b)	IF NO neutral loss of 28 amu	CO, C_2H_4
	OR NO parent ion at m/z 43	C_2H_3O
	OR NO parent ion at m/z 45	C_2H_5O
	THEN the ETHOXY substructure is ABSENT	

Table 3. Inclusion rule for the benzyl substructure generated at $U = 100\%$, (*a*) with and (*b*) without intensity data

(*a*)	IF medium intensity neutral loss of 60 amu	C_5
	OR strong intensity neutral loss of 60 amu	C_5
	OR medium intensity neutral loss of 75 amu	C_6H_3
	OR weak intensity neutral loss of 78 amu	C_6H_6
	OR medium intensity neutral loss of 92 amu	C_7H_8
	OR strong intensity line in primary scan at 90 amu	C_7H_6
	OR strong intensity daughter of *m/z* 29 from *m/z* 69 (40 amu)	C_3H_4
	OR medium intensity daughter of *m/z* 51 from *m/z* 65 (14 amu)	C_2H_2
	OR weak intensity daughter of *m/z* 51 from *m/z* 91 (40 amu)	C_3H_4
	OR strong intensity daughter of *m/z* 91 from *m/z* 93 (2 amu)	H_2
	THEN the BENZYL substructure is PRESENT	
(*b*)	IF neutral loss of 60 amu	C_5
	OR neutral loss of 62 amu	C_5H_2
	OR neutral loss of 92 amu	C_7H_8
	OR daughter of *m/z* 49 from *m/z* 77 (28 amu)	C_2H_4
	OR daughter of *m/z* 51 from *m/z* 65 (14 amu)	C_2H_2
	OR daughter of *m/z* 91 from *m/z* 93 (2 amu)	H_2
	THEN the BENZYL substructure is PRESENT	

applied to the training set with and without intensities. False positives and the reliability factor were not plotted as these were 0% and 100% respectively for all values of M. At $C = 100\%$, exclusion rules for 25 substructures were generated with an average of 7 clauses per rule with intensity data, while exclusion rules for 41 substructures were generated with an average of 14 clauses per rule without intensity data. Thus, *in order to increase the number of rules generated and the number of clauses per rule, intensity data should be neglected in generating exclusion rules.* Recall is substantially improved at large values of M without the use of intensity data, as shown in Fig. 3.

In Fig. 4, recall, false positives, and the reliability factor are plotted as a function of M when exclusion rules (without intensities) generated at three different values of C are applied to the training set. This information is used to determine the optimal values of C and M for exclusion rules. The variable M specifies the *maximum* degree of match necessary between an exclusion rule and an unknown, for an exclusion prediction to be made. As M increases, the number of rule clauses required to be absent from the set of features from an unknown, for an exclusion prediction to be made, decreases, and thus the conditions necessary for an exclusion prediction to be made are relaxed and both recall and false positives increase. At $M = 0\%$, *all* exclusion rule clauses must be *absent* from an unknown's features for a prediction to be made. This will result in very low recall, as some of the clauses in an exclusion rule may be present for an unknown if they are not unique to that substructure. At $M = 100\%$, *all* of the exclusion rule clauses must be *present* in the unknown's features for a prediction to be made. This value of M, however, is useless since it is the *absence* of features which is indicative of the absence of substructures. A value of $M = 99.9\%$ (used in Fig. 4) means that *one or more exclusion rule clause(s) must be absent from an unknown for a prediction to be made.* The use of this value of M for exclusion-rule application maximizes recall.

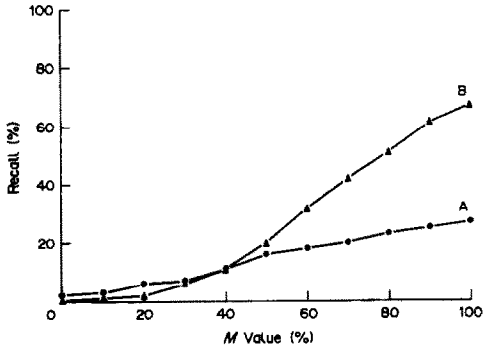

Fig. 3. Recall *vs.* M value for exclusion rules (generated at $C = 100\%$) with (A) and without (B) use of intensity data.

Given a spectral feature which has a high level of correlation with a substructure, its absence from an unknown strongly suggests the absence of that substructure. If another spectral feature has a lower level of correlation with the same substructure it does not always appear whenever that substructure is present in a compound. Hence the absence of such a feature in an unknown is not indicative of the *certain* absence of that substructure, and its use in an exclusion rule may thus lead to a false positive (which in this case is an incorrect prediction of the absence of a substructure). As C decreases, more features are allowed into each exclusion rule, effectively loosening the conditions necessary for an exclusion prediction to be made. Thus, recall and false positives both increase with decreasing c as shown in Fig. 4. Only at $C = 100\%$ are false positives minimized.

When the exclusion rules are generated at $C = 100\%$ and applied to the training set at $M = 99.9\%$, recall is maximized, false positives are minimized, and the reliability factor is optimized, as

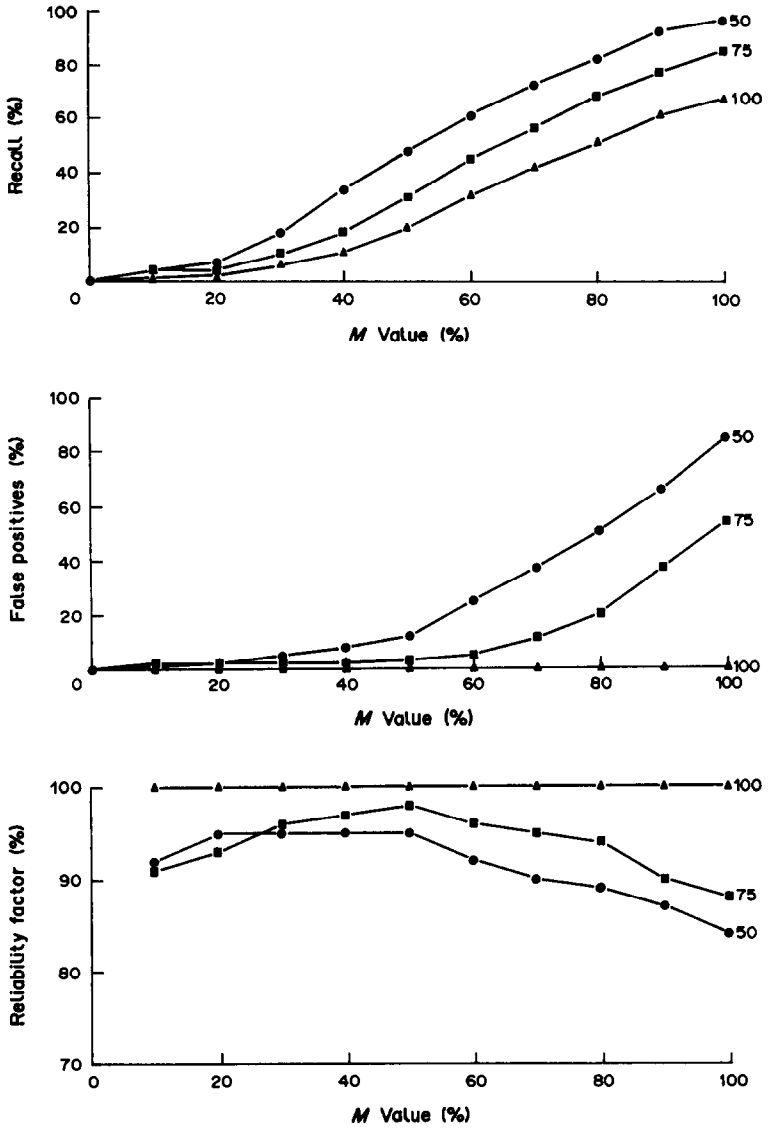

Fig. 4. Recall, false positives, and reliability factors *vs.* M value for exclusion rules generated at $C = 100\%$, 75% and 50%.

shown in Fig. 4. Since these rules contain only those clauses with features that correlate perfectly with each substructure, the degree of match between a given rule and each compound in the training set that contains the substructure will always be 100%. Since only those cases with $M < 100\%$ will lead to an exclusion prediction, no false positives will occur when the exclusion rules are applied against the training set. When values of $C = 100\%$ and $M = 99.9\%$ are used, exclusion rules logically operate in the following manner:

IF NO (spectral feature a)
OR NO (spectral feature b)
...
...
THEN the X substructure is ABSENT

False positives are possible when exclusion rules generated at $C = 100\%$ are applied to true unknowns. For example, the exclusion rule for the phthalate ester substructure contains "line in daughter scan at m/z 149" as a clause. However, diphenyl 1,2-benzenedicarboxylate (diphenyl phthalate) does not produce this feature, most likely because of steric hindrance in fragmentation of the molecule to form this daughter ion. When the phthalate ester exclusion rule is applied to this compound at $M > 94\%$ (given that this rule contains 15 clauses), a false positive results. This problem underlines the importance of accurately characterizing each substructure in the training set, *i.e.*, ensuring that each substructure in the training set is represented in a sufficient variety of molecular environments.

Exclusion predictions were not possible with the previous version of MAPS. These predictions are often valuable in eliminating candidate structures for an unknown and are thus useful for molecular structure elucidation. Exclusion rules for 25 substructures were obtained by using optimal criteria for exclusion-rule generation and application. These rules have overall recall = 67% and false positives = 0% when applied to the 76 training-set compounds.

Inclusion rule optimization

Adding intensity data to the inclusion rules increases their information content, results in features with higher uniqueness factors, and thus is expected to improve their predictive abilities. In Fig. 5, recall is plotted as a function of M when the inclusion rules (generated at $U = 100\%$) are applied to the training set with and without intensities. False positives and the reliability factor are not plotted, as these were 0% and 100% respectively for all values of M. At $U = 100\%$, inclusion rules for 18 substructures were generated with an average of 6 clauses per rule without intensity data, and inclusion rules for 22 substructures were generated with an average of 9 clauses per rule with intensity data. Thus, *in order to increase the number of rules generated and the number of clauses per rule, intensity data are helpful in generating inclusion rules.* Somewhat higher recall values are achieved with the use of intensity data, as shown in Fig. 5. The fact that a more substantial improvement in rule performance is not seen when intensity data are used in inclusion-rule generation supports our original hypothesis that for structural interpretation the presence or absence of a feature is far more significant than its relative intensity.

In Fig. 6, recall, false positives, and the reliability factor are plotted as a function of M when inclusion rules (with intensities) generated at three different values of U are applied to the training set. This information is used to determine the optimal values of U and M for inclusion rules. The value of M specifies the *minimum* degree of match necessary between an inclusion rule and an unknown for an inclusion prediction to be made. As M decreases, the number of rule clauses required to be present in an unknown's features for an inclusion prediction to be made, decreases, and thus the conditions necessary for an inclusion prediction to be made are relaxed and both recall and false positives increase. At $M = 100\%$, *all* inclusion rule clauses must be *present* in an unknown's feature list for a prediction to be made. This will result in low recall, as these features may not always be exhibited whenever that substructure is present in an unknown, since they are selected for their high uniqueness rather than for high correlation factors. A value of $M = 0\%$ is nonsensical, since this results in a prediction only when an unknown does not possess *any* inclusion rule's features. At $M = 0.1\%$ (used in Fig. 6), *at least one inclusion rule clause must be present in an unknown's feature list for a prediction to be made.* Thus, the use of a value of $M = 0.1\%$ for inclusion-rule application maximizes recall.

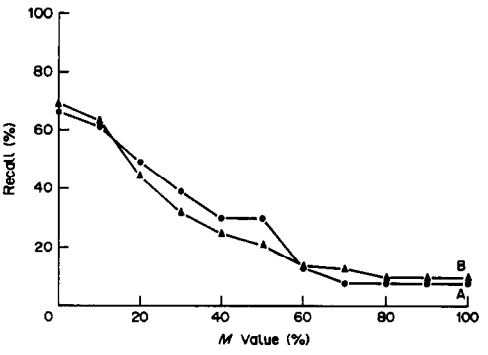

Fig. 5. Recall *vs.* M value for inclusion rules (generated at $U = 100\%$) with (A) and without (B) use of intensities.

If a spectral feature that is unique to a substructure is present in an unknown, the presence of that substructure is strongly indicated. A spectral feature which is not unique to that same substructure (and thus has some correlation with other substructures) cannot be used as conclusive evidence of the presence of that substructure in unknowns, since it may lead to incorrect predictions (false positives). As U decreases, more features are allowed into each inclusion rule, effectively loosening the conditions necessary for an inclusion prediction to be made. Thus, recall and false positives both increase with decreasing U, as shown in Fig. 6. Only at $U = 100\%$ are false positives minimized.

When the inclusion rules are generated at $U = 100\%$ and applied to the training set at $M = 0.1\%$, recall is maximized, false positives are minimized, and the reliability factor is optimized, as shown in Fig. 6. Since these rules contain only clauses that are unique to each substructure, the degree of match between a given rule and any training-set compound which does not contain the substructure will always be 0%. Since only those cases with $M > 0\%$ will lead to an inclusion prediction, no false positives will occur when the inclusion rules are applied against the training set. When values of $U = 100\%$ and $M = 0.1\%$ are used, inclusion rules logically operate in the following manner:

IF (spectral feature a)
OR (spectral feature b)
...
...
THEN the X substructure is PRESENT

False positives can occur when inclusion rules generated at $U = 100\%$ are applied to true unknowns. Features which had appeared unique to each substructure based on the training set may also be produced by the presence of other substructures in unknowns. For example, the inclusion rule for the

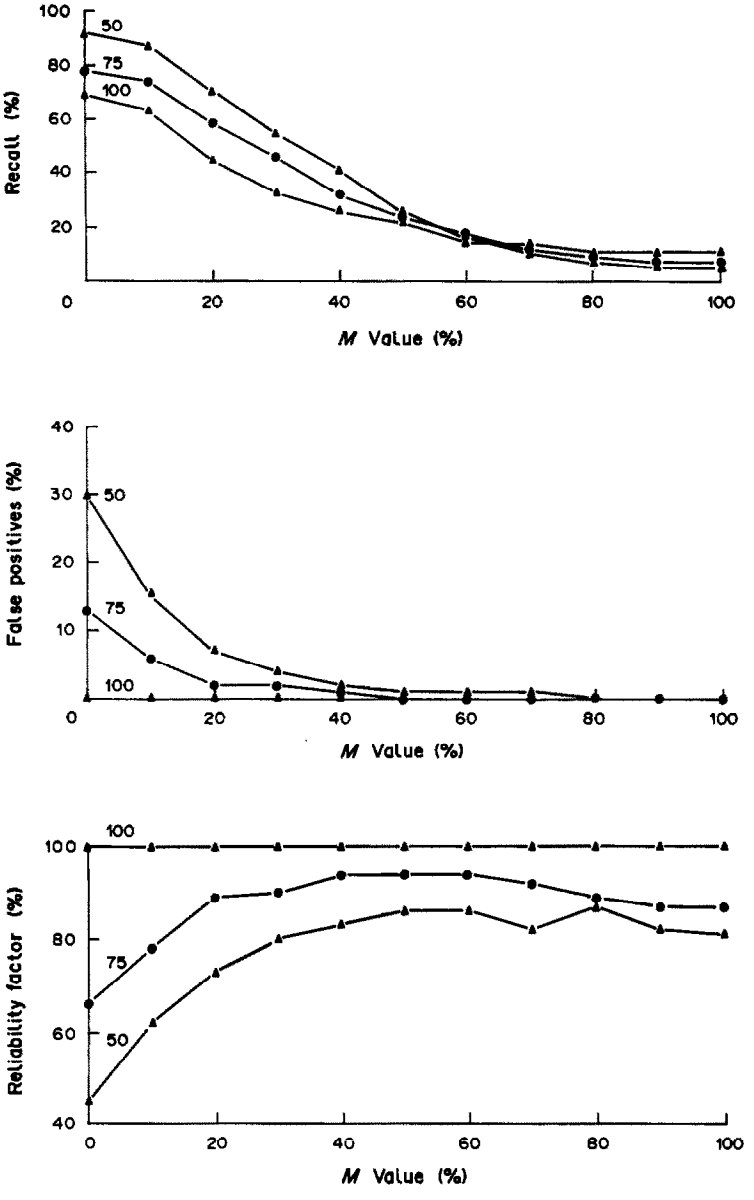

Fig. 6. Recall, false positives, and reliability factor *vs.* M value for inclusion rules generated at $U = 100\%$, 75% and 50%.

bromo substructure contains a clause which represents a medium intensity neutral loss of 82 amu, attributed to a loss of $H^{81}Br$. However, 1,3-benzenedicarboxylic acid di-allyl ester also produces this feature, which can then most likely be attributed to a loss of $C_4H_2O_2$. When the bromo inclusion rule is applied to this compound at $M < 33\%$ (given that there are three clauses in this rule), a false positive results. This problem again underlines the importance of accurately characterizing each substructure in the training set.

Inclusion rules for 22 substructures were obtained by using optimal criteria for inclusion-rule generation and application. These rules have an overall recall = 69% and false positives = 0% when applied to the 76 training-set compounds. With the previous version of MAPS, reliable inclusion rules for only 13 substructures were obtained, with an overall recall of only 12% and false positives = 0.2% when applied to the training set. The use of intensity data and optimal values of U and M has greatly improved the predictive abilities of the inclusion rules. In the previous version of MAPS, low-performance rules were identified by monitoring their predictive abilities when applied to the training set. This poor performance resulted from a lack of unique features in the inclusion rules for certain substructures. Since inclusion rules are now generated by using a unique-

ness filter rather than a correlation filter, no rules are obtained for those substructures with rules which were formerly unreliable.

CONCLUSIONS

The approach described here for identifying the presence and absence of substructures has identified the criteria for optimal inclusion- and exclusion-rule performance. Exclusion-rule predictions are now possible and are characterized by 67% recall and 0% false positives when applied to the training set. Performance figures for inclusion rules have been significantly improved and yield 69% recall and 0% false positives when applied to the training set. This new approach, however, now presents some new performance trade-offs. Recall can be improved by using lower values of C or U in the rule generation, but this produces a concomitant increase in false positives. In addition, use of the optimal values of M for inclusion and exclusion rules may sometimes lead to predictions based on the presence or absence of only one feature; this may lead to false positives when the rules are applied to unknowns. False positives can be reduced by using higher (for inclusion rules) or lower (for exclusion rules) values of M, but this results in a corresponding decrease in recall. Further work on the expansion of the training set will reveal the full extent of the new trade-off factors.

SOLID STATE CHEMICAL IONIZATION FOR CHARACTERIZATION OF ORGANIC COMPOUNDS BY LASER MASS SPECTROMETRY

KESAGAPILLAI BALASANMUGAM, SOMAYAJULA KASI VISWANADHAM and DAVID M. HERCULES
Department of Chemistry, University of Pittsburgh, Pittsburgh, PA 15260, U.S.A.

(*Received* 25 *July* 1988. *Accepted* 19 *August* 1988)

Summary—A new technique involving the addition of a compound to the analyte to serve as a source of "reagent" ions has been developed for negative-ion laser mass spectrometry. This "solid state chemical ionization" leads to ions characteristic of the analyte, owing to ion–molecule reactions between the "reagent" ion and the neutral analyte in the laser-generated plume. Polycyclic aromatic hydrocarbons show formation of an ion corresponding to $(M + O - H)^-$ in their negative-ion laser mass spectra when mixed with compounds such as *sym*-trinitrobenzene, sodium nitrate and sodium peroxide. NO_2^-, O^-, and O_2^- serve as "reagent" ions in these compounds. Formation of $(M + Cl)^-$ is seen in the laser mass spectra of glycosides mixed with hexachlorobenzene. Chloride serves as the "reagent" ion in this case.

Recent developments in the ionization of involatile and thermally labile compounds directly from the solid state has made it possible to characterize these compounds by mass spectrometry. These "soft ionization" techniques include field desorption,[1] laser ionization,[2–4] plasma desorption,[5] fast atom bombardment (FAB)[6,7] and secondary-ion mass spectrometry (SIMS).[8] It has been demonstrated[9–11] that the mass spectra obtained by using these ionization processes are comparable, and a common mechanism for ion formation has been proposed.[12–15]

The mass spectra obtained by using solid state ionization methods are characterized by ions due to proton attachment $(M + H)^+$ and cation attachment $(M + \text{metal})^+$ which aid in the determination of molecular mass number weight.[16,17] These desorption ionization techniques are ideally suited for the analysis of preformed ionic compounds; precharged species only need be desorbed from the surface. The fast atom bombardment technique requires that the compound analyzed be "surface active".[18]

In order to enhance the sensitivity of detection of various compounds by means of desorption processes, techniques have been developed to take advantage of the observations made about these ionization processes. The sample support, for example, has been treated with acid to provide protons for $(M + H)^+$ formation.[19] Addition of proton sources and alkali-metal halides has become a common method of sample preparation for enhanced formation of $(M + H)^+$ and $(M + \text{metal})^+$ ions in positive-ion spectra,[20–25] and bases are added for the formation of $(M - H)^-$ in the negative-ion spectra.[26]

Neutral samples have been derivatized *in situ* to form precharged species to increase specificity.[26–30] The derivative prepared is chosen to have a greater surface activity for FAB analysis.[31] Dilution of analyte with ammonium chloride has been shown to be effective in enhancing the signals due to intact analyte and decreasing the fragmentation in SIMS.[32] Matrix compounds having strong resonant absorption at the wavelength of the laser (266 nm) used for ionization enhance the ionization yield of the substrate, by energy transfer.[33]

All these variations in sample preparation for application of desorption processes have been developed to modify the analyte either chemically or physically to facilitate the ensuing characterization by soft ionization processes. These modifications enhance the sensitivity and selectivity of these methods.

The present study involves the use of matrix compounds that serve as a source of "reagent ions" for subsequent reaction with neutral substrates as a part of the analytical process in negative-ion laser mass spectrometry. Understanding the ion–molecule reactions which occur during the analysis of mixtures should aid in the application of laser microprobe techniques to complicated tissue-like matrices. The study is further aimed at developing selective "reagent ions" for the identification of different classes of compounds. The work is an outgrowth from an ion–molecule reaction observed[34,35] in the negative-ion laser mass spectra of aromatic nitro compounds, leading to $(M + O - H)^-$ ion formation. When polycyclic aromatic hydrocarbons (PAHs) are mixed with nitro compounds, an ion corresponding to $(M + O - H)^-$ is produced from the PAHs on laser irradiation; otherwise only carbon cluster ions appear in the negative-ion laser mass spectra.

EXPERIMENTAL

All laser mass spectra (LMS) were obtained with a commercially available laser microprobe mass analyzer, the LAMMA-500, which has been described in detail else-

where.[36] The output of a frequency-quadrupled and *Q*-switched Nd–YAG laser (265 nm, 15 nsec pulse width) was focused onto the sample by a 32× microscope objective. The spot diameter of the laser beam was approximately 3 μm. The power density of the laser was 10^7–10^8 W/cm^2. Ions produced by laser irradiation were extracted at 180° to the incident beam (transmission mode) and were accelerated (3 kV) into the drift tube of a time-of-flight mass spectrometer. After amplification by a 17-stage Cu–Be secondary electron multiplier, the signals were converted from analog to digital (Biomation 8100 ADC) with a minimum sample interval of 10 nsec. The digital signals were stored in a fast multichannel analyzer having 2048 channels. Data were ultimately processed in an HP 1000E series computer.

All polycyclic aromatic hydrocarbons and other chemicals were purchased from Chem. Service, West Chester, PA, and used without further purification. The samples that involved mixing 1,3,5-trinitrobenzene with PAHs, and glycosides with hexachlorobenzene, were prepared by making 1% w/w solution of both substances in toluene and evaporating a few drops of the mixed solution on a Formvar-filmed copper grid. The samples involving inorganic salts (sodium nitrate or peroxide) were prepared by evaporating a 1% solution of the salts in 1:1 v/v methanol–water on top of the PAH, which had already been deposited on the Formvar-coated copper grid from toluene solution.

The Formvar-coated copper grids used in these experiments were sufficiently thin to give no significant contribution to the spectra; only weak peaks in the region below *m/z* 100 were seen.

RESULTS AND DISCUSSION

Negative-ion laser mass spectra (LMS) of nitro aromatic compounds showed formation of ions at *m/z* corresponding to $(M + O - H)^-$ (M = molecular mass number weight of the compound). Double resonance experiments and kinetic studies using Fourier transform mass spectrometry have established[35] that these ions are formed by an ion–molecule reaction between NO_2^- ions and the neutral nitro aromatic compound in the laser plasma. Such ion–molecule reactions could easily occur in the high-pressure region adjacent to the site of impact of the laser beam.[2] This region is best thought of as a rapidly expanding gas, going from near liquid to near vacuum in a few μm. The ion–molecule reaction involving NO_2^- ions can be depicted as shown below, with initial formation of an intermediate, which then loses HNO, leading to $(M + O - H)^-$, *i.e.*, the phenate derived from the substrate.

$$ArH + NO_2^- \rightarrow \left[\begin{array}{c} NO_2^- \\ Ar \\ H \end{array}\right]^- \rightarrow ArO^- + HNO \quad (1)$$

Figure 1 shows the negative-ion LMS of 1,3,5-trinitrobenzene as an example. The peak at *m/z* 228 corresponds to $(M + O - H)^-$. Other ions observed include $(M - NO)^-$, C_7N^- (98), C_5N^- (74), C_3N^- (50), NO_2^- (46), CNO^- (42) and CN^- (26).

Such an ion–molecule reaction has been observed for various nitro aromatic compounds.[35] Such reactions open up the possibility of a new kind of chemical ionization for solid state mass spectrometry. Chemical ionization in the gas phase involves initial formation of reagent ions which subsequently react with the substrate, leading to characteristic analyte ions, often providing the molecular weight of the compound. In solid state mass spectrometry, an analyte can be mixed with an appropriate compound which will serve as a source of "reagent ions", and the

triphenylene	coronene
benzo(*a*)pyrene	decacyclene

mass spectrum of such a mixture can be obtained. Such studies could be quite useful if the reagent ion induces characteristic peaks from ion–molecule reactions for compounds that do not otherwise give informative spectra. The technique is distinctly different from other processes, such as cationization, in that a fragment ion from the added "reagent" interacts with the substrate. The usefulness of "solid state chemical ionization" involving NO_2^- ions and PAHs in characterizing the latter compounds by negative-ion laser mass spectrometry is the focus of the present study.

PAHs show peaks for $M^{+\cdot}$ in their positive-ion laser mass spectra.[37] However, their molecular anions can be seen only in negative-ion spectra taken by using the LAMMA-1000 (reflection mode), while spectra taken with the LAMMA-500 (transmission mode) do not yield any ion characteristic of the PAHs; instead they show ions corresponding to carbon clusters C_n^- and C_nH^-.[37,38] The intensities of these clusters decrease with increasing mass, in a pattern comparable to that observed for graphite.[39] The negative-ion LMS of twenty PAHs given in Table 1 were by obtained using the LAMMA-500, and all show only carbon cluster ions and give no structural information.

In an attempt to produce diagnostic ions, the negative-ion LMS of PAHs were obtained from PAH mixtures with an equal amount of 1,3,5-trinitrobenzene (TNB), the latter serving as a source of NO_2^- ions. The negative-ion LMS of decacyclene mixed with TNB is shown in Fig. 2a. The peak at m/z 465 corresponds to $(M + O - H)^-$. The base peak at m/z 183 corresponds to $(M - NO)^-$ from TNB. The peaks at m/z 213 and 228 are for $M^{-\cdot}$ and $(M + O - H)^-$ of TNB. Except for m/z 46 (NO_2^-) and m/z 26 (CN^-), all other ions observed in the lower mass range ($m/z < 160$) are carbon cluster ions.

Figures 2b and 2c show the negative-ion LMS of 1,12-benzoperylene and 1,2,5,6-dibenzanthracene mixed with TNB, showing $(M + O - H)^-$ at m/z 291 and 293, respectively. Formation of $(M + O - H)^-$ was observed for all PAHs studied. The intensity of the $(M + O - H)^-$ peak varied from shot to shot for the same compound. This variation is attributed partly to differences in the concentrations of TNB and PAH in the microscopically small region analyzed by the laser (3 μm diameter) and to differences inherent in the technique.[40] The intensity of the $(M + O - H)^-$ peak for various PAHs varied from 5 to 25% of that of the base peak. It is interesting that the intensity of the $(M + O - H)^-$ peak for PAHs is either comparable to or higher than that for the corresponding TNB peak in the spectra of mixtures. Even though the nucleophilic reaction is favored for TNB, the greater number of reactive sites in PAHs could explain the observed intensities.

Other sources of NO_2^- reagent ions for solid state chemical ionization have been considered in attempts to enhance the signal due to ion–molecule reactions. The LMS of sodium nitrate show the peak due to NO_2^- as the base peak. Further, the laser mass spectrum of sodium nitrate is fairly simple (Fig. 3), thus not leading to interfering ions in the spectra of mixtures. Other ions present, in addition to NO_2^-, include O^-, O_2^-, NO_3^-, $NaNO_3^-$, $(NaNO_3 + O)^-$ (m/z 101), $Na(NO_2)_2^-$ at m/z 115, and $[Na(NO_2)(NO_3)]^-$ at m/z 131.

Sodium nitrate was used as a source of NO_2^- for the analysis of PAHs. Figure 4a shows the negative ion LMS of benzo(*a*)pyrene mixed with sodium nitrate; the peak at m/z 267 corresponds to $(M + O - H)^-$ and is the base peak in the spectrum. Other ions seen include $Na(NO_2)_2^-$ (m/z 115), C_6^- and C_6H^-. Figures 4b and 4c show the negative ion spectra of 1,2,3,4-dibenzanthracene and 1,12-benzoperylene mixed with sodium nitrate as additional examples. The intensity of the $(M + O - H)^-$ peak varied between 15 and 100% of that of the base peak for the PAHs studied; variations from shot to shot for the same compound were seen, for the reasons already discussed. The relative intensity of the $(M + O - H)^-$ peak is higher when sodium nitrate is used as "reagent" then when TNB is used, for all PAHs studied. The difference is ascribed to the fact that sodium nitrate provides more NO_2^- reagent ions. Further, laser irradiation of sodium nitrate also leads

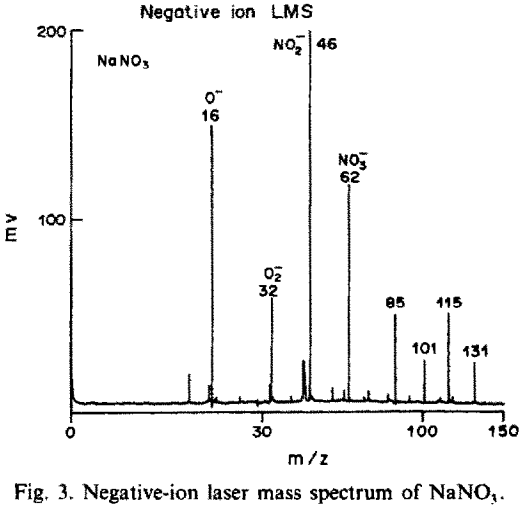

Fig. 3. Negative-ion laser mass spectrum of $NaNO_3$.

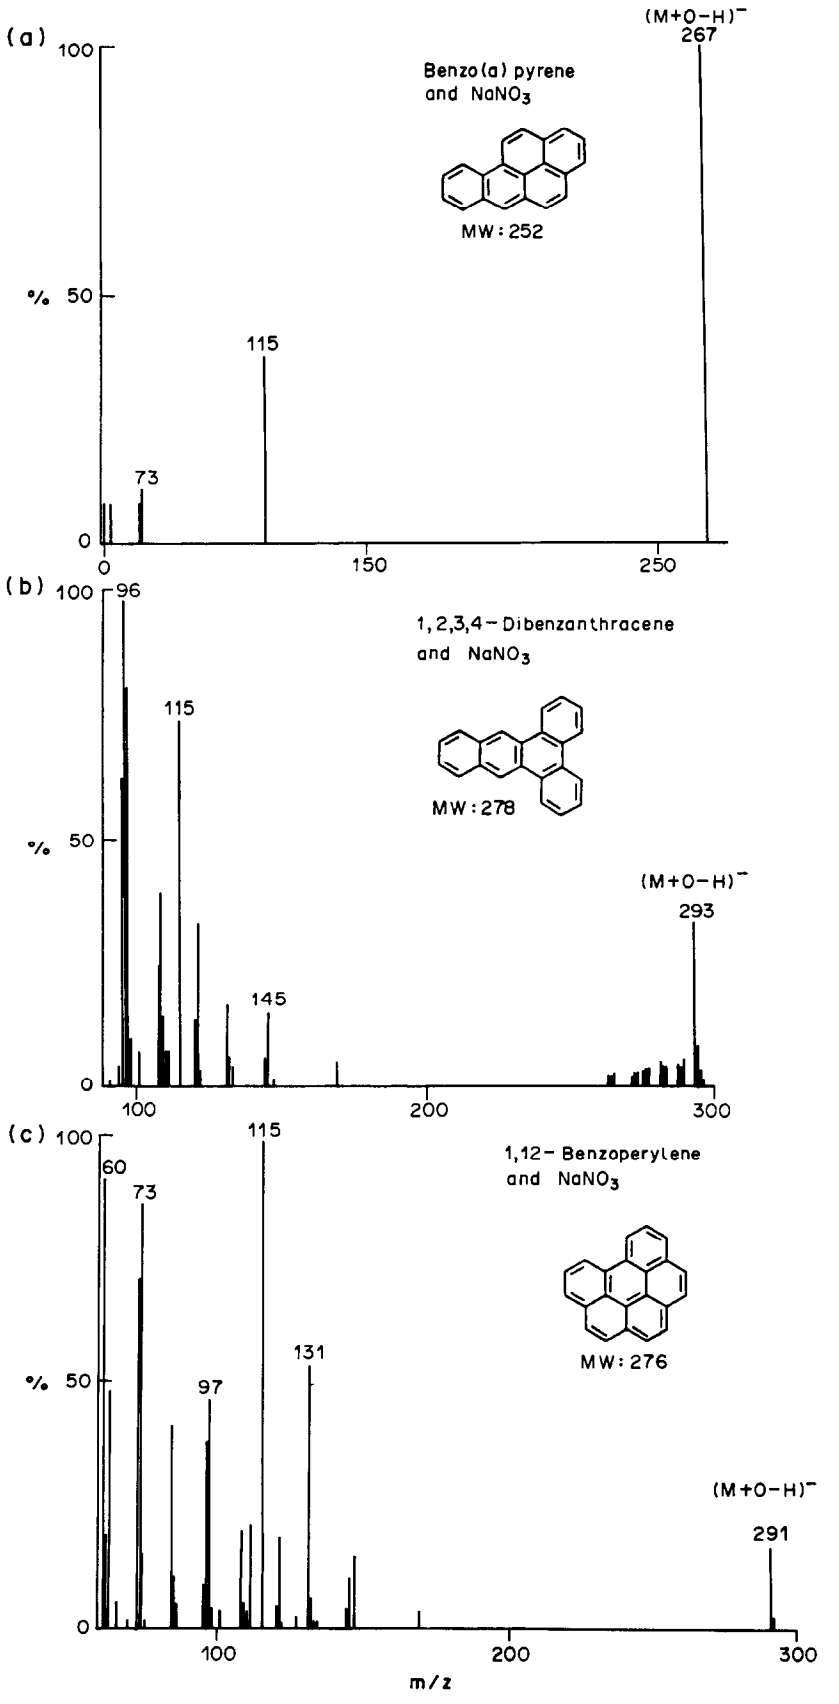

Fig. 4. Negative-ion LMS of (a) benzo(*a*)pyrene, (b) 1,2,3,4-dibenzanthracene, (c) 1,12-benzoperylene, mixed with sodium nitrate.

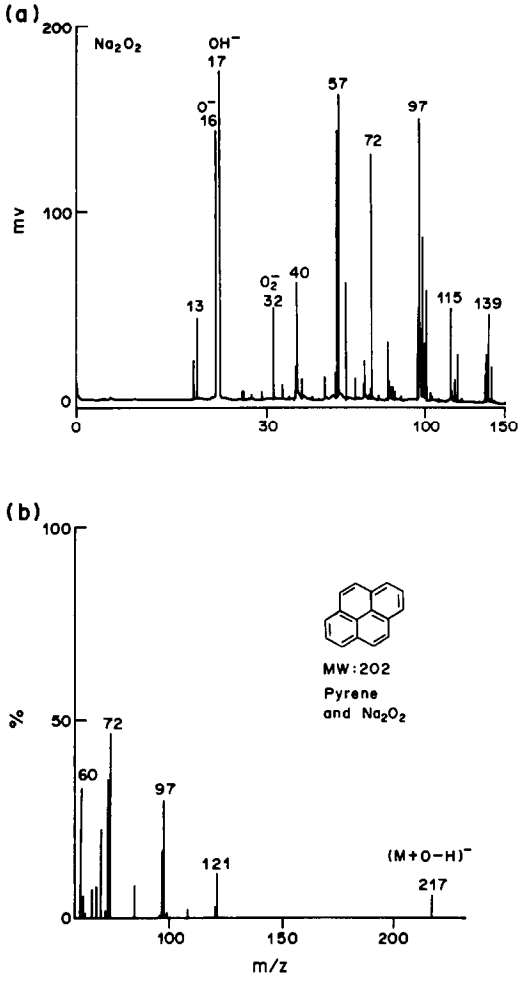

Fig. 5. Negative-ion LMS of (a) Na_2O_2, (b) pyrene mixed with Na_2O_2.

to O^- and O_2^- ions, which could enhance the formation of $(M+O-H)^-$ by reactions (2) and (3), shown below. Ion–molecule reactions involving these nucleophiles are known in the gas phase.[41,42]

$$ArH + O^{-\cdot} \rightarrow \left[\begin{array}{c} O \\ Ar \\ H \end{array}\right]^- \rightarrow ArO^- + H^{\cdot} \quad (2)$$

$$ArH + O_2^- \rightarrow \left[\begin{array}{c} O_2 \\ Ar \\ H \end{array}\right]^- \rightarrow ArO^- + HO^{\cdot} \quad (3)$$

Formation of $(M+O-H)^-$ by the reaction of ions other than NO_2^-, possibly by reactions (2) and (3), was suggested by the following observation. The negative-ion laser mass spectrum of sodium peroxide shows peaks due to O^- and O_2^- but not NO_2^-, as seen in Fig. 5a. The negative-ion laser mass spectrum of pyrene mixed with sodium peroxide (Fig. 5b) shows an ion due to $(M+O-H)^-$. This ion is most likely formed by the reaction of O^- and/or O_2^-. Thus, in the case of sodium nitrate, three possible reactions could contribute to the formation of $(M+O-H)^-$ since the negative-ion laser mass spectrum shows all three ions. Thus, sodium nitrate is the reagent of choice for the analysis of PAHs by phenate formation in their negative-ion LMS.

Chloride ions (Cl^-) generated by laser irradiation of hexachlorobenzene have served as reagent ions in the characterization of glycosides by negative-ion laser mass spectrometry. The negative-ion laser mass spectrum of phenyl-β-glucopyranoside mixed with hexachlorobenzene is shown in Fig. 6a. An ion at m/z 291 corresponding to $(M+Cl)^-$ is observed. The ion at m/z 93 corresponds to the phenate ion. Except for the Cl^- ion, all other ions observed in the lower mass range are due to carbon cluster ions (C_n^-). The negative-ion laser mass-spectrum of helicin mixed with hexachlorobenzene also shows an ion at m/z 319

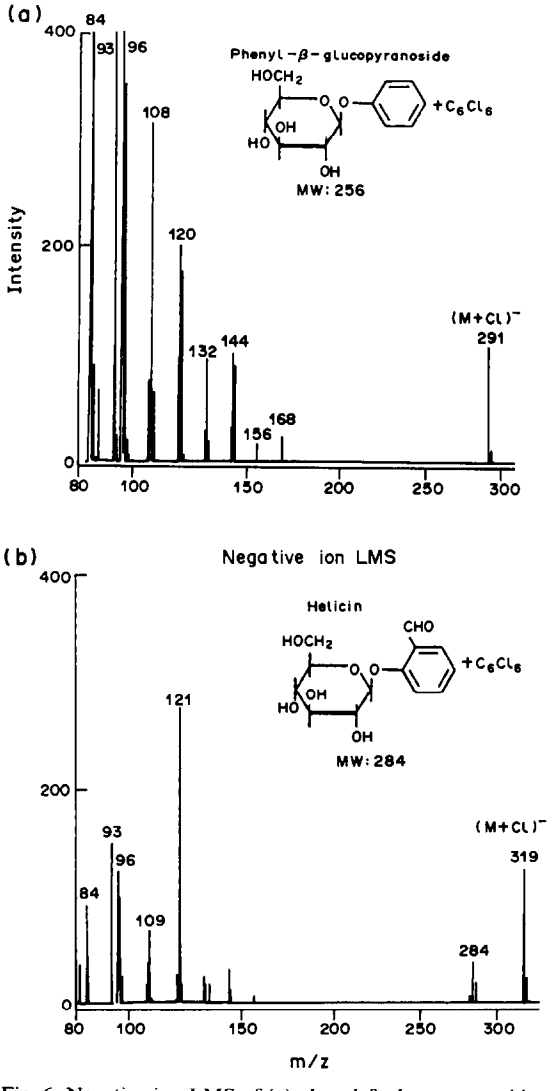

Fig. 6. Negative-ion LMS of (a) phenyl-β-glucopyranoside, (b) helicin, mixed with hexachlorobenzene.

due to the attachment of a Cl^- ion, as shown in Fig. 6b. These results demonstrate that anionization by chloride attachment can be used for the characterization of glycosides.

Solid state chemical ionization should be a useful technique for the analysis of mixtures. Figure 7 shows the negative-ion laser mass spectrum of a mixture of benz(*a*)anthracene, benzo(*a*)pyrene and 1,2,3,4-dibenzanthracene (1:1:1) with sodium nitrate. The PAHs in the mixture show ions corresponding to $(M + O - H)^-$ at m/z 243, 267 and 293, respectively.

CONCLUSIONS

It has been shown that the addition of compounds such as sodium nitrate, sodium peroxide and 1,3,5-trinitrobenzene to PAHs leads to the formation of $(M + O - H)^-$ ions in the negative-ion laser mass spectrum. It has been shown further that sodium nitrate is a superior solid state chemical ionization reagent for PAHs, leading to intense peaks for ions due to ion–molecule reactions. Addition of hexachlorobenzene to glycosides leads to the formation of the $(M + Cl)^-$ ion for these compounds.

This type of reaction opens up the possibility of developing specific and selective analysis of a given class of compounds in a matrix by using laser mass spectrometry.

DIFFERENTIAL-POLARIZATION DUAL-BEAM FT-IR SPECTROMETER FOR SURFACE ANALYSIS

HELMUTH HOFFMANN, NORMAN A. WRIGHT, FRANCISCO ZAERA and PETER R. GRIFFITHS
Department of Chemistry, University of California, Riverside, Riverside, CA 92521, U.S.A.

(*Received* 11 *May* 1988. *Accepted* 12 *July* 1988)

Summary—A new system for reflection–absorption Fourier transform infrared spectroscopy is described. It is based on an optical subtraction of the two output beams of a cube-corner interferometer, which are recombined, orthogonally polarized and passed onto a single detector, where only the difference signal of the two components is detected. The dynamic range of the signal is thereby reduced by at least an order of magnitude. Owing to the cube-corner reflectors the dual-beam optics are relatively simple and readily convertible for operation in the conventional single-beam mode. First results with an incompletely optimized system show high photometric accuracy and equal signal-to-noise ratio compared to the single-beam operation. Methods for further improving its performance are proposed.

Reflection–absorption infrared spectroscopy (RAIRS) is a technique widely used for the study of a variety of samples (*e.g.*, Langmuir–Blodgett films, polymers, lubricants, gaseous reactants on catalyst surfaces) on reflecting substrates. In recent years RAIRS has also become increasingly popular as a surface-science technique incorporated in an ultra-high vacuum (UHV) system, owing to its potential for studying catalytic processes under real reaction conditions (high pressure). Most of these studies have investigated the adsorption of CO on various metals, and detection limits below 1% of a monolayer have been reported.[1–4] In catalytically more relevant systems, that involve hydrocarbon fragments, however, the identification of weakly absorbing reaction intermediates by IR spectroscopy still demands a significant improvement in sensitivity.

With the conventional single-beam technique, in which a spectrum of the adsorbate-covered substrate is ratioed against a spectrum of the clean substrate, the signal-to-noise ratio can be optimized by (*a*) choosing an incident angle for the incoming light that is close to grazing (the optimum angle can be calculated from the optical constants of the substrate and is 88° for most metals[5]) and (*b*) minimizing the throughput loss by matching the beam image at the sample position to the sample size. The two conditions cannot both be completely fulfilled at the same time, since a uniform incident angle would require a perfectly collimated beam, while a spot size equal to the typical size of a single crystal (≈ 1 cm^2) requires a highly focused beam with a concomitant wide range of incident angles. A compromise has therefore to be found in choosing reflection optics with relatively high *f*-numbers. Reported noise levels of about 0.1% in a single-scan reflection–absorption spectrum at 2 cm^{-1} resolution with a sample of about 1 cm^2 surface area[6] have shown that even with throughputs of only a few per cent, digitization noise ultimately limits the signal-to-noise ratio of this technique.

Several ways of circumventing the limitations imposed by the currently available analog-to-digital (A/D) converters have been proposed, most of which are aimed at suppressing the center-burst of the nonabsorbed light and detecting only a signal equal to the small fraction of light absorbed by the sample. One approach classified as optical subtraction or dual-beam spectrometry is based on the detection of a difference signal from the two output beams of an interferometer which are 180° out of phase. The two beams may be passed onto a single detector, where an optical null occurs, or they may be individually detected at two detectors and electronically summed prior to digitization. The first dual-beam FT-IR systems were primarily designed for FT-IR measurements of gas-chromatographically separated materials;[7–11] to date only one system has been described for reflection–absorption spectrometry.[12] The requirement of having two optically identical beams has resulted in rather complex designs dedicated to one specific application. The optical alignment of all dual-beam FT-IR systems described so far is quite difficult.

An alternative method of reducing the dynamic range of the signal is polarization-modulation FT-IR spectroscopy, which was first applied to surface analysis in combination with reflection–absorption spectroscopy by Dowrey and Marcott.[13] It is based on the phase-sensitive detection of the difference signal of s- and p-polarized light modulated by a photoelastic modulator (PEM) at high frequencies (≈ 70 kHz). This technique has been shown to eliminate noise due to background gas adsorptions, but the overall gain in signal-to-noise ratio over the conventional single-beam technique was lower than initially expected, owing to considerable throughput losses at the PEM-

crystal and the increase in noise as a result of imperfect polarization (as a PEM can be tuned to a half-wave retardation for only one particular wavelength).

Another method of polarization-modulation, based on a polarizing Michelson interferometer, first developed by Martin and Puplett for the far-infrared region,[14] has been applied recently by use of a modified mid-IR FT spectrometer.[15] A polarizing beam-splitter separates the incoming light into two orthogonally polarized components of equal intensity, which after recombination form a beam modulated in its polarization state rather than the intensity, by scanning the interferometer mirror. This instrument can be adapted for several spectroscopic techniques where polarized radiation is needed (*e.g.*, ellipsometry, reflection–absorption spectroscopy, vibrational circular dichroism). The conversion into an intensity-modulated output beam, however, requires a special polarizing beam-splitter and two additional linear polarizers. The low throughput of this system makes it uncompetitive with a standard FR-IR spectrometer for conventional spectroscopic techniques.

The system described in this paper is a dual-beam system, in which the two modulated output beams of a commercial cube-corner interferometer are recombined and orthogonally polarized by a beam-combining polarizer. The recombined beam is focused on the sample surface and refocused onto a single detector. Because of the 180° phase shift between the two original components, only the difference signal is measured.

EXPERIMENTAL

Optics

The optical layout of the dual-beam reflection–absorption system is shown in Fig. 1. It required only minor modifications to a commercial FT-IR spectrometer (Mattson Sirius 100). The interferometer of this particular instrument is equipped with cube-corner retro-reflectors, which allow both modulated output beams of the interferometer to be used, whereas in the conventional mode of operation of an FT-IR spectrometer the reflected beam usually returns to the source and is not detected. In our system this beam is reflected by a plane pick-up mirror and passes through a wire grid polarizer, which is at 45° to the beam. Ideally this polarizer splits the beam into two equal halves, one of which is transmitted and p-polarized owing to the vertical orientation of the wires, while the other is reflected through 90° and s-polarized. The notation p- and s-polarized refers to the plane of incidence at the sample surface. The polarizer transmits radiation from the reflected beam of the interferometer and reflects radiation from the transmitted beam in the direction of the detector. The recombined beams are passed to a 60° off-axis paraboloidal mirror with an effective focal length of 25 cm, which focuses the light at an incident angle of $80 \pm 3°$ onto the metal substrate inside a vacuum chamber. After reflection from the substrate, the beam is recollimated by a second paraboloidal mirror and finally focused onto a narrow-band mercury cadmium telluride

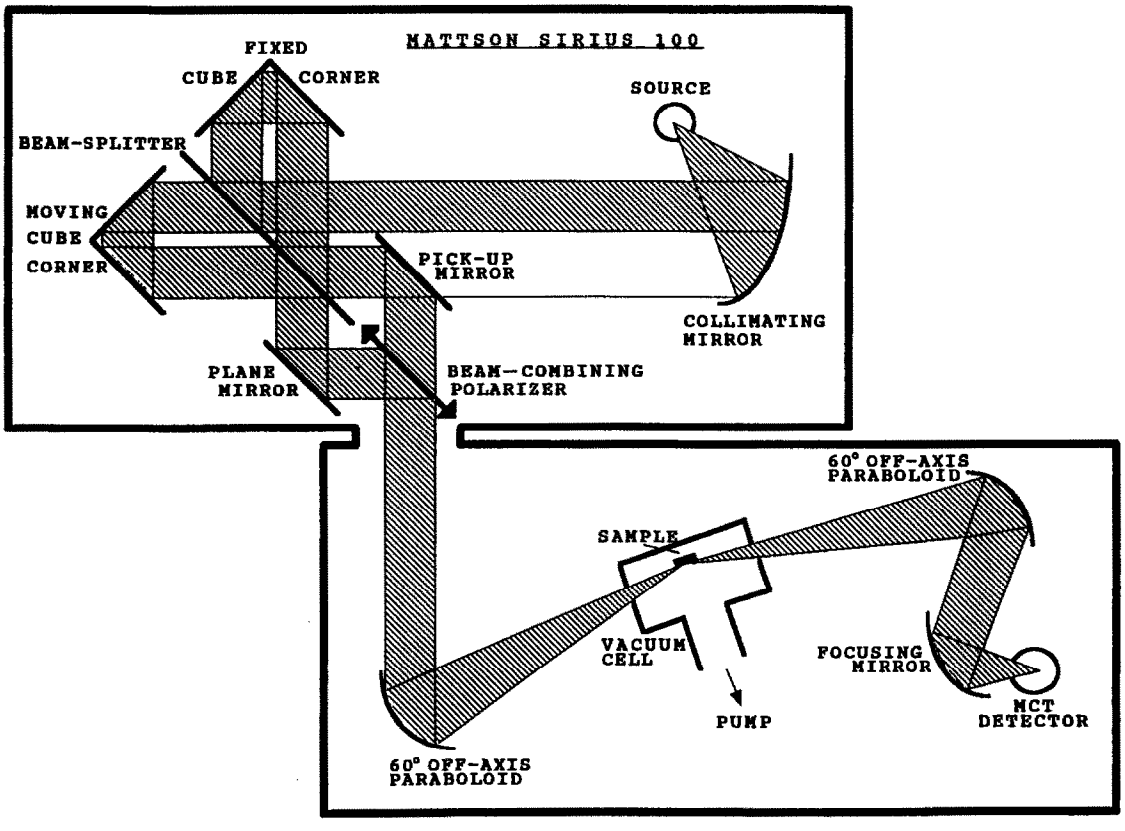

Fig. 1. Optical diagram of a differential polarization dual-beam FT-IR spectrometer.

(MCT) detector (4 mm² active area). It may be noted that the other half of the radiation from the interferometer incident on the polarizer is not passed to the sampling optics and is therefore not detected.

Signal processing

The two output beams in this dual-beam system are of about equal intensity, orthogonally polarized, and 180° out of phase. Their interferograms are therefore optically subtracted upon recombination at the polarizer. With a clean metal substrate at the sample position only a small residual interferogram (dual-beam background interferogram) is detected (Fig. 2), which after amplification and Fourier transformation gives a background spectrum of the residual uncancelled light. When a gas sample is chemisorbed on the metal surface, only p-polarized light is absorbed, while the s-polarized component has a node at the surface and is not absorbed by this sample.[5] The detected signal (dual-beam sample interferogram) increases owing to this imbalance and is proportional to the amount of light absorbed by the sample. Amplification and Fourier transformation give the sample spectrum with the absorption bands due to the adsorbate superimposed on the dual-beam background. Because of the orientation of the wires of the beam-combining polarizer, the absorption bands are seen as upward-going peaks. The final step is a digital subtraction of the background from the sample spectrum, resulting in the dual-beam spectrum of the adsorbate.

If $R_p/R_p^0(\nu)$ describes the reflection–absorption spectrum of the sample measured by the single-beam technique with p-polarized light, the dual-beam spectrum is given by $B(\nu)[1 - R_p/R_p^0(\nu)]$, where $B(\nu)$ is the single-beam background spectrum. Because of the way the signal is processed, the dual-beam spectrum is therefore the absorptance spectrum of the sample multiplied by the relative spectral energy of the single-beam background spectrum. The ratio of the peak-to-peak amplitudes in the center-burst region of the single-beam and the dual-beam interferogram is usually called the *nulling ratio*. The dual-beam interferograms can be amplified by this factor to fill the A/D converter. The nulling ratio is therefore the theoretical improvement in signal-to-noise ratio of the dual-beam technique over a single-beam measurement that is limited by digitization noise. Nulling ratios between 10 and 20 have been achieved with this system.

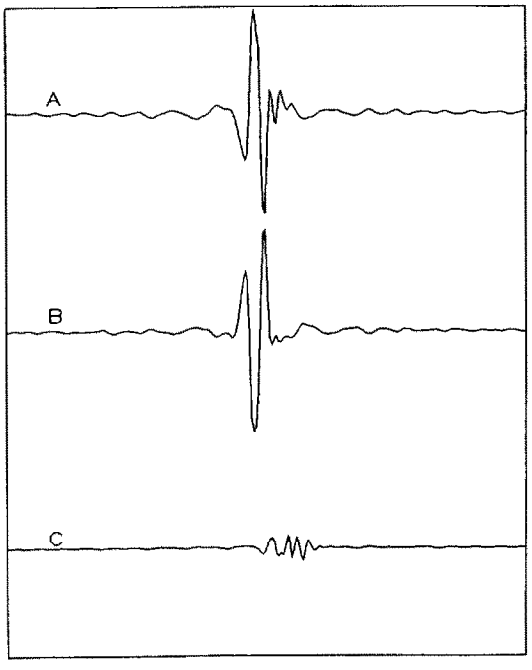

Fig. 2. Single-beam interferograms of the s-polarized beam (A), the p-polarized beam (B) and the resulting "optical null" interferogram (C).

Sampling technique

Since this technique was primarily developed for studies of adsorption processes on metal single crystals, we have built a small high-vacuum cell (Fig. 3), which is pumped by a turbomolecular pump (Balzers TPH 050) to a base pressure of about 10^{-8} torr. The cell consists of an aluminium cell body with two O-ring sealed sodium chloride windows and a top plate, where the sample and all devices for heating and cooling and the gas lines are mounted. The sample, a nickel(100) crystal, is mounted on two tantalum wires, spot-welded to the back of the crystal. The ends of the wires are connected to electrical feedthroughs. In this way the sample can be heated resistively to about 1000° in less than 1 min. It can also be cooled to about 100 K by a copper braid, mounted at the back of the crystal and connected at the other end to a hollow copper cylinder which acts as a reservoir for liquid nitrogen and can be filled from outside. The temperature of the sample is measured by a chromel–alumel thermocouple spot-welded to the edge of the crystal. The pressure inside the cell is monitored by an ionization gauge (Inficon CC-3), located between the cell and the turbomolecular pump. The admission of gases from a gas manifold to the cell is controlled by a leak valve connected to one of the gas lines. The second gas line, intended for continuous flow measurements, is plugged. n-Butanol was used in these first experiments, and was simply condensed onto the cold surface to give different coverages. We did not try to clean the crystal prior to adsorption, which explains the absence of chemical adsorption effects in the spectra shown here. The butanol coverage on the crystal surface was estimated from the exposures used by assuming that an exposure to 10^{-6} torr for 1 sec (1 Langmuir) results in a monolayer coverage.

RESULTS AND DISCUSSION

Spectra of butanol at coverages of 5, 1 and 0.1 monolayers, measured by either the dual-beam or the conventional single-beam technique with p-polarized light are compared in Figs. 4–6. As discussed earlier, the dual-beam spectra contain the relative spectral energy at any particular wavenumber, and the relative intensities of the bands are therefore not directly comparable to the single-beam absorbance spectra. The agreement in peak positions and peak shapes is very good, however, and we did not find any evidence of phase errors in the dual-beam spectra. The signal-to-noise ratio in the single-beam and dual-beam spectra is about the same. As mentioned earlier, an improvement with the dual-beam technique can only be expected if the single-beam measurement is limited by digitization noise. We are currently trying to improve our system by using a smaller detector (1 mm²) with higher specific detectivity D^* to reduce the noise-equivalent power by reducing the noise in the spectrometer electronics and by modifying the source optics in such a way that the full light-beam from the source can pass the pick-up mirror (which currently blocks half of the light) and enter the interferometer.

Three successive dual-beam spectra of 5 mono-

layers of butanol subtracted from the same background spectrum (Fig. 7) show that the baselines in the mid-wavenumber region (2500–1200 cm^{-1}), where the spectral energy is highest, are quite sensitive to small fluctuations of the spectrometer stability. These instabilities produce spectral artifacts at around 1400 cm^{-1} because of poor cancellation of a strong band due to the beam-splitter, which obscures the CH-bending modes of the sample and causes the appearance of interference fringes (also appearing to

originate from the beam-splitter). A different beam-splitter might improve the flatness of the baselines. These effects are less severe in the single-beam spectra (Fig. 8) where the ratio of the sample and background spectra is used instead of their difference. However, a slight discontinuity from the beam-splitter band at 1400 cm^{-1} can also be seen in the spectrum of the s-polarized light. The high polarization efficiency of the beam-combining polarizer for both transmitted (p-polarized) and reflected (s-polarized) light, (the latter showing practically no absorptions), is also demonstrated in Fig. 8.

CONCLUSIONS

A dual-beam technique for reflection–absorption FT-IR spectroscopy has been developed, based on

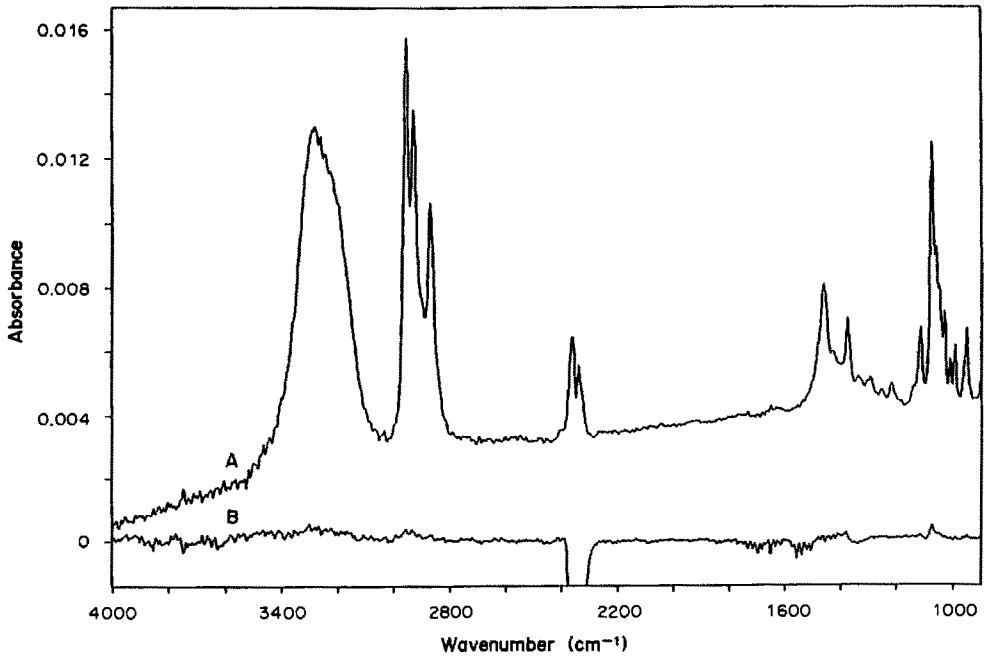

Fig. 8. Single-beam absorbance spectra of n-butanol (5 monolayers) on nickel(100) measured with p-polarized light (A) and s-polarized light (B).

center-burst suppression by optical subtraction of the transmitted and reflected output beams of a cube-corner interferometer. The dual-beam optics in this system are relatively simple and can readily be converted for standard single-beam operation. The first results obtained with this new technique are essentially identical to those obtained with conventional single-beam arrangements. Further noise reduction and improvements in spectrometer stability should enable the full potential of this technique to be realized. We expect at least a factor of 10 improvement in signal-to-noise ratio relative to the single-beam method at the A/D conversion limit. We are also currently constructing an infrared cell connected to a UHV-chamber, where the sample can be cleaned and characterized by standard surface-science techniques and moved to the IR cell without breaking the vacuum, so that spectra can be measured at any pressure between UHV and ambient.

MULTIELEMENT CONTINUUM-SOURCE ATOMIC-ABSORPTION SPECTROMETRY WITH AN ECHELLE-SPECTROMETER/IMAGE-DISSECTOR SYSTEM

RONALD MASTERS*, CHUNMING HSIECH and HARRY L. PARDUE
Department of Chemistry, Purdue University, West Lafayette, IN 47907, U.S.A.

(*Received* 15 *April* 1988. *Accepted* 2 *August* 1988)

Summary—The continued development of the echelle-spectrometer/image-dissector system for multielement determination by continuum-source atomic-absorption spectrometry is presented. Modifications of the instrument include the use of a 20-groove/mm echelle grating blazed at 76°, and the removal of the magnetic shield from the image dissector. The spectral range is from 300 to 430 nm and the observed resolution is better than 0.005 nm at 400 nm. Calibration curves are linear up to an absorbance of 0.2, and absorption sensitivities are up to 4-fold better than with the previous design. Fundamental characteristics of the detector limit the application of the instrument to sequential single-element quantification with the electrothermal atomizer, and to sequential multielement quantification with the flame atomizer. The further development of the instrument for simultaneous multielement quantification is discussed.

A previous report[1] from this laboratory described the results of a study of the use of an echelle-spectrometer/image-dissector combination for continuum-source atomic absorption (CSAA). Although the echelle/image-dissector system was originally designed[2–5] to help solve the classical problem of range *vs.* resolution in dispersive spectrometry, the results of the above-mentioned study indicated that multielement quantification by CSAA would require levels of resolution and range significantly beyond those available with the original design. The approach that was taken to solve this problem was to replace the echelle grating with one that would provide the desired spectral characteristics. An echelle grating that matched the required specifications was not commercially available, so a new echelle grating was custom-designed and manufactured for the spectrometer. Details of that system and a description of an optical phenomenon that can result in simultaneous improvements in resolution, range and throughput for the echelle-spectrometer/image-dissector system will be described elsewhere.

This paper presents a detailed description of the modified instrument, data that characterize its capabilities and limitations with regard to multielement CSAA, calibration data for both electrothermal and flame atomization, and a discussion of the further development of the instrument for simultaneous multielement quantification by CSAA.

EXPERIMENTAL

Instrumentation

The instrumental system consists of a continuum source, atomizer, echelle spectrometer, and image-dissector camera interfaced to a computer. Since the last report,[1] there have been enough changes in design to warrant a detailed description of the major components of the instrument.

Echelle spectrometer. A block diagram of the instrument is given in Fig. 1. The spectrometer is an $f/15$, modified Czerney–Turner configuration with a focal length of 75 cm. The echelle grating (E) is a custom-designed, 20-groove/mm grating with a blaze angle of 76° (Hyperfine, Inc., Boulder, Colorado). The ruled width and groove-length of the grating are 10 cm and 5 cm, respectively. The separation of the orders of the echelle spectrum is accomplished by a 300-groove/mm grating (V) that is blazed at 300 nm in the first order. The ruled width and groove-length of this grating are both 5 cm. An important feature of the spectrometer as shown in Fig. 1 is that the echelle grating is positioned so that the angle of incidence (83.5°) is significantly steeper than the blaze angle (76°). The reason for this choice of angular working conditions is discussed later. For all data presented in this report, the width and height of the entrance slits were set at 100 and 50 μm respectively.

Detector. The image-dissector system has been described elsewhere.[2] For all data presented here, the working area of the photocathode corresponds to a rectangle with a width of 18 mm and a height of 30 mm. The magnetic shield was removed from the focus and deflection coil housings, and as will be shown later, this modification results in significantly improved quantitative performance.

For purposes of comparison, a photodiode-array detector (Model 1412, EG & G—Princeton Applied Research) was included in one of the studies reported here. This detector has been described elsewhere.[6]

Contunuum source. The lamp used for the experiments in this report was a "super-quiet" 300-W xenon arc lamp (Model L2479, Hamamatsu Corp.) in an air-cooled housing.

Atomizer. Electrothermal and flame atomizers were used. For the electrothermal atomizer (HGA2100, Perkin-Elmer),

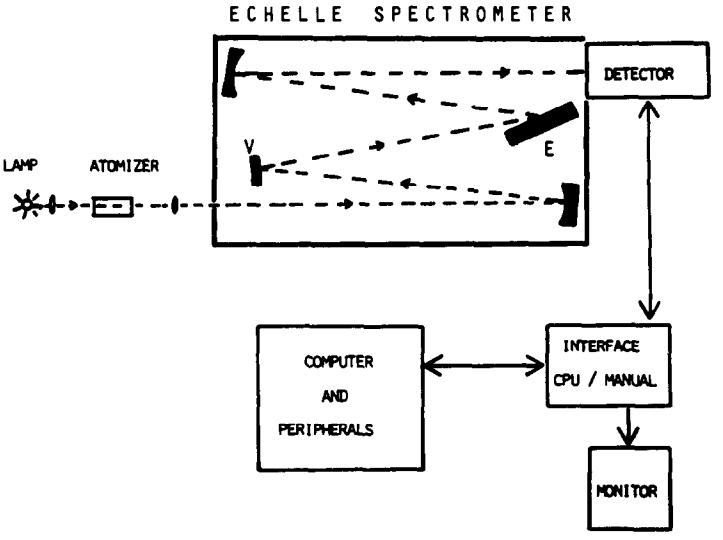

Fig. 1. Block diagram of the echelle-spectrometer/image-dissector system as used in this work. E, echelle grating; V, order-sorting grating.

the argon flow-rate was 60 ml/min, and the "interrupt" mode was used to provide optimum sensitivity. The program consisted of drying a 20-μl sample for 30 sec at 100°, charring the remaining solids for 1 sec at 1000°, and atomizing the residue for 15 sec at 2700°.

The flame atomizer was a previously described[2] burner system. The acetylene and air flow-rates were 1.2 and 6 l./min, respectively, and the sample uptake was 6.7 ml/min. The observation height was 5 mm above the burner head.

Reagents

Solutions of the elements of interest were prepared by appropriate dilution of certified atomic-absorption standards (Alfa Products, Danvers, MA 01923) with distilled, demineralized water. Single-component solutions were used for studies with the electrothermal atomizer, and multi-component mixtures were used for studies with the flame atomizer.

RESULTS AND DISCUSSION

This section presents the results of studies of the performance of the image dissector and the echelle spectrometer as separate units with regard to the requirements for multielement quantification by CSAA, discusses the characteristics of the combined system, and then presents calibration data for CSAA with both electrothermal and flame atomization. Although wavelengths have been rounded to the nearest 0.1 nm, with appropriate calibration the system is capable of measurements to the nearest 0.01 nm.

Instrument system

Image dissector. Because the image dissector is a photomultiplier-type detector, its output should be linear with respect to changes in the input optical flux. However, our data indicate that this relationship is linear only for changes of intensity over a moderate area of the photocathode (>1 mm^2). The atomic absorption features in an echelle spectrum of a continuum source consist of small (50 × 50 μm) dark areas in the midst of a bright background. An accurate measurement of the intensity profiles of these dark areas is necessary if accurate absorbance values are to be obtained. The image dissector was tested for this capability by focusing an optical test pattern on the photocathode. The pattern consisted of a bright field (orders of echelle spectrum) crossed by two dark lines, side by side, with widths of 1 and 0.2 mm. Photographs of this pattern show that intensity of each dark line is less than 0.1% of the intensity of the surrounding bright field. The output of the image dissector for this test pattern is shown in Fig. 2A and the output of the photodiode-array detector for the same test pattern is shown in Fig. 2B. The image dissector samples the intensity within a single order, whereas the photodiode array integrates the intensities from several orders within the test pattern. This instrumental difference produces different background slopes for the scans in Figs. 2A and 2B, but does not affect the intensities of the minima (dark levels). These data show that the image dissector is very limited in its ability to provide an accurate measurement of the dark level in the midst of a bright background, and that this limitation gets worse as the size of the feature gets smaller. The solid-state detector is clearly superior in this application. For the 0.2-mm feature, the image dissector gives an absorbance of 0.6, the photodiode array gives an absorbance of 1.1, and the true value should be above 3. It is reasonable to conclude that these values are close to the maximum attainable for a feature of this size. It is not surprising, therefore, that previously reported[1] calibration curves obtained with the echelle/image-dissector system were linear only up to an absorbance of 0.1.

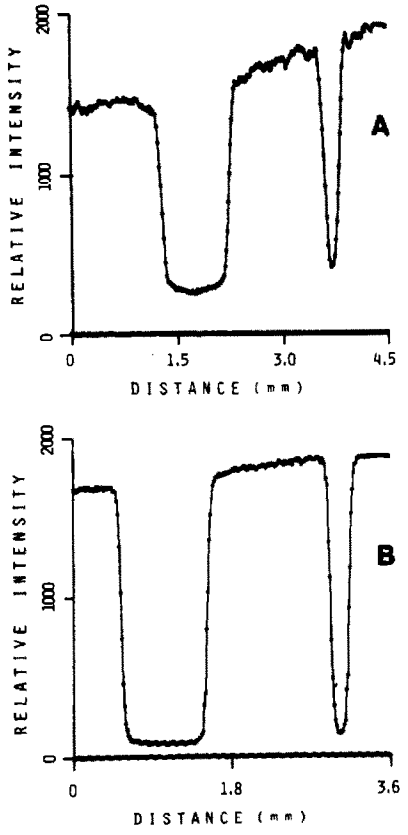

Fig. 2. Responses of the image dissector (A) and the photodiode array (B) to a test image.

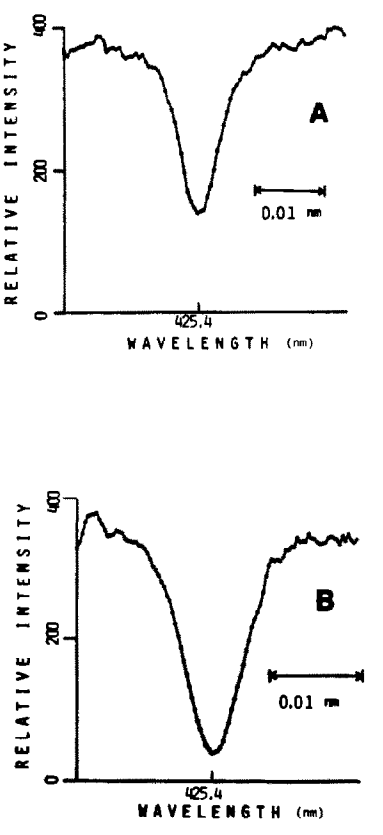

Fig. 3. Responses of the image disssector to an absorption feature (CR, 425.4 nm) in the echelle spectrum of the continuum source (A) with and (B) without the magnetic shield.

Through a series of experiments related to the effect of the magnetic shield on the performance of the image dissector, it was discovered that removal of the shield significantly improves the quantitative performance of the detector. The shield was originally removed in order to minimize the effects of boresight hysteresis[7] in which the effective position of a given feature depends upon the scan history. In this case, the shield becomes magnetized by the deflection and focus coils, which disrupts the effective fields that act on the beam of photoelectrons within the drift region of the tube. The quantitative performance of the detector depends upon the quality of the focusing of the photoelectrons, which is subject to the effects mentioned above. The removal of the shield minimizes these stray fields and improves the quantitative performance of the detector. This improvement is shown in Figs. 3A and 3B, which are the responses of the image dissector to a particular atomic-absorption feature in the echelle spectrum, with and without the shield, respectively. The absorption feature, observed at 425.4 nm, was generated by the electrothermal atomization of a 200-ng sample of chromium, a mass large enough to produce an absorbance of well above 1. These data show that the removal of the magnetic shield improves the quantitative performance of the image dissector to a level that is similar to that obtainable with a solid-state detector. Taking all the available data into consideration, it is reasonable to expect that the upper limit of the linear range of the image dissector for fine spectral features should be an absorbance of about 0.2 with the shield removed, and the maximum attainable absorbance should be about 1. Calibration data presented later were all obtained with the magnetic shield removed from the image dissector.

Echelle spectrometer. The positioning of the echelle grating so that the angle of incidence (83.5°) is steeper than the blaze angle (76°) results in the simultaneous improvement of resolution, range and throughput by factors of 2.1, 1.5 and about 2, respectively. These benefits arise from the fact that the angular conditions result in a 70% reduction in the width of the image of the entrance slit at the focal plane, but only a 33% reduction in the dispersion. The most easily observed benefit of this phenomenon is that a given level of resolution can be obtained with a much wider entrance slit than when the echelle grating is used with the angle of incidence equal to the blaze angle. Thus, a 100-μm wide, 50-μm high entrance slit appears as a 30-μm wide, 50-μm high image at the focal plane. These dimensions, which are those used

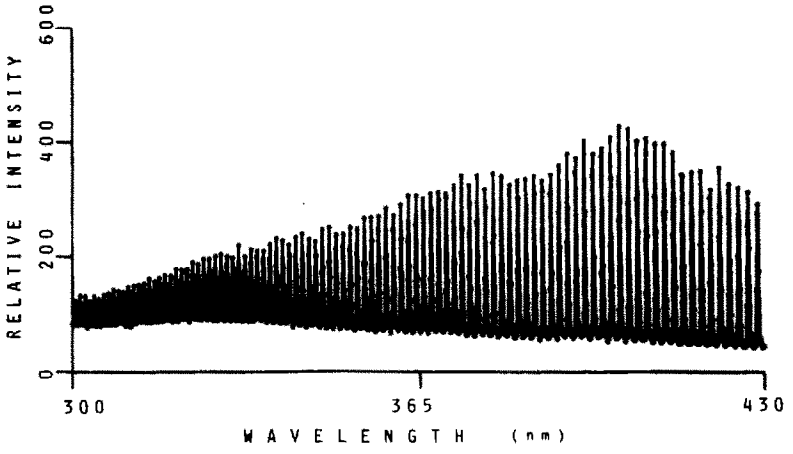

Fig. 4. Profile of the orders of an echelle spectrum for a continuum source.

for the experiments included in this report, represent a good match with the 30-μm aperture of the detector.

The primary reason for the choice of blaze angle and groove spacing for the new echelle grating is to provide a spectrum that fits the size of commonly available imaging detectors while maintaining a high level of resolution. With the new grating (20 grooves/mm, 76° blaze angle) in the 75-cm spectrometer, the observed resolution is better than 0.005 nm at 400 nm, and the width of the spectrum ranges from 10 mm at 225 nm to 30 mm at 675 nm. Thus, a detector with a width of 30 mm and sufficient height could cover the entire ultraviolet–visible spectrum up to 675 nm. However, the wavelength of most atomic-absorption lines of interest is shorter than 430 nm, so a detector with a width of about 18 mm would suffice, and this is the reason for setting the range of the horizontal scan of the image dissector to 18 mm. With this choice of horizontal range, the maximum available vertical range is about 30 nm.

The spectral range of the instrument depends upon the total number of orders than can fit into the 30-mm range of the detector. Ideally, if the spectrum were pure (no false orders or scattered light from the echelle grating) and entirely uniform, and if the imaging quality of the detector were perfect, a total of $(3 \times 10^4\ \mu\text{m})/(38\ \mu\text{m/order}) = 789$ orders, could be stacked adjacent to one another within the available space. In practice, only about one-fourth of this number of orders would fit because, even if the spectrum were pure, it is nonuniform and the imaging quality of the detector is not perfect. This number of orders would cover a wavelength range from about 230 to 430 nm. A grating with about 150 grooves/mm, used in the 75-cm spectrometer to disperse the orders of the echelle spectrum, would provide this range.

Unfortunately, the new echelle grating does not produce a pure spectrum. Every principal order of the spectrum is accompanied by many weak false orders and scattered light. The intensity of each of these false features is less than about 1% of the nearest principal order, but when a continuum-source is used, and the principal orders are positioned close to each other to obtain maximum range, the false orders are unresolved and sum together to provide a continuous level of scattered light that underlies the principal orders of the spectrum. As the orders are packed closer together, the number present within a given spatial resolution element increases, so the intensity of the scattered light also increases. Fortunately, when the packing of the principal orders is such that they are fully baseline-resolved, the intensity of the scattered light can easily be measured between the orders. Experimentally, this baseline resolution is achieved when a 300-groove/mm grating is used to disperse the orders, and this is the reason for choosing such a grating.

Figure 4 is a plot of a vertical scan through the orders of the echelle spectrum from about 300 to 430 nm with the 300-groove/mm grating. Each peak represents one order, with the range from 430 to 300 nm corresponding to the 226th to the 323rd order of the echelle spectrum, respectively. The locus of the minima between the orders defines the level of scattered light as a function of wavelength. This level, relative to the intensity of the principal orders, continuously increases with decreasing wavelength, as would be expected for a scattering phenomenon. At 430 nm, the level of scattered light is 14%, and it rises to about 50% at 300 nm. For a given configuration of the spectrometer, these relative levels are reproducible over extended periods of time. For example, ten measurements of the stray light near the 425.4-nm Cr line within a given day gave an average of $14.3 \pm 0.2\%$. Several days later the value was $14.2 \pm 0.4\%$.

Experimentally, it is observed that the atomization of a very concentrated sample of an element reduces the intensity of the principal order at the peak wavelength to a level that is equal to the average of the intensities of the scattered light on each side of

that order. Thus, the intensity of scattered light that underlies a given order can be calculated from the measured intensities on each side of that order. For the purpose of calculating an absorbance value, the dark level (0%) should be considered to be equal to the intensity of the scattered light because this light is not subject to atomic absorption.

Because the relative level of the scattered light increases to over 50% at wavelengths shorter than 300 nm, the instrument is not very useful for such wavelengths. An echelle grating with improved quality would solve this problem, but the manufacture of high-quality echelle gratings with fewer than 30 grooves/mm represents a formidable technological challenge[8] that for the most part has been avoided for the last two decades. The manufacturer of the echelle grating used to obtain the data presented here has stated that it is now possible to improve upon the quality by about 50%, which should extend the usable range down to about 250 nm.

Combined system. This section briefly examines those characteristics of the combined system that limit its utility for multielement quantification by CSAA.

Although the echelle spectrometer displays the entire spectrum simultaneously on the face of the detector, the image dissector is not an integrating detector and accordingly is not capable of simultaneously accumulating all this information. Thus, the present system does not have the so-called multiplex advantage. Additionally, even with the improved throughput of the echelle system that was mentioned earlier, the observed photoelectron transmission through the aperture of the detector is of the order of 20 kHz. With this rate, a minimum of 0.5 sec is required to obtain a reasonably certain measurement of the intensity at a given location, and because the detector is inherently sequential, every location observed adds proportionately to the total time of measurement. These characteristics necessarily limit the use of the echelle/image-dissector system to sequential, single-element determination with electrothermal atomization, because of the transitory nature of the signal produced by this type of atomizer. With flame atomization, however, the instrument can be used for sequential multielement quantification provided the amount of sample is sufficient to last for the time required to measure the intensities for all the elements of interest.

One inherent advantage of CSAA over line-source atomic-absorption (LSAA) is the ability to obtain absorbance profiles of atomic lines with a single lamp. This information can be used to calculate the background-corrected absorbance. For these calculations, I_0 is the average of the intensities measured on each side of a line and I is the intensity measured at the peak wavelength, both values being measured at the center of the order which contains the line. Because the echelle/image-dissector system is not a multiplex instrument, however, the acquisition of the additional information required to properly define the profile of a line significantly increases the time required for the measurement. This limitation of the instrument restricts the collection of data to two points (one at the peak location and one at a single background location) per line-profile for studies with the electrothermal atomizer. This method is very susceptible to positional drift (mechanical, electronic, electrostatic or magnetic), which is yet another limitation of the image dissector. For studies with the flame atomizer, data can be collected for the entire profile of each line examined, which requires about 8 sec per line. Because of the length of time required to measure the profile of a single line, only four elements were included in the multicomponent samples studied. About 0.5 min was required for each sample.

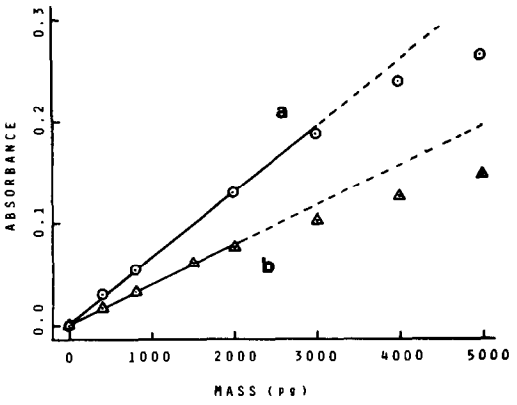

Fig. 5. Comparison of calibration curves for chromium (425.4 nm) by (a) the instrument described in this work, (b) the instrument previously described.[1]

Calibration results

Electrothermal atomizer. Calibration data were obtained for single-component solutions of Cr (425.4 and 357.9 nm), Ca (422.7 nm), Mn (403.1 nm) and Cu (324.8 nm) with the electrothermal atomizer. Figure 5 shows a comparison between a calibration curve for Cr (425.4 nm) obtained with the redesigned instrument (curve a) and one obtained with the instrument used in the previous work[1] (curve b). The combination of improved spectral resolution (0.005 *vs.* 0.01 nm) with the improved quantitative performance of the detector (removal of magnetic shield) affords a 1.6-fold increase in sensitivity (slope) and a 2-fold increase in the upper limit of linearity.

Calibration data are listed in Table 1, which includes the standard error of the estimate for a linear least-squares fit of absorbance (A) *vs.* mass (pg) for each element, as well as the upper limit of the linear range and the characteristic mass, which corresponds to an absorbance of 0.0044. Values of the characteristic mass and the upper limit of the linear range obtained for each element with the instrument used in the previous work[1] are included for comparison. The absorbance at the upper limit of the linear range for each element reported here is about 0.2, whereas

Table 1. Summary of results for elements determined by CSAA with electrothermal atomization

			This work	Ref. 1	This work	Ref. 1
Ca	422.7	0.002	6	26	200	300
Cr	425.4	0.003	71	116	3000	2000
Cr	357.9	0.005	44	46	2000	800
Cu	324.8	0.003	26	81	1200	2000
Mn	403.1	0.001	24	94	1000	4000

*Standard errors of absorbance.
†Mass required to give an absorbance of 0.0044.

in the previous work it was about 0.1. Each element shows a significant improvement in its characteristic mass, or its upper limit of linearity, or both. The fact that improvements are better for some lines than for others is related to differences in line shapes; in general, the narrower the lines, the greater the improvements.

Smoothing of the absorbance *vs.* time profiles allows the shot-noise to be reduced to levels that correspond to an absorbance of 0.005, so the detection limits can be calculated as multiples of the characteristic masses for any desired level of confidence. These data could have been acquired in a virtually simultaneous multielement mode by scanning rapidly from one location to the next and then smoothing the resulting absorbance *vs.* time profiles, but the level of noise and limit of detection for each element would be substantially increased. These studies indicate that the level of noise is intolerably high even when only two lines are measured.

Flame atomizer. Calibration data were obtained for multicomponent mixtures of Cr (357.9 nm), Ca (422.7 nm), Mn (403.1 nm), and Cu (324.8 nm) with the air/acetylene flame. These data are listed in Table 2, which includes the standard error of the estimate for a linear least-squares fit of absorbance *vs.* concentration (ppm) for each element, as well as the characteristic concentration, and the upper limit of the linear range. Previously reported[2] values of the sensitivity for each element quantified by LSAA (multielement hollow-cathode lamp) were used to calculate the characteristic concentration values that are included in Table 2 for comparison. Because calcium was not included in the multielement lamp its value for comparison was obtained with the echelle/image-dissector system by using a calcium hollow-cathode lamp and the same experimental conditions with which the CSAA value was obtained. Except for chromium, the CSAA sensitivities are within a factor of two of the LSAA values that are listed for comparison. Calcium gives especially good results; other data show that this line is very broad, so the nonideal quantitative performance of the detector is not as likely to cause a loss of sensitivity for this line as it would for narrower lines.

Smoothing of the absorbance *vs.* wavelength profiles allows the noise to be reduced to levels that correspond to absorbances of 0.005, so the detection limits can be calculated as multiples of the characteristic concentrations for any desired level of confidence. Alternatively, lower levels of noise and limits of detection can be obtained by imposing a longer time constant for the analog filter or digital smoothing routine, which in turn would require a longer time for the measurement of the profile of each line.

Discussion

The fundamental concept that underlies the work presented here and in previous reports is that it should be possible, by utilizing an appropriately designed echelle spectrograph combined with a modern two-dimensional imaging detector, to simultaneously and quantitatively examine a wide spectral region, with a very high level of resolution. The system described in this report is limited in two principal respects. First, the quality of the echelle grating limits both the total spectral coverage (packing limited by false orders) and the utility of the

instrument in the ultraviolet range. Second, the image dissector is inherently sequential, which prevents the instrument from being used to accumulate information simultaneously at multiple spectral locations. In spite of these limitations, it has been demonstrated that the present system combines the resolution and range required for practical multielement quantification by CSAA. It should be possible to improve some of the performance features of the instrument with the use of higher quality echelle gratings and integrating two-dimensional detectors. Work is continuing in these areas.

(*Received* 28 *June* 1988. *Accepted* 21 *July* 1988)

Summary—The collection, processing and certification of a new sediment Standard Reference Material (SRM), SRM 2704, is described. Collected from the bottom of the Buffalo River in New York State during the fall of 1986, SRM 2704 is certified for 25 elements with information provided on another 22 elements. Improvements in analytical methods as well as the application of well-defined quality-control procedures for collection, processing and analysis have resulted in a reference material that is more completely characterized than previous NIST sediment reference materials.

Reference materials are "well-characterized, stable, homogeneous materials having one or more physical or chemical properties determined within stated measurement uncertainties".[1] These properties are sufficiently well-established to be used for the calibration of an apparatus or the assessment of a measurement method.[2] Reference materials thus play an essential role in analytical chemistry. They are used to evaluate the accuracy of new analytical methods and to maintain the quality of established measurement procedures. Sediments are among the most useful types of reference materials for inorganic elemental analysis, since their complex composition makes the greatest demands on the dissolution and analysis methods used for their characterization. Bottom sediment reference materials from numerous aqueous environments (rivers, ponds, bays, streams, gulfs, *etc.*) have been prepared by various organizations thoughout the world.[3] These organizations issue certified reference materials (CRMs) with critically-evaluated concentration values for inorganic or organic constituents. Additional data for both certified and uncertified constituents in CRMs have been obtained by numerous analysts worldwide, and are available in the scientific literature.[4] The usefulness of a reference material will depend on the number of certified elements and their concentration levels, as well as the estimate of uncertainty placed on each certified concentration. The estimated uncertainty is frequently expressed as 95% tolerance limits for an individual subsample,[5] although there is no standard method for deriving these limits. Typically, the uncertainties are a function of the sample homogeneity, the precision and accuracy of the analytical measurement, and the integrity of each step in the certification process.

The planning that goes into the preparation of a Standard Reference Material (SRM), which is a CRM issued by the National Institute of Standards and Technology (NIST), involves the selection of analytical techniques that have adequate sensitivity and precision for specific analyses. In laboratories dedicated to the development of SRMs, such as the Center for Analytical Chemistry at NIST, there are a number of analytical methods operated by personnel experienced in the requirements for high-accuracy analyses. The availability of control materials and rigorous quality-assurance procedures in such dedicated certification laboratories results in much lower uncertainties than would be possible by using a large number of co-operating laboratories in a round-robin consensus approach to certification. A primary goal in the development of a new river sediment SRM was to reduce the uncertainties associated with certified values to below those previously attained for NIST sediment reference materials.

This paper will describe the collection, processing, and certification of the new NIST sediment reference material, SRM 2704, collected from the Buffalo River in New York State. We believe that improvements in analytical techniques as well as the application of well-defined quality-control procedures for collection, processing, and analysis has resulted in a reference material that is superior to previous NIST sediment reference materials.

PCBs and pesticides: Arochlor 1242 in the Times Beach sediment was 3.58 ± 0.24 μg/g. The Buffalo River PCB fraction showed peaks with retention times corresponding to hexachlorobenzene, 4,4′-DDE, and PCB 153, 138, and 180, and the Buffalo River pesticide fraction showed peaks with retention time corresponding to τ-chlordane, α-chlordane, transnonachlor, 4,4′-DDD, and 4,4′-DDT at levels in the low μg/g range.

THE CERTIFICATION PROCESS

Collection, processing and characterization of candidate sediments

Although the ideal sediment reference material should be certified for both inorganic and organic constituents, this is usually not possible. The criteria for collection, processing and storage are different for these two types of constituents. The most desirable equipment for the collection of materials to be certified for the one group is the most probable source of contamination with the other. Since the SRM 2704 was designed as an inorganic reference material, the collection and processing procedures were designed to minimize inorganic contamination. However, organic contamination was also kept to a minimum by using Teflon enclosures whenever possible.

In April of 1985, preliminary samples of sediment were collected with a clamshell-type grab-sampler from three locations along the Buffalo River in Buffalo, NY. Another sample was taken with a core sampler from the Times Beach confined disposal facility at the mouth of the river. The sediments were placed in half-gallon polyethylene containers, refrigerated within 2 hours of sampling and kept under refrigeration during shipment to NIST. The samples were then homogenized, freeze-dried, and sieved through a 60-mesh plastic screen. Sediment that passed through the screen was selected for analysis. The Times Beach sample appeared heterogeneous, with small white particles distributed throughout the bulk, and had a high organic content as evidenced by the odor and color. The Buffalo River sediments appeared homogeneous, with some coal particles visible under microscopic examination.

Inorganic constituents were characterized by using lithium metaborate fusion for sample preparation, and analysis by inductively-coupled and direct-current plasma emission spectrometry, flame atomic-absorption and emission spectrometry. Carbon was determined by inert gas fusion and infrared detection,

and arc emission spectroscopy provided a qualitative analysis. Organic constituents in methylene chloride extracts of the sediment were characterized by gas chromatography (GC) for PCBs and pesticides and gas chromatography/mass spectrometry (GC/MS) for polycyclic aromatic hydrocarbons (PAHs). The semiquantitative results for the preliminary sediment samples are summarized in Table 1.

Collection and processing of SRM 2704

Though less interesting from the standpoint of organic constituents, the Buffalo River sediment collected in the vicinity of the Ohio Street bridge had the homogeneity, particle size, and element concentration characteristics appropriate for a useful reference material. The sampling procedure was a compromise between the methods used in the collection of SRM 1645 (River Sediment) and SRM 1646 (Estuarine Sediment).[5,6] SRM 1645 had been collected with a large clamshell bucket that had a capacity of 14 gallons. The contents of the bucket were dumped directly into 55-gallon polymer-lined drums. This resulted in a time-efficient sampling operation but produced a relatively heterogeneous sample, which complicated the sieving and homogenization processes. SRM 1646 had been collected with a small 1-gallon capacity grab-sampler, a method which was both time and labor intensive but resulted in a homogeneous sample. The distribution of river sediment is not as predictable as that of estuarine or marine sediment and such a small-scale sampling scheme would be unsatisfactory for collecting 1000 lb of sediment. The compromise involved small-scale sampling from a large collected sample.

The Buffalo River sediment was collected with the co-operation of the U.S. Army Corps of Engineers in late November of 1986. An unpainted, cleaned, and rinsed clamshell bucket suspended from the crane of

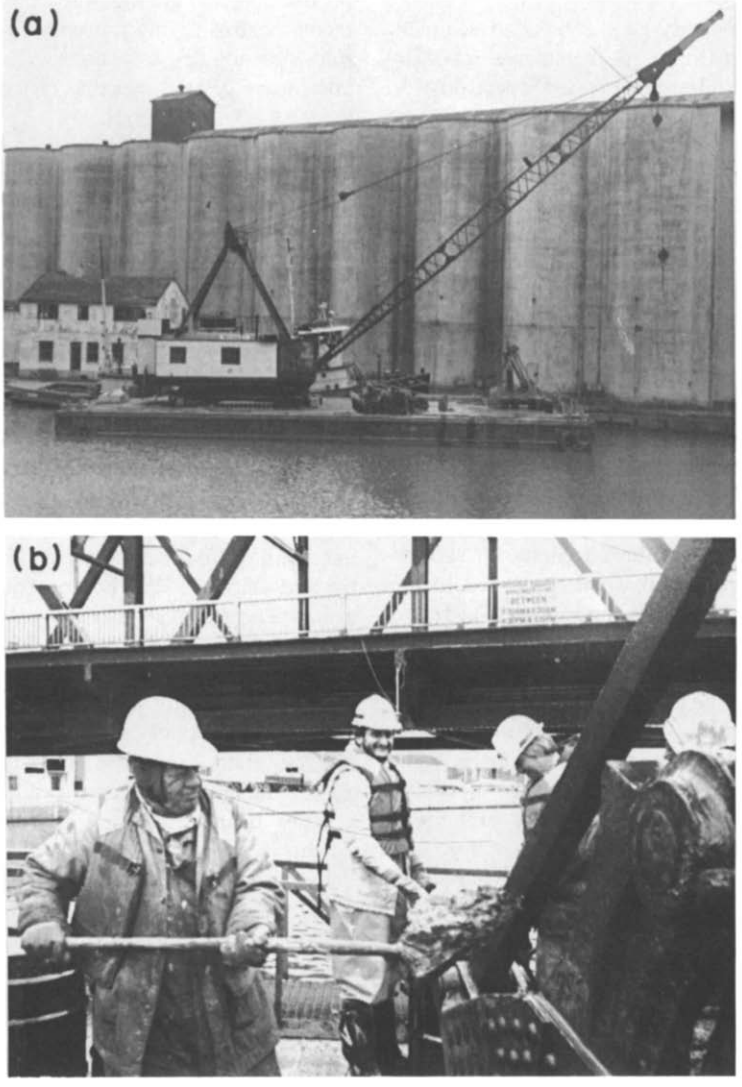

Fig. 1. Collection of the Buffalo River sediment. (a) The derrick boat and clamshell bucket used to collect the sediment. (b) The transfer of sediment with a Teflon-coated shovel from the clamshell bucket to a plastic-lined steel drum.

a derrick boat [Fig. 1(a)] was used for the collection. The sampling site, about 100–200 m on the upstream side of the bridge, had not been dredged in over two years. The river bottom sediment was sampled to a depth of approximately 1 m with each bucketfull. The sediment was transferred with a Teflon-coated shovel to 55-gallon steel drums lined with Teflon bags nested inside polyethylene bags, as shown in Fig. 1(b). Teflon-coated shovels were used to minimize contamination, and care was taken to ensure that the material transferred had not been in direct contact with the inside of the bucket. Once the drums were filled, the bags and drums were sealed and transferred to a refrigerated truck. The sediment was then transported to a facility where it was mixed, freeze-dried, screened to pass a 100-mesh sieve, remixed, and placed in polyethylene-lined aluminum cans. The sediment was radiation-sterilized at a minimum dose of 2.5 Mrad to reduce the rate of any biodegradation and returned to NIST for evaluation of gross homogeneity.

The gross homogeneity of the blended sediment was assessed by means of measurements made by inductively-coupled plasma emission spectrometry. Representative samples (0.3 g) were taken from the cans of sediment and decomposed by lithium metaborate fusion. Four target elements were chosen for examination. Iron and chromium were selected since they were among the most likely contaminants from the collection and processing of a sediment. Both elements had been found to be inhomogeneously distributed in SRM 1645.[4] Silicon was chosen as a target element since microscopic examination of the new sediment revealed large quartz particles. Sodium was selected since it had been found to be inhomogeneously distributed in preliminary, unblended samples of the sediment.

An analysis of variance (ANOVA) was used to separate the bottle-to-bottle, sample-to-sample, and instrument variances. No inhomogeneity for sodium or silicon could be detected when compared to the instrumental measurement variance. Bottle-to-bottle inhomogeneity was observed for chromium at the 99% confidence level, and for iron at the 97.5% confidence level. On the basis of this information, the sediment was reblended at NIST in a cone blender. Subsequent evaluation of the reblended material indicated satisfactory homogeneity for these elements. Fraction analysis indicated that the entire sample was smaller than 100-mesh and 70% of the sample was smaller than 324-mesh. The material was then bottled in 50-g units, producing a total of approximately 3300 units. Fifty bottles, randomly selected from the entire population, were used for the analytical measurements.

Humidity/drying study

The behavior of SRM 2704 under varying environmental conditions was evaluated by use of an environmental chamber equipped for accelerated humidity and drying studies.[7,8] In this device, sample weight changes can be monitored while the sample undergoes a wide range of temperature and relative humidity (% RH) cycles. Such studies are necessary for stating drying conditions by which all users of an SRM can obtain a starting material of the same moisture content. The nominal weight loss of SRM 2704 was 0.8% under the recommended drying conditions of 2 hr at 110°. Exposure of the sediment to cyclic humidity changes between 40 and 80% RH resulted in weight gains of as much as 1.3%, but the original dry weight was restored when the material was dried under the recommended conditions. When exposed to 33% RH conditions for 30 min, the dry sediment regained almost 70% of the water loss from drying. Thus, care must be exercised in weighing the material. However, up to 50% RH the undried sample showed little tendency to pick up water vapor. The composition of SRM 2704 tended to be reproducible at a given % RH, and a sample could be dried to a reproducible composition when the recommended drying procedure was used. The material does not dry to a constant composition under microwave drying[8] and that procedure is not recommended.

Evaluation of sediment homogeneity

The extreme difficulty in quantitatively assessing the homogeneity of a reference material can be seen by the manner in which the homogeneity of elemental composition in reference materials has often been defined. Statements such as "satisfactory" and "all bottles . . . have substantially the same composition" have been used to describe the homogeneity of distribution of some elements,[5,6] although more specific estimates may be provided for a few other elements.

Ideally, homogeneity information should provide an estimate of the amount of material required in order to avoid exceeding a series of defined sampling uncertainties for each certified element. As discussed by Kratochvil *et al.*,[9] homogeneity is estimated by using the relationship $WR^2 = K_s$, where W is the weight of sample, R is the RSD (%) of sample composition, and K_s is Ingamell's sampling constant, which is the weight of sample required to limit the sampling uncertainty to 1% with 68% confidence. The sampling constant can be determined by estimating the between-sample standard deviation, from a series of measurement sets of different sample weights.

The sampling uncertainty and its dependence on sample size will not be the same for all elements unless the elemental distribution is the same within each particle of the bulk matrix. While this may be approximated in a reference material, such as a glass, that has been formed (without segregation) from a homogenized liquid melt, in most reference materials the composition of particles of different size will vary significantly. This is particularly true for naturally heterogeneous materials like sediments. In these ma-

terials, the sampling standard deviation may become rather large for some elements when small (< 100 mg) sample weights are used.

Detailed studies of reference material homogeneity by analysis of varied sample sizes have been performed for mixed diet,[10] lobster,[11] dogfish and oyster tissue.[12] The homogeneity of the bottled units of SRM 2704 was assessed by using X-ray fluorescence (XRF) spectrometry. Duplicate 1-g samples from 8 randomly selected bottles were fused with lithium tetraborate and analyzed for Al, Si, K, Ca, Ti, Fe, Zn, Sr, P, Mn, Rb, and Zr. No statistically significant differences, within or between bottles, in the elemental composition of samples were observed relative to the uncertainty in the XRF measurement, which was less than 0.4%. Sample homogeneity was also assessed from certification analysis results by applying ANOVA to bottle-to-bottle, sample-to-sample, and instrument variance information provided by each analytical method. This method uncovered an inhomogeneity of approximately 4% for Pb from measurements made by thermal ionization isotope-dilution mass spectrometry (TI–IDMS) and laser-enhanced ionization spectrometry (LEIS) on samples weighing between 250 and 500 mg.

Decomposition procedures

Though some analytical methods, such as instrumental neutron activation analysis (INAA) and inert gas fusion (IGF), could be used to analyze the sediment directly with little or no sample preparation, most techniques required a decomposition step before analysis. In order to maintain the "independence" of analytical methods, different decomposition procedures were specified for similar methods. For example, a lithium metaborate fusion was selected for direct-current plasma (DCP) analysis, since this commonly uses lithium as an interference buffer. Acid digestion was chosen for inductively-coupled plasma (ICP) emission spectrometry to maintain method independence. Information on the decomposition procedures for all the analytical methods is listed in Table 2.

SRM 2704 was readily brought into solution after a lithium metaborate fusion. However, several analysts reported that acid digestion in an open vessel, with a combination of hydrofluoric, nitric and perchloric acids, left a small residue of dark particles. These particles were examined by several analytical methods. Arc emission spectroscopy reported Ti as the major component, Al, Ca, Fe, Mg, Mn, Si, Zr as minor components, and Cu as a trace component. ICP (lithium metaborate fusion) revealed the presence of Ti, Fe, Ca, and Al. The electron microprobe showed rutile (TiO_2), zircon ($ZrSiO_4$), chromite ($FeCr_2O_4$), and unknown particles which were possibly coal (C, S) and glass (Na, Si, Ca, Mg, K, Al). X ray diffraction indicated diaspore and boehmite [AlO(OH)], rutile and anatase (TiO_2), zircon ($ZrSiO_4$) and corundum (Al_2O_3). Figure 2 shows two of the particles that were recovered from the acid digestion.

Of the elements reported present in the residue from acid digestion, only Ti showed a negative bias when results from techniques which used fusion of samples (XRF, DCP) or direct analysis (INAA) were compared with techniques using acid digestion (ICP). The ICP result for soluble Ti in the acid-digested SRM 2704 was approximately 10% lower than the total Ti reported for the XRF, DCP, and INAA determinations.

Analytical measurements

The co-operating laboratories, the elements determined, participating analysts, and the techniques selected for certification analysis are listed in Table 2. Each laboratory was given a set of instructions which detailed the number of samples to be analyzed, the drying procedure, the dissolution procedure (if applicable), the control samples to be analyzed, and the information relative to method bias and precision which should be included with the individual reports of analysis.

RESULTS

Certified values

The certified values determined from SRM 2704 are listed in Table 3. Each certified value is a weighted mean of results from two or more independent analytical techniques. When only NIST laboratory results were used to determine the certified values, the weights for the weighted means were computed according to the iterative procedure of Paule and Mandel.[16] When co-operating laboratory results were included in calculation of the certified values, all results were weighted equally. The procedure of Paule and Mandel assumes that the uncertainty limits placed on analytical results accurately reflect both random and systematic error and that method bias has not been underestimated. The assumption is made for results obtained at NIST because of the strict in-house controls on analysis procedures and data-reporting that are required.

Noncertified values are given in Table 4 for a large number of elements. There are several reasons why a concentration value may not be certified. If a bias is suspected in one or more of the methods required for certification, or if two independent methods are not available, the element concentration cannot be certified. Certified values for some of these elements will eventually be provided in a revised certificate when more data are available.

Uncertainty in certified values

The uncertainty reported for each certified element reflects the material inhomogeneity and random and systematic errors among the methods used for

(b) Titanium—results by the technique using acid digestion (ICP) were eliminated in the determination of the certified value. (c) Cadmium—one result by the GFAAS technique was biased but results from other laboratories or techniques made certification possible.

certification. The total uncertainty is the sum, in quadrature, of estimates for each component of uncertainty. It is expected that the limits defined by the uncertainty estimate will cover the concentration in a minimum sample size of 250 mg for 95% of subsamples, with 95% confidence. The statistical evaluation of this SRM as well as others will be detailed in a future publication.[17]

Figure 3 compares results obtained by individual techniques in the determination of certified values and uncertainties for calcium, titanium, and cadmium. For calcium, in Fig. 3(a), agreement between all analytical methods was obtained, and the certified value fell within the uncertainties reported for all analytical methods. In Fig. 3(b), the ICP determination of soluble titanium is included in the figure (but not in the certification) to show the degree of bias caused by the rutile (TiO_2) left after the acid digestion. For the determination of titanium following acid digestion, the reason for technique bias was known and results based on acid digestion could be eliminated on a firm basis. For cadmium, in Fig. 3(c), one set of GFAAS data appears to be significantly in error, but the reason for the bias could not be found. In this example, the information from other laboratories using GFAAS, or from other analytical methods, was sufficient to allow elimination of the data from the biased method. Certification was then based on the remaining results. At the time of writing this paper, two elements, sulfur and strontium, could not be certified because of discrepancies between the results from different analytical techniques.

Table 5 lists the uncertainties in the certified values for SRM 2704 and several other sediment reference materials issued since 1980. The uncertainties are presented as "per cent relative uncertainties" (%RU), which are derived from the equation (%RU = 100 × U/C), where U is the total range of the uncertainty (from lower to upper bound) and C is the certified value. The values of %RU given in Table 5 are the average %RU for the designated concentration range. The values of %RU should be viewed only qualitatively, since they are influenced by many variables such as sample homogeneity, element

concentration, number of elements certified, certification procedure, and method of calculation. Nevertheless, two major trends are apparent in the data set.

First, the uncertainties increase as the certified concentrations decrease. The highest concentration range, greater than 1000 μg/g, represents measurements by classical analytical techniques capable of high precision and by instrumental methods used in high precision modes. Bias of individual techniques or laboratories and sample inhomogeneity contribute greatly to the uncertainty in this concentration range. As the constituent concentrations in these materials decrease, the uncertainty associated with reported values increases, since method bias caused by matrix-induced interferences and contamination makes larger contributions to the overall uncertainty of the individual analytical techniques. At the lowest concentrations, where the detection limits of the techniques are approached, random and systematic error due to fundamental instrument processes (*e.g.*, shot-noise, scatter) become significant, and the number of useful techniques becomes limited.

Second, the confidence limits for certified values at all concentration levels decrease by a factor of almost two for the newest sediment SRMs, such as SRM 2704 and the Pacific Coast sediment (PACS-1) issued by the National Research Council of Canada. This improvement at high concentrations can be attributed to experience gained in the collection and processing of previous sediment materials as well as improved quality control and analytical procedures. At low concentrations, much of the improvement is due to the developments in analytical methodology for trace analysis that have occurred in the last decade.

Acknowledgements—The authors which to thank John R. Adams and the U.S. Army Corps of Engineers, Buffalo, NY, for their help in the site selection and collection of the Buffalo River sediment. The statistical analyses involved in the certification process were performed by Susannah Schiller of the NIST Statistical Engineering Division. Acknowledgement and thanks are due to all the participants in the certification, as listed in the text of the manuscript.

LASER-EXCITED ATOMIC-FLUORESCENCE SPECTROMETRY IN AN ELECTROTHERMAL ATOMIZER WITH ZEEMAN BACKGROUND CORRECTION

J. P. DOUGHERTY, F. R. PRELI, JR. and R. G. MICHEL*
Department of Chemistry, University of Connecticut, Storrs, CT 06268, U.S.A.

(*Received* 17 *March* 1988. *Accepted* 21 *July* 1988)

Summary—A pulsed excimer-pumped dye laser was used to excite atomic fluorescence in a graphite tube electrothermal atomizer. A 60-Hz ac magnetic field was applied around the atomizer and parallel to the excitation beam, for Zeeman background correction. The correction system was found to degrade the detection limits for silver, cobalt, indium, manganese, lead, and thallium by a factor of between 1 and 10. An increase in magnetic field strength, or a decrease in laser linewidth, should improve the detection limits, but was not possible here. For copper, the application of Zeeman background correction was unsuccessful because the instrumentation was unable to resolve the sigma components from the laser emission profile sufficiently during the background correction measurement. For elements that exhibit sufficient Zeeman splitting, the linear dynamic range was the same with or without background correction. Zeeman background correction was used to correct for scatter, in the resonance fluorescence determination of manganese in a zinc chloride matrix and in mouse brain tissue.

Electrothermal-atomizer (ETA) laser-excited atomic-fluorescence spectrometry (LEAFS) is currently one of the most sensitive techniques for the determination of metals.[1-5] For the elements that have been studied, ETA–LEAFS detection limits are 3–5 orders of magnitude better than flame–LEAFS, and up to 4 orders of magnitude better than ETA atomic-absorption spectrometry (ETA–AAS). In addition, the linear dynamic range of ETA–LEAFS is typically 5–7 orders of magnitude.

The use of Zeeman background correction for electrothermal-atomization, atomic-absorption spectrometry (ZETA–AAS) is widely accepted, and several reviews have been published.[6-8] The advantages of the Zeeman technique, compared to other background correction techniques, are that the background correction measurement is made *at* the analytical wavelength, and that only one radiation source is required.

Three instrumental configurations are possible for applying the inverse Zeeman effect (field situated around the atom cell) to ETA–LEAFS in a tube furnace, and are the same as those appropriate for conventional excitation sources.[9] An ac field can be placed parallel to the laser excitation beam, or an ac or dc magnetic field can be placed perpendicular to the laser excitation beam. For all three configurations, the background-correction measurement is made at the same wavelength as the atomic-fluorescence measurement.

In the configuration used here, an ac magnetic field was positioned around the ETA, parallel to the laser excitation beam. In Fig. 1, the atomic energy levels are shown for the "field off" and "field on" conditions, assuming that there is a normal Zeeman splitting pattern. When the field is off, analyte atomic fluorescence is collected, along with various possible background signals. When the field is on, the analyte atomic energy levels are split into sigma components that are displaced away from the laser excitation wavelength, and no analyte atomic fluorescence occurs. The background-corrected atomic-fluorescence signal results from subtraction of the "field on" signal from the "field off" signal.[10]

The following discussion summarizes the sources of background in ETA–LEAFS with respect to the ability of the Zeeman effect to provide background correction.

SOURCES OF BACKGROUND FOR ETA–LEAFS

The most commonly reported sources of background in LEAFS are scattered and stray laser

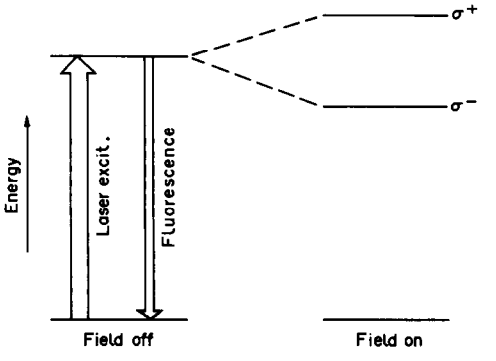

Fig. 1. Zeeman energy levels for an ac magnetic field parallel to the excitation beam.

*Author to whom correspondence should be sent.

radiation and black-body emission from the atom cell. Scattered radiation arises from sample matrix particles formed within the furnace during the atomization step. The stray radiation is laser light reflected into the monochromator from the various parts of the instrument. Atomic and molecular fluorescence from species other than the element of interest may also pose a background problem.

Scattered laser radiation and black-body emission

For resonance LEAFS, scattered or stray laser radiation appears to be the major source of background in ETAs. For nonresonance LEAFS, stray light may be important when a wide-bandpass monochromator is used and the detection wavelength is relatively close to the excitation wavelength. Neither scatter nor stray light is dependent on the magnetic field strength. ZETA–LEAFS would be expected to correct for both. It has already been shown that Zeeman background-correction can correct for scatter in flame atomic-fluorescence spectrometry (AFS) when a conventional source of excitation is used.[11]

For ETA–LEAFS, the magnitude of the black-body emission signal from the atomizer is dependent on the type of atomizer (cup, tube or rod), the temperature required for atomization and the wavelength of detection. ETA black-body emission can degrade the limit of detection at high atomization temperatures, and for detection of fluorescence in the visible region of the spectrum.[4,5] For tube ETAs, the amount of black-body emission reaching the detector can be reduced by carefully baffling the radiation emitted from the walls of the hot tube and imaging the center of the tube onto the slit of the monochromator.[4,5] Black-body emission is unaffected by a magnetic field and therefore can be corrected for by ZETA–LEAFS.[10]

Atomic fluorescence

The common spectral overlaps of various atom lines have been studied in conventional-source AFS. The extent of a spectral overlap in LEAFS will increase with an increase in the laser linewidth over that of a hollow-cathode lamp (HCL) or electrodeless-discharge lamp (EDL). Weeks *et al.*[12] reported a spectral interference in the resonance LEAFS determination of manganese in the presence of gallium. Both elements were excited at 403.3 nm in an air/acetylene flame by radiation from a dye laser with a 0.01 nm linewidth. This interference was circumvented by exciting the resonance transition for manganese at 403.1 nm. At this wavelength, a resonance transition for gallium does not occur. Direct atomic spectral overlaps cannot be corrected for by ZETA–LEAFS (or ZETA–AAS) because the transition will be split away from the laser wavelength during the "field on" measurement and the magnitude of the signal will be different from the "field off" measurement. We have not yet studied any matrices that give rise to direct spectral overlaps for ZETA–LEAFS.

Molecular fluorescence

Fujiwara *et al.*[13] and Bonczyk *et al.*[14] have reported laser-induced fluorescence spectra of the common molecular species found in air/acetylene and nitrous oxide/acetylene flames. These species included OH, CH, C_2 and CN. Other workers[15–17] have identified laser-induced molecular fluorescence spectra for various species formed in the flame after aspiration of solutions of metal salts into the flame. The species identified included metal chlorides, metal oxides and metal hydroxides.

Molecular fluorescence should not be as prevalent for ETA–LEAFS as it is for flame–LEAFS, because atomization in the ETA occurs in an argon atmosphere. However, the presence of small molecules in furnaces has been confirmed by absorption techniques[18–20] and it is possible that these molecules could exhibit laser-induced molecular fluorescence. Broadband molecular fluorescence is relatively unaffected by magnetic field strength and could be corrected for by ZETA–LEAFS. If the molecular spectra contain fine structure, then the situation becomes analogous to ZETA–AAS, where molecular interferences have been shown to interfere with Zeeman background correction.[20] Molecular interferences have not been studied for ZETA–LEAFS.

Radiofrequency noise

High-power, high-repetition rate, pulsed laser systems (such as excimer and copper vapor lasers) generate radiofrequency (rf) interference that can add to the background signal and noise levels in LEAFS. Rutledge *et al.*[21] showed several methods to correct and/or reduce the rf noise created by a high-repetition rate copper vapor laser. The rf noise produced by most laser systems can be reduced by properly shielding the laser and the detection electronics. Any remaining rf signal can be corrected for by ZETA–LEAFS because the magnitude of the signal would be the same for both the "field on" and "field off" measurements. A degradation in the detection limit for ZETA–LEAFS would be expected, however, from the noise component of the rf signal.

ZETA–LEAFS

We have already shown that ZETA–LEAFS can be used to correct for furnace black-body emission,[10] which can be the major source of background in ETA–LEAFS when nonresonance fluorescence transitions are used. In that paper, ZETA–LEAFS was used to correct for scatter and stray light for the resonance fluorescence determination of manganese in a zinc chloride matrix. ZETA–LEAFS was also used to determine manganese in mouse brain tissue.

EXPERIMENTAL

ZETA–LEAFS instrumentation

The details of the ZETA–LEAFS instrumentation have been given elsewhere,[10] but are summarized here. The instrument used an excimer-pumped dye laser with capability for frequency doubling. The laser was operated at a pulse repetition rate of 80 Hz. A small portion of the excimer laser beam was used to trigger a two-channel boxcar averager to process the fluorescence signals from a monochromator/photomultiplier tube (PMT)/pre-amplifier assembly placed at right angles to the laser excitation beam. Each channel of the boxcar was operated at 40 Hz to collect the "field off" and "field on" signals alternately. We have published a summary of our laser operating parameters and atomic transitions.[4] The laser power was sufficient to saturate the copper, indium, lead, and thallium transitions. The dye laser radiation was frequency-doubled for all the elements tested, except indium and thallium.

Details of the furnace atomizer have been described elsewhere.[4] Furnace tubes were fabricated from POCO AXF-5Q1 graphite, and were 8 mm long, with an outside diameter of 9.6 mm and a wall thickness of 1.0 mm. A 4-mm diameter hole was drilled through the wall of the tube to allow laser radiation to pass through at a right angle to the bore of the tube. A 10-μl sample aliquot was atomized from the wall of the furnace tube, and the fluorescence emitted along the axis of the tube was measured.

An ac electromagnet, with a variable field strength of up to 13 kG was used to split the atomic transition into its Zeeman components.[10]

The "field off" and "field on" signals were separately processed by a boxcar averager, and their difference could be obtained by the boxcar to provide the background-corrected atomic-fluorescence measurement. The "field off" signal was comprised of the analyte atomic fluorescence + background. The signal in this channel of the boxcar was the usual ETA–LEAFS measurement. The "field on" signal was comprised ideally of background only, but could also arise from sigma-component atomic fluorescence if the sigma components were not far enough removed from the laser excitation profile. The corrected signal was the result of subtraction of the "field on" signal from the "field off" signal. Any of the three boxcar signals could be processed by the computer, which calculated both peak area and peak height of the furnace signal. Peak area data were used exclusively.[10]

Limits of detection and calibration curves

The limit of detection was determined by extrapolation of the calibration curve to a signal level equal to three times the standard deviation of 16 measurements of the blank. For elements where the environmental contamination level was high, the measurement of the blank noise was performed with the laser tuned first to the analytical wavelength and then to a wavelength approximately 0.1 nm away from the analytical wavelength. The first measurement gave rise to a detection limit degraded by the additional noise present from the blank signal. The second measurement was indicative of the detection limit possible if the source of environmental contamination were controlled.

The calibration curves were constructed by using a combination of PMT voltages and neutral density filters.[10] The solutions used to determine the detection limits and linear ranges were prepared daily, in a class 100 clean-air environment, by serial dilution of a 1-mg/ml standard. A medium of 0.04*M* nitric acid in demineralized water was used.

ZETA–AAS conditions

Manganese was determined with a commercial ZETA–AAS instrument for comparison with ZETA–LEAFS. A Perkin-Elmer Zeeman 5000 AAS instrument was used with an HGA-500 furnace controller and an AS-40 autosampler. Magnesium nitrate (50 μg) was used as the matrix modifier. A 20-μl sample was atomized from a L'vov platform at a temperature of 2200°. The manganese absorption transition at 279.5 nm was used, with a spectral bandpass of 0.7 nm. Further details of the AAS method have already been given.[22]

RESULTS AND DISCUSSION

Detection limits and precision

Table 1 contains a comparison of detection limits for ZETA–LEAFS and ETA–LEAFS, made with the same ETA system, as well as a comparison with the best reported ETA–LEAFS values. A comparison with the ETA–AAS detection limits published by Slavin[23] also appears in Table 1. The use of Zeeman background correction degraded the detection limits by factors of 1–10 relative to those for ETA–LEAFS. The magnitude of the ZETA–LEAFS signal was dependent on the Zeeman splitting, the laser linewidth, and the atomic spectral profile. For the ideal case, the only signal in the "field on" channel of the ZETA–LEAFS instrument would be background. When the atomic transition did not exhibit sufficient splitting, a signal arose in the background channel from analyte atomic fluorescence of the sigma components that overlapped the laser emission profile. The overlap became worse if the laser emission profile

†Could not be measured, see text.

was broad, or if the sigma component atomic spectral profile was broad.[24]

The ZETA–LEAFS detection limits were expected to be somewhat inferior to the ETA–LEAFS detection limits because the boxcar repetition rate for the ZETA–LEAFS analyte signal channel was 40 Hz, instead of the 80 Hz used for ETA–LEAFS. The ZETA–LEAFS background signal was also measured at 40 Hz repetition rate. This led to poorer sampling statistics and hence poorer analytical precision. The precision of the ZETA–LEAFS measurements was found to be 30% RSD for 10 successive atomizations of 100 pg of cobalt. The precision of ETA–LEAFS measurements made under similar conditions was 13% RSD.[10] The precision of thallium ZETA–LEAFS signals was 20% RSD. The improvement for thallium probably occurred because the thallium transition was saturated, whereas the cobalt transition was not. Under saturation conditions, pulse to pulse fluctuations in the laser power have only a minor effect on the resultant signal, because the fluorescence is only slightly dependent on laser power. In contrast, for unsaturated transitions, the fluorescence signal is linearly dependent on laser power. The relative standard deviation of the pulse to pulse power fluctuations for the laser used was approximately 10%.

The detection limits for indium, lead, and thallium were obtained under saturation conditions. The ZETA–LEAFS detection limit for indium is better by a factor of 2 than that reported previously for ETA–LEAFS, whereas the lead detection limit is a factor of 5 worse than the best reported value. It is difficult to compare the thallium detection limit with literature values because it was obtained by using the 377 nm/535 nm (excitation wavelength/fluorescence detection wavelength) transition, different from that generally used in the literature reports (276 nm/353 nm). It was assumed that the literature detection limit quoted here was obtained by using the more sensitive transition, but this was not stated in the report.[2] We have since improved upon the ETA–LEAFS thallium detection limit by a factor of 17 (decreasing it from 0.1 pg to 0.006 pg) by using the more sensitive transition.[25] The ZETA–LEAFS detection limits for indium, lead, and thallium were better than the ETA–AAS values by factors of 325, 800, and 30, respectively.

The application of Zeeman background correction to nonresonance LEAFS of copper was unsuccessful because of the incomplete splitting of the sigma components away from the emission profile of the laser at a field strength of 12 kG.[24] A narrower laser linewidth or a larger magnetic field (*i.e.*, wider splitting of the sigma components) should allow Zeeman background correction to be used for ETA–LEAFS of copper.

Although the quantum states for the silver and copper transitions were identical, and the laser linewidth was the same, the loss in sensitivity for ZETA–LEAFS of silver was not as severe as it was for copper. A large atomic-fluorescence signal was measured in the "field on" channel for silver, owing to the sigma components, but this signal was smaller than the one measured for copper because the atomic spectral profile for silver was somewhat narrower. This meant that the sigma component overlap was smaller for silver than for copper. A detection limit of 0.2 pg of silver was obtained for ZETA–LEAFS. The detection limit was a factor of 10 poorer than for ETA–LEAFS.

Stray light was a more serious problem for the ZETA–LEAFS determination of manganese by resonance fluorescence, than for ETA–LEAFS, because the ac electromagnet caused the furnace assembly to move when a 12-kG field was applied. Movement of the graphite tube caused the laser beam to be reflected from the sides of the laser ports into the monochromator, which added to the noise level of the blank measurements. The movement was due to the magnetic field generated by the current passing through the furnace assembly. This movement was not as serious a problem for nonresonance ZETA–LEAFS because stray light was usually not the limiting noise source. The detection limit for resonance ZETA–LEAFS of manganese, at 279.5 nm, was 1 pg, which is considerably worse than for ETA–LEAFS but the same as for ETA–ASS.

Choice of excitation transition for ZETA–LEAFS

The use of a tunable laser for excitation offers the possibility of using alternative atomic transitions for ZETA–LEAFS, unlike use of conventional radiation sources which cannot be wavelength tuned. As shown above, the use of Zeeman background correction may degrade the detection limit if the sigma component splitting is poor. In these cases, another transition might be used that exhibits better Zeeman splitting. The principle of alternative line selection for ZETA–LEAFS is described below for manganese.

The laser linewidth used to excite manganese at 279.5 nm was approximately 0.003 nm, and there was a significant overlap of the sigma components with the laser emission profile when Zeeman background correction was applied. This overlap produced a fluorescence signal, when the magnetic field was applied, that was 50% of the fluorescence signal in the absence of the magnetic field, leading to a significant degradation in the detection limit. The degradation resulted not only from the 50% signal loss, but also from the additional noise incurred by the poorer sampling statistics of ZETA–LEAFS.

The Zeeman splitting patterns for the three manganese transitions that occur near 280 nm are shown in Fig. 2. The splitting patterns were calculated with assumption of Russell–Saunders coupling.[6] A field strength of 11.7 kG was used in the calculations. In the figure, the upper profiles are the convolution of the analyte atomic spectral profile and the laser

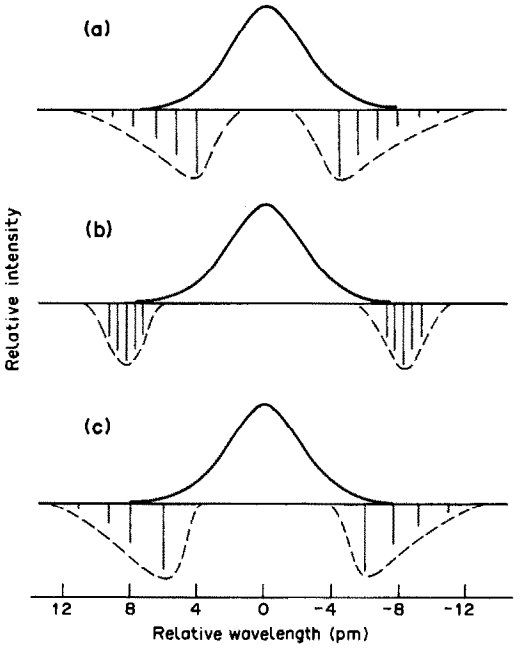

Fig. 2. Zeeman splitting patterns for Mn. The convolution of the laser emission profile and atomic spectra profile is shown along with the (inverted) calculated sigma component splitting pattern. (a) 279.5 nm ($^6S_{5/2}$–$^6P_{7/2}$), (b) 279.8 nm ($^6S_{5/2}$–$^6P_{5/2}$), (c) 280.1 nm ($^6S_{1/2}$–$^6P_{3/2}$).

linewidth, measured with the field off.[24] The calculated sigma component profiles are shown inverted for clarity. From the figure it would be concluded that the best Zeeman splitting occurs at the 279.8 nm transition, which is accessible with the laser dye used for 279.5 nm.

The 279.8 nm transition produced a "field on" fluorescence signal that was only 6% of the fluorescence signal when the field was off. Excitation of the resonance atomic transition at 279.8 nm produced LEAFS signals approximately 20% smaller than those produced from the more sensitive 279.5 nm transition. (The sensitivity difference was determined by measuring the LEAFS signal for a 1 μg/ml manganese standard in an air/acetylene flame with a laser power of 2 μJ/pulse.) In this case, an improvement in the detection limit would be expected with excitation at 279.8 nm rather than 279.5 nm, because of better Zeeman splitting, even though the 279.8 nm transition is less sensitive. We did not measure the detection limit at 279.8 nm, but the "field off" noise level would be expected to be identical to that measured at 279.5 nm, while the "field on" noise level would be less. The linear dynamic range would also be expected to improve because the onset of sigma component overlap from broadening of the atomic spectral profile would be expected to occur at a higher concentration for the 279.8 nm transition. The effect of atomic spectral profile broadening on the linear dynamic range is discussed below.

It is interesting to note that, if the fluorescence transition is saturated, this does not mean that the excitation of the sigma components, by overlap with the laser emission spectral profile, will also be saturated. This is because the absorption coefficient is relatively small in the wings of the sigma component profile. Hence, an increase in laser power will increase the "field on" fluorescence of the sigma components to a greater extent than the "field off" fluorescence at the saturated analytical line. This extra sigma component fluorescence will be subtracted from the "field off" signal and the detection limit will be degraded. To minimize the relative contribution of the sigma component fluorescence, it is prudent to use the minimum laser power required to saturate the transition. Doing this also minimizes the signal and noise contributions from scatter and stray light backgrounds. For the manganese data reported above, the transition was not saturated, and so these considerations did not apply.

Linear dynamic range

The ZETA–LEAFS calibration curve for cobalt was linear (within 10%), with a relative slope of 1, for 5.5 orders of magnitude from the detection limit, and started to curve at 100 ng (10 μg/ml).[10] For indium, lead, and thallium, the linear range was 6 orders of magnitude. The calibration curves for indium and lead started to curve at approximately 10 ng (1 μg/ml). The thallium ZETA–LEAFS calibration curve was linear up to 100 ng (10 μg/ml). The ZETA–LEAFS linear dynamic ranges for cobalt, indium, lead, and thallium were the same as the linear dynamic ranges obtained for ETA–LEAFS.

Zeeman background correction decreased the linear portion of the calibration graph for silver from 5.5 to 3.5 orders of magnitude. At high concentrations, the atomic spectral profile broadened owing to a combination of pre- and post-filter effects, and self-absorption.[26] The broadening of the sigma component spectral profile increased the signal in the "field on" channel, causing more curvature, at high concentrations, for ZETA–LEAFS calibration graphs compared to ETA–LEAFS calibration graphs. For most elements, the onset of this effect occurs at concentrations above the linear range of ETA–LEAFS. For silver, however, the sigma component overlap with the laser emission line was relatively large even at low concentrations. Therefore, the curvature caused by sigma component line-broadening occurred at a relatively low concentration. A more detailed discussion of the factors affecting the linear dynamic range for ZETA–LEAFS has been given elsewhere.[24]

Inverse ZETA–LEAFS

The ZETA–LEAFS calibration graph for silver was extended by an extra order of magnitude before the onset of curvature, by measuring the "inverse"

ZETA–LEAFS signal as follows. For "normal" ZETA–LEAFS, the laser was tuned to the analytical wavelength. The analyte atomic-fluorescence signal was measured while the magnetic field was off, and the background was measured while the field was on. For "inverse" ZETA–LEAFS, the analyte atomic fluorescence was measured while the field was on, by tuning the laser towards the sigma component absorption maximum. This allowed the background to be measured while the field was off, because analyte atomic fluorescence no longer occurred at the laser wavelength.

In Fig. 3, a plot of the silver fluorescence signal *vs.* excitation wavelength in the vicinity of the absorption profile, with and without the application of the magnetic field, is shown. Each point on the figure represents a single furnace atomization obtained after shifting the laser excitation wavelength away from the analytical wavelength by 3-pm increments. The maximum difference between the "field off" and "field on" signals occurred at the center of the absorption profile (labelled 0 in the figure). This is the analytical wavelength, where normal ZETA–LEAFS measurements were made. When the laser was tuned about 9 pm away from the center of the absorption profile, the "field on" signal became significantly larger than the "field off" signal. At this point, the "field off" analyte atomic spectral profile approached the baseline, and the "field on" sigma component atomic spectral profile was near its maximum. Calibration graphs were constructed for both normal and inverse ZETA–LEAFS, at the two wavelengths (0 and 9 in the figure) and are shown in Fig. 4. For the inverse ZETA–LEAFS calibration graph, measured at 9 pm from the line center, the signal was measured as "field on" minus "field off", the inverse of the normal ZETA–LEAFS signal which is measured as "field off" minus "field on". The calibration graph for normal ZETA–LEAFS starts to curve before the inverse ZETA–LEAFS graph does, owing to the differences in the extent of overlap of the sigma components with the laser emission profile. For ZETA–LEAFS, a large sigma component atomic-fluorescence signal was observed in the background

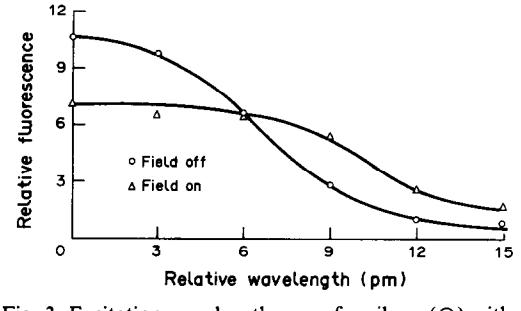

Fig. 3. Excitation wavelength scans for silver, (○) without application of a magnetic field, (△) with an applied field of 12 kG.

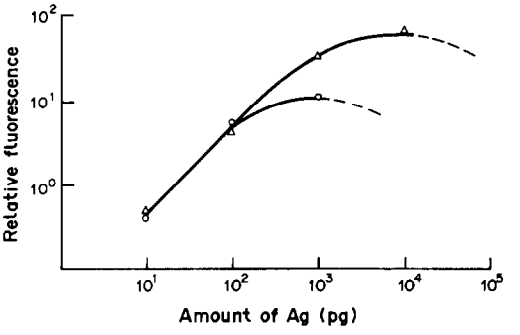

Fig. 4. The upper range of the ZETA–LEAFS calibration curves for Ag (○) measured with laser tuned to the resonance wavelength (328.1 nm), and (△) with laser tuned 9 pm away from the resonance wavelength.

channel at low concentrations. The sigma component fluorescence signal increased further as both sigma components began to broaden and overlap the laser emission profile from both sides of the analytical wavelength. For inverse ZETA–LEAFS, the fluorescence signal in the background channel increased because of the broadening of the "field off" absorption profile. This signal was minimized by tuning the laser to as far from the central wavelength as possible.

Inverse ZETA–LEAFS could be used to extend the calibration curves for those elements for which the Zeeman splitting is marginal, and a narrow laser linewidth or larger field strength is unavailable. Alternatively, normal ZETA–LEAFS could be used with a narrower linewidth to reduce the overlap of the sigma components with the laser emission profile. In addition, a stronger magnetic field could be used to split the sigma components further away from the laser emission profile. The signal magnitude for inverse ZETA–LEAFS would be decreased by at least a factor of 2 relative to ETA–LEAFS because, theoretically, each sigma component absorbs only half as much radiation as the analyte does in the "field off" channel of normal ZETA–LEAFS. For anomalous transitions a further reduction in the signal size may result from sigma component splitting. Detailed experiments were not performed to assess the utility of inverse ZETA–LEAFS for sample analysis.

Correction for furnace black-body emission

We have shown that ZETA–LEAFS corrects for furnace black-body emission, which was the main source of background in the nonresonance fluorescence determination of cobalt.[10] Here, furnace black-body radiation was also the major source of noise for the nonresonance fluorescence determination of indium, lead, and thallium, and was corrected by ZETA–LEAFS.

Correction by ZETA–LEAFS for scatter

ZETA–LEAFS resonance fluorescence, at 279.8 nm, was used to determine manganese in a 1 mg/ml

Table 2. Determination of manganese by ZETA–LEAFS

Technique	Calibration method	Sample matrix	Mn,* *ng/ml*	RSD, %
ZETA–AAS	Aqueous calibration	$ZnCl_2$	4.8 ± 0.1	2
ZETA–AAS	Standard additions	$ZnCl_2$	5.1 ± 0.1	2
ZETA–LEAFS	Aqueous calibration	$ZnCl_2$	5.0 ± 1.5	30
ZETA–AAS	Aqueous calibration	Mouse brain	1.6 ± 0.1	6
ZETA–LEAFS	Standard additions	Mouse brain	1.9 ± 0.4	20

*Mean ± standard deviation.

zinc chloride solution. The results are compared in Table 2 with results obtained with ZETA–AAS.

A signal from scattered radiation was measured by ETA-LEAFS when a zinc chloride solution was analyzed. The scattered radiation appeared to be independent of the laser excitation wavelength. Figure 5 shows the scattered radiation on analysis of 10 μl of a 1-mg/ml zinc chloride solution, measured at several different laser excitation wavelengths in the vicinity of the manganese 279.8 nm line. Three furnace atomizations were made for each wavelength increment and the error bars in the figure represent ± 1 standard deviation of the scatter signal measured. The precision of the scatter measurements is poor, but the signal is essentially constant across the wavelength range. Also shown in the figure is the approximate atomic spectral profile for 50 pg of Mn.

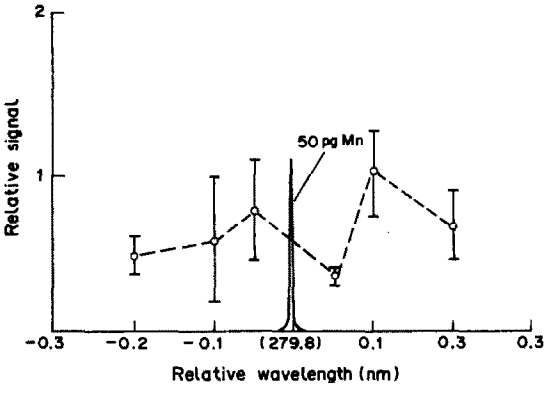

Fig. 5. Scatter signal as a function of excitation wavelength for a 10-μl aliquot of a 1 mg/ml solution of $ZnCl_2$. The error bars represent 1 standard deviation of the measurement. An ETA–LEAFS atomic spectral profile for 50 pg of Mn is shown for comparison.

ZETA–LEAFS was used to correct for the scattered radiation caused by the zinc chloride matrix. Aqueous manganese standards were used to determine the manganese present in this matrix. The furnace signals for the sample are shown in Fig. 6. The "field on" signal was primarily the scattered radiation caused by the matrix. The "field off" measurement consisted of scattered radiation and manganese atomic fluorescence. The corrected signal ("field off" – "field on") consisted of the manganese

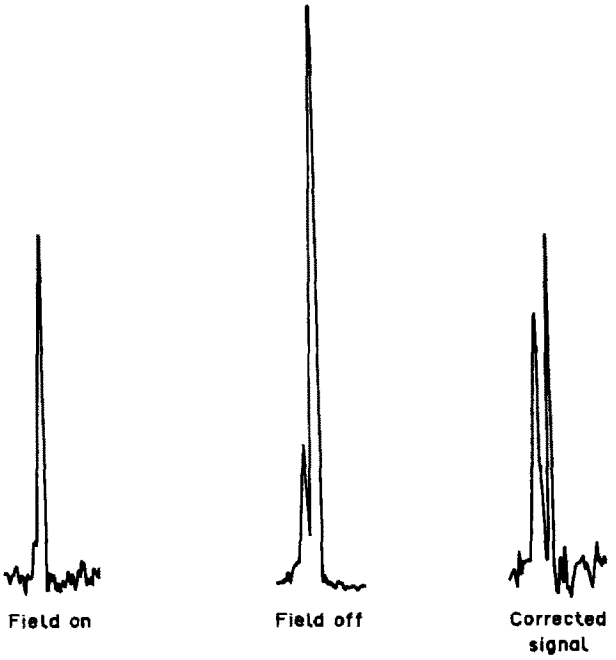

Fig. 6. ZETA–LEAFS furnace signals for 5-ng/ml Mn in a 1-mg/ml $ZnCl_2$ matrix. The "field on" signal is mostly due to scatter. The "field off" signal is analyte atomic fluorescence + scatter. The subtraction of the "field on" signal from the "field off" signal results in the corrected signal.

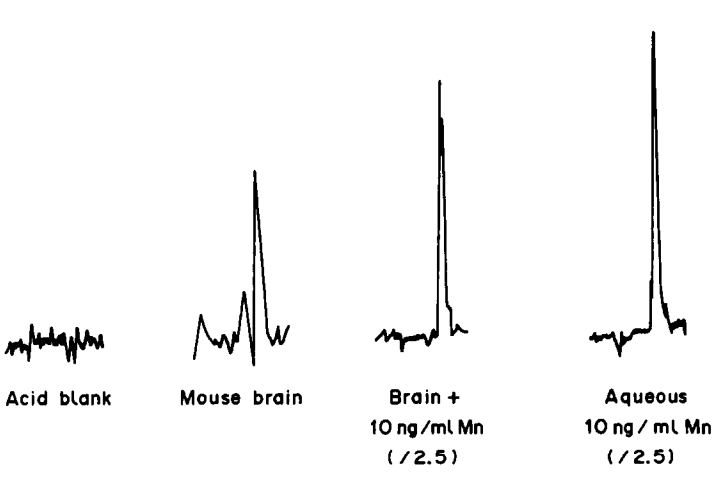

Fig. 7. ZETA–LEAFS furnace signals for the determination of Mn in mouse brain tissue.

atomic fluorescence only. The noise of the corrected signal was worse than that of the other two signals because of the poorer sampling statistics for ZETA–LEAFS compared to ETA–LEAFS. The signal caused by scatter was approximately of the same magnitude as the analyte fluorescence signal. The "background-corrected" signal was evaluated by means of a calibration graph constructed by use of aqueous manganese standards. The results agreed well with those obtained by ZETA–AAS analysis of the same sample (Table 2). For ZETA–AAS, both aqueous calibration and the method of standard additions were used to determine the concentration of manganese in the sample, with similar results for both approaches.

Determination of manganese in mouse brain tissue

ZETA–LEAFS was also used to determine manganese in a mouse brain matrix. Each whole mouse brain was digested in nitric acid according to a procedure used before.[22] For ZETA–LEAFS, the furnace conditions for the determination of manganese in the mouse brain matrix were not rigorously optimized. The furnace used for ZETA–LEAFS did not have temperature feedback, which precluded the use of a L'vov platform. ZETA–LEAFS furnace signals obtained in the determination of manganese in mouse brains are shown in Fig. 7. The signal for the mouse brain sample plus a 10-ng/ml standard addition of manganese was smaller than that obtained for the 10-ng/ml aqueous manganese standard, owing to vapor phase interferences, and the method of standard additions was required for the determination of manganese in mouse brains by ZETA–LEAFS. The same types of interferences occur in ZETA–AAS, and were minimized here by the use of a rapidly heated furnace, platform atomization, and matrix modifiers.[22] Matrix modifiers were not used for ZETA–LEAFS. The results of the standard-additions ZETA–LEAFS analysis (Table 2) agreed well with those obtained by ZETA–AAS.

CONCLUSION

ZETA–LEAFS has been shown to correct for background for the nonresonance fluorescence determination of cobalt, indium, lead, and thallium in aqueous solutions, and for the resonance fluorescence determination of manganese in aqueous solution, a zinc chloride matrix, and in mouse brain tissue.

The degradation of the detection limit by a factor of 1–10, in comparison to ETA–LEAFS, is somewhat worse than the results obtained for ETA–AAS.[27] For ETA–ASS the detection limit is degraded by approximately a factor of 2–3 for most elements. This was not considered here to be a significant detraction from the ZETA–LEAFS technique, because the detection limits could be improved by the use of a laser with a narrower linewidth, or by the application of a greater magnetic field strength. For ETA–ASS, a magnetic field strength of 8 kG is sufficient to split the sigma components away from the HCL or EDL emission profile.[27] For ZETA–LEAFS a field strength of 12 kG was not able to split the sigma components far enough away from the laser emission profile for some elements (*e.g.*, silver, copper). A field strength of approximately 16 kG would be required to accomplish this. Alternatively, the use of intracavity diffraction gratings to narrow the laser radiation to <0.002 nm would reduce the field strength requirements.

The linear calibration range for ZETA–LEAFS does not suffer, in ccomparison to ETA–LEAFS, for elements that exhibit sufficient Zeeman splitting. For ZETA–AAS, the use of Zeeman background correction causes "rollover" of the calibration curves. In ETA–ASS, the linear calibration range is approximately 2–3 orders of magnitude. Zeeman background correction can decrease the linear range.[28]

The benefits of using an atomizer with temperature feedback and the L'vov platform for ZETA–LEAFS should be similar to those obtained for ZETA–AAS, for the analysis of complicated sample matrices. The current ZETA–LEAFS system is being modified to study matrix effects and backgrounds in more detail.

SAMPLE INTRODUCTION AND SEPARATION IN CAPILLARY ELECTROPHORESIS, AND COMBINATION WITH MASS SPECTROMETRIC DETECTION

RICHARD D. SMITH*, HAROLD R. UDSETH, JOSEPH A. LOO, BOB W. WRIGHT and GERALD A. ROSS
Chemical Methods and Separations Group, Pacific Northwest Laboratory, Richland, WA 99352, U.S.A.

(*Received* 11 *April* 1988. *Revised* 21 *June* 1988. *Accepted* 11 *July* 1988)

Summary—Capillary-electrophoresis methods are attracting interest owing to the ability to yield rapid high-resolution separations, but many aspects, such as sample injection, separation conditions and detection, need further development. Effects related to sample injection and buffer composition have been investigated. Automated methods for electromigration injection of nl-size sample volumes are shown to give a precision of approximately ±1%. Problems encountered with manual injection procedures have been examined by an electric field reversal technique. The effect of buffer pH on capillary zone-electrophoresis (CZE) separations can be attributed to changes in electro-osmotic flow velocities and to changes in the isoelectric points of analytes. The interfacing of capillary electrophoresis with mass spectrometry is described and demonstrated for a range of conditions, with a quaternary phosphonium salt mixture. Separations obtained by CZE and capillary isotachophoresis are compared and the relative advantages of the two techniques discussed.

Capillary electrophoresis consists of a set of micro-scale analytical separation methods, including capillary zone electrophoresis (CZE), isotachophoresis, isoelectric focusing and electrokinetic chromatography (the last is considered a chromatographic method, since it involves partitioning of the analyte with an electrophoretically migrating micellar phase).

Capillary zone electrophoresis is a form of free zone electrophoresis conducted in small diameter capillaries and capable of ultrahigh-resolution separations[1] based on differences in the electrophoretic mobilities of the analytes. CZE can be used for compounds of quite high molecular weight. The apparatus is easily assembled and separations involving more than 10^6 theoretical plates have been achieved in less than 20 min.[2–4] The electro-osmotic flow of the buffer medium makes CZE an elution technique which resembles chromatography, although the use of capillaries filled with gels is also feasible.[5] Thus CZE provides high-resolution separations and selectivities which can be manipulated by changing the electrophoretic medium (typically the pH and the buffer composition), as well as by utilizing the equilibria with electrophoretically migrating micellar phases. CZE is applicable to broad compound-classes and limited only by the necessity for adequate solubility and a non-zero net electrophoretic mobility. It is restricted to use of very narrow capillaries (generally < 150 μm i.d.) to suppress convection caused by a radial temperature gradient from Joule heating in the electrophoretic medium. The nearly flat flow-profile provided in the capillary by the electro-osmosis allows high separation efficiencies to be realized.

In this article we describe the results of experiments which demonstrate the operating conditions and performance of CZE. In particular, we deal with aspects of sample injection, the effect of buffer pH on separations, and some of the conditions necessary to obtain high efficiency separations. We also briefly consider the demands on detection in CZE. The CZE–MS combination developed in our laboratory, based on an electrospray ionization interface, is described. Finally, results obtained by using CZE–MS and capillary isotachophoresis–MS are compared and contrasted to illustrate the potentially important role of the latter method for many applications.

EXPERIMENTAL

Several different CZE instrumental arrangements were utilized for this research, the main difference being in the detector. CZE was conducted by use of a fused-silica capillary with automated electro-osmotic sample introduction at the high-potential electrode (the anode in most cases). The automated injection allowed precise introduction from small-volume vials containing the sample of interest. The apparatus used a Spellman high-voltage power supply capable of producing ±100 kV and an electronically controlled automated injection device located in a "Plexiglas" box equipped with safety interlocks to prevent contact of the user with high voltage. The electronically timed electro-osmotic injections (at 9 kV) could be varied from 0.1 to 30 sec. The fused-silica capillary (100 μm i.d., 1.5 m length) was filled with the CZE buffer (various pH values) and inserted in the buffer reservoirs both inside and outside

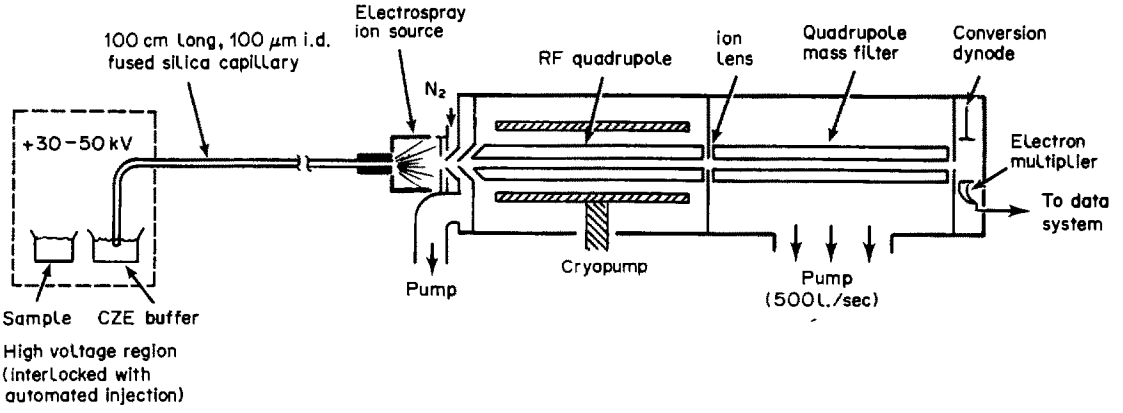

Fig. 1. Schematic illustration of the instrumentation for combined capillary electrophoresis–mass spectrometry.

the high-voltage region. Electrical contacts were made with the high voltage and ground potentials by means of platinum electrodes.

A laser-based fluorescence detection system for CZE provided detection limits in the attomole to subattomole range for suitable compounds. An HeCd laser (Liconix 4240N, 10 mW with 325 nm optics), with appropriate lenses and filters, provided an excitation beam focused onto the bare portion of the fused silica column. The fluorescence emission was filtered by using appropriate cut-off and band-pass optics and focused onto a high efficiency Centronix photomultiplier tube. In addition, more conventional CZE arrangements with a fluorescence (McPherson FL-748 spectrofluorometer) or UV absorption (ISCO V^4) detector modified for on-column application were used. The detector cell length was ~0.8 mm for fluorescence and 1.0 mm for UV detection, corresponding to cell volumes of 6.3 and 7.9 nl, respectively.

The instrumentation for CZE–MS with an electrospray ionization (ESI) inferace has been described in detail elsewhere.[6,7] Operation of CZE with ESI requires an uninterrupted electrical contact with the electro-osmotically eluting liquid at the capillary terminus. The electrical contact for the buffer at the low-potential (detection) end of the capillary was through a sheath of liquid, generally methanol or 2-propanol. This electrical contact also served to define the ESI voltage and was typically in the range 3–5 kV. The ESI focusing electrode was typically at +300 V (for positive ion operation). A nozzle-skimmer bias of 80–150 V was found to give optimum performance.

Figure 1 shows a schematic illustration of the CZE–MS instrumentation. Figure 2 gives a detailed view of one version of the liquid-sheath electrode and ESI interface. A precise pulse-free liquid flow for the sheath electrode was provided by a small syringe pump (Sage Instruments, Model 341B). The sheath electrode liquid allows the compositions of the electrosprayed liquid to be controlled independently of the CZE buffer, affording operation with buffers which could not be used previously (*e.g.*, aqueous and high ionic strength buffers).[8] The interface operation is independent of the CZE flow-rate. CZE capillaries are easily replaced and require no additional preparation. Since the electrospray

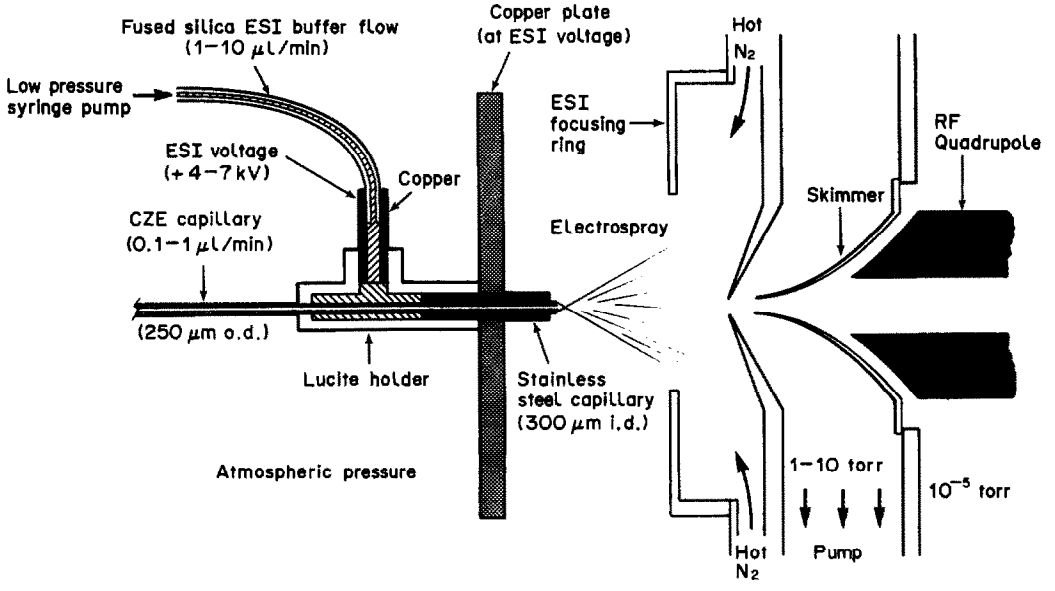

Fig. 2. Detailed schematic illustration of the electrospray ionization interface for capillary electrophoresis with mass spectrometry. A small-volume syringe pump is used to produce a liquid sheath electrode (ESI buffer).

occurs directly from the CZE capillary terminus, additional mixing volumes and metal surfaces are avoided and the electrophoretic efficiency appears unperturbed. The dead volume associated with the electrospray interface is < 10 nl, corresponding to a time of <0.1 sec for typical flow-rates of the sheath electrode liquid.[8]

Ions created by the ESI process were sampled through a 0.5-mm orifice (nozzle) into a region mechanically pumped at 50 l./sec by a single-stage Roots blower. The ions entering this region were sampled through a 2-mm diameter skimmer orifice located 0.5 cm behind the nozzle orifice. Ions passing through the skimmer enter a radiofrequency focusing quadrupole. This region is differentially pumped with a specially designed Leybold–Heraeus cryopump, consisting of a standard compressor and cold head with a custom-built cylindrical second stage baffle (cooled to ~ 14 K) which encloses the quadrupole and provides an effective pumping speed of >30000 l./sec for N_2. The analyzer quadrupole chamber was pumped at 500 l./sec with a turbomolecular pump. A single ion lens with a 0.64-cm aperture separated the ion focusing and analysis quadrupole chambers. The pressures in the focusing and analysis chambers were $\sim 1 \times 10^{-6}$ and 2×10^{-7} torr, respectively. The countercurrent flow of nitrogen (at ~70°) for desolvation of the electrospray was in the range 3–6 l./min. The mass spectrometer (Extrel Corp., Pittsburgh, PA) had an upper limit of $m/z = 2000$.[6,7]

RESULTS AND DISCUSSION

Sample injection

The two widely practiced methods for injection in CZE involve either electromigration by means of a combination of electrophoresis and electro-osmosis, or hydrodynamic flow, induced most precisely by having the sample reservoir higher than the terminal buffer reservoir. The electromigration method is particularly simple; the buffer-filled capillary is placed in the sample vial, high voltage is applied briefly, the buffer reservoir is replaced, and high voltage is applied to separate the sample components by the differences in their electrophoretic mobilities. However, manual injections can result in poor precision and injection artefacts. Figure 3 shows an example of peak "tailing" which resulted from poor injection rather than other phenomena which might normally be suspected (such as adsorption on capillary surfaces, which can result in similar peak profiles). The origin of the peak tailing shown in Fig. 3 was confirmed by reversal of the electric field at 12.8 min so that the direction of electro-osmotic flow was reversed. This caused the sample component to migrate past the detector a second time, resulting in a near "mirror image" of the first observation. Peak tailing due to adsorption, if important, would have resulted in a more symmetrical peak for the second

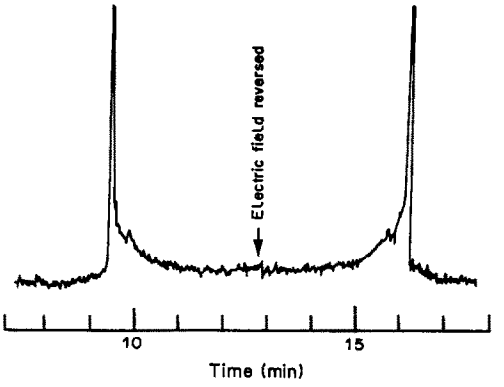

Fig. 3. Illustration of peak tailing due to a poor manual injection. Reversal of the electric field polarity at 12.8 min results in passage of the sample band through the UV detection region for a second time, producing of near "mirror image" of the peak.

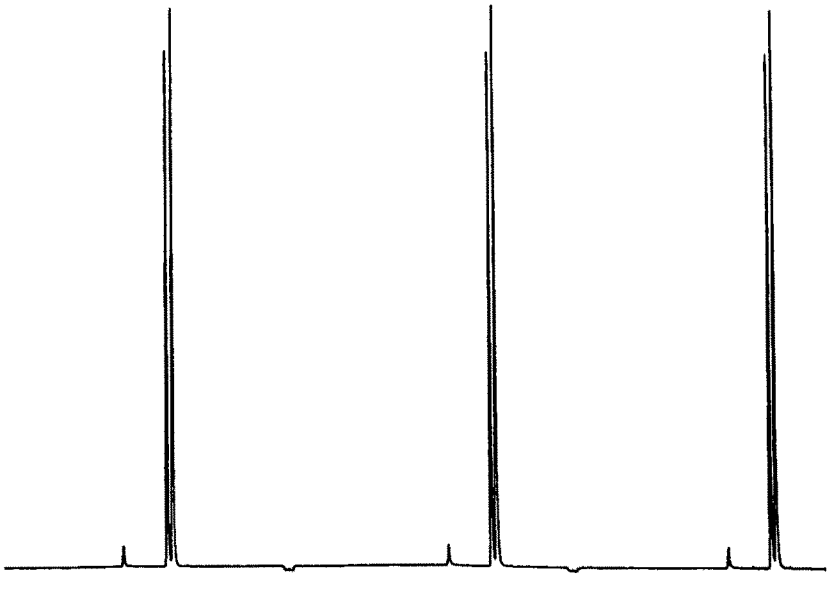

Fig. 4. Example of injection-to-injection reproducibility obtained with automated electromigration injection.

observation. However, the tailing in this case is clearly revealed as an injection artefact.

In contrast to manual injection, automated electromigration injection can be both precise and accurate. Our experiments have indicated that the injection process requires gentle handling of the capillary (avoiding rapid changes in direction for any capillary movements), a smooth and flat capillary end, and well filtered samples in containers having the same height as the terminal (ground) reservoir. Figure 4 shows the excellent reproducibility typically obtained for separations with our automated electromigration injections (1.1% relative standard deviation, 10 injections). This is rather better than the 4.1% standard deviation recently reported by Rose and Jorgenson[9] for automated electromigration methods. Rose and Jorgenson also reported precision of 2.9% for hydrodynamic injection and 13.4% for manual electromigration injection.

It is important to realize the electromigration injection is subject to two well characterized discrimination effects which must be taken into account to determine the actual sample size injected. First, if the sample conductivity is less than that of the buffer, a larger sample will be injected for ionic components than would be the case for samples having the same conductivity as the buffer. Since the electrical current in the capillary must be constant through both the buffer and sample segments, the ionized component in the sample will be concentrated (or diluted) during injection to meet this requirement. Thus, sample size will show a nearly inverse linear relationship to sample solution conductivity (as recently demonstrated by Huang *et al.*[10]).

Sample size is also related to both electro-osmotic flow and electrophoretic mobility. Fortunately, knowledge of the sample elution time (t_e) gives an accurate measure of these contributions, allowing the sample size to be calculated from:

$$\text{sample size} = Cv_C t_i V_i k_B / t_e V_{CZE} k_S$$

where C is the analyte concentration, k_S is the conductivity of the sample solution, k_B is the conductivity of the buffer solution, v_C is the capillary volume (to the detector), t_i is the injection time, V_i is the injection voltage, and V_{CZE} is the separation voltage. Thus, the sample size in electromigration injection can be accurately determined. Low-conductivity sample solutions can also be used to advantage with electromigration injection, giving a relatively narrow sample band compared to that obtained with hydrodynamic injection. However, hydrodynamic injection offers the clear advantage of simplifying the determination since analyte and solution effects (conductivity) causing the above-mentioned discriminations are eliminated.

CZE Separations

Figure 5 shows a CZE separation of a mixture of shellfish toxins derivatized with fluorescamine, with

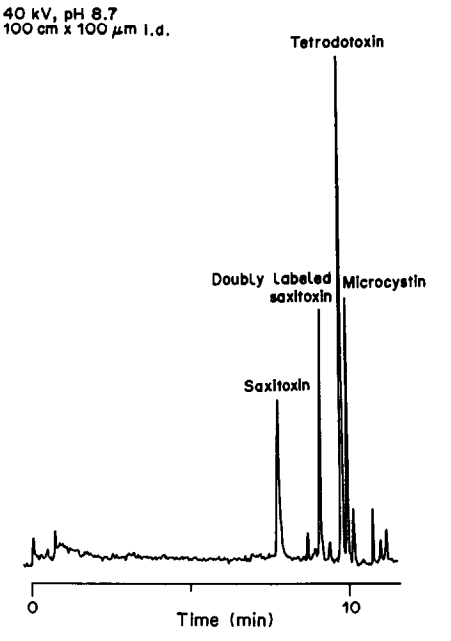

Fig. 5. Separation of fluorescamine-labeled toxins by CZE with fluorescence detection.

detection by the laser-based fluorescence detector. The separation was obtained by using a 1.0 m × 100 μm i.d. fused-silica capillary at 40 kV with a phosphate buffer at pH 8.7. This separation demonstrates both the high separation efficiency possible with CZE and its application to a mixture of toxins, where detection limits in the attomole range are clearly advantageous.

A useful and easily manipulated parameter in CZE separations is the buffer pH. This can affect both the electro-osmotic velocities in fused-silica capillaries and the relative electrophoretic mobilities of many compounds, owing to the differences in their isoelectric points.

Figure 6 shows the effect of buffer pH on the electro-osmotic flow coefficient in an untreated fused-

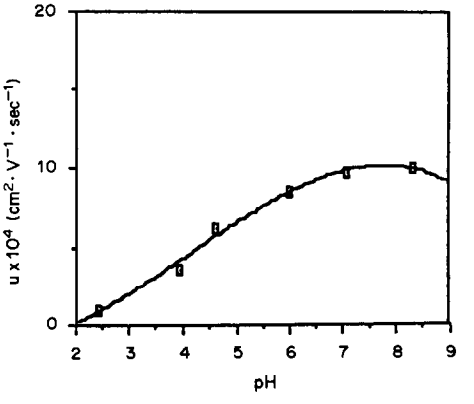

Fig. 6. Effect of pH of $10^{-2}M$ phosphate buffers on electro-osmotic flow coefficients in untreated fused-silica capillaries.

silica capillary. At high pH the surface of the fused silica is characterized by abundant negative ion sites and the electro-osmotic flow is quite rapid in the direction of the anode (which is usually at ground potential). At lower pH the electro-osmotic flow coefficient drops, and at pH 2.5 is only about one-tenth of that at pH 9.

Figure 7 illustrates the effect of pH on a separation of the four major ribonucleosides adenosine (A), guanosine (G), uridine (U) and cytidine (C) in $10^{-2}M$ phosphate buffers prepared at six different pH values. The separation was conducted at 30 kV in a 75 cm × 100 μm i.d. capillary, with absorbance detection at 260 nm. At the two higher pH values the nucleosides have no net charge in solution and migrate at the velocity of the electro-osmotic flow. At lower pH values the electro-osmotic velocity continues to decrease, but the nucleosides begin to exhibit a non-zero net charge and migrate at different velocities. The optimum pH appears to be close to 3.

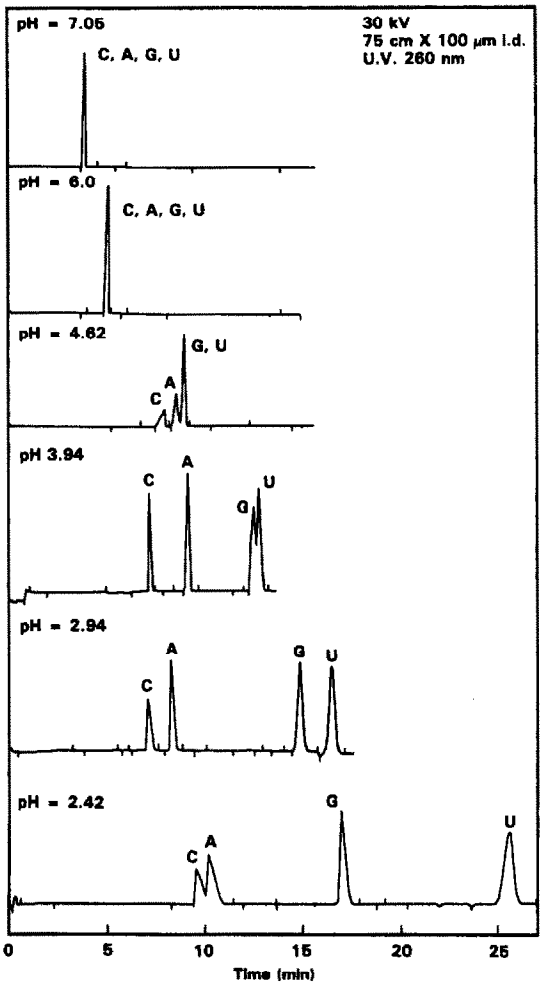

Fig. 7. Effect of buffer pH on the CZE separation of nucleosides in a short 75 cm × 100 μm i.d. capillary with UV detection at 260 nm: cytidine (C), adenosine (A), guanosine (G), and uridine (U).

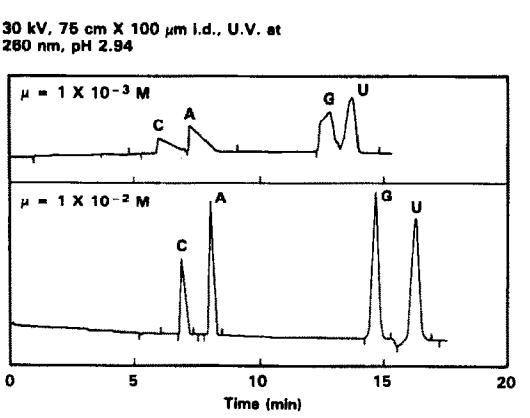

Fig. 8. Illustration of the effect of buffer ionic strength on CZE separation quality.

The ionic strength of the buffer can also have a small effect on the electro-osomotic flow coefficient. However, if the ionic strength of the buffer is less than about two orders of magnitude greater than that of the sample, a dramatic degradation of separation efficiency is obtained. These effects are illustrated in Fig. 8 for the separation of the four nucleosides at pH 2.94 (see Fig. 7). The nucleoside concentrations are $\sim 5 \times 10^{-5}M$ and a decrease in buffer ionic strength from 10^{-2} to $10^{-3}M$ results in a slight increase in the electro-osmotic flow, but severe distortion of the bands and loss of separation efficiency. The latter effect can be ascribed to distortion of the local electric field strength round the migrating sample bands, owing to the variations in conductivity due to the analyte ions.

Capillary zone electrophoresis–mass spectrometry

The advantages of capillary electrophoresis are primarily related to the fast high-efficiency separations that can be obtained, the extreme flexibility allowed by the range of analytical techniques (CZE, isotachophoresis, isoelectric focusing etc.), the ease of automation and the small sample size necessary. The primary drawback is the high detector sensitivity needed. Mass spectrometric detection provides a highly sensitive method with broad applicability, as well as high selectivity.

The combined CZE–MS approach developed in our laboratory is based on use of an electrospray ionization interface (see Figs. 1 and 2). The electrospray produces ions from the end of the CZE capillary at atmospheric pressure by an electrically induced nebulization process. The highly charged droplets are exposed to a countercurrent flow of dry nitrogen, which facilitates evaporation and causes the droplets to reach their maximum charge (for a given size) allowed for droplet stability. Subsequent evaporation results in break-up of the droplets to produce smaller droplets which proceed along a similar course until they are sufficiently small for direct field assisted desorption (or evaporation) of ions to occur from the

droplet surface. The precise sequence of events, the competition between these processes, and the dependence on droplet size, as well as the role of other possible contributions, is not fully understood. Most significantly, the effect of liquid composition on ion desorption efficiencies is also largely unexplored. However, the net result of the ESI process is the desorption of analyte ions by a gentle process which does not require heat (other than that supplied by the flow of dry nitrogen, which is heated to $\sim 70°$ in our apparatus). The 3–6 kV potential gradient used for ESI can produce positive or negative ions, depending on the polarity of the electric field.

The electrospray interface shown in Fig. 2 is distinctly better than earlier interfaces, providing operation over a much broader range of buffer compositions and flow-rates.[6,7] The improved interface uses a flow of liquid over the tip of the capillary to augment the flow due to electro-osmosis, or to produce a mixture which is more easily electrosprayed.[8] The actual CZE electrical contact is effectively made with the thin sheath of liquid which flows over the fused-silica capillary. The CZE capillary need extend only a short distance beyond the metal capillary (>0.2 mm) to provide good performance. The voltage drop across the sheath electrode is small and under typical conditions the behavior of both ESI and CZE is consistent with the expected electric field gradients. Thus, the CZE effluent avoids contact with any metal surfaces and is isolated from loss by electrochemical reactions.

The sheath electrode liquid can be the same as the CZE buffer, but it is often advantageous to use another liquid (providing lower surface tension) to improve the electrospray performance. For example, aqueous buffers could not previously be electrosprayed, but with either methanol or 2-propanol as the sheath electrode liquid, aqueous CZE buffers with up to 0.2*M* ionic strength can be used. The sheath electrode liquid can also be used to modify the electrospray process either by manipulation of the liquid-phase chemistry related to the ion desorption or, potentially, by post-column derivatization to yield an analyte providing distinctive mass spectral information or more efficient ionization. Our results indicate that mixing in the electrospray cone is extensive since the ESI performance can be dramatically improved for CZE buffers which could not otherwise be used (*i.e.*, aqueous solutions). Details of the design and performance of this interface are given elsewhere.[8]

In the following we use a simple mixture of four quaternary phosphonium salts to illustrate the characteristics of CZE–MS separations and to illustrate the potential analytical value of these new methods. This particular sample is noteworthy only because it is not amenable to "conventional" ultraviolet or fluorescence CZE detection methods. The CZE–MS total and single-ion electropherograms for the quaternary phosphonium salts are shown in Fig. 9. Electromigration was used to inject a sample plug containing approximately 1 pmole of component, by the methods described above. The separation was conducted in a relatively short 60-cm capillary, with an 11-kV CZE voltage drop. Buffer conductivities were generally chosen to be about 10^3 μmho/cm. The separation in Fig. 9 was obtained with a 0.05*M* potassium hydrogen phthalate aqueous buffer adjusted to pH 4.8 by titration with sodium hydroxide and containing $10^{-4}M$ potassium chloride. The sheath electrode liquid was 8.7% water in 2-propanol containing 0.1*M* ammonium acetate and $2 \times 10^{-5}M$ hydrochloric acid and having a pH of 8.9. Although $(4–8) \times 10^4$ theoretical plates are obtained in the separation of the individual components, as shown for the single-ion electropherograms, the four-component mixture is resolved into only two peaks. It is not surprising that the vinyltriphenyl- and

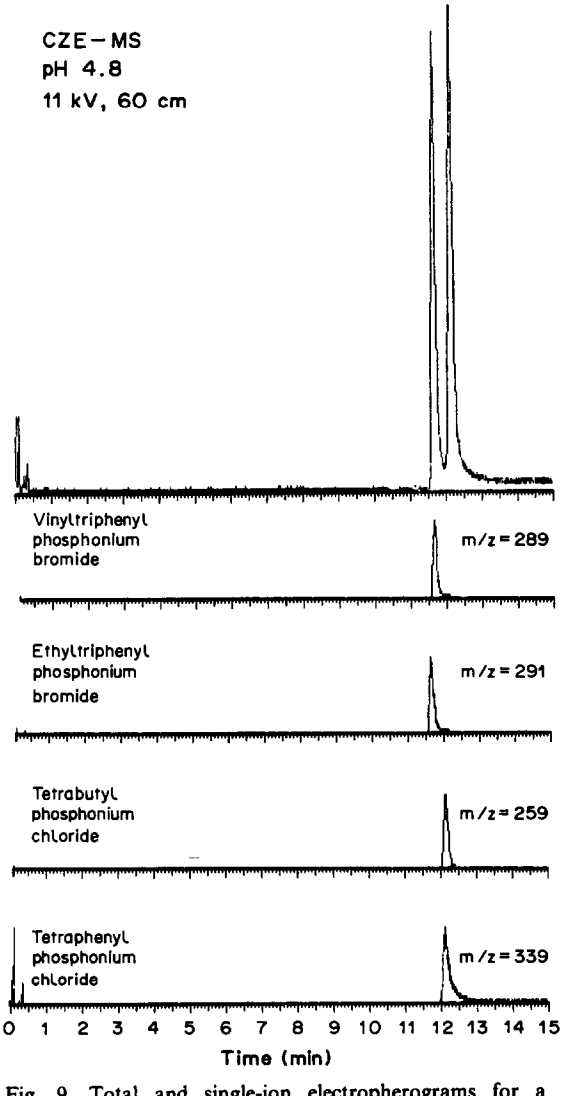

Fig. 9. Total and single-ion electropherograms for a CZE–MS separation of a mixture of quaternary phosphonium salts at pH 4.8 in a 60 cm × 100 μm capillary at 11 kV.

ethyltriphenylphosphonium ions are eluted simultaneously, since their electrophoretic mobilities are similar; it is somewhat more surprising that the tetrabutyl- and tetraphenylphosphonium ions are co-eluted. If the voltage drop is increased to 24 kV a proportional decrease in elution time is expected. As shown in Fig. 10 an even greater decrease in elution time is observed (probably due to modification of the fused-silica capillary by an amine mixture used in the preceding separation). However, the increased electric field strength does not yield an improved separation and it appears that the separation efficiency may be degraded by the Joule heating due to the larger current (in fact, improved separations were obtained at lower voltages, consistent with this suggestion). Manipulation of buffer pH also affects separations, as discussed earlier. Increasing the buffer pH to 6 results in the expected increase in electro-osmotic velocity and a 26% decrease in elution times, as shown in Fig. 11. However, as expected, the electrophoretic mobilities were unaffected and resolution of the four components was not obtained. The higher pH also results in a substantial loss of efficiency, which may be attributed to increased interaction of the phosphonium cations with the fused silica surface. Currently there is extensive interest in treatment of CZE capillary surfaces both to manipulate the velocity of electro-osmotic flow and to create more passive surfaces.[11]

The CZE–MS interface incorporating the liquid sheath electrode allows the electrospray ionization interface to be operated for almost any buffer system of interest for CZE. This includes aqueous and relatively high ionic strength buffers which could not otherwise be electrosprayed. In addition, the interface provides a simplicity of operation and day to day reproducibility not previously attainable. The CZE capillary can be easily and rapidly replaced and no special treatment or preparation is required. The electrospray interface provides exceptional sensitivity, does not affect CZE efficiency and avoids a pressure drop across the capillary. The sheath flow also provides a convenient method of introducing reagents for mass spectrometer calibration, manipulation of the ESI process, or post-column derivatization.

Capillary isotachophoresis–mass spectrometry

Isotachophoresis in a capillary is an alternative electrophoretic method which provides an attractive complement to CZE.[12] The instrumentation used for capillary isotachophoresis (CITP) can be nearly identical to that of CZE. In CZE, analyte bands are separated on the basis of the differences in their electrophoretic mobilities in an electric field gradient, which ideally is unperturbed by their presence (owing to the much lower effective concentrations). In contrast, in isotachophoresis the analyte mobilities define the electric field strength. Two different electrolyte solutions are chosen as the leading and terminating electrolyte solutions, which have sufficiently high and low electrophoretic mobilities, respectively, to bracket the electrophoretic mobilities of the sample components of interest. The sample is inserted in the capillary between the two electrolyte solutions and the sample components are separated into distinct bands on the basis of their electrophoretic mobilities. The electric current in the capillary is determined by the leading electrolyte, which defines the ion concentration in each band. The electric field strength varies in each band, the highest field strength being found in the bands with the lowest mobility. The length of a band is then proportional to the concentration of its ions in the sample. As with CZE, resolution is ultimately limited by band broadening due to electro-osmosis, molecular diffusion and Joule heating.

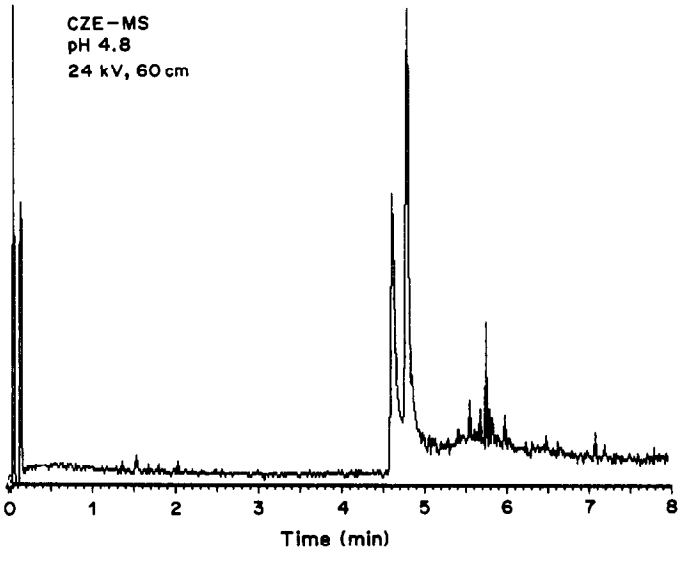

Fig. 10. CZE–MS separation of quaternary phosphonium ions at pH 4.8 at 24 kV (see Fig. 9).

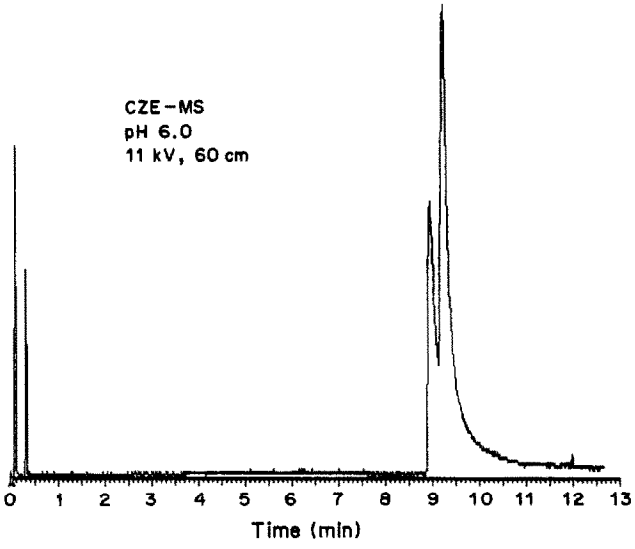

Fig. 11. CZE–MS separation of quaternary phosphonium ions at pH 6 (see Fig. 9).

A direct CITP–MS combination is an attractive complement to CZE for a number of reasons. First, the sample size which can be introduced is greater by several orders of magnitude than can be tolerated in CZE and is limited primarily by the volume of the capillary and the separation time allowed (which is inversely related to the voltage). Secondly, CITP generally results in concentration of analyte bands (depending on their concentration relative to the leading electrolyte), which is in contrast to the inherent dilution obtained with CZE. These two features can provide a substantial improvement in detection limits compared to CZE. It must be remembered that although 10-attomole detection limits have been reported for CZE, the 10-nl injection volume typical of CZE corresponds to a concentration detection limit of about $10^{-9}M$ with single-ion detection. If the ionization efficiency is lower, or full-scan mass spectra are required, the CITP–MS detection limits will be substantially better than those obtainable by CZE–MS. A third benefit of CITP is derived from the nature of the separations compared to CZE or chromatographic methods. The chromatographic peak capacity needed to separate all the components of a sample generally greatly exceeds the number of components, and for much of the time the detector is observing only the baseline. In contrast, with isotachophoresis, one sample band immediately follows another and detector time is not wasted (once a separation is obtained).[13] In addition, all the bands have similar ion concentrations, so there should be no large differences in signal intensities between bands and a broad dynamic range detector is generally not required. Similarly, additional information on analyte concentration is conveyed by the length of the analyte band.

The application of CITP–MS to the phosphonium salt mixture used for the CZE–MS experiments provides an interesting comparison of these electrophoretic methods. The separation was conducted at 35 kV, with a 2 m × 100 μm i.d. untreated fused-silica capillary. The leading electrolyte was $10^{-3}M$ ammonium acetate and the trailing electrolyte was $10^{-3}M$ tetraoctylammonium bromide in a 1:1 v/v

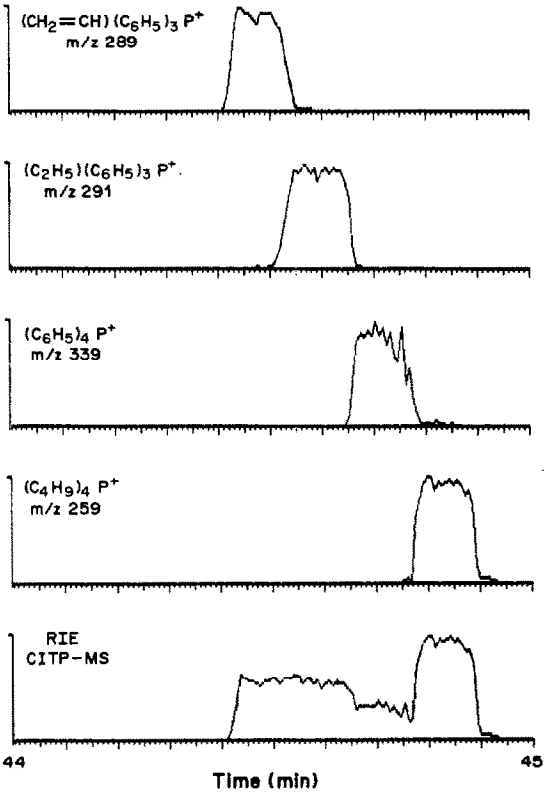

Fig. 12. Capillary isotachophoresis–MS separation of the quaternary phosphonium salt mixture in a 2 m × 100 μm i.d. capillary at 35 kV.

water–methanol mixture as solvent. The concentrations of the four quaternary phosphonium halide were all $10^{-5}M$, in a 1:1 v/v water–methanol mixture. The sample was loaded by electromigration for 60 sec at 30 kV. Figure 12 shows the CITP–MS single and total ion isotachopherograms. The separation is well developed, with minimum band overlap and sharp edges. The widths of the four bands are nearly equivalent, consistent with the similar sample concentrations and the minor discrimination expected from use of electromigration for introduction of the mixture.

The most striking feature of the separation shown in Fig. 12 is the excellent resolution of the four phosphonium salts, which were *not* resolved in the shorter CZE separations. The fact that the vinyltriphenyl- and ethyltriphenylphosphonium ions are clearly resolved illustrates the potential of CITP–MS for high-resolution separations. Another advantage is the greater signal-to-noise ratio. A detailed description of the techniques, separation of other materials, and the potential applications of CITP–MS will be given elsewhere.[13]

CONCLUSIONS

The CZE–MS approach offers a combination of separation efficiencies and detection limits that makes it uniquely suited for many biological samples. For example, it is possible to couple a micropipette to CZE directly, providing a basis for direct sampling of single cells by electromigration. Separations requiring less than a few minutes are possible by use of short capillaries, particularly where sensitive detection methods allow the sample volume to be minimized. The development of capillary isotachophoresis–MS promises to extend the capability of these methods further and provides a complement of CZE–MS. The rapid developments in injection techniques and the use of buffer media providing enhanced selectivities promise increasing interest in these attractive instrumental methods.

QUALITY-ASSURANCE PROCEDURES FOR GRAPHITE-FURNACE ATOMIC-ABSORPTION SPECTROMETRY

W. SLAVIN, D. C. MANNING and G. R. CARNRICK
The Perkin-Elmer Corporation, 901 Ethan Allen Highway, Ridgefield, CT 06877, U.S.A.

(*Received* 31 *May* 1988. *Accepted* 24 *August* 1988)

Summary—A procedure is described for quality-control in graphite-furnace atomic-absorption spectrometry. It uses an NBS standard reference material to avoid errors in standard preparation, and very simple instrumental conditions, with no matrix modifier or pyrolysis step. The characteristic mass and the Zeeman ratio are calculated for Ag, Cu and Cr, and deviations from the expected values for these quantities are correlated with potential instrumental malfunctions.

It has been shown that when the modern graphite furnace is used correctly, it is remarkably free from interferences.[1–3] L'vov invented the furnace technique in 1959 and in his first paper[4] expressed the hope that the method might become absolute, that is, needing no standard, as well as being very sensitive. During the 1970s the graphite furnace was shown to be very sensitive indeed but, unfortunately, plagued by interferences. This problem was partly due to the effort by the instrument makers[5,6] to adapt L'vov's technique to the commercial atomic-absorption spectrophotometers, which at that time utilized a flame. This necessitated many compromises that had a strong influence on analytical performance.

About 10 years ago a determined effort was made[7,8] to understand the requirements of the furnace technique and to adapt the instruments to provide more nearly optimum conditions. We have called this assemblage of modern conditions the stabilized temperature platform furnace technique, STPF.[9] The more important of these conditions are use of the L'vov platform,[7] fast digital electronic signal processing,[10] automatic baseline compensation,[11] integration of the absorption,[4] rapid heating of the furnace,[12] calibration with simple analytical standards, pyrolytically coated tubes,[4,13] and Zeeman background correction.[14] The individual efforts to optimize each of these conditions have been the work of many laboratories in America and Europe, as partially noted in the references.

When STPF conditions are used, analyses are performed by calibration with simple standard solutions and the method of additions is avoided.[15] Though in ideal situations the method of additions will not introduce errors, it is slow and reduces the analytical precision. The freedom from interferences means that the slope of the analytical curve does not depend upon the materials in the sample matrix. Thus the slope of the working curve is a property of the particular element being determined. The characteristic mass, m_0, is the value used to define the slope of the working curve, or the reciprocal sensitivity. It is the mass of analyte (in pg) that produces an integrated absorbance signal with area equal to 0.0044 absorbance.sec (or 1% absorption.sec). This characteristic mass has been shown[3] to be constant within 20%, when determined by different operators, with different instruments, matrices, *etc.* Though some experimental conditions can alter the slope to some extent, these variations appear to be controllable. L'vov *et al.*[16] showed that this stability of the characteristic mass was explainable on physical principles.

The sources of variability in characteristic mass have been studied with a view to their control. As this work continued, it became clearer that the ability to achieve the expected characteristic mass could be used as an effective method for quality control of the analytical process. A test procedure has been developed[17] that has been used for many purposes, *e.g.*, to uncover instrumental alignment problems, to monitor the quality of instrumentation and methodology on a daily basis, to compare different furnace designs.

Three elements have been chosen, each selected for a particular characteristic. Silver is used because contamination is likely to be small and we believe there are few interferences.[18] Copper is used because, at the 324.8-nm line, it is sensitive to variability of the Zeeman magnetic field. Its complex hyperfine structure broadens that line considerably, making it impossible to separate the Zeeman-split absorption line fully from the wings of the source radiation. Chromium is used because it requires a rather high atomization temperature and a relatively long wavelength. It is thus subject to trouble from emission of dc radiation from the furnace wall and is therefore a sensitive indicator of furnace misalignment.

In addition to the characteristic mass, we measure two other properties of the analytical system. The light energy, E, for given conditions is a good indi-

cation of incipient lamp failure, or gross misadjustment of optical elements. It is an instrumental parameter that should be monitored routinely. The Zeeman ratio is also measured. This is the ratio of the Zeeman signal to the Zeeman plus background signal in the absence of true background absorption.

EXPERIMENTAL

Several Perkin-Elmer® Zeeman/5100 and Zeeman/3030 atomic-absorption instruments, equipped with the AS-60 autosampler, were tested. Only single-element hollow-cathode lamps should be used for this test. No effort was made to use the same lamp for all tests. A previously unused pyrolytically coated tube is used for the series of tests.

The energy signal, E, provided on the modern Perkin-Elmer AAS instruments is an indication of the signal reaching the photomultiplier tube. The automatic gain control, AGC, circuit provides a constant signal in the amplifiers following the photomultiplier.[11] This is achieved by adjusting the dynode voltage across the photomultiplier dynode resistors to provide the chosen signal output. The instrumental reading has an arbitrary relationship to the dynode voltage, V:

$$E = (1000 - V)/10$$

The electronics for the Zeeman 5000 were discussed in some detail previously.[11] The electronics used with the Zeeman 5100[19] and the Zeeman 3030, the instruments used for the experiments in this paper, are very similar. During each cycle of the ac line (1/50 or 1/60 sec, depending on the line frequency), two signals are measured in rapid sequence. The total atomic-absorption signal, including any background that is present, is measured with the magnet off. The background signal, B, is measured with the magnet on. The difference between the two signals is the Zeeman signal, Z. When this signal is expressed as absorbance, it is proportional to the analyte concentration in the sample.

In all practical cases the magnetic field is not sufficient to separate the absorbing lines of the analyte vapor fully from the source radiation. Thus, even if no background absorbance is present, there will be some residual signal when the magnet-on signal is measured. For most elements, but not all, this residual signal is less than 10% of the atomic absorption. The Zeeman ratio, R is defined:

$$R = Z/(Z + B)$$

In the tests, we are interested in a stable and reproducible value for the characteristic mass, so the conditions which have been chosen are somewhat different from those usually used for routine analysis.[20] Matrix modifiers have been avoided (a) because of the potential for introduction of contamination and (b) to keep the conditions simple. Since materials are used which produce negligible background, a pyrolysis step is also avoided.

It is important to avoid sample preparation errors in this work. To ensure confidence in the absolute value of the characteristic mass, we use the NBS 1643b Standard Reference Material, Trace Metals in Water. It is a particularly convenient material since, for all three test elements, the amount present in the NBS reference material is large enough to provide precise results, that is, an integrated absorbance signal with an area greater than about 0.2 absorbance.sec but still within the linear range of the analytical curve. For these quality-assurance tests it is convenient to stay within the linear range because we are also studying the ratio of the Zeeman sensitivity to the conventional AAS sensitivity. In normal analytical situations there is no reason to stay within the linear range. A low lamp current is used, to provide narrow line-width by minimizing self-absorption in the lamp. For the three elements used in this test, the spread in the NBS certified values is about 10% and we accept this potential error.

It is preferable that the autosampler cups be soaked for several hours in 20% v/v nitric acid, rinsed in distilled demineralized water, dried and stored in a sealed container. Just before addition of the test solution to the cup, 2 ml of 2% v/v nitric acid are let stand in the cup for a few minutes and then emptied out, with shaking out of the residue. If there is doubt as to the purity of the nitric acid and distilled water, these materials are checked.

The autosampler tray is filled with water to a depth of about 1 cm and closed with the autosampler cover. This will reduce evaporation errors by saturating the atmosphere above the cups. When full, the sampler cups hold about 2 ml. The test solutions are poured directly into the cups, without use of transfer containers. About 1–1.5 ml of test solution is placed in the cup.

The test solution sample transferred by the autosampler is dried on the platform and the residue is atomized directly. The conditions are shown in Table 1. After the drying step at about 140°, the temperature is raised to 500° for 5 sec as a practical step to ensure that the test solution is fully dried. The tube is then returned to room temperature for long enough to be sure that the atomization step will proceed from a cool environment to achieve STPF conditions. This is the cool-down step.[21,22] Then the material is atomized with maximum power heating and gas stop.

The temperature is set with a pyrometer if one is available. We used an Ircon Modline 2000 Series Automatic Optical Pyrometer focused through the sample-fill hole onto the platform. The temperature is read after it has come to equilibrium and the reading is no longer changing (measurement of the rising temperature would be in error since radiation from the wall will be reflected from the platform; at thermal equilibrium, the measurement is reliable).

The tube is then fired again 6 times to remove any residual contamination or carry-over and to confirm that the integrated Zeeman and background absorbance signals are less than about 0.004 absorbance.sec. The raw signal is not corrected for the blank reading. The test solution is fired 6 times to provide useful statistical results. The characteristic mass, m_0, and the Zeeman ratio, R, are calculated. Typical absorbance profiles are recorded for each of the three test elements since the profiles are an important part of this test.

The characteristic mass, m_0, is calculated from the relationship:

$$m_0 = (0.0044/S)m$$

where S is the average integrated absorbance reading (in absorbance.sec) and m is the mass of analyte (in pg). The NBS certified value for each of the three elements, in μg/l., is multiplied by the sample aliquot volume taken, 15 or 20 μl, to yield the mass in pg shown in Table 1.

The series for each of the three elements is completed in less than 30 min so the complete test requires less than 1.5 hr. The test solutions should not be on the autosampler table for more than 2 hr or evaporation errors can become significant. The series of measurements consumes somewhat less than 400 μl of the NBS SRM and the residue left after the test should be discarded.

Graphite furnaces rarely produce unexplained wild signals. There is no point in confusing the judgements intended in this work, by including such rare accidents. Therefore, discrepant single readings are discarded from the average. This is done by calculating the standard deviation for the six replicates. If the extreme value appears to be an outlier, that is confirmed by deleting that point and recalculating the standard deviation. If the resulting standard deviation is smaller than half its value obtained for the six points, the five-point average and standard deviation are used.

RESULTS

Data obtained with 4 different Zeeman instruments for the three elements, collected over a 6-month period, were reported earlier.[17] Those data and the range of results reported are shown for each test element in the first two lines of Tables 2–4. More recent data for some of those instruments are also shown. Data from several different Z/3030 and Z/5100 instruments have been lumped together in these tables.

Typical absorbance profiles from the Zeeman/5100 are shown in Figs. 1–3 for Cr, Ag and Cu. In all the figures the Zeeman signal, *Z*, is the solid line and the background signal, *B*, is the dotted line. In the curves for Cu the Zeeman signal and background signal are plotted to the same scale. For Cr, full-scale absorbance is 0.1 for the background and 0.3 for the Zeeman signal. For Ag, the full-scale absorbance is 0.1 for background and 0.6 for the Zeeman signal. For Cu, the background signal is typically slightly smaller than the Zeeman signal, as shown in Fig. 3.

If the peaks are significantly narrower than those shown in these figures, the atomization temperature is probably too high and the characteristic mass can be expected to be somewhat larger than expected. Conversely, if the peaks are broader than those shown here, the atomization temperatures are somewhat low and the characteristic mass can be expected to be a little better (smaller) than anticipated.

In some situations the Cr peak has a tendency to have a small leading spike, illustrated in Fig. 4. This is probably an indication that the thermal conditions have not quite stabilized. We ignore this effect.

Table 2. Chromium data

	Z/3030		Z/5100

Figure 5 shows an example (from a Cr test on a Zeeman/3030) of what happens when the drying conditions are not adequate; a large early background peak is observed. This is due to re-vaporization of the water condensed on the cooler tube ends during the drying step. The presence of this peak will grossly disturb the Zeeman ratio data. The drying conditions should be changed so that this peak does not appear.

We had expected that, for any specific instrument, the variation in characteristic mass would be small. The variations were larger than we expected so we looked for and found several causes of variability.

One such cause is variation in the magnetic field caused by fluctuations in the power supplied to the instrument. This is particularly the case for elements which display Zeeman ratio values, R, that are not close to unity. Experimental data for the two common Cu lines are shown in Table 5. For the 324.8-nm line the variation in R is almost 20% over the range of voltages shown, while at the 327.4-nm line the variation is much smaller. Table 6 gives the same kind of data for Ag. For the 396.2-nm line, for which R is quite close to 1, there is very little variation over the range of voltages used, in contrast to the case for copper.

Another cause of variability turned out to be evaporation of water from the NBS sample on the autosampler table. The table includes a water bath that will saturate the air above the sample cups and thus reduce evaporation. A baffle is mounted above the sample cups, exposing only the cup which is about to be sampled. In fact, in some of our experiments, the cup was left in the exposed position during the whole run, and in the early experiments the saturating bath was not filled.

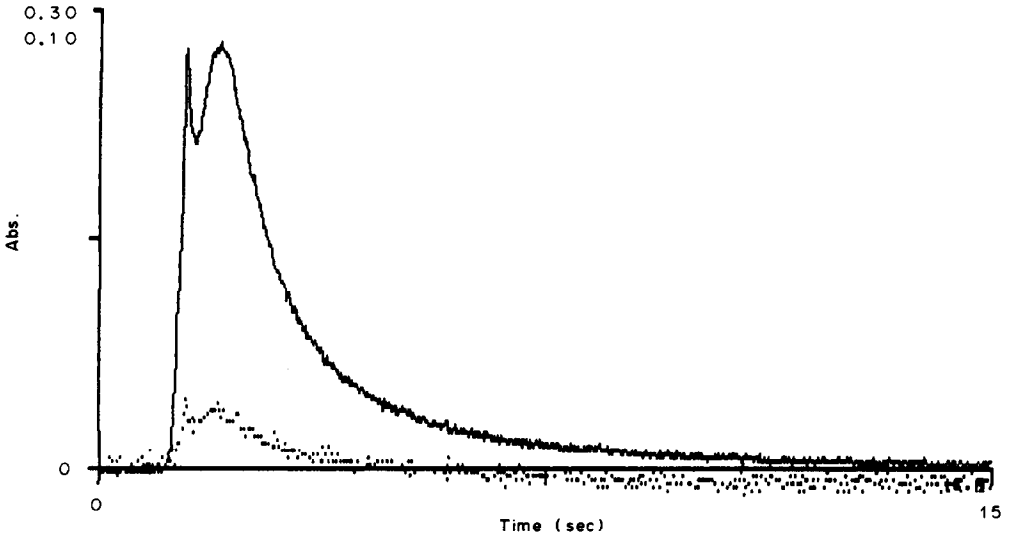

Fig. 4. The Cr absorbance profile demonstrating a split peak.

In a set of experiments on a winter day when the humidity in the laboratory was probably low, an accurately weighed sample cup was filled about 2/3 full with water. We found that 34.5 ± 1.0 μl of water evaporated per hour. A second experiment was run in much the same room environment but with the saturating bath filled and the cup mounted beneath the baffle plate. Though different experiments on different days produced different evaporative losses, from 6 to 11 μl/hr, the general rate of evaporation was about 10 μl/hr.

This effect can introduce a significant analytical error if appropriate precautions are not taken. When full, the cup contains about 2 ml of sample. If it is half-full and the bath is not filled, leaving the cup on the table for an hour would produce a positive error of 3.5% under the low humidity conditions mentioned above. If very small amounts of sample are used, the error can become very large. This effect is greatly reduced if the water bath is filled and the cups are not left on the table longer than necessary, especially if small sample volumes are used.

270	1.03	0.98	0.49	0.26	0.78	0.75

Still another cause of variability is the atomization temperature. In our experience, with some instruments and some tubes, there may be a difference of up to 200° between the pyrometer reading and the instrument setting. The effect of temperature on the integrated absorbance signal for Ag is plotted in Fig. 6. Theory shows that under STPF conditions where thermal equilibrium has been achieved prior to elemental volatilization, the diffusion coefficient of the fill gas, and therefore the residence time of the analyte atoms, will depend on the atomization temperature. This relationship is an exponential function of the absolute temperature and L'vov *et al.*[23] suggest the relation $D_T = D_0(T/273)^{1.75}$ where D_T and D_0 are the diffusion coefficients at T and 273 K respectively. To determine the change in signal due to diffusion at different temperatures, the equation is easily rearranged to $D_{T_2}/D_{T_1} = (T_1/T_2)^{1.75}$.

Assuming that the analytical signal is proportional to the residence time, which itself is proportional to the diffusion coefficient, this equation can be used to calculate the signal change between 2000 and 2200°. A signal loss of 14% is calculated for the higher temperature, and the experimental data in Fig. 6 show the loss to be 13%, in excellent agreement. Thus for Ag, near its usual atomization temperature, there is a variation of about 7% per 100° if the temperature is not accurately measured.

We have recently instituted the Cu and Cr part of this test, using the NBS 1643b reference material, for all Zeeman Model 5100 instruments shipped from our factory in Connecticut. The Cu and Cr data from some 70 instruments are analyzed in Table 7. Not only were different instruments used, but different electronic technicians performed the experiments, and different power lines and light-sources were used. No effort was made to prevent contamination and the sample cups were not precleaned.

Table 6. Effect of voltage on Ag signal (absorbance.sec)

	Signal at 396.2 nm			Signal at 309.3 nm

260	0.07	1.35	0.95			

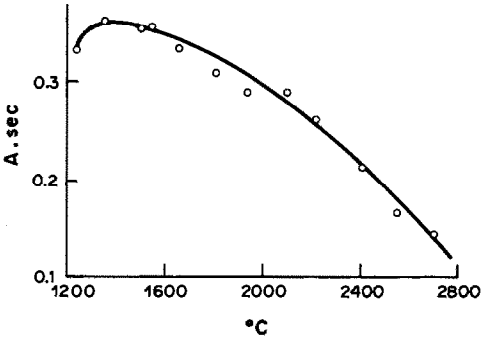

Fig. 6. The variation with temperature of the signal for Ag from 15 μl of the NBS SRM 1643b Trace Metals in Water, 149 pg of Ag. The characteristic mass at the recommended atomization temperature of 1800° is 2.0 pg. (A.sec = absorbance.sec).

In Table 7 we list the average characteristic mass, m_0, and Zeeman ratio, R, for each element. In the case of Cu, we also list the average RSD of each set of 5 readings and the average energy reading, E. The second line of Table 7 gives the RSD of the data for all the instruments.

The energy signals, E, were remarkably similar, with an SD less than 3 even though many different Cu lamps were used and the different photomultipliers displayed different gain characteristics. For each instrument five separate readings of the absorbance and the Zeeman ratio were taken for the material, and the corresponding average and RSD values were calculated. For Cu, the average of these individual RSD values was 1.2%. The average absorbance signal is reported in Table 7 as the characteristic mass, m_0. The spread in these average absorbance signals, from all the instruments, was 16%, calculated as the RSD of the individual characteristic masses from each instrument. The characteristic mass from these data is 8.5 ± 1.2 pg, in good agreement with our expectations, 8.0 pg.[20] The RSD of the Zeeman ratio, R, was only 2%.

The Cr data collected on the instruments are also shown in Table 7. Note that, in this case, the RSD of the average test signal is only 8%. In other words, all the instruments shipped produced only an 8% RSD for the slope of the Cr analytical curve. The fact that this is half the spread of the Cu data suggests that copper contamination in the workplace atmosphere may have been a problem with the Cu tests, and we plan to pursue this further. The characteristic

RSD (%)	8	1.0	4	16		2.0

mass from these data is 3.26 ± 0.25 pg, in very good agreement with the expected 3.3 pg.[20]

DISCUSSION

Probably the most important improvement that can be made in furnace AAS is the reduction of operator concern about potential analytical error. It is this concern which has inhibited the use of furnace AAS over the past 15 years. Therefore instrumental improvements which lead to analytical ruggedness are being sought. A test procedure that flags potential problems is an important step in this process.

A furnace AAS instrument-test procedure is described which has been used extensively to identify instrument malfunctions and some procedural problems. It uses an undiluted NBS standard reference material and no matrix modifiers, so that sample preparation errors and contamination errors are reduced or eliminated. The procedure avoids the effects of tube contamination or carry-over by preceding each set of measurements with a group of dry firings. Thus no blanks are required, or used. Having to take blanks into account degrades the precision. Because of the procedure and test material used, no pyrolysis step is used, although an additional drying step at 400 or 500° is used to be sure that there is no condensed moisture that will vaporize during the atomization step.

In experiments in our laboratory, the effects of furnace misalignment in the optical system were shown to elevate the Zeeman ratio for Cr and, if the situation was sufficiently severe, the Zeeman ratio for Cu. Incorrect line voltage alters the magnetic field used for generating the Zeeman effect, and this is indicated by departure of the Zeeman ratio for Cu from the expected value.

Characteristic mass values should be within less than 15% of the expected values for the three test elements. If all are low or high by similar amounts, the cause may be inaccuracy in the temperature or the pipetting, or may arise in the circuit that handles the calculation of absorbance; the most likely cause is error in the temperature. Contamination should be suspected if the characteristic mass is correct for Ag but better than expected for Cu or Cr, usually Cu. Many more relationships will emerge as the procedure continues to be used.

IMPROVEMENTS IN POLARIZATION SPECTROSCOPY BASED ON HIGH-FREQUENCY MODULATION

PATRICE L. CHRISTENSEN and EDWARD S. YEUNG*
Ames Laboratory-USDOE and Department of Chemistry Iowa State University, Ames, IA 50011, U.S.A.

(*Received* 31 *May* 1988. *Accepted* 23 *August* 1988)

Summary—Improvements are reported for trace elemental analysis by polarization spectroscopy. By using higher frequency (150 kHz) modulation and setting the polarizers off-extinction to produce a dispersion-shaped signal, linear calibration curves and a limit of detection ($S/N = 2$) of 2 ng/l. sodium can be obtained for solutions aspirated into a conventional flame source.

Trace analysis is of great interest in a variety of fields ranging from environmental and clinical analysis to industrial process monitoring. The quest for lower detection limits has been pursued by modifications of traditional techniques and the development of new ones. As analysts develop more sensitive methods, the specificity requirements increase as well. As an example, a background or noise component in an absorbance measurement may have negligible effects on the signal generated by an analyte at ppm concentrations, but may severely hinder the determination at analyte concentrations lower by a factor of 1000. In spectroscopic methods, lasers have the advantage of being highly monochromatic. This makes them capable of exciting very specific transitions in a species of interest. Hence, they allow the spectroscopist to develop methods with high specificity.

One technique that exhibits both high sensitivity and specificity is Doppler-free laser polarization spectroscopy, first demonstrated by Weiman and Hänsch.[1] The method uses two counter-propagating laser beams which overlap in the sample region. In the simplest case, both beams are tuned to an absorption transition of the analyte atoms (or molecules). The higher power pump beam is circularly polarized, but could also be linearly polarized at 45° to the probe beam polarization. It induces an optical anisotropy in the sample by depleting the analyte populations in certain sublevels. The left and right circular components of the linearly polarized probe beam sense this anisotropy as differences in absorption coefficients and refractive indices. This results in a change in the polarization plane of the probe beam, which can be measured as increased transmission through a crossed polarizer, frequently called an analyzer. The amount of probe light reaching the detector is related to the number of analyte species present. The technique is Doppler-free because the counter-propagating beams must interact with the same atoms simultaneously. In practice, some Doppler broadening is observed, owing to the finite crossing angle of the pump and probe beams.

Our group previously applied this technique to elemental analysis by use of a flame and a continuous-wave (cw) ring dye laser.[2] The polarization of the pump beam was modulated between left and right circular polarizations at a frequency of 800 Hz and detection was by means of a lock-in amplifier. The reported limits of detection ($S/N = 2$) of 30 ng/l. and 37 μg/l. for sodium (D_1) and barium respectively are comparable to those obtained by atomic-fluorescence techniques. More recently, Lanauze and Winefordner[3] applied a wider bandwidth pulsed (excimer-pumped) dye laser with boxcar averaging detection to the determination of sodium (D_2) by polarization spectroscopy. They obtained a 2 μg/l. detection limit ($S/N = 3$) by averaging 3000 pulses.

Lanauze and Winefordner reported that a poor extinction ratio (200) severely limited their system. In comparison, the polarimeter system developed by our group has been shown[4] to have extinction ratios as high as 10^{10}. This improved extinction ratio certainly figures significantly in the improvement seen in the cw[2] *vs.* the pulsed[3] laser systems. Typically, extinction ratios deteriorate substantially as the number of optical components between the polarizers increases. Because of this, we choose to use configurations that minimize the number of surfaces and thereby limit additional birefringence between the polarizers. However, in the Lanauze and Winefordner system,[3] several optical components are placed between the polarizers, and it is likely that this contributes to the poor extinction ratio observed.

The limiting noise in the pulsed laser experiment is the pulse-to-pulse variation in power that is commonly seen in such lasers. The limiting noise in the cw laser system can be attributed to flicker in the probe beam. High-frequency modulation (> 100 kHz) with cw lasers has been shown to im-

*Author for correspondence.

prove detectabilities in polarimeters[5] and other laser-based detectors[6,7] by reducing the effect of flicker noise. It is therefore reasonable to assume that similar improvements would be seen for polarization spectroscopy at high modulation frequencies. In this paper, we present results showing an improvement in the limit of detection for polarization spectroscopy based on this principle.

THEORY

Doppler-free laser polarization spectroscopy was first demonstrated as a high-resolution spectroscopic technique.[1] Early applications centered around precise measurements of spectroscopic fine structure[1,8-10] and evaluation of physical constants.[11] In light of this, it is not surprising that most of the early theoretical descriptions did not emphasize the nature of the relationship between the measured signal and the concentration of the absorbing species. In our experiments, we are interested in verifying this relationship to substantiate the usefulness of polarization spectroscopy for trace analysis.

There are two different phenomena that can be observed in these experiments. The first is a dichroism effect. The circularly polarized pump beam selectively depletes the population of some states relative to others, causing one circular component of the probe beam to interact with fewer ground-state atoms. This produces slight changes in the absorption coefficients for the left ($\Delta\alpha^-$) and right ($\Delta\alpha^+$) circular components. Reduced absorption of one component relative to the other results in a slight increase in overall intensity of the probe beam and produces elliptical character in the probe polarization. Some of this light is transmitted by the analyzer, producing a signal at the detector. This dichroism signal has a Lorentzian line-shape (determined by lifetime broadening or pressure broadening) which can be observed by varying the dye laser frequency and recording the absorption. The second effect is due to dispersion, or birefringence, a difference in refractive indices for the two circular components of the probe beam. The changes in refractive index, Δn^+, Δn^-, result from an anisotropic distribution of angular momentum orientations, which is caused by pump-induced non-uniformity in populations of (orientational) M sublevels. The birefringence causes a rotation of the polarization plane of the probe beam and thereby increases the amount of light passing through the analyzer. This birefringence effect produces a dispersion-shaped signal as a function of frequency.

A mathematical description is helpful in understanding these signals. Making the assumptions that the probe beam is weak and does not change the optical properties of the sample and that the pump-induced anisotropies are small, we can express the probe beam intensity (I_T) transmitted by the analyzer as[1]

$$I_T = I_0\left[\theta^2 + \theta\frac{s}{2}\frac{\chi}{(1+\chi^2)} + \left(\frac{s}{4}\right)^2\frac{1}{(1+\chi^2)}\right] \quad (1)$$

Here, I_0 is the probe intensity and θ is the angle of offset of the analyzer transmission axis from the exactly crossed position. The detuning of the laser frequency from resonance is given by χ, defined as

$$\chi = (\omega - \omega_0)/\gamma \quad (2)$$

where ω_0 is the resonant frequency and γ is the natural or the pressure-broadened line-width, whichever is the larger. The quantity s, which contains information related to sample concentration, path-length and pump power, is given by

$$s = -\tfrac{1}{2}(1-d)\alpha_0 lI/I_{sat} \quad (3)$$

The unsaturated background absorption of the probe is α_0 and is directly proportional to N^0, the total number density of absorbers in the ground state. The absorption path-length is l and the pump beam intensity I. The term I_{sat} refers to the saturation intensity, which gives a measure of the ease with which the pumped transition may be saturated. The parameter d is defined by

$$d = \frac{\Delta\alpha^-}{\Delta\alpha^+} \quad (4)$$

and is a measure of the magnitude of the anisotropy, which depends on the angular momenta and decay rates of the states involved.

Substituting equations (3) and (4) into equation (1) gives

$$I_T = I_0\left\{\theta^2 + \frac{\theta}{2}\left[-\frac{1}{2}\left(1-\frac{\Delta\alpha^-}{\Delta\alpha^+}\right)\alpha_0 lI/I_{sat}\right]\frac{\chi}{1+\chi^2} + \left(\frac{1}{4}\right)^2\left[-\frac{1}{2}\left(1-\frac{\Delta\alpha^-}{\Delta\alpha^+}\right)\alpha_0 lI/I_{sat}\right]^2\frac{1}{1+\chi^2}\right\} \quad (5)$$

Here, the concentrations are low and the dichroic attenuation term for I_0 can be neglected. The first term will be a constant for a given analyzer rotation. The second term describes the dispersion-shaped signal. The refractive index change, $\Delta n^\pm = \Delta n^+ - \Delta n^-$, can be related to the dichroism, $\Delta\alpha^\pm = \Delta\alpha^+ - \Delta\alpha^-$, by the Kramers–Kronig[1,2] relation such that

$$\Delta n^\pm = -\tfrac{1}{2}\Delta\alpha^\pm\chi c/\omega \quad (6)$$

The last term in equation (5) describes the Lorentzian-shaped dichroism signal. When the polarizers are perfectly crossed, $\theta = 0$, and the third term leads to a purely Lorentzian signal. If the analyzer is offset from extinction so that θ dominates over s, the last term becomes insignificant and a dispersion-shaped signal is observed. Thus, selection of the analyzer transmission axis allows observation of a signal that is due to the effect of dichroism or birefringence

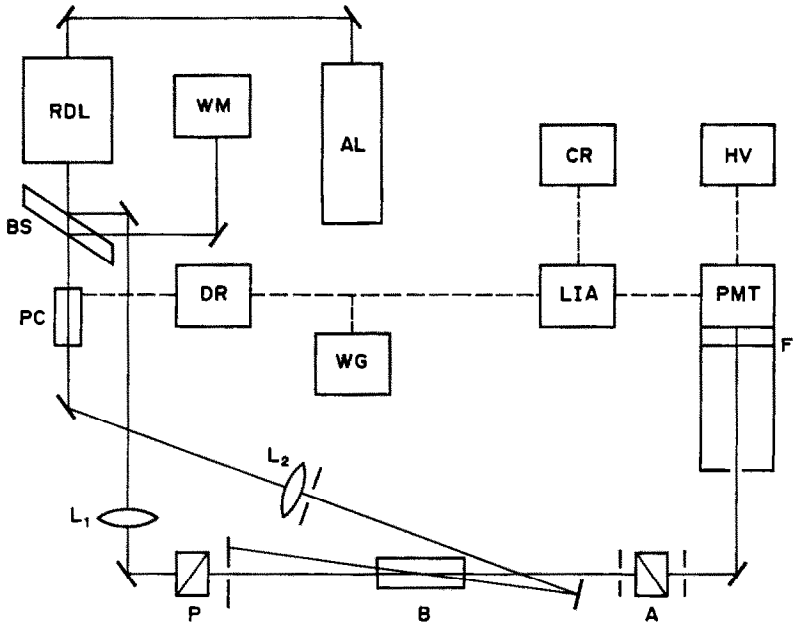

Fig. 1. Experimental system for atomic polarization spectroscopy. Solid lines indicate optical paths and broken lines show electrical connections. alone. At intermediate θ values, the signals will reflect a combined effect.

From equation (5) it is evident that the Lorentzian signal depends on the square of the concentration of the absorbing species, as the s term is squared. In contrast, the dispersion signal is linearly dependent on concentration. These relationships have been experimentally verified for sodium concentrations in the range 100–1000 ppm.[3,12] It is also interesting to note the signal dependence on laser power. Equation (5) shows that the signal intensity for the Lorentzian term is proportional to $I_0 I^2$ and therefore should increase as the cube of the laser power. The dispersion term increases as $I_0 I$ and shows a square dependence on the laser power.

In practice, the finite extinction ratio also contributes to the total intensity at the detector. The term $I_0\xi$ should be added to the right-hand side of equations (1) and (5) to correct for this. However, because the extinction ratio remains constant for a given optical alignment and we measure only differences in the intensity, this $I_0\xi$ term does not invalidate the linear relationships for signal *vs.* (concentration)^2 in the Lorentzian mode and signal *vs.* concentration in the dispersion mode, as described above. It does, however, affect the signal *vs.* power relationships, and the measured signals do not exhibit exact (power)^3 and (power)^2 dependence for the Lorentzian and dispersion modes, respectively, if this contribution is not first subtracted from the measured signal.

It is clear that we can get larger signals by working well away from the extinction position. In fact θ should be as large as possible. The noise, however, increases as θ increases, because of the residual intensity transmitted to the phototube. A good compromise is to increase θ to the point where flicker noise in the transmitted probe beam becomes comparable to, but not larger than, the noise from other sources. Since flicker noise here is drastically reduced by high-frequency modulation, a gain in detectability over the earlier work[2] is obtained by working off-null.

EXPERIMENTAL

A schematic diagram of the experimental system is shown in Fig. 1. It is very similar to the previous system.[2] An argon ion laser (Control Laser, Orlando, FL, Model 554A) serves as the pump laser for the ring dye laser (Spectra Physics, Mountain View, CA, Model 380A). The ring laser is operated with Rhodamine 6G dye (Eastman Kodak Co., Rochester, NY) and tuned to the sodium D_1 resonance line.

The dye laser beam is divided into three portions by a beam-splitter. The first weak reflection from the beam-splitter is used as the probe beam. The noise is proportional to the probe beam intensity, so, it is better to have more light in the pump beam for a given total laser output. The probe beam passes through a 50-cm focal length lens and then through selected positions on the Glan–Thompson polarizer and analyzer prisms (Karl Lambrecht Corp., Chicago, IL, Model MGT-25-E8-90). The focal point of the probe beam lies half way between the crossed polarizers at the center of the 6-cm slot burner (Varian Techtron, Palo Alto, CA, Model 02-100035-00). The polarizers are mounted in rotational stages (Aerotech Inc., Pittsburgh, PA, Model ATS-301R) having 0.0006° resolution. The rotational

stages and burner are mounted on 5/8-in. thick aluminum plates extending from the edge of the optical-table (Newport Research Corp., Fountain Valley, CA) so that the flame can be positioned low enough to allow a more rigid mounting of the optical components. The portion of the probe beam that passes through the analyzer prism is directed through a pinhole aperture, a cylindrical light tunnel and a line filter (Promfret Research Optics, Inc., Orange, VA, Model 11-5890-1) before reaching the photomultiplier tube (PMT) (Hamamatsu, Middlesex, NJ, Model R928). The PMT is operated at −1000 V dc by a high-voltage power supply (EMI Gencom Inc., Plainview, NY, Model 3000R). The second weak reflection from the beam-splitter is directed to a wavemeter (Burleigh Instruments, Fishers, NY, Model WA-20) for wavelength calibration.

The major portion (80%) of the dye laser beam, the pump beam, passes through the beam-splitter and the Pockels cell electro-optic modulator (Lasermetrics Inc., Teaneck, NJ, Model 3030). This pump beam is also focused by a 50-cm focal length lens and overlaps the probe beam as it is counter-propagated through the flame. The pump beam strikes a black beam-stop on the back side of the polarizer mount after passing through the flame. Several other pinhole apertures are placed along the beam paths to minimize the stray and scattered light reaching the detector. A black shield completely encloses the region from the analyzer stage on the back side of the PMT enclosure, to reduce background from the dye laser cavity. To further reduce scatter from the pump beam, the sides and back of the last reflecting mirror are painted black. The crossing angle between pump and probe beams is minimized to optimize the degree of overlap within the flame.

The linear polarization of the pump beam is modified to create left and right circularly polarized light (LCPL and RCPL) by the action of the Pockels cell. By proper alignment of the Pockels cell and appropriate selection of driving voltages, we can produce LCPL and RCPL without the need for a Fresnel rhomb.[13] The required voltages are provided by a high-voltage driver (Conoptics, Danbury, CT, Model 25) driven by a +1-V pulse at 150 kHz from a waveform generator (Wavetek, San Diego, CA, Model 162). This makes the present system simpler than that described previously and allows more stable modulation at high frequencies.[2] To verify the modulation of LCPL and RCPL, we insert a Fresnel rhomb (Karl Lambrecht Corp., Chicago, IL, Model ER4-25-580) and a Promaster polarizing filter (Photographic Research Org. Inc., Fairfield, CT) into the pump beam near the burner. The rhomb converts LCPL and RCPL into horizontal and vertical linearly polarized light (LPL). The polarizer discriminates between the linear polarizations, producing amplitude modulation. The degree of modulation is detected by a photodiode (Hamamatsu Corp., Middlesex, NJ, Model S1790) after passing through a neutral density filter of optical density 0.5 and is displayed on an oscilloscope (Tektronix, Beaverton, OR, Model 7904). The signal from the PMT is sent to a lock-in amplifier (EG&G PARC, Princeton, NJ, Model 5202) which is also synchronized to the modulation frequency of the waveform generator. A 1 or 10 sec time-constant is used. The demodulated signal from the lock-in amplifier is displayed on a chart recorder (Measurement Technology Inc., Denver, CO, Model CR452).

A standard stock solution of sodium (2.403 g/l.), prepared by dissolving electrolytic sodium hydroxide pellets (Fisher Scientific Co., Fairlawn, NJ) in quadruply distilled demineralized water and stored in a sealed polyethylene bottle, was used. Standard sodium solutions were prepared by diluting this stock solution with distilled demineralized water that had been purified by a four-cartridge Milli Q system (Millipore Corp., Bedford, MA). The demineralized water contains trace amounts of sodium, so the standards are actually sodium addition standards. Calibration standards were prepared in the range 9.612–96.12 ng/ml added sodium, stored in polyethylene bottles and used the same day as prepared.

The standard solutions were aspirated into a laminar air–acetylene flame at a rate of 8.4 ml/min for optimum signal amplitude. The optimized air:acetylene ratio was 4.8:1.0 as measured on gas flowmeters (Emerson Electric Co., Hatfield, PA, Model 1355-00A1FAA).

The various components in this experimental system are optimized separately before any polarization spectra can be obtained. Alignment of the argon laser and dye laser is set to achieve maximum output power at the desired wavelength. The argon laser is servo-controlled at 4.0 W to increase power stability. This produces about 80 mW total dye laser power at 589.757 nm, the vacuum wavelength for the sodium D_1 line as measured by the wavemeter. The probe beam is carefully directed through positions on the polarizer and analyzer previously found to give the optimum extinction ratio. We set the polarizer to give the highest transmission of the horizontally polarized probe beam. Total probe laser power in the cavity between the polarizers is 7.5 mW. Fine tuning of the analyzer is accomplished by monitoring the PMT current (extinction current) while rotating the analyzer transmission axis. The crossed position is determined as that giving the lowest extinction current reading, typically about 1.0 μA. This (maximum extinction) alignment is used when obtaining Lorentzian-shaped dichroism signals. For observing the dispersion-shaped birefringence signals, the analyzer is rotated 0.040° counterclockwise away from extinction. Under this condition, the PMT current is about 64 μA. The pump beam is directed to overlap with the probe in the flame, and the modulation is optimized by adjusting the Pockels cell position and the driver input and bias voltages to produce approximately 95% modulation between left and right circularly polarized light (CPL).

To set the detection electronics, a solution containing sodium is aspirated into the air–acetylene flame. The PMT signal is connected to the lock-in amplifier and the phase settings are optimized while the dye laser is tuned to the absorption maximum. Final adjustments of burner position, pump beam overlap with probe, and the Pockels cell bias voltage are necessary to produce the maximum sodium signal. Proper shielding from scattered pump and flame emission is critical in obtaining good signal to noise (S/N) ratios. We observe the baseline noise on an expanded scale to verify that light scattering from the pump laser is not the limiting noise source. When these preliminary optimizations are complete, the dye laser wavelength is set to the start frequency of the 30 GHz scan range. Sodium spectra are collected as the wavelength is scanned from 589.772 to 589.738 nm (vacuum λ). Scan times vary from 40 to 400 sec.

RESULTS AND DISCUSSION

Our initial goal was to repeat the earlier work,[2] using higher modulation frequency and a more stable optical system. We have the advantage of modulation electronics that are more suitable for high frequencies than were the electronics used previously (which were limited to 800 Hz). The Conoptics driver is capable of very stable Pockels cell voltage modulation up to the MHz range. The actual voltages applied to the Pockels cell are in the range from −200 to +200 V. A high frequency lock-in amplifier enables us to make use of modulation frequencies above 100 kHz. We have also been able to produce highly efficient (>90%) modulation between LCPL and RCPL from the Pockels cell directly, without the need for a Fresnel rhomb as was used in the earlier work. The

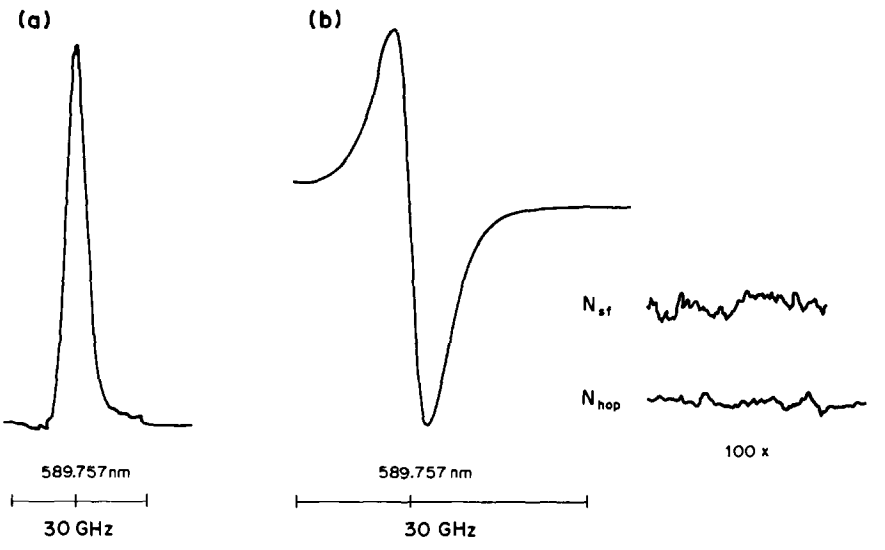

Fig. 2. Polarization signals for Na at 1.95 μg/l. (a) Lorentzian signal for $\theta = 0°$; and (b) dispersion signal for $\theta = 0.040°$. Noise in (b) is expanded 100×.

reduction in the number of optical components needed makes the alignment procedure simpler and may improve alignment stability as well. In addition, without the need for the rhomb, the pump and probe overlap angle can be made smaller, which should allow the observation of narrower line-widths and a longer interaction length. The former can be important in experiments where high spectral resolution is critical, but we did not make line-width comparisons in this study.

We were concerned about alignment stability because the extinction ratio of the polarizers is highly dependent on beam position. In other polarimeter systems, we have seen excessive baseline noise that was caused by unstable optical mounts. Therefore, in contrast to the arrangement used earlier,[2] we decided to keep all optical components mounted close to the table top, on short rigid mounts.

Since we did not have access to sodium-free water, we used distilled demineralized Millipore-filtered water, which was the best purified water available. The amount of sodium in an early sample of this water was found to be 27 μg/l. by ICP–MS analysis with the standard-addition method. We first used a crossed polarizer arrangement to examine Lorentzian-shaped signals for the sodium D_1 line. An example of a Lorentzian signal for sodium is shown in Fig. 2a. We did not observe the previously reported[2] linear relation between the Lorentzian peak height and the sodium concentration C. The Lorentzian signal, S_L, was instead linearly related to C^2 as evidenced in a series of samples containing 0–100 μg/l. added sodium. Three different measurements of four sodium standards were conducted with total laser powers ranging from 30 to 80 mW. Each series showed linearity between S_L and C^2, with a correlation coefficient $r \geq 0.999$. This is in agreement with equation (5) and is the expected behavior.

To evaluate the dependence of the dispersion signal on concentration, we rotated the analyzer 0.040° counterclockwise from the extinction position. Figure 2b shows a dispersion signal for sodium in distilled demineralized water. Clockwise rotation produced dispersion signals of the same magnitude and opposite symmetry. Although larger dispersion signals can be obtained with larger analyzer offset angles, the baseline noise also increases. We found 0.040° to be a suitable angle for collecting dispersion spectra while maintaining a good S/N ratio. Each dispersion signal, S_D, was measured as the peak to trough magnitude for the scan. As expected, a linear relationship was observed between S_D and C.

While examining these relationships and attempting to maximize the S/N ratios for optimum detectability, we noticed that the baseline noise at the starting frequency of the laser scan, N_{sf}, increased as the sodium concentration increased from 10 to 100 μg/l. One possible explanation for this is that since the sensitivity is very high, N_{sf} is actually caused by the fluctuating sodium signal in the wings of the absorption line. If this is the case, then we can expect even less noise at a wavelength further removed from the absorption line. We therefore tuned the laser from 589.772 nm, which corresponds to the starting frequency, to 589.684 nm, which is one fine etalon-mode separation ("hop") (75 GHz) away. The total laser power and the extinction current remained constant, so the noise comparisons are valid. At the second wavelength, the baseline noise, N_{hop}, remained relatively constant for the same set of concentration standards. Because the absolute light levels at the detector are smaller in the Lorentzian mode, the

increase in N_{sf} with concentration is less obvious than in the dispersion mode. Since we cannot measure true noise fluctuations at the maximum absorption wavelength, λ_{max}, in the total absence of signal (because some sodium is always present), we have chosen to use N_{hop} as the relevant noise measurement for S/N_{hop} and LOD calculations. Although Lorentzian and dispersion S/N_{hop} ratios for the distilled demineralized water were similar, the dispersion signal facilitated straightforward standard-addition analysis and extrapolation to the limit of detection, because of the linear relation between S_D and C. Further, the dispersion signal is larger because of the square term in equation (5). For these reasons, the dispersion mode was employed in the final optimizations and LOD determinations.

A second sample of the distilled demineralized water was then obtained. By comparison of dispersion signals, it was apparent that the new water had a substantially lower sodium concentration than the first sample (27 μg/l.). New sodium addition standards were prepared with the newly obtained water. All experimental parameters were optimized for maximum S_D/N_{hop} at 150 kHz modulation frequency and 80 mW total laser power. At this power, the pump and probe powers are 65 and 7.5 mW, respectively. Dispersion signals were obtained in triplicate for the water sample and for seven other addition standards with 10–100 μg/l. added sodium. The precision of this analysis is characterized by an average RSD of 2%, and good qualitative reproducibility of spectral line-shape is observed. Linear regression analysis of this data-set for S_D (μV) *vs.* C (μg/l. added sodium) gives a straight line of slope 222 μV.l.μg^{-1} and intercept 520 μV. The correlation coefficient, r, is 0.9955. The calculated amount of sodium present in the water is 1.95 μg/l., as determined from the x-axis intercept in this standard-addition method.

Once the concentration of sodium in the "pure" water is known, we can use the S_D/N_{hop} ratio for that to calculate the LOD for sodium at $S/N = 2$. The actual dispersion signal for these conditions (10-sec time-constant) is shown in Fig. 2b. Both N_{sf} and N_{hop} are also shown at higher sensitivity for the same conditions. Using an average of five sodium signals (S_D) for this demineralized water and extrapolating to $S/N = 2$, we obtain an LOD of 2 ng/l. for sodium. This shows a significant improvement over the previous result[2] of 30 ng/l. The magnitude of this improvement is reasonable for the increase in modulation frequency from 800 Hz to 150 kHz, although it was not possible to make a direct comparison of the performance of this system at the two frequencies, because of the low-frequency limit on the lock-in amplifier used. We did try other modulation frequencies between 150 kHz and 1 MHz, but no substantial improvement was seen above 150 kHz. It is encouraging that we were able to obtain this improvement in detection limit even though we used only moderate laser powers (P) (*e.g.*, compared to earlier work[2]). We found S_D to be roughly proportional to P^2 and N_{hop} roughly proportional to P. Thus, we expect further improvements in S/N and LOD as the laser power is increased.

High-frequency modulated polarization spectroscopy provides detection limits that compare favorably with those of other atomic spectroscopy methods such as atomic-fluorescence spectrometry and graphite-furnace atomic-absorption spectrometry. It has better stray-light rejection and is ideal for highly luminous or highly scattering environments. The technique has similarities to coherent forward scattering (CFS), in which a magnetic field is used to induce anisotropy in the sample. However, the LOD for sodium obtained here is four orders of magnitude lower than that reported for laser-excited CFS.[14] The signals here are larger and the noise levels are lower. In conclusion, the detection power of polarization spectroscopy for elemental analysis has been substantially improved by the use of high-frequency modulation to reduce the effects of laser flicker noise, so that advantage can be taken of the larger dispersion signal.

TWO-COLUMN ION-EXCHANGE METHOD FOR THE DETERMINATION OF COPPER-COMPLEXING CAPACITY AND CONDITIONAL STABILITY CONSTANTS OF COPPER COMPLEXES FOR LIGANDS IN NATURAL WATERS

YAN LIU* and J. D. INGLE, JR.†

(*Received* 16 *May* 1988. *Accepted* 9 *September* 1988)

Summary—Sample solutions titrated with Cu^{2+} ions are passed sequentially through two ion-exchange columns in an automated flow system. The first column is packed with Chelex-100 resin and retains Cu^{2+} ions that are free or derived from copper complexes that dissociate in the column. The second column is packed with AG MP-1 anion-exchange resin and retains negatively charged Cu(II) complexes. The retained copper species are then eluted from the columns and determined on-line with a flame atomic-absorption spectrophotometer. It is necessary to correct for a small fraction of free Cu^{2+} ions that pass through the first column and are retained by the second column. The Cu(II)-complexing capacity of sample solutions is determined from plots of the concentration ratio of free Cu^{2+} ions to Cu(II) complexes *vs.* the concentration of free Cu^{2+} ions. Conditional stability constants of the copper complexes are also estimated from these plots. The complexing capacity of sample solutions is also determined rapidly by measuring the concentration of complexed Cu(II) after spiking the sample with an excess of Cu^{2+} ions. The sample solutions tested were 4.0μM NTA, 4.0-mg/l. humic acid, and a river water.

The determination of trace metal complexing capacity and conditional complexation constants of ligands in natural waters is important in understanding the fate and toxicity of metal ions added to natural water. The complexing capacity is usually interpreted as the total concentration of ligands capable of binding a specified metal ion. A number of techniques, including anodic stripping voltammetry (ASV), ion-selective electrode (ISE) potentiometry, ion-exchange methods, ultrafiltration, dialysis, solubilization, and bioassay, have been used to determine the complexing capacity of natural waters.[1-3]

Most methods for determination of complexing capacity are based on measurement of the concentration of a particular fraction of Cu(II) species in a sample solution spiked with free Cu^{2+} ions. Normally, a titration curve is constructed by plotting the concentration of the fraction of Cu(II) species measured against the total Cu(II) concentration added. The "break point" in the titration curve is related to the Cu(II)-complexing capacity. The measurement technique for monitoring the titration process is often ISE potentiometry, which responds directly to free Cu^{2+} ions, or ASV, which detects free Cu^{2+} ions plus the so-called "ASV-labile" Cu(II) (*i.e.*, Cu^{2+} from dissociation of labile complexes).

The titration process can also be monitored with atomic spectrometric techniques after separation of free Cu^{2+} ions from Cu(II) complexes by ion-exchange techniques. Crosser and Allen[4] used Dowex 50W X-8 strong cation-exchange resin. After equilibration of the spiked test solutions with the resin for 24 hr, the concentrations of Cu(II) in the solution were measured by flame atomic-absorption spectrophotometry (FAAS). From the titration plots, the ligand concentration and the conditional stability constant of the copper complexes were calculated for sample solutions of glycine, EDTA and peat extract.

Stolzberg and Rosin[5] used Chelex-100 chelating resin in a one-point determination of the complexing capacity of phytoplankton media. After addition of an excess amount of Cu^{2+} ions, the sample solution was passed through a Chelex-100 column which retains free Cu^{2+} ions and Cu^{2+} ions dissociated from weak complexes. The concentration of complexed Cu(II) species in the column effluent was determined by FAAS and reported as the measure of complexing capacity of strong ligands in the sample. Stolzberg[6] and Wood *et al.*[7] applied similar methods to the determination of the copper-complexing capacity of lake water and sea-water, but did not estimate conditional stability constants for the Cu(II) complexes.

Van den Berg and Kramer[8] developed a method for determining both Cu(II)-complexing capacity and the related conditional stability constants of the complexes, for the ligands in river water and lake water samples, based on the adsorption of free Cu^{2+} ions by

*Present address: Dionex Corp., 1228 Titan Way, Sunnyvale, CA 94088, U.S.A.
†Author to whom correspondence should be addressed.

a fine dispersion of MnO_2. The concentrations of Cu(II) complexes and Cu^{2+} ions remaining in test solutions spiked with free Cu^{2+} were measured by ASV. Van den Berg[9,10] also reported the use of the MnO_2 adsorption technique for sea-water.

In this paper, we present a method based on an automated two-column ion-exchange system developed recently.[11] The application of the method is demonstrated by determining the Cu(II)-complexing capacities and the conditional stability constants of the complexes formed, for 4μM NTA, 4-mg/l. humic acid, and a river water sample.

EXPERIMENTAL

Reagents

Stock and test solutions of Cu(II) and 100 mg/l. humic acid (HA) were prepared, and natural water samples from the Willamette river were obtained and filtered as previously described.[11] Chelex-100 resin (100–200 mesh) in the NH_4^+ form and AG MP-1 macroporous anion-exchange resin (100–200 mesh) in the OH^- form were prepared as previously described.[11] A solution of 0.025M cysteine/0.5M NH_3/2.0M NH_4NO_3 was used as the stripping reagent. A 0.01M NTA solution was prepared from the sodium salt of NTA.

Preparation of ion-exchange columns

Two modified 3 mm i.d. × 50 mm Altex microbore glass columns[12] were used in the experiments. One column, the "Chelex-100 column", was packed with a water-slurry of Chelex-100 resin. The other column, the "Ag MP-1 column", was packed with a water-slurry of AG MP-1 resin up to about 90% of the column volume and the top 10% was then packed with Chelex-100 resin.

Apparatus

The automated two-column ion-exchange system and its application to determination of the speciation of trace metals in natural waters have been described in detail elsewhere.[11] Briefly, a fixed volume of the sample solution, loaded in an injection-valve sample-loop, is passed sequentially through the Chelex-100 column and the AG MP-1 column (which are arranged horizontally) by a carrier stream from a constant flow-rate pump. The Chelex-100 column retains metal ions that are free or derived from complexes that dissociate in the column. The undissociated anionic metal complexes are retained by the AG MP-1 column. Next, the metal species are stripped off the columns separately with a suitable reagent and detected on-line with an atomic-absorption spectrophotometer with an air–acetylene flame. The absorbance of Cu at 324.7 nm was monitored in all studies in this paper. All operations (*e.g.*, sample-loading, column-elution, regeneration of the resins with 2M ammonia solution, data-acquisition, *etc.*) were controlled by a microcomputer.

Instrumental parameters were similar to those used previously,[11] except as noted below. The column washing time during the elution step is increased from 40 to 70 sec for the Chelex-100 column to ensure complete removal of Cu(II). After each sample run, the carrier buffer solution (0.02M ammonium acetate, pH 6.8) is passed through the ion-exchange columns for 150 sec before the next run, to remove any of the stripping or column regeneration reagents that are still in the flow-path. The sample loop volume was 1.0 ml. The flow-rate of the carrier buffer stream was 5.0 ml/min. The throughput rate of the system is about 6 samples/hr.

Procedures

Solutions of 1.26, 2.52, 5.04, 10.1, 18.9, 31.5, 63.0, 126, 252, 441, and 630μM Cu(II) were prepared in each complexing medium tested and in 0.01M ammonium acetate and were adjusted to pH 6.8. These solutions were analyzed with the two-column ion-exchange system. The concentration of Cu(II) species retained on the AG MP-1 column was measured for each of the solutions and treated as a titration data-point.

For each complexing medium tested, freshly-packed Chelex-100 and AG MP-1 columns were used because it was found that the retention efficiency of the Chelex-100 column for Cu^{2+} decreased somewhat when the column was used for more than 10 hr. To determine the retention efficiency of the Chelex-100 column for Cu^{2+}, the 126, 252, 441 and 630μM Cu^{2+} solutions in 0.01M ammonium acetate, adjusted to pH 6.8, were analyzed with the two-column system to determine the concentration of free Cu^{2+} retained by the AG MP-1 column.

The complexing media tested were 4.0μM NTA, 4.0-mg/l. HA, and the Willamette River water sample. All solutions were prepared about 8–12 hr before measurement, to allow equilibration of the Cu^{2+} spikes with the sample solution.

RESULTS AND DISCUSSION

Two-column measurement scheme

The basis of the scheme is shown in Fig. 1. Being a chelating resin, Chelex-100 binds most free transition-metal ions strongly and competes with other organic ligands for trace metal ions bound to them; some weakly complexed metal species can thus be dissociated and contribute to the fraction of metal species retained by the resin. AG MP-1 resin is a macroporous strongly basic anion-exchange resin which has been shown to retain anionic metal complexes and some metal ions strongly associated with

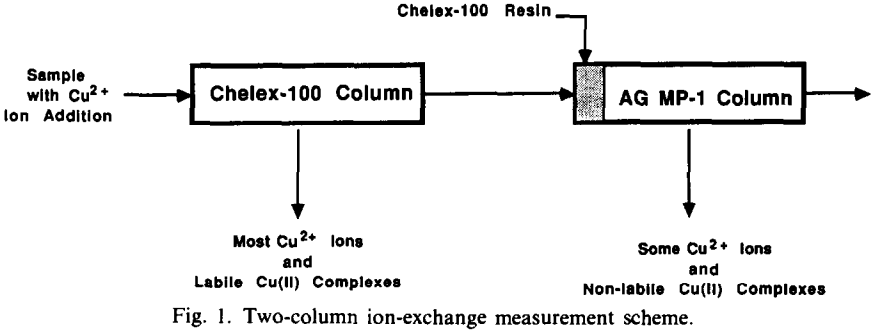

Fig. 1. Two-column ion-exchange measurement scheme.

negatively charged organic colloidal matter such as humic acid.[11]

In batch experiments, where a test solution containing Cu^{2+} ions is in contact with Chelex-100 for a sufficiently long time, equilibrium is established between Cu^{2+} in solution and Cu^{2+} bound by the iminodiacetate chelating group (R) on the resin [$Cu^{2+} + R(NH_4)_2 \rightleftharpoons CuR + 2NH_4^+$], and the following equation applies:

$$K'_{CuR} = \frac{[CuR]}{[Cu^{2+}](c_R - [CuR])} \quad (1)$$

where K'_{CuR} is the conditional stability constant for complexation of Cu(II) with the iminodiacetate chelating group on the resin, [CuR] the concentration of the Cu^{2+} retained by the resin, [Cu^{2+}] the concentration of Cu^{2+} ion left in the solution, and c_R the total concentration of the chelating groups on the resin. If [CuR] is much smaller than c_R, equation (1) may be rearranged to:

$$c_R K'_{CuR} = \frac{[CuR]}{[Cu^{2+}]} \quad (2)$$

In a column experiment, a plug of test solution containing Cu^{2+} ions is passed through the Chelex-100 column at a given flow-rate. For this study, the sample volume (1 ml) is greater than the void volume of the packed column (~0.12 ml). Most of the Cu^{2+} ions in the solution are retained by the Chelex-100 column, but a small fraction is not. The quantity of Cu^{2+} ions in the column effluent is much greater than that predicted by the batch model as described by equation (2) and estimates of K'_{CuR} and c_R (about 10^{10} and 0.3 meq/ml of resin bed). Possibly, some of the Cu^{2+} ions follow a flow-path through the column such that they do not contact the chelating functional groups on the resin beads, or possibly channelling may occur. Hence the kinetics of the transport rather than the kinetics of complexation by the resin may limit the quantity of Cu^{2+} ions retained.

The batch model therefore cannot be applied to the column experiment, but the efficiency (E) of the Chelex-100 column for retention of Cu^{2+} can be described empirically by

$$E = \frac{N_1}{N_2} = \frac{[Cu^{2+}]_1}{[Cu^{2+}]_2} = \frac{c_{Cu} - [Cu^{2+}]_2}{[Cu^{2+}]_2} \quad (3)$$

where N_1 is the number of moles of Cu^{2+} ions retained by the Chelex-100 column, and N_2 is the number of moles of Cu^{2+} ions that pass through the Chelex-100 column and are retained by the AG MP-1 column. Most (>95%) of the Cu^{2+} ions not retained by the Chelex-100 column are retained by the AG MP-1 column.[11]

The second and third forms of equation (3) are written in terms of effective concentrations [defined as the number of moles of Cu(II) retained by a column, divided by the sample volume]. $[Cu^{2+}]_1$ and $[Cu^{2+}]_2$ are the effective concentrations of Cu^{2+} ion retained by the Chelex-100 and AG MP-1 columns, respectively; c_{Cu} is the total copper concentration in the original sample solution. Effective concentrations are used in the further discussion and are determined by comparing the area of the copper elution peak for a test solution with that for an equal volume of a standard Cu^{2+} solution. Note that the true concentrations of Cu^{2+} ion bound to the resin and in the carrier stream, vary along the length of the column and with time when the sample passes through the column.

To determine E, the third form of equation (3) is employed. A series of Cu^{2+} ion standard solutions (without ligand present) of concentration high enough for the amount of Cu^{2+} retained by the AG MP-1 column to be detectable, is injected into the system. Under these conditions, the absorbance of the elution peak for the Chelex-100 column is outside the linear range of response of the AA spectrophotometer, so $[Cu^{2+}]_1$ is taken as the difference between c_{Cu} and $[Cu^{2+}]_2$. A plot of $(c_{Cu} - [Cu^{2+}]_2)$ *vs.* $[Cu^{2+}]_2$ is constructed for a series of Cu^{2+} standard solutions, and E is determined from the slope; it is typically 200–300. The value of E is affected by variables such as pH, flow-rate, Chelex-100 resin particle-size, column length and column packing. However, the retention efficiency is a constant for a given column if all these variables are kept constant and the amount of Cu^{2+} ion retained is much smaller than the resin capacity, as is the case in this study.

In a sample solution containing Cu^{2+} ion and a ligand, L, the complexation equilibrium ($Cu^{2+} + L \rightleftharpoons CuL$) is described by

$$K'_{CuL} = \frac{[CuL]}{[Cu^{2+}][L]} = \frac{[CuL]}{[Cu^{2+}](c_L - [CuL])} \quad (4)$$

where K'_{CuL} is the conditional stability constant and c_L is the total concentration or complexing capacity of the ligand.

As a plug of sample solution moves through the Chelex-100 column, the concentration of Cu^{2+} ion in the solution decreases to a small fraction of the initial concentration, which can result in some dissociation of the CuL complex. Thus the concentration of CuL in the solution leaving the Chelex-100 column may be lower than the initial concentration entering the column.

It is assumed in further discussions that the dissociation rate constant of the CuL complex is sufficiently large for Cu^{2+}, L, and CuL to be in local equilibrium at all points in the Chelex-100 column. K'_{CuL} can be defined as the value calculated from the effective concentrations of Cu^{2+}, L, and CuL in the solution leaving the Chelex-100 column (*i.e.*, $[Cu^{2+}]_2$, $[L]_2$, and $[CuL]_2$).

The solution leaving the Chelex-100 column contains both Cu^{2+} and CuL, which are retained by the Chelex-100 resin and the AG MP-1 anion resin respectively, in the AG MP-1 column (if CuL is negatively charged). Then the total amount ($[Cu]_2$) of copper retained by the AG MP-1 column can be

obtained from:

$$[Cu]_2 = [Cu^{2+}]_2 + [CuL]_2 \quad (5)$$

In the two-column scheme, $[Cu]_2$ is determined from the area of the elution peak for the AG MP-1 column. The value of $[Cu^{2+}]_2$ is calculated for a given initial total Cu(II) concentration by using the measured retention efficiency, E, of the Chelex-100 column used: $[Cu^{2+}]_2 = ([Cu^{2+}]_1)/E = (c_{Cu} - [Cu]_2)/E$. $[CuL]_2$ is obtained from the difference between $[Cu]_2$ and $[Cu^{2+}]_2$. It is assumed that any Cu^{2+} ions released by dissociation of the Cu(II) complexes in the Chelex-100 column are retained there with the same efficiency as the Cu^{2+} ions in a ligand-free sample solution. It might be expected that the Cu^{2+} ions released from dissociation of Cu(II) complexes further down the column would be retained with a lower efficiency. In other studies[11] it was found that when a Cu(II)–glycinate solution in which all the Cu(II) was initially complexed was passed through the Chelex-100 column, over 99% of the Cu(II) was retained by the column. This demonstrates that the retention efficiency for Cu^{2+} ions released by dissociation of the Cu(II) complexes is greater than 100 and reasonably close to that measured for ligand-free solutions. For titration points with $c_{Cu} \gg [Cu]_2$, the contribution to $[Cu^{2+}]_2$ from dissociation of Cu(II) complexes would be expected to be lower (*i.e.*, the degree of dissociation would be much less than 100%).

Equation (4) is rearranged to equation (6) to determine the Cu(II) complexing capacity and to estimate K'_{CuL}.

$$\frac{[Cu^{2+}]_2}{[CuL]_2} = \frac{[Cu^{2+}]_2}{c_L} + \frac{1}{K'_{CuL}c_L} \quad (6)$$

The experimental data are fitted to equation (6) by constructing a plot of $[Cu^{2+}]_2/[CuL]_2$ *vs.* $[Cu^{2+}]_2$ for a series of solutions containing different known amounts of Cu(II) in a given sample or ligand medium. The plot gives a straight line with slope $1/c_L$. The conditional stability constant, K'_{CuL}, can be obtained by dividing the slope by the intercept. In all cases, the slope and intercept were estimated by a linear least-squares fitting procedure.

If there are two different ligands, L1 and L2, in the sample solution, the effective concentration of complexed Cu retained on the AG MP-1 column becomes

$$[CuL]_2 = [CuL1]_2 + [CuL2]_2 \quad (7)$$

In this case, a plot of $[Cu^{2+}]_2/[CuL]_2$ *vs.* $[Cu^{2+}]_2$ is not linear. To determine the Cu(II) complexing capacity and conditional stability constant of Cu(II) with each ligand, an estimation procedure similar to that of van den Berg[13] is used.

When the total Cu(II) concentration is low, if $K'_{CuL1} \gg K'_{CuL2}$ and $c_{L1} \sim c_{L2}$, the formation of CuL1 is predominant (*i.e.*, $[CuL]_2 \sim [CuL1]_2$). A plot of $[Cu^{2+}]_2/[CuL]_2$ *vs.* $[Cu^{2+}]_2$ is then approximately linear and is used to obtain initial estimates for c_{L1} and K'_{CuL1}. The estimated value of $[CuL1]_2$ is calculated for each titration point from

$$[CuL1]_2 = \frac{K'_{CuL1}[Cu^{2+}]_2 c_{L1}}{1 + K'_{CuL1}[Cu^{2+}]_2} \quad (8)$$

The calculated value of $[CuL1]_2$ is used to estimate $[CuL2]_2$, at the higher total Cu(II) concentrations, by use of equation (7). A plot of $[Cu^{2+}]_2/[CuL2]_2$ *vs.* $[Cu^{2+}]_2$ then gives the first estimates of c_{L2} and K'_{CuL2}. These estimated values are then used to correct the contribution of $[CuL2]_2$ to $[CuL]_2$ by using an equation similar to equation (8) (*i.e.*, with L2 substituted for L1) to obtain better estimates of $[CuL1]_2$. A plot of $[Cu^{2+}]_2/[CuL1]_2$ *vs.* $[Cu^{2+}]_2$ is constructed to obtain the second estimates of c_{L1} and K'_{CuL1}. The final values of c_{L1}, K'_{CuL1}, c_{L2} and K'_{CuL2} are found by several such iterations.

Application to water samples

An example of a plot of $(c_{Cu} - [Cu^{2+}]_2)$ *vs.* $[Cu^{2+}]_2$ for the determination of the retention efficiency of Cu^{2+} by the Chelex-100 column is shown in Fig. 2. For each study (*i.e.*, each type of complexing medium), a new Chelex-100 column was used and E was determined. The values of E found were 190 (3), 259 (5), and 235 (7) for the Chelex-100 column used for the 4.0μM NTA, 4.0 mg/l. HA, and Willamette River water sample solutions, respectively, with the standard deviations given in parentheses. The variation in the retention efficiency is possibly caused by slight differences in the packing of each Chelex-100 column.

The titration curve for the NTA solution is shown as curve (a) in Fig. 3. During the early stage of the titration, the effective concentration of Cu(II) species retained by the AG MP-1 column, $[Cu]_2$, increases rapidly with the total Cu(II) concentration because a major fraction of the Cu(II) added to the sample solution is complexed. The rate of increase of $[Cu]_2$ decreases as the titration proceeds. After the complexing capacity is exceeded, the titration curve has a constant slope and the increase in $[Cu]_2$ is solely due to the contribution of Cu^{2+} ion not retained by

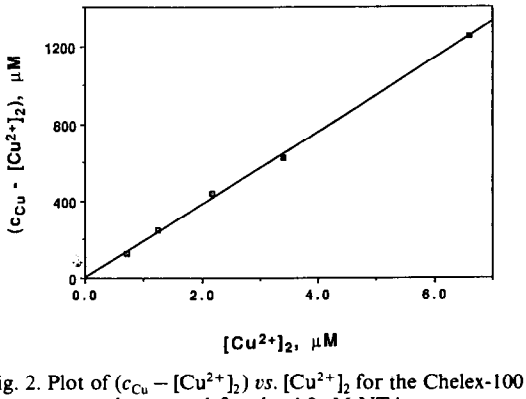

Fig. 2. Plot of $(c_{Cu} - [Cu^{2+}]_2)$ *vs.* $[Cu^{2+}]_2$ for the Chelex-100 column used for the 4.0μM NTA.

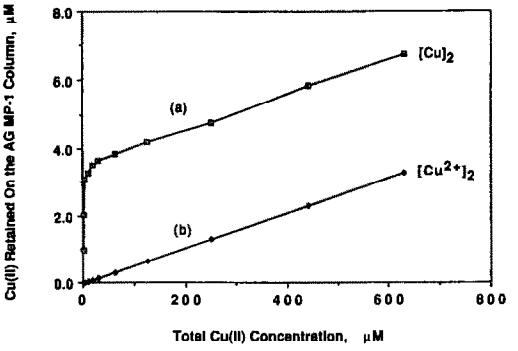

Fig. 3. Typical titration curves with the two-column method.

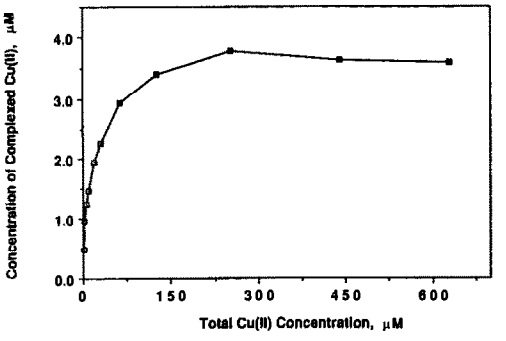

Fig. 5. Corrected titration curve for the 4.0 mg/l. HA solution.

the Chelex-100 column. The effective concentration of Cu^{2+}, $[Cu^{2+}]_2$, calculated from the retention efficiency, E, for each titration point is shown by curve (b) in Fig. 3.

The effective concentration of the complexed Cu(II) species, $[CuL]_2$, for each titration point is obtained from the difference between $[CuL]_2$ and $[Cu^{2+}]_2$. The resulting corrected titration curves ($[CuL]_2$ *vs.* c_{Cu}) are shown in Figs. 4–6. $[CuL]_2$ increases and reaches a plateau as the total Cu(II) concentration increases. The Cu(II) complexes in the sample solution dissociate to some degree, owing to the decrease in the free Cu^{2+} concentration as the sample solution passes through the Chelex-100 column. This degree of dissociation and hence the shape of the corrected titration curve depend on the retention efficiency of the column, the stability constants and dissociation rate constants of the Cu(II) complexes, and the complexing capacity of the ligands. For a given complexing capacity (*i.e.*, the total ligand concentration), the plateau of the corrected titration curve is reached at higher total Cu(II) concentrations for weaker ligands (*i.e.*, a higher Cu^{2+} concentration is required to shift the equilibrium so that essentially all the ligand ions are complexed). If the stability constants of the Cu(II) complexes are too low, the plateau of the corrected titration curve may not be reached at a reasonable total Cu(II) concentration.

The CuL concentration at the plateau of the titration curve indicates the Cu(II) complexing capacity of the sample solution, because all the ligands in the sample solution are effectively saturated when the concentration of added Cu^{2+} ion is high enough. Note that these three complexing media have similar Cu(II) complexing capacity, but the humic acid and ligands in the river water samples form weaker Cu(II) complexes than does NTA, since the plateau in their titration curves is reached at higher Cu(II) concentrations.

Plots of $[Cu^{2+}]_2/[CuL]_2$ *vs.* $[Cu^{2+}]_2$ were constructed for the three complexing media as shown in Figs. 7–9, For the NTA solution, the curve of $[Cu^{2+}]_2/[CuL]_2$ *vs.* $[Cu^{2+}]_2$ is linear, as expected for the 1:1 Cu(II)–NTA complex. For the humic acid solution and the river water, the curves are nonlinear. To determine the Cu(II) complexing capacity and conditional stability constants, the titration data for the NTA solution were analyzed with the one-ligand model. The titration data for the humic acid solution and the river water sample were analyzed with both one- and two-ligand models. With the two-ligand model, the first four titration points for the humic acid solution and the first five for the river water were used to obtain the estimates of c_{L1} and K'_{CuL1}. Later titration points were used to obtain the estimates of c_{L2} and K'_{CuL2}.

Table 1 summarizes the Cu(II) complexing capacities and conditional stability constants found by the one- and two-ligand models. It is noteworthy that the total complexing capacity obtained from both models agrees well with the $[CuL]_2$ value at the plateau of the titration curve. This indicates that the total complexing capacity of the sample solution can also be determined rapidly with a single titration point on the plateau region of the titration curve. For example, the results suggest that the Cu(II) complexing capacity of a sample solution with c_L of $\sim 1\mu M$ and $\log K'_{CuL} = 7$–8 can be rapidly determined with a single addition of copper yielding a total Cu(II) concentration of 630μM.

Because it forms essentially only a negatively charged 1:1 complex with Cu^{2+} under the experimental conditions, NTA was chosen as a model ligand to test the two-column measurement method. The conditional stability constant found for the Cu(II)–NTA complex was $\log K' = 8.64$, which is in reasonable agreement with the value $\log K' = 9.26$ calculated from the literature value [14] with adjustment to the conditions (pH 6.8 and ionic strength 0.01M) used in the experiment. However, the total concentration of NTA found was lower than expected, which might indicate slightly incomplete retention of the complex by the AG MP-1 column.

The results obtained for the humic acid and river water generally agree with those reported for similar samples. Van den Berg and Kramer[8] reported the Cu(II) complexing capacities of a fulvic acid solution and a river water to be 2.2 and 2.5μM, with $\log K' = 7.8$ and 8.5 at pH 7.6. Hart and Jones[15] found (by an ASV method) that the Cu(II) complexing capacity of a creek water sample was about 0.2μM, with K' about 10^8 at pH 6.0. Using an ISE method, McKnight *et al.*[16] showed that aquatic humic substances could be modeled as having two types of Cu(II)-binding sites: one with $\log K'_{CuL1} \simeq 6$ and $c_{L1} = 1.0 \pm 0.4\mu M$ per mg of C and the other with $\log K'_{CuL2} \simeq 8$ and $c_{L2} = 2.6 \pm 1.6\mu M$ per mg of C, at pH 6.25.

The complexation of Cu(II) by the ligands in humic acids or natural waters is very complex and

*The standard deviations in the values of c_L and $\log K'_{CuL}$ are calculated from the standard deviations of the slope and intercept of the linear least-squares fit of titration data to equation (6). The standard deviations in $[CuL]_{max}$ are the standard deviations of data on the plateau of the titration curve of $[CuL]_2$ *vs.* c_{Cu}.

†NTA = 4.0μM NTA solution, HA = 4.0 mg/l. humic acid solution, and River = Willamette River water sample. All solutions were buffered at pH 6.8.

cannot be fully described with the one- or two-ligand models. The ligands in such samples are a multitude of different species that contain complexing sites of different strengths. Thus the conditional stability constants determined represent weighted average values of a distribution. Recently, there have been some reports on discrete and continuous multiligand metal-binding models and their applications.[17-19]

The values of log K'_{CuL1} obtained for the humic acid solution and river water sample have relatively large standard deviations, possibly because only a few data points were obtained in the initial portion of the titration curve. To obtain better estimates for log K'_{CuL1} and c_{L1}, the sample solution could be spiked with very small amounts of Cu^{2+} ions. A larger sample loop (*e.g.*, 10 ml) could be used to increase the preconcentration factor to allow small concentrations of complexed Cu(II) to be determined with better accuracy.

One potential problem associated with the two-column measurement scheme is that nonlabile natural metal complexes and metal ions strongly associated with very large colloidal matter may not be retained by AG MP-1 resin[11] because it is an anion-resin with a molecular exclusion limit of 7.5×10^4. It was found that there was about 4% of this fraction present for 0.32-mg/l. Cu(II) in the 4.0-mg/l. HA solution. Thus, the Cu(II) complexing capacity determined by the method is operationally defined and may be slightly negatively biased.

The data treatment scheme used in this study assumes that the species Cu^{2+}, L, and CuL are in equilibrium when they leave the Chelex-100 column. However, if CuL is nonlabile, equilibrium may not be reached in the time-scale of the experiment (the contact time of the sample solution with the resin in the Chelex-100 column is only about 1.4 sec). In the limiting case when CuL does not dissociate at all, because of very slow dissociation kinetics, the measured effective concentration of CuL would be equal to the concentration of CuL in the original sample solution even at the titration points corresponding to low total Cu(II) concentrations. The conditional stability constant determined by using equation (6) would be larger than the true value, but the complexing capacity determined would still be correct. For very strong complexes (*e.g.*, $CuEDTA^{2-}$), dissociation in the Chelex-100 column is insignificant and the lability of the complexes is immaterial when the ligand concentrations are at μM level. When, there is no curvature in the corrected titration curve, the intercept in the plot of $[Cu^{2+}]_2/[CuL]_2$ *vs.* $[Cu^{2+}]_2$ is indistinguishable from zero, and the stability constant cannot be estimated.

For the three complexing media tested, the significant curvature of the corrected titration curves shows that significant dissociation of Cu(II) complexes occurs in the column. The measured effective concentrations of CuL for the titration points corresponding to low total Cu(II) concentrations are reasonably close to the equilibrium effective concentrations in the solution leaving the Chelex-100 column, estimated from the measured values of E, log K'_{CuL}, and c_L, and smaller than the calculated concentrations of CuL in the original sample solution. This demonstrates that the assumption of equilibrium between Cu^{2+}, L and CuL in the solution leaving the Chelex-100 column is a reasonable approximation for the ligands studied.

CONCLUSIONS

The automated two-column ion-exchange system provides a new rapid method for determining the trace-metal complexing capacity of ligands in natural waters. Compared to other ion-exchange methods, the two-column method is simple and rapid, owing to the automation of the measurement process. One distinct characteristic of the method is that the complexed metal species are preconcentrated and measured directly. In most methods, the free metal fraction is measured and used to calculate the complexed fraction. The ability to measure the complexed fraction directly allows a rapid (10 min), one-point determination of complexing capacity.

The measurement scheme can also be used to estimate conditional stability constants in a certain range for ligands in natural water. To determine the stability constants more accurately, it would be necessary to develop a model that accounts for the concentration profiles of all species along the Chelex column. At present the model used gives order-of-magnitude estimates of the stability constants, in a certain range, if the dissociation of the complex is relatively fast in comparison with the rate of passage through the column. If the corrected titration curve exhibits no curvature, the stability constants cannot be estimated.

(*Received* 6 *May* 1988. *Accepted* 8 *September* 1988)

Summary—Near-infrared reflectance spectrometry of blood serum can yield values for serum cholesterol that correlate reasonably well ($r = 0.96$) with those from common reference analytical methods. However, the variability of serum can cause ostensibly validated calibrations to fail on new samples. The determination of blood components such as cholesterol and triglycerides by near-infrared reflectance is complicated by their low concentrations, the variety of forms in which they appear, and by the natural variability of the blood matrix. These difficulties, when combined with the problems encountered in obtaining a representative sample from a given individual, can make it almost impossible to select, by a regression procedure, a wavelength combination that is characteristic of the complete blood matrix. The failure of the regression process to find characteristic wavelengths generates a false-sample problem in which even small changes at the analytical wavelengths produce a grossly unreliable cholesterol or triglyceride determination.

Epidemiological studies performed over a period of years have indicated that reduction of blood cholesterol levels significantly reduces the risk of atherosclerosis, ischemia, myocardial infarction and death. For some time these data have been cited in experimental attempts to prevent arterial disease. A 1% reduction in plasma cholesterol concentration in individuals at risk for cardiovascular disease has been shown to reduce the risk of cardiac events in these individuals by approximately 2%.[1] More recent data[2] indicate that lowering the cholesterol level improves the condition of coronary arteries partially blocked by atherosclerotic lesions, and can actually effect regression of the disease. These data have been used to make a case for creating a target level for total blood cholesterol of 185–200 mg/dl, a level below the average for the U.S. population. Another report has indicated the discovery of a new mechanism by which atherosclerosis may initiate high blood pressure, cardiac disease, and transient ischemic attacks in the brain.[3] In this report, the accumulation of deposits in arterial walls is described as interfering with the supply of endothelium-derived relaxing factor (EDRF) to muscle fibers, resulting in the onset of vasospasm. Animals fed high-fat diets developed atherosclerotic changes in blood vessels, accompanied by impaired EDRF secretion. Switching to a normal diet restored endothelial production of EDRF, indicating that a low-cholesterol diet may actually act to reduce vasospasms in addition to bringing about the reduction of atherosclerotic lesions.

Plasma cholesterol itself has been the object of considerable research. Cholesterol has been shown to be almost totally carried in lipoprotein particles of different size, density, and lipid and apolipoprotein composition.[4] Cholesterol and triglycerides in different lipoprotein particles take different metabolic pathways, and have different effects on arterial disease. High-density lipoproteins (HDLs) have been identified as removing cholesterol from tissues (and exhibiting a protective effect against arterial disease) by a process known as reverse cholesterol transport.[4] Apolipoprotein A-I, the principal apoprotein of HDLs, activates the plasma enzyme lecithin cholesterol acyltransferase, forming nonpolar cholesteryl ester and shifting cholesterol from the surface of the HDL particle to the hydrophobic core for transport to the liver. In the liver, cholesterol can be eliminated from the body either as bile acids or as cholesterol, but predominantly as the former. Low-density lipoprotein (LDL), composed of esterified and

*Present address: College of Pharmacy, University of Kentucky, Lexington, KY 40536-0082, U.S.A.
†Author to whom correspondence should be addressed.

nonesterified cholesterol as well as phospholipid, transports cholesterol to peripheral cells for membrane synthesis. Elevated levels of LDL have been shown to increase the risk of cardiovascular disease.

The increase in knowledge of lipoprotein metabolism and atherogenesis has been accompanied by an abundance of experiments designed to test a variety of treatments for atherosclerosis and hypercholesterolemia. Dietary studies have suggested that foods containing pectin,[5] such as grapefruit, and calcium pectate,[6] such as carrots, onions, and cabbage, may be useful in reducing cholesterol levels. Calcium pectate appears to lower cholesterol by sequestration of bile acids.[6] Though the effectiveness of fish oils in modifying lipoprotein levels has been debated, ethanol in small daily doses has been shown to increase levels of HDL_2 and HDL_3 (the major blood HDL components), leading to a 46% reduction in the risk of myocardial infarction.[7] Of course, ethanol consumption can lead to another set of health problems, and use of ethanol to increase HDL levels is never recommended.[4] Experiments to modify cholesterol levels with drugs are continually being conducted. Niacin, which in low doses acts as a vitamin, when administered in doses of more than 300 mg/day reduces LDL cholesterol by interfering with the initial secretion of atherogenic particles. Cholestyramine resin and colestipol hydrochloride reduce cholesterol by sequestering bile acids.[4] New drugs, based on the inhibition of HMG (hydroxymethylglutaryl) coenzyme A reductase, break the chain of cholesterol synthesis at the mevalonic acid stage and appear even more effective in reducing cholesterol levels than colestipol, cholestyramine, and niacin.[8] Finally, surgical remedies for cardiovascular disease such as balloon angioplasty (150,000/yr in the U.S.) and coronary bypasses (220,000/yr in the U.S.) are being augmented by a number of methods intended to make certain that newly opened arteries remain open. Stents (tubes left inside blood vessels to hold them open), sound waves from modified lithotriptors, and laser catheters made of sapphire-tipped optical fibers were all described at the recent 60th American Heart Association meeting in Anaheim, CA.[9] In short, the role of lipoprotein cholesterol in cardiovascular disease is becoming increasingly clear, and methods for interdiction of the disease are becoming increasingly numerous and effective.

The natural question for the analytical chemist, then, is how to identify individuals with hyperlipoproteinemia. On the surface this appears to be a question that was answered long ago: clinical blood-analysis instruments from Technicon and Dupont,[10] among others, have been available for some time. However, concern about the accuracy of the present determinations as well as calls for the mass-screening of individuals to detect incipient hyperlipoproteinemia have indicated the need for a new, rapid, low-cost method of blood analysis. On 5 October 1987 the National Cholesterol Education Program of the National Heart, Lung, and Blood Institute released a widely publicized report[11,12] calling for the testing of all adults, aged over 20, every five years. If the test result is in excess of 200 mg/dl (total serum cholesterol) or other risk factors exist (such as being male, a smoker, obese, diabetic, hypertensive, or having a family history of premature coronary disease), then more frequent (as often as several times each year) and more complex (simultaneous LDL cholesterol determination) testing may be indicated. These tests can cost from $11 to $40 apiece, and even then do not ensure an accurate reading of an individual's cholesterol levels. A 1985 College of American Pathologists Comprehensive Chemistry Survey found that 47% of the 5000 testing laboratories volunteering for the survey could not get a result within 5% of the true cholesterol value.[12] This error is significant because clinical risk brackets are generally less than 10% wide.[10] Laboratory inaccuracies and natural biological variation (which can be[10] as high as 10% even in individuals maintained under metabolic-ward conditions) combine "to render a single test virtually meaningless." Further,[12] in order "to be sure [of the actual value] within 5%, the test... need[s] to be repeated five to ten times." Still, a single test remains a better screening method than no test at all.

The large number of tests generated by a mass-screening program is made much larger by the number of repeat tests necessary to achieve a clinically meaningful result, creating an analytical problem with a solution that appears expensive in terms of both time and money. The development of a rapid, low-cost, and completely spectroscopic method of analyzing blood with good precision and accuracy would be a major step toward achieving the mass-screening goal. Work has been done on completely spectroscopic cholesterol determinations in both the infrared and near-infrared. In the infrared,[13] simultaneous determinations of relatively pure tripalmitin, dipalmitoyl-DL-α-phosphatidylcholine, and cholesteryl palmitate in reagent-grade choloroform solution were performed by using 15 wavelengths and a multiple linear regression procedure. A training set of 85 mixtures of these reagents was required for the regression even with these carefully prepared samples. Near-infrared determination of serum cholesterol in 30 human sera samples (ranging from 3 to 12m*M* in 0.3m*M* increments) by a similar multiple linear regression procedure has been reported.[14] The report described the careful construction of the training set and regression at 5, 6, and 7 wavelengths to give correlations with total cholesterol, with r values ranging from 0.92 to 0.93.

The present report describes not only the near-infrared determination of cholesterol and triglycerides, but also lists a number of factors that often thwart such determinations. The pattern-recognition spectroscopic analysis of samples such as blood serum is complicated by (1) the large number of very

similar components present at about the same low concentration, (2) the lack of a satisfactorily accurate reference method, (3) the natural variability of the matrix relative to the components of interest (*e.g.*, different diets, fitness levels, and diseases affect the lipid distribution in serum), and (4) the difficulty in obtaining a representative sample from a given individual (*e.g.*, it is known that both the time the tourniquet is left on and the standing or sitting position of an individual during sample-drawing can affect the cholesterol measurement[11]). Instrumental factors such as drift, inadequate signal-to-noise ratio, and lack of availability of sufficient independent wavelengths can also increase the difficulty of spectroscopic pattern-recognition. Finally, the large number of samples required to represent adequately the variability of the population can also become an obstacle to developing effective pattern-recognition methods.

EXPERIMENTAL

Apparatus

A Technicon InfraAlyzer 400 filter spectrophotometer was used to collect near-infrared reflectance data at 18 different wavelengths. The spectral data were analyzed on a VAX 11/780 computer (Digital Equipment Corp., Maynard, MA). The data-analysis programs were written in Speakeasy IV Epsilon (VMS version, Speakeasy Computing Corp., Chicago, IL). Serum samples were analyzed in a 70-μl disposable microcell[15] designed for use in the Technicon spectrophotometer.

Materials

The near-infrared method of serum analysis requires no reagents. The serum samples were acquired from participants in a "Fitness Fair" conducted by the Indiana University School of Medicine in Indianapolis, IN. Blood samples were permitted to clot and were then centrifuged. The resulting serum was transferred to the microcell with a precision pipet (Rainin Instrument Co., Woburn, MA). Four scans were taken of each sample and these scans were averaged prior to data analysis.

Reference cholesterol values for the samples were obtained by using a Dupont aca instrument that was provided by the Department of Pathology. The reproducibility of measurements taken with such a device is good[10] and the bias is unlikely to be very large as long as reference samples are regularly employed to control it. Additional biochemical screening tests were performed with an Eastman Kodak Ektachem 700 instrument.

RESULTS AND DISCUSSION

An initial experiment was performed with a small training set (30 samples) that was carefully assembled to cover the entire range of human cholesterol values. This experiment is similar to the one described by Peuchant *et al.*,[14] where the cholesterol range from 4 to 12mM was covered by 30 samples in 0.3mM increments. To enhance the realism of the test, this experiment was performed with unaltered clinical samples (no cholesterol added), so total coverage of the range from 4 to 12mM had to be approximated by samples drawn from the Fitness Fair pool. These samples ranged from about 4 to 10mM (156–373 mg/dl) total cholesterol (no samples with higher cholesterol concentration were available). A validation set of 30 samples (*i.e.*, samples not used to develop a calibration equation) was also drawn.

The calibration equation was developed by principal-component regression (Speakeasy Computing Corp.) on the 18-wavelength data for the 30 samples in the training set. The correlation coefficient (r) between the experimental values and the fitted values for the training set was 0.966, and the corresponding standard error of estimate (SEE) was 12.4 mg/dl (*i.e.*, RSD = 6%). The calibration equation was then applied to determination of the total cholesterol values of the validation set. The correlation coefficient between the cholesterol values determined by the reference method mentioned above and the values obtained by application of the calibration equation (to the reflectance data for the validation samples) was 0.960, somewhat better than had been obtained by Peuchant *et al.*[14]

Unfortunately, such a small number of carefully selected samples can easily fail to cover the range of variations that can exist in a complex sample such as blood serum. Clinical samples are often affected by hemolysis or turbidity, for instance. The presence of large numbers of chylomicrons in some samples must be expected. Furthermore, the determination of total serum cholesterol is really the determination of cholesterol contained in a number of particles that are quite different. About two-thirds of the total cholesterol in plasma is carried in LDL and IDL (intermediate-density lipoprotein) particles 21–35 nm in diameter. The LDL particles have a surface layer that contains about 8% cholesterol, while about 42% of the core is formed of cholesteryl esters. The remainder of the LDL particles comprises 6% triglycerides (found in the core), 22% phospholipids (found at the surface), and 22% protein (also found at the surface). The principal LDL apolipoprotein is apoB (95% of the apolipoprotein content), but traces of at least 7 other apoproteins can be found. IDL has a surface composition similar to LDL and a core that contains more triglycerides (23%) but less cholesteryl ester (29%).

The second-largest carrier of plasma cholesterol is HDL, which contains mostly protein (about 50% located at the surface), phospholipids (also at the surface, about 30%), and esterified cholesterol (in the core, about 15%). The major HDL apolipoprotein is apoA-I (64% of apolipoprotein content), but significant amounts of A-II, C-I, C-III, ARP, and D can also be found in HDL particles. This may seem already complex enough, but plasma HDL can actually be separated into two distinct components, HDL_2 (particles about 10 nm in diameter) and HDL_3 (particles about 7.5 nm in diameter). HDL_2 has more cholesteryl ester (in the core) and phospholipid (on the surface) and less protein (on the surface) than HDL_3.

Cholesterol and cholesteryl ester are also found

in smaller quantities in VLDL (very low-density lipoprotein) and chylomicrons as well as in certain abnormal lipoproteins.

If the total cholesterol concentration for an individual were to be partitioned into the six or so major particle-environments for cholesterol, the average cholesterol concentration in each environment would be roughly 30 mg per dl of the total serum. This concentration is low by near-infrared standards, suggesting that a good, general calibration equation for cholesterol may be difficult to achieve. Kisner *et al.*[13] discussed the problem of infrared determination of cholesterol, and needed 85 three-component training samples (prepared as solutions in chloroform, in the laboratory) monitored at 15 wavelengths, to develop a useful calibration equation. Indeed, larger training-set sizes were proposed as a means of generating more accurate calibrations. The components interfered with one another substantially even though there were only 3 of them. The situation is exacerbated in the near-infrared, where the signals consist largely of overtones and combinations of fundamental infrared vibrations.[16]

The Fitness-Fair blood-sample pool contained normal samples, icteric samples, hyperlipoproteinemic samples, samples from both sexes, samples from fasting and nonfasting individuals, samples containing drugs, samples that were refrigerated prior to analysis and samples that were not, samples with hemolysis and turbidity, *etc.* When all the blood samples in the Fitness Fair pool (a total of 162) were used to develop a near-infrared calibration equation for cholesterol, the standard error of estimate for the calibration rose to 36.5 mg/dl. Dividing the samples into two groups and calibrating with 81 training samples gave an SEE of 33.5 mg/dl. On the surface it appeared that the pool contained a number of sample subgroups, each of which might best be considered separately in attempts to develop a near-infrared calibration for cholesterol.

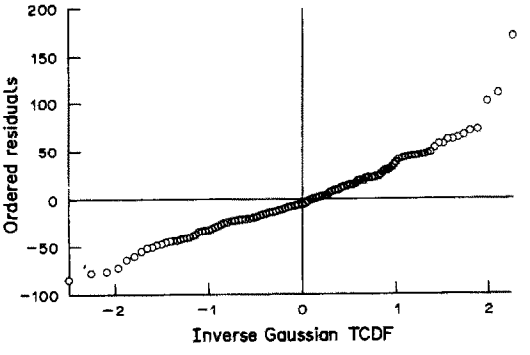

Fig. 1. An empirical QQ plot of the residuals from the ordinary least-squares line through the values for all the samples in the pool. Fitting was performed between the principal-component spectra and the reference cholesterol values. The ordered residuals from the fitting process are plotted on the ordinate, and the values of the inverse Gaussian theoretical cumulative distribution function (Φ^{-1}) are plotted on the abscissa. With the exception of the three outlying points at the top of the graph, all the points form a single line, suggesting a single group.

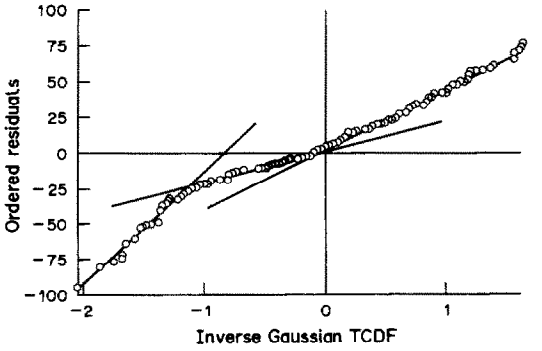

Fig. 2. An empirical QQ plot of the ordered residuals from a robust-fit line through the results for all the samples in the pool. Fitting was performed betweeen the principal-component spectra and the reference cholesterol values. The outlying points at the top of the graph (see Fig. 1) are omitted by scaling to expand the range around the 3 lines that suggest 3 groups.

Leverage effects in least-squares regression force calibration lines to the best simultaneous fit through all of the groups present in a sample pool.[17] This forced fit increases the error in application of the calibration to new samples, and may also obscure the fact that subgroups are present. Determining subgroup membership from sample spectra is analogous to detection of samples that have been tampered with, and the extent to which false samples can be detected largely determines the suitability of pattern-recognition methods for blood analysis.

Robust methods of regression,[17] combined with quantile–quantile (QQ) plots of residuals from the fitting process, are useful in identifying the presence of subgroups in spectral data. Distinct patterns emerge in these plots, that are indicative of underlying structures in the data.[19] In general, every straight line or line segment in the plot corresponds to a group of residuals. When the ordered residuals from a fitting process are plotted (on the ordinate) *vs.* the inverse Gaussian cumulative distribution function (on the abscissa) the slope of each segment in the plot is equal to the standard deviation of the corresponding group of residuals (see Fig. 1). Furthermore, the intercept of each line in the plot is equal to the mean of the corresponding group of residuals. Finally, curvature in lines indicates skew in the residuals.

The ARCANE multivariate robust regression,[20] based on a repeated-medians procedure[21] and weighted multiple least-squares, was used to generate a cholesterol calibration line by use of all the test specimens obtained at the Fitness Fair. A QQ plot of the residuals from the ARCANE fit appears in Fig. 2. Some scatter appears in the points because they represent actual experimental data, hence the best-fit straight line to each cluster is also shown in order to delineate the groups better. We will call the three groups apparent in Fig. 2 groups 1, 2, and 3.

Table 1. Probability* of two cholesterol groups sharing the same mean level of a background constituent

	Albumin		Sodium	
	Group 2	Group 3	Group 2	Group 3
Group 1	88	23	11	2
Group 2	—	27	—	1
	Protein		Triglycerides	
	Group 2	Group 3	Group 2	Group 3
Group 1	82	13	1	24
Group 2	—	23	—	45
	Glucose			
	Group 1	Group 3		
Group 1	5	63		
Group 2	—	19		

*Probability given as % by a 2-tailed t-test.

If the sample matrix were the same for each of the cholesterol groups, the same cholesterol calibration would work for every group. Table 1 gives the percentage overlap ($P[\text{data}|H_0:\mu_1=\mu_2]$, 2-tailed t-test) between two cholesterol groups with different albumin, sodium, protein, triglyceride, or glucose values. The sodium concentration appears to differentiate the cholesterol groups most effectively; for instance, the probability that groups 2 and 3 have the same Na^+ concentration is only 1%. Other differences can be found between the groups as well, *e.g.*, although the overall pool membership was nearly 75% female, the membership of group 3 was 55% male. Interestingly, group 3 also had the lowest average cholesterol concentration of the three groups (177.5 mg/dl). These compositional differences do not lead to distinct spectroscopic groups when the n-wavelength spectra are projected as points into an n-dimensional hyperspace, however. For example, when the BEAST algorithm,[18] a nonparametric method of measuring distances in hyperspace, is used, the mean distance of the group-2 spectral points from the center of the group-1 training set is 5.4 standard deviations (SDs). (Complete separation between two groups of similar size is ordinarily defined as 6 SDs.) The mean distance from the center of the group-1 pionts to the group-3 points is just 4.3 SDs. The combination of the spectral overlap of the cholesterol groups with the prediction error of the sodium calibration equation is more than enough to prevent assignation of a single sample to a single cholesterol group on the basis of a sodium concentration determined by near-infrared spectroscopy. Of course, sets of samples can often be assigned to a certain group even when the groups overlap.[22] Unfortunately, while this set-assignment technique is useful for process-control applications and exploratory analyses of multidimensional distributions, its utility in serum analysis is limited because sets of samples from a given individual are seldom available.

If additional information vectors could be found that resulted in the formation of a space in which the groups were all separated by more than 6 SDs, fairly accurate cholesterol determinations could still be performed by a pattern-recognition technique such as principal-component regression. Additional information vectors could be anything from use of new near-infrared wavelengths to results from completely separate analytical techniques such as chromatography. If a single serum sample could be unambiguously assigned to a specific cholesterol group, the prediction errors for the three groups would be 12.5 mg/dl (for group 1), 14.7 mg/dl (for group 2), and 10.7 mg/dl (for group 3). These prediction errors were obtained by dividing each of the three cholesterol groups in half, generating a near-infrared calibration equation with one half of each group, and using this to predict the cholesterol concentrations of the samples in the other half. While these are acceptable errors by themselves, they do not reflect the error introduced by improper assignment of a specific sample to a certain group. Combining the assignment error with the prediction error could be expected to raise the prediction error to the level obtained for calibration with the entire 162-sample pool.

Grouping effects similar to those observed in the cholesterol system have also been noted in triglyceride calibrations (see Fig. 3). Perhaps the worst problem encountered in performing cholesterol and triglyceride determinations with an 18-filter instrument, however, is that even after principal-axis transformation, the largest signal for both cholesterol and triglycerides is found on the same axis (the 8th). Cholesterol and triglyceride levels are not particularly correlated (see Fig. 4) and thus give substantial mutual interference at the analytical wavelengths used in our instrument (see Table 2). (It should be noted that the filters in the InfraAlyzer were not chosen for serum analysis in particular, but instead for their suitability for other analyses.) The standard error of the triglyceride calibration based on all 162 samples in the pool was 52 mg/dl.

Other blood constituents can also be determined with the near-infrared technique; for example, albumin and total protein determinations on the entire sample pool produced RSDs of 6 and 4%, respect-

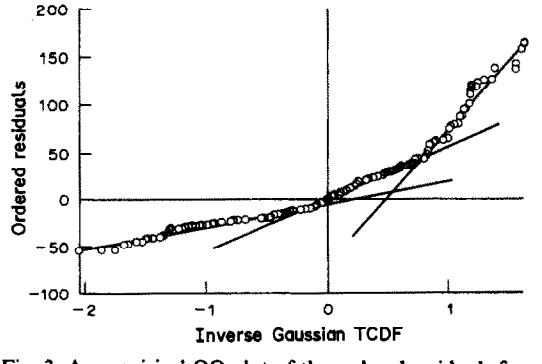

Fig. 3. An empirical QQ plot of the ordered residuals from a robust-fit line for all the samples in the pool. In this case, fitting was done between the principal-component spectra and the reference triglyceride values.

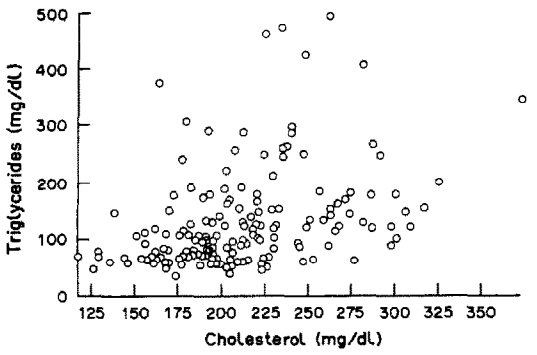

Fig. 4. A scatter-plot showing the relationship between the reference cholesterol and triglyceride values of all the samples in the pool ($r^2 = 0.14$).

ively. These constituents are present at fairly high concentrations, however. Unfortunately, there is a large number of rather similar, partially correlated serum constituents present at or near the levels of the lipoproteins, greatly complicating the near-infrared spectral analysis. In a practical sense, an instrument that produces a useful cholesterol result for only half the samples seems unlikely to gain wide clinical acceptance, even if the instrument is able to tell the operator that it cannot predict the cholesterol concentration in the remainder of the samples.

CONCLUSIONS

This study provides an indication of what still needs to be done in order to create a completely optical, reliable near-infrared method of serum analysis. Obviously, the subclustering observed inside training sets can be the result of a number of phenomena, including (1) a lack of sufficient training samples that are well-distributed across the range of sample variability, (2) a shortage of independent wavelengths available for describing the variability of the training set and its natural groups, and (3) noise factors, including not only random instrumental noise but also operator effects (such as work by different analysts on different days), temperature variations, lack of sample reproducibility (noted in other cholesterol determinations described earlier), and others. Whenever a system has a large number of independent variables (*e.g.*, chemical constituents), and monitoring is accomplished by using a small number of independent information vectors (*e.g.*, wavelengths), variations in the system that are theoretically meaningful will appear to be random noise, complicating the problem of analysis.

Attempts to correlate group membership with known parameters of the sample pool indicated that the groups are different in a number of ways. To a certain extent these differences, too, could be a function of the limited number of samples available. Determining the source or sources of serum spectral subclustering will inevitably require the gathering of a larger sample pool.

The development of a broadly applicable near-infrared method of analyzing blood serum, using relatively small training sets (30 samples) and a few wavelengths (less than 20) in a standard filter instrument, appears to be confounded by the false-sample problem (the problem that arises in pattern-recognition when something unexpected appears in a sample). Nevertheless, considerable evidence indicates that accurate near-infrared determination of a number of blood constituents is possible. The next step is the acquisition of a high S/N training set with a thousand or more samples, the full near-infrared spectra of which will be analyzed at a few hundred wavelengths.

THE UTILITY OF TIME-RESOLVED EMISSION SPECTROSCOPY IN THE STUDY OF CYCLODEXTRIN–PYRENE INCLUSION COMPLEXES

GREGORY NELSON, GABOR PATONAY and ISIAH M. WARNER
Chemistry Department, Emory University, Atlanta, GA 30322, U.S.A.

(*Received* 19 *April* 1988. *Accepted* 7 *September* 1988)

Summary—The application of time-resolved emission spectroscopy to the characterization of cyclodextrin inclusion complexes of pyrene in the presence of various alcohols is described. Such measurements offer a means of selectively studying the characteristics of inclusion complexes in the presence of uncomplexed pyrene. The fluorescence lifetimes and formation constants of these complexes are enhanced in the presence of alcohols. These enhancements are reportedly due to the formation of pyrene–alcohol–CD ternary complexes.

Cyclodextrins (CDs) have been studied over the past several years because of their unique physical properties.[1,2] The CD molecule may accommodate appropriately sized molecules in its hydrophobic interior and thus is well suited as an organizing medium in aqueous systems. This molecular organizing property has been shown to have a marked effect on the photophysical properties of an included guest molecule.[3–5]

The use of fluorescence spectroscopy for the study of CD systems has increased.[6,7] This is because changes in the spectral characteristics of a probe molecule such as pyrene provide information about the immediate microenvironment in the CD cavity.[8] Changes in the fluorescence intensity as a function of CD concentration can be used to calculate formation constants for inclusion compounds.[9,10] In addition, the temporal properties and equilibrium concentrations of included fluorophores may be examined by using fluorescence lifetime measurements.[11]

The interaction of third components with CD inclusion complexes has been recently described. Much attention has been focused on excimer formation in the CD cavity.[4,12] Other studies have investigated retardation and enhancement of fluorescence quenching due to inclusion of the quencher, fluorophore, or both, in the CD cavity.[13–15] Mixed systems of CDs and surfactants have been demonstrated to have unique properties.[16,17] Alcohols have been shown to change the inclusion and spectral characteristics of a guest molecule.[18–21] Changes in the apparent hydrophobicity of the CD cavity[22] and in pyrene fluorescence lifetime have been shown to accompany complexation in the presence of alcohols.[23]

The introduction of time-resolved emission spectroscopy (TRES) on a nanosecond time scale by Ware *et al.*[24] provided an experimental method for studying emission from systems as a function of wavelength and time. A time-resolved (TR) emission spectrum may be recorded by scanning with an emission monochromator and recording the fluorescence intensity at some time after sample excitation by a nonosecond light source. These measurements were originally accomplished by use of a nanosecond flash lamp and a traveling wave photomultiplier.[24–26] The technique was quickly adapted to time-correlated single-photon counting (TCSPC) fluorescence lifetime measurements.[25] Various methods of constructing TR emission spectra from fluorescence decay curves by using data-analysis techniques have also appeared in the literature.[27,28] These methods can be applied when components with very different[27] or similar[28] decay times are involved. Although the methodology for obtaining time- or wavelength-resolved fluorescence data is different in these newer methods, the resulting goal is the same, viz. utilizing the temporal nature of fluorescence to elucidate spectral parameters for a given system. In this paper, we will review the methodology for the direct recording of TR emission spectra by use of TCSPC instrumentation for fluorescence lifetime measurement, and demonstrate the utility of TRES in the study of inclusion complexes of pyrene and cyclodextrins in the presence of various alcohols.

THEORY

TRES measurements

In TCSPC measurements (see the monographs by Demas[29] and O'Connor and Phillips[30] for a thorough description of TCSPC measurements), data are collected by using a multichannel analyzer (MCA), which sorts into a histogram the times measured for excitation–emission events. After the collection of several hundred thousand of these events, a fluorescence decay curve such as that depicted in Fig. 1a is obtained. In this experimental apparatus,

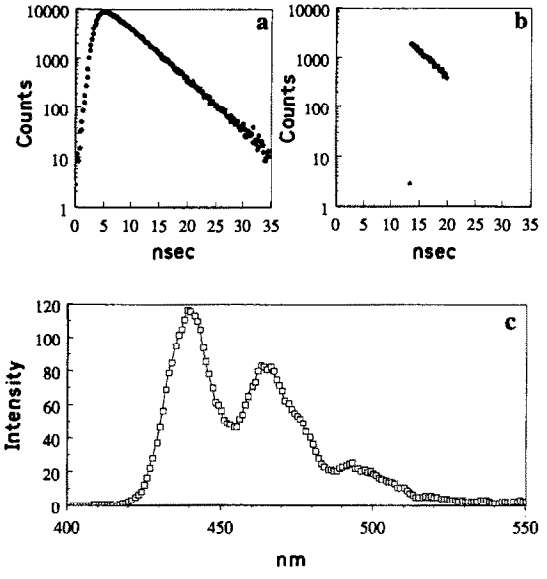

Fig. 1. Perylene time-resolved emission: (a) fluorescence decay of perylene; (b) "windowed" perylene fluorescence decay; (c) perylene TR emission spectrum for the window in (b).

the analog/digital converter (ADC) in the MCA is set to accept voltages (times) covering a large time scale relative to the fluorescence lifetime of the sample (usually 3–5 times the decay period of the longest-lived fluorophore). If the ADC is adjusted so that a narrow time window is accepted, only the corresponding section of the decay curve will be recorded. Figure 1b demonstrates this situation. If the total number of events occurring in this time window is plotted against emission wavelength, a fluorescence spectrum is formed.

Most multichannel analyzers facilitate the TRES experiment by allowing the user to sum all of the events in a given time window into a single channel and sweep through the channels with respect to time. This process effectively converts the MCA unit into a single-channel analyzer (SCA). As an SCA, the MCA unit sums all of the emission events falling into the time window defined by the ADC settings, into a single storage channel. Data may be taken in this channel for any prespecified time, after which data are collected in a new storage channel. If the scanning by the emission monochromator is synchronized with the sweep rate of the SCA, then a fluorescence emission spectrum is recorded. The contents of a data-storage channel in the selected time window correspond to the emission intensity at a given wavelength. Figure 1c shows the emission spectrum of perylene for the time window defined in Fig. 1b.

Time-resolved emission spectra directly recorded by use of TCSPC instrumentation have spectroscopic behavior similar to that of the steady state spectra. For example, Fig. 2 shows the effect of emission monochromator slit-width on the spectral resolution observed for perylene fluorescence. In addition,

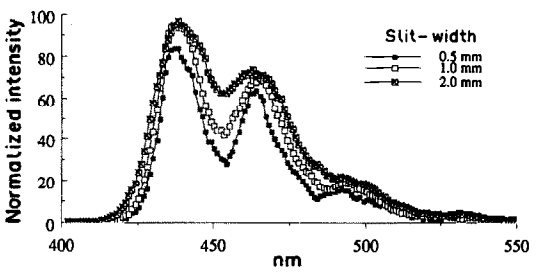

Fig. 2. Perylene TR emission spectra as a function of emission monochromator slit-width.

quantitative information can be obtained by using the TRES technique. The perylene fluorescence spectra obtained during the time window defined in Fig. 1b, for different perylene concentrations are presented in Fig. 3. A calibration curve can be obtained by plotting the area under the spectral envelopes against perylene concentration. Such quantitative measurements must be attempted with care, since several factors may introduce errors. Lamp emission-intensity and stability can be less than desired in the pulsed light-source utilized in TCSPC measurements. A large change in the lamp intensity can produce anomalous data in a quantitative measurement. Short-term lamp fluctuations can be eliminated by sweeping through the spectrum quickly, so that the lamp intensity is reasonably constant for all the wavelengths. The averaging of several spectral sweeps also helps to eliminate some of the noise. These considerations must be balanced against the need to obtain a calibration curve or point as closely in time as possible to the measurement of a sample of unknown concentration.

Directly recorded TR emission spectra are also susceptible to convolution errors from the lamp. If a TR spectrum is recorded for a time window that is close in time to the excitation pulse, it will not accurately describe the spectral properties of the system. Consideration of this type of error is particularly important for TRES of short-lived fluorophores. In this case, TR spectra can only be accurately obtained through techniques which generate derived spectra.[27,28] Such techniques rely on a global data-analysis scheme which will be discussed below.

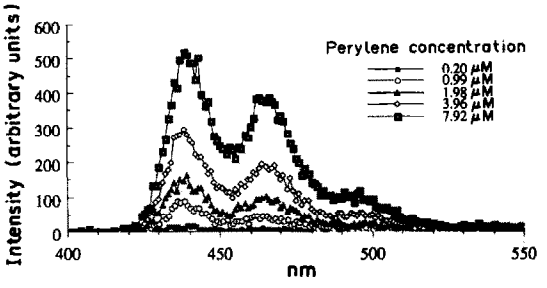

Fig. 3. Perylene TR emission spectra as a function of perylene concentration.

Pyrene–cyclodextrin equilibrium

Time-resolved emission spectroscopy can be effectively employed in the study of cyclodextrin complexation processes. In many cases, an increase in fluorescence lifetime accompanies inclusion of a guest molecule in a cyclodextrin. Nelson *et al.* have shown that the fluorescence lifetime of naphthalenes[11] and pyrene[23] are substantially changed in the presence of CD. The detection and quantification of such inclusion complexes is readily facilitated by TRES measurements.

The equilibrium for the formation of the 1:1 pyrene–CD inclusion complex can be expressed as

$$K_f = \frac{[I]}{[C][P]} \quad (1)$$

where K_f is the formation constant of the complex and [I], [C], [P] are the equilibrium concentrations of pyrene–CD complex, uncomplexed CD, and uncomplexed pyrene, respectively. This expression can be simplified if [CD] is $\gg$[P] so that $[C] \sim C_0$, and the substitution $[P] = P_0 - [I]$ is made (where C_0 and P_0 are the analytical concentrations of CD and pyrene). Equation (1) then becomes

$$[I] = \frac{K_f C_0 P_0}{1 + K_f C_0} \quad (2)$$

When TRES is used, the early fluorescence of the uncomplexed pyrene can be gated out, so that the measured fluorescence spectrum is that of the longer-lived pyrene–CD complex. If the fluorescence spectrum is integrated, the area is proportional to the concentration of pyrene–CD inclusion complex. The equilibrium expression can then be written as:

$$A_I = \frac{\alpha K_f C_0 P_0}{1 + K_f C_0} \quad (3)$$

where A_I is the area under the TR spectrum of the inclusion complex and α is a proportionality constant. A plot of A_I *vs.* [CD] yields a curve which can be analyzed by nonlinear least-squares curve-fitting to obtain the formation constant for the complex. The form of equation (3) is particularly convenient, since α or P_0 need not be known in order to find the formation constant.

EXPERIMENTAL

Pyrene, β-cyclodextrin, γ-cyclodextrin, and the alcohols and diols used in this study were obtained in high-purity form from Aldrich and used as received. The pyrene concentration was held at $1\mu M$ and the alcohol concentration at 1% v/v. Cyclodextrin stock solutions were prepared, and appropriate volumes were transferred by micropipet to give the desired CD concentrations.

Fluorescence decay curves for pyrene–CD inclusion complexes were obtained by using Photochemical Research Associates System 3000 fluorescence-lifetime instrumentation. Fluorescence lifetimes of the pyrene–CD complexes in the presence of various alcohols were obtained by nonlinear least-squares curve-fitting of fluorescence decay data against a biexponential decay model.[11,23] Time-resolved emission spectra were recorded as described in the previous section. Each spectrum was scanned fifteen times to increase the signal/noise ratio. The gate time was 800 nsec, which was approximately five times the decay period of free pyrene. This ensured that the fluorescence from free pyrene recorded in the TRES of the pyrene–CD complexes contributed less than 1% to the total intensity. The spectra were taken over the range 360–480 nm, with an excitation wavelength of 340 nm. No excimer bands for pyrene were observed.

The TRES data were integrated by a routine included in the MCA hardware. These integrated areas were plotted against CD concentration, and nonlinear least-squares curve-fitting of the data to equation (3) yielded the formation constants of the complexes.

Table 1. Fluorescence lifetimes of pyrene–cyclodextrin complexes in the presence of various alcohols and diols

Alcohol	τ^{β}, *nsec*	χ_r^2	τ^{γ}, *nsec*	χ_r^2
Propyl alcohol	451	0.87	320	0.97

1,3-Propanediol	481	1.08	425	1.07
1,5-Pentanediol	356	1.08	499	1.06

RESULTS

The fluorescence lifetimes of pyrene–CD complexes in the presence of various alcohols are reported in Table 1. The fluorescence lifetimes of all these complexes are short enough to facilitate TRES measurements with an 800-nsec gate time. This gate time is at most twice the fluorescence decay period of the complex, and a substantial portion of the total fluorescence of the complex remains to be measured by TRES.

The fluorescence lifetimes reported in Table 1 show good agreement with previously reported observations of long pyrene–CD lifetimes in the presence of alcohols.[23,31] The lengthening of pyrene lifetimes by inclusion in CD in the presence of alcohols has been ascribed to the formation of ternary complexes.[31]

The plot presented in Fig. 4 shows that the model presented in equation (3) gives an accurate fit to the data from TRES analysis of the pyrene–γ-CD complex in the presence of benzyl alcohol. The formation constants of such complexes in the presence of various alcohols are reported in Table 2. Many of these formation constants indicate that some alcohols can produce significant enhancement in the stability of the complexes. The formation constants for pyrene–β-CD and pyrene–γ-CD complexes have been reported by Patonay *et al.* to be 277 and 399 l./mole respectively. All the formation constants measured for pyrene–CD complexes in the presence of alcohols, reported in Table 2, are larger than those measured in the absence of alcohol. Several of the

1,3-Propanediol	3.025	2.340
1,5-Pentanediol	2.765	3.427

alcohols enhance the formation constants of pyrene–CD complexes by 1–2 orders of magnitude.

Whereas in previous studies the complexes were formed in the presence of 10% v/v alcohol,[23] in the present work they were formed at a much lower alcohol concentration (1%). The reduction in alcohol concentration did not produce a substantial change in the fluorescence lifetime of the complexes, but caused a significant change in the measured formation constants. For example, the formation constants for the complexes in the presence of the propyl alcohols are over four times greater at the lower alcohol concentration. This difference could arise from two effects. First, the formation of alcohol–CD complexes (2:1, 3:1, . . .) has been observed,[32] and the formation of such complexes would be more likely at higher alcohol concentrations and could compete with the formation of ternary pyrene–alcohol–CD complexes. Secondly, at higher alcohol concentrations, the bulk properties of the aqueous solvent system are more favourable for the solvation of pyrene, so the equilibrium could be shifted towards uncomplexed pyrene in such cases. Either or both of these effects could account for the increase in formation constants when the alcohol content is reduced from 10% to 1% v/v.

That the formation constants reported in Table 2 are dependent on alcohol concentration indicates that these are conditional formation constants, and intimately related to the interaction of the alcohol with both CD and the pyrene–CD complexes. Nelson *et al.* have shown that the amount of complex formed at a given CD concentration is dependent on alcohol concentration.[31] This indicates that there exists, for each alcohol studied, an optimum concentration, at which maximum enhancement is produced. Thus, if a particular alcohol–CD system is needed, this optimum point must be found. It has been suggested by Nelson *et al.* to occur at approximately the alcohol concentration at which each CD molecule is complexed with one alcohol molecule. This indicates that if the alcohol–CD complex formation constant is known, a reasonable approximation to the point of maximum enhancement of CD inclusion-complex properties can be determined.

Not only can the equilibrium for the formation of CD inclusion complexes be investigated, but the spectral properties of included fluorophores can also be observed. Spectral shifts often accompany the inclusion of a fluorophore in the CD cavity. In many cases, a large excess of CD must be added in order for the steady-state emission spectrum to be recorded. In some cases, the addition of excess of CD may not be favorable since 1:2 and 2:2 fluorophore–CD complexes may form. By use of TRES, the spectral distribution of long-lived inclusion complexes can be recorded at CD concentrations which ensure 1:1 complexation. Figure 5 shows the TRES spectrum of the pyrene–β-CD and pyrene–γ-CD complexes in the presence of *sec*-butyl alcohol. These spectra could be obtained by steady-state fluorescence spectroscopy only if a large amount of CD were present, so that all of the pyrene was present as the 1:1 complex. For many systems this constraint could not be met, since high CD concentrations often promote formation of the 1:2 complex.

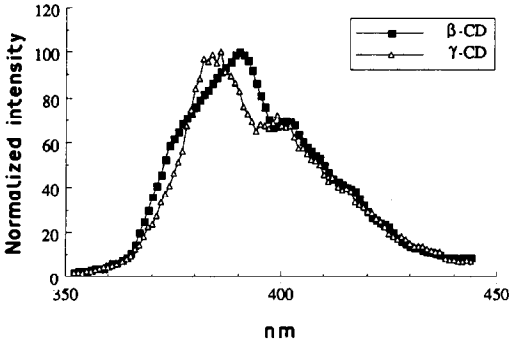

Fig. 5. Time-resolved emission spectra of pyrene:CD complexes in the presence of *sec*-butyl alcohol.

CONCLUSIONS

Time-resolved emission spectroscopy has been shown to be a useful technique in the study of pyrene–CD complexes, since the emission from pyrene overlaps that from its CD inclusion complex. Gating out the early fluorescence of pyrene makes it possible to determine the longer lived complex. The formation constants and spectra of pyrene–CD complexes in the presence of various alcohols have been measured by this technique. The TRES measurements may prove useful in the study of many types of inclusion complexes, where equilibrium and spectral information is desired. In addition, the enhancement of CD complex properties by alcohols could find application in many areas of CD separation techniques.

CASCADE SYSTEM FOR RAPID ON-LINE DILUTIONS IN FLOW-INJECTION ANALYSIS

DAVID A. WHITMAN and GARY D. CHRISTIAN
Center for Process Analytical Chemistry, Department of Chemistry, BG-10, University of Washington, Seattle, WA 98195, U.S.A.

(*Received* 6 *May* 1988. *Accepted* 12 *August* 1988)

Summary—A system for on-line dilutions in flow-injection analysis (FIA) is described. The system requires two flow-through pumps (peristaltic) and a conventional rotary injection valve. No precision timing or computer-controlled valves are required. The "cascade" dilution technique is demonstrated by the determination of 0–1.7*M* chloride. Viscosity effects are studied for samples with viscosities of 1–150 relative to water. Sample-zone volume reduction by splitting streams is combined with dilution by merging streams to achieve effective dilution factors of nearly 500. The reciprocal mole fraction is proposed as a variable for the characterization of open flow-injection systems and compared with the dispersion coefficient. An equation is included to predict this factor as a function only of the flow-rates used in the system. The cascade dilution system yields reproducible dilution factors with relative standard deviations of less than 3%, with sampling rates up to 100/hr.

One of the major benefits of flow-injection analysis is a high rate of analysis. Sampling rates of hundreds per hour are meaningless if up to 10 min may be required to pretreat each sample prior to injection. On-line pretreatment and dilution, with sampling rates of the order of those of single-line FIA would help to fully exploit the benefits of FIA and make it compatible with the requirements of process control.

There have been several designs for on-line pretreatment, including merging streams,[1] dialysis,[2] gradient chambers,[3] and zone sampling.[4] All of these techniques perform dilutions; however, each has limitations. The merging streams method is limited to flow ratios less than 1:20. Dialysis membranes are fragile. Gradient chambers have low sampling rates and high reagent consumption. Zone sampling requires high-precision timing and computer-controlled valves.

We describe here a novel cascade dilution system that combines the technology of merging streams with on-line sample-volume reduction by stream splitting to obtain precise dilution factors from 100 to nearly 500. In addition, the reciprocal mole fraction is proposed as a useful parameter for the characterization of all open-flow injection systems.

EXPERIMENTAL

Apparatus

Manifold design. The cascade manifold (Fig. 1) is constructed from a black PVC block (70 × 45 × 10 mm) equipped with a Teflon six-bore rotary valve injector. The injector design is described elsewhere by Erickson *et al.*[5] Three holes of 1.5 mm diameters are drilled through the block to mark the inlet and outlets for the V-shaped channels. The diameter of the holes is slightly smaller than the outer diameter (OD) of the 0.51-mm inner diameter (ID) Micro-Line tubing which is used to connect up the system. The V-channels are stamped into the PVC block by pressing a 2 cm long 1 mm diameter wire, bent at 60°, into the block with a hydraulic press. This yields approximately semi-circular channels 0.5 mm deep (because the wire does not press entirely into the block). These are indicated in Fig. 1 by the thick "V"s, and the lighter lines represent the Micro-Line tubing. All connections are by friction fit. The manifold is backed with an acetate film fixed with pressure-sensitive adhesive to close the channels. Two mixing coils are used, one after the injection valve and one after T_2 (Fig. 1). The lengths of these coils were varied to determine their effects on dilution.

A "blank" system is defined as a system analogous to the cascade system, but requiring manual dilution prior to injection. A system of this kind is made by placing the injection valve after T_3 and pump 2 in the cascade system. The blank system is used as the basis of comparison for the cascade system's dilution effects.

Pumps. Tygon pump tubes with appropriate IDs to give the desired flow-rates, and two Ismatec Mini-S 860 peristaltic pumps are used to propel the solutions.

Flow cell design. Two flow cells are used, the first for the spectrophotometric determination of chloride, the second of low dead-volume for the biamperometric determination of chloride, to investigate the dispersion effects of the first cell.

The spectrophotometric flow cell is home-made, of reflected-transmittance type with a 3-mm diameter cavity 1.5 mm deep, approximately 10 μl (as measured with a Hamilton syringe) in total volume. The flow cell is made by stamping a flow cavity into a white PVC block (7 × 45 × 70 mm) with a 3 mm ball bearing. Two holes (1.5 mm diameter) are drilled at 45° to the block plane on either side of the flow crater. These holes are plumbed with 0.51 mm ID Micro-Line tubing. Two 16-strand acrylic fiber optic bundles are immobilized with epoxy cement (Devcon Five-Minute Epoxy) in a black PVC block (10 × 10 × 20 mm). The optical surface is polished, centered, and bolted over the flow cavity (Fig. 2).

To prepare a low dead-volume biamperometric flow cell, a 0.5 mm channel is drilled into an acrylic block (10 × 20 × 25 mm). Counter-bores 5 mm deep and 1.5 mm in diameter are drilled to make flush, friction fit connections to 0.51 mm ID Micro-Line tubing. The electrodes are mounted by drilling two 0.5 mm set holes to intersect the flow channel perpendicularly on opposite sides of the block. Five-mm sections of 0.5 mm silver wire are connected

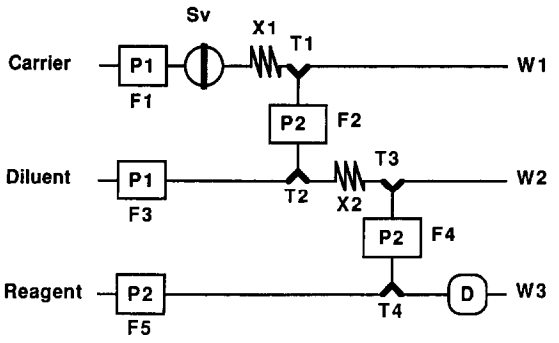

Fig. 1. Schematic of the cascade system manifold. P1 and P2 are peristaltic pumps, S_v is the injected sample volume, X1 and X2 are mixing coils, F_1–F_4 are flow-rates, D is the detector, and T_1–T_4 are the V-shaped connections.

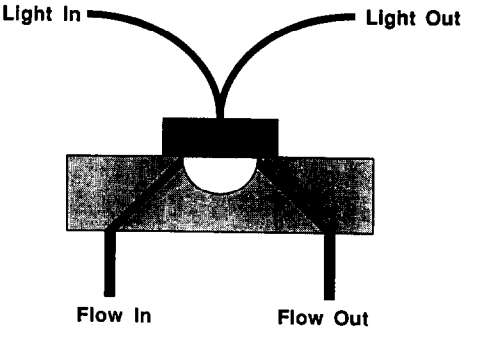

Fig. 2. Illustration of the reflected-transmittance flow cell.

to brass male DB pins by crimping, without solder. These electrodes are then heated with a soldering iron and inserted into the set holes. The acrylic melts and conforms to the electrode shape, thus preventing leakage. The flow channel is then redrilled to remove resolidified plastic blocking the channel and to make a clean electrode surface. The resulting system has essentially no dead-volume (Fig. 3).

Detectors. The spectrophotometric detector is a Milton Roy Mini Spec-20 spectrophotometer. The light-source is a Halogen-Bellephot 8 V projector bulb equipped with a variable voltage power supply. Transmission of light to the cell and of the reflected transmittance signal to the detector is by acrylic fiber optic cables. The transmittance signal is converted into an absorbance signal by a log converter.

The low dead-volume flow cell is connected to an IBM EC/225 voltammetric analyzer to provide the 200 mV potential between the electrodes for biamperometric measurements.

Signals are recorded by a Radiometer REA 112/REC 51 strip-chart recorder for both detection systems.

Reagents

Unless otherwise stated, the cascade system was characterized by the spectrophotometric determination of chloride by displacement of thiocyanate from mercury(II) thiocyanate and its subsequent complexation with iron(III). The intensely red complex is measured at 480 nm.[2,6-8] All solutions are prepared with demineralized water. All reagents are ACS reagent grade. The mercury thiocyanate reagent solution is prepared according to Růžička and Hansen.[2] A quantity of 0.3 g of mercuric thiocyanate is dissolved in 75 ml of methanol, 15.2 g of ferric nitrate are added, and after the addition of 2.4 g of concentrated nitric acid the volume is brought to 500 ml with water.

Samples are prepared by making appropriate mixtures of stock solutions of 0.4*M* boric acid and 2.0*M* sodium chloride in 0.4*M* boric acid to yield calibration standards with between 0 and 1.7*M* chloride concentration.

Samples for viscosity experiments are prepared from mixtures of the 2.0*M* sodium chloride stock and 50% v/v glycerol solution for samples with 1–4.5 viscosity relative to water ($\eta/\eta°$), 85% glycerol for 10–38 $\eta/\eta°$, and 100% glycerol for 55–150 $\eta/\eta°$, as indicated in Table 1.

Flow rate measurements

Input flow-rates (F_1, F_3, and reagent) and output flow-rates (W_1, W_2, and W_3) are measured. The carrier stream input flow is equal to flow-rate F_1. The splitting stream flow-rate, F_2, is equal to the difference between the input flow-rate F_1, and the output flow-rate, W_1. F_3 is equal to the diluent input flow-rate. Because pump tubes of the same inner diameter are used for both splitting lines, the output flow-rate at W_2 equals that of the diluent input, and the splitting stream flow-rate, F_4, equals F_2. To confirm this, F_4 was checked by measuring the difference between the input at the reagent stream and the W_3 effluent ($W_3 = F_4 + F_5$).

The flow-rate stabilities were evaluated by placing Gilmont falling ball flowmeters on-line. There were no significant changes in flow-rates after 10 hr of continuous operation. The flow-rates for each system tested are listed in Table 2.

RESULTS AND DISCUSSION

The cascade system (Fig. 1) utilizing the simple merging stream technique is combined with on-line sample-volume reductions by stream splitting to obtain the desired dilution. A somewhat similar manifold was illustrated in 1976 by Růžička and Hansen

and called "derivative dilution".[2] The system lacked the hydrodynamic stability necessary to maintain a constant splitting ratio. This was due to the absence of flow-through pumps at the splitting streams. The discussion of the system was also very limited. Low sampling rates (<80/hr) and poor precision were observed and the idea was not pursued.

The technique here utilizes a conventional rotary injection valve to inject a sample into the carrier, at flow-rate F_1. The carrier and diluent can be either a buffer or water; in these experiments water was used. At T_1 the sample zone is split, with a flow-rate ratio of F_2/F_1. Flow ratio stability is maintained by the use of flow-through pumps at each splitting line. The sample-volume reduction produces a sample zone of the same concentration as the injected sample. The resultant zone merges with diluent at T_2. In the dilution, the sample-zone volume increases in the same proportion, $(F_2 + F_3)/F_2$. The sample zone is split again at T_3 with a ratio of $F_4/(F_2 + F_3)$. The sample is then "injected" into the reagent stream. This system can yield reproducible peaks and effective dilution factors of up to 500 with respect to the injected sample.

Dilution factors may be defined in several ways. The first and most straightforward definition is conventional dilution with respect to concentration, or homogeneous dilution. Strictly speaking, homogeneous dilutions are never obtained in flow injection systems but rather a concentration gradient is formed in both the axial and radial directions. Therefore, Růžička and Hansen[9] introduced another definition, which expresses an apparent dilution with respect to the injected sample concentration, given by the dispersion coefficient, D. The dispersion coefficient for the imaginary element of fluid corresponding to the peak maximum (D^{max}) is defined by equation (1). An empirical relation to sample volume has also been given.[9]

$$D^{max} = 1/[1 - e^{-kS_v}] = C^\circ/C = H^\circ/H \qquad (1)$$

where k is $0.693/S_{1/2}$ and $S_{1/2}$ is the sample volume required to give D^{max} equal to 2, S_v is the injected sample volume, C° is the concentration of the injected sample, C is the concentration of the dispersed sample at the detector, H° is the "peak" height of the steady-state signal, and H is the peak height of the dispersed sample. It is important to note that for injection volumes less than $S_{1/2}$ there is an approximately inverse linear relationship between the dispersion coefficient at peak maximum and S_v.

It is useful to be able to calculate descriptive parameters when designing a flow-injection system. This is especially important with on-line dilution systems when a rough idea of the dilution factor is required. In addition to D, we use another variable to describe the cascade system, the reciprocal mole fraction (X^{-1}).

The dispersion coefficient can be calculated as a function of the dispersion factor ($\beta_{1/2}$). In a closed system, analogous to chromatographic systems, the dispersion factor $\beta_{1/2}$ can be calculated by statistical moments. Specifically, the sum of the peak variance (flow-independent) contributions is equal to the overall peak variance, σ^2_{tot}. The square root of this variance is related to the dispersion factor as follows:

$$\beta_{1/2} = \sigma_{tot}(\pi/2)^{1/2} \qquad (2)$$

Hungerford[10] has shown that the dispersion factor is inversely proportional to the dispersion coefficient when D^{max} is greater than 2. Because the variances are not usually flow-independent and this FIA system is not closed, this relation cannot be used. In short there is no way to calculate the expected dispersion coefficient in the cascade system.

The reciprocal mole fraction [X^{-1} defined by equation (3) below] is another parameter used in this laboratory to characterize FIA systems. It is very useful in "open" FIA systems where not all of the injected material travels to the detector. Some open flow-injection techniques are dialysis, gas diffusion,

Table 2. Summary of flow-rates (F_1–F_4), *ml/min*, and calculated reciprocal mole fractions (X^{-1}) for cascade systems Cl_1–Cl_5; X^{-1} calculated from equation (4)

System	F_1	F_2	F_3	F_4	X^{-1}
Cl_1	2.2	0.20	2.2	0.20	130
Cl_2	2.2	0.20	3.4	0.20	200
Cl_3	3.4	0.20	3.4	0.20	300
Cl_4	3.4	0.20	4.3	0.20	380
Cl_5	4.3	0.20	4.3	0.20	470

stream splitting, zone sampling, and zone splitting. In these systems the mass balance is important for characterization. This approach is attractive because simple mass balance is used, which is more tangible than the dispersion of an imaginary element of fluid that is used for defining the dispersion coefficient. Merging streams do not affect the mass balance, whereas splitting streams do have an effect, the opposite of the dispersion coefficient. Therefore D and X^{-1} are complementary and more information is available when they are used in combination to characterize a flow-injection system.

$$X^{-1} = M^{\circ}/M = kA_d^{\circ}/A \qquad (3)$$

where M° is the number of moles injected, M is the number of moles remaining in the diluted sample zone at the detector, and A is the area of the peak at the detector. The inverse mole fraction can be calculated empirically from the ratio of the "steady-state" area (A°) to the peak area, but because there is no steady-state area, the area (A_d°) of a sample of known dilution injected into a "blank" system, multiplied by the known dilution factor (k), is used as the steady-state area. For example, a too-concentrated sample (concentration C) is manually diluted k-fold, then injected into the cascade system after T_3 and pump 2. The area of this peak, multiplied by k, is used as the steady-state area (A_d°) for the cascade system and a sample of concentration C.

Whereas the dispersion coefficient compares peak height for the sample, as it passes through the detector, with the peak height for the sample prior to injection (*i.e.*, at steady state) for detectors linearly responding to concentration, the reciprocal mole fraction compares peak areas (Fig. 4).

The reciprocal mole fraction is easily calculated for the cascade system as a function only of the flow-rates used in the system [equation (4)]. This equation is simply the inverse of the product of the splitting ratios at T_1 and T_3.

$$X^{-1} = F_1(F_2 + F_3)/F_2F_4 \qquad (4)$$

where F_1–F_4 are the flow-rates in the cascade system (see Fig. 1). To verify equation (4), a 20-μl 1.7M sodium chloride sample was injected into the cascade system and a 20-μl sample (manually diluted X^{-1}-fold) was injected into the blank system. Because the peak areas were identical, the number of moles in each sample was the same. The cascade system yields taller and narrower peaks than the blank system (see Tables 3 and 4). This is not unexpected. Although the number of moles is the same, there is no reason why the two samples will be of the same concentration or occupy the same volume.

Sample volume

"... dilution of overly concentrated sample material is best achieved by reducing the injected volumes."[9] This is the traditional method of dilution in FIA. With our injector, the limit of this approach is an

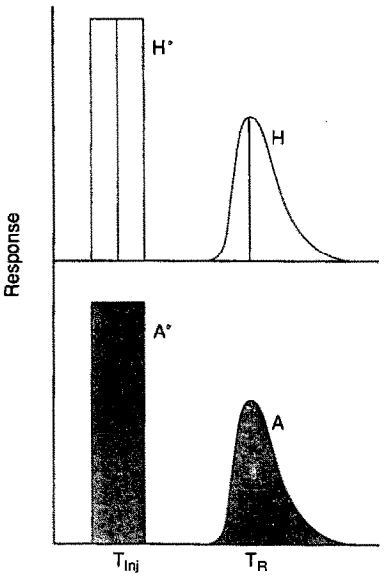

Fig. 4. D^{max} pictorially compared to X^{-1}. (A) peak height at steady state divided by height at peak maximum equals D^{max}. (B) Injected "area" (number of moles) divided by peak area equals X^{-1}.

8-μl injection. Decreasing the injected volume makes the reproducibility poorer, and increasing the volume decreases the sampling rate. Therefore the optimal volume for injection is a compromise between the sampling rate, dilution, and reproducibility desired.

Peak height is plotted *vs.* sample volume in Fig. 5 for 1.7M chloride injections of 20, 50, 75, and 100 μl into system Cl_4 (see Table 2). The shape of the plot is typical of all flow-injection systems. Here $S_{1/2}$ is about 60 μl. It is not necessary to decrease the volume to the lower limit because the net dilution can be

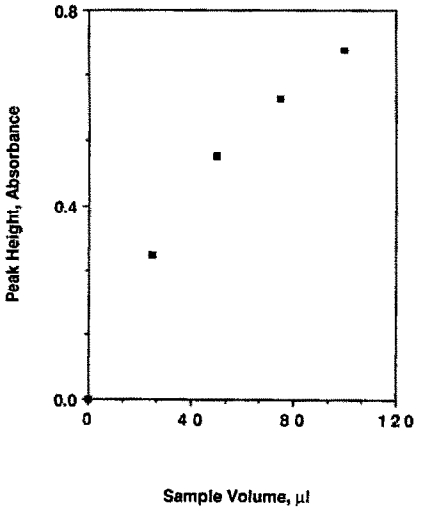

Fig. 5. Sample volume *vs.* peak height in the cascade system Cl_4.

Table 3. The effects of flow-through pumps on peak parameters (Cl_4 blank system): H is mean peak height (mm), W is mean width at half height (mm), A is area (mm^2), and s is the corresponding standard deviation for three replicate injections; system I uses injection after pump 2 and system II injection before pump 2

System	H	s_H	W	s_W	A	s_A
I	80	1	7	0	560	7
II	79	2	7	0.2	553	2

System	H	s_H	W	s_W	A	s_A
$X_1 = 0$ µl $X_2 = 0$ µl	110	0	5.5	0.5	555	5
$X_1 = 400$ µl $X_2 = 400$ µl	111	1	5.0	0	555	5

varied easily by a change in the flow-rates. Because the peak width increases with an increase in sample volume, the sampling rate decreases. Therefore, 20 µl was used as the sample volume for all subsequent experiments unless otherwise noted.

Flow-through pumps

The introduction of flow-through pumps at the splitting streams yields a more constant splitting ratio, owing to the added stability in flow-rates. The effects, if any, of the flow-through pumps at F_2 and F_4 on the sample zone were investigated. Peak profiles were compared for injections into F_4 (the blank system) after the pump (system I) and before the pump (system II). Superimposition of the recorded peaks shows there is no significant change in the profiles. The differences in the mean peak height, width, and area are less than the standard deviations for serial injections of a standard. Table 3 gives the mean peak height, width at half height, area, and standard deviation of each parameter for systems I and II.

Dispersion

The effect, on the peak parameters, of dispersion in the cascade system up to T_4 was investigated by varying the mixing coil lengths. Both coils (X_1 and X_2) are varied from 0 to 400 µl in volume. The total volume of the system is 350 µl when X_1 and X_2 are both zero. Interestingly, there are no significant changes in the peak shape (Table 4) when both X_1 and X_2 are increased to 400 µl. This indicates that the dispersive effects of the coils are not the dominant ones.

When the response of an undiluted 20-µl sample injected into the cascade system (Cl_4, $X^{-1} = 380$) is compared with that of a manually diluted (X^{-1}-fold) 20-µl sample injected into the blank system, a ratio of 1.4:1 is found for their peak heights. A much larger ratio (17) would be expected (with a corresponding sample volume of about 1 µl after T_3) in system Cl_4 for the extreme hypothetical case of plug flow and no dispersion (*i.e.*, the concentration decreases only at T_2, so $22.5^{-1}/380^{-1} = 17$, see Table 5 below). Because the ratio is lower than expected, we can be confident there is significant dispersion in the system. The dispersion may arise in the V-channels, the Micro-Line/pump tube connections, and/or the flow cell. The flow cell (10 µl) would be expected to have a greater effect (as a gradient device) on the small sample volume predicted for the cascade system (1 µl) than on the relatively large sample injected into the blank system (20 µl).

The flow-cell dispersion hypothesis was confirmed by using a new biamperometric system with low dead-volume in the flow cell. A 200 mV potential was applied between the silver electrodes. The current produced as a result of the silver/silver chloride reversible couple is proportional to the concentration of chloride (and flow-rate).

As the dead-volume decreases in the system, so does the peak width, with a corresponding increase in peak height. The ratio of the cascade system peak height to that for the blank system was 2.8 in this flow-cell configuration. This result indicates that the sample zone volume of the cascade system is less than the volume injected into the blank system and that the spectrophotometric flow cell acts as a gradient chamber for the cascade system sample, compared to the blank system sample. The magnitude of these dispersive effects may be approximated by studying the dispersion coefficients obtained in each of the systems described thus far. The total dispersion coefficient (D_{tot}) obtained by the spectrophotometric system at peak maximum can be calculated as the product of the dispersion coefficient obtained from merging the streams at T_2 ($D_{T2} = (F_2 + F_3)/F_2$), the dispersion coefficient from the spectrophotometric flow cell (D_{cell}), the dispersion coefficient in the

Table 5. Summary of the contribution of merging streams (D_{T2}), flow cell (D_{cell}), and system dispersion (D_{sys}) to overall dispersion coefficient (D_{tot}); D_{man} is the manual dilution factor, which is set equal to the reciprocal mole fraction, which is constant for all Cl_4 systems (380)

System	D_{T2}	D_{cell}	D_{sys}	D_{man}	D_{tot}	X^{-1}
Spectrometric cell	22.5	2	6	—	270	380
Biamperometric cell	22.5	1	6	—	135	380
No dispersion	22.5	1	1	—	22.5	380
Blank	—	1	—	380	380	1

remainder of the system (D_{sys}), and any manual dilution (D_{man}):

$$D_{tot} = D_{T2} D_{cell} D_{sys} D_{man} \quad (5)$$

Table 5 lists D_{tot}, X^{-1}, D_{T2}, D_{cell}, D_{sys}, and the manual dilution factor D_{man}. The "no dispersion" system is a hypothetical Cl_4 system where there is no axial dispersion due to the flow-through manifold components. X^{-1} is fixed for each Cl_4 system. D_{T2} is the merging ratio. It is assumed that the biamperometric cell has no dispersive effects on the sample zone for either system; therefore D_{cell} equals 1 in this system. D_{cell} for the spectrophotometric system is given by the ratio of the cascade to blank system D_{tot} ratios for the biamperometric and spectrophotometric systems (2.8/1.4, from above). The D_{sys} values were calculated from known D_{tot} values. D_{man} is the known dilution factor.

Because overall dilution is the goal of this system, some dispersion is not only acceptable, but desired. It is also important to note that the cascade system, by decreasing the sample zone volume, allows the dispersion of the element of fluid corresponding to D_{tot} to be greater than that expected for a larger sample flowing through the same length of tubing.

Calibration curves

Calibration curves for the spectrophotometric measurement of chloride show increased linearity with an increase in dilution. The curves obtained with systems Cl_1–Cl_4 are shown in Fig. 6. A calibration curve for injection of 500-fold manual dilutions into the blank system is also shown. The calibration curves for the cascade system approach that for the manual dilution goal. Typical cascade-system peaks are shown for the calibration run of system Cl_5 (Fig. 7). The 470-fold dilution was made on 20-μl injections of 0–1.7M sodium chloride in 0.4M boric acid.

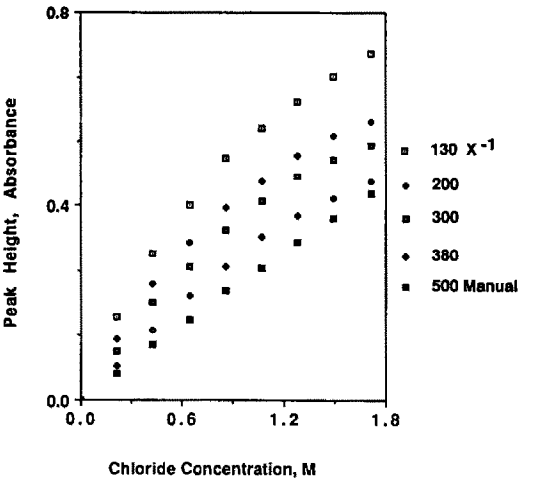

Fig. 6. Peak height *vs.* concentration for calculated X^{-1} [by equation (4)] values of 130, 200, 300, and 380, and for 500-fold manually diluted samples injected into F_4.

Viscosity effects

In conventional FIA, increased sample viscosity increases the pressure drop within the system and reduces the dispersion and mixing. The pressure drop increase is so predictable that it has been used by Betteridge *et al.* for the measurement of viscosity.[11,12] Clark *et al.*[13] have shown the effects of viscosity on mixing length in merging streams.

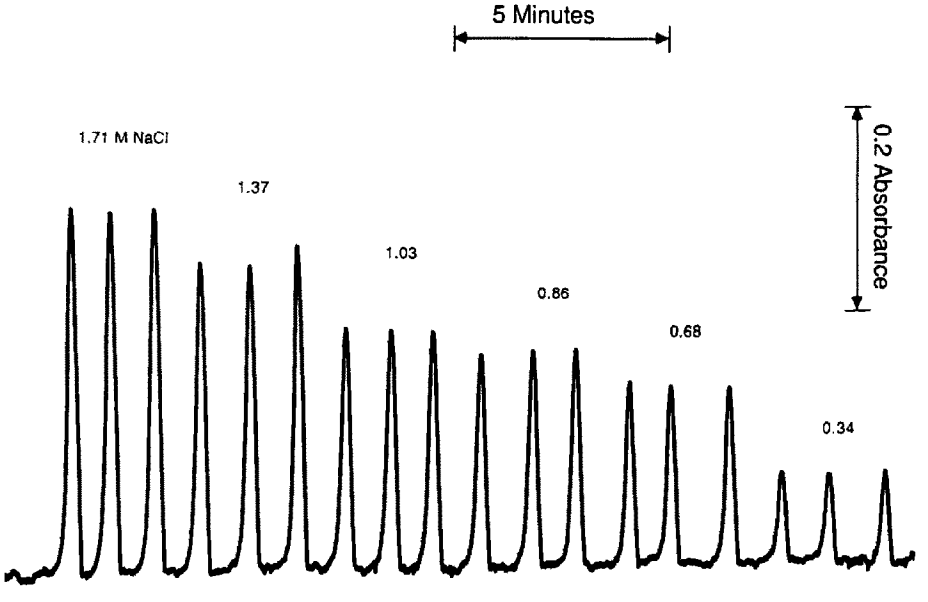

Fig. 7. Typical cascade system peaks. Given are triplicate injections with a calculated dilution factor of 470. Samples are 1.71, 1.37, 1.03, 0.86, 0.68, and 0.34M NaCl from left to right.

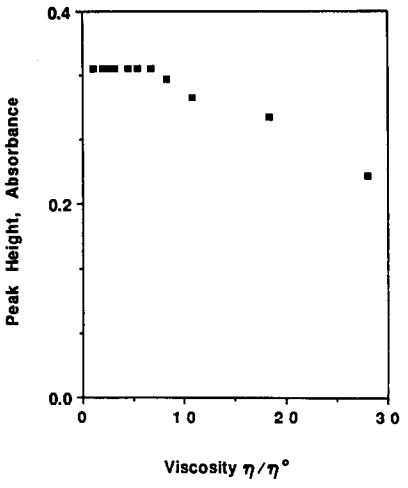

Fig. 8. Peak height *vs.* relative viscosity in two-line FIA (blank system). Peaks are for 2m*M* NaCl.

Peak height in a two-line flow-injection system (blank for the cascade system) begins to decrease at viscosities above 8 cP (Fig. 8), owing to less complete mixing with the reagent. This effect can be reduced somewhat by traditional methods to increase the dispersion factor, such as increasing the reaction coil length or decreasing the injected sample volume.

Glycerol was used to increase the viscosity of chloride samples. The viscosities listed in Table 1 are the nominal relative viscosities expected for the samples,[14] and the relative viscosities measured at 22° with an Ostwald viscometer. The peak height remains constant for injections of 1.7*M* sodium chloride for $\eta/\eta°$ from 1 to 150, in the cascade system (Cl_4 or Cl_5).

We have found that glycerol also has a chemical effect on the measurement. Increasing glycerol concentrations decreases the absorbance due to chloride. The dilution removed this effect in addition to the viscosity effects on dispersion, as shown by the absorbance being unaffected by the viscosity, at constant chloride concentration.

CONCLUSION

The cascade system provides rapid on-line dilutions of up to nearly 500-fold without use of precision timing or computer-controlled valves. Relative standard deviations of less than 3% are observed in the determination of chloride. Sampling rates of over 100 determinations per hour are easily obtained. Because water is used as the carrier and diluent, reagent consumption is the same as that of conventional FIA.

The reciprocal mole fraction has been shown to be a useful parameter to describe open flow-injection systems. An equation has been derived to predict X^{-1} as a function only of the flow-rates used in this system. The equation has been verified experimentally. Extension to a three-tier cascade system may provide dilution factors of up to 10^4.

As a result of dilution, many interferences are removed. This is illustrated by the removal of both chemical and viscosity interferences caused by glycerol, by the cascade system. Although the diluent was water in this study, a buffer or another reagent stream may be used in the cascade system for on-line pretreatment, such as derivatization or pH adjustment.

LASER-INDUCED SITE-SELECTION MATRIX-ISOLATION FLUORESCENCE SPECTROMETRY OF DIBENZACRIDINE ISOMERS

BRIAN F. MACDONALD* and E. L. WEHRY†
Department of Chemistry, University of Tennessee, Knoxville, TN 37996, U.S.A.

(*Received* 26 *April* 1988. *Accepted* 5 *August* 1988)

Summary—Laser-induced matrix-isolation site-selection fluorescence spectrometry is used to obtain narrowed-line spectra, linear dynamic ranges and limits of detection for four isomeric dibenzacridines in argon at 15 K. Site-selection fluorescence is used to determine dibenzacridines in two synthetic mixtures, a four-component mixture of the isomeric dibenzacridines and a thirteen-component polycyclic aromatic hydrocarbon mixture. The capabilities of site-selection and Shpol'skii fluorescence spectrometry for the identification and determination of aza-arenes in complex mixtures are compared.

Interest in the chemical analysis of aza-arenes (nitrogen heterocyclic derivatives of polycyclic aromatic hydrocarbons) stems from the fact that many of these compounds are carcinogenic.[1-3] Fluorescence techniques have often been applied to the detection and determination of aza-arenes in mixtures.[4-7] Unfortunately, the fluorescence spectra of large organic molecules in liquid solution at room temperature are usually broad and featureless, making identification and quantification of individual compounds in mixtures difficult unless the measurement of fluorescence is preceded by extensive separations. Fluorescence spectral bandwidths may be dramatically decreased when spectra are measured at low temperature.[8]

Matrix isolation (hereafter abbreviated to MI) is a low-temperature sample preparation method, wherein analytes in the vapor phase are co-deposited with a diluent gas (such as argon or n-octane) on a strongly cooled surface.[8,9] The advantage of MI over simply freezing a liquid sample into a low temperature solid is that solubility considerations are irrelevant and aggregation of analyte molecules is avoided because mixing of the "solvent" and "solute" molecules occurs in the gas phase.[8-10] Thus, acquisition of reproducible spectra for identification and quantification of individual constituents of mixtures is facilitated by use of MI.

When an organic fluorophore is isolated in a polycrystalline solid matrix, such as argon, the individual molecules of that compound usually occupy discrete microenvironments or matrix "sites".[11] Analyte molecules located in different sites exhibit slightly different electronic transition energies, causing their absorption and fluorescence spectra to be inhomogeneously broadened. If severe inhomogeneous spectral broadening occurs for each constituent of a mixture, their absorption and fluorescence spectra are likely to overlap, and the selectivity is thereby reduced. However, if a highly monochromatic excitation source (*e.g.*, a laser) is employed, it may be possible to generate a fluorescence spectrum having a bandwidth much smaller than that of the inhomogeneously-broadened absorption spectrum of the analyte. This procedure is termed "site-selection" fluorescence spectrometry;[12,13] its objective is to distinguish spectroscopically between molecules of an analyte that are situated in different matrix sites, so as to produce highly resolved spectra suitable for identification and determination of individual constituents of mixtures.[14]

It must be emphasized that the bandwidths of the absorption spectrum of the analyte (and of potential interferents) are unchanged in a site-selection experiment. Thus, site selection differs in principle from "Shpol'skii" fluorometry, wherein a matrix is chosen in which molecules of the analyte are constrained to occupy one site (or, at most, a few well-defined types of site), with a corresponding decrease in the extent of inhomogeneous broadening both in absorption and fluorescence.[8,15,16] The identity of the optimal Shpol'skii matrix differs for analytes of diverse molecular size and shape. Site-selection fluorometry does not rely on steric compatability between the analyte and the solvent to obtain narrowed-line spectra. Hence, site selection offers the possibility of achieving selective fluorometric detection of many different analytes with a single matrix material.

Although the site-selection fluorometry of polycyclic aromatic hydrocarbons has been studied extensively and applied to the characterization of complex samples,[14,17,18] little attention has been devoted to the site-selection fluorescence of polar derivatives of aromatic hydrocarbons. The site-selection fluorescence

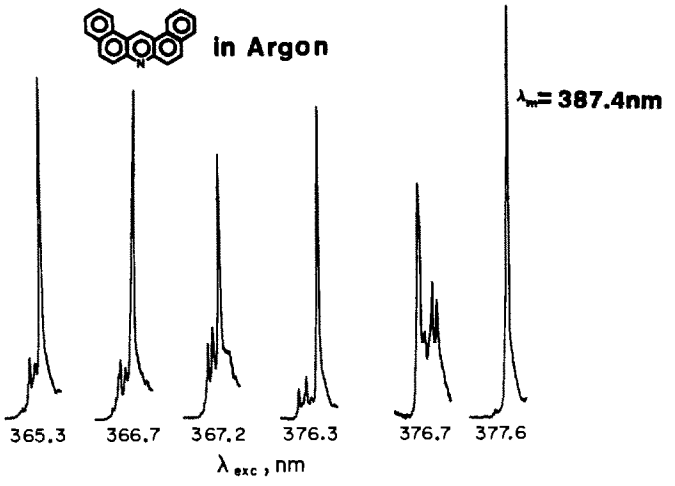

Fig. 1. Fluorescence spectra of dibenz[*a*,*j*]acridine in solid argon at 15 K as a function of excitation wavelength (indicated at bottom of each spectrum). For each spectrum, the total wavelength range scanned was 5 nm (385–390 nm).

of one aza-arene (dibenz[*a*,*j*]acridine) has previously been reported, and was obtained by using laser-induced site-selection fluorescence spectrometry in argon matrices.[10] We now describe the analytical application of the site-selection fluorometry of this compound and several of its isomers. Some comparisons of the site-selection and Shpol'skii fluorometry of these compounds are also presented.

EXPERIMENTAL

Chemicals

Commercially available "research grade" argon and n-octane were used as matrix materials without further purification. Dibenz[*a*,*j*]acridine (Sigma), dibenz[*a*,*c*]acridine (Community Bureau of Reference, Brussels, Belgium), dibenz[*a*,*h*]acridine (Community Bureau of Reference) and dibenz[*c*,*h*]acridine (Community Bureau of Reference) were used as received. Commercially available polycyclic aromatic hydrocarbons were used without further purification. Benzo[*a*]pyrene (Fluka), employed as an internal standard, was also used as received.

Spectrometric instrumentation

The home-built fluorescence spectrometer used radiation from a Molectron DL-14 dye laser, pumped by a Molectron UV-24 nitrogen laser, for excitation. At a repetition rate of 10 Hz, the laser produced pulses of *ca.* 6 nsec duration and 0.02 nm bandwidth. The dyes used to cover wavelength ranges of 354–364, 360–386 and 377–399 nm were PBD in *p*-dioxan, PBD in a 1:1 mixture of ethanol and toluene, and BBQ in a 1:1 mixture of ethanol and toluene, respectively.

The fluorescence was dispersed by a 1-m grating monochromator (Jobin-Yvon HR-1000, equipped with a 1800 grooves/mm holographic grating blazed at 300 nm) having a reciprocal linear dispersion of 0.8 nm/mm, and was detected by an RCA 8850 photomultiplier tube. The electrical signal from the photomultiplier tube was processed by a Tektronix 5440 oscilloscope with a 350-psec sampling head; the fluorescence spectra were plotted by an *X*–*Y* recorder. Time-resolved spectra were obtained; the techniques of time-resolved matrix isolation fluorometry are described elsewhere.[10] All spectra were obtained with a 20 nsec delay time between the laser pulse and opening of the sampling gate, in order to minimize interference from scattered laser light.

Sample preparation and quantitative procedures

All samples were deposited on a gold-plated oxygen-free copper cold finger maintained at 15 K and mounted on the head of a closed-cycle helium cryostat ("Spectrim", CTI Cryogenics). Depositions were performed in the Knudsen effusion–vacuum sublimation apparatus by the techniques described previously.[10,19] The laser intensity was optimized for the first deposit in any series, and the laser wavelength was adjusted for optimum fluorescence intensity for a particular compound. Before any subsequent deposit was illuminated with the laser, a fresh dye solution was placed in the laser without disturbing the optics. The same position on the cold finger was probed by the laser for each successive deposit.

Determinations were made by the combined internal standard–successive standard-addition procedures.[19,20] Benzo[*a*]pyrene was frequently used as internal standard because it has an intense fluorescence feature that can be induced at the "optimal" excitation wavelength for each of the dibenzacridine isomers. The data from successive standard additions for each sample were treated by conventional statistical procedures.[21,22]

RESULTS AND DISCUSSION

Site-selection fluorescence spectra of pure aza-arenes

Figure 1 shows fluorescence spectra of dibenz[*a*,*j*]-acridine (DajA, $C_{21}H_{13}N$) in solid argon, as a function of excitation wavelength. As is generally observed in site-selection fluorometry,[8,12] small alterations in the excitation wavelength cause dramatic changes in the fluorescence spectrum. The multiplet patterns observed in many of the fluorescence spectra are presumed to result from excitation of DajA molecules occupying different types of discrete sites in the polycrystalline argon matrix (similar multiplet patterns in the fluorescence spectrum of naphthalene in solid argon have been analyzed extensively[11]). The "single-site" fluorescence spectrum for DajA pro-

Table 1. Spectral and quantitative data for pure dibenzacridine isomers

*Liquid chromatography with fluorescence detection.[4]
†Fluorescence quenching.[5]
§Thin-layer chromatography with low-temperature fluorescence detection.[6]

duced by excitation of 377.6 nm is considered optimal for analytical purposes because it consists of a single sharp feature.

The fluorescence spectra of dibenz[*a*, *c*]acridine (DacA), dibenz[*a*, *h*]acridine (DahA), and dibenz-[*c*, *h*]acridine (DchA) exhibit excitation-wavelength dependences similar to those for DajA. For each of the four isomers, there exists an "optimum" excitation wavelength (listed in Table 1) that produces a single-site fluorescence spectrum analogous to that shown in Fig. 1 for DajA.

Limits of detection and linear dynamic ranges for pure aza-arenes

Because site-selection fluorometry probes only a small fraction of the analyte molecules in a sample (*i.e.*, those molecules capable of absorbing photons from the narrow-line source), limits of detection for the technique are of particular interest. The limit of detection is defined as the quantity of analyte that produces an instrumental response with a signal-to-noise ratio of 2. Limits of detection for DacA, DahA, DajA and DchA are listed in Table 1. The limits of detection are in the 0.005-1 ng region.

Table 1 compares the limits of detection obtained by other fluorometric methods with those obtained in this work for DahA and DajA (the only dibenzacridine isomers for which such data are found in the literature). The results reported in the present study are generally better than those obtained by other fluorescence techniques, except for DahA, for which a fluorescence quenching method[5] produced a lower limit of detection than that reported here. These results imply that the lower sensitivity[8] of site-selection fluorometry does not automatically produce detection limits inferior to those obtained by other, more sensitive, luminescence techniques, owing to the extremely efficient rejection of interfering luminescence and scattering that is characteristic of the site-selection technique, coupled with the fact that the limits of detection in fluorescence spectrometry are usually limited by the blank.[23]

The limits of detection of aza-arenes by site-selection fluorometry could be improved by using a laser producing subnanosecond pulses. The fluorescence decay times for most aza-arenes are shorter than those for aromatic hydrocarbons, and are often less than 10 nsec.[24] In this work, it was necessary to delay detection of the fluorescence by 20 nsec relative to each laser pulse, in order to allow interfering scattered laser radiation and amplified spontaneous emission to decay. In so doing, a substantial loss in fluorescence signal was incurred, owing to the relatively short fluorescence lifetimes of the aza-arenes (<20 nsec). This problem could be circumvented by using a laser exhibiting a pulse-width significantly shorter than the fluorescence lifetime of the aza-arenes, but such a laser was not available for these studies. Neveretheless, the results indicate that laser-induced site-selection fluorescence spectrometry produces limits of detection competitive with those obtained for DahA and DajA by other, less selective, fluorescence techniques.

The linear dynamic range is the range over which the signal is linear with respect to concentration or quantity of analyte. The linear dynamic ranges for DacA, DahA, DajA and DchA are compiled in Table 1. The linear range for DajA exceeds three decades, while those for DacA, DahA and DchA extend over at least 2.5 decades.

Spectral resolution of dibenzacridine isomers in mixtures by site-selection fluorometry

To characterize the resolving power of site-selection fluorescence spectrometry for the isomeric dibenzacridines, a methanolic solution containing DacA ($8.22 \times 10^{-5} M$), DahA ($7.70 \times 10^{-5} M$), DAjA ($7.28 \times 10^{-5} M$), and DchA ($7.07 \times 10^{-5} M$) was studied. Benzo[*a*]pyrene (BaP, $9.83 \times 10^{-5} M$) was also present in this mixture as an internal standard. A deposit of this solution in solid argon was prepared and fluorescence spectra were obtained with the optimum excitation wavelength for each pure aza-arene (see Table 1).

Figure 2 shows a fluorescence spectrum obtained by using the optimum excitation wavelength for pure DacA. DacA and DajA (as well as the internal standard, BaP) are resolved. When the optimum excitation wavelength for pure DajA was used, a spectrum containing the intense features of DajA and BaP was obtained; this spectrum is shown in Fig. 3. A small feature, presumed to be from DahA and/or

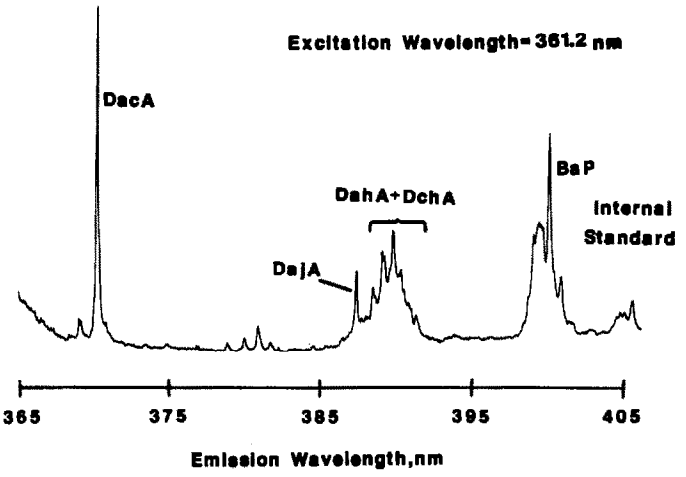

Fig. 2. Fluorescence spectrum of four-component dibenzacridine mixture in solid argon at the optimum excitation wavelength for dibenz[*a*, *c*]acridine. Benzo[*a*]pyrene was added as internal standard.

DchA, is observed at 389 nm; nevertheless, the resolution in this spectrum is clearly sufficient for identification and determination of DajA.

Several excitation wavelengths were employed to attempt to resolve DahA and DchA in this mixture. However, the fluorescence spectra of these compounds are so similar at all excitation wavelengths that no spectrum containing resolved lines for either compound was obtained. Similarly, time-resolution fluorometry failed to resolve DahA from DchA; the fluorescence lifetimes of DahA and DchA are virtually identical. Thus, in argon matrices, neither spectral nor temporal resolution can distinguish between these two isomeric compounds.

Spectral resolution of dibenzacridine isomers in mixtures by Shpol'skii fluorometry

Because DahA and DchA could not be distinguished spectrally in argon matrices, the fluorescence of these compounds was examined in n-octane, a Shpol'skii solvent. The excitation wavelength which produced the sharpest emission lines for DahA in octane was 385.7 nm; the most intense fluorescence peak appeared at 394.9 nm. For DchA, the optimum excitation wavelength in octane was 385.4 nm; the most intense fluorescence band appeared at 396.7 nm.

When the four-component dibenzacridine mixture was examined in octane, by use of the optimal excitation wavelength for DchA, virtually no interfering fluorescence from DahA was observed (see Fig. 4). Determination of DchA in the presence of substantial quantities of DahA would pose no significant difficulties in an octane matrix but would be impossible in argon matrices. However, even in octane, there exists no excitation wavelength at which a fluorescence spectrum for DahA can be produced that is free from major contributions from DchA (typical spectra are shown in Fig. 5). Though DahA can be identified in the presence of DchA in the Shpol'skii matrix (octane), accurate determination of DahA in the presence of appreciable quantities of DchA would be extremely difficult; a well-defined baseline for the DahA fluorescence cannot be established owing to the interfering fluorescence of DchA. Hence, for the DchA–DahA isomeric pair, the selectivity of laser-induced low-temperature fluorometry in Shpol'skii matrices is superior to that exhibited by site-selection fluorescence in argon matrices; however, neither technique exhibits sufficient selectivity for both compounds to be determined accurately in samples containing substantial quantities of each.

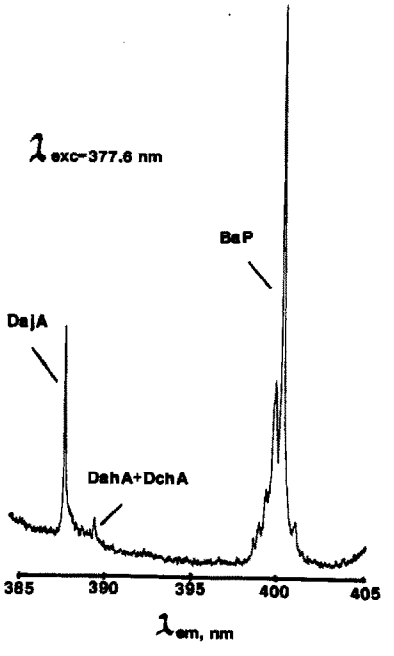

Fig. 3. Fluorescence spectrum of four-component dibenzacridine mixture in solid argon (at 15 K) at the optimum excitation wavelength for dibenz[*a*, *j*]acridine. Benzo[*a*]pyrene was added as internal standard.

Sample	Analyte	Actual value, μg/ml	Found, μg/ml	Error, %
4-Isomer mixture	DacA	22.8	22.8 ± 2.2*	0.0
4-Isomer mixture	DajA	20.2	20.9 ± 2.7	3.5
13-PAH mixture	DajA	209	212 ± 24	1.4

*95% confidence interval as calculated by the method of Larsen *et al.*[22]

Quantification of aza-arenes is also complicated by the tendency of the solutes to undergo photodecomposition in Shpol'skii matrices. For example, under the conditions of our experiments (in which a high-power dye laser was not used), the fluorescence intensities of DahA and DchA decreased by 18 and 22%, respectively, after illumination for 20 min at the optimum excitation wavelengths for the two isomers. Photodecomposition of these analytes proceeded much less rapidly in argon than in Shpol'skii matrices at 15 K.

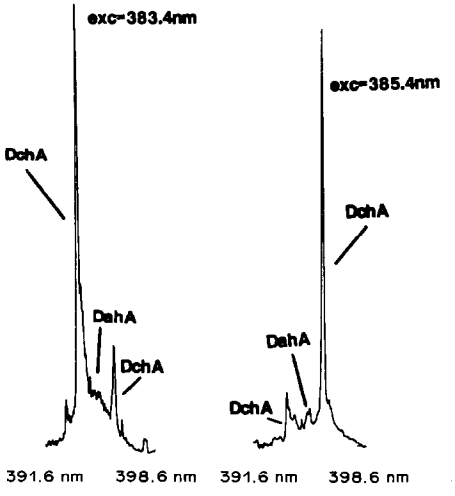

Fig. 4. Fluorescence spectra of four-component dibenzacridine mixture in solid n-octane (at 15 K) at the optimum excitation wavelengths for dibenz[*c*, *h*]acridine.

Determination of dibenzacridines by site-selection fluorometry in argon

Four-component mixture. DacA and DajA were determined in a synthetic four-component aza-arene mixture containing virtually equal quantities of the four dibenzacridines; the results are summarized in Table 2. The experimental results are in excellent agreement with the actual values. These experiments demonstrate both the resolving power of site-selection fluorometry and the ability of the technique to determine individual components accurately in a mixture of isomeric aza-arenes.

Thirteen-component polycyclic aromatic hydrocarbon mixture. Another mixture was prepared to test the possibility of identifying and determining an aza-arene, DajA, in the presence of twelve polycyclic aromatic hydrocarbons (PAHs). The composition of the mixture, which was prepared in methylene chloride, is listed in Table 3. The optimum excitation and emission wavelengths for DajA in an argon matrix were employed to obtain the spectrum for DajA and the internal standard, benzo[*a*]pyrene, shown in Fig. 6. The DajA content of this mixture, as determined by site-selection fluorometry, exhibits excellent agreement with the true value (Table 3).

This result indicates that aza-arenes can be determined in the presence of a sizable number of PAHs, without prior separation, by laser-induced site-

selection fluorometry in argon matrices. This result is important in view of the fact that most real samples containing detectable quantities of aza-arenes also contain many different PAHs, often in concentrations much greater than those of the aza-arenes.

CONCLUSIONS

Narrowed-line fluorescence spectra can be obtained for each of the isomeric dibenzacridines by laser-induced matrix-isolation site-selection fluorescence spectrometry at 15 K. The limits of detection observed were in the pg–ng region, with linear dynamic ranges of at least 2.5 decades. Accurate determinations of two of the compounds in synthetic mixtures of dibenzacridines and polycyclic aromatic hydrocarbons were achieved. Neither site-selection nor Shpol'skii fluorometry is capable of full spectral resolution of two of the isomers (dibenz[*c, h*]acridine and dibenz[*a, h*]acridine).

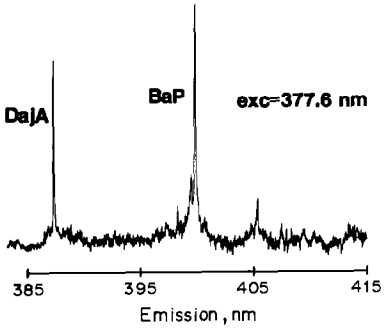

Fig. 6. Fluorescence spectrum of thirteen-component PAH mixture in solid argon at the optimum excitation wavelength for dibenz[*a, j*]acridine. Benzo[*a*]pyrene is used as internal standard.

CONTINUOUS-FLOW PERFORMANCE OF CARBON ELECTRODES MODIFIED WITH IMMOBILIZED Fe(II)/Fe(III) CENTERS

AMPEROMETRIC RESPONSE TO N_2O, NO AND NO_2

(*Received* 5 *May* 1988. *Accepted* 24 *August* 1988)

Summary—The amperometric performance of two types of chemically modified carbon electrodes developed for the determination of oxides of nitrogen in continuous-flow systems is presented. The modification consists in immobilization of reversible Fe(II)/Fe(III) centers. The first type of electrode is a simple modification made by direct mixing of carbon paste with tris-4,7-diphenyl-1,10-phenanthroline-iron(II) perchlorate; the other is a glassy-carbon surface modified by oxidative electropolymerization of tris-[5-amino-1,10-phenanthroline]iron(II) perchlorate. Detection is accomplished by transporting an injected sample plug to the sensing surface with the aid of gravitational flow of an aqueous solution of supporting electrolyte. The polymer-coated electrochemical detector compares favourably with the chemically modified carbon paste. It offers excellent resistance to poisoning and a competitive limit of detection [about 2 ppb (2 parts in 10^9) v/v], at +1.0 V *vs.* Ag/AgCl, and good selectivity for NO_2 when used in a thin-layer cell. Incorporation of the cell in a continuous-flow system allows injection of about 120 samples per hour. The typical concentration range amenable to determination is 2–25 ppb v/v but depends on the thickness of the polymeric film. Nitrogen monoxide can also be detected but only in undiluted, pure form. Dinitrogen oxide gives no amperometric signal at any of the modified surfaces.

The oxides of nitrogen relevant to air pollution are N_2O, which, although not a product of combustion, is used as a carrier gas in aerosol containers; NO, the main product of combustion of nitrogen compounds; and NO_2, a strong absorber of ultraviolet light and participant in photochemical reactions that produce smog. Mixtures of NO and NO_2 are referred to as NO_x and are generated mainly by automobiles and by electric power plants. The relevance of these species is widely recognized and has received special attention in an open meeting of the Executive Committee of SCOPE (Scientific Committee on Problems of the Environment) held in Bangkok, 7–13 February 1987, at which N_2O, NO_x, and methane were singled out as species to receive special attention in the first phase of a study on trace gases of biological origin.[1] The analytical chemistry of these species is consequently of particular interest. The analytical methods generally used for determination of these species[2–4] normally involve gasometric procedures, absorption in liquids and subsequent determination (*e.g.*, by titration or spectrophotometry), infrared spectroscopy, gas chromatography or mass spectrometry. These methods are often time-consuming, elaborate, require expensive equipment, or have poor limits of dectection. Gas-phase chemiluminescence, with competitive limits of detection, has been designated by the U.S. Environmental Protection Agency as the reference technique for measurement for NO_2.[5]

Electrochemical detection, potentially offering competitive limits of detection with simple instrumentation, has mainly been used for the determination of the nitrite or nitrate ions formed by absorption in liquids. N_2O is relatively inert, but NO undergoes stepwise oxidation in 4*M* sulphuric acid.[6] This behavior has been exploited for the continuous-flow determination of nitrite and nitrate ions,[7] after reduction to NO with hydroquinone at pH 2 (phosphate buffer) and sweeping with nitrogen gas to an anodically polarized membrane-covered Pt electrode. Trojanek and Bruckenstein[8] also used a continuous flow approach to determine subnanogram amounts of nitrite, but detected NO with an electrode made by depositing a porous gold layer on one side of a porous Teflon membrane.

Chemically modified electrodes have attracted considerable attention,[9] but few analytical applications have been documented. From a practical viewpoint they are potentially useful as sensing devices because chemical modification of the electrode surface may result in (*a*) a change in electrochemical reaction rates, (*b*) protection of the electrode surface from fouling, and (*c*) enhancement of selectivity and/or sensitivity with a concomitant improvement in detection limits.

The modifier is often an electroactive chemical species (*e.g.*, reversible redox centers) and an electro-

*Author for correspondence.

catalytic process is responsible for the enhanced analytical performance. The work described in this paper is part of a comprehensive study of chemically modified electrodes based on metal-complex redox couples of the 1,10-phenanthroline family of ligands for use in continuous-flow detection of oxidizing and reducing species in the gaseous state. Three different ways of producing modified surfaces are being studied: (*a*) direct mixing of carbon pastes with a relatively insoluble salt (in aqueous media) of a complex cation,[10] (*b*) covalent binding of the complex cation to chemically modified graphite and pasting liquids, and (*c*) oxidative electropolymerization of some derivative complex cations of the same ligand family.[11] This paper reports the use of some chemically modified electrodes with immobilized Fe(II)/Fe(III) reversible redox centers, and their amperometric response to some oxides of nitrogen in continuous-flow systems. The Fe(II)/Fe(III) centers have been incorporated in carbon-paste electrodes by mixing tris[4,7-diphenyl-1,10-phenanthroline]iron(II) perchlorate with graphite before forming the paste[10] or coated on glassy-carbon electrodes by oxidative electropolymerization of tris[5-amino-1,10-phenanthroline]iron(II) perchlorate in acetonitrile.[11]

The response of these surfaces to NO_2 in flow-through thin-layer cells exhibits competitive limits of detection and good sensitivity and selectivity, providing a simple and reliable approach to the determination of this oxidizing species in gases (*e.g.*, air) on a continuous or repetitive basis. High reproducibility, excellent protection from surface poisoning and good long-term stability are properties that single out the electropolymerized coating as a competitive sensor for pollution monitoring.

EXPERIMENTAL

Apparatus

The continuous-flow system (Fig. 1) includes a thin-layer cell with two working electrodes and a reference electrode compartment, with an auxiliary electrode in the form of the metal tubing serving as the exit to waste. This four-electrode arrangement is available from Bioanalytical Systems (West Lafayette, IN) and, although it does not compensate significantly for solution resistance, it draws no current through the reference electrode[12] and permits simultaneous reponses to be obtained on modified and unmodified working surfaces. A 0.1-mm thick Teflon spacer provides the gap for passage of solution in the thin-layer cell compartment. The same basic arrangement as in Fig. 1 was also used with a home-made cell having a planar glassy-carbon auxiliary electrode opposite the working electrode (gap between electrodes = 1 mm), with the reference electrode located downstream.[13] An Ag/AgCl reference electrode was used in both cells. The thin-layer cell gave better responses and lower limits of detection, despite the fact that the surfactant pretreatment[14] was not useful with it because of obstruction of the cell channels by flakes of graphite.

Gravity flow was used for the carrier solution because it provides excellent flow characteristics for electrochemical detection.

The pH was measured with an Orion 601A digital pH-meter with an epoxy-body combination electrode. Absorbance measurements were made with a Spectronic 21 spectrophotometer (Bausch & Lomb).

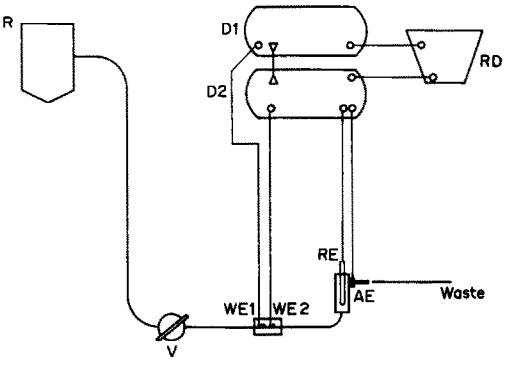

Fig. 1. Configuration for continuous-flow determination of oxides of nitrogen by using chemically modified electrodes in a thin-layer configuration [two working electrodes (WE1 and WE2) in parallel configuration]. R, reservoir with carrier electrolyte; D1 and D2, amperometric detectors connected in tandem (Model LC4B from Bioanalytical Systems); RD dual-pen chart recorder (Model RYT-DP, Bioanalytical Systems); V, intercalation valve (Rheodyne Type 50, 4-way Teflon rotary valve); RE, reference electrode; AE, auxiliary electrode.

Working electrodes

A thin-layer cell with two working electrodes was used. One of the electrodes had an unmodified surface (WE1 in Fig. 1) and the second was chemically modified (WE2 in Fig. 1). The polymer-coated electrode[11] in the thin-layer configuration was prepared by application of 122 cycles (at 50 mV/sec) between 0 and +1.30 V *vs.* an Ag/AgCl reference. The modified carbon-paste electrode[10] contained 10% w/w modifier, 55% graphite (UCP-1-M from Ultra Carbon, Bay City, MI) and NF/FCC light paraffin oil (Saybolt viscosity 158 maximum) from Fisher Scientific (Fair Lawn NJ). The tris[4,7-diphenyl-1,10-phenanthroline]iron(II) perchlorate was precipitated, washed, and dried, then mixed with a slurry of the graphite in acetone, and the acetone was allowed to evaporate while mixing was continued. The resulting powder was finally mixed with the mineral oil in an agate mortar to obtain the modified carbon paste.

Reagents

Unless otherwise specified, reagents were of analytical reagent grade. The carrier electrolyte solution (0.10*M* potassium chloride, pH 4.00) was prepared with demineralized distilled water.

The NO_2 was prepared in a gas-tight glass container by exposing a given volume of concentrated nitric acid to sunlight until a constant concentration of NO_2 was found [determined by use of sulfanilic acid and *N*-(1-naphthyl)ethylenediamine dihydrochloride in acetic acid].[15] The stock NO_2/air mixtures, from which dilutions (with air) were made as required, were standardized by the same procedure. The gas sample was introduced from the sample loop of a Rheodyne 4-way valve, filled from a gas-tight Hamilton syringe tightly attached to its entry port. Nitric oxide and nitrous oxide were obtained from the Aldrich Chemical Co.

RESULTS AND DISCUSSION

Response to N_2O

No detectable signal in the range from 0 to +1.3 V *vs.* Ag/AgCl was observed with any of the chemically

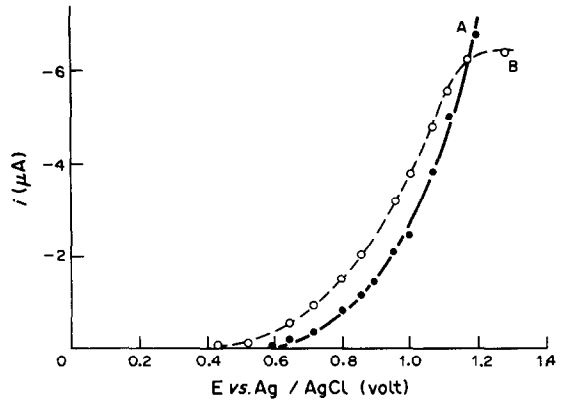

Fig. 2. Voltamperogram showing the response to pure NO(g) at a polymer-coated glassy carbon electrode (A) and a modified carbon paste electrode (B). Carrier supporting electrolyte 0.10*M* KCl (pH 4.00). Flow-rate 2.0 ml/min. Injected sample size 250 μl.

modified electrodes, even when undiluted N_2O was injected.

Response to NO

Nitric oxide could be detected with both unmodified and modified electrodes but only at very high concentrations. The response to undiluted NO at unmodified electrodes was, however, irreproducible and the electrode surface soon deteriorated until even qualitative detection was doubtful. The peaks were broad and distorted, particularly after use of an applied potential of 1 V to unmodified carbon-paste. The naked glassy-carbon electrode showed some irreproducible and relatively insensitive response at an applied potential of 0.6–1.0 V but no response at above 1 V. Figure 2 shows the voltamperograms for detection of a continuous flow of undiluted NO with the two types of chemically modified electrode. These electrodes, particularly the polymer-coated glassy-carbon one, showed clearly defined responses and good reproducibility. The responses in Fig. 2 were obtained with NO taken directly from the cylinder, to avoid any formation of NO_2 by exposure to aerial oxygen.

Response to NO_2

As expected, NO_2 readily underwent redox reaction at the immobilized Fe(II)/Fe(III) centers in both types of modified electrode. Figure 3 shows the amperometric responses obtained by continuous-flow operation with modified and unmodified carbon-paste electrodes; the response to injection of air alone is also shown (curve A). Only oxidation peaks were observed and the air peaks were similar for both the modified and unmodified electrodes. Since the normal content of NO_2 in air is $\sim$1 ppb (1 part in 10^9) v/v, these responses probably resulted from flow disturbances rather than electrochemical detection. Curve B in Fig. 3 shows the response at an unmodified carbon-paste surface, which can be interpreted as resulting from:

$$N(IV) \rightarrow N(V) + e^- \quad (1)$$

This response is only about one-third of that at the chemically modified surface with Fe(II)/Fe(III) centers (curve C). Signals at modified carbon surfaces are believed to result partly from reaction (1), but also to have a contribution from an electrocatalytic process such as:

$$Fe(II) + N(IV) \rightarrow Fe(III) + N(III) \quad (2)$$

$$N(III) \rightarrow N(IV) + e^- \quad (3)$$

For reaction (2) it is assumed that at potentials $\leq$ 1.0 V the predominant species in the immobilized iron centers is Fe(II), in accordance with the cyclic voltammetric behavior of carbon-paste electrodes modified with tris[4,7-diphenyl-1,10-phenanthroline]iron(II).[10] The possibility that N(V) rather than N(IV) oxidizes Fe(II), with a coupled catalytic cycle involving reaction (1) cannot be ruled out. Although the population of Fe(III) centers should be considerably lower, contribution to the signal from:

$$Fe(III) + N(IV) \text{ [or } N(V)] \rightarrow Fe(II) + N(III) \text{ [or } N(IV)] \quad (4)$$

$$Fe(II) \rightarrow Fe(III) + e^- \quad (5)$$

cannot be totally disregarded.

The response at the polymeric film deposited on glassy-carbon surfaces, on the other hand, shows reduction peaks at low positive potentials and oxidation peaks at high positive potentials with an "inert" electrochemical behavior at around +0.60 V. This behavior can be seen in Fig. 4, in which the response to NO_2 at both modified and unmodified

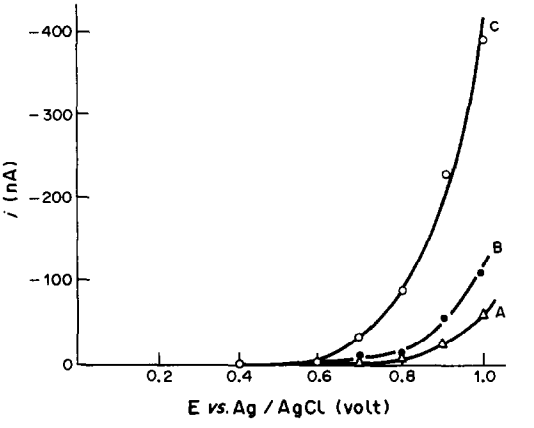

Fig. 3. Voltamperogram showing the response to NO_2 (30 ppb v/v) at a modified (10% w/w) carbon paste electrode. Flow-rate 2.0 ml/min, injected sample size: 250 μl. Carrier supporting electrolyte: 0.10*M* KCl (pH 4.00). (A) Response to air injection for both chemically modified and unmodified electrodes; (B) NO_2 response of an unmodified carbon paste electrode; (C) NO_2 response of modified carbon paste electrode.

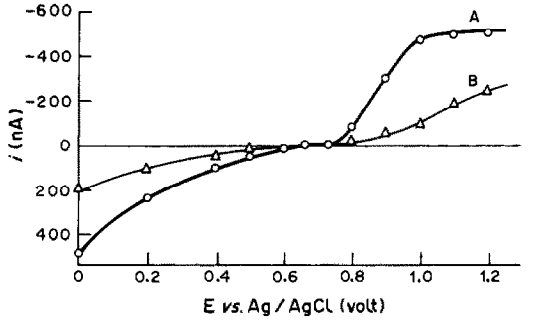

Fig. 4. Voltamperogram showing the response to NO_2 (25.0 ppb v/v) at a polymer-coated glassy carbon electrode. Flow-rate, 2.0 ml/min; injected sample size, 250 μl; carrier supporting electrolyte, 0.10*M* KCl (pH 4.00). Polymer coating produced with 12 cycles between 0 and +1.3 V *vs.* Ag/AgCl with the glassy-carbon working electrode immersed in a 0.060m*M* solution of tris[5-amino-1,10-phenanthroline]-iron(II) perchlorate in acetonitrile (0.10*M* $NaClO_4$) at a scan rate of 50 mV/sec. (A) response at polymer-coated glassy-carbon electrode; (B) response at naked glassy-carbon electrode.

glassy-carbon surfaces is shown. Figure 5 shows typical amperometric signals obtained under continuous-flow conditions at an applied potential of 1.0 V *vs.* Ag/AgCl. The reduction signals observed at potentials below 0.6 V at unmodified glassy-carbon electrodes are interpreted as resulting from:

$$N(IV) + e^- \rightarrow N(III) \qquad (6)$$

The enhanced response at the polymeric film/glassy-carbon sensor does not result from the reactions above, but from the electrocatalytic process:

$$Fe(II) + N(IV) \rightarrow Fe(III) + N(III)$$

$$Fe(III) + e^- \rightarrow Fe(II)$$

The oxidation peaks at potentials above 0.6 V at the naked glassy-carbon surface result from the conversion into N(V) in reaction (1) and the response at polymer-coated surfaces results from:

$$Fe(III) + N(IV) \rightarrow Fe(II) + N(V)$$

$$Fe(II) \rightarrow Fe(III) + e^-$$

As shown in Fig. 6, the N(IV) species behaves differently at the two types of modified electrodes. The presence of the polymer-based film favors a CE mechanism, whereas the response at the modified carbon-paste electrode may comprise both CE and EC processes.

Effect of density of Fe(II)/Fe(III) centers at the electrode surface

An increase in the number of Fe(II)/Fe(III) centers per unit area should result, up to a point, in an increased response to NO_2.

With the carbon-paste electrodes, 10% of modifier provided the most sensitive surfaces, as shown in Table 1. The decrease in response with higher levels of modifier indicates that there is a critical ratio in the bulk composition of the paste. This could be interpreted as the need for a given number of carbon centers on the surface to facilitate fast electron exchange with the conducting material in the electrode,

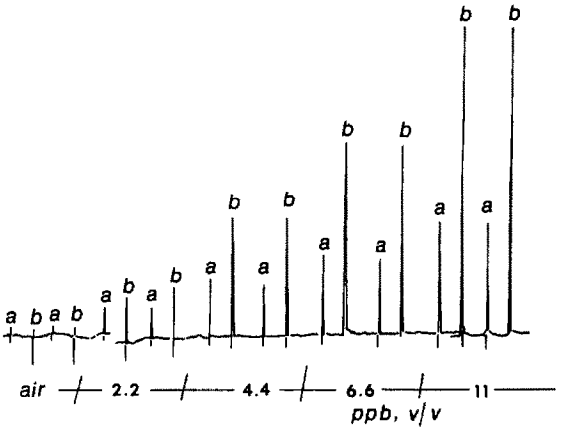

Fig. 5. Typical transient signals due to NO_2 injection at a two working-electrode thin-layer cell. The cell is assembled with one naked glassy-carbon electrode and one chemically modified by polymer coating. (a) Response at naked glassy carbon; (b) response at polymer-coated electrode. *A surface coverage of about 1.2×10^{-8} mole/cm^2 is provided by every 10 cycles.[3]

because electron hopping, within areas occupied by the complex, is slower than electron transfer from complex to carbon electrode.

Although electron hopping in the polymer-coated glassy-carbon electrodes is competitively fast,[11] a decrease in response would be expected as the number of polymer layers deposited on the surface increases. Table 1 includes data verifying this expectation, as reducing the number of cycles used for the electrochemical polymerization results in an increase in signal. Figure 7, depicting calibration data, also provides insight into the expected analytical performance when the number of polymer layers is varied on the surface of glassy carbon. Increasing the number of layers increases the concentration range of NO_2 determinable, though at some expense in sensitivity (curves A and B).

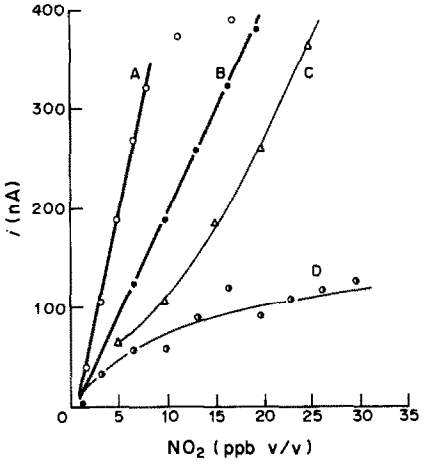

Fig. 7. Dependence of signal height on injected NO_2 concentration. (A) polymer-coated glassy-carbon electrode prepared with 10 cycles; (B) polymer-coated glassy-carbon electrode prepared with 120 cycles; (C) modified carbon paste electrode; (D) naked glassy-carbon electrode. Applied potential 1.0 V *vs.* Ag/AgCl. Flow-rate 2.0 ml/min. Injected sample size 250 μl. Carrier supporting electrolyte 0.10*M* KCl (pH 4.00).

Effect of pH of carrier solution, injected sample size, and flow-rate

Figure 8 shows the dependence of signal height on the pH of the carrier electrolyte solution. The same pH-dependence was observed with both types of chemically modified electrode. A pH of about 4 is recommended. Since the immobilized Fe(II)/Fe(III) centers show practically the same electrochemical response at pH 1–5,[10] the observed behavior seems to be the result of the intrinsic rates of the chemical steps involved in the response, irrespective of the method of electrode construction.

Sample sizes in the 100–300 μl range give the best sensitivity. The flow-rate giving the best compromise between sensitivity and time for return to baseline is in the neighborhood of 0.1 ml/sec, which provides an injection rate of 100–200 samples per hour.

Sensitivity, limit of detection, dynamic range, selectivity, and stability

The slopes of the calibration curves in Fig. 7 define the sensitivity, and the polymer-film modified glassy-carbon sensor exhibits better sensitivity (18 nA/ppb) than the doped carbon-paste electrode. It also offers better linearity. As already mentioned, its sensitivity is a function of the number of layers (and hence the number of application cycles) deposited on the conducting surface. The value of 18 nA/ppb was obtained with electrodes modified by use of 122 cycles; if only 10–20 cycles are used the sensitivity improves to 21.3 nA/ppb but the linear dynamic range is reduced to about 10 ppb. The limit of detection, calculated as the concentration corresponding to the blank (air) signal plus three times the standard devi-

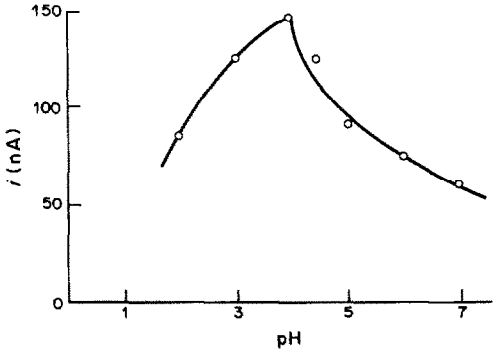

Fig. 8. Effect of pH on signal height for NO_2 determination. Nitrogen dioxide concentration 5.5 ppb; applied potential 1.0 V *vs.* Ag/AgCl; flow-rate 2.0 ml/min; injected sample size 136 μl; carrier supporting electrolyte 0.10*M* $NaClO_4$.

Table 2. Repetitive response of a polymer-coated glassy carbon electrode to 18 ppb NO_2; carrier supporting electrolyte 0.10*M* KCl (pH 4.00); injected sample volume, 250 μl; flow-rate, 2.0 ml/min.

Age	*i*, *nA*	No. of determinations

24 hr	353 ± 3	3
Electrode kept in contact with supporting electrolyte between runs		

ation of this blank is about 2 ppb NO_2. Figure 7 also shows the response to NO_2 at a naked glassy-carbon electrode; the poisoning of the surface and consequently the inadequacy of its use for NO_2 detection after a few injections can be observed.

The electrode is insensitive to N_2O and O_2 but shows response to other oxidizing gases such as chlorine, and reducing species such as SO_2. Chlorine gives no signal at +1.0 V *vs.* Ag/AgCl and then does not interfere with NO_2 determination, but it can be detected at +0.6 V, at which the electrode is insensitive to NO_2. The response to SO_2 is about two orders of magnitude less sensitive than the response to NO_2.

Table 2 shows typical data illustrating the good short-term stability of the polymer-coated glassy carbon in continuous operation. The electrode could be stored in air or in supporting electrolyte without any significant difference in its performance. A modified glassy-carbon surface kept for a month in supporting electrolyte exhibited no deterioration and provided as good performance for NO_2 detection as

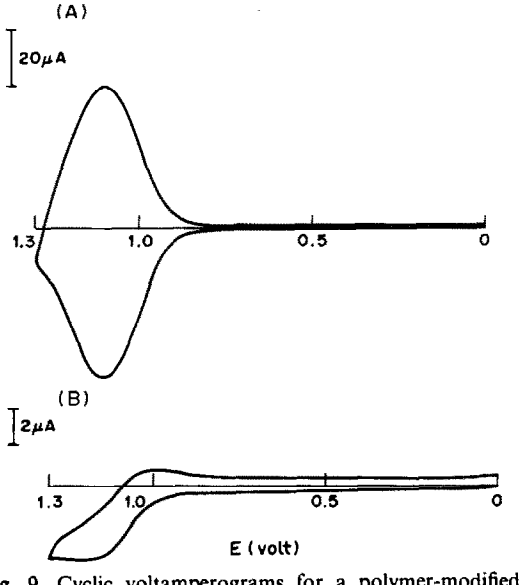

Fig. 9. Cyclic voltamperograms for a polymer-modified glassy-carbon electrode before (A) and after 4 hr (B) use as an NO_2 detector. Coating was performed with 122 cycles. Scan-rate 50 mV/sec. Supporting electrolyte 0.10*M* KCl (pH 4.00).

when freshly prepared; this points to long-term shelf stability. There was no significant deterioration in the signal from surfaces used for detection for up to 7 hr continuously or more than one week intermittently. The relative standard deviation (typically 5%) is mainly the result of uncertainties arising from the mode of injection. Cyclic voltamperograms obtained with freshly prepared polymer-coated surfaces differ from those obtained with surfaces that have been used for repetitive determination of NO_x. There is (*a*) greater peak separation and (*b*) a marked blurring of the peaks. This deformation in peak shape is more noticeable at low coverage. Evidently the protecting action of thicker films is responsible for this behavior, which is illustrated in Fig. 9. Response to NO_2 is not, however, significantly impaired and the surfaces can be used for detection in continuous-flow procedures despite the apparent change in cyclic voltammetric response.

CONCLUSIONS

The observations and discussion presented above point to the usefulness of chemically modified electrodes for the detection and determination of oxidizing species, NO_2 in particular, under continuous-flow conditions. The continuous "bathing" of the sensor surface with supporting electrolyte ensures the presence of an unbroken film of ions to support electrical migration and satisfy the electroneutrality requirement. This, and the continuous-detection mode, are advantages resulting from the use of a continuous-flow mode of operation.

Both types of surface modification described can be used for detection of NO_2; the polymer-coated glassy-carbon surface, however, has characteristics that make it highly convenient. The modified carbon-paste electrode is easier to prepare and polish but its analytical performance (sensitivity and reproducibility) is inferior to that of the polymer-coated glassy-carbon surfaces. The limit of detection for NO_2 is competitive and the response is very selective towards this oxide of nitrogen.

The clear advantages of electrocatalytic response by means of reversible redox mediators immobilized on conducting surfaces and the protecting action of film coating are well illustrated in the results and observations presented. The practical aspects illustrated here add to the increasing interest in electrocatalysis resulting from chemically modified electrodes.[16]

Summary—This paper describes the development of active materials for optically enhanced Raman and fluorescence spectroscopy. The substrates for surface-enhanced Raman scattering investigated in this study involved silver-coated microspheres on glass plates. The effect of various experimental parameters, such as angle of incidence and excitation wavelength, were investigated. The substrate used for surface luminescence analysis consisted of a cellulose membrane coated with fumed silica microparticles, to enhance the sensitivity of analysis. Examples of analysis of benzo[*a*]pyrene and its derivatives are used to illustrate the efficacy of the analytical techniques.

The development of sensitive and selective methods and instrumentation for detection of trace quantities of toxic chemicals and related biological indicators is critical for the achievement of environmentally acceptable and safe technologies. Problems pertaining to the identification of specific compounds at ultra-trace levels, the analysis of complex mixtures, and the assessment of biological effects continue to create new analytical challenges.

An important problem area in chemical analysis is the sensitive characterization of complex mixtures. In order to detect minute amounts of a compound in a complex "real-life" sample, analytical techniques must be able not only to differentiate compounds having different molecular sizes but also to identify specific substituents and/or derivative chemical groups attached to the basic structure. In many situations, several techniques are required to provide unambiguous identification and accurate quantification. The various analytical techniques investigated in our laboratories for trace organic analysis include synchronous luminescence,[1,2] room-temperature phosphorescence,[3,4] surface-enhanced Raman spectroscopy[5–8] and fiber-optics laser spectroscopy.[9,10] For many of these techniques, research has been directed towards development of methods, instruments or substrate materials that can improve the selectivity and sensitivity of the analytical techniques. For instance, heavy atoms and cyclodextrins were used to enhance phosphorescence analysis,[4] and antibodies were developed to improve the specificity and sensitivity of laser-based biochemical sensors.[9,10] This paper presents an overview of some recent advances in the development of Raman and luminescence methods of analysis.

In this study, the development of various active materials for Raman and fluorescence analysis is discussed. The substrates for surface-enhanced Raman scattering (SERS) studies consisted of glass plates covered with silver-coated microspheres. The effects of experimental factors such as angle of incidence and excitation wavelength were investigated in detail. The results obtained with SERS-active substrates for *in situ* analysis are presented for benzo[*a*]pyrene *r*-7,*t*-8,9,10-tetrahydrotetrol. In luminescence analysis, cellulose substrates were developed for rapid screening of organic chemicals by the synchronous luminescence spot-test method. The use of fumed silica microparticles to enhance the sensitivity of fluorescence analysis is described. Examples with benzo[*a*]pyrene were used to illustrate the efficacy of the spot-test method.

The SERS technique

The discovery of SERS[11,12] has stimulated a great deal of research activity over the past few years.[13] Extensive efforts have been devoted to the investigation and determination of the sources of enhancement. The experimental facts related to SERS, and the enormous Raman enhancement, are believed to be the result of several mechanisms. There are at least two major types of mechanism that contribute to the SERS effect: (*a*) an electromagnetic effect associated with large local fields caused by electromagnetic resonances occurring near metal surface structures, and (*b*) a chemical effect involving a scattering process associated with chemical interactions

*Author to whom correspondence should be addressed.

between the molecule and the metal surface. Some aspects of SERS, such as the contribution of electromagnetic interactions, have been extensively investigated and are reasonably well understood. Other aspects, such as the contribution of chemical effects, are less well known and are currently topics of extensive research. The reader is referred to a number of reviews for further details.[13-15]

Electromagnetic interactions between the molecule and the substrate are believed to provide most of the enhancement in the SERS process, and are divided into two major classes: (*a*) interactions that occur only in the presence of a radiation field, and (*b*) interactions that occur even without a radiation field.

The class (*a*) interactions are believed to play a major role in the SERS process. A major contribution to electromagnetic enhancement is due to surface plasmons. Surface plasmons are associated with collective excitation of surface conduction electrons in metal particles. Raman enhancements result from excitation of these surface plasmons by the incident radiation. At the plasmon frequency, the metal becomes highly polarizable, resulting in large field-induced polarizations and thus large local fields on the surface. These local fields increase the Raman emission intensity, which is proportional to the square of the applied field at the molecule. Additional enhancement is due to excitation of surface plasmons by the Raman emission radiation from the molecule.

Surface plasmons are not the only source of enhanced local electromagnetic fields.[13,14] Other types of electromagnetic enhancement mechanisms are: (*a*) concentration of electromagnetic field lines near high-curvature points on the surface, *i.e.* the "lightning rod" effect, (*b*) polarization of the surface by dipole-induced fields in adsorbed molecules, *i.e.*, the image effect, and (*c*) Fresnel reflection effects.

The chemical effect is associated with the overlap of metal and adsorbate electronic wave-functions, which leads to ground-state and light-induced charge-transfer processes.[13,14] In the charge-transfer model, an electron of the metal, excited by the incident photon, tunnels into a charge-transfer excited state of the adsorbed molecule. The resulting negative ion (adsorbate molecule plus electron) has a different equilibrium geometry from the original neutral adsorbate molecule. Therefore, the charge-transfer process induces a nuclear relaxation in the adsorbate molecule which, after the return of the electron to the metal, leads to a vibrationally excited neutral molecule and to emission of a Raman-shifted photon. The "adatom model" also suggests additional Raman enhancement for adsorbates at special active sites of atomic-scale roughness, which may facilitate charge-transfer enhancement mechanisms.[13-15]

Synchronous luminescence spectroscopy

Luminescence measurement involving two experimental parameters (excitation and emission wavelength) has long been recognized to offer superior spectral selectivity over absorption techniques. In conventional luminescence spectroscopy, either the excitation (λ_{ex}) or the emission wavelength (λ_{em}) remains fixed. With synchronous luminescence (SL), λ_{ex} and λ_{em} are scanned simultaneously with a fixed wavelength interval, $\Delta\lambda$, between them.

Improved selectivity with minimal increase in complexity is the main advantage of this method. In general, the spectral structure of the system becomes better resolved because of bandwidth narrowing of the individual emission lines and decrease of spectral overlap from various components in the mixture. The methodology and rationale for this technique have been discussed previously.[1,2] Another major attribute of the synchronous technique is the simplicity of instrumentation. The technique often requires no additional equipment other than the spectrometer used in conventional fixed-excitation measurement. Several instruments, where interlocking of the two monochromators is a standard feature, are commercially available. More recently the SL concept has been extended to the constant-energy scanning method.[16] The concept of synchronous excitation–emission can be applied both to fluorescence (synchronous fluorimetry, SF), and phosphorescence (synchronous phosphorimetry, SP). In the case of SF, the Stokes shift determines the optimum value of $\Delta\lambda$ and is often set at 3 nm. For SP the singlet–triplet energy difference determines the optimum value of $\Delta\lambda$.[17]

EXPERIMENTAL

Instrumentation and procedures

Raman measurements. Raman spectra were measured with two Raman spectrometers. The first consisted of a Spex Model 1403 double monochromator with a Spex Datamate DM1 control and data-acquisition system. The detection employed the photon-counting technique, accomplished with a cooled RCA C31034-02 photomultiplier tube. Excitation was provided by a Spectra Physics Model 166 argon-ion laser, a Coherent Radiation Model Innova 90K krypton-ion laser, or a Liconix Model 4240PS helium–cadmium laser.

The second system was based on a Jobin-Yvon/ISA Ramanor 2000M double monochromator. The data-acquisition system was an LSI 11/23 minicomputer purchased from data Translation Corporation and a DSD/880 Winchester/floppy disk drive. Photon counting was accomplished as for the first instrument. The excitation was provided by a Spectra Physics Model 171 argon ion laser.

The substrate preparation involved two steps. The first was the deposition of microbodies (such as polystyrene latex spheres or titanium oxide particles) on glass plates. This was accomplished by placing a glass slide on a spin-coating device, putting a few drops of sphere/water suspension on the slide, and immediately spinning the slide at 2000 rpm for 20 sec. Spinning has been found necessary to preclude clumping of spheres on the glass surface. The spheres adhered to the glass, providing uniform coverage. The second step was the coating of the sphere-covered glass slide with silver. The slide was attached to a motor mount and placed inside a vacuum evaporator (Thermionics Labora-

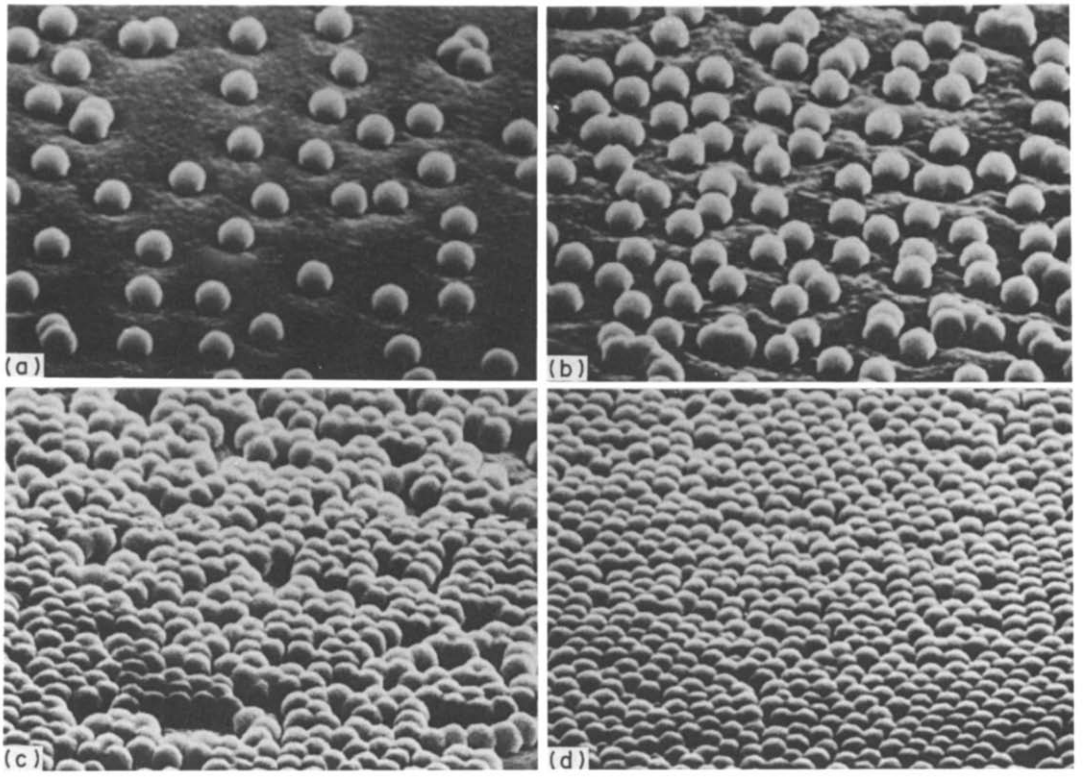

Fig. 1. Scanning electron micrographs (taken with an ISI DS 130 instrument) of silver-coated microsphere substrates (176-nm diameter spheres). Substrates prepared with: (a) 0.33%; (b) 1%; (c) 3.3%; and (d) 10% w/w suspensions.

tory Inc.), then rotated over the silver source at an angle of 40° to the direction of silver evaporation. The pressure was less than 5×10^{-6} torr. The rotation at an angle was to ensure uniform coverage with silver. The rate of silver deposition was controlled at approximately 1.5–2.0 nm/sec. The rate and thickness of silver deposition were measured with a Kronos Model QM-311 quartz crystal thickness monitor, with a relative standard deviation of 10%. After deposition of the silver, 2–4 μl of sample solution were spotted on the silver-coated substrate. The Raman spectrum was then scanned over the region of interest. For solution measurements, 1 ml of the sample solution was pipetted into a standard silica cell. The silvered substrate was then inserted directly into the cell and the SERS spectrum was recorded.

Luminescence measurements. All fluorescence spectra were obtained with a Perkin-Elmer 650–40 ultraviolet spectrometer equipped with a 150-W xenon lamp excitation source and a R928 Hamamatsu photomultiplier tube. Data-acquisition and spectrometer-control were accomplished with an IBM-XT computer.

Spot-test measurements were made in the following manner. First 2.5 μl of a 5% w/v aqueous suspension of grade LM130 fumed silica were applied to filter paper and allowed to dry for approximately 2 min. On the same spot, 2.5 μl of $1 \times 10^{-4}M$ ethanolic solution of benzo[*a*]pyrene (BaP) were applied. The fluorescence of BaP without sensitizing agent (fumed silica) was also measured and plotted on the same scale for comparison. Appropriate background spectra were obtained and subtracted for all measurements. For excitation scans, the emission wavelength was set to 408 nm; for emission scans, the excitation wavelength was set to 378 nm. For synchronous luminescence measurements, $\Delta\lambda$ was set at 17 nm. The spectral resolution was set at 1.0 nm for all measurements.

Materials and reagents

Amorphous fumed silica (grade LM130) was obtained from the CABOT Corporation. Benzo[*a*]pyrene was acquired from the National Institute of Health Repository. Spectral grade ethanol was purchased from Warner Graham Company and distilled water was purchased from American Scientific Products. Grade 2043A filter paper from Schleicher and Schuell Inc. was used for all measurements.

Ordinary glass microscope slides were used as a base for the substrates. Polystyrene latex spheres were purchased as 10% w/v suspensions from Duke Scientific Corporation, Palo Alto, California. All chemicals were commercially available and only those of highest purity were purchased.

RESULTS AND DISCUSSION

Studies of SERS substrates

Figure 1 shows scanning electron micrographs of SERS-active substrates consisting of silver-coated microsphere on solid surfaces. An important advantage of these substrates is their ease of preparation. In general, microspheres have been used on filter paper substrates, which provide simple and inexpensive practical supports.[6] For the present studies we used glass plates as solid planar supports. The size of the surface microstructure can be easily controlled by simply selecting the appropriate microsphere sizes. As illustrated in Fig. 1, the density of the microprotrusions on the surface can also be controlled by varying the concentration of the suspension of

176-nm diameter microspheres used in the preparation of the substrate. The microsphere suspension concentrations investigated ranged between 0.33 and 10% w/w. Lower concentrations of the microspheres (0.33, 1 and 3.3%) produced substrates having microprotrusions separated from one another whereas a concentration of 10% produced a substrate with closely packed microspheres. Substrates prepared with 1% solution gave the best SERS enhancement for 176-nm microspheres.

In this work, silver was used as the coating metal for SERS substrates. Previous research had indicated that the type of metal on the surfaces is an important factor affecting the SERS effect.[13] Silver exhibits the strongest enhancement, followed by copper and gold. The development of SERS as an analytical technique is relatively recent and many experimental factors require careful optimization in order to yield the maximum signal enhancement. One of the major difficulties in the development of the SERS technique for analytical applications is the development of surfaces or media that have an easily controlled protrusion size and reproducible structure. In a preliminary work[7] we have shown that the SERS effect depends upon several factors, including excitation wavelength, sphere size, and silver coating thickness. Using 364-nm diameter sphere, and different excitation frequencies we measured the SERS signal intensity. In the present study, we further investigated this excitation-dependence effect for a variety of sphere size and silver coating thickness combinations. The 1240-cm^{-1} vibration of 1-nitropyrene was used as the reference signal. Different excitation frequencies from five argon-ion laser emission lines, three krypton-ion laser lines, and one helium–cadmium laser line were used. Comparative measurements of the Raman enhancement were made by varying the excitation wavelength for six sphere sizes from 38 nm to 482 nm. The results of the excitation wavelength study are given in Table 1. All Raman experimental factors must be taken into account in the selection of optical conditions. For our spectrometer/photomultiplier combination the sensitivity drops strongly with increase in wavelength. Maximum SERS signals are obtained with the 514.5-nm excitation. The relative standard deviation of our measurements is approximately 15%.

Another important experimental parameter that can affect SERS signals is the angle of incidence. Comparative measurements of the enhancement obtained with the silver-coated sphere substrates were made by varying the angle of incidence of the exciting radiation. A standard geometry with the excitation beam at right angles to the direction of detection was employed. Therefore, the angle of detection changed when the angle of incidence changed. Figure 2 shows a diagram of the geometry. Table 2 gives a summary of the data taken from five different sample runs. During each sample run, a series of SERS measurements was taken for each incident angle. The results in Table 2 show the relative variation of the SERS signal during each sample run. Note that signals from different samples used in different sample runs were not normalized and, therefore, are not directly comparable. Glass slides, covered with 176-nm diameter spheres which were coated with a layer of silver 48 nm thick, were used as the substrate. The experimental SERS intensities increased rapidly as the incident angle of exciting radiation increased from 10° to approximately 60°, then very little as the angle of incidence was further increased to 80°, and

finally decreased as the angle of incidence was changed from 80° to 85°.

In situ *SERS analysis*

The development of SERS-active substrates that allow direct measurements in liquid samples is essential for *in situ* analysis. SERS has been observed with use of different solid substrates such as metal electrodes, metal islands, films, glass or cellulose coated with silver-covered microspheres.[13] Most SERS studies with solid substrates have been performed in the dry state, so far, or with metal electrodes and colloidal solutions. In this work, we investigated the technique of measuring SERS in solution by using a glass plate covered with silver-coated latex microspheres as the substrate.

Benzo[*a*]pyrene (*r*-7,*t*-8,9,10-tetrahydrotetrol) (BPT) was used in this study. BPT is the product obtained by acid hydrolysis of benzo[*a*]pyrenediol epoxide (BPDE), *r*-7,*t*-8-dihydroxy-*t*-9,10-epoxy-7,8,9,10-tetrahydrobenzo[*a*]pyrene, a major carcinogenic metabolite involved in binding to DNA.[18] In previous works BPT samples were analyzed in the dry state by using the room temperature phosphorescence[19] and SERS[20] techniques. A 5-μl sample of the solution was spotted onto the substrate, allowed to dry, and then subjected to SERS analysis. In the present work, SERS analysis was performed *in situ* with the substrate in direct contact with the liquid sample.

Another difference in the solution SERS technique is the substrate geometry with respect to the incident laser beam. It was found that by focusing the laser beam onto the back of the substrate (the laser beam penetrates first the glass, then the microsphere substrate and the silver layer, and finally the scattering molecule) and by collecting the SERS signal also from the back side of the substrate, the solution SERS intensity was enhanced approximately twofold (Fig. 3). This geometry is unusual; normally SERS measurements in the dry state are done by focusing the laser beam onto the silver-coated side of the substrate. Similar observations have been reported by Jennings *et al.*[21] for copper and zinc phthalocyanine complexes adsorbed on silver island films. They attributed observation of the SERS signal from the back to the non-continuous nature of the silver film. Also, in excitation from the back, the observed scattering was mainly due to molecules forming the first monolayer of the phthalocyanine film. A similar process is most likely responsible for the increased SERS signal from adsorbed molecules observed when the back-excitation geometry is used in solution SERS. There is, however, a noteworthy difference between the substrate surface consisting of silver islands used in the previous work[21] and the one used here, which has a continuous 75-nm thick layer of silver. The detection of the SERS signal in the back-geometry configuration on the present work indicated that the Raman radiation could be transmitted through the silver layer. Similar results have been observed in our work on development of SERS-based biochemical sensors.[22]

An important feature of the solution SERS method is that we were able to obtain SERS spectra with a

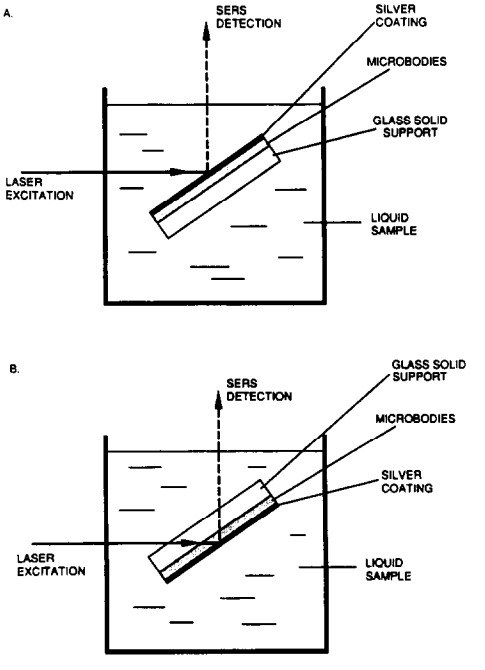

Fig. 3. Substrate for *in situ* analysis: (A) front surface SERS measurements; (B) back surface SERS measurements.

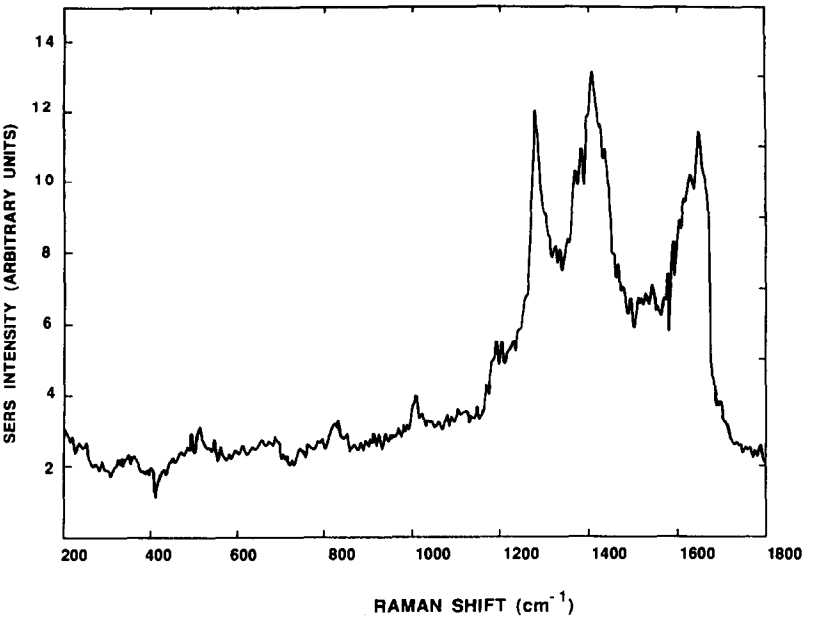

Fig. 4. *In situ* SERS spectrum of henzo[*a*]pyrene *r*-7,*t*-8,9,10-tetrahydrotetrol in solution.

very high signal-to-noise ratio with a portable, air-cooled argon-ion laser using a laser power of only 10 mW. This aspect is important because it would eliminate the need to use the powerful and expensive lasers that are normally used with Raman spectroscopy and demonstrate the feasibility of a portable SERS system.

Figure 4 shows the solution SERS spectrum of a 32 ppm BPT solution, obtained with the portable argon-ion laser and a glass-slide with silver-coated microspheres. The back-geometry arrangement was used. This spectrum is very similar to the SERS spectrum of BPT (dry sample) adsorbed on a silver-coated cellulose substrate.[20] It shows three major bands at 1256, 1384 and 1620 cm^{-1}. The peaks at 1384 and 1620 cm^{-1} are superimposed on broad bands (1300–1600 cm^{-1}) that might be related to the substrate. These broad bands were similar to those observed previously in Raman scattering on a silver surface in tunnelling structures[23] and on polycrystalline silver treated in potassium cyanide solutions.[24] They were attributed to Raman scattering from contaminated carbon.[23,25] The exact nature of this broad emission is under investigation. Weak bands at 1520, 1172, 990 and 815 cm^{-1} are also present in the solution SERS spectrum of BPT. In general, the bands and the spectral shape of the solution SERS spectrum of BPT are comparable to those of the spectrum of BPT adsorbed on a cellulose substrate. The limit of detection (LOD) of BPT with the maximum SERS peak at 1384 cm^{-1} was also calculated. Although the experimental parameters were not optimized, the limit of detection for BPT in solution was 0.73 ppm.

Fumed silica substrates for the SL spot-test

Fluorescence is often one of the most sensitive analytical tools which can complement Raman spectroscopy for the detection of organic substances such as the polyaromatic compounds. In this study, we investigated active solid substrates for the synchronous luminescence (SL) technique used as a rapid spot-test procedure to analyze organic samples spotted onto solid substrates. Benzo[*a*]pyrene (BaP) was selected as the model compound. This compound has great environmental and biological significance since it has been found in many industrial and residential environments and is known to be carcinogenic in animal laboratory bioassays.[18] There is, therefore, a great deal of interest in simple analytical techniques for BaP detection. As far as we know, this is the first time that the SL method has been applied to solid-surface measurements by use of a simple spot-test procedure. Most previous SL studies were performed with liquid solutions. Scattered light is an important factor in solid-surface measurements by SL, for several reasons. Cellulose substrates generally have highly reflective surfaces and can produce scattered light. Front surface illumination/detection geometry for solid-surface measurements produces higher levels of scattered light than do solution measurements, where a 90° geometry is generally used. All these problems are more pronounced in the SL technique, where the excitation and emission wavelengths are often very close. With background subtraction, the spectral overlap effect of scattered light can be decreased substantially, thus making the spectral features of the analytes more easily distinguishable.

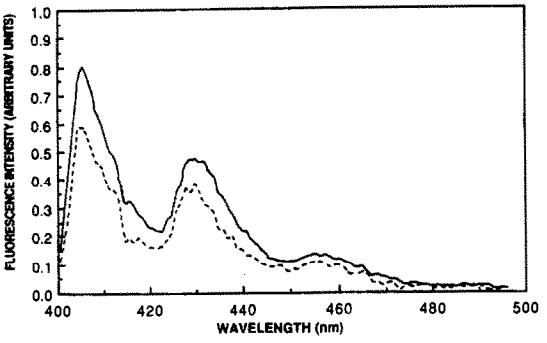

Fig. 5. Emission fluorescence spectra of benzo[*a*]pyrene: --- on filter paper; —— on paper treated with fumed silica.

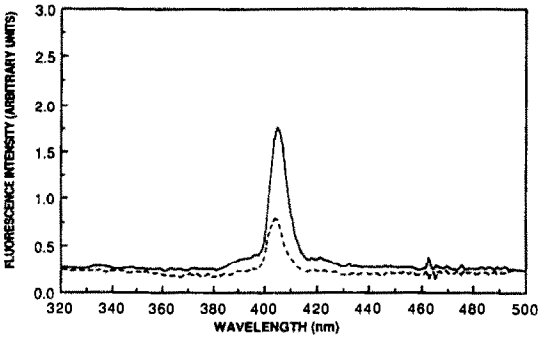

Fig. 7. Synchronous fluorescence spectra of benzo[*a*]pyrene: --- on filter paper; —— on paper treated with fumed silica.

Another important feature of this work is the treatment of the cellulose substrate with fumed silica to induce enhanced fluorescence signals. Figures 5 and 6 show the excitation and emission spectra of BaP adsorbed on filter paper treated with fumed silica. For comparison, spectra obtained with BaP on paper substrates without fumed silica are also shown. The samples consisted of 2.5 μl of a $10^{-4}M$ solution of BaP in ethanol. Background subtraction was performed to obtain the spectra. The emission (excitation) spectra were obtained with excitation (emission) at 372 nm (408 nm). Figure 7 depicts the corresponding synchronous fluorescence spectrum of BaP. The results indicate that the intensity of the synchronous fluorescence is about three times that obtained with the paper treated with fumed silica.

Fumed silica materials have a sub-μm particle size; particles with diameters varying from 0.007 to 0.027 μm have been investigated. Although further investigations are required, the fluorescence enhancement effect of the fumed silica treatment might have several causes. The effect of fumed silica is not a "sensitized luminescence" effect. Sensitized luminescence refers generally to the photophysical process by which the excitation energy absorbed by a donor molecule is transferred to an acceptor molecule, the luminescence of which is detected.[26] The fluorescence enhancement might be due to an improved adsorption of BaP into the surface treated with fumed silica. Fumed silica may help to retain more BaP molecules on the surface. The microstructure of fumed silica particles might also induce surface-enhanced mechanisms in the fluorescence emission. Investigations are currently under way to study the nature and extent of this enhancement mechanism.

The results of this study demonstrate that the use of fumed silica as a fluorescence-enhancing agent is attractive for several reasons. Fumed silica is an inexpensive material which is easy to handle. It is inert, and exhibits no interfering fluorescence emission. The procedure is simple, rapid, and cost-effective, and therefore suitable for routine analyses.

CONCLUSION

Raman and luminescence spectroscopy are spectrochemical techniques that have a number of important advantages for chemical analysis. The examples shown in this work illustrate the different uses of the two techniques for the detection of important biological compounds such as nitropyrene, benzo[*a*]pyrene and related products. These compounds are polycyclic aromatic molecules, which are generally strongly fluorescent and can be easily detected by luminescence. At room temperature, a simple spot-test method can be used to screen these compounds in the environment. Room-temperature phosphorescence (RTP) can also be used, but discussion of recent developments in RTP is beyond the scope of this work. Luminescence spectra exhibit reasonably well-resolved emission bands, but their spectral selectivity is limited at room temperature. At room temperature, Raman spectroscopy can provide an analytical tool having analytical figures of merit that complement those of luminescence. The Raman technique is well known for its high selectivity. The SERS technique, which can amplify the Raman signal by several orders of magnitude, will therefore provide a technique with the added merit of improved sensitivity due to the surface-enhanced effect.

(*Received* 6 *May* 1988. *Accepted* 29 *August* 1988)

Summary—Electrodeless conductivity is a technique for measuring the concentration of electrolytes in solution and utilizes a probe consisting of two toroids in close proximity, both of which are immersed in the solution. In special cases, the toroids may be mounted externally on insulated pipes carrying the solution. One toroid radiates an alternating electric field in the audiofrequency range and the other acts as a receiver to pick up the small current induced by the ions moving in a conducting loop of solution. Coatings which would foul contacting electrodes, such as suspensions, precipitates or oil, have little or no effect. Applications are chiefly to continuous measurement in the chemical processing industries, including pulp and paper, mining and heavy chemical production. The principles and practical details of the method are reviewed and cell-diameter, wall, and temperature effects are discussed.

Measurement of the electrical conductivity of a solution is useful in both physical and analytical chemical studies. It is used for determining the degree of dissociation and the ionization constants of weak electrolytes, the study of precipitation and complex formation reactions, the determination of solubility products and formation constants, and for reaction-rate studies. Analytical applications include direct quantitative analysis of strong and weak acids and bases, salt solutions, and aqueous and non-aqueous conductometric titrations. Industrial applications include continuous monitoring of oceanographic salinity, aluminum and pulp industry processing liquors, pickling, plating, anodizing and degreasing baths, and chromatographic eluates.[1,2]

The classical technique measures the electrical resistance (or its reciprocal, the conductance) between two inert conducting electrodes in contact with the solution. Alternating current is usually employed to minimize electrolytic reactions and polarization at the electrode/solution interface. The frequency of the applied voltage is chosen to minimize the effects of the impedance of the electrode/solution interface and various other capacitances. Physical chemical studies of conductivity and its theory and practice are discussed in standard reference works.[1-3] Conductivity measurements are routinely accurate within a few tenths of 1%, and are reliable and continuous. However, difficulties often arise because of contact of the electrodes with the solution. In addition to the more subtle problems of capacitance and polarization errors, coatings may increase the impedance of the interface, changing both the capacitive and conductive components. The significance of this effect depends on the magnitude of the conductivity being measured and the nature of the coating. Insulating or diffusion-hindering layers may be formed by oils, metal precipitates, waste streams, and body fluids. Coating is especially prevalent in alkaline solutions where anions such as phosphate, carbonate, hydroxide, and sulfate form precipitates with heavy-metal ions, in suspensions such as latex, and in the liquors of the pulp, paper and aluminum processing industries.

Conductance measurements may also be made without electrodes in contact with the solution. There are two frequency domains in which this occurs. The first is a high-frequency method in the MHz region. The electrodes take the form of a pair of metal sheets or bands on the outside of the sample cell, which is made of an insulating material such as glass. Alternatively, the glass-encased sample may be placed inside an induction coil which is part of the detection circuit. In the first case the glass plays the part of the dielectric in a capacitor in series with the impedance of the sample. The frequency of the applied voltage is high enough to make the impedance of the capacitor relatively low in comparison with that of the sample. Even so, the measured impedance is a complex function of the dielectric constant and thickness of the glass, the conductivity and dielectric constant of the sample, and the frequency of operation.

High-frequency conductometry, also called oscillometry, has been treated extensively by Blake,[4] Sherrill *et al.*[5] and Pungor,[6] and is now seldom used. The most recent paper known to us concerned the electronic design of a high-frequency oscillometer and appeared in 1981.[7] The use of noncontacting electrodes when electrode coatings would have a significant effect on the cell constant, was the subject of a paper by Pungor *et al.*[8] This approach has not become popular though it has been developed for determining the end-point of a titration and for determining dielectric constants. Oscillometry will not be discussed further in this paper.

†Please address requests for further information to this author.

A second method of measuring conductance without the use of contacting electrodes has become popular, especially in the chemical process industries. Usually referred to simply as "electrodeless conductivity", it has also been called "inductive" or "magnetic" conductivity. This method is the subject of this paper and is described below.

Electrodeless conductivity was initiated by Relis, who discussed it in a thesis in 1947.[9] Subsequent improvements were made by Fielden,[10] who described a method for mounting the toroids on a nonconducting pipe external to the electrolyte solution, by Gross,[11] who improved the coupling and efficiency of the toroid cores, and by Koski, who designed a high-temperature probe.[12] Although instruments for electrodeless conductivity measurement have been commercially available since the 1950s for process industry applications, there is relatively little literature on the subject. A historical perspective and literature review to 1988 has been given by Light.[13] The present paper will discuss some of the principles and technical details of the method.

The electrodeless conductivity measuring system utilizes a probe consisting of two encapsulated toroids in close proximity to each other, as shown in Fig. 1. One toroid radiates an electric field in the solution, while the other acts as a receiver to pick up the small alternating current induced in the electrolytic solution, as illustrated in Fig. 1. The equivalent electrical circuit (Fig. 2) is two transformers connected by a resistance which corresponds to the loop of conducting solution which couples the two toroids.

Several configurations for the sensing cells are possible. Cells designed for immersion and available in several sizes are shown in Fig. 3. The toroids are covered with a chemically resistant fluorocarbon or other high-temperature resistant nonconducting material. Any precipitates or coatings adhering to this probe have little or no effect on the measured conductance as long as they do not displace a significant fraction of the solution.

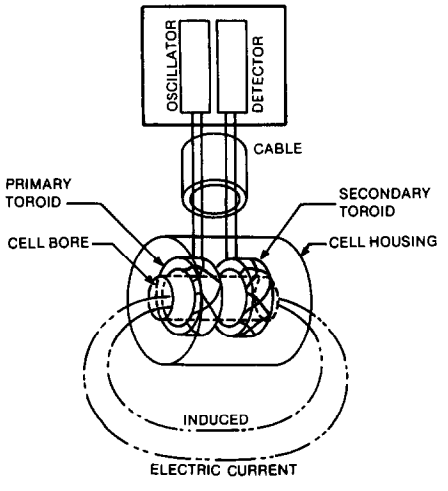

Fig. 1. Principle of the electrodeless conductivity cell and instrument.

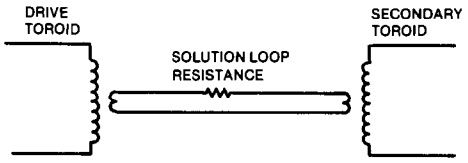

Fig. 2. Equivalent electrical circuit for electrodeless conductivity cell.

The radiating toroid is energized from a stable audiofrequency source, typically 20 kHz. The pick-up toroid is connected to a receiver which controls the current through the secondary winding so as to hold the total flux in the pick-up toroid at zero. This current, which is proportional to the solution conductivity, is then amplified, converted into direct current and displayed on a meter or an analog strip-chart recorder. It may also be used to control a reagent valve or an alarm or to signal a computer. The output is a direct function of the conductance of the solution in the loop, as in traditional measurement with contacting electrodes.

The full scale range of commercially available instruments extends from 0–100 μS/cm to 0–2 S/cm, with a relative error of a few tenths of 1% of full-scale. (The siemens, S, is the SI unit for conductance and is identical with the "mho" or reciprocal ohm.) Conductance is temperature-dependent and a temperature sensor with a compensation circuit which corrects all readings to the standard reference temperature of 25° is incorporated in the toroid probe. Many salts have conductivity temperature coefficients of about 2% per degree. The temperature coefficients are nonlinear and in some cases may vary from 2 to 7% per degree over a 100° range.[14] Microprocessor-based electrodeless conductivity instruments may provide compensation for this lack of linearity.[15]

The electrodeless conductivity technique using low-frequency inductive cells is available for analysis and control in the chemical process industries and in other continuous monitoring applications. Although it is more stable and accurate than the contacting electrode conductivity techniques, and needs no maintenance, the lack of bench models of this type has hindered its laboratory use and application to date.

Two of the reasons why electrodeless conductivity is not favored as a laboratory tool are the size of the probes and the sample size requirement. The smallest electrodeless probe is about 3.8 cm in diameter and has an equivalent cell constant of 2.5 cm^{-1}. It requires a minimum solution volume of several hundred ml to ensure that there is a complete loop in the solution, without any wall effects to distort the apparent cell constant. For a large probe of 8.9 cm diameter, the cell constant is 0.45 cm^{-1} and a solution volume of several liters may be needed, as discussed

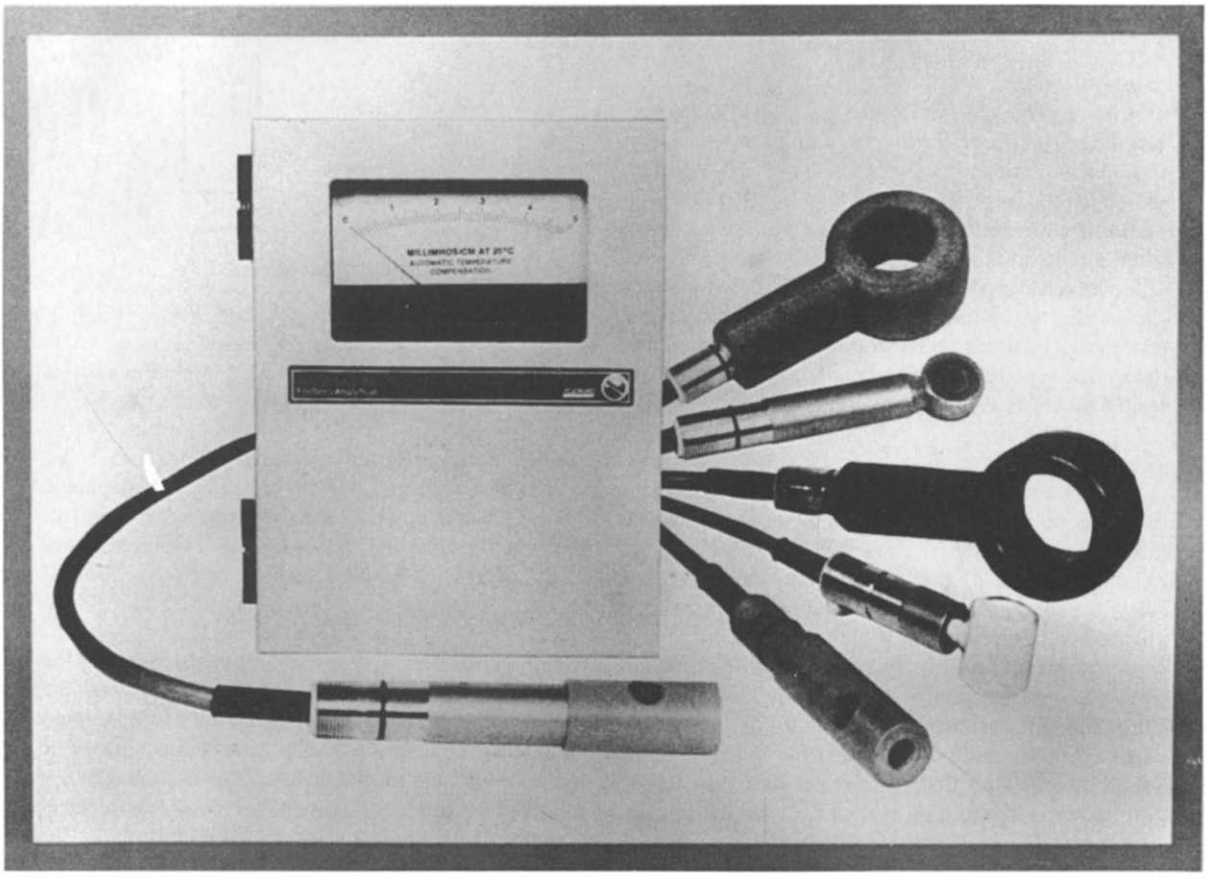

Fig. 3. Various types of immersion cells for electrodeless conductivity with an associated instrument (courtesy of The Foxboro Company).

below. For the lower conductance ranges, which require a smaller cell constant, the diameter of the probe and the measuring container must be increased. Accurate measurement of conductivity below approximately 10 μS/cm is not practical.

The experiments and applications described here were carried out with electrodeless conductivity sensors and instrumentation produced by The Foxboro Company and made especially for continuous on-line measurements in the process industries. Although this equipment is not designed for laboratory scale work, some "beaker" experiments may readily be performed. The instrument output is in the form of the signals usually desired for process and control instrumentation, such as elevated zero, 4–20 mA current or 0–10 V d.c. Reproducibility is 0.1% of full scale and suppressed zero ranges are available to increase the sensitivity to low-level conductivity changes in the presence of higher conductivity backgrounds. The electrodeless conductivity method is useful over most of the conductivity spectrum, although it is not considered applicable to low-conductivity liquids such as distilled or demineralized water.

Figure 3 shows an electrodeless conductivity instrument with several immersion sensors ranging in diameter from 3.8 to 8.9 cm. Various construction materials are used to cope with harsh process conditions such as an alkaline environment at up to 190° and 1.75 MPa (250 psig). The monitoring instrument may be line operated, or coupled to a two-wire transmitter which sends the power to the instrument over the same lines through which the sensing signal is returned. A microprocessor-controlled instrument has been described by Queeney and Downey.[15] It provides temperature compensation, conductivity- and temperature-curve characterization and calibration, flexible ranging, output expansion, damping, and suppression.

The cell constant, also called the cell factor, for conventional contacting conductivity electrodes is theoretically determined by the ratio of the distance, d (cm), separating the conductivity faces, to the area, A (cm^2), of the electrodes. The ratio, T, is referred to as the cell constant, with units of reciprocal length (cm^{-1}).

The corresponding cell constant for electrodeless conductivity sensors may also be determined. This cell constant is effectively governed by the ratio of the current path-length to the cross-sectional area of the hole in a doughnut-like toroid. However, end-effects and the geometrically complex current-distribution outside the toroid present difficulties in the accurate computation of the constants for toroidal cells. In

practice the electrodeless conductivity cell constant, T, may be determined by several methods which are discussed below.

A method of determining cell constants that closely reproduces the conditions of actual measurement requires immersion in solutions with known conductivities and temperature coefficients. It is best to disconnect the temperature sensor and substitute a standard resistor equivalent to a temperature of 25°. The cell constant, T, is determined by immersing the cells in standard solutions with known conductivity values and computing the ratio of the theoretical conductivity, σ (S/cm), to the observed conductance, C (S):

$$T\ (\text{cm}^{-1}) = \sigma/C \qquad (1)$$

The conductivities of solutions of potassium chloride over moderate concentration and temperature ranges[16] are given in Table 1. There is a scarcity of reliable data for the high conductivity ranges. However, for higher conductivities and temperatures, excellent data are available for sulfuric acid.[17] For process applications, it may be possible to first determine the conductivity of the process solution with contacting conductivity instrumentation.

A method for calibrating a cell of known geometry (and its associated transmitter) without the use of solutions involves looping a wire through the toroids as shown in Fig. 4. The ends of the wire are connected

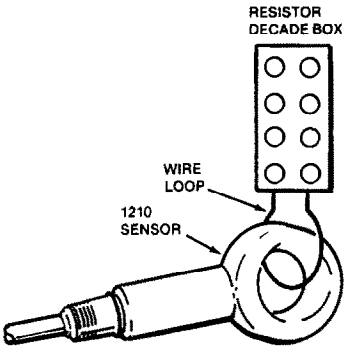

Fig. 4. Single-loop calibration circuit for measurement of cell constant (Foxboro MI 611-117, p. 24, Fig. 28).

to a standard (±0.1%) resistance box or resistor, set to R ohms, corresponding to the full-scale instrument reading, M, in conductance units (S/cm). For the designated probe and its associated transmitter, this relationship is given by:

$$T\ (\text{cm}^{-1}) = [M\ (\text{S/cm})][R\ (\Omega)] \qquad (2)$$

For calibration, the meter is adjusted until the value of T in equation (2) agrees with the known value. This method allows removal of differences caused by changes in the coil windings, magnetic material or transmitter sensitivity. Nominal wire-loop cell constants, T (cm^{-1}), for two sizes of electrodeless conductivity cells are shown in Table 2. For

Cell type	Solution measurement*	Wire loop measurement†	Equation§
Small probe (3.8 cm diameter) $a = 0.792$ cm $c = 4.20$ cm	2.49	2.45	2.76
Large probe (8.9 cm diameter) $a = 2.47$ cm $c = 5.32$ cm	0.44	0.45	0.48

*Standard KCl solutions, see text.
†Standard resistance box, see text.
§Equation (6), see text. Because the experiments are done in a large bath, $d \to \infty$, so b is inconsequential in equation (6).

Table 3. Electrodeless conductivity cell constants as a function of container size

Cell type	250 ml	600 ml	1000 ml	4000 ml	8000 ml	Wire loop
Small probe (3.8 cm diam.)	2.69	2.61	2.50	2.49	2.48	2.45
Large probe (8.9 cm diam.)	*	*	*	0.456	0.444	0.45

*Probe diameter is larger than container diameter.

equation (2) to be accurate the probe must be thermostatically kept at 25°C, because it contains a temperature-correction sensor. To eliminate the need for correction to a standard temperature, the temperature-sensor portion of the circuit may be disconnected and replaced with a standard resistor equivalent to a temperature of 25°C.

This method may have a large experimental error if a small resistance is required and the wire connecting leads contribute a significant portion of the total resistance. For example, referring to Table 2, if the instrument to be calibrated uses the Foxboro type EV probe and if full scale is 500 mS/cm, then a 4.90 ohm resistor would be needed if the theoretical cell factor is 2.45 cm^{-1}. Even if the resistance of the wire leads were as low as 0.1 ohm, it could then contribute significantly to the circuit resistance. However, if a coil of n turns is looped around the sensor coil, the resistance required increases by n^2, and the equation for the wire-loop cell constant calibration becomes

$$T = MR/n^2 \tag{3}$$

Then for the same 500 mS/cm instrument reading, but with 5 turns in the coil, the resistance box would be set to 122.5 ohm instead of 4.90 ohm, and 0.1 ohm resistance in the wire leads would be negligible. The wire-loop calibration method is valid for a given sensor and transmitter.

The current which flows from the radiating toroid to the receiving toroid, as illustrated in Fig. 1, is influenced by the geometry of the toroids relative to the sample solution. In the extreme case, if the ends were sealed and the solution were trapped in the interior of the doughnut-like cell, then no current would reach the receiving toroid, and no conductance would be measured. If the current is partially obstructed by the wall of a container, a lower conductance than expected would be measured, and the cell constant would become larger, as seen from equation (4). As a general rule, if the wall of the container is distant by at least the diameter of the sensing probe, then this geometry effect, which is also known as the wall effect, is not significant. Table 3 shows the magnitude of this effect for small and large probes, of diameter 3.8 and 8.9 cm respectively. The wire-loop cell constant, which is independent of the use of solutions, is taken as the reference cell constant, and Table 3 indicates that geometry effects may cause as much as 10% difference in the cell constant. However, if the geometry remains fixed, as might be the case if the sensing probe were permanently placed in a pipeline only slightly larger in diameter than the probe, the modified cell constant would be accurate for that installation.

Calculation of cell constants is complicated by the geometry involved. A simplified two-dimensional (axisymmetric) geometry is shown in Fig. 5. Analysis of this geometry essentially ignores the effect of the "stem" connecting the toroid to the outside. Even with this idealization, simple analytical solutions are, to our knowledge, possible in only a few cases.

The symmetry of the problem demands that at $z = 0$ all the electric field is directed in the z direction. The problem of finding the cell constant is then equivalent to finding the current that flows through a solution of unit conductivity ($\sigma = 1$ S/cm) from the positive terminal to the negative terminal of the imaginary battery shown in Fig. 6. Two limiting cases have simple solutions. The first is that of a long cylinder ($a/c \ll 1$). As this limit is approached, the bulk of the resistance is within the cylinder, the field lines are in essence all in the z direction and are uniform, and the cell constant is given by:

$$\lim_{a/c \to 0} (T) = c/\pi a^2 \tag{4}$$

The other limit which has a simple analytical solution is that of a "pancake" cell ($a/c \gg 1$, $b/a \gg 1$). The method of solution is described by Carslaw and Jaeger.[18] The cell constant in this case is

$$\lim_{a/c \to \infty} (T) = 1/2a \tag{5}$$

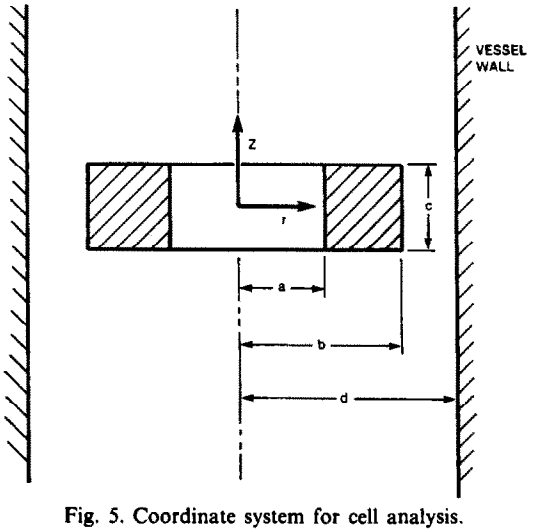

Fig. 5. Coordinate system for cell analysis.

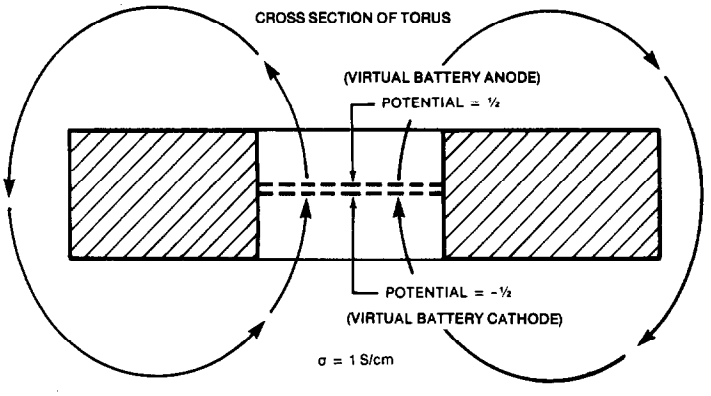

Fig. 6. Potential method for cell analysis. A very thin disc is pictured, centered in the toroid, with the upper surface of the disc at a potential of +1/2 and the lower surface of the disc at a potential of −1/2. The total current flowing from the anode to the cathode (through a solution with conductivity 1 S/cm) in this imaginary battery is numerically equal to the cell constant.

For cases other than these two a rough approximation to the cell constant can be obtained by noting that the two resistances in the limiting cases are in effect in series. This is not an exact solution by any means, because in fact the end effects are more complicated. In addition the effect of proximity of walls to the cell adds another resistance in series with these two resistances. Adding all three effects gives the expression:

$$T = \frac{c}{\pi a^2} + \frac{1}{2a} + \frac{c}{\pi(d^2 - b^2)} \qquad (6)$$

Actual electrodeless conductivity cells do not conform physically to an ideal geometrical configuration. Nevertheless, the equation above furnishes some insight into the effect of the cell dimensions and the surrounding walls. Table 2 shows that for two probes approximately 3.8 and 8.9 cm in diameter, with corresponding "a" and "c" dimensions, the constants given by the equation agree with the experimental values within 6–12%.

More accurate solutions which take into account the actual geometry as well as providing a much more accurate solution to the field problem can be found by numerical techniques. In particular the finite element method[19] is well suited to this problem.

Table 2 presents a comparison of the three methods for obtaining electrodeless conductivity cell constants. Differences of several per cent are generally obtained between the values from these methods and it should be noted that any given result is valid only for a particular instrument and sensor combination. The wire-loop cell constant method is the most fundamental and reproducible of these methods and is adopted as the reference method. It is dependent primarily on the construction and interaction of the radiating and sensing toroids. The quantity of solution interacting with the toroids, as well as the wall proximity of the container in which they are immersed, is reflected in the solution cell constant, which then becomes a more realistic cell constant but is more difficult to reproduce. The calculated cell constant, being based on idealized geometry, serves as a useful guide to geometric variations.

The temperature coefficient of solution conductivity is relatively large. For the hydrogen ion, the change in conductivity is approximately 1.5% per degree; for the hydroxide ion it is 1.8%/degree and for other ions from 2.0 to 2.6%/degree and is dependent on the nature and concentration of the solution. For pure water, the temperature coefficient may be as large as 7%/degree, and is derived and discussed by Light and Sawyer.[20] The temperature coefficient is nonlinear and in order to make conductances observed at any particular temperature useful in terms of concentration, the data may be reduced instrumentally to a reference temperature, which is frequently 25°.

Though the electrodeless technique is somewhat more cumbersome than the conventional technique it is the method of choice in continuous process control because of its relative insensitivity to fouling, particularly in high-conductivity solutions which are corrosive or fouling. Conventional techniques often fail in these situations. It yields equivalent information with greater long-term reliability and less maintenance. The earliest application of the electrodeless conductivity method was the measurement of ocean salinity.[9] More recent uses have included the determination of the equivalent conductance of salts, the monitoring of acid concentrations in radioactive waste, and the measurement of chemical processes in the mining, metallurgy, pulp and paper, aluminum processing and other chemical industries. These applications have been reviewed.[13]

Attempts to extend practical measurement to solutions of low conductivity, less than 10 μS/cm, and to further reduce the cell size are current areas of research. The problems involve decreased sensitivity, noise, susceptibility to interfering effects such as stray coupling between toroids, and effects due to the dielectric constant of the solution.

THE EFFECT OF ON-COLUMN STRUCTURAL CHANGES OF PROTEINS ON THEIR HPLC BEHAVIOR

BARRY L. KARGER* and RIGOBERTO BLANCO
Barnett Institute and Department of Chemistry, Northeastern University, Boston, MA 02115, U.S.A.

(*Received* 24 *May* 1988. *Accepted* 9 *September* 1988)

Summary—Whenever proteins are found in environments different from those provided by physiological conditions, structural alterations can occur which can dramatically affect their adsorption and chromatographic behavior. The resultant behavior is often kinetically controlled and thus dependent on such factors as contact time of the protein with the adsorbent surface. Examples are given of the appearance of multiple peaks from seemingly pure species, as a result of these structural changes. In one case (papain in reversed-phase LC), multiple peaks are shown to arise from different conformational states. In a second case (β-lactoglobulin A in hydrophobic interaction chromatography), a series of three peaks is a result of self-association or aggregation. Finally, recent work on an examination of structural changes of proteins on chromatographic supports, by means of intrinsic fluorescence and HPLC, is presented. The value of these studies for the elucidation of the retention mechanism in HPLC and the assessment of purity of proteins is demonstrated.

Recent advances in biotechnology have created increasing demands on separation scientists for the analysis and purification of genetically engineered products.[1,2] In conventional synthesis of pharmaceutical materials, relatively simple molecules often occur in a medium of limited complexity. Though chiral separations can at times be challenging, well established tools are generally available for analysis and purification. However, this is not yet true for recombinant materials.

For peptides/proteins produced by gene technology, many separation/analysis challenges exist with respect to the molecules themselves. Some of the aspects of protein structure that need to be identified include subtle differences in amino-acid substitution, dimerization, de-amidation, proteolytic clips, oxidation, glycosylation and folding.[3] Some of the trace impurities found along with these altered structures may be immunogenic, and, therefore, the proper characterization of recombinant materials is a significant issue in the biotechnology field. A new discipline, analytical biotechnology, has developed in recognition of these challenges.[4]

High-performance liquid chromatography (HPLC) is an important method for analysis and purification in biotechnology. The resolution of species that differ in a subtle manner requires an understanding of the retention process and the factors that control elution. In addition, it is possible for elution of a seemingly pure protein to yield several chromatographic peaks or a highly broadened and asymmetric peak.[5] It is essential to understand why this behavior occurs, to recognize it, and to devise conditions for its elimination, if successful substance characterization is to result.

*Author for correspondence.

For simple organic molecules, chromatographic retention models have generally assumed that the species does not undergo structural changes (*e.g.*, isomerization) during the adsorption and desorption processes. The study of the HPLC of such molecules has generally confirmed this assumption, with notable exceptions.[6] However, proteins are living polymers, and it is well-known that structural changes (*e.g.*, conformational changes) can occur whenever the environment of the species differs from that provided by physiological conditions.[7,8] Conformational changes in this context mean alteration in the three-dimensional structure of the protein. It is these changes (as well as chemical reactions), kinetically controlled, which can produce chromatographic "artifacts".

Adsorption-induced conformational changes in proteins have been documented in the literature.[9] Moreover, conformational changes have been widely used as a means to achieve elution in chromatography. For example, for elution of glycogen phosphorylase B from a hydrophobic matrix, a deforming buffer, imidazole citrate, was used.[10] The buffer was assumed to alter the protein structure slightly to weaken its hydrophobic interaction with the adsorbent surface, and thus cause elution. In another example, α-lactalbumin was adsorbed on a hydrophobic matrix with an EDTA solution.[11] Upon addition of calcium ions to the mobile phase, elution of the protein occurred. In this case, α-lactalbumin, a calcium-binding protein, underwent a conformational change to a less hydrophobic form with addition of the metal, resulting in solute desorption.

We can expect that these structural changes will be important in hydrophobic interaction chromatography, where a partial dehydration takes place with close contact of the hydrophobic patches of the

biopolymer with the absorbent surface.[12] It has also been suggested that in reversed-phase chromatography of proteins, elution is a consequence of a structural alteration on the surface, caused by the mobile phase gradient.[13] Such changes also occur on elution in affinity chromatography[14] and have been observed in ion-exchange chromatography.[15]

It should be emphasized that these conformational alterations need not cause loss in biological activity. Indeed, it is well known that enzymes often maintain their biological activity when adsorbed on hydrophobic surfaces.[16] However, whether subtle or extensive, these changes can yield a different interaction of the species with the stationary phase, thus affecting adsorption and chromatographic behavior. It is therefore necessary to study the structure of the protein in contact with the surface in order to understand the retention process.

Our laboratory[5,17,18] and various others,[19-21] have been active in examining conformational changes in reversed-phase and hydrophobic interaction chromatography. In this paper we shall survey several of the significant aspects of this work and discuss future directions.

PAPAIN–SURFACE CONFORMATIONAL CHANGES

The study of protein adsorption in static systems has revealed the possibility of a variety of energetic states of different binding strengths for proteins in contact with adsorbents.[22] Experimental evidence of this behavior has recently been reviewed;[23] however, the authors hoped that further studies would demonstrate definite evidence for multiple states on adsorbent surfaces.

HPLC has already provided direct evidence for the existence of multiple states of proteins on adsorbent surfaces. Figure 1 shows a series of chromatograms of papain, a proteolytic enzyme, in reversed-phase LC at 5°.[17] In Fig. 1a, a standard elution gradient was used, with injection occurring simultaneously with the start of the gradient. (There is, of course, a delay before the gradient reaches the head of the column, which in this example was 4 min.) Two peaks of roughly equal area were observed. Separate studies (SDS-gel electrophoresis and re-injection) revealed that the two peaks arise from the same species, the first peak being enzymatically active and the second inactive. Since active purified papain was injected, it can be concluded that the two peaks result from the irreversible denaturation of some of the papain in acid media on the reversed-phase packing. Interestingly, papain is known to unfold irreversibly in solution at low pH.[24] Separate solution studies revealed that at 5° in mobile phase A (pH 2.2) papain was denatured very slowly. Hence, the adsorbent can be viewed as a catalyst for conformational unfolding of papain.

The other chromatograms in Fig. 1 demonstrate further details of the surface denaturation process. In

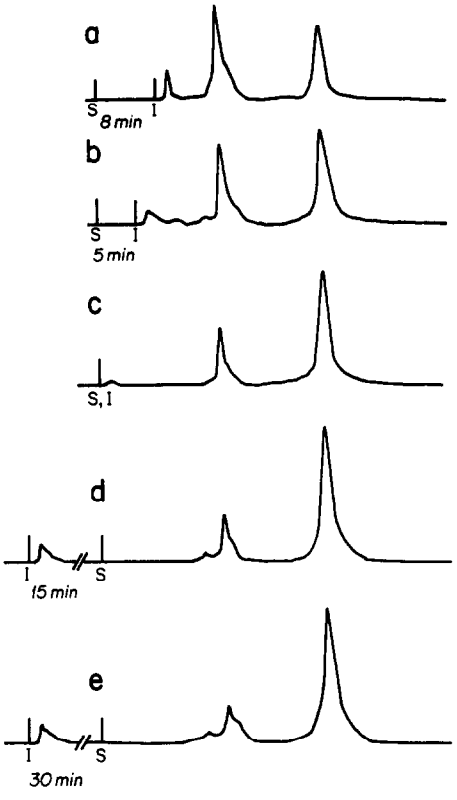

Fig. 1. Chromatographic behavior of papain as a function of incubation time on the adsorbent surface: column, C4 bonded phase on 10-μm Lichrospher SI 500; mobile phase A, 10mM H_3PO_4, pH 2.2; mobile phase B, H_2O/1-propanol, 55/45 v/v, 10mM H_3PO_4; temperature: 5°C. I: injection time; S: start of the gradient. Reproduced from S. A. Cohen, K. P. Benedek, S. Dong, Y. Tapuki and B. L. Karger, *Anal. Chem.*, 1984, **56**, 217, by permission. Copyright 1984, American Chemical Society.

Figs. 1b–1e, the protein was injected into the column and incubated on the surface (*i.e.*, an isocratic noneluting eluent was used) for specific periods of time. Subsequently, the protein was eluted from the column by means of the gradient. It can be seen that the longer the incubation time, the greater the area of the denatured second peak, at the expense of the first peak. The first-order rate constant for unfolding on the surface was measured to be 8×10^{-4} sec^{-1}, with a half-life of roughly 15 min. These results provide direct and quantitative evidence of a protein existing in two different conformational states on the adsorbent surface. Moreover, Fig. 1 illustrates one mechanism by which a pure species can appear to be impure in HPLC.

It is straightforward to compare rates of unfolding under various conditions. For example, variation in column temperature yielded an activation energy of ~20 kcal/mole. Increasing the mobile phase pH from 2.2 to 3.1 slowed the rate of unfolding. Finally, addition of small amounts of the organic modifier, 1-propanol, in the incubation solvent, did not significantly alter the rate of unfolding.[17] However,

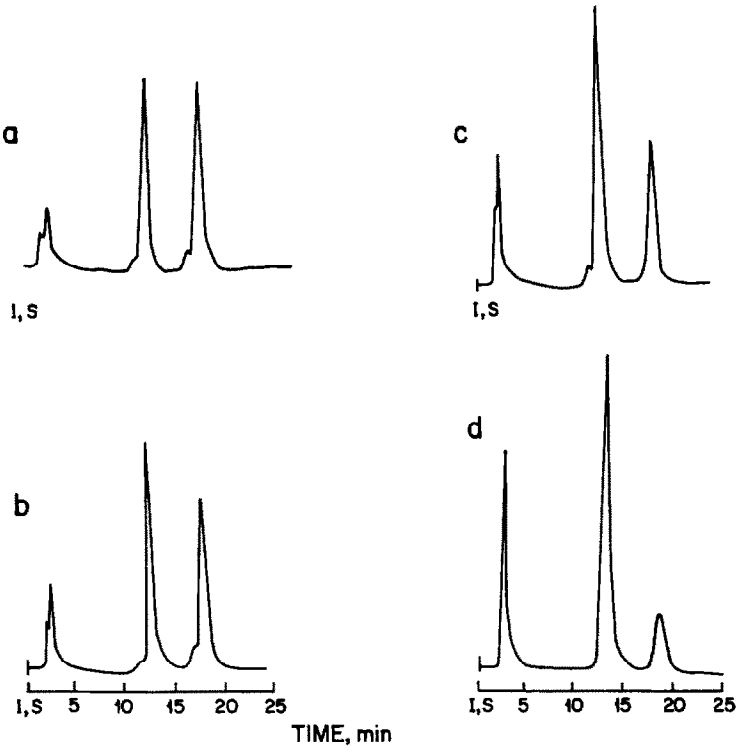

Fig. 2. Chromatographic behavior of papain as a function of the l-propanol concentration in mobile phase A with constant surface contact time. a = 0% propanol; b = 1.8% l-propanol; c = 3.6% l-propanol; d = 5.4% l-propanol. Other conditions: see Fig. 1. Reproduced from K. P. Benedek, S. Dong and B. L. Karger, *J. Chromatog.*, 1986, **317**, 227, by permission. Copyright 1986, Elsevier Science Publishers.

for a fixed period of contact of papain with the adsorbent surface, increases in the 1-propanol content increased the amount of native protein relative to the denatured species, see Fig. 2.

There are several significant points concerning the results in Fig. 2. First, the behavior suggests biphasic kinetics in which there is a rapid denaturation step followed by a slower unfolding step. It is interesting to note that other workers in examining phosphorylase B on a hydrophobic adsorbent also observed biphasic kinetics for a static system.[25] The addition of 1-propanol to the mobile phase caused the stationary phase to become less hydrophobic, as a result of adsorption of the alcohol on the bonded n-alkyl chains, creating a less hydrophobic surface.[17] It was presumed that the adsorbed 1-propanol slowed the rapid unfolding step. Relative to the hydrophobically "dense" n-alkyl reversed-phase surface, more hydrophilic phases would appear less denaturing, *i.e.*, surfaces typically used in hydrophobic interaction chromatography.[26]

The results in Figs. 1 and 2 also suggest some very practical points for the HPLC separation and purification of biopolymers. The initial adsorption step, when the protein first contacts the surface, would appear to be critical. Thus, control of injection conditions, *e.g.*, sample concentration and solvent, is essential. Moreover, it may be possible to minimize protein unfolding by limiting the amount of time the species remains on the chromatographic surface. In this regard, HPLC which has the characteristic of high-speed separation, would appear to be advantageous since contact of the protein with the surface is short. Consideration also needs to be given to control of column conditions, *e.g.*, temperature or mobile-phase composition, in order to stabilize the native state. Understanding the processes of surface change is clearly essential for successful chromatographic operation.

β-LACTOGLOBULIN A—SELF-AGGREGATION

The work with papain has shown that the conditions under which the protein first contacts the chromatographic system play an important role in determining chromatographic behavior in protein HPLC. A further example of this can be seen in the self-association of β-lactoglobulin A under high anti-chaotropic salt conditions. This protein normally occurs as a dimer under physiological conditions; however, in acid media of pH 4.5, it is known that the dimeric form can yield higher order aggregates, partly as a consequence of protonation of carboxylic groups, followed by hydrogen-bond self-association.[27]

Figure 3 shows the effect of injecting purified β-lactoglobulin A, (dissolved at pH 6, where only dimer forms) into a mobile phase of 3*M* ammonium

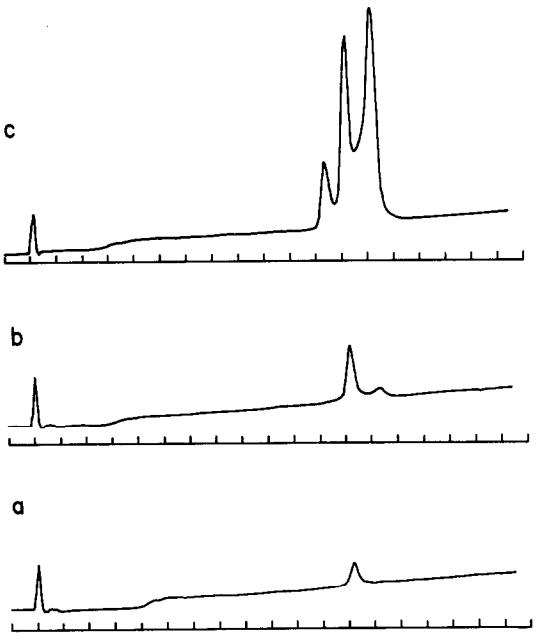

Fig. 3. HIC chromatographic behavior of β-lactoglobulin A as a function of injection protein concentration. Column: CAA—Beckman, HIC; mobile phase A: 3*M* $(NH_4)_2SO_4$, buffer 20m*M* ALPHIL, pH 4.5; mobile phase B: buffer 20m*M* ALPHIL, pH 4.5; 20-min gradient: flow-rate, 1 ml/min; temperature: 4°C. ALPHIL: 20m*M* 4-(2-hydroxyethyl)-l-piperazine ethanesulfonic acid, 20m*M* 2-(*N*-morpholino)ethanesulfonic acid, and 20m*M* acetic acid. (a) 0.5 mg/ml protein. (b) 1.0 mg/ml protein. (c) 20 mg/ml protein.

sulfate in 0.02*M* ALPHIL-buffer at pH 4.5. It can be seen that at low analyte concentrations a single peak occurs, which at higher concentrations is followed by a second, later-eluting, peak and at the highest concentrations injected is preceded by a third peak. Variation in the amount injected and use of a mass-balance equation revealed that the middle peak was for a tetramer, the last peak for an octamer, and the first peak for a dodecamer.[28]

The chromatogram in Fig. 3 represents an example of discrete aggregation, in which specific aggregates or self-associates occur under given solute concentration conditions. Once formed, the aggregated species do not dissociate, at least during passage through the chromatographic column. The model that emerges from this work is that when the dimeric form (at pH 6) comes into contact with the mobile phase of pH 4.5, a diffusion-controlled reaction occurs, leading to aggregation. With such rapid processes (msec time scale), sufficient time is available for aggregate formation to take place before the protein can contact the adsorbent surface. It is presumed that the higher order aggregates (octamer and dodecamer) form as a consequence of hydrophobic binding. It can thus be hypothesized that when the species contact the surface, the aggregate distribution is frozen, since higher order aggregates are prevented from forming owing to the hydrophobic binding of the species to the stationary phase. A variety of studies, *e.g.*, incubation of the aggregate mixture on the bonded phase, flow-rate variation, *etc.* show this picture to be reasonable during the injection process. If the protein were to be left in a solution of 3*M* ammonium sulfate for long periods of time, a precipitate would form. As a result, the chromatograms in Fig. 3 may represent the initial stages of precipitation, *i.e.*, the nucleation steps. The bonded phase prevents further aggregation leading to precipitation.

With some proteins, indefinite aggregation can take place, and a broad chromatographic band profile can be observed. We have seen such a case with zinc-insulin aggregation.[29] The protein system can clearly determine the chromatographic behavior as a function of the concentration of the injected sample.

The results in Fig. 3 further demonstrate the importance of the conditions under which injection takes place. The formation of aggregates can be of significance in preparative scale chromatography and can determine the limit of sample capacity of a chromatographic system. Moreover, the formation of mixed aggregates would clearly lead to loss of separation. A more detailed study of aggregation in chromatographic systems is warranted.

INTRINSIC FLUORESCENCE OF ADSORBED PROTEIN SPECIES

Returning to surface conformational changes, it is necessary to study directly proteins adsorbed on chromatographic surfaces in order to elucidate in more depth the unfolding processes that take place. Fluorescence spectroscopy has been employed in the static mode on flat surfaces[22] as well as on a chromatographic support,[30] for the examination of adsorbed species. We have begun work on the combination of the surface fluorescence and chromatography of proteins. Our initial results in this area, dealing with lysozyme adsorbed on a reversed-phase support, have recently appeared.[31] The experiment involves packing a chromatographic support into a 35-μl fluorescence cell, which is then connected to a chromatographic pump and a detector. In this manner, the cell can serve the dual purpose of a fluorescence cell and a microchromatographic column.

In reversed-phase chromatography, we have observed that lysozyme exhibits two peaks at low temperature (5°) in mobile phases of buffered 0–4% methanol/water. The amount of each peak depends on the contact time with the adsorbent surface, as in the case of papain.

When their intrinsic fluorescence is used to follow the environmental changes of the tryptophan groups (Trps) of lysozyme, a rapid red shift of the emission maximum from the value of 347 nm in solution to roughly 354 nm is found to occur on contact of the lysozyme with the surface. Trps are clearly being more fully exposed to mobile-phase solvent on con-

tact with the reversed-phase chromatographic surface.[32] The result is not surprising, since it is expected that a rapid unfolding step occurs. Over a period of 2 min, the wavelength maximum shifts from 354 nm back to 349 nm, indicative of an average change of the Trps into a somewhat more hydrophobic form, see Fig. 4. This blue shift may be interpreted as a conformational/orientational change of the hydrophobic Trps as they interact with the hydrophobic n-alkyl bonded-phase surface. By measuring the change in fluorescence intensity as a function of time at a given wavelength (in this case 347 nm), it has been possible to measure the first-order kinetic rate constant over the 2-min period.[31] This rate constant was found to be 2.7×10^{-2} sec^{-1}, which can be compared with 1.8×10^{-2} sec^{-1} as measured by chromatography. It is clear that the chromatography and fluorescence methods are measuring essentially the same process.

These results indicate that it is indeed possible to examine the spectroscopic changes of proteins adsorbed on chromatographic surfaces and to associate these changes with the resultant chromatographic behavior. The fluorescence is a measure of structural changes, while the chromatography is a measure of changes of state (*i.e.*, changes in chemical potential). The coupling of these two complementary methodologies thus provides enhanced means of studying protein adsorption.

The picture of lysozyme adsorption on a reversed-phase surface with a mobile phase of 1% methanol at low pH emerges as follows. There is a rapid step of conformational change upon contact with the chromatographic surface. This is followed by a rapid, albeit slower, change as the protein accommodates itself to the adsorbent surface. This latter change yields the two-peak phenomenon. It is interesting to note that this behavior is similar to that already suggested for papain. In addition, this model has previously been put forward to describe the kinetics of protein adsorption, without experimental evidence.[33] Finally, it is useful to note that the protein does not remain fixed as the unfolded species on the chromatographic surface. Studies over a period of 6–8 hr show changes in peak pattern with time.[34] This means that the protein is not fixed but is continually changing in some fashion on the chromatographic surface. From a thermodynamic point of view we are not measuring an equilibrium state but rather a metastable state of the adsorbed protein. The study of the spectroscopy of proteins attached to chromatographic surfaces is important and will no doubt yield significant insight into protein adsorption in the years ahead.

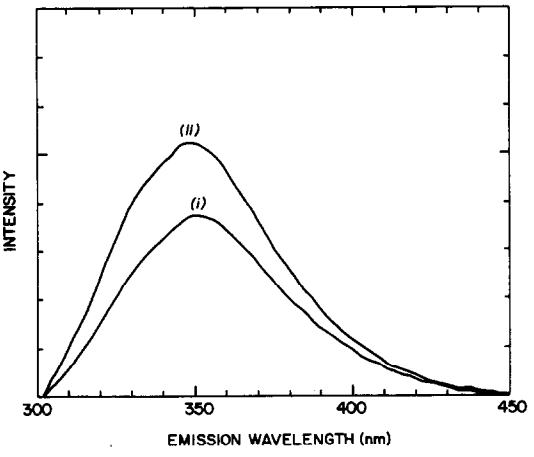

Fig. 4. Emission spectra of adsorbed lysozyme collected on initial contact (*i*) and after 90 sec incubation (*ii*). Conditions: excitation wavelength, 295 nm; band-width, 4 nm; scan-rate, 2.5 nm/sec; flow-rate, 0.3 ml/min; 1% methanol in 10 m*M* phosphoric acid, pH 2.3; temperature 4°C; 5 μg of lysozyme injected. CONCLUSION

From this survey, it is clear that HPLC of proteins is not a simple process of adsorption and desorption. It is important that we probe more deeply into the processes of adsorption to help understand the chromatographic behavior at a deeper level. At the same time such studies will be of value in the general exploration of protein adsorption.

In the future, we can expect to obtain a more refined picture of the retention mechanism of protein HPLC. This picture will permit a better design of stationary phases and manipulation of structural changes. As noted in the introduction, this area is especially fruitful for selective elution of species, leading to improved separations. Moreover, contact of protein with any surface (including another protein molecule) often involves a conformational change to yield the appropriate interaction. An improved understanding of this behavior ought to be of fundamental significance, *e.g.*, in association behavior, protein–cell surface interactions and even cell–cell interactions and communication.

STRATEGIES FOR THE REVERSIBLE IMMOBILIZATION OF ENZYMES BY USE OF BIOTIN-BOUND ANTI-ENZYME ANTIBODIES

UDITHA DE ALWIS and GEORGE S. WILSON*
Department of Chemistry, University of Kansas, Lawrence, KS 66045, U.S.A.

(*Received* 5 *May* 1988. *Revised* 1 *August* 1988. *Accepted* 9 *September* 1988)

Summary—Glucose oxidase (E.C. 1.1.3.4) is reversibly immobilized in a reactor coupled to a flow-injection analysis system using an immunological reaction. The antibody used is irreversibly immobilized on the reactor support by an avidin–biotin linkage. The bond between avidin and biotin is nearly irreversible under normal elution conditions for antibody–antigen reactions. The reactor is packed with a support on which avidin is covalently attached and a biotin-bound second antibody is passed over the reactor packing, which immobilizes this antibody. An immune complex of the enzyme, or first anti-enzyme antibody followed separately by enzyme, is introduced into the flow system, resulting in enzyme immobilization. The reactor produced can be used in the determination of 1×10^{-11}–1×10^{-6} mole of glucose with a sample size of 20 μl and a sample throughput of 20–30/hr. These results are comparable to or better than those obtained with glucose oxidase directly immobilized on the same support. The enzyme can be removed by elution with low-pH buffers, and the reactor regenerated by injection of the anti-enzyme antibody and the enzyme.

The analytical use of immobilized enzymes packed into reactors and coupled to flow systems has been well demonstrated.[1,2] However, the enzymes immobilized in these configurations suffer from several limitations, such as limited lifetime, susceptibility to inhibitors, and steric problems created by the immobilization, which limit the transfer of substrate to the enzyme layer and block access to the active site. We have demonstrated[3] that by using immobilized antibodies which are specific to the enzyme or using indirect immunochemical reactions, it is possible to immobilize enzymes with high efficiency, while retaining their maximum activity. The use of antibodies in the immobilization of enzymes allows the operator to replace the bound enzyme reproducibly in less than 20 minutes in the event of a loss of enzyme activity, without having to remove or replace the packing material. The flow-injection mode of analysis has the advantage of rapid sample throughput and minimal sample handling.

The supports described previously by us involve covalent attachment of the antibody fragments through highly selective reactions which preferentially couple the antibody through the hinge-region thiol group.[3] This involves the use of supports activated with 2,2,2-trifluoroethanesulfonyl chloride[4] or maleimide-activated supports[5] with Fab′ fragments. These Fab′ fragments are unstable and can undergo polymerization and oxidation reactions in addition to coupling to the surface. This can result in highly immunologically active solid supports with low antibody loading. The low binding capacity in this case stems from the low yields of attached antibody.

The low yield of attached antibody can be overcome easily by the use of another coupling technique. It is well known that avidin binds to biotin with a binding constant of 10^{15} and that this binding is therefore irreversible under conditions where the antibody–antigen interactions can be reversed.[6,7] This situation provides a method for immobilizing the primary antibody with high efficiency without resorting to complicated coupling chemistry. In this publication we shall describe the use of avidin–biotin interactions for the reversible or irreversible immobilization of enzymes. By use of both monoclonal and polyclonal anti-glucose oxidase antibodies, glucose oxidase can be immobilized and used for the determination of glucose. These methods of immobilization of proteins in reactors use two biospecific reactions, one of which is irreversible and the other reversible. The biospecific reactants are therefore amenable to selective elution and regeneration.

EXPERIMENTAL

Materials

Avidin was purchased from Calbiochem Behring (San Diego, CA) and used without further purification. Sulfosuccinimidyl-6-(biotinamido) hexanoate (NHS-LC-biotin) and Reactigel HW-65 were obtained from Pierce Chemical Co. (Rockford, IL). Anti-glucose oxidase antibodies raised in goats were obtained from Jackson Immunoresearch Laboratories Inc. (West Grove, PA) as the IgG fraction and used without further purification. Mouse monoclonal anti-glucose oxidase (IgG_1) ($IIF_{12}H_{12}$) was a

*To whom correspondence should be directed.

generous donation from Mr. Rohan Wimalasena (Department of Chemistry, University of Kansas). Polyclonal goat anti-mouse serum and polyclonal rabbit anti-goat antibodies were a generous donation from American Qualex International Inc. (La Mirada, CA). Glucose oxidase (E.C. 1.1.3.4) type GO-3A (specific activity 266 IU/mg protein) was obtained from Biozyme (San Diego, CA). All reagents used were of analytical grade and all water used in preparation of the buffers used for flow-injection analysis (FIA) was obtained from a Barnstead Nanopure II system and refiltered through 0.45 μm filters after the buffers were prepared.

Preparation of reactigel loaded with avidin

The avidin (5 mg/ml) was dissolved directly in 0.1*M* carbonate buffer (pH 9.5) and mixed in 2:1 v/v ratio with the activated HW-65 gel. Just before the mixing, the gel was washed according to the manufacturer's instructions. The avidin and gel were mixed by mechanical inversion for 30 hr at 4°. The coupled gel was collected and washed on a glass frit according to the manufacturer's instructions and stored in 0.1*M* phosphate-buffered saline (PBS) pH 7.5. The gel loading with avidin was determined as 5–6 mg/ml by protein balance from an absorbance measurement at 280 nm. The washed gel was stored in 0.1*M* PBS (pH 7.4) containing 0.01% sodium azide, at 4°.

Preparation of Sepharose loaded with mouse and rabbit IgG

These immunosorbents were prepared similarly to avidin-loaded reactigel under the same conditions but with Reactigel 6X.

Preparation of biotin-bound antibody

Antibody solutions (3 mg/ml) were made in 0.1*M* carbonate buffer and NHS-LC biotin (2 mg/ml in dimethyl sulfoxide) was added dropwise (170 μl per μl of antibody solution) with rapid agitation of the solution. The mixture was stirred for 2 hr and passed through a Sephadex G-25 (1.5 × 30 cm) column previously equilibrated with 0.1*M* PBS (pH 7.4). The product was eluted with the buffer at a flow-rate of 0.5 ml/min and then dialyzed extensively against the same buffer with 3 changes over 2 days.

Preparation of biotin-bound enzyme

The enzyme was bound by the same method as that used for the antibody and was stored similarly.

Affinity purification of goat anti-mouse and rabbit anti-goat antisera

The antisera were 33% saturated with ammonium sulfate by the slow addition of the solid sulfate (192 g/l.) with stirring, and then stirring for a further hour. The material was centrifuged at 3000 *g* for 15 min at 4° and the supernatant liquid was discarded. The precipitate was washed with 40% ammonium sulfate solution and centrifuged again. The precipitate was dissolved in 0.1*M* PBS (pH 7.4) and dialyzed extensively against the same buffer with 3 exchanges. The gamma-fraction obtained was applied to a mouse IgG–Sepharose (CL-6B) or rabbit IgG–Sepharose (CL-6B) affinity column for purification of the anti-mouse or anti-rabbit IgG, respectively. The nonspecific IgG was washed off with 10 column volumes of 0.1*M* PBS (pH 7.4) and the bound IgG was eluted with 0.1*M* phosphate buffer (pH 2.2). The eluate was neutralized immediately with 0.5*M* sodium hydroxide and dialyzed against 0.1*M* PBS (pH 7.4) overnight. The precipitate formed in the affinity-purified product was removed by centrifugation for 5 min. A 10% sodium azide solution was added to the product to give a final concentration of 0.01% and the mixture was stored in a refrigerator at 4°.

Preparation of the avidin reactor

The avidin-activated support was packed into a 0.4 × 3 cm stainless-steel reactor (Upchurch Scientific Inc., Oak Harbor, WA) by attaching a short length of Tygon tubing to one end of the reactor, which had the end-fitting assembled at the other end. A slurry of the support was introduced into the Tygon tube with suction applied to the opposite end. When all of the gel had settled, the Tygon tube was removed and the other end-fitting was screwed on. The reactor was coupled to the FIA system and washed for an hour with the assay buffer (0.1*M* PB, pH 6.8).

Preparation of the enzyme reactor (reactor A)

The avidin-coupled reactor packing (0.4 ml) was placed in a test-tube and the storage buffer was removed after the gel had settled. The biotin-bound enzyme was added (8 mg in 4 ml of PBS) and the tube was capped with parafilm, then gently agitated for 15 min at room temperature. A sample of the supernatant liquid was withdrawn and the amount of enzyme attached to the reactor packing was determined by protein-uptake calculations based on absorbance measurements at 280 nm. The excess of reagent was removed after centrifugation at 500 *g* for 5 min, and the gel was washed twice with 2 ml of 0.1*M* PBS (pH 7.5). After each wash, the gel was resuspended, agitated and centrifuged. The material was packed in the reactor or stored at 4° in PBS containing 0.01% sodium azide.

Preparation of the goat anti-GOD reactor (reactor B)

This reactor was initially prepared by mixing 1 ml of goat anti-GOD (15 mg/ml) with 0.4 ml of the activated packing material and gently agitating the mixture for 15 min. To this mixture 10 mg of GOD, dissolved in 0.1*M* PBS (pH 7.4) were added and the mixture was further agitated for 15 min. The supernatant liquid was discarded and the support material was packed into a reactor.

Preparation of the goat anti-mouse/mouse anti-GOD/GOD reactor (reactor C)

In the first step, 5 ml of biotin-labelled goat anti-mouse IgG (2 mg/ml) were mixed with 0.5 ml of the avidin support. The mixture was gently agitated for 15 min and the unreacted reagent was washed away as already described. To the anti-mouse immunosorbent thus prepared, 1 ml of mouse anti-GOD solution (11 mg/ml) was added and the mixture was agitated for another 15 min. To this 5 ml of 2 mg/ml GOD solution in PBS were added and the mixture was agitated for 10 min. The excess of reagent was removed by washing with PBS buffer and the material was packed into the reactor.

Preparation of rabbit anti-goat/goat anti-GOD/GOD reactor (reactor D)

This reactor was prepared as described for reactor C but with 5 ml of rabbit anti-goat IgG/biotin solution (2 mg/ml) in the first step and 1 ml of goat anti-GOD solution (15 mg/ml) in the second step, followed by addition of 5 ml of GOD solution (2 mg/ml).

Enzyme regeneration

Reactor regeneration was examined with reactors B, C and D. The bound enzyme was eluted by passage of 0.1*M* phosphate buffer (pH 2.0) for 4 min. After re-equilibration for 10 min with 0.1*M* phosphate buffer (pH 7.4), the reactors were regenerated with the appropriate reagents, as follows.

Reactor B was regenerated by injecting 100 μl of glucose oxidase solution (2 mg/ml), followed by a 15-min wash with 0.1*M* phosphate buffer (pH 7.4). The reactor was then tested with standard glucose solutions.

Reactor C was regenerated by injecting 100 μl of an immune complex prepared as follows. Glucose oxidase (10 mg) was added to 1 ml of anti-glucose oxidase ascites fluid (11 mg/ml IgG_1) and agitated on a vortex mixer until all the solid had dissolved.

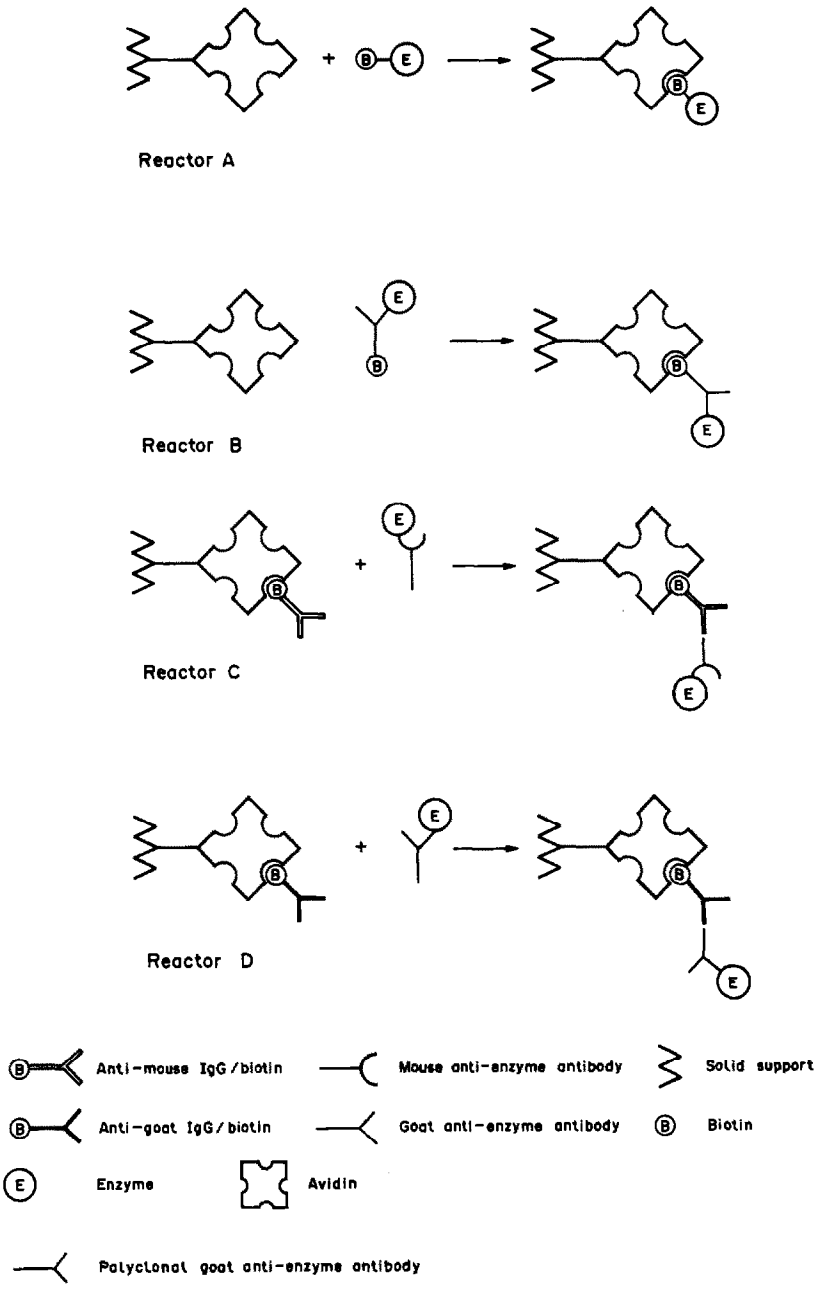

Fig. 1. Schematics of enzyme immobilization reaction sequences.

Reactor D was regenerated by injecting 100 μl of goat anti-GOD solution (15 mg/ml) followed by 100 μl of GOD solution (2 mg/ml).

In each case the reactor was washed with 0.1 *M* phosphate buffer (pH 7.4) for 15 min and the response to standard glucose solutions was tested several times.

Apparatus

A Shimadzu LC-6A liquid chromatograph was used, in a system consisting of an SCL-6A controller, LC-6A pump, FCV-3A low-pressure solvent-selection valve, SIL-6A auto injector, FCV-2AH high-pressure switching valve and C-R4A integrator (all from Shimadzu Corporation, Kyoto, Japan) and a BAS LC-4B amperometric detector (Bioanalytical Systems Inc., West Lafayette, IN) coupled to an LC-17AT flow-through thin-layer electrochemical cell. This set-up has been fully described elsewhere.[8]

RESULTS AND DISCUSSION

A schematic diagram of the immobilization schemes is shown in Fig. 1. The simplest case considered was the direct immobilization of glucose oxidase by covalent linking to LC-biotin on the avidin-activated reactor matrix. The reaction between avidin and biotin/GOD results in an immobilization of

Table 1. Reactor characteristics*

Reactor	Lower detection limit, *mole*	Linear dynamic range (orders of magnitude)	Efficiency, † %
A	2.7×10^{-10}	3	31
B	1.3×10^{-10}	4	36
C	1.3×10^{-10}	4	38
D	5×10^{-11}	4–5	48

†Defined as the ratio of response curve slopes (amperometric detection) for glucose and hydrogen peroxide, respectively.

GOD that is irreversible except by washing with 6*M* guanidine hydrochloride at pH 1.5. Therefore, this linkage is irreversible under the conditions used in these experiments. The enzyme immobilized in this manner was used as reference for comparison of the enzyme activity and the immobilization efficiency of other methods of immobilization. The results are summarized in Table 1. With reactor A, calibration graphs were prepared with 1×10^{-11}–1×10^{-7} mole of glucose. The lower detection limit for the reactor was 2.7×10^{-10} mole and the linear detection range was 4 orders of magnitude. However, with higher amounts of glucose, a loss of reproducibility of the signal was observed upon rapid multiple injections. This can be attributed to depletion of oxygen in the system, as observed by us previously.[8] This problem is usually dealt with by addition of oxygen to the mobile phase or by stirring the mobile phase in the reservoir. This phenomenon will be referred to as the "fatigue" effect. The reactor was also tested for the stability of the immobilized enzyme. The decrease in enzyme activity was measured by injection of glucose standards and evaluation of the amperometric detector response. The decrease of enzyme activity in this reactor was found to be 6–7% per week.

Reactor B was prepared by immobilizing goat anti-GOD/biotin on the avidin matrix. The uptake of goat anti-GOD by the matrix was measured by protein difference, from the absorbance change at 280 nm. It was found that the matrix was capable of binding 12 mg of goat anti-GOD/biotin per ml of avidin. After this step, GOD was added to the matrix (with its attached antibody), resulting in immobilization. This reactor had a capacity which is similar to that of reactor A (directly immobilized GOD), a detection limit of 1×10^{-10} mole, and a linear detection range of 4 orders of magnitude. This reactor showed a decrease of 2–3% in activity after a week of constant use, but no fatigue effects compared to reactor A.

Reactor C was prepared by immobilization of goat anti-mouse IgG/biotin on the avidin matrix. The uptake of this antibody on the matrix was 12 mg/ml, which matches the capacity of reactor B. The anti-mouse IgG matrix produced in this step was then exposed to mouse anti-GOD. The protein uptake in this step was 6–8 mg per ml of matrix. This indicates that not all of the antibody bound to the matrix in the first step is accessible or immunologically active. The anti-GOD matrix prepared in the previous step was exposed to free GOD in solution. The reactor was tested as already described for reactors A and B, and the linear detection range was found to be 4 orders of magnitude with a lower detection limit of 1.3×10^{-10} mole. The reactor lifetime was much shorter than that of reactor A or B and the loss of activity in this reactor was 3–4% per day. There were no observable fatigue effects. The rapid loss of activity compared to the other reactors can be attributed to the loss of antibody activity. It is possible that the monoclonal antibody, which is known to have a shorter half-life[9] than the goat or rabbit antibody, is irreversibly denatured. This was further confirmed when a solution of GOD was injected into the reactor; only 40% of lost activity was restored. This indicates that in addition to the normal reversal of the antibody–antigen reaction, some antibody molecules are also irreversibly denatured. The anti-GOD–GOD complex was dissociated from the anti-mouse IgG by lowering the pH of the mobile phase to pH 2.4. After reconditioning of the matrix with the assay buffer (0.1*M* PB, pH 7.5), fresh samples of anti-GOD and GOD were sequentially injected. The activity of the immobilized material was tested as before and the elution and reloading cycle was repeated several times. In each case the enzyme activity was restored to within $\pm$ 5% of that in the first cycle.

Reactor D was prepared by first adsorbing rabbit anti-goat/biotin on the avidin matrix and subsequently adsorbing goat anti-GOD and GOD on the anti-goat and anti-GOD matrices formed. When this reactor was intially prepared, the anti-GOD antibody was added to the tube containing the anti-goat matrix, and after 15 min the GOD solution was added to the same tube without removal of the excess of anti-GOD. The intention of this experiment was to determine whether cross-linking of the GOD with excess of anti-GOD antibody would increase the loading and stability of the immobilized GOD. The matrix produced was washed and packed into the reactor and evaluated as before. This reactor had a lower detection limit, 5.0×10^{-11} mole, and the linear dynamic range was 4 orders of magnitude. There were no detectable fatigue effects and a 2–3% decrease in activity was observed over a 24-hr period during which the reactor was in constant use. When the material in the reactor was eluted and reloaded five times, no change in loading was noted. However, since the reactor is not equilibrated with the initial reactants in the reloading process and the cross-linking does not occur, the reactor loading under these conditions was similar to that of reactor C. The main difference observed is that the amount of enzyme immobilized in the *in situ* loading is lower than in the first loading where a large reagent excess is employed. This condition can be simulated in the *in*

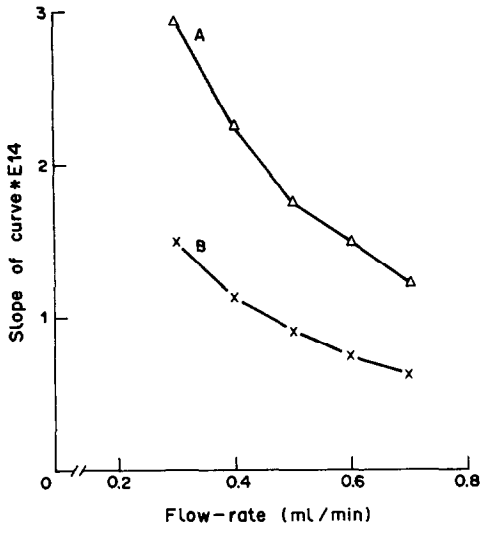

Fig. 2. Detector response as a function of flow-rate: A—hydrogen peroxide injection; B—glucose injection into enzyme reactor (peroxide detection), glucose and hydrogen peroxide concentrations were equal.

situ loading by alternately injecting the antibody and the enzyme several times per loading cycle.

For all the reactors, the efficiency of conversion of the substrate into product and the dependence of the reactor response on flow-rate were studied. The detector response was tested with H_2O_2 standards at the same flow-rates and with the reactor in the flow stream, to allow for any dispersion which occurs. The slope of the calibration graph (peak area *vs.* concentration) was plotted as a function of the flow-rate. The flow-rate dependence of the detector response to glucose injected into reactor C, and to hydrogen peroxide, are shown in Fig. 2. The two curves are roughly parallel in the 0.4–0.6 ml/min range, but the slopes for glucose are lower than those for H_2O_2. This indicates that the factor limiting the conversion is the rate of mass transfer in the reactor. The conversion efficiency of glucose at a flow-rate of 0.5 ml/min is given in Table 1. It is seen from the data that reactor D has the highest conversion efficiency and reactor A the lowest. The reactor conversion efficiency is defined as the ratio of the response-curve slopes for glucose (injected into the enzyme reactor) and peroxide.

In all the reactors, the correlation coefficients for calibration curves were of the order of 0.999 and the detection limits were in the range 1×10^{-11}–1×10^{-10} mole. This is important in the analysis of micro-samples; for instance a triplicate analysis would need only 2 μl of serum, which would be extremely useful in the case of neonatal determinations. A collection of 30 serum samples was analyzed with the apparatus and the results obtained correlated well with readings from a Beckman Astra instrument. Reactor D was used in this study and no deterioration in the detector signal was observed after the assays. All reagents used in these reactors are commercially available. Others are easily prepared and are stable. The amount of a particular antibody added to a reactor is highly controllable. This allows the preparation of multienzyme reactors which contain precise amounts of a given enzyme. The reactors prone to loss of activity can be regenerated periodically to maintain the level of enzyme activity.

DETERMINATION OF RELATIVE GAS-PHASE BASICITIES BY THE PROTON-TRANSFER EQUILIBRIUM TECHNIQUE AND THE KINETIC METHOD IN A QUADRUPOLE ION-TRAP

J. S. BRODBELT-LUSTIG and R. G. COOKS*
Department of Chemistry, Purdue University, West Lafayette, IN 47907, U.S.A.

(*Received* 30 *March* 1988. *Accepted* 16 *May* 1988)

Summary—It is shown for the first time that a quadrupole ion-trap mass spectrometer permits determination of gas-phase basicities. Two methods for measuring relative values of these molecular parameters are demonstrated, the proton-transfer equilibrium technique and the kinetic method. The proton-transfer equilibrium technique is the more accurate and precise, and is useful for a wider range of relative basicities. The kinetic method proves more valuable for determining basicities of solids, owing to their low volatilities. For example, the basicity of 1-adamantanamine has been measured for the first time and found to be 903.9 ± 0.8 kJ/mole. Basicity values found for substituted pyridines agreed with the literature values to within 1 kJ/mole.

The quadrupole ion-trap has been employed by various investigators as a means of storage and mass-analysis of ions[1-3] since its development by Paul *et al.* in 1958.[4] In contrast to other trapping devices, it employs only electrical fields in its operation. The small structure consists of two end-cap electrodes and a central ring electrode, all of hyperbolic cross-section. Radiofrequency (rf) and/or dc voltages are applied to the electrodes.

A new method for trap operation, the mass-selective instability mode,[5] utilizes only an rf voltage to achieve the mass analysis. The magnitude of the applied potential determines the mass-to-charge ratios of ions stored within the field, and as the rf voltage is raised, ions escape from the trap in order of increasing mass and are externally detected. For best performance, the motion of the ions stored within the trap is damped by a high background pressure of helium. The quadrupole ion-trap is commercially available in two forms, the ion-trap detector[5] (introduced as a detector in gas chromatography, but usable as a simple ion–molecule reactor) and the ion-trap mass spectrometer,[6] a tandem mass spectrometer with many additional capabilities. Both instruments are compact, relatively inexpensive and readily modified.

The mass-selective instability mode is a new method of operation which changes the way in which the trap functions. Thus, the ion-trap can be treated as a new device and its capabilities explored and charted.

Proton-transfer reactions have been widely studied in solution and gas-phase chemistry.[7-9] They are often studied in order to measure gas-phase basicities and proton affinities of molecules so that correlations between molecular parameters and intrinsic basicity can be established and solvation energies calculated.[10-12] There are several methods for the determination of both absolute and relative basicities. Absolute values can be calculated from appearance potential or ionization potential measurements,[13-15] which give heats of formation of protonated molecules, or (for some olefins) from heats of formation derived from hydride-transfer equilibrium constants for the corresponding carbonium ions.[16,17] Relative basicities may be derived by using the bracketing method[18] in which the basicity of a compound is assigned by observation of the occurrence or non-occurrence of proton-transfer reactions with a series of bases of known basicities, or by measuring the rate constants of the forward and reverse proton-transfer reactions with a compound of known basicity.[19] Relative basicities may also be determined by using the recently developed kinetic method.[20] In this method, the proton-bound dimer formed from two bases is collisionally activated to cause dissociation into the individual protonated bases. The relative abundances of the protonated bases formed from the competitive dissociation reactions of the dimer correlate with their relative basicities. Most relative basicity determinations are based on measurement of the equilibrium constants of gas-phase proton-transfer reactions.[21,22] In this method, proton exchange occurs between two bases, establishing an equilibrium. The equilibrium constant is found from the composition of the mixture and the abundances of the two protonated bases, measured by mass spectrometry. The equilibrium constant may then be used to calculate the standard free-energy change of

*Author for correspondence.

the reaction (relative gas-phase basicity), which differs from the enthalpy change (relative proton affinity) by the entropy term. The entropy changes for proton-transfer reactions are calculated from changes in molecular rotational symmetry numbers, and are often negligible. Equilibrium constants have been obtained by use of high-pressure ion sources,[23,24] flowing afterglow methods,[25-27] ion cyclotron-resonance spectrometers[28-31] and an ion-trap/quadrupole hybrid mass spectrometer.[32,33]

In this paper, we present results demonstrating the applicability of the proton-transfer equilibrium technique and the kinetic method using a quadrupole ion-trap. With the development of the mass-selective instability mode of operation,[5] the trap has proven to be a versatile device for chemical ionization,[34] collision-activated dissociation[6] and photodissociation,[35] and as an ion–molecule reactor.[36] Because of its ability to store ions for long periods (msec), the ion trap is also potentially useful for studies of proton-transfer equilibrium and for the determination of relative basicities, as will now be discussed.

EXPERIMENTAL

All equilibrium measurements were made with a Finnigan Ion Trap Detector™ described previously.[34] An ionization gauge was added to the vacuum manifold for pressure measurements, and a three-valve inlet system to allow introduction of volatile compounds. The radiofrequency voltage applied to the ring electrode was about 150 V (peak to trough) at 1.1 MHz. The electron ionization period was typically 0.5 msec and the proton-exchange interval was varied from 1 msec to 1.5 sec until equilibrium was established. The mixture of two bases was introduced from a glass bulb which had been chilled in liquid nitrogen while being evacuated. Then the bulb was warmed to room temperature and the gaseous mixture was admitted into the ion trap through a Granville–Phillips valve. Nominal sample pressures varied from 5×10^{-7} to 5×10^{-6} torr. The temperature of the ion trap, measured by a thermocouple attached to the vacuum manifold, was 438 K.

The kinetic method experiments were done with a prototype Finnigan Ion Trap Mass Spectrometer (ITMS) described previously.[6] Since this method does not require knowledge of the sample partial pressure, the two bases were simply mixed in a glass sample tube and admitted through a metering valve. The total sample pressure was nominally 1.5×10^{-6} torr, and the helium pressure 3×10^{-4} torr. The proton-bound dimer ions were isolated and activated for 2 msec at 1.0 V (peak to trough) at 73500 Hz. The daughter ions generated by collision-activated dissociation were mass-analyzed by use of the MS/MS scan mode.[6] Each measurement was repeated 3–5 times.

RESULTS AND DISCUSSION

Proton-transfer equilibrium method

The equilibrium constant for the proton-transfer reaction

$$B_1H^+ + B_2 \rightleftharpoons B_1 + B_2H^+ \qquad (1)$$

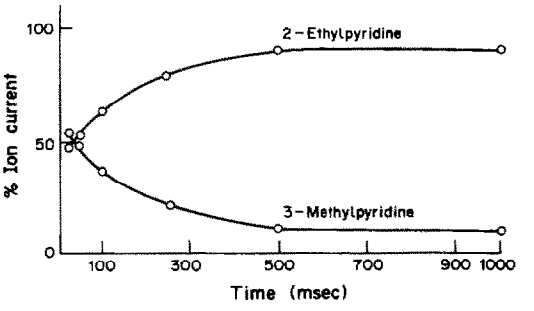

Fig. 1. Attainment of equilibrium for a mixture of 2-ethylpyridine and 3-methylpyridine in an ion trap. The relative basicities of the two bases is calculated as 8.6 kJ/mole from the concentration ratio of protonated 2-ethylpyridine to protonated 3-methylpyridine.

can be defined as:

$$K_{eq} = [(B_2H^+)/(B_1H^+)][(B_1)/(B_2)] \qquad (2)$$

where $(B_1)/(B_2)$ is the ratio of the concentration of the bases in the gaseous mixture in the mass spectrometer and $(B_2H^+)/(B_1H^+)$ is the ratio of the concentration of the two protonated bases measured by mass spectrometry after equilibrium is attained. The standard free-energy change for the proton-transfer is

$$\Delta G^\circ = -RT \ln K_{eq} = \Delta H^\circ - T\Delta S^\circ \qquad (3)$$

When the entropy effects are negligible, the free-energy change may be equated with the enthalpy change, giving access to the relative proton affinities of the two bases. For the series of substituted pyridine compounds discussed, the entropy changes were similar for each of the compounds,[7] resulting in cancellation of the entropy term in any comparison of the free-energy changes.

For every pair of bases, the proton-transfer reactions were studied as a function of time and sample pressure to ensure that equilibrium had been reached. A total sample pressure of 1×10^{-6} torr was necessary to ensure sufficient ion–molecule collisions took place for equilibrium to be achieved during a reaction period of less than 1 sec. A plot indicating the approach to equilibrium for a mixture of 2-ethylpyridine and 3-methylpyridine is shown in Fig. 1. The abundance ratio of m/z 108 from protonated 2-ethylpyridine to m/z 94 from protonated 3-methylpyridine changes little after 500 msec reaction time. The relative basicities of these bases calculated from the data of Fig. 1 by use of equation (3) and the trap temperature of 438 K, is 8.8 kJ/mole, which agrees with the literature value of 8.8 kJ/mole.[7]

Table 1 compares the differences in basicities obtained for ten pairs of substituted pyridines by using the ion trap, with the accepted literature values. Most of the values agree with the literature data within 0.8 kJ/mole. The only exception is for 2,6-dimethylpyridine and 4-methylpyridine, for which there is a difference of 1.7 kJ/mole. This pair

Table 1. Differences in gas-phase basicities of pairs of substituted pyridines

Pair of pyridine bases	Difference in basicity, *kJ/mole*	
	Literature value[7]	Ion trap
3-Ethyl/4-methyl	0.8	0.8
4-Ethyl/4-methyl	3.8	3.8
3-Ethyl/3-methyl	4.6	4.2
2-Ethyl/4-methyl	5.0	4.6
4-Ethyl/3-methyl	7.5	6.7
2-Ethyl/3-methyl	8.8	8.8
2,5-Dimethyl/4-methyl	10.4	10.4
3,5-Dimethyl/3-methyl	11.3	11.3
2,6-Dimethyl/4-methyl	14.2	12.5
2,6-Dimethyl/3-methyl	18.0	17.2

and the 2,6-dimethylpyridine/3-methylpyridine pair (which differs from the literature value by 0.8 kJ/mole) both show larger differences in gas-phase basicities than expected. It seems likely that these differences are due to steric inhibition to proton transfer, which prevents the attainment of equilibrium on the time scale of the experiments, a factor established in an earlier investigation of these systems.[31]

Figure 2 shows a "ladder" of relative basicities of these substituted pyridines, constructed from the values obtained by using an ion trap. The relative basicities could be measured directly for pairs of bases with basicities differing by 0.8–17.1 kJ/mole. The upper limit to the direct measurements of basicity differences is set by the inability to measure accurately ion-abundance ratios greater than about 100. The ladder covers a range of 17.1 kJ/mole.

The attainment of equilibrium for proton-transfer reactions in the ion trap also has analytical utility. When complex mixtures are studied, the relative ion abundances of the components having higher basicities can be enhanced simply by allowing the components to interact for a longer time. As an example, a 500:25:1 mixture of anisole, 3-methylpyridine and 2-ethylpyridine was introduced into the ion trap and the relative abundances of the protonated ions were monitored as a function of time. Initially, protonated anisole was the dominant ion, but protonated 3-methylpyridine gained abundance as the anisole ions were deprotonated. Protonated 2-ethylpyridine increased at a slower rate, but eventually matched the abundance of the protonated 3-methylpyridine. These trends are illustrated in Fig. 3. This result indicates that the ion abundance of a sample component constituting only a fraction of a mole percent of the total mixture but possessing a relatively high basicity can be enhanced by using a longer reaction interval.

Several experimental variables were studied to establish their effects on the equilibrium technique. First, the trap operates optimally with a relatively high pressure of helium which damps the motion of the ions through collision.[5] It was of interest to determine the effect of helium on the attainment of equilibrium. Because the helium pressure was about 100 times the sample pressure, the protonated ions experienced many more collisions with helium than

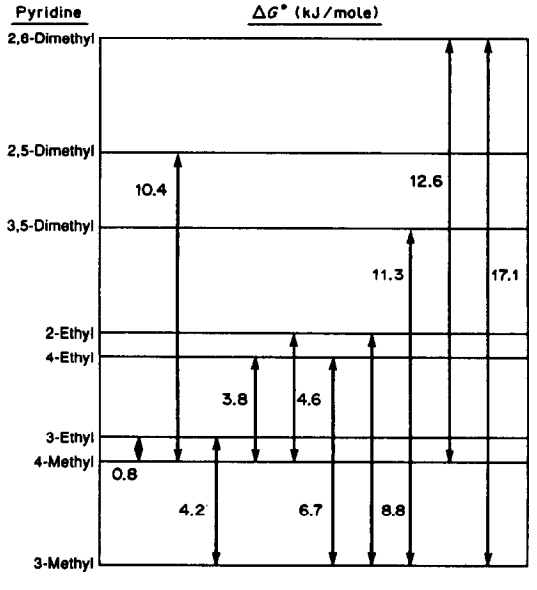

Fig. 2. Ladder of relative gas-phase basicities for pairs of substituted pyridine bases.

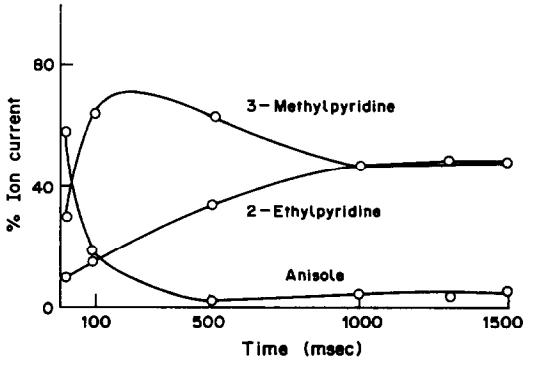

Fig. 3. The ion abundances for a 500:25:1 molar mixture of anisole, 3-methylpyridine and 2-ethylpyridine, as a function of time.

with neutral sample molecules. Regardless of the helium pressure, the equilibrium attained and the rate of attainment remained constant within experimental limits. However, the total ion current was greatly reduced at low helium pressures. This suggests that although helium does help to trap ions more efficiently, it does not accelerate or alter the attainment of equilibrium.

The equilibrium experiments were repeated with isobutane ($C_4H_9^+$) as a secondary protonating agent. The final equilibrium attained is the same with or without the presence of isobutane in the trap, although isobutane does affect the rate at which equilibrium is attained. Also, as the sample pressure is increased, the rate of attainment of equilibrium increases. This is due to the greater number of collisions the protonated ions experience with the neutral sample molecules, causing a higher probability for proton transfer to occur.

Kinetic method

In the kinetic method, the proton-bound dimer of two bases of interest is collisionally activated, resulting in dissociation to the protonated constituent bases [equation (4)].

$$B_1HB_2^+ \begin{cases} \rightarrow B_1H^+ + B_2 \\ \rightarrow B_1 + B_2H^+ \end{cases} \qquad (4)$$

The relative rate constants for the competitive dissociations to the two constituents reflect the relative basicities, and in the absence of entropy effects, the rates are a direct function of the activation energies for each dissociation path. Thus, the relative abundances of the two protonated bases correlate with their relative basicities.[37] For a series of dimers formed from substituted pyridines, the natural logarithm of the ratio of the ion abundances of the two bases is plotted as a function of the difference in their basicities. If steric factors are negligible, the line should pass through the origin. Once the dimers from 4 or 5 pairs of bases with known relative basicities have been examined and their dissociation ratios plotted, the graph may be used to determine (by interpolation) the difference in proton affinities of pairs of bases with unknown basicities. For example, as shown in Fig. 4, if the proton-bound dimer of 4-ethylpyridine and 4-methylpyridine (m/z 201) is isolated, then activated, two dissociation products are obtained with m/z 108 and 94. The abundance ratio determined from Fig. 4 can then be interpolated in Fig. 5.

The advantage of this method over the equilibrium method is that the sample concentrations and purities need not be known for calculation of the relative basicities. Furthermore, since solid bases are difficult to characterize by the equilibrium method because of their low volatilities, the kinetic method is critically important for determining their basicities. It must be stated, however, that the method has certain disadvantages: (*i*) the range of basicity differences which can be studied is smaller than that by the equilibrium method (about 8.4 kJ/mole for the kinetic method *vs.* 17.1 kJ/mole for the equilibrium method) and (*ii*) the

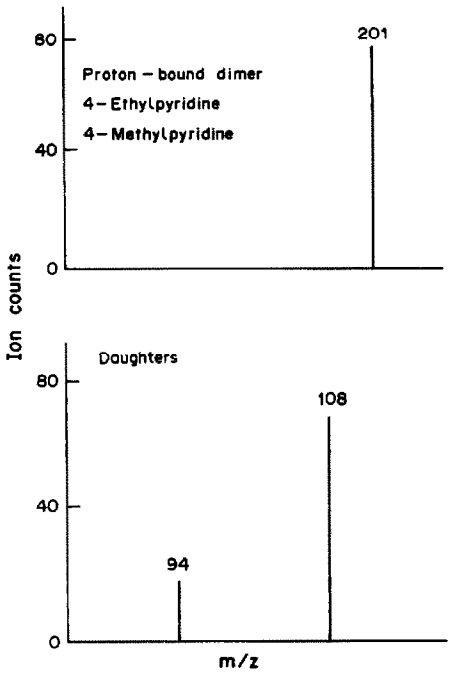

Fig. 4. Mass spectrum for the proton-bound dimer formed between 4-ethylpyridine and 4-methylpyridine, observed at m/z 201. It dissociates to compounds with m/z 108 and 94 after collisional activation.

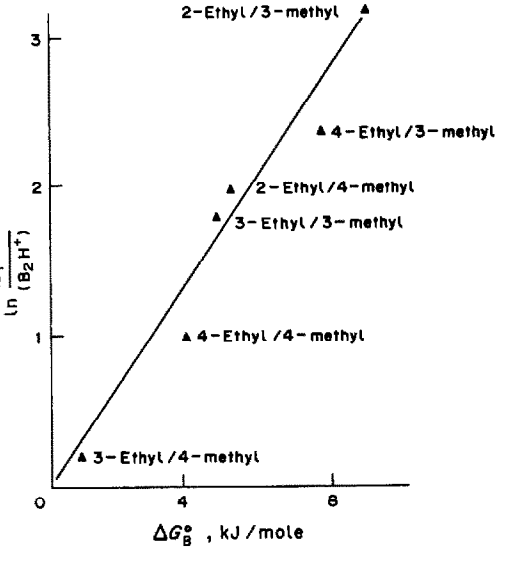

Fig. 5. Plot of log (ion abundance ratio) *vs.* basicity difference.

method is less precise because a large number of collisional activation conditions must be reproduced on a daily basis, introducing a greater variability in the technique.

A measure of the internal energy, or effective temperature,[37] of the dimer ions can be estimated from the slope of the logarithmic plot, since the equation for the line is $\ln (B_1H^+)/(B_2H^+) = \Delta E_a/RT$ where $(B_1H^+)/(B_2H^+)$ is the concentration ratio of the two protonated bases produced from the dissociation of the dimer ions and ΔE_a is the difference in activation energies for the two competing fragmentations and is represented by the difference in the basicities of the two pyridine compounds. From the data plotted in Fig. 5, an effective temperature of 335 K is calculated for the dimer ions after collisional activation.

The kinetic method may also be used to determine the basicities of uncharacterized compounds. For example, the proton affinity of 1-adamantanamine ($C_{10}H_{17}N$) has not yet been published. When this compound is introduced into the ion trap together with 3-ethylpyridine, basicity 903.2 kJ/mole,[1] a proton-bound dimer (m/z 259) is formed. On activation, the dimer dissociates to produce protonated 1-adamantanamine (m/z 152) and protonated 3-ethylpyridine (m/z 108) with an abundance ratio (152/108) of 1.2. By interpolation in Fig. 5, the basicity difference is estimated to be 0.4 kJ/mole, yielding an estimated basicity of 903.7 kJ/mole for 1-adamantanamine. To confirm this result, the proton-bound dimer of 4-ethylpyridine (basicity 906.2 kJ/mole)[1] and 1-adamantanamine was studied. This dimer dissociates to give an ion abundance ratio (152/108) of 0.75, corresponding to a basicity difference of 2.1 kJ/mole, and yielding a basicity of 904.1 kJ/mole for 1-adamantanamine. These results are consistent and demonstrate the utility of the kinetic method for calculating unknown basicities of gas-phase species.

CONCLUSIONS

A quadrupole ion trap may be used for the determination of relative gas-phase basicities by either the proton-transfer equilibrium technique or the kinetic method. Most relative basicities obtained by using the equilibrium technique agree with accepted literature values within 0.8 kJ/mole. The equilibrium established between compounds of different basicities can be used to enhance the ion abundance of a trace compound (in a mixture) having a high proton affinity. The basicity of 1-adamantanamine is 903.9 ± 0.8 kJ/mole as determined by the kinetic method.

Extension of the methods used here to the measurement of other thermochemical properties[38,39] should be straightforward. Ion abundances measured in the quadrupole ion-trap are more sensitive to operating parameters than are say, measurements made with a conventional quadrupole mass filter. However, the increasing availability of ion traps and the ease with which thermochemical quantities can be estimated, suggest that the traps will see increasing use for this purpose. Recent experiments[40] have demonstrated that relative rate constants for ion–molecule reactions can also be measured by using the simple commercial version of the ion trap. Together, these developments suggest that ion traps will see important uses in fundamental studies to complement their already established value in chemical analysis.

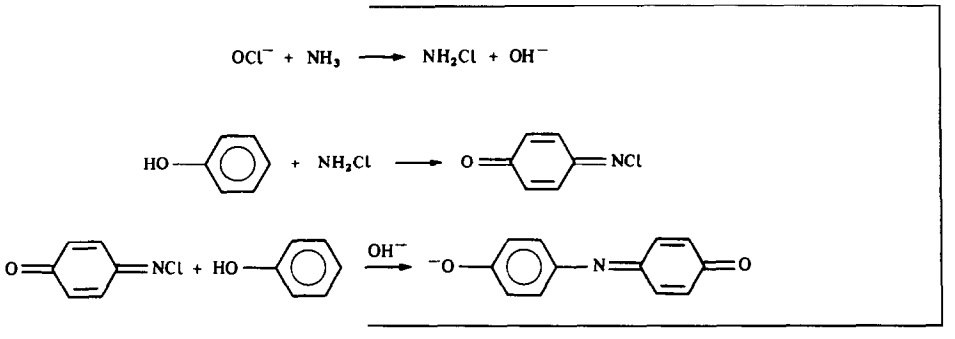
KINETIC STUDY OF BERTHELOT REACTION STEPS IN THE ABSENCE AND PRESENCE OF COUPLING REAGENTS

R. G. HARFMANN and S. R. CROUCH
Michigan State University, East Lansing, Michigan, MI 48824, U.S.A.

(*Received* 8 *August* 1988. *Accepted* 8 *September* 1988)

Summary—Several reaction steps in the Berthelot reaction for the determination of ammonia have been separately studied. A reaction order of two has been confirmed for the reaction between HOCl and NH_3. The rate constant for this reaction has been determined to be 3.2×10^6 l.mole^{-1}.sec^{-1}. The first evidence for the formation of benzoquinonechlorimine is presented. Pentacyanoferrate coupling reagents which accelerate the production of indophenol have been found to operate on the reaction between NH_2Cl and phenol. The rate constant for the final step of the reaction sequence has been determined to be 5.3×10^{-3} l.mole^{-1}.sec^{-1}. A reaction between chlorimine and pentacyanoferrate compounds has been found to be responsible for the formation of a green product in the presence of excess of coupling reagent.

The Berthelot reaction[1] is the basis for sensitive and selective methods for the determination of ammonia. A host of analytical methods based on this reaction have emerged since the discovery that sodium nitropentacyanoferrate[2] greatly accelerates the rate of the reaction. A recent review[3] indicates how widespread the use of this reaction has become. Despite this, the reaction that occurs between HOCl, NH_3, and phenol has never been completely characterized. The proposed reaction mechanism[4] consists of three consecutive steps given as:



This reaction sequence is widely accepted as correct, although the intermediate product, benzoquinonechlorimine, has never been directly identified. Very little is thus known concerning the kinetics of the second reaction step. Though the first step of the reaction has been investigated,[5–9] the rate constants obtained in these studies vary widely. The most recent kinetic data for the reaction suggest[9] a reaction order of 0.8 for NH_3.

Reactions similar to the third step of the reaction sequence have also been studied,[10–15] but the specific reaction involving benzoquinonechlorimine has not. Finally, it has been determined[6,7] that aquopentacyanoferrate, which is produced in aqueous solutions of nitropentacyanoferrate,[16,17] is responsible for accelerating the overall Berthelot reaction. However, the reaction step during which this compound acts has not been determined. Furthermore, the reaction responsible for the formation of a green product[6,7,18] in the presence of excess of coupling reagent has not been determined.

In this work, the reaction order and rate constant for the reaction between HOCl and NH_3 have been determined. The reaction between NH_2Cl and phenol has been studied and the reaction product has been identified. The final step of the Berthelot reaction sequence has also been investigated. Finally, the reaction responsible for the formation of the green product has been identified. These studies, in conjunction with our previous work,[7] provide a clearer understanding of the reactions involved in converting NH_3 into indophenol in the absence and presence of pentacyanoferrate compounds.

EXPERIMENTAL

Apparatus

Reaction-rate data for all rapid reactions were collected with a stopped-flow instrument built in this laboratory.[19] The modified instrument has already been described.[20,21] The instrument performance was evaluated by classical techniques employing a well characterized reaction.[22-25] An instrumental precision of 1.8% RSD was obtained. The dead-time of the instrument was found to be 6 ± 1 msec.

A Perkin-Elmer Lambda 3 spectrophotometer with a Model 3600 Data Station was used to collect spectrophotometric data to identify the product formed in the second step of the Berthelot reaction sequence. Time-dependent ultraviolet spectra for hydrolysis of chlorimine were also recorded with this instrument. A Perkin-Elmer Hitachi 200 spectrophotometer was used for fixed-wavelength studies of the hydrolysis of chlorimine. The instrument was connected to a microcomputer programmed to collect and store absorbance data at regular intervals.

Reagents

Commercially available liquid bleach was used as a stock reagent for all hypochlorite solutions. The total hypochlorite concentration in these bleach solutions was determined by iodometric titration.

Ammonium chloride was used as the source of NH_3 throughout these studies. Accurately weighed amounts of the dried salt were used to prepare stock solutions. These solutions were kept slightly acidic to minimize evaporative loss of NH_3. Fresh stock solutions were prepared daily.

Stock solutions of monochloramine were prepared from NH_4OH by the procedure of Kleinberg.[26] The concentration of stock NH_2Cl was determined by thiosulfate titration.

Stock solutions of phenol and sodium borate ($0.050M$) were prepared from appropriate amounts of the reagent-grade salts with no further purification. Buffer solutions in the pH range 8–11 were prepared by mixing sodium borate with appropriate volumes of $0.1M$ hydrochloric acid or $0.1M$ sodium hydroxide.

Sulfitopentacyanoferrate, SpF, was used as the coupling reagent instead of aquopentacyanoferrae. It was synthesized by the procedure of Baran and Müller.[27] The SpF can be made in purer form than the aquo compound[28] and is more stable. It is just as effective in accelerating the rate of the Berthelot reaction.[21] The dried compound was stored in a vacuum desiccator in the dark.

Benzoquinonechlorimine, hereafter referred to as chlorimine, was synthesized from *p*-aminophenol by the procedure described by Patton.[6] The *p*-aminophenol was first purified by filtering a hot aqueous solution through activated carbon and then cooling, and recrystallizing the compound from distilled water. The resulting crystals were immediately used to synthesize chlorimine. The dried chlorimine solid was purified by recrystallization from diethyl ether. Chlorimine was stored in a vacuum desiccator in the dark.

Procedures

The reaction between HOCl and NH_3. The rapid rate of the reaction between HOCl and NH_3 required that stopped-flow mixing be used for the collection of kinetic information. Pseudo-first-order conditions were usually employed for the reaction order determinations. Second-order conditions were employed for most of the rate constant determinations. Appropriate volumes of $6M$ sodium perchlorate were added to solutions to adjust the ionic strength to the 0.01 or $0.10M$ level. Borate buffers were used to adjust the pH of each solution over the range 8–11. Before mixing, solutions were placed in a thermostatic water-bath to equilibrate to constant temperature. Absorbance–time data for the reaction were collected by monitoring either the disappearance of OCl^- (at 292 nm) or the appearance of NH_2Cl (at 245 nm).

The effect of the coupling reagent SpF was determined by preparing ammonia reagent solutions containing accurately weighed quantities of SpF. The NH_3–SpF solutions were mixed with hypochlorite solutions prepared to provide second-order reaction conditions. Data for the reaction were collected with the stopped-flow instrument.

The reaction between NH_2Cl and phenol. Distribution ratios were determined for the species involved in the second step of the Berthelot reaction. Aqueous solutions of chlorimine, SpF, and phenol were prepared. The absorbances of these solutions were measured at the respective wavelengths of maximum absorbance, λ_{max}, before and after extraction with n-heptane. Distribution ratios were determined for these compounds from the collected absorbance data.

Monochloramine solutions were prepared for these distribution studies as follows. Several ml of an NH_4Cl solution were added to a 35-ml vial containing 5 ml of n-heptane. A suitable amount of sodium hypochlorite was placed in the vial and the mixture was shaken thoroughly for several minutes. The organic phase was removed and the aqueous phase discarded. The spectrum of the organic phase was recorded from 320 to 230 nm. An absorption band for NH_2Cl was present and the absorbance was measured at 245 nm. Then 4 ml of the organic phase were shaken with 1 ml of distilled water. The absorbance of the organic phase was again measured at λ_{max}.

The product of this reaction was identified by using absorption spectra of phenol, phenolate and chlorimine. The Berthelot reagents were added to a 75-ml vial containing pH 10.7 borate buffer. At the first appearance of a blue color, n-heptane was added and the vial was shaken. The spectrum of the organic phase was recorded over the range 320–230 nm. The organic phase was then placed in a vial and shaken with distilled water. The spectrum of the washed organic phase was recorded and stored. This process was repeated for a second wash of the organic phase with distilled water.

The reaction between chlorimine and phenol. Stock solutions of chlorimine were prepared by dissolving appropriate amounts of the solid in about 1 ml of ethanol. Stock solutions were buffered to pH 8, diluted to volume with distilled water and refrigerated to reduce the effect of hydrolysis.[21] Reagent solutions were prepared from the stock and used as rapidly as possible.

The reaction between chlorimine and phenol was studied under pseudo-first-order conditions. Chlorimine solutions were prepared from 10 successive 100–2000 μl aliquots withdrawn from a $5.9 \times 10^{-4}M$ stock solution. Each aliquot was mixed with 500 μl of $0.105M$ phenol, 3 ml of borate buffer ($\approx$pH 9.5) and enough distilled water to make the total volume 5.500 ml. The chlorimine was added last, and the mixture was shaken rapidly and placed in a thermostatic cell. The reaction was monitored by collecting absorbance data at 635 nm for the appearance of indophenol. The pH was measured after the reaction.

Pseudo-first-order conditions were used to determine the effect of SpF on the rate of the reaction. A series of phenol solutions was prepared, containing various amounts of SpF. Solutions of chlorimine were then prepared to maintain a constant chlorimine to SpF ratio for each of the phenol–SpF solutions. The phenol concentration was kept constant at $2.02 \times 10^{-3}M$ throughout the study and the pH was measured to be 10.38. The solutions were mixed in the stopped-flow instrument, and absorbance data at 635 nm were collected.

RESULTS AND DISCUSSION

The reaction order for NH_3

Although the initially proposed Berthelot reaction sequence[4] suggested that a reaction occurs between

OCl^- and NH_3, other studies[5-9] indicate that undissociated hypochlorous acid is the reactive species. This reaction can be written as:

$$HOCl + NH_3 \rightarrow NH_2Cl + H_2O \quad (1)$$

Since the reaction order for NH_3 is uncertain, the reaction rate can be expressed in terms of the unknown order, n, and the reagent concentrations, as:

$$\text{Rate} = k_1[HOC][NH_3]^n \quad (2)$$

The HOCl and NH_3 establish mutually dependent acid–base equilibria in the solution. These equilibria are given by:

$$HOCl + H_2O \rightleftharpoons OCl^- + H_3O^+ \quad (3)$$

$$NH_3 + H_2O \rightleftharpoons NH_4^+ + OH^- \quad (4)$$

These proton exchange reactions occur rapidly relative to the rate of reaction (1). As reaction (1) proceeds, the individual equilibria shift to form more of the two neutral molecules. It is thus the change in the total analytical concentration of each reactant that indicates the extent of the reaction. The total hypochlorite concentration, $[Cl_T]$, and total ammonia concentration, $[N_T]$, are given by:

$$[Cl_T] = [HOCl] + [OCl^-] \quad (5)$$

$$[N_T] = [NH_3] + [NH_4^+] \quad (6)$$

With the equilibrium constant expressions for reactions (3) and (4), equations (5) and (6) can be rewritten as:

$$[HOCl] = \frac{[Cl_T]}{1 + K_a/a_H\gamma} \quad (7)$$

$$[NH_3] = \frac{[N_T]}{1 + K_b a_H/K_w\gamma} \quad (8)$$

where K_a is the acid dissociation constant for HOCl, K_b is the base dissociation constant for NH_3, a_H is the hydrogen-ion activity, and γ is the mean ionic activity coefficient. If the pH and ionic strength remain constant during the reaction, all values in the denominators of equations (7) and (8) are constant. Substituting equations (7) and (8) into equation (2) and collecting constants gives:

$$\text{Rate} = k'[Cl_T][N_T]^n \quad (9)$$

Equation (9) indicates the dependence of the rate on the total analytical concentrations of both hypochlorite and ammonia.

Under pseudo-first-order conditions with hypochlorite in excess, $[Cl_T]$ remains constant and can be collected into k' to give:

$$\text{Rate} = k''[N_T]^n \quad (10)$$

where k'' is given by:

$$k'' = \frac{k_1[Cl_T]}{(1 + K_a/a_H\gamma)(1 + K_b a_H/K_w\gamma)^n} \quad (11)$$

Equation (10) was used to derive a mathematical model based on a reaction order of unity for ammonia. The integrated rate expression was written in terms of solution absorbance, time, k'' and other constants characteristic of the solutions. The mathematical model was written into a nonlinear simplex curve-fitting routine.[29] The program fits the model to the data by varying a set of adjustable parameters to minimize the sum of the squares of the residuals between calculated and real absorbance values. Three adjustable parameters were used in the reaction model: k''; the initial solution absorbance, A_0; and the final solution absorbance, A_f. The absorbance values are fairly well known, but slight errors in them can cause deviations in the fit. A successful reaction model necessarily reproduces the entire absorbance–time reaction profile. The program was run for each data set until a consistent value of the sum of the squares of the residuals was achieved. Figure 1 shows a typical fit of the model to the data. An excellent fit was obtained for each of the solutions tested. In every case the values of A_0 and A_f returned by the fitting routine agreed with the observed experimental values.

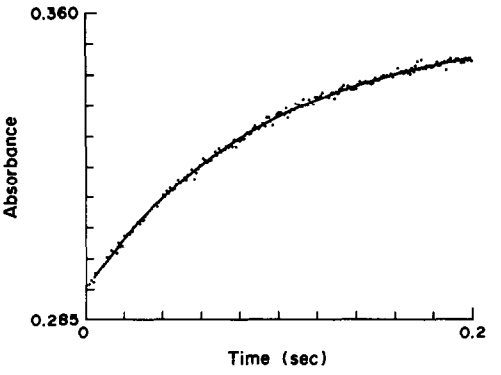


Fig. 1. Fit of a nonlinear reaction model (solid line) to absorbance data collected for the reaction of $6.50 \times 10^{-3}M$ Cl_T with $1.5 \times 10^{-4}M$ N_T. Solution absorbance data collected at 245 nm for the appearance of NH_2Cl. Reaction model is based on a reaction order of 1.0 for NH_3.

The pseudo-order rate constant returned by the fitting routine is derived from absorbance data collected during the reaction. Equation (11) shows the rate constant derived in terms of concentration units. The molar absorptivity, ϵ, and the cell path-length, l, must be used as a factor to equate the two. Equation (10), written in terms of the initial reaction conditions and the absorbance, gives:

$$(\text{Rate})_0 = k''\epsilon l[N_T]_0^n \quad (12)$$

Values for $[N_T]_0$ and k'' from the fitting routine were used to calculate $(\text{Rate})_0$ for each solution. This theoretical initial rate provides a value for $(\text{Rate})_0$ that is not influenced by the instrument dead-time or by noise in the data. Taking the logarithm of both sides of equation (12) gives:

$$\ln(\text{Rate})_0 = n \ln[N_T]_0 + \ln(k''\epsilon l) \quad (13)$$

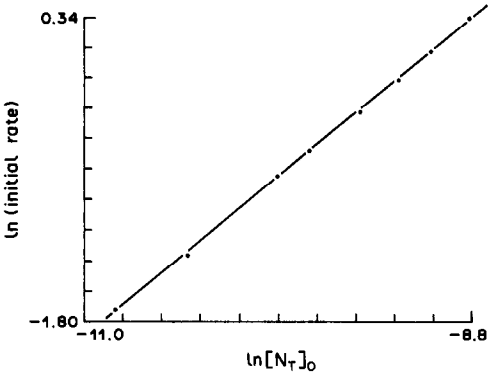

Fig. 2. Plot to determine the reaction order for NH_3. Initial rates are determined from values of k'' returned by the nonlinear fitting routine. Slope = 1.023_6. Standard error of the estimate = 0.019_3. Variance of the slope = 1.1×10^{-4}.

A plot of the logarithm of $(\text{Rate})_0$ *vs.* the logarithm of $[N_T]_0$ should yield a line with a slope equal to the reaction order for ammonia. Values k'' were determined from each experiment. A log–log plot of the data is shown in Fig. 2. Linear-regression analysis of the line provided a value of 1.02 for the slope and thus, from equation (13), the reaction order for NH_3.

A reaction model was then derived, based on equation (10) and a reaction order of 0.8 for NH_3. The collected data were re-analyzed with the nonlinear fitting routine.[29] A consistent pattern in the residuals to the fit indicated that the model with a reaction order of 0.8 for NH_3 did not fit the data as well as did the model with an order of unity.

As a further test, the nonlinear fitting routine was supplied with a model in which the reaction order was an adjustable parameter. With this model, the fitting reproduced the data well at each concentration tested. Since the reaction order was a parameter, a "best fit" value was returned by the program. Reaction order values in the range 0.93–1.03 were returned after each fit. The reaction order values for these experiments all indicate a reaction order of unity for NH_3, and this reaction order has also been determined from experiments[21] performed with excess of ammonia present.

Determination of the rate constant for the initial Berthelot reaction step

The second-order rate expression given in equation (9) cannot be integrated directly. However, the change in concentration of the two reagents is linearly related. Equation (9) can be written in terms of an "extent of reaction" variable, x, giving:

$$dx/dt = k'(a - x)(b - x) \qquad (14)$$

where a and b represent the initial concentrations of the two reactants, and k' is given by:

$$k' = \frac{k_1 \epsilon l}{(1 + K_a/a_H\gamma)(1 + K_b a_H/K_w\gamma)} \qquad (15)$$

Equation (14) can be expressed in terms of absorbance for the reacting solution. After substitution of the appropriate terms, and integration, it has been shown[30] that equation (14) provides:

$$\ln \frac{(A_f - A_0) - (a/b)(A - A_0)}{(A_f - A)} = k'(b - a)t \qquad (16)$$

A reaction model based on equation (16) was written into the previously described simplex fitting routine.[29] The program was used to analyze data collected from experiments done under second-order conditions. Values of k', A_0 and A_f were used as adjustable parameters. The model reproduced the data very accurately, showing only random noise in a plot of the residuals. Figure 3 shows a typical fit to the data at 292 nm for disappearance of OCl^-. Equation (15) was used to determine the second-order rate constant from values of k' returned by the fitting routine. The values 3.2×10^{-8} and 1.774×10^{-5} were used for K_a for HOCl[31] and K_b for NH_3,[32] respectively. The rate constant was determined to be $(3.24 \pm 0.05) \times 10^6$ $1.\text{mole}^{-1}.\text{sec}^{-1}$. In the rate constant determinations in these studies it was assumed that the errors were confined to the value of k'.

Another series of second-order kinetics experiments was done to determine the rate constant from data collected by monitoring the appearance of NH_2Cl, by measurements at 245 nm. The model again gave a close fit to the data, as seen in the typical example shown in Fig. 4. The rate constant determined from the series of experiments was $(3.0 \pm 0.3) \times 10^6$ $1.\text{mole}^{-1}.\text{sec}^{-1}$. The loss of precision in this set of results is due to the small ΔA obtained during the reaction, and the consequent decrease in precision. These results are summarized in Table 1 and compared with previously determined rate constant values.

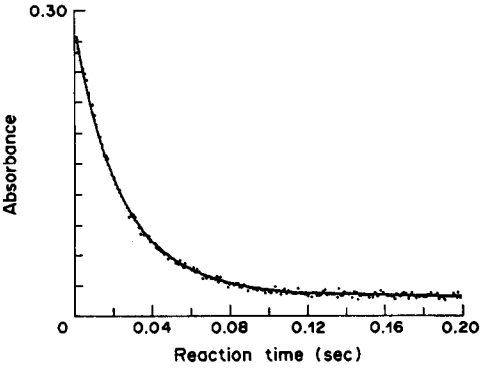

Fig. 3. Fit of a second-order reaction model (solid line) to absorbance data collected for the reaction of $1.98 \times 10^{-3}M$ Cl_T with $5.11 \times 10^{-3}M$ N_T. Solution absorbance data collected for the disappearance of OCl^- at 292 nm. $k' = 1.744 \times 10^4$. Rate constant: $k_1 = (3.24 \pm 0.05) \times 10^6$ $1.\text{mole}^{-1}.\text{sec}^{-1}$.

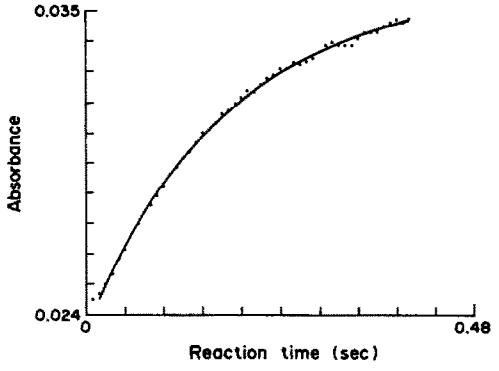

Fig. 4. Fit of a second-order reaction model (solid line) to absorbance data collected for the reaction of $2.40 \times 10^{-4}M$ Cl_T with $1.20 \times 10^{-3}M$ N_T. Solution absorbance data collected for the appearance of NH_2Cl at 245 nm. $k' = 2.467 \times 10^4$. Average $k_1 = 3.01 \times 10^6$. Standard deviation $= 2.6 \times 10^5$. Rate constant: $k_1 = (3.0 \pm 0.3) \times 10^6$ $l.mole^{-1}.sec^{-1}$.

Effect of pentacyanoferrate compounds on the initial reaction

Solutions of HOCl and NH_3 containing SpF were prepared and absorbance data for these mixtures were analyzed with the simplex fitting routine and the same second-order reaction model used for the reaction in the absence of SpF. Again, the model closely reproduced the data for each concentration tested; residuals for the fit showed only random variations. The coupling reagent produced no noticeable effect on the results. Values of k_1 were calculated from k'. The rate constant determined in the presence of SpF was $(3.13 \pm 0.06) \times 10^6$ $l.mole^{-1}.sec^{-1}$, which is equivalent (within the error limits) to be value obtained with SpF absent. The coupling reagent thus does not effect the first step of the Berthelot reaction sequence.

The reaction between NH_2Cl and phenol

The ultraviolet spectra for $10^{-4}M$ NH_2Cl and $10^{-5}M$ phenol were recorded, scaled and summed to represent the spectrum of the reaction mixture at the instant of mixing. Ultraviolet spectra recorded for the reaction mixture at pH 8 were found to be identical with the theoretical spectrum when the reaction time exceeded 3 hr. Similar experiments performed at various pH values (8–10) likewise indicated little or no change in the reaction mixture spectra with time.

Experiments under the same conditions as for this study were performed, with the exception that the phenol solutions contained the coupling reagent SpF ($10^{-4}M$). Under these conditions the reaction mixture spectrum rapidly changed from that of NH_2Cl and phenol to a spectrum identical to that of indophenol. The solutions became blue shortly after mixing. SpF was thus found to affect directly the second step of the Berthelot reaction sequence. In the presence of SpF (and other pentacyanoferrate compounds), the reaction progresses rapidly through the final step of the Berthelot reaction sequence.

Isolation of chlorimine from reaction mixtures

In the Berthelot reaction sequence proposed by Bolleter *et al.*,[4] NH_2Cl couples with phenol to produce chlorimine. This product has never been directly identified as a Berthelot reaction intermediate. Although chlorimine absorbs in the ultraviolet region, phenol exhibits such broad, strong absorption bands that chlorimine and other ultraviolet-absorbing species are obscured. Chlorimine must first be extracted from Berthelot reaction mixtures if it is to be identified spectrophotometrically.

Beer's law can be used to determine distribution ratios from absorbance data collected for the species involved in the second step of the Berthelot reaction sequence. The concentration distribution ratio, D_c, is given by $D_c = [C]_0/[C]_w$. For extraction from water (with 1:1 phase-volume ratio), $D_c = (A_{tot} - A_f)/A_f$, where A_{tot} and A_f are the initial and final absorbances of the phases from which the extraction is made. When the extraction is from n-heptane into water, D_c is the reciprocal of this fraction. Table 2 lists distribution ratios for several Berthelot reagents. Only chlorimine is preferentially extracted into n-heptane. It should thus be possible to extract into n-heptane some of the chlorimine produced in the reaction

Table 1. Rate constants for the reaction between HOCl and NH_3

Table 2. Distribution ratios between water and n-heptane

Chemical species	Extracted from	A_{tot}	A_f	D_c
chlorimine	water	0.407	0.088	3.6
phenol	n-heptane	1.177	0.137	0.132
phenolate	water	0.988	0.987	ns
SpF	water	0.635	0.635	ns
indophenolate	water	0.742	0.742	ns
monochloramine	n-heptane	0.302	0.066	0.28

A_{tot} is the absorbance at λ_{max} in the indicated phase before the extraction from it.
A_f is the absorbance at λ_{max} for the same phase after the extraction.
ns indicates species that are nonsoluble in n-heptane.

between phenol and NH_2Cl. Phenol and NH_2Cl, which might be extracted along with the chlorimine, could be washed back into the aqueous phase with water.

Figure 5a shows the ultraviolet spectrum of an n-heptane extract from an aqueous solution in which the Berthelot reaction was in progress. Also shown in Figure 5a are the spectra recorded for the same n-heptane phase after two successive washes with distilled water. As can be seen, the major peak in the original organic phase belonged to a species which was preferentially washed from the n-heptane, leaving behind a component that gave a peak which had appeared as the shoulder in the original spectrum. Figure 5b compares the spectrum of the n-heptane extract after the final aqueous wash, with the spectrum of a lower concentration of chlorimine dissolved in n-heptane. This evidence shows that chlorimine is indeed formed in the reaction between phenol and monochloramine. The major band consisting of three peaks was identified as that for undissociated phenol. As indicated by the distribution ratios in Table 2, phenol should be stripped into an aqueous phase preferentially to chlorimine. This back-extraction of phenol leaves behind most of the chlorimine, which is easily identified in the n-heptane phase. This represents the first direct evidence of the formation of chlorimine in the Berthelot reaction sequence.

Hydrolysis of chlorimine

The time-dependent spectra of a solution of chlorimine undergoing hydrolysis are shown in Figure 6. Hydrolysis occurs as a first-order process, owing to the large excess of water in aqueous solutions. The rate of hydrolysis can be written as:

$$\text{Rate} = \frac{-(\mathrm{d}[C])}{\mathrm{d}t} = \frac{-\mathrm{d}A}{\epsilon b\,\mathrm{d}t} = k_h[C] \qquad (17)$$

where C represents chlorimine and A is the absorbance of chlorimine during the reaction. As with other first-order processes, the rate constant for hydrolysis can be determined from a plot of the initial rate *vs.* the initial concentration of chlorimine. The initial rate is determined from the initial slope of the reaction curve for a solution undergoing hydrolysis. Initial rates were determined for each reacting solution. The slope of the resulting line was determined by linear-regression analysis. The rate constant for hydrolysis was determined from the known molar absorptivity of chlorimine[21] and the cell path-length. The value of 3.8×10^{-6} sec^{-1} (2.3×10^{-4} min^{-1}) was calculated for k_h. Values for k_h in the range $2\text{–}9 \times 10^{-6}$ sec^{-1} have been determined[21] from data collected under various reaction conditions.

The reaction between chlorimine and phenol

Pseudo-first-order conditions were chosen for studying the reaction between chlorimine and phenol.

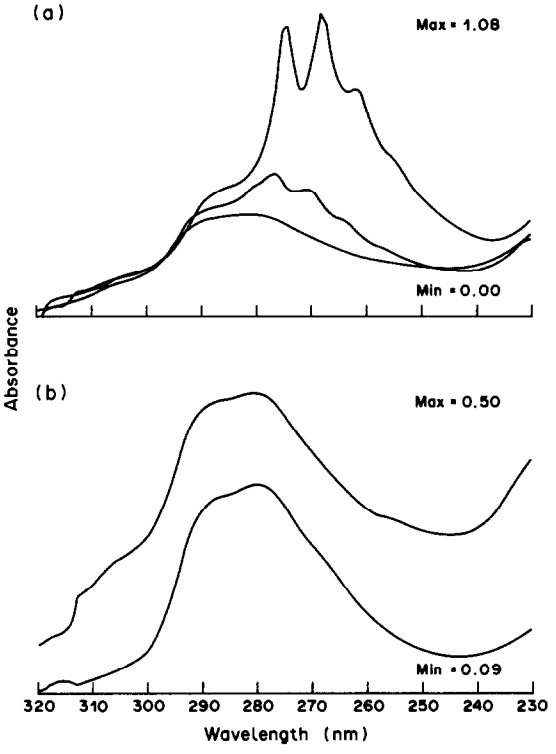

Fig. 5. (a) Spectra of an n-heptane extract of a Berthelot reaction mixture (upper spectrum) and the same n-heptane phase after two successive washes with an equal volume of water (lower two spectra). (b) Comparison of the spectrum of chlorimine in n-heptane (lower curve) with the spectrum obtained by extracting and isolating an intermediate from an aqueous solution undergoing the Bertholet reaction. The solutions are not of equal concentration.

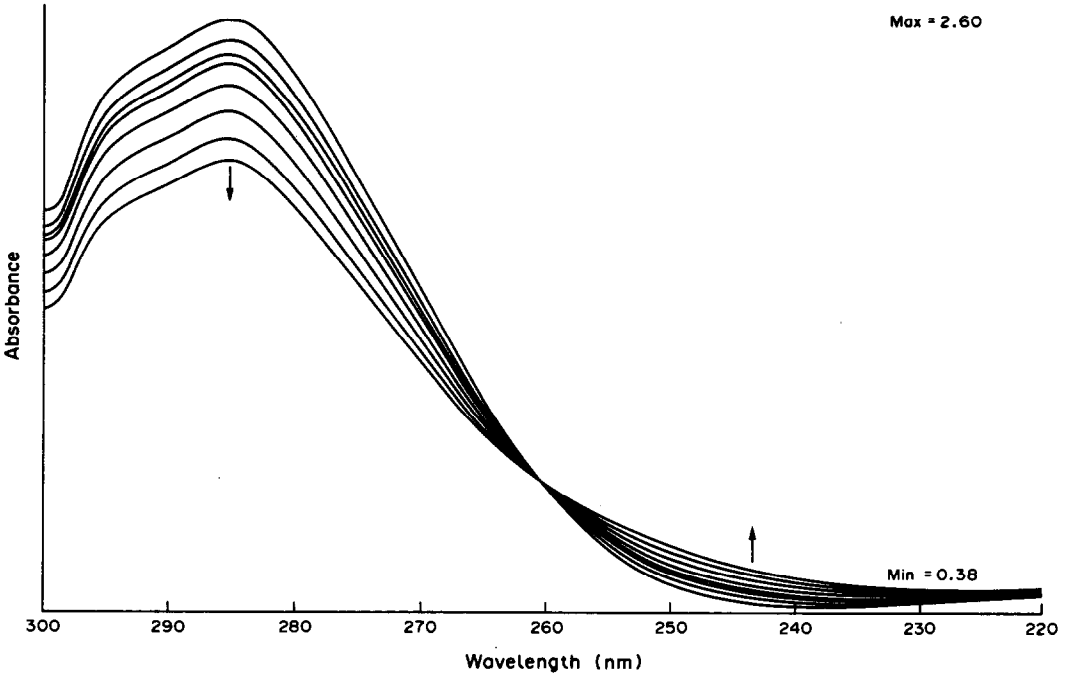

Fig. 6. Time-dependent spectra of an aqueous chlorimine solution at pH 10. Multiple spectra are recorded over a 4-hr interval. The absorption band of chlorimine at 287 nm decreases with time, owing to hydrolysis.

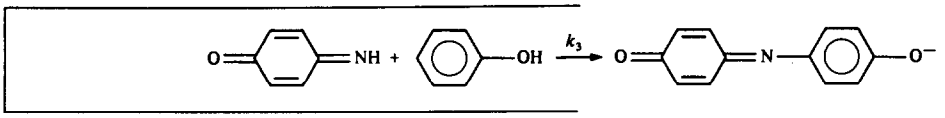
The absorbance–time reaction profile was found to be sigmoidal. Such a reaction profile is similar in shape to reaction curves obtained from multi-step reactions.[30] Clearly, some unexpected reaction contributes to the overall rate to produce the observed reaction profile, but the absorption spectrum of the final mixture was found to be identical to that of indophenol; indophenol is still the only observed product of the reaction.

Svobodová *et al.*[14,15] have found that hydrolysis of 2,6-dichloroquinonechlorimine produces 2,6-dichloroquinoneimine. Both compounds were shown to react with phenol to produce indophenol. Surprisingly, the hydrolysis product, quinoneimine, was found to react at a faster rate than the parent 2,6-dichloroquinoneimine. Such a mechanism could cause a sigmoidal reaction profile.

In solutions containing a large excess of phenol, chlorimine undergoes parallel first-order reactions: Equation (18) represents hydrolysis of chlorimine. Equation (19) represents the reaction between chlorimine and phenol to produce indophenol. Quinoneimine formed by reaction (18) will also react with phenol to produce indophenol:

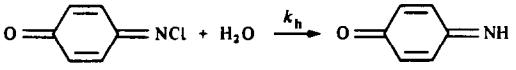


(20)

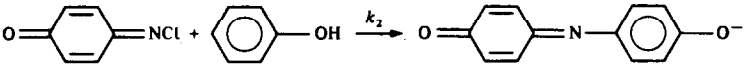
If $k_2 \gg k_h$, hydrolysis is negligible in comparison to the rate of reaction (19). However, if k_2 is not significantly greater than k_h, hydrolysis will produce a measurable amount of quinoneimine. As quinoneimine forms, it reacts with phenol to produce indophenol in parallel with reaction (19). The rate of formation of indophenol can then be written as:

$$\frac{d[\text{Indophenol}]}{dt} = k_2[C][PhOH] + k_3[Q][PhOH] \quad (21)$$

where [C] is the concentration of chlorimine, [Q] is the concentration of quinoneimine, and [PhOH] is the phenol concentration. The observed increase in the reaction rate would then occur if $k_3 > k_2$.



(18)



(19)

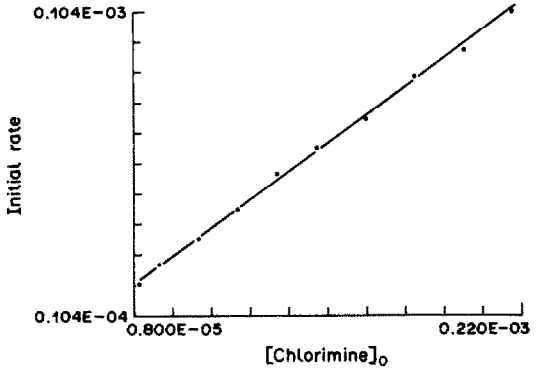


Fig. 7. Plot of the initial reaction rate *vs.* the initial concentration of chlorimine for the reaction of a series of chlorimine solutions (1.1×10^{-5}–$2.2 \times 10^{-4} M$) with $9.54 \times 10^{-3} M$ phenol at pH 9.71. Slope = 0.446. Standard error of the estimate = 6.6×10^{-6}. Variance of the slope = 9.8×10^{-4}.

Under pseudo-first-order conditions with phenol in excess, the pseudo-order rate constants k_2' and k_3' are given by:

$$k_2' = k_2[\text{PhOH}] \tag{22}$$

$$k_3' = k_3[\text{PhOH}] \tag{23}$$

A value for k_3' at pH 9.71 and $9.54 \times 10^{-3} M$ phenol is calculated, from the k_3 value reported by Corbett,[13] to be 3.8×10^{-2} min^{-1}.

Since the concentration of quinoneimine is zero at the start of the reaction, equation (21) reduces to:

$$(\text{Rate})_0 = k_2' \epsilon l [\text{C}]_0 \tag{24}$$

The data were analyzed to determine initial rates through linear-regression analysis of the initial slope of the sigmoidal-shaped reaction curves. A plot of initial rate *vs.* initial concentration is shown in Fig. 7. The slope of the line provides a value for k_2'. With log $\epsilon = 3.95$ for indophenol,[7] k_2' is calculated to be $(5.0 \pm 0.3) \times 10^{-5}$ sec^{-1} (3.0×10^{-3} min^{-1}). This value is sufficiently greater than k_h for the initial reaction rate indeed to be free from hydrolysis effects. However, it is not large enough for hydrolysis of chlorimine to be negligible. As quinoneimine is produced, it reacts with phenol more rapidly than does chlorimine. The effect is an increase in the rate of production of indophenol. Such multi-step reaction mechanisms are known to produce sigmoidal-shaped reaction profiles.

The rate constant for the reaction between chlorimine and phenol can be determined by using equation (23) and the value of k_2'. The second-order rate constant for the reaction is thus determined to be $(5.3 \pm 0.4) \times 10^{-3}$ l.mole^{-1}.sec^{-1}.

The effect of SpF on the final reaction step

Previous studies[6,7] on the effect of aquopentacyanoferrate, AqF, on the Berthelot reaction indicated that the greatest amount of indophenol was produced when the concentration of AqF equalled that of NH_2Cl. Greater concentrations of AqF caused the resulting solutions to turn green rather than the blue characteristic of indophenols. The product responsible for the green color was not identified.

Mole-ratio experiments performed to study the effect of SpF on the Berthelot reaction correlated well with these previous results.[21] Furthermore, SpF was found to react rapidly with chlorimine to produce a green product. The spectrum of the resulting green solutions[21] matched the absorption spectra of the previously noted green products.[6,7] This reaction would also account for the formation of a green product, observed by Corbett,[18] under similar conditions. The reaction responsible for the formation of the green product has thus been identified as a reaction occurring between chlorimine and the pentacyanoferrate compound.

Figure 8 shows a pseudo-first-order nonlinear fit to the reaction data for a solution containing $1.58 \times 10^{-5} M$ chlorimine and $6.29 \times 10^{-5} M$ SpF. The solution was allowed to react with an excess of phenol. The model used to fit the data was identical to the model used in the absence of SpF, yet the model still reproduces the data well. The presence of SpF at four times the concentration of chlorimine does not alter the reaction rate profile derived for the reaction between chlorimine and phenol. Other more concentrated solutions prepared to determine the rate were influenced by the reaction between chlorimine and SpF (evidenced by the formation of a green color in solution). It was not possible to determine rate constants from these solutions. However, from these limited data, SpF appears to have little or no effect as a catalyst in the reaction between chlorimine and phenol.

Conclusions

The results of these studies indicate that NH_3 has a reaction order of 1 and not 0.8 in the reaction between HOCl and NH_3. The first step of the

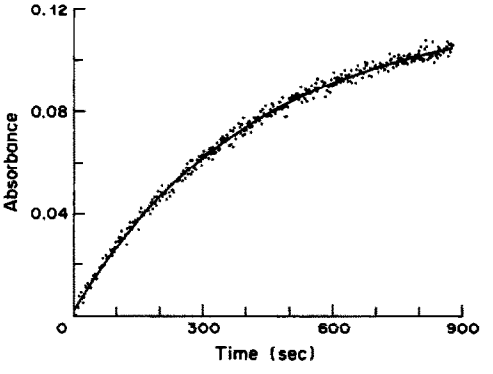

Fig. 8. Fit of a pseudo-first-order reaction model (solid line) to data collected for a reaction between phenol and chlorimine in the presence of SpF.

Berthelot reaction is rapid, with a rate constant of 3.2×10^6 l.mole^{-1}.sec^{-1}. Pentacyanoferrate coupling reagents have no effect on the rate of this reaction.

The second step of the Berthelot reaction is rate-limiting in the absence of pentacyanoferrate coupling reagents. Pentacyanoferrate compounds directly affect the rate of the second reaction step. The product of the second step of the Berthelot reaction has been shown to be benzoquinonechlorimine.

The final step of the Berthelot reaction involves a reaction between chlorimine and phenol to produce indophenol. The rate constant for the reaction was determined to be 5.3×10^{-3} l.mole^{-1}.sec^{-1}. Chlorimine hydrolyzes at a lower (but not negligible) rate than that for its reaction with phenol. The hydrolysis product also reacts with phenol to produce indophenol. Pentacyanoferrate compounds have little or no affect on the reaction between chlorimine and phenol. However, aquopentacyanoferrate and sulfitopentacyanoferrate do react with chlorimine to produce an unidentified green product which interferes with the Berthelot reaction. It thus is necessary to avoid excess amounts of these compounds during Berthelot ammonia determinations.

POTENTIOMETRIC ION- AND BIO-SELECTIVE ELECTRODES BASED ON ASYMMETRIC CELLULOSE ACETATE MEMBRANES

GEUN SIG CHA and MARK E. MEYERHOFF*
Department of Chemistry, The University of Michigan, Ann Arbor, MI 48109-1055, U.S.A.

(*Received* 6 *May* 1988. *Accepted* 14 *July* 1988)

Summary—The potentiometric response properties of ammonium-, carbonate-, and proton-selective electrodes prepared by incorporating appropriate neutral carriers within novel asymmetric cellulose acetate membranes are reported. The membranes are formed by first casting a thin layer of cellulose triacetate without carrier, hydrolyzing one side of this film with base, and then on the other side casting a second layer of cellulose triacetate containing the membrane active components. The resulting asymmetric ion-selective membranes function equivalently, in terms of selectivity and response slopes, to non-asymmetric cellulose triacetate membranes and conventional poly(vinyl chloride)-based membranes. The hydrolyzed surface of the asymmetric membranes can be activated in aqueous solution with carbonyldiimidazole for the direct immobilization of proteins on the surface of the membranes, without loss in potentiometric ion-response. As an example, the immobilization of urease on the surfaces of ammonium- and carbonate-selective membranes yields potentiometric bio-selective urea-probes with desirable dynamic response properties.

Over the last two decades, a variety of potentiometric ion- and gas-selective membrane electrodes have been used as detection elements to prepare novel bio-selective electrodes.[1–6] Such bio-electrodes are generally fabricated by immobilizing appropriate biological species (*e.g.*, enzymes, intact cells, antibodies, etc.) in a layer adjacent to the sensing membrane of the electrodes. Often, this process involves covalently attaching the bioreagents to a secondary membrane which can then be mounted on the ion- or gas-sensing membrane. Alternatively, the bioreagents can be crosslinked or entrapped within a gel layer adjacent to the sensing surface. However, the adhesiveness, thickness, and enzyme-loading factor of these layers are critical to the performance (including response times and stability) of the resulting devices.[4–8] In this paper, we report on the development of a new type of ion-selective polymeric membrane to which enzymes and other biospecies can be covalently attached directly, for the purpose of preparing potentiometric bio-selective electrodes with improved response properties.

Interest in using solvent/polymeric membrane electrodes as the sensors in bio-electrodes arises from the high ion-selectivities, rapid response times (compared to gas-sensors), and ease of fabrication (for disposable sensors) associated with these devices. Traditionally, the most analytically useful membranes are prepared by incorporating electrically neutral carrier molecules into plasticized poly(vinyl chloride) (PVC) membranes.[9–12] Direct covalent attachment of bioreagents to the surfaces of such membranes would require the incorporation of functional groups, either in the form of membrane-soluble lipophilic additives or derivatized polymeric materials. However, such changes in membrane composition can result in loss of potentiometric ion-selectivity.[12,13] Recently, various groups have demonstrated that carboxylated-PVC can be used as a replacement for regular PVC without decreasing the selectivity of neutral carrier-based membranes.[14–16] Moreover, certain enzymes or crosslinked enzyme gels have been shown to adhere tightly, albeit non-covalently, to the surfaces of these carboxylated membranes.[17,18]

One of our long-term goals has been to devise methods for covalent attachment of very thin films, even monolayers, of bioreagents directly to the surface of polymeric ion-selective electrodes (ISEs) without altering the ion-response of the electrodes. Although some success has been achieved by using aminated-PVC as a membrane matrix,[16] we now describe a new approach involving asymmetric plasticized cellulose acetate membranes. Though ISEs for calcium, based on cellulose acetate membranes, have been described previously,[19] the use of cellulose acetate in the fabrication of solvent/polymeric electrodes is not widespread, nor have there been any attempts to use such membranes to prepare biosensors.

In the proposed method, one side (the sample side) of a thin layer of cellulose triacetate cast without active membrane components is hydrolyzed with base. A second layer of cellulose acetate containing the appropriate neutral carrier and plasticizer is then cast on the other side of the cellulose triacetate film

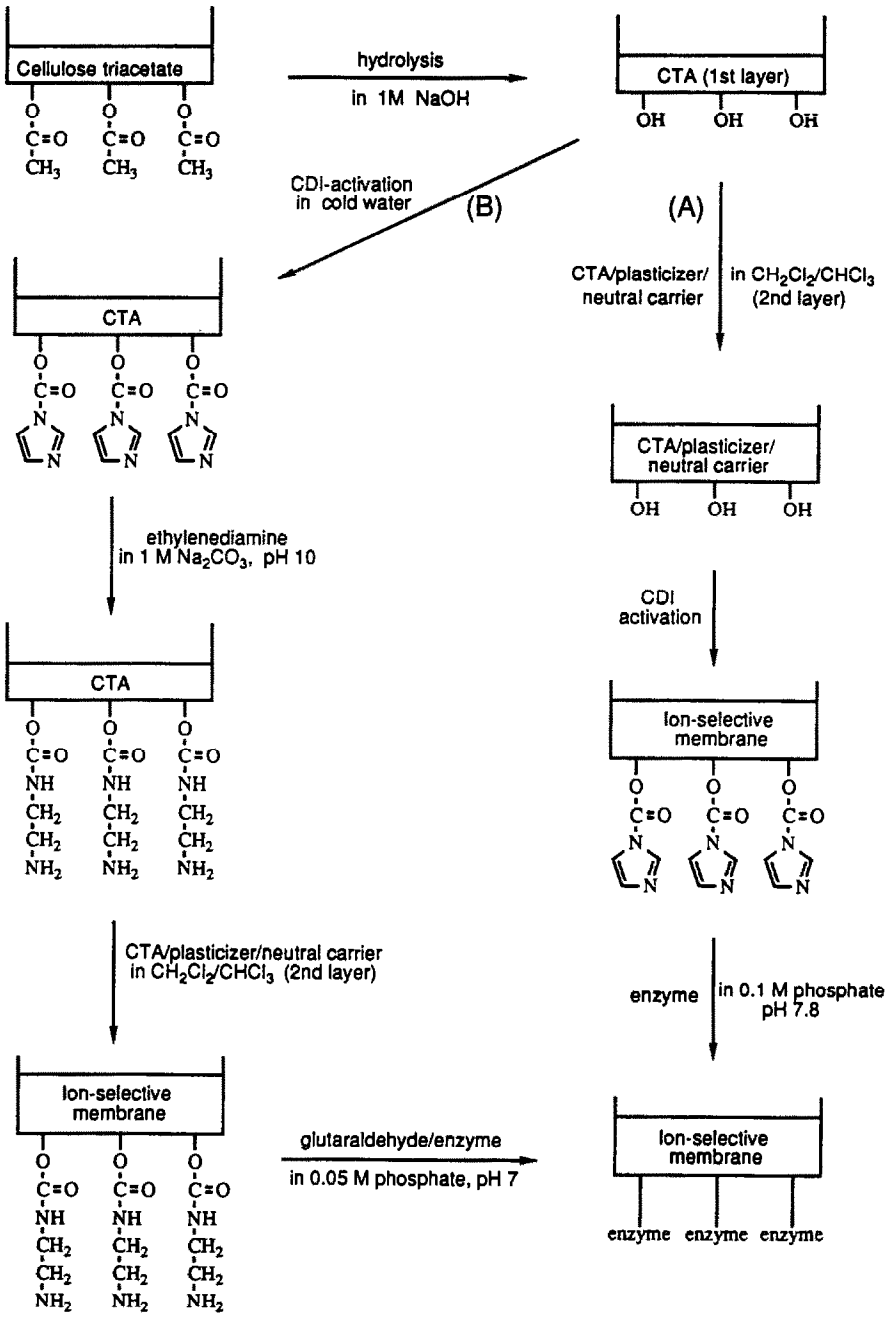

Fig. 1. General schemes used to prepare enzyme-immobilized asymmetric ion-selective cellulose triacetate membranes; (A) the direct CDI method for the hydroxylated membrane; (B) the glutaraldehyde method for aminated membrane.

(see Fig. 1). Ammonium-, carbonate-, and pH-selective membranes serve as models for these investigations. These membranes are prepared with nonactin, trifluoroacetyl-*p*-butylbenzene, and tridodecylamine, respectively. The hydroxyl groups on the hydrolyzed surface of the membrane can be activated in aqueous solution with carbonyldiimidazole (CDI). Three different methods can then be used to attach enzymes or other proteins directly to the surface of the ion-selective electrodes. The relative advantages and disadvantages of each attachment method are demonstrated by evaluating the performance of a number of urea-selective electrodes prepared with immobilized urease.

EXPERIMENTAL

Apparatus

The external reference electrode was a Fisher double-junction Ag/AgCl electrode with an outer cracked-bead junction. All membranes were mounted in Phillips electrode

bodies (IS-561) (Glasblaserei Möller, Zurich). For potentiometric measurements of ion-responses, the ISEs and external reference electrode were connected through high-impedance amplifiers to a Zenith Z-100 PC computer equipped with a Data Translations (DT2801) analog-to-digital converter. The potentiometric response of enzyme electrodes was measured with a Fisher Model 620 pH/mV meter and recorded on a Fisher Recordall Series 5000 strip-chart recorder.

Reagents

Cellulose triacetate (CTA), 1,1′-carbonyldiimidazole (CDI), bis(2-ethylhexyl) sebacate and nonactin were obtained from Fluka (Ronkonkoma, NY), and dipentyl phthalate, tridodecylamine, and sodium tetraphenylborate were products of Eastman Kodak (Rochester, NY). Trifluoroacetyl-*p*-butylbenzene (TFABB) was purchased from Specialty Organics, Inc. (Irwindale, CA), tridodecylmethylammonium chloride from Polysciences, Inc. (Warrington, PA), 1,1,2,2,-tetrachloroethane from Aldrich Chemical Co. (Milwaukee, WI) and urease (Type VII, from jack beans) from Sigma Chemical Co. (St. Louis, MO).

All other chemicals used were analytical-reagent grade. Standard solutions and buffers were prepared with demineralized water.

Preparation of various ion- and bio-selective membranes

Figure 1 summarizes the schemes used to prepare asymmetric ion-selective CTA membranes with immobilized enzymes. Details of these methods are described below.

Hydroxylated or aminated cellulose triacetate membranes. A thin membrane (*e.g.*, 50 μm) was prepared by dissolving 100 mg of CTA in a mixed solvent (1.5 ml of methylene chloride, 0.5 ml of chloroform and 0.5 ml of 1,1,2,2-tetrachloroethane) and casting the mixture in a 36-mm (i.d.) glass ring placed on a glass plate. The solvent was allowed to evaporate for 2 days. Acetyl groups on the bottom side of the membrane were then hydrolyzed by floating the membrane on 1*M* sodium hydroxide for 4.5 hr. After washing with distilled water, the membrane was air-dried.

To introduce amino groups onto the membrane, the hydroxyl groups (resulting from the hydrolysis procedure) of the membrane were activated with CDI by immersing the bottom side of the membrane in 20 ml of cold distilled water (4°) and adding an excess of 1,1′-carbonyldiimidazole (about 50 mg) in 10–15 mg portions over a 15-min period. After brief washing with cold water, the membrane was immersed in a 12.5% (w/v) ethylenediamine solution in 1*M* sodium carbonate buffer (pH 10) for 3 hr at room temperature. After extensive washing with water, the membrane was air-dried.

Asymmetric cellulose triacetate ion-selective membranes. The hydroxylated or aminated membranes were placed on a glass plate with the derivatized surface face down. The unmodified upper surface of the membrane was then pretreated for 30 min with 1.2 ml of methylene chloride inside a 22-mm (i.d.) glass ring placed on top of the membrane. During this period, the membrane was kept inside a desiccator to reduce evaporation of the methylene chloride. A mixture containing the appropriate amounts of membrane components, depending on which ion-selective membrane was being prepared, was then put inside the glass ring. In all cases, 35 mg of CTA was utilized with a mixed solvent of 0.8 ml of methylene chloride and 0.8 ml of chloroform. Additional components (*i.e.*, plasticizer, neutral carrier, or lipophilic additive) for each ion-selective system were as follows: 6 mg of nonactin and 120 μl of dipentyl phthalate for NH_4^+; 100 μl of bis(2-ethylhexyl) sebacate, 8.3 mg of trifluoroacetyl-*p*-butylbenzene, and 3.1 mg of tridodecylmethylammonium chloride for CO_3^{2-}; 155 μl of dipentyl phthalate, 20 mg of tridodecylamine, and 12 mg of sodium tetraphenylborate for H^+. Again, the mixed solvent was allowed to evaporate very slowly by keeping the membrane in a vacuum desiccator with the tap only slightly open. In this manner, the two membrane layers were fused into a single asymmetric membrane.

Smaller disks were punched from these membranes and mounted in Phillips electrode bodies with the derivatized side facing the outer sample solution. The inner filling solution varied, depending on which ion-selective membrane was being evaluated (0.1*M* NH_4Cl for NH_4^+-selective membranes; 0.1*M* NaH_2PO_4/0.1*M* Na_2HPO_4/0.01*M* NaCl for CO_3^{2-}-selective membranes; 0.02*M* NaH_2PO_4/0.03*M* Na_2HPO_4/0.015*M* NaCl for H^+-selective membranes). All potential measurements were made at room temperature, with 200 ml of sample solution, after conditioning the membranes overnight.

Direct immobilization of urease on hydroxylated asymmetric ion-selective membranes. Hydroxylated membranes mounted in electrode bodies were immersed in cold water and activated by adding an excess of 1,1′-carbonyldiimidazole as described above for amination. After brief washing of the membranes with cold water, 10 μl of urease solution [1 mg of urease (615 μmole units/mg) per 10 μl of 0.1*M* sodium phosphate/0.5*M* sodium chloride buffer (pH 7.8)] were applied directly to the surface of the membranes. The reaction was allowed to continue for 12 hr at 4°. The membranes were thoroughly washed with 0.05*M* Tris-HCl buffer (pH 7.2) to remove unbound enzyme and block unreacted active groups.

Immobilization of urease on aminated ion-selective membranes. For the one-step glutaraldehyde method, 10 μl of urease solution (1 mg of urease per 10 μl of 0.05*M* sodium phosphate buffer, pH 7.0) and 4.5 μl of 2.5% glutaraldehyde solution in the same buffer were sequentially applied to the aminated surface of the ion-selective membrane mounted in an electrode body.

For the two-step glutaraldehyde method, the membrane was first activated in 2.5% glutaraldehyde solution for 5 min. After a brief washing of the membrane, 10 μl of urease solution were applied directly to its surface.

After the coupling reactions for 12 hr at 4° the membranes were thoroughly washed with Tris-HCl buffer to remove any excess of glutaraldehyde and unbound enzyme and stored in buffer at 4° when not in use.

Evaluating potentiometric response of ion-selective and enzyme electrodes

The potentiometric responses of various CTA membranes to ions, and corresponding enzyme electrodes to urea, were evaluated with different background electrolytes, depending on which ion-selective system was being examined (0.05*M* Tris-HCl, pH 7.2 for NH_4^+ or urea response with an NH_4^+-selective membrane; 0.1*M* Tris-H_2SO_4, pH 8.75 for CO_3^{2-} response or pH 8.4 for urea response with a CO_3^{2-}-selective membrane; 11.4m*M* boric acid/6.7m*M* citric acid/10.0m*M* NaH_2PO_4 for pH response, or 0.001*M* Tris-HCl/0.1*M* NaCl, pH 7.0 for urea response with a proton-selective membrane). The calibration plots were obtained from additions of standard inorganic salt or urea solutions to 200 ml of background electrolyte at room temperature. The solutions were magnetically stirred throughout and the steady-state or equilibrium potentials were recorded.

RESULTS AND DISCUSSION

A scanning electron micrograph of the cross-section of a typical asymmetric ion-selective cellulose acetate membrane is shown in Fig. 2. It can be seen that the membrane consists of two fused layers; a dense ion-selective plasticized layer covered with a thin modified layer (upper layer). The hydrolyzed

Fig. 2. Scanning electron micrograph showing the cross-section of a typical asymmetric ion-selective cellulose triacetate membrane.

hydrophilic thin layer (approximately 5 μm in thickness) is immiscible with organic solvents (plasticizers) and can be used for covalent immobilization of biomolecules such as enzymes, by CDI-activation methods. Although the initial studies were focused on the direct hydrolysis of homogeneous plasticized CTA membranes, this approach was abandoned since a much longer period (more than 5 days) is required to produce a sufficient number of surface hydroxyl groups and the critical membrane active components (*e.g.*, nonactin) may be degraded during this hydrolysis period.

Previously, organic solvents (*e.g.*, dioxan or acetone) have been used for the CDI-activation of the hydroxylic polysaccharide matrices (*e.g.*, crosslinked agarose or dextran, cellulose, *etc.*).[20-22] Unfortunately, these organic solvents will dissolve the membrane active components (*i.e.*, neutral carrier or plasticizer) and may, in fact, deform the ion-selective membranes. Therefore, it was critical to find an activation method which would work in aqueous solutions. In subsequent experiments, we found that the CDI-activation can be done in aqueous solution provided that a relatively large amount of CDI is used. Indeed, after coupling of ethylenediamine to the hydrolyzed surface through aqueous CDI-activation (as described in the Experimental section), treatment of the membrane with trinitrobenzenesulfonate reagent (TNBS)[23] gave an immediate orange-red color, indicating that the surface of the membrane had been aminated to a significant degree. Such an experiment provided clear evidence that the hydrophilic layer of the asymmetric membranes could be derivatized and used as a site for later attachment of biomolecules.

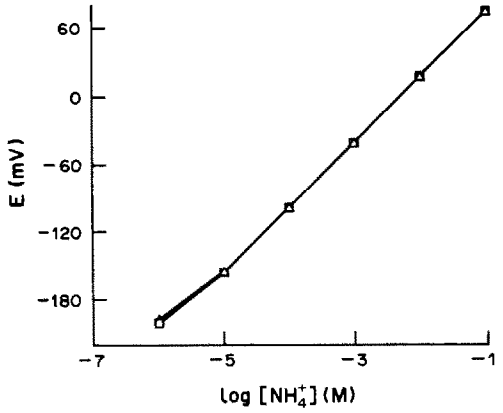

Fig. 3. Potentiometric ammonium response of various cellulose triacetate-based membranes doped with nonactin: (△) hydroxylated asymmetric membrane; (×) aminated asymmetric membrane; (□) unmodified cellulose triacetate membrane.

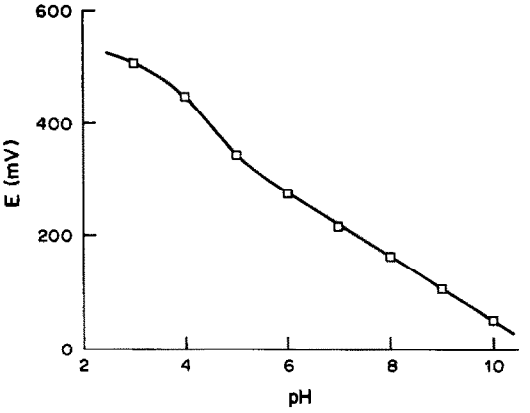

Fig. 5. Potentiometric pH response of a typical TDDA-doped hydroxylated asymmetric membrane. The pH was adjusted by the addition of sodium hydroxide to a buffer containing 11.4m*M* boric acid, 6.7m*M* citric acid, and 10.0m*M* NaH_2PO_4, and monitored with a glass membrane electrode.

Potentiometric ion response and selectivity of asymmetric membranes

The potentiometric response characteristics of the various asymmetric cellulose acetate based ion-selective membranes were evaluated and are shown in Figs. 3–5 and Table 1. As can be seen, the asymmetric ammonium-selective membranes exhibit little or no change in response slope or selectivity compared to the unmodified cellulose triacetate membrane (Fig. 3). The response slope (57 mV per decade over the range from 10^{-5} to $10^{-1}M$ NH_4^+) and the high selectivity for NH_4^+ relative to several other cations (Table 1) were essentially the same as those for PVC-based membranes.[12,16]

Figure 4 illustrates the potentiometric response of trifluoroacetyl-*p*-butylbenzene (TFABB)-doped cellulose acetate membranes to carbonate and several other anions. Again, asymmetric modification (to form hydroxyl groups) had little or no effect on the response characteristics of the membrane. The response slope and selectivity (or lack of it with respect to salicylate) observed are essentially the same as those found for PVC-based membranes previously reported by Greenberg and Meyerhoff.[27] Similar results were obtained with proton-selective asymmetric membranes prepared with tridodecylamine as the membrane active component (see Fig. 5). Although the effect of surface hydroxyl or amine groups on the selectivity of the pH-sensing system was not studied in detail, the fact that nearly Nernstian pH-response was observed between pH 5 and 10 in the presence of 10m*M* Na^+, suggests that the high selectivity relative to alkali-metal cations is preserved when the asymmetric membrane is used.

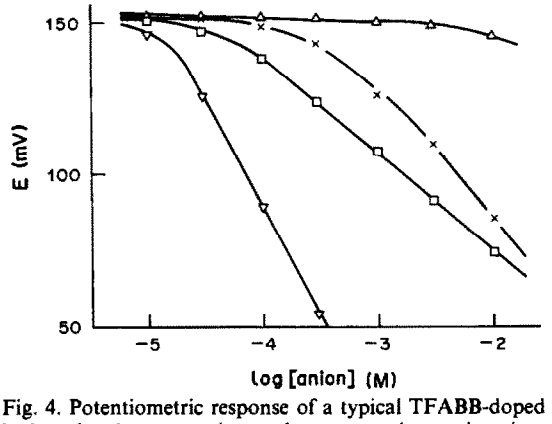

Fig. 4. Potentiometric response of a typical TFABB-doped hydroxylated asymmetric membrane to various anions in a background of 0.1*M* Tris-H_2SO_4, pH 8.75: (△) Cl^-; (×) NO_3^-; (□) total CO_2 (predominantly carbonate and hydrogen carbonate); (▽) salicylate.

Response characteristics of bio-electrodes prepared with asymmetric ion-selective membranes

All three ion-selective membranes (NH_4^+, CO_3^{2-}, pH) were evaluated as sensing elements in bio-electrodes. As a model system, we chose to immobilize urease on each of the asymmetric membranes, using a variety of procedures. Urease catalyzes the reaction

$$(NH_2)_2CO + 2H_2O \rightarrow 2NH_4^+ + CO_2 + 2OH^-$$

Thus, each of the products can be detected directly or indirectly by one or other of the asymmetric ion-selective membranes. In the case of the CO_3^{2-} sensor, buffering the sample solution at pH 8.4 allows a fixed fraction of the CO_2 present to be in the form of carbonate anions, detectable by the membrane doped with TFABB.

Initial experiments involved the covalent immobilization of urease on asymmetric ammonium-selective membranes. In one case, the urease was attached directly to the hydroxylated membrane by the aqueous CDI-activation method. In further studies, the urease was coupled to the surface of amine-derivatized membranes by either a one- or two-step

Table 1. Selectivity coefficients of nonactin-based membranes prepared in various matrices

Membrane matrix	$\log k^{pot}_{NH_4^+,j}$*						
	Li^+	Na^+	K^+	Mg^{2+}	Ca^{2+}	$(CH_3)_4N^+$	H^+
CTA	−4.7	−2.9	−0.9	−3.2	−5.0	−3.7	−4.3

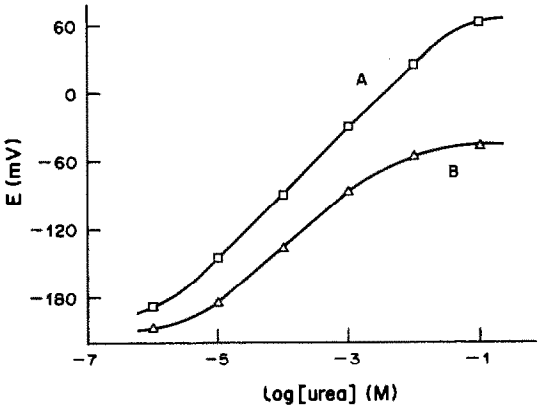

Fig. 6. Typical calibration curves for the urea electrodes prepared by using asymmetic ammonium-selective cellulose triacetate membranes: (A) urease–aminated membrane prepared by the one-step glutaraldehyde method; (B) urease–hydroxylated membrane prepared by the direct CDI activation method.

glutaraldehyde procedure.[25] With the one-step glutaraldehyde method, a thin enzyme layer was formed on the surface of the membrane by crosslinking between enzymes. In all cases, however, immobilizing the enzyme had little or no effect on the response slopes and selectivity of the resulting membranes toward ammonium ions (not shown).

Typical calibration plots for the urea electrodes prepared by using asymmetric ammonium-selective membranes are shown in Fig. 6. The urease-aminated membrane prepared by the one-step glutaraldehyde method displayed a wide linear response with a slope of 57 mV per decade in the range from 10^{-5} to $10^{-2}M$ urea (curve A). However, the response was reduced when the urease was immobilized on the hydroxylated membrane in conjunction with direct CDI-activation (a slope of 44 mV per decade for 10^{-5}–$10^{-2}M$ urea; curve B). Analogous results were obtained for the urease–aminated membrane prepared by the two-step glutaraldehyde method (not shown). The degree of urea response is still significant, considering that the enzyme is directly attached to the surface of the membrane as a monolayer, without crosslinking networks between enzymes. It is well known that the steady-state potential of enzyme-electrodes can be affected by the amount of immobilized enzyme.[4–8] Thus, in the case of urease immobilized directly on CDI-activated membranes, or by the two-step glutaraldehyde method involving aminated membranes, the enzyme loading levels appear to be significantly lower than those observed with a thicker layer of crosslinked urease.

Owing to an extremely fast mass transfer of species between the external bulk solution and the ion-selective surface, the response of the monolayer enzyme membranes was almost instantaneous upon additions of urea to the sample (see curve A in Fig. 7). The noise on such traces results from the effects of magnetic stirring, causing rapid fluctuations in the steady-state ammonium ion activities in the very thin monolayer of enzyme adjacent to the ion-selective membrane. However, more stable steady-state potentials were obtained with the thicker

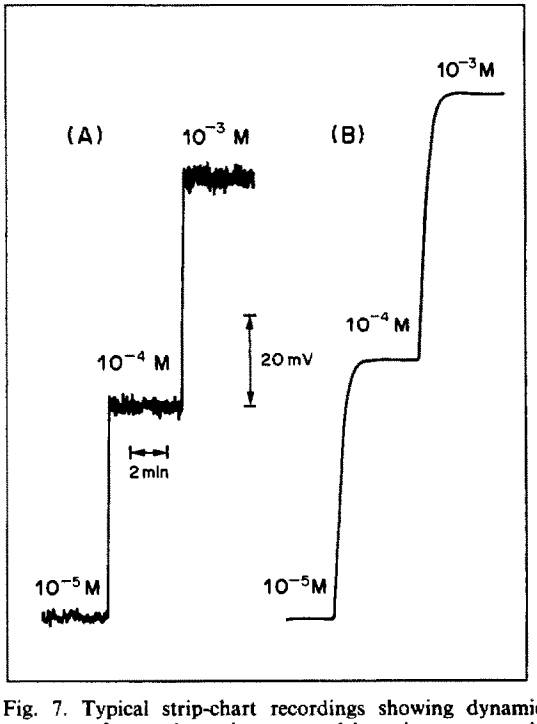

Fig. 7. Typical strip-chart recordings showing dynamic response of urea electrodes prepared by using asymmetric ammonium-selective cellulose triacetate membranes: (A) urease–aminated membrane prepared by the one-step glutaraldehyde method; (B) urease–hydroxylated membrane prepared by the direct CDI- activation method.

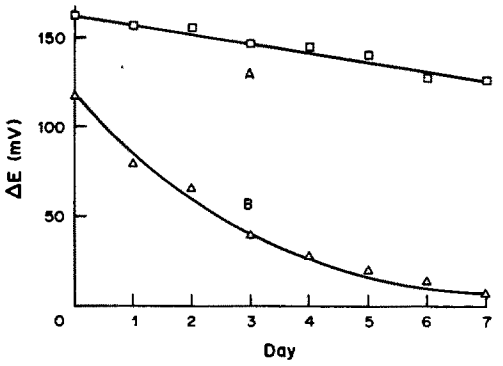

Fig. 8. Stability of urease immobilized on the hydroxylated ammonium-selective cellulose triacetate membranes: (A) covalent attachment with direct CDI-activation; (B) nonspecific adsorption (without CDI- activation). The absolute potential changes towards $10^{-3}M$ urea in $0.05M$ Tris-HCl, pH 7.2 were recorded over a period of 1 week.

one-step glutaraldehyde crosslinked urease membrane (curve B in Fig. 7). The response of this electrode was still faster than reported previously for similar devices prepared with polyacrylamide-encapsulated films of urease coating ammonium-selective membranes.[26] Indeed, the 98% steady-state potential was reached in 45 sec for a concentration change from 10^{-4} to $10^{-3}M$ urea.

The stability of immobilized urease was also evaluated for each covalent attachment procedure. The crosslinked enzyme layer on the aminated membrane still remained active after one month, and during this period, only a slight change in the response slope was observed. On the other hand, the crosslinked enzyme layer on a blank membrane (*i.e.*, urease immobilized by the one-step glutaraldehyde procedure on a hydrolyzed membrane or a nonasymmetric membrane) was easily removed by brief washing with buffer (poor adhesion). The stability of urease attached to the hydrolyzed membrane by the direct CDI method was also checked over a period of 1 week by determining the absolute potential responses to $10^{-3}M$ urea (Fig. 8). The response of the membrane (curve A) was not substantially reduced after a week, whereas the response of the blank membrane (*i.e.*, urease applied to a hydrolyzed membrane without CDI-activation) sharply decreased (curve B). The response in the latter case results from nonspecifically adsorbed urease. It should also be mentioned that the degree of nonspecific adsorption of urease was much greater (approximately 5 times) on nonasymmetric plasticized CTA membranes.

Urea-selective bio-electrodes were also prepared by immobilizing urease on carbonate-selective asymmetric membranes either by the one-step glutaraldehyde method for an aminated membrane (Fig. 9; curve A) or by the direct CDI method for a hydrolyzed membrane (Fig. 9; curve B), The response slopes of each membrane were -29 mV (curve A) and -14 mV (curve B) per decade over the range from 10^{-4} to $10^{-2}M$ urea, respectively. Again, the lower slope for the membrane obtained by the direct CDI immobilization method suggests a decreased level of enzyme loading compared to the crosslinked enzyme membranes. In the case of all bio-electrodes prepared with the carbonate sensor, the response time of the base membranes toward carbonate ions was increased by enzyme immobilization. For all types of enzyme-linked carbonate membranes, the response time (98%) was found to be 55 sec for a concentration change from 10^{-3} to $10^{-2}M$ urea.

Finally, urease was immobilized on the surface of tridodecylamine-based H^+-selective asymmetric membranes. As with other pH-based enzyme electrodes,[27] the calibration curves for urea were obtained in a weakly buffered background electrolyte solution ($0.001M$ Tris-HCl/$0.1M$ NaCl, pH 7.0), and are shown in Fig. 10. Substantial pH changes were observed at the surface of the crosslinked enzyme

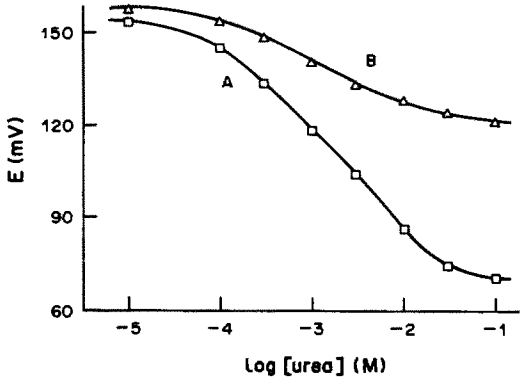

Fig. 9. Typical calibration curves for the urea electrodes prepared by using asymmetric carbonate-selective cellulose triacetate membranes: (A) urease–aminated membrane prepared by the one-step glutaraldehyde method; (B) urease–hydroxylated membrane prepared by the direct CDI-activation method. Potential measurements were made in $0.1M$ Tris-H_2SO_4, pH 8.75.

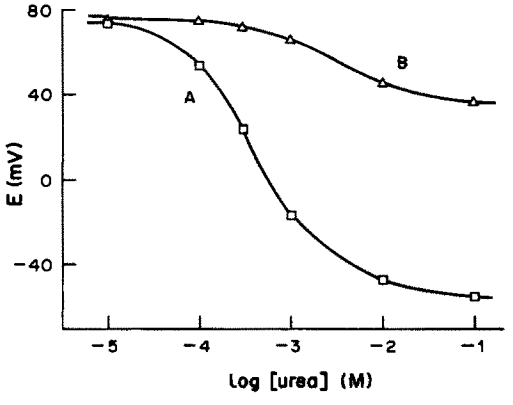

Fig. 10. Typical calibration curves for the urea electrodes prepared by using aminated H^+-selective cellulose triacetate membranes. Urease was attached by one-step glutaraldehyde method (curve A) or two-step glutaraldehyde method (curve B). Potential measurements were made in $0.001M$ Tris-HCl/$0.1M$ NaCl, pH 7.0.

layer membrane in the range from 10^{-5} to $10^{-2}M$ urea (total change 125 mV), whereas bio-electrodes prepared with monolayer enzyme coverage exhibited relatively poor response owing to the rapid transfer of H^+ out of the ultrathin enzyme-layer (*i.e.*, it is not possible to sustain a steady-state pH change adjacent to the pH-sensing membrane.)

In summary, we have described the preparation and performance of a new type of asymmetric ion-selective membrane based on cellulose acetate. The potentiometric response of these membranes toward ions is essentially the same as that of conventional plasticized PVC membranes. More importantly, the hydroxylated side of the membranes can be used to immobilize bioreagents covalently by a variety of reaction schemes without affecting the ionic response or selectivity of the membranes. While immobilization of the enzyme urease in thin crosslinked films results in urea-selective bio-electrodes with a greater degree of enzyme loading, and thus larger urea responses (regardless of the base ion-sensor), the ability to immobilize thin monolayers of biological reagents on the surfaces of functional ISEs by the direct CDI method may prove extremely valuable in the design of other types of bio-electrode systems; *e.g.*, disposable immunoelectrodes, *etc.* Work in this direction is in progress.

MULTIFUNCTIONAL CHEMICALLY MODIFIED ELECTRODES WITH MIXED COBALT PHTHALOCYANINE/NAFION COATINGS

JOSEPH WANG* and RUILIANG LI
Department of Chemistry, New Mexico State University, Las Cruces, NM 88003, U.S.A.

(*Received* 3 *March* 1988. *Accepted* 23 *April* 1988)

Summary—A novel composite electrode coating based on a mixture of cobalt phthalocyanine and Nafion is described. The resulting film has better properties than either of the two components alone, resulting in several potential-sensing applications. In particular, it exhibits electrocatalytic, preconcentration and permselectivity properties simultaneously. For example, effective differentiation between compounds undergoing electrocatalysis, based on their characteristic charge, is illustrated. Enhanced sensitivity is achieved simultaneously for solutes undergoing electrocatalysis or electrostatic binding. Cyclic voltammetry and rotating disk experiments are employed to characterize the catalytic, loading and transport characteristics. Factors determining the film's performance are explored. The practical analytical utility is illustrated by selective flow-injection measurements of hydrazine or hydrogen peroxide in the presence of oxalic or ascorbic acids, respectively. Low detection limits (*e.g.*, 5.7 ng of hydrazine) are obtained.

Research into sensors is proceeding in a number of interesting directions. Electrochemical sensors hold a very promising position among the systems being developed, and have already proven themselves in use, particularly in clinical analysis.[1,2] In the past, electrochemical sensing probes have been based primarily upon potentiometric detection, but new technologies using modified electrode surfaces, microelectrode arrays and solid-state devices appear to shift the balance toward voltammetry.[1] Chemically modified electrodes (CMEs) are particularly promising sensors and considerable effort has gone into their development.[3,4] Deliberate and controlled modification of the electrode surface can produce sensing devices with new and interesting properties that may form the basis for novel analytical applications. Proper choice of the surface modifier can lead to a wide variety of improvements, including acceleration of electrochemical reaction rates, preferential collection of the analyte and improved selectivity and stability. The utility of these functions has been demonstrated in various practical sensing applications.[5-8]

Much more powerful sensing devices may result from the incorporation of two (or more) surface modifiers (possessing different functions) into the same electrode. Such multifunctional operation can be attained by the use of mixed (composite) polymeric films or multilayer coatings, as demonstrated recently in our laboratory. For example, a cellulose acetate/Nafion bilayer assembly offered attractive size- and charge-exclusion characteristics,[9] while a poly(vinylpyridine)/cellulose acetate composite film coupled the binding of counter-ion analytes with protection against surfactant adsorption.[10] Other promising combinations of chemical and structural/mechanical functions have been described recently by Penner and Martin,[11] Fan and Bard,[12] Van Koppenhagen and Majda[13] and Montgomery *et al.*[14]

In this paper we describe a new trifunctional electrode coating based on a mixture of cobalt phthalocyanine and Nafion. Metallo-phthalocyanines have been used for a long time as electrocatalysts in a wide range of chemical reactions.[15] In particular, the electrocatalytic activity of cobalt phthalocyanine (CoPC) has been exploited for various sensing applications.[5,16] Nafion, a perfluorinated sulfonate cation-exchange polymer, has been extensively explored as a membrane on the surface of voltammetric electrodes.[8,17] Nafion films offer effective accumulation of hydrophobic cations, as well as exclusion of anions from the surface. Such dual-function operation of Nafion is coupled in the present work to the electrocatalytic function of CoPC. The CoPC/Nafion films have better properties than either component alone, resulting in several potential-sensing applications. In particular, we will demonstrate the analytical advantages associated with the coupling of the selectivity (discriminative) features of Nafion with the sensitivity enhancement associated with the electrocatalytic and preconcentration functions. The extent of each function can be manipulated (by a change in the film composition) for specific sensing applications.

EXPERIMENTAL

Apparatus

The flow-injection system has been described elsewhere.[7] A 20-μl sample loop and a glassy-carbon thin-layer detector (Model TL-5, Bioanalytical Systems) were used. An

*Author for correspondence.

Ag/AgCl reference was used in all experiments. The auxiliary electrode was either a platinum wire or a stainless-steel tube (for static and flow experiments, respectively). Cyclic voltamperograms were obtained with an EG & G PAR Model 264A voltammetric analyzer and a Houston Instrument X-Y recorder. A 3-mm diameter glassy-carbon disk (Bioanalytical Systems Model MF2012) was used, together with a Bioanalytical Systems Model VC-2 electrochemical cell. Some experiments used a rotating disk electrode (Model DDI 15, Pine Instruments) and a 50-ml glass cell. A removable end-piece, made of a 'Plexiglas' sleeve and a 3-mm diameter glassy-carbon disk, was machined to form an interface with the rotating shaft.

Reagents

All solutions were prepared with doubly distilled water. Cobalt phthalocyanine, oxalic acid (Kodak), cellulose acetate (Aldrich), hydrazine sulfate, ascorbic acid (Baker), and dopamine (Sigma) were used without further purification. Hydrogen peroxide (H_2O_2, 27.5%) was purchased from Hydrox Chemical Co. A 5% solution of Nafion (1100 EW) was obtained from Solution Technology. A 0.05*M* phosphate buffer (pH 7.4) was used as supporting electrolyte and carrier solution in most experiments, but in some a pH-5.0 phosphate buffer solution was used.

Electrode coating procedures

The CoPC/Nafion solutions were prepared by mixing different volumes of the Nafion and CoPC solutions and sonicating the mixtures for 5 min. The CoPC solution was made by dissolving 1 mg of CoPC in 10 ml of acetone and stirring for 10 min. "Mixed" coating compositions ranging from 16/84 to 37.5/62.5% v/v Nafion/CoPC were employed. Fresh "mixed" solutions were prepared every second day. Prior to coating, the glassy-carbon electrode was polished with 0.05-μm alumina particles, sonicated for 4 min, and allowed to dry in air. The electrode was coated with 5 μl of the CoPC/Nafion solution, placed to cover the active disk and its surroundings, and the solvents were then allowed to evaporate. Plain CoPC-coated electrodes were prepared by syringing 10 μl of a CoPC solution (in sulfuric acid) onto the electrode; after 3 min the electrode was rinsed with doubly distilled water and the surface was allowed to dry. This CoPC solution was prepared by dissolving 1.2 mg of CoPC in 20 ml of concentrated sulfuric acid and stirring for 50 min.

RESULTS AND DISCUSSION

Transport, loading and catalytic properties

The new CoPC/Nafion coating exhibits electrocatalytic, preconcentration and permselectivity properties simultaneously. Such multifunctional character is illustrated in Figs. 1–3. Voltamperograms for a solution containing hydrogen peroxide and ascorbic acid are used in Fig. 1 to illustrate the electrocatalytic and discriminative features. The CoPC-coated electrode exhibits a substantial lowering of the overvoltage for both compounds (compare curves a and b for the bare and CoPC-coated electrodes, respectively). The mixed CoPC/Nafion coating (curve c) excludes the ascorbate anion from the surface, while maintaining the catalytic response to hydrogen peroxide. The Nafion component of the film therefore allows differentiation between solutes undergoing electrocatalysis at the CoPC component. The bioanalytical utility of such permselective/electrocatalytic behavior is obvious. As will be shown below, amperometric detection of hydrogen peroxide, which suffers from severe ascorbate interference at a CoPC-modified electrode, can proceed without interference at the mixed CoPC/Nafion coated electrode.

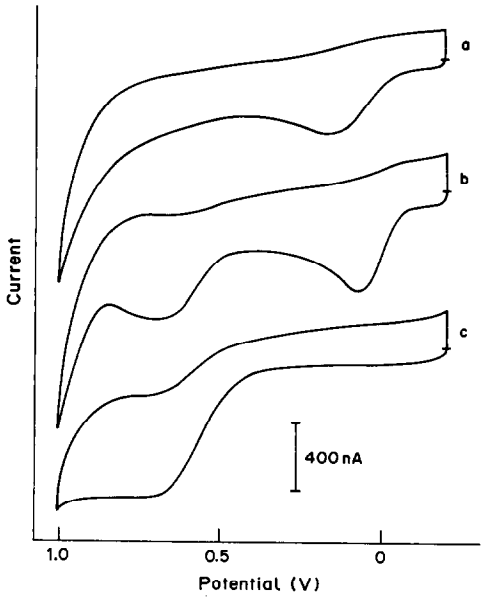

Fig. 1. Cyclic voltamperograms for a solution containing $2 \times 10^{-4}M$ ascorbic acid and $1 \times 10^{-3}M$ hydrogen peroxide, recorded at bare (a), CoPC-coated (b) and CoPC/Nafion (84/16% v/v) coated (c) glassy-carbon electrodes. Supporting elecrolyte, 0.05*M* phosphate buffer (pH 7.4); scan-rate 100 mV/sec.

Another example of differentiation between solutes undergoing electrocatalysis at CoPC films is illustrated in Fig. 2. Baldwin and co-workers have demonstrated the ability of CoPC-modified electrodes to yield a substantial lowering of the overvoltage for the oxidation of hydrazine[18] and oxalic acid.[5] However, because of an overlapping response, it is not possible to measure hydrazine selectively in the presence of oxalic acid [voltamperogam A(b)]. The charge-exclusion feature of the CoPC/Nafion film results in effective rejection of oxalate from the surface [voltamperogram B(a)], hence allowing selective measurement of hydrazine [voltamperogram B(b)]. Note also that the mixed coating exhibits an enhanced catalytic activity toward hydrazine (compare curves b).

The ability of CoPC/Nafion coatings to incorporate hydrophobic cations and simultaneously to enhance the electron-transfer kinetics of other solutes is illustrated in Fig. 3. As with Nafion films alone, dopamine can be readily accumulated and retained at the CoPC/Nafion coating [compare (b) and (a)—with and without preconcentration, respectively]. A subsequent addition of hydrogen peroxide [voltamperogram (c)] resulted in the characteristic electrocatalytic response; the ability to incorporate dopamine was not effected.

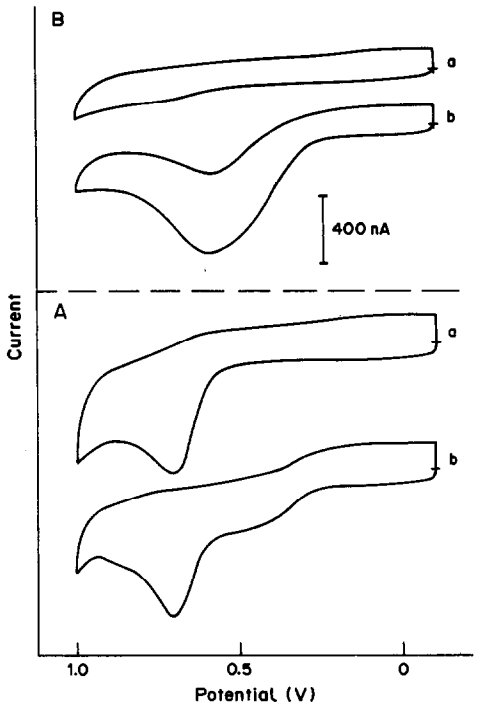

Fig. 2. Cyclic voltammetric response at the plain CoPC (A) and CoPC/Nafion (B) coated electrodes. (a) Response for $2 \times 10^{-4}M$ oxalic acid; (b) as (a) but after addition of $2 \times 10^{-4}M$ hydrazine. Supporting electrolyte, $0.05M$ phosphate buffer (pH 5.0); scan-rate 100 mV/sec.

The design of mixed electrode films for electroanalytical applications requires a good understanding of the way in which they function. Rotating disk and cyclic voltammetry experiments have offered useful information on the preconcentration, catalytic, and permselectivity functions of CoPC/Nafion films. For example, the cation-exchange binding properties of different film compositions were evaluated for the incorporation of dopamine. Figure 4 shows cyclic voltamperograms recorded with the electrode in pure supporting electrolyte after immersion for 20 min in a stirred $1 \times 10^{-4}M$ dopamine solution (the immersion period ensured that equilibrium was reached). As expected from the increased binding capacity of the electrode, the amount of dopamine partitioned is strongly affected by the film composition. Notice also the shift in the dopamine oxidation peak potential (from 0.17 to 0.42 V) upon increasing the Nafion content in the coating. Integration of the oxidation currents (Fig. 4) was used to calculate the quantity of dopamine incorporated at different film compositions, with the results in Table 1. The quantity of dopamine incorporated ranges from 2.7×10^{-10} to 4.6×10^{-9} mole/cm^2 for Nafion contents of 16 and 37.5% v/v respectively. The 37.5% Nafion system yielded an ion-exchange binding capacity similar to that of a plain Nafion coating (4.6×10^{-9} mole/cm^2).

Figure 5 shows current–potential curves for the oxidation of hydrazine at a glassy-carbon rotating-disk electrode coated with different film compositions. These data indicate that the electrocatalytic function of the film increased with the CoPC content (limiting currents of 13.8, 17.8 and 24.6 μA for the 62.5, 75 and 84% CoPC films, respectively). The hydrazine limiting current increased linearly with the square root of the electrode rotation speed over the range 0–3600 rpm (slope 48 nA.rpm$^{-(1/2)}$, correlation coefficient, 0.995; 84% CoPC). However, the resulting plot exhibited a large (6.2 μA) intercept, and the corresponding Koutecky–Levich plot ($1/i$ *vs.* $1/\sqrt{\omega}$) was not linear. The linear portion of this plot (over the 400–1600 rpm range), which reflects conditions of mass-transport control, had an intercept (0.111 μA^{-1}) corresponding to transport through the film. These rotating-disk experiments indicate the participation of various processes in the control of the overall rate of the electrocatalytic reaction, as expected for an irreversible mediation reaction.[19] (Accurate analysis in terms of theoretical models is not possible, because such models assume homogeneous structures[19]). Cyclic voltammetric data for $2 \times 10^{-4}M$ hydrazine, obtained with different film compositions, are given in Table 2. The various coatings exhibit significant (~300 mV) lowering of the overvoltage, compared with the unmodified elec-

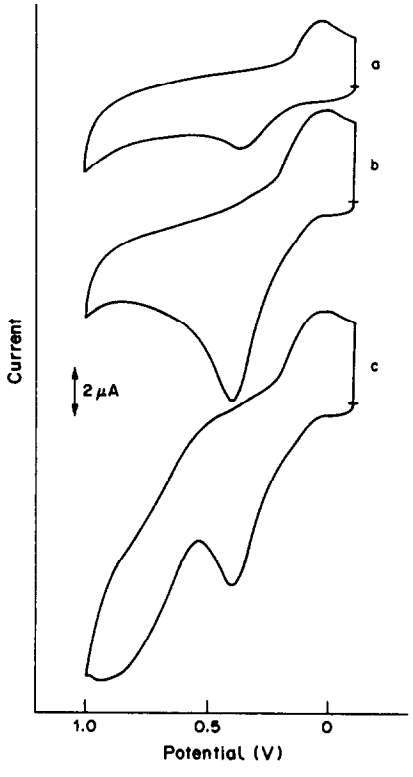

Fig. 3. Cyclic voltammetric response of the CoPC/Nafion (75/25% v/v) coated electrode. (a) Response for $5 \times 10^{-5}M$ dopamine, (b) as (a) but following 5 min accumulation (with 400 rpm stirring at open-circuit), (c) as for (b) but after addition of $2 \times 10^{-3}M$ hydrogen peroxide. Scan-rate and electrolyte as for Fig. 1.

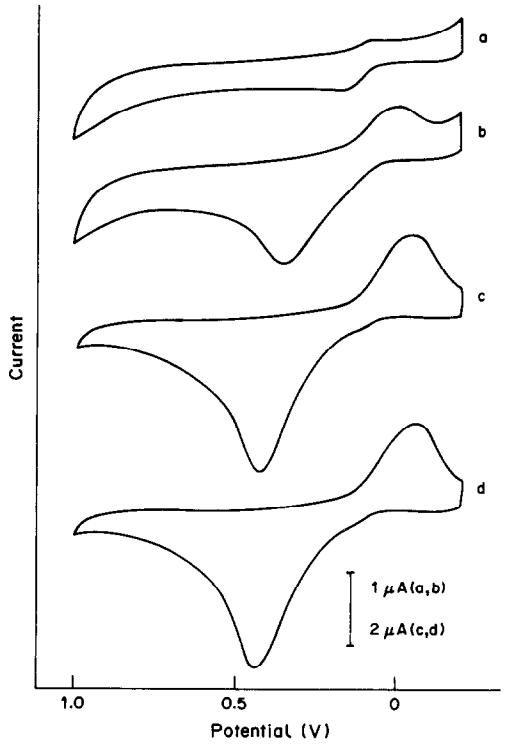

Fig. 4. Effect of film composition on the electrostatic uptake of dopamine. Cyclic voltamperograms for $1 \times 10^{-4}M$ dopamine following 20-min accumulation. Nafion content (% v/v): (a) 16; (b) 25; (c) 37.5; (d) 100. The accumulation step was followed by transfer of the electrode to a blank (phosphate buffer) solution, for recording of the voltamperogram.

trode. Relatively small changes in the peak potential and current are observed upon changing the film composition.

Analytical utility

Amperometric detection in flow-injection systems was used to illustrate the practical analytical utility of the CoPC/Nafion coatings. Figure 6 compares the flow-injection response peaks for $5 \times 10^{-5}M$ hydrazine obtained at the ordinary electrode (a), and electrodes coated with CoPC (b) and CoPC/Nafion (c). Several points are to be noted from these data. First, the electrocatalytic behavior of the mixed coating is similar to that of the plain CoPC film; the signals from the coated electrodes are about 9 times

Table 1. Effect of composition of CoPC/Nafion coatings on the incorporation of dopamine*

Nafion content, % v/v	Q, μC	Γ, mole/cm^2
16	3.5	2.7×10^{-10}
25	16.9	12.8×10^{-10}
37.5	61.7	46.9×10^{-10}

*$2 \times 10^{-4}M$ hydrazine in $0.05M$ phosphate buffer (pH 7.4); scan-rate 100 mV/sec.

as large as those from the unmodified electrode. Second, the CoPC/Nafion-coated electrode rapidly responds to the dynamic changes in the analyte concentration that characterize flow-injection systems; the peak shapes are similar to those obtained with the bare and CoPC-coated electrodes (with fast increase and decrease of the current).

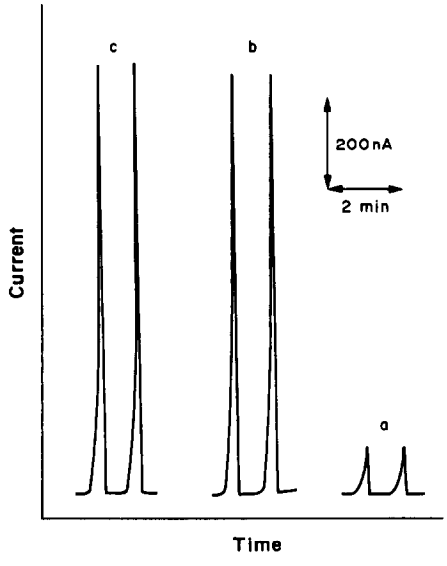

Fig. 6. Flow-injection peaks for $5 \times 10^{-5}M$ hydrazine at the bare (a), CoPC(b) and CoPC/Nafion (75/25% v/v) (c) electrodes. Applied potential +0.45 V; supporting electrolyte, phosphate buffer (pH 7.4); flow-rate 1 ml/min.

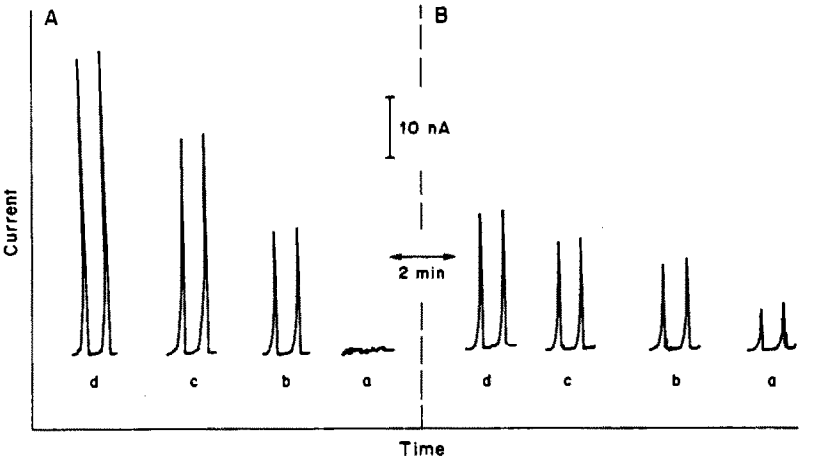

Fig. 7. Flow-injection peaks for oxalic acid solutions containing increasing hydrogen peroxide concentrations, at the CoPC/Nafion (84/16% v/v) (A) and CoPC (B) coated electrodes: $1 \times 10^{-4}M$ oxalic acid; (b–d), as for (a) but after successive additions of $2 \times 10^{-4}M$ hydrogen peroxide. Applied potential, +0.80 V; other conditions as for Fig. 6.

The electrocatalytic function of CoPC-coated electrodes has been shown before,[5,16] but the multifunctional character of the CoPC/Nafion coatings offers additional advantages for analytical sensing, particularly in flow-injection measurements. For example, the CoPC films can differentiate between compounds undergoing electrocatalysis, on the basis of their characteristic charge. Such dual-function operation is illustrated in Figs. 7 and 8. With the plain CoPC film (B), an additive response is observed for mixtures of solutes. Hence, selective detection of hydrogen peroxide or hydrazine in the presence of oxalic acid and ascorbic acid, respectively, is not feasible. In contrast, the CoPC/Nafion film (A) effectively excludes the acid anions from the surface, thus allowing convenient measurement of hydrogen peroxide and hydrazine. Such behavior is in accordance with the cyclic voltammetric behavior described earlier (Figs. 1 and 2). The data in Figs. 7 and 8 demonstrate that CoPC/Nafion-coated electrodes greatly enhance the selectivity of flow-injection measurements, while maintaining the improved sensitivity of electrocatalytic surfaces. Detection limits of $1.2 \times 10^{-5}M$ hydrogen peroxide and $9 \times 10^{-6}M$ hydrazine (*i.e.*, 7.2 and 5.7 ng, respectively, in the 20-μl sample) can be estimated from the signal-to-noise characteristics ($S/N = 3$) of the peaks shown in Figs. 7 and 8 [A(b)].

The concentration dependence of the CoPC/Nafion-coated detector signal was evaluated by using five successive injections of hydrazine solutions of increasing concentration, $1–5 \times 10^{-4}M$ (conditions as in Fig. 8). The peak height increased linearly with the concentration; the slope of the resulting calibration plot corresponded to a sensitivity of 2.06 nA.l.μmole^{-1} (correlation coefficient 0.996).

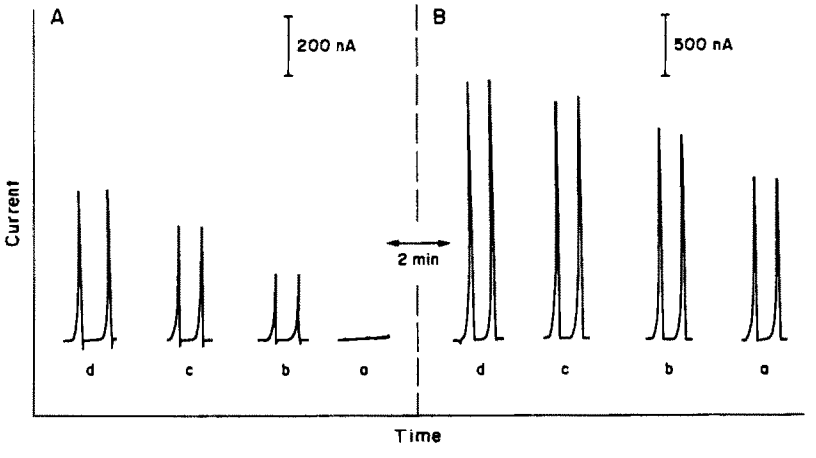

Fig. 8. Flow-injection peaks for ascorbic acid solutions containing increasing hydrazine concentrations, at the CoPC/Nafion (84/16% v/v) (A) and CoPC (B) coated electrodes: (a) $1 \times 10^{-4}M$ ascorbic acid; (b–d) as for (a) but after successive additions of $1 \times 10^{-4}M$ hydrazine. Applied potential, +0.70 V; other conditions as for Fig. 6.

We also explored the utility of CoPC/Nafion coatings for minimizing electrode fouling caused by adsorption of surface-active compounds. Unfortunately, the catalyst was not protected against gelatin and albumin. The extent of electrode poisoning was similar to that observed for plain CoPC-coated electrodes. Improved stability in the presence of such surfactants can be achieved, however, by incorporating cobalt phthalocyanine into cellulose acetate films.[20] Finally, differentiation between solutes undergoing catalysis at CoPC films was also obtained with a bilayer configuration (with the Nafion film on top of the catalytic layer). Such a configuration allowed, for example, the selective flow-injection detection of $1 \times 10^{-4}M$ hydrazine in the presence of $2 \times 10^{-4}M$ ascorbic acid at an applied potential of +0.8 V.

In conclusion, this study has demonstrated that CoPC/Nafion electrode coatings can enhance the power of electrochemical sensors. Significant advantages have been achieved by combining the electrocatalytic function of CoPC with the charge-exclusion and preconcentration features of Nafion. Such functions are qualitatively similar to those observed for electrodes coated with the individual compounds. Considering the potential of multifunctional coatings, other heterogeneous microstructures are envisaged. It is clear that the versatility of tailoring electrode surfaces can benefit electroanalytical measurements in many practical situations. Work along these lines is in progress in this laboratory.

CHROMATOGRAPHIC CHARACTERIZATION OF ELECTROCHEMICALLY GENERATED TECHNETIUM–HEDP* SKELETAL IMAGING AGENTS

RAYMOND B. SCOTT†, PAMELA J. SCHOFIELD§, EDWARD A. DEUTSCH and WILLIAM R. HEINEMAN‡
Biomedical Chemistry Research Center, Department of Chemistry, University of Cincinnati, Cincinnati, OH 45221, U.S.A.

(*Received* 5 *May* 1988. *Accepted* 9 *September* 1988)

Summary—Reduction of pertechnetate [$^{99m}TcO_4^-$] by controlled-potential coulometry in the presence of 1-hydroxy-1,1-ethanediphosphonate (HEDP) leads to the formation of ^{99m}Tc complexes which are suitable for bone imaging. The complex radiopharmaceutical mixtures can be separated into their respective components by anion-exchange high-performance liquid chromatography. The distribution of the complexes in the mixtures is dependent on the cell potential, pH, technetium concentration, and presence or absence of air. A single component formed in high yield and isolated from the mixture by HPLC was investigated as a potential bone-imaging agent. This particular complex is produced only in low yields when prepared by chemical reduction of $^{99m}TcO_4^-$. Thus electrochemistry shows promise in aiding in the development of a more efficacious bone-imaging agent by allowing selective generation of individual ^{99m}Tc–HEDP complexes.

Radiopharmaceuticals for skeletal imaging are prepared by the reduction of $^{99m}TcO_4^-$ in the presence of a diphosphonate ligand (Fig. 1) such as 1-hydroxy-1,1-ethanediphosphonate (HEDP) and methylenediphosphonate (MDP). The resulting ^{99m}Tc–diphosphonate complexes are injected into the bloodstream of the patient. The affinity of the diphosphonate ligand for calcium causes some of the radioisotope to be retained by the bone, which enables an image of the skeleton to be obtained with a gamma camera.[1] This procedure is commonly used for the detection of skeletal disorders, especially metastatic bone cancer.[2]

The chemistry involved in the formulation of diphosphonate radiopharmaceuticals is complicated and can lead to the formation of mixtures that contain numerous Tc–diphosphonate complexes. The development of separation procedures such as anion-exchange,[3] gel-permeation,[4] and reversed phase chromatography[5] has enabled some aspects of the formulation chemistry to be investigated. For example, we have shown that the yields of different complexes in a formulation are highly dependent on the following conditions: reaction pH, nature of the reductant, presence or absence of oxygen, ligand-to-metal ratio, and the time elapsed after formulation. This has been demonstrated for HEDP,[6] MDP,[7] dimethylaminomethylenediphosphonate (DMAD),[8] and 2,3-dicarboxypropane-1,1-diphosphonate (DPD)[9] (Fig. 1). Separation of a radiopharmaceutical mixture into its component complexes enables the skeletal imaging properties of each component to be evaluated. Biological distribution data and skeletal images obtained for HPLC-isolated Tc-complexes in rats show that the different complexes exhibit a wide range of imaging characteristics.[10,11] Consequently, the quality of skeletal images can be dramatically influenced by adjusting the formulation conditions to produce a single complex, or a narrow range of complexes, with optimal imaging properties.

The nature of the reductant in the formulation chemistry is one of the factors that we have been

studying. Since Tc can exist in several different oxidation states in the diphosphonate complexes, the reduction potential of the reductant might be expected to affect the composition of the radiopharmaceutical preparation. Electrolytically prepared ^{99m}Tc–MDP complexes were investigated by Savelkoul *et al.*[12] and found to have reasonable uptake by bone but less than ^{99m}Tc–MDP formulations prepared by reduction with tin(II), which may contain mixed-metal Tc/Sn complexes. The effect of the reduction method on the composition of HEDP complexes was reported by de Groot *et al.*[13] who found that the type of reduction affects the complexes which are formed. The complexes formed by sodium tetrahydroborate and electrolysis probably have the same stoichiometric composition but differ in charge on the complex. The complexes formed by reduction with tin(II) are completely different and cannot be correlated with the complexes formed by sodium tetrahydroborate and electrolytic reduction.

Since electrochemical reduction provides a facile means of varying the redox potential by simply changing the cell potential, we have begun a study of the electrochemical generation of ^{99m}Tc–diphosphonate radiopharmaceuticals. The principal objective of this work is to determine whether a judicious choice of reduction potential can be used to give high yields of Tc–diphosphonate complexes with optimum imaging properties. Our initial results on the formation of Tc–HEDP complexes by reduction at a mercury electrode showed a significant effect of reduction potential on the distribution of the complexes in the formulation.[14] This observation has also been reported by others.[15] In this paper we present a detailed analysis of the effects of reduction potential and other formulation variables on the number and distribution of Tc–HEDP complexes formed by reduction at mercury and carbon electrodes.

EXPERIMENTAL

Reagents

Distilled water was further purified with a NANOpure ion-exchange system (Sybron/Barnstead, Boston, MA). Unless otherwise noted, all chemicals were of reagent grade. 1-Hydroxy-1,1-ethanediphosphonate, disodium salt, (Na_2H_2HEDP) was generously provided by the Procter and Gamble Company (Cincinnati, OH). $K^{99}TcO_4$ was prepared from $NH_4{}^{99}TcO_4$ (Oak Ridge National Laboratories, Oak Ridge, TN) by metathesis with potassium hydroxide and was purified by several crystallizations from warm water. $^{99m}TcO_4^-$ was obtained by elution from commercially available ^{99}Mo/^{99m}Tc generators (Cintichem/Union Carbide Corp., Tuxedo, NY) with 0.9% aqueous sodium chloride solution provided by the manufacturer. These elutions were performed by the staff of the Eugene L. Saenger Radioisotope Laboratory, University Hospital, Cincinnati, OH. L-Ascorbic acid was obtained from MCB Manufacturing (Cincinnati, OH). Instrument-grade mercury (Bethlehem Apparatus Company, Hellertown, PA) was passed through a pinhole before use.

Apparatus

Electrochemistry. Coulometric experiments were performed at either a mercury pool electrode or a reticulated vitreous carbon (RVC, 30 pores per linear inch) electrode. The electrochemical cell used for coulometry at a mercury pool electrode has been described.[14] The same cell was used for cyclic voltammetry with a drop of mercury suspended from a gold button previously amalgamated with mercury. RVC electrodes were made by cutting a disk approximately 0.75 in. in diameter and 0.2 in. thick from RVC material and cementing it to a wire with conductive silver paint and then epoxy resin. The cell used for coulometry at the RVC electrode consisted of a standard BAS electrochemical cell with a cap. A calomel electrode with saturated sodium chloride filler solution (SSCE) was used as the reference electrode. Its potential relative to a standard saturated potassium chloride SCE was measured with a Fisher Accumet pH-meter/voltmeter, as 0.6–0.7 mV. The auxiliary electrode used for the coulometry experiments was a small piece of platinum foil fixed to the end of a piece of 22-gauge platinum wire. The electrode was platinized, fixed to a rubber cap, and isolated from the solution by a sodium chloride salt bridge. A bare unisolated platinum wire was used for the cyclic voltammetry experiments.

Cyclic voltammetry was performed with an EC 225 Electrochemical Analyzer (IBM Instruments, Inc., Danbury, CT) and an Omnigraphic 199 X–Y recorder (Houston Instruments, Austin, TX). Coulometry was performed with a model 173 Potentiostat/Galvanostat (Princeton Applied Research Corp., Princeton, NJ).

HPLC. The HPLC system was an LC-304 (Bioanalytical Systems, Inc., West Lafayette, IN). A detailed description of this chromatograph has been published.[15] The mobile phase was 0.85*M* aqueous sodium acetate filtered through a 0.2-μm GA-8 filter (Gelman Sciences, Inc., Ann Arbor, MI). Dissolved oxygen was removed by heating at 100° for 1 hr under argon. The solution was then maintained at 45° under argon. Stainless-steel tubing was used throughout the HPLC apparatus to maintain an oxygen-free environment. The flow-rate was 0.2 ml/min. A guard column (7.0 × 2.1 mm) was filled with AE-pellionex anion-exchange resin (Cat. No. 4161–010, Whatman Chemical Separations, Inc., Clifton, NJ) for the purpose of removing unreacted TcO_4^-. (*Note:* this material has been discontinued by the manufacturer and is not the material currently supplied in anion-exchange guard column kits available through Whatman, Inc.) The analytical column (250 × 4.0 mm) was packed with Aminex A27, an anion-exchange resin consisting of a quaternary ammonium substituted styrene–divinylbenzene copolymer (Bio-Rad Laboratories, Rockville Centre, NY).

Procedures

Electrochemically reduced Tc–HEDP mixtures were prepared as follows. Na_2H_2HEDP (30 mg) and ascorbic acid (30 mg) were weighed into a 10-ml beaker, and 2.00 ml of 0.85*M* sodium acetate were added. Nitrogen or argon was bubbled through the solution both to deoxygenate the solution and aid in the dissolution process. Once this was complete, the pH was adjusted with either 6*M* hydrochloric acid or 6*M* sodium hydroxide. The solution was then transferred to the electrochemical cell, which had been previously prepared by addition of 2.0 ml of mercury and a magnetic microstirrer bar. Fresh mercury was used for each preparation. In the "carrier added" preparations, 0.20 ml of a 35m*M* $K^{99}TcO_4$ stock solution was added, and in all cases, approximately 5 mCi of $^{99m}TcO_4^-$ solution were added before the cell cap and electrodes were positioned. The final assembly is shown in Fig. 1 of reference 14. Since metallic mercury will itself spontaneously reduce pertechnetate, the technetium solution was added last, and the potential was immediately applied to the cell. With the electrodes in place, the nitrogen or argon stream was directed into the electrochemical cell. In the "no carrier added" preparations, the reduction time was 10 min, but for the "carrier added" preparations it was increased to 20 min or until a stable residual current was achieved. "Carrier added" preparations

were subsequently filtered through a 0.2 μm syringe filter (Gelman Sciences, Ann Arbor, MI) and 20 μl aliquots were injected into the HPLC system.

This procedure was modified slightly for coulometry at the RVC electrode: 60 mg each of Na_2H_2HEDP and ascorbic acid were weighed into the electrochemical cell and 4.00 ml of 0.85*M* sodium acetate were added. No pH adjustments were made. The nature of the RVC matrix causes it to trap air bubbles, which must be dislodged by slight agitation. Since the RVC material is fragile, a stirrer bar was not used. Instead, electrolysis was allowed to continue for 1 hr, after which the monitored current had decayed to a stable residual level.

Biological distribution

A biological distribution study was conducted on the radiopharmaceutical preparation electrochemically generated at −1.200 V and pH 7.0; 1.5 ml of the preparation were diluted to 5.0 ml with 0.05*M* sodium phosphate buffer, pH 7.4, to yield a physiologically compatible solution of 0.15*M* ionic strength. The biodistribution study employed 14 female Sprague–Dawley rats weighing between 175 and 200 g. Each rat was anesthetized and 0.2 ml of the diluted electrochemically reduced technetium–HEDP [^{99m}Tc(EC)HEDP] mixture containing 80 ± 2 μCi of ^{99m}Tc was injected into its jugular vein. Seven animals were killed after 1.5 hr and another seven after 3.0 hr, by asphyxiation with carbon dioxide. Samples of blood, liver, femur muscle, heart, kidney and femur were excised and rinsed (except the blood) with saline. These samples were weighed and assayed for ^{99m}Tc by γ-ray scintillation counting (Model 1185 Automatic Gamma System, Searle Analytic Inc.), with counting standards prepared from the initial injection mixture.

Skeletal imaging

Skeletal imaging studies were performed with 2 female Sprague–Dawley rats. The electrogenerated mixture and HPLC-isolated component *c* (see below) were each diluted with 0.05*M* phosphate buffer, pH 7.4, to give a physiologically compatible ionic strength of 0.15*M*. The animals were injected as described above. One animal was killed after 1.5 hr and the other after 3.0 hr and their posterior skeletal images were recorded by obtaining 100,000 counts on an Ohio Nuclear Series 100 radioisotope camera equipped with a high-resolution collimator.

RESULTS AND DISCUSSION

The potential required for reduction of TcO_4^- in a radiopharmaceutical reaction mixture was determined by cyclic voltammetry at a hanging mercury drop electrode. Current–voltage curves were recorded for solutions containing HEDP, ascorbic acid, and sodium acetate at various pH values. An initial current–voltage curve was recorded for this solution with no pertechnetate added, and no reduction wave was observed. After the addition of pertechnetate, the experiment was repeated and a second curve recorded (Fig. 2). An irreversible reduction wave for TcO_4^- was found, with peak potential at approximately −0.6 V *vs.* SSCE. This reduction potential was pH-dependent, as depicted in Fig. 3. There was also a positive shift in the negative limit, caused by hydrogen evolution. Only the first scan for pertechnetate reduction is shown in Fig. 2, since in the second scan the hydrogen wave shifted even further in the positive direction and the TcO_4^- wave became obscured. This large shift in the hydrogen wave is evidence that some form of the reduced technetium species is absorbed on the mercury electrode surface, altering its hydrogen overvoltage. This phenomenon has been reported before[17] and is one of the complicating features of technetium electrochemistry.

The reduction potentials for controlled-potential coulometry were chosen from the cyclic current–voltage curve in Fig. 2 and ranged from −800 to −1500 mV. Figure 4 shows the current–time response during the coulometric reduction of pertechnetate at −900 mV *vs.* SSCE. After the initial charging-current spike, a precipitous drop is recorded, followed by a current increase. This behavior is further evidence for complex surface effects occurring at the mercury electrode. After a 2 min

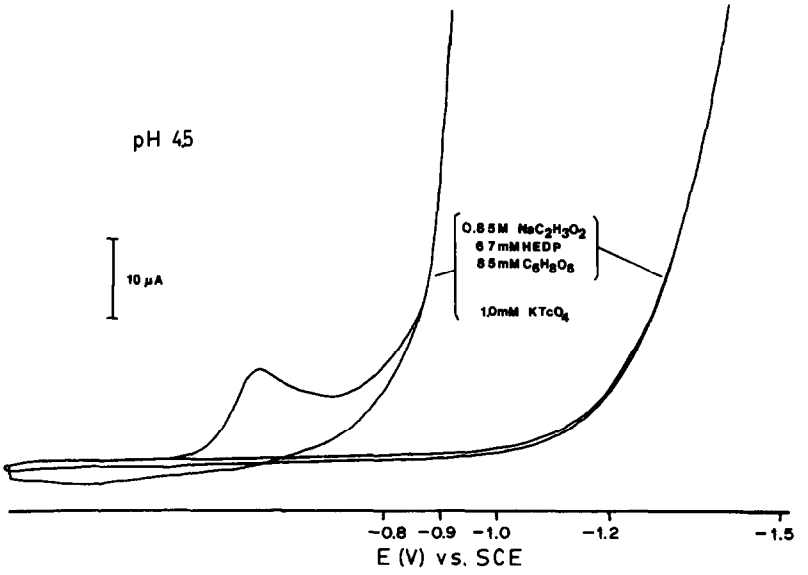

Fig. 2. Cyclic current–voltage curves for supporting electrolyte (0.85*M* sodium acetate, 67m*M* HEDP, 85m*M* ascorbic acid) and 1.0m*M* TcO_4^- in supporting electrolyte; pH 4.5.

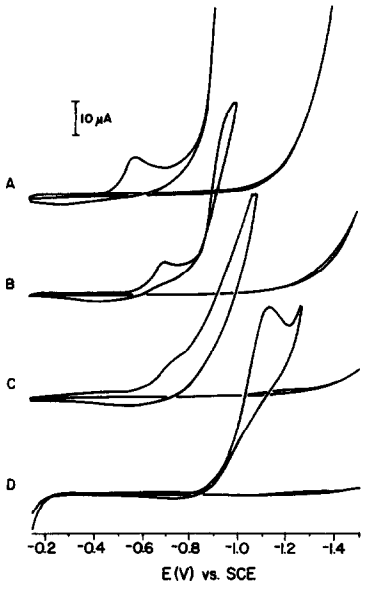

Fig. 3. Cyclic current–voltage curve for supporting electrolyte (same as for Fig. 2) and 1.0m*M* TcO_4^- in supporting electrolyte at pH values of (A) 4.5, (B) 5.6, (C) 7.0 and (D) 9.0.

electrolysis, the curve begins to follow the $(time)^{1/2}$-dependent exponential decay associated with controlled-potential electrolysis.

The Tc–HEDP radiopharmaceuticals prepared by coulometry were analyzed by HPLC to determine the number and distribution of Tc–HEDP complexes. Previous work on chemically reduced formulations has shown that the reaction conditions can strongly influence the distribution of the components.[6,7] Chromatograms of "no carrier added" preparations, at pH 4.5, are shown in Fig. 5. Analyses were conducted for each coulometry experiment performed, at each applied potential. These analyses led to a number of observations. (*i*) Six major Tc–HEDP components can be identified on the basis of chromatographic retention time. (*ii*) These 6 components have been observed in previous studies on $NaBH_4$-reduced preparations of Tc–HEDP.[3,6] Apparently, electro-

chemical reduction generates no species that are different from those obtained by chemical reduction with sodium tetrahydroborate. (*iii*) The applied potential has a significant effect on the distribution of Tc among the six complexes. At −0.800 V only complexes *g* and *j* are present. Shifting the potential (towards the hydrogen wave) to −0.900, −1.000 and −1.200 V causes the predominant species to become component *f* instead of component *g*. (*iv*) Shifting the potential to −1.5 V results in substantial evolution of hydrogen from the mercury electrode. Complex *f* is still a major component, in addition to *a*, *c* and *d*. Little of component *g*, which was the major component at −0.800 V, is detectable in the mixture prepared at −1.5 V.

The distribution of electrochemically generated Tc–HEDP components is also strongly influenced by the solution pH, as is the distribution of chemically reduced Tc–diphosphonate components.[6,7] Figure 6 shows the chromatograms of "carrier added" formulations prepared at a reduction potential of −1.200 V and various solution pH values. As the pH of the solution is increased, there is an increase in the number of components formed. This trend has also been observed in some chemically reduced "carrier added" preparations.[7] By careful selection of the reduction potential and solution pH, the yield of a particular component in the complex mixtures can be controlled.

Another variable which affects the distribution of components in chemically reduced Tc–diphosphonate formulations is the concentration of technetium.[6-9] Figures 7 and 8 illustrate the effect of varying the reduction potential for preparing a "carrier added" Tc–HEDP mixture at pH 4.5 and 7.0, respectively. Under acidic conditions, only one major species is formed at all reduction potentials, with a small amount of a late-eluting component formed at the most negative potentials. Under neutral and basic conditions, at reduction potentials of −0.800 and −0.900 V, the "carrier added" preparations have only a small number of components. As the reduction potential is reduced, there is an increase in the number of components formed. Figures 5 and 9 show the effects of reduction potential on the composition of "no carrier added" Tc–HEDP mixtures prepared at pH 4.5 and 9.0, respectively. Under both acidic and basic conditions, as the reduction potential is reduced, there is an increase in the number of components formed. At higher pH values, only one or two species predominate. From the chromatograms illustrated in Figs. 5–9, it can be seen that the composition of electrochemically generated Tc–HEDP mixtures depends strongly on the reduction potential, pH and concentration of technetium.

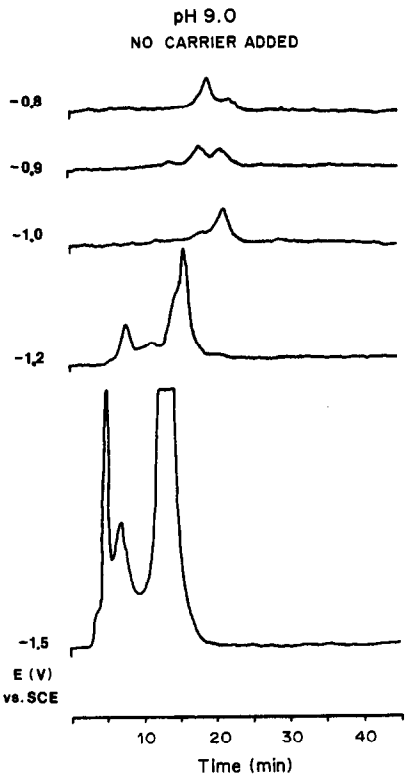

Fig. 9. HPLC of "no carrier added" ^{99m}Tc–HEDP mixtures prepared by coulometric reduction of TcO_4^- at pH 9.0 and various reduction potentials. Conditions as for Fig. 5.

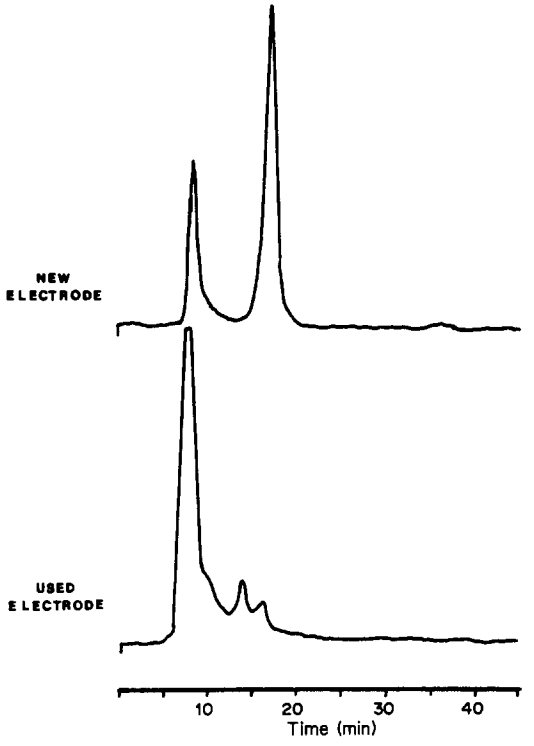

Fig. 10. The effect of "used" and "fresh" Hg on an electrochemically reduced ^{99m}Tc—HEDP mixture prepared at −1.200 V and pH 5.6.

One aspect of the mercury pool electrode which was investigated was the use of "fresh" and "used" mercury pools for the reduction of TcO_4^-, "used" meaning that the same mercury was used throughout the experiment, and not changed for each reduction. It was found that using "fresh" mercury causes the formation of two species with retention times of 8 and 18 min, whereas "used" mercury causes the formation of only one species, with a retention time of 8 min. The reduction potential was −1.200 V and the pH 5.6. This effect is illustrated in Fig. 10. This result supports the previously mentioned indications that reduction of pertechnetate modifies the surface of the mercury. Modification of electrodes by reduction of pertechnetate has been reported by Russell for tetracycline and EDTA as complexing ligands,[16] and by Lawson *et al.*[17] and Miller *et al.*[18] for polyphosphates and tripolyphosphates.

Some experiments were conducted to determine whether the nature of the working electrode material had an effect on the distribution of the Tc–complexes formed. The RVC electrode was used instead of a mercury pool electrode in standard pertechnetate reductions at −1.000 V and pH 5.6. The resulting chromatograms are shown in Fig. 11. The results are similar to those obtained with the "used" and "fresh" mercury electrodes, where the electrode tends to produce the early eluting components as its surface becomes altered by repetitive pertechnetate reductions. By measuring the residual gamma-activity present on the electrode following electrolysis, it was found that approximately 50% of the available technetium had been adsorbed on the RVC, after one

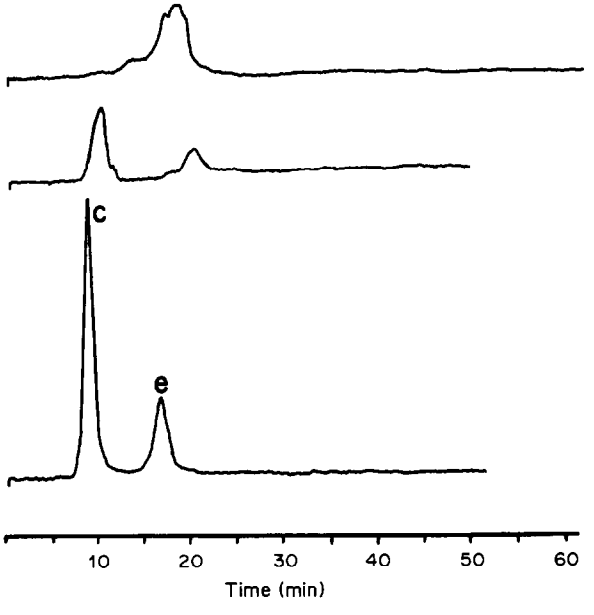

Fig. 11. The effect of an RVC electrode on the resulting ^{99m}Tc–HEDP mixture prepared by coulometric reduction at −1.000 V and pH 5.6.

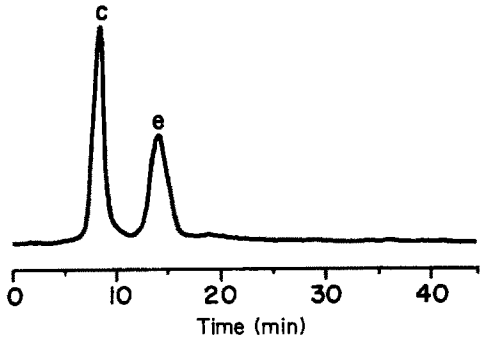

Fig. 12. HPLC of "no carrier added" ^{99m}Tc–HEDP mixture prepared by coulometric reduction at −1.200 V and pH 7.0. Conditions as for Fig. 5.

pertechnetate reduction modifying its surface. From the chromatograms in Fig. 11, it is apparent that once the electrode surface is modified, pertechnetate reduction results in the formation of a high yield of component *c* and a small amount of component *e*. Different yields of these species were obtained with the mercury pool electrode. The evidence suggests that the RVC working electrode does not form any new complexes, but maximizes the yields of those obtained by mercury pool reduction and chemical reduction.

A preliminary biodistribution study was performed on an electrochemically reduced ^{99m}Tc–HEDP formulation to confirm its affinity for bone. The formulation conditions were "no carrier added", pH 7.0, reduction potential −1.200 V. Component *c* was isolated from the radiopharmaceutical mixture giving the chromatogram illustrated in Fig. 12, and contained 58% of the total technetium eluted. Table 1 presents the biodistribution data. These results are

Table 1. Biological distribution data* for ^{99m}Tc–HEDP "no carrier added" component *c* (per cent of initial dose per g of sample for rats killed at different times after injection)

generally typical for a good bone-imaging ^{99m}Tc–diphosphonate radiopharmaceutical. The absolute uptake by bone is relatively high, whereas the uptakes by soft tissue are correspondingly low. Moreover, the activity clears more rapidly from the soft tissues than from bone. Scintillation radiographs of rats 3 hr after injection of HPLC-isolated component *c* and the unseparated Tc–HEDP mixture are shown in Fig. 13. These images confirm the results of the biodistribution study, showing good uptake by bone with minimal uptake by soft tissue. Thus, electrochemical reduction provides Tc–HEDP complexes which can act as good skeletal-imaging agents.

CONCLUSIONS

Several conclusions can be drawn from this work. Electrochemical reduction of $^{99m}TcO_4^-$ in the presence of HEDP leads to a mixture of ^{99m}Tc–HEDP complexes, which can be separated by HPLC. These electrogenerated preparations contain the same complexes as do chemically reduced preparations. Moreover, the applied potential used in the electro-

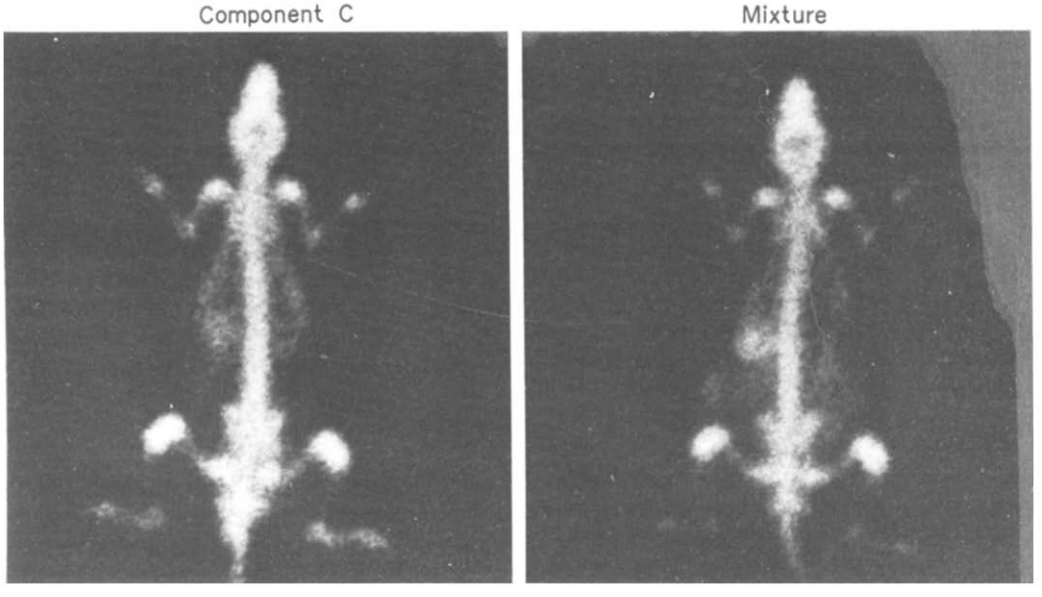

Fig. 13. Scintillation radiographs of Sprague–Dawley rats imaged with component *c* of electrogenerated ^{99m}Tc–HEDP and the unseparated reaction mixture, at 3 hr after intravenous injection.

generation is quite effective in controlling the final distribution of the products, especially when used in concert with choice of solution pH. RVC working electrodes offer great promise for producing high yields of Tc–diphosphonate complexes, and their use would be much more suitable than use of mercury electrodes for a clinical setting. Moreover, the use of RVC electrodes would guarantee that mixed-metal complexes, often seen in Tc–diphosphonate formulations prepared by reduction with tin(II), could not be formed. Finally, the electrochemical reduction of pertechnetate in the presence of HEDP, under the proper conditions, gives a very high yield of complex *c*, which has been shown to have good uptake by bone. This particular complex is produced only in low yields when prepared by chemical reduction of $^{99m}TcO_4^-$.[3] Thus electrochemistry shows promise in aiding in the development of a more efficacious bone-imaging agent by allowing selective generation of individual ^{99m}Tc–HEDP complexes.

(*Received* 8 *June* 1988. *Revised* 16 *August* 1988. *Accepted* 13 *September* 1988)

Summary—The determination of traces of metals by high-performance liquid chromatography of their n-butyl-2-naphthylmethyldithiocarbamate complexes, with a fixed-wavelength absorbance detector, is described. Metal complexes of this ligand are thermodynamically stable and kinetically inert towards dissociation. Various metal complexes, including those of nickel(II), iron(III), mercury(II), thallium(III), platinum(II), palladium(II), copper(II), and cobalt(II) are readily determined. The practical aspects of their separation on various nonpolar stationary phase columns are discussed. The detection limits compare very favorably with those of atomic spectrometry and are about 0.1 ng or approximately 10n*M*.

The application of high-performance liquid chromatography (HPLC) to the determination of metal ions has received a great deal of interest over the past decade.[1–5] In particular, the separation of a number of dialkyldithiocarbamate complexes by HPLC has been studied extensively.[6–10] However, this approach is limited by both dissociation and decomposition of the complexes on the chromatographic column, and by differences in the spectroscopic properties of the metal complexes. Because of the very significant differences in the wavelength of maximum absorbance of the most intense bands, it is not possible to set a detector to work at a single optimum wavelength for more than a few judiciously selected metals. Thus, it is not possible to optimize the overall performance of the method without using a multichannel spectrometric detector. Furthermore, the dissociation of metal dithiocarbamate complexes[11] at very low concentration limits their utility for trace determinations by HPLC unless some of the complex-forming reagent is present in the mobile phase. Addition of the ligand to the mobile phase has several deleterious effects. The baseline noise will increase and the reagent can attack the metal components of the chromatographic system.

Earlier, we reported[12] on the design, synthesis and use of a novel ligand, *viz.* n-butyl-2-naphthylmethyldithiocarbamate (BNMdtc), that had nearly optimal chromatographic and chromogenic properties as a precolumn complexing agent for trace metal ions. We found that the naphthyl group imparts very high absorptivities ($>10^5$ l.mole^{-1}.cm^{-1}) to the complex, and the combination of the bulky naphthyl and butyl groups tends to stabilize the metal complexes formed with this reagent. Metal complexes of this ligand are thermodynamically stable and kinetically inert even at the $1 \times 10^{-8}M$ level. However, the detection limits were only about 1–2 ng with a variable-wavelength absorbance detector. To be competitive with other analytical methods for trace metals such as anodic stripping voltammetry, atomic-absorption spectrometry, and neutron-activation analysis, detection of sample concentrations as low as 1×10^{-8}–$1 \times 10^{-7}M$ is required. Although the BNMdtc complexes are electrochemically active, we found that the high background current and the poor reproducibility of the measurement combined to yield detection limits which were no better than those obtained with a variable-wavelength absorbance detector. Similar results with diethyldithiocarbamate complexes were obtained in other laboratories.[13,14]

Improved detection limits should be attainable by fluorescence spectrometry, but the BNMdtc complexes do not fluoresce directly despite the presence of the naphthyl group. Fortunately, BNMdtc undergoes the photochemical reactions characteristic of other dialkyldithiocarbamates.[15] Its photodecomposition product, BNM amine, is very strongly fluorescent. Thus, we were able to develop a post-column photochemical detector for detection of BNMdtc complexes.[16] Detection of metal ions at the $10^{-8}M$ level is possible. More recently, this limit of detection has been achieved by the simple expedient of using a fixed-wavelength (229 nm) absorbance detector. This results because all BNMdtc complexes have maximal absorbances at 221 nm and fixed-wavelength detectors have quite low noise (absorbance $<2 \times 10^{-5}$).

*This work is dedicated to our good friend and colleague, Piet Kolthoff, on the anniversary of his ninety-fifth birthday.

EXPERIMENTAL

Reagents

All chromatographic mobile phases used here were prepared from HPLC grade solvents (MCB Reagents, Gibbstown, NJ, or Mallinckrodt, Inc., St. Louis, MO) and filtered through 0.45 μm filters (Millipore Corp., Bedford, MA) to remove particulate matter before use. Solvents were degassed by sonication under vacuum prior to mixing. HPLC grade water was prepared from doubly-demineralized water which had been filtered through a 0.45 μm HA type filter (Millipore).

Buffer solutions were prepared from analytical reagent grade Tris hydrochloride (Sigma Chemical Co., St. Louis, MO), and filtered through 0.45 μm nylon filters prior to use. Solutions of 100m*M* metal nitrates were prepared from reagent grade salts and acidified with dilute nitric acid to prevent hydrolysis. Zinc butylnaphthylmethyldithiocarbamate, $Zn(BNMdtc)_2$, used as the chelating agent, was prepared in the laboratory.[12]

Apparatus

All chromatography was performed with a modular system consisting of the following components: an Altex pump, Model 110A (Beckman Instrument Inc., Fullerton, CA), a Rheodyne 7125 bypass valve fitted with an injection port (Rheodyne, Inc., Cotate, CA), a Waters Radial Compression Module (Waters Associates, Inc., Milford, MA), a Laboratory Data Control UV-1203 detector fitted with a 229 nm conversion kit (Laboratory Data Control, Division of Milton Roy Co., Riviera Beach, FL) and a Linear Instruments Aerograph recorder (Linear Instruments Corp., Irvine, CA).

Several types of reversed-phase analytical columns were employed in this work to ensure that the method would be reasonably flexible. An RCM-100 cartridge (Waters Associates, Inc.) containing Radialpack C_{18} was used in the Radial Compression Module. Other columns investigated were Zorbax ODS (E. I. Dupont & Nemours, Inc., Wilmington, DE) and ODS Hypersil (Shandon Southern Instruments, Inc., Sewickley, PA).

Two large-particle precolumns were placed before the injector. The first contained acid-washed silica gel that saturated the basic mobile phase with silica to inhibit dissolution of the analytical column. The second precolumn contained ethylenediamine-loaded silica gel which removed metal ions present in the mobile phase.

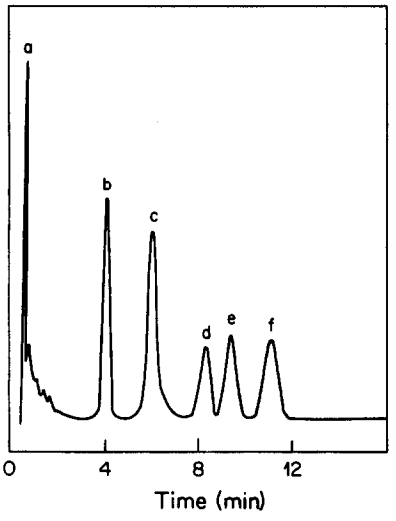

Fig. 1. Chromatogram of a mixture of iron(III), nickel(II), copper(II), mercury(II) and cobalt(II). The chromatogram is run on the radial compression cartridge column under the conditions described in the text. The metals are present at concentrations of about 10μ*M*.

Chromatographic conditions

Optimal conditions for the separation of butylnapthylmethyldithiocarbamates on a Radialpack C_{18} RCM-100 cartridge are as follows. The mobile phase was methanol–water (95:5) buffered at pH 7.5 with 1m*M* Tris. The chromatograms were developed at a flow-rate of 2 ml/min with the column at ambient temperature. In general, 20-μl samples were injected by means of a fixed-volume loop. This column and the conditions above were used to obtain the data given in Tables 1–3 and Figs. 1 and 2. We note in passing that the capacity factors for the metal dithiocarbamates are very sensitive to the stationary phase, and the mobile phase conditions must be optimized whenever a new column is employed. Furthermore, the capacity factors for these solutes do not equilibrate rapidly after the mobile-phase composition is altered. It is therefore necessary to store the column in the mobile phase which is to be used. We also need to point out that at the pH used in this

*All results were obtained with the Radial Compression Cartridge described in the text.

work the columns tend to age rather rapidly. For example, over a 50-day period of reasonably constant use the capacity factor for the mercury(II) complex decreased from 20.0 to 16.5. The capacity factors reported here were computed from the retention of the peak of interest relative to that of the zinc(II) complex. In preliminary work we showed that the zinc complex had the same retention time as uracil and a mismatched solvent peak.

Standard preparation

An aqueous solution of the metal nitrate was added to an excess of $Zn(BNMdtc)_2$ in the mobile phase that was to be used for the separation. The solutions were allowed to stand for 5–10 min to ensure completeness of reaction. Excess $Zn(BNMdtc)_2$ must be added to prevent complex dissociation and decomposition of the ligand prior to injection onto the column.

RESULTS AND DISCUSSION

A typical chromatogram showing a separation of a mixture of iron(II), nickel(II), copper(II), mercury(II) and cobalt(II) is given in Fig. 1. All the peaks are sufficiently well resolved for analytical purposes. The first peak is due to the excess of the zinc complex, and the ragged tail with minor peaks on it is quite typical of what we observe for a blank injection. The reason for these small peaks is not known, but we hypothesize that they are due to reaction of the zinc reagent with the metal components of the chromatographic system.

Calibration graphs for a series of metal complexes were generated by injections of serial dilutions of the 100mM stock solutions. Figure 2 shows the linearity of response over the concentration range 0.1–10μM. These studies were performed with a series of metal complexes in 95/5 v/v methanol–water, 1mM Tris, pH 7.5. The graphs for the BNMdtc complexes of Cu(II), Tl(III), Pt(II), Pd(II), Hg(II), Ni(II) and Co(II) showed good linearity, with the correlation coefficients (r) greater than 0.999 over the concentration range from 1.0×10^{-7} to $1.0 \times 10^{-5} M$. The linearity of the calibration graph for $Fe(BNMdtc)_3$ ($r = 0.977$) is not as good as that for the other complexes. This is due to iron contamination from the system, which could not be eliminated even after silanization of frits, syringes and sample vials to prevent attack of the reagent on stainless-steel surfaces, or after replacing the precolumns, and flushing the system with ethylenediamine in methanol to remove iron from the system.

The reproducibility of the chromatographic method as a function of the solute concentration was determined from 3–5 replicate injections of the standard solutions at each of the indicated concentration levels (Table 1). The relative standard deviation of the signals was generally better than 5% for all the species studied, at concentrations down to about $0.3 \times 10^{-6} M$ but deteriorated at lower levels. The decrease in the precision at concentrations below about $10^{-7} M$ is due to the decrease in the signal-to-noise ratio as the detection limit is approached. The detection limits obtained by observing the peak at maximum detector sensitivity (0.001 absorbance full scale) ranged from 30 to 400 pg, depending on the metal (Table 2). The minimum detectable amount or concentration was taken as that which produced a peak which was twice the baseline noise level. The detection limits were also calculated from the linearity study. With a signal-to-noise ratio of 2, the detection limits for a 20-μl sample ranged from 400

*All conditions are given in the text for the Radial Compression Cartridge column (dead volume 1.1 ml). Zn(BNMdtc)$_2$ was present in all samples at a concentration of 50μM.

pg for Tl(III) down to 30 pg for Ni(II) and Co(II). Detection limits in HPLC are very sensitive to the size of the column as well as to the analyte capacity factor. No attempt was made in this work to use small columns or optimize the capacity factor for any particular solute. Some differences in detectability are due to small variations in the molar absorptivity from solute to solute, as well as to a slight amount of dissociation of the complex on the column. In general, the molar absorptivities are in proportion to the number of BNMdtc groups associated with the metal.

The ability of various complexing agents to interfere with the formation of the BNMdtc complexes was checked. Metal BNMdtc complexes were formed in the presence of 10- and 100-fold excess of common complexing agents (acetate, phosphate, thiocyanate, and EDTA). The effect of the potential interferent on the complex formation and chromatography was then assessed (Table 3). In all cases, excess Zn(BNMdtc)$_2$ was present at a concentration of 50μM. The data in Table 3 show that the added complexing agent had no effect on either the absorbance or the capacity factor. To some extent, the robustness of the reagent is due to the presence of the excess of BNMdtc as well as the presence of zinc, which acts to mask the potential interferent.

The chromatographic properties of the various reversed-phase columns are compared in Table 4. This study indicates that the separation of the metal BNMdtc complexes is possible on a number of

reversed-phase C_{18} columns if the mobile phase is appropriately adjusted. These data show that even a fairly small change in the amount of organic modifier has a rather drastic effect on the capacity factors, much more than generally expected for small solutes at such high levels of methanol. This effect may be a consequence of the large size of the metal complexes. It should be noted that the solute capacity factors are, within the precision of measurement, independent of the amount injected (see Table 5). Based on the known differences between these columns, we believe that the chromatographic resolution improves as the number of available silanol groups increases. This and the above-mentioned fact that the capacity factors of the solutes take a long time to become fully equilibrated after a change in mobile-phase composition indicates that the solutes interact fairly strongly with the silica and the retention mechanism is not "pure" reversed-phase. The separation times do decrease when columns with a high carbon load or end-capped columns are used. On the basis of these observations, we tested the effect of adding triethylamine, a common silanol group blocking agent, to the mobile phase. As shown in Table 6, we found a most unexpected result, namely, that for three of the metal species [copper(II), mercury(II) and cobalt(II)] the retention actually increased. We expected the usual result, namely, a decrease in retention upon addition of an amine to the mobile phase. In contrast, the retention of iron(III) and nickel(II) first increased and then decreased with increase in amine concentration. It is conceivable that the metal complexes formed an adduct with the triethylamine, thereby making them more hydrophobic. In any case, these results substantiate our view that the process for retention of nonpolar metal complexes on reversed-phase columns is not as simple as that for the retention of low molecular-weight organic solutes.

Conclusion

The RCM-100 cartridge appears to be a good choice for the separation of these metal complexes at trace levels. The linearity and reproducibility for all complexes showed that the complexes did not dissociate at the lower concentrations studied, indicating that complex lability is not a problem with this type of derivative. Neither complex formation nor the chromatography was affected by addition of other complexing agents, indicating that normal environmental interferences should not be a serious problem.

(*Received* 22 *September* 1988. *Accepted* 24 *September* 1988)

Summary—Spark ablation–inductively coupled plasma (SA–ICP) spectrometry is applied to the measurement of hafnium–zirconium ratios in zircons and to the determination of cerium, cobalt, iron, lead, nickel and phosphorus in ferromanganese nodules. Six operating parameters used for the high-voltage spark and argon-ICP combination are established by sequential simplex optimization of both signal-to-background ratio and signal-to-noise ratio. The time-dependences of the atomic emission signals of analytes and matrix elements ablated from a finely pulverized sample embedded in a pressed disk of copper demonstrate selective sampling by the spark. Concentration ratios of hafnium to zirconium in zircons are measured with a precision of 4% (relative standard deviation, RSD). For ferromanganese nodules, spectral measurements based on intensity ratios of analyte line to the Mn(II) 257.610 nm line provide precisions of analysis in the range from 7 to 14% RSD. The accuracy of analysis depends on use of standard additions of the reference material USGS Nod P-1, and an independent measurement of the Mn concentration.

Approaches to the introduction of solids into the inductively coupled plasma include the direct insertion of powders, the nebulization of slurries, and the production of aerosols by laser ablation, by direct current discharges or by high-voltage radiofrequency (RF) spark discharges.[1,2] Recent applications of the diode-shunted spark indicate that the generation of aerosols by this discharge provides a viable sampling technique for electrically conductive materials, particularly iron alloys, in inductively coupled plasma (ICP) emission spectrometry.[3–6]

Geologic materials generally have neither the requisite electrical conductivity nor the degree of homogeneity exhibited by alloys. However, the potential for direct analysis of these complex solids is quite appealing because some of the problems commonly associated with the use of solutions may be avoided, *viz.* (*a*) the large dilution factors ($\geqslant 200$) incurred in transforming a solid sample into an aqueous solution, (*b*) addition (contamination) or loss of sample components in a fusion–dissolution process, (*c*) the insolubility of certain resistive mineral phases, such as berite, beryl, cassiterite, chromite, rutile, tourmaline and zircon, and (*d*) the risk of nebulizer clogging because of the high concentration of salts from a fusion process. Spark ablation of solid samples, combined with excitation in an ICP, has the potential for reducing both sample handling and analysis time.

The feasibility of ICP spectrometric analysis of electrically nonconductive materials has been shown by Aziz *et al.*[7] The requirement for electrical conductivity is met by incorporating a pulverized nonconductive sample into a conductive matrix. Thus, a pulverized sample is mixed with a metallic powder, such as aluminum or copper, and subsequently pressed into a disk that can be used as an electrode for a point-to-plane spark. More recently, a method has been described for the determination of metals in coal fly-ash incorporated into a pressed graphite disk,[8] and initial results have been reported on the analysis of manganese nodules in a copper disk.[9,10]

Manganese nodules and the mineral zircon were selected for the current study as materials that typify the complexity and insolubility of geologic materials, respectively. Manganese nodules, which represent an important mineral resource for metals required by modern technology,[11,12] are a complex mixture of organic and colloidal matter and nucleus fragments in addition to crystallites of various minerals of detrital and authigenic origins. Conventional methods based on atomic-absorption spectrometry[13] and on ICP spectrometry of aqueous solutions[14] are normally used in the analysis of these materials. The ratio of hafnium to zirconium in a zircon serves as a good indicator of the conditions for crystallization from a magma source and of the origin of a particular zircon.[15–17]

EXPERIMENTAL

Apparatus

All spectral measurements were made with a dual direct-reading spectrometer system (model 1160, Thermo Jarrell Ash Corp.) and a single argon ICP.[18] The nominal first-order band-pass of each spectrometer was 0.036 nm. Argon for operation of the plasma was supplied from a Dewar container of liquid argon, and the ICP was generated

*Author for correspondence. Present address: Ross Laboratories, 625 Cleveland Ave., Columbus, OH 43215.
†Department of Chemistry, George Washington University, Washington, DC 20052.

in a Fassel-type torch by a 27.12-MHz, 2-kW generator. The argon used to transport and inject the spark-generated aerosol was supplied from a cylinder of the compressed gas.

The diode-shunted spark was generated by an electronic adjustable waveform power supply operated at 17 kV (model 96-778, Thermo Jarrell Ash Corp.). The current waveform of the spark [for example, see Fig. 2(b) of reference 19] was measured by a wide-band pulse-current transformer (model 110, Pearson Electronics) that was connected to the input amplifier of an oscilloscope having a frequency response of 100 MHz (model LB0-516, Leader Co.). The calibrated response of this induction-pickup current transformer was 100 mV/A. During each 12-μsec breakdown cycle, a current peak of approximately 85 A was followed by a rapid oscillatory decay to zero. An RF-current of approximately 6 A (rms) was observed during continuous operation of the spark.

The spark was established between a thin, sharply-pointed (60° cone) tungsten electrode and the flat surface of a conductive sample disk (cathode). Electrical polarity was maintained to effect sampling of the disk and to minimize erosion of the pointed electrode. Aerosol particles having mean diameters that range from a fraction of a μm to approximately 100 μm are produced by a unidirectional high-voltage spark.[20] Many of the larger particles, which are found at distances of several cm from the spark, are aggregates of numerous small particles. During each cycle of spark ablation, the spark chamber was swept by argon, which transported aerosol from the 4-mm spark gap into the ICP. Flow of argon through the spark chamber was maintained by a calibrated mass-flow controller (model 8200, Matheson Co.). The aerosol traveled approximately 1 m through a 6-mm i.d. polyethylene tube into a modified Scott-type spray chamber. Large particles were deposited on the inner walls of the tubing and on the surfaces of the spray chamber, including the surfaces of the polytetrafluoroethylene (PTFE) baffles placed within the spray chamber. Thus, the surfaces of the tubing, the spray chamber, and the baffles acted as a particle filter for the aerosol generated by the spark.

The Scott-type spray chamber for solution nebulization had been modified by the manufacturer to allow introduction of solid aerosol from the spark source into the top of the spray chamber, at a location immediately after the PTFE holder of the solution nebulizer. The spark-generated solid aerosol from the transport line was directed into the spray chamber by a special, three-piece PTFE connector provided by the manufacturer. Use of this connector caused instability of the plasma, owing to gas leaks into the spray chamber. This problem was eliminated by using a single-piece fused-silica connector, in the form of a ball joint, attached to the spray chamber.

Particles transported from the spark through the polyethylene tubing passed through a 5-cm section of flexible, thin-walled silicone tubing before entering the spray chamber. This flexible tubing connected the more rigid polyethylene tubing to a Pyrex ball-joint connector on the spray chamber. The section of thin-walled tubing passed through a pinch-clamp solenoid valve (Angar Scientific Co., part no. 388NC1151010) that acted as an on–off switch for control of aerosol entry into the spray chamber. The original pinch valve installed on this instrument by the manufacturer gave a fluctuating flow, as a result of valve chatter.

When the pinch-clamp valve was in the "off" position, a fixed cross-flow nebulizer operated to wash the spray chamber continuously with 10% v/v nitric acid. This washing was necessary to prevent build-up of deposits of fine particles that would clog the liquid nebulizer. Also, a fixed pressure of less than 35 psig was maintained in all the gas lines of the spark chamber. The fine aerosol particles emerging from the spray chamber were injected into the argon ICP, where vaporization, dissociation, ionization and excitation of emission from free atoms and ions occurred.

Reagent

High-purity copper powder (Johnson-Matthey Puratronic: 22-mesh Cu powder, with impurities Bi, Si = 2 ppm; Ca, Fe, Na, Ni = 1 ppm; and Al, Mg, Mn each < 1 ppm).

Procedure

In this approach to spark ablation–ICP spectrometry, pulverized solids for both standards and samples were mixed with pure copper powder and pressed to form disks that were sparked directly. The aerosol formed by the spark was then injected into an argon ICP. The resulting spectral signals were measured by direct-reading spectrometry.

In accordance with the optimal conditions established in this investigation, 1 g of manganese nodule or zircon (ground to 100-mesh) was mixed with 4 g of high-purity copper powder. Mixing was accomplished on a Fisher–Kendall mixer that continuously agitated the powdered materials for 4–8 hr. Each mixture of sample and copper powder was poured onto 1–2 g of copper powder in a 2.5-cm die, and a force of 18000 lb was then applied for 60 sec to form a layered disk. This layered disk presented sample to the spark-eroded side, and a mechanically stable highly conductive surface to the electrical pressure-contact on the opposite side.

The forward power to the ICP was 1.3 kW, and the reflected powder was typically less than 5 W. An outer flow-rate of 18 l./min and an intermediate flow-rate of 0.5 l./min of argon were maintained for all measurements. The observation height for spectral measurements was 19 mm above the load coil. For a spark power setting of 85% (RF current = 5.8 A) and a spark-break frequency of 2 breaks per half-cycle, the flow-rate for the argon injection gas was fixed at 0.86 l./min by a mass-flow controller. At the end of a period of 80 sec (pre-integration), spectral line signals were integrated for 20 sec. Between samples, the spark chamber was flushed for 60 sec with argon.

RESULTS AND DISCUSSION

Because the low alloy steel NBS SRM 1263 provided a homogeneous, well-characterized, conductive material, it was used to determine initial operating conditions for the spark ablation–ICP combination. These conditions were established by sequential simplex optimization (SSO) of composite signal-to-background ratios and composite signal-to-noise ratios as response functions.[9,10,18] A simplex computer program for signal-to-background (S/B) optimization was modified to enable optimization of signal-to-noise (S/N). Composite responses (ratios) were measured for 12 elements, with five successive samplings by the spark source. Optimum conditions were achieved after approximately 30 experiments.

The spectral line used for each element, the concentration of each element in the standard, and the location for background subtraction on the direct-reading spectrometer, are listed in Table 1. The variables included in the SSO studies and their optimal values are summarized in Table 2. This set of operating conditions for the low-alloy steel is considered to represent only a starting point that can be altered to fit nonconductive geological matrices and other groups of elements. The major conclusions drawn from this study were: (*a*) the operating conditions for optimal S/B or S/N ratios were roughly the same, (*b*) the observation height used for the solid

aerosol should be 5 mm higher than that commonly used for solution nebulization, and (*c*) signal integration should commence 70–80 sec after aerosol injection.

Several conductive materials, including aluminum, copper, graphite, indium and zinc were tested for suitability as conductive substrates. Generally, an electrically conductive material was sought that: (*a*) binds sufficiently well to form a rigid disk of 2.5-cm diameter under a force of 18000 lb, (*b*) has an atomic emission spectrum with few lines in the 200–500 nm region, (*c*) has good electrical conductivity, (*d*) is available in a highly-pure powder form, and (*e*) is relatively inexpensive.

Indium flowed in the die of a hydraulic press, thus binding together the die components. Zinc formed a mechanically stable disk, but melted too readily as a cathode for a spark discharge. Graphite disks produced large particles that glowed brightly as they passed through the ICP discharge. Both aluminum and copper powders formed pressed disks that had the mechanical strength to support the same material and not break up when clamped in the spark stand. For identical operating conditions, spark sampling from an aluminum cathode has been reported to be more effective than sampling from a copper cathode.[19] Because high-purity copper powder was less expensive than equivalent aluminum powder, copper was chosen for use in this study. This choice was supported by result obtained by other investigators[7] for the spark sampling of aluminum oxide and calcium carbonate from pressed Cu disks.

USGS Nod A-1 and USGS Nod P-1 standards[22] were used as materials representative of manganese

Table 2. Operating conditions for SA-ICP determined by sequential simplex optimization for NBS SRM 1263

Parameter*	Boundary values	Optimal conditions	
		S/N†	S/B§
Forward power, *kW*	1.0–1.8	1.2	1.3
Observation height, *mm*	9–31	23	21
Spark power, %	40–90	75	76
(rms RF current, *A*)		(4.3)	(3.6)
Breaks per half-cycle	2–5	3	4
Ar injector flow, *l./min*	0.5–2.0	1.0	0.8
Pre-integration period, *sec*	30–120	72	73

*All other parameters were constant: outer gas flow = 17 l./min Ar; intermediate gas flow rate = 0.1 l/min; solution nebulizer injector gas flow = 0.65 l./min when the solid aerosol was not injected into the ICP; solution nebulizer uptake rate = 1 ml/min of 10% nitric acid; flush period for spark source = 60 sec. During the flush period, an argon gas flow of 20 l./min transports residual solid particles (produced by the previous experiment) from the spark chamber and the associated transport line to the drain. Signal integration time = 1 sec.

†S/N: signal-to-noise ratio, calculated as the average line peak height divided by the rms noise of the background adjacent to the spectral line for 5 replicate measurements.

§S/B: signal-to-background ratio, calculated as the average line peak height divided by the background adjacent to the spectral line.

nodules. Weight ratios of sample-to-copper in the range from 1:2 to 1:10 were tested to find compositions that give both reproducible spark sampling and atomic emission signals conducive to precise measurements. A ratio of 1:4, the same as that chosen by Aziz *et al.*,[7] was selected for the continuation of this study.

The observed ICP atomic emission signals for nonconductive materials indicated that just as for electrically conductive samples with a spark current of 6 A and an argon injection flow of 1 l./min, the first 70–80 sec constituted a period of erratic signal growth and decay. Typically, the signal exhibited exponential-like growth until it reached a maximum in 10–15 sec, then dropped to a relatively constant level, where it could be integrated for the next 10–20 sec. The spark processes responsible for the aerosol production appeared to be sensitive to the composition of the sample matrix, as indicated by differences in the growth and decay of spectral line signals. Thus, thermal processes, such as fusion and vaporization, rather than ion sputtering only, appear to be quite important.[19]

For the 4:1 mixture, the diameter of the sampled area increased from about 3 to 7 mm as the number of breaks per half-cycle was changed from 2 to 5 at the spark power setting of 85%. Although the highest intensities for analyte lines were observed for 2 breaks per half-cycle, time profiles obtained at 4 and 5 breaks per half-cycle showed more stable plateaus than those at lower break frequencies.

In the spark sampling of nodules, the Mn(II) 257.6-nm line intensity grew with Mn concentration in a monotonic fashion. This concentration-dependent behavior of Mn line intensity indicated the potential of Mn as internal reference element. A regular trend in the behavior of the growth curves was noted for Ce, Co, Fe, Ni, P and Pb when the weight ratio of each element to Mn was plotted *vs.* the intensity ratio of the spectral line for each element to Mn(II) 257.6 nm. Linear plots were not obtained for Al, Ba and K, thus reaffirming the dependence of spark sampling on the matrix.

The concentrations found for three elements in USGS Nod P-1 standard, along with the precision of the measurements and the accepted values for the standard, are shown in Table 3. These results were obtained from standard-addition calibration curves prepared from six disks of Nod A-1 and Nod P-1 standards. The precision of these measurements ranged from 7 to 14% RSD.

As mentioned in the introduction, the ratio of hafnium to zirconium in a zircon is indicative of the crystallization conditions and the origin of a particular zircon. The ratios of the background-corrected relative intensities of the Hf(II) 277.336 nm and Zr(II) 339.198 nm lines were measured by SA–ICP spectrometry for the group of zircons listed in Table 4. The zircons had previously been characterized by X-ray fluorescence (XRF) spectrometry and direct-current (DC) arc emission spectrography. The concentration ratios presented in the third column of

Table 4. Concentration ratio of hafnium to zirconium in zircons

*Field identification number for zircon.
†SA–ICP: spark ablation–inductively coupled plasma spectrometry.
§The typical concentration of hafnium in these zircons ranged from 1 to 2%.
‡XRF: X-ray fluorescence spectrometry.
DCA: direct-current arc atomic-emission spectrography.

Table 4 were estimated from a least-squares regression line fitted to four points that included the origin and the three Hf/Zr ratios for which exact agreement was exhibited (underlined) between XRF spectrometry and DC arc spectrography. The correlation coefficient for this regression line was 0.9993. The concentration ratios determined by SA–ICP spectrometry are similar to the ratios determined by XRF spectrometry and DC arc spectrography.[15–17] The precision of SA–ICP spectrometry was approximately 4% RSD when solid zircons were used to prepare the calibration curve.

Results from this investigation confirm that spark ablation provides a useful means for the direct sampling of nonconductive materials for ICP spectrometry. However, the spark efficiency depends on the sample matrix, and therefore direct analysis of complex nonconductive materials, such as ferromanganese nodules and zircons, is a complicated task that requires matching of the sample and standards. This matching requirement precludes the use of aqueous standards in place of solid standards for the preparation of calibration curves in analysis of certain geologic materials. These limitations of SA–ICP emphasize the need for the development of new techniques for direct analysis of solids, that would be applicable to complex samples such as those cited in the introduction to this report.

Acknowledgements—The authors are grateful to Jean Kane for assisting in the modification of the sequential-simplex algorithm to enable optimizations based on signal-to-noise ratios. Also, their sincere thanks to David Gottfried for supplying the analyzed zircons.

STUDIES OF THE HOMOGENEOUS IMMUNOCHEMICAL DETERMINATION OF INSULIN BY USING A FLUORESCENT LABEL

KASEM NITHIPATIKOM and LINDA B. MCGOWN*
Department of Chemistry, P.M. Gross Chemical Laboratory, Duke University, Durham, NC 27706, U.S.A.

Summary—Fluorescence intensity, lifetime and polarization were investigated for use in the homogeneous immunochemical determination of bovine and human insulin. Both antibody-labelled and antigen-labelled schemes were studied. A competitive, antigen-labelled immunoassay based on the difference in fluorescence polarization between free and antibody-bound fluorescein-labelled insulin was found to be the most sensitive approach. The problem of adsorption of insulin on the cuvette surfaces was studied, and sodium salicylate was used with silica cuvettes to minimize the adsorption. Anti-porcine insulin antibody and fluorescein-labelled bovine insulin were successfully used for the determination of both human insulin and bovine insulin.

Nonisotopic immunochemical techniques have been extensively developed and widely used for clinical determinations in recent years.[1] Fluorescence techniques such as antigen-labelled fluoroimmunoassay (FIA) and antibody-labelled immunofluorimetric analysis (IMFA) are often used because of the high sensitivity and selectivity of fluorescence detection, as well as the suitability of fluorescent labels for homogeneous (nonseparation) analysis. Homogeneous fluorescence techniques are based on differences in fluorescence characteristics, such as spectral maxima, intensity, lifetime and polarization, of the fluorescent labelled species in the free and bound forms. However, spectral shifts and large changes in intensity are not usually observed for the high quantum-yield labels that are commonly used for FIA and IMFA. In previous work, it has been shown that intensity and lifetime differences can be combined in order to improve the discrimination between the free and bound species, by using phase-resolved fluorescence spectroscopy.[2-4]

Fluorescence polarization has been one of the most successful approaches to homogeneous immunochemical determinations. Since the polarization difference between free and bound labelled reagent is a function of the difference in molecular size, polarization techniques are most sensitive for competitive FIA determinations of low molecular-weight haptens, which on binding to the antibody form a unit of much greater size than their original one. The analyte hapten competes with the fluorescent labelled hapten for the antibody, resulting in a decrease in polarization as the fluorescent labelled hapten is displaced from the antibody by increasing concentrations of analyte.

In this paper, the homogeneous polarization FIA of bovine insulin and human insulin is described. Insulin is an interesting analyte for several reasons, including its size (MW 5600), which is intermediate between low molecular weight haptens and macromolecular antigens, its very low physiological concentration range (10–100pM) and the similarity between insulins from different mammals. Immunochemical techniques for the determination of insulin that have been described include radioimmunoassay[5] and enzyme immunoassay[6,7] (the latter for the determination of human insulin). An automated flow-cell polarization fluorometer has been used for the determination of porcine insulin at concentrations of about $10^{-8}M$.[8]

EXPERIMENTAL

Materials

Demineralized HPLC-grade water was used for all preparations. Solutions were prepared in 0.050M TRIZMA buffer, pH 7.6 unless otherwise noted. Zinc chloride (gold label, Aldrich), sodium salicylate, (NaSy, gold label, Aldrich), Triton X-100 (reduced form, RTX, Aldrich), urea (EM Science) and sodium sulfate (Fisher Scientific) were used as received.

Stock solutions of the solid reagents, including bovine insulin (Sigma) and fluorescein-labelled bovine insulin (Sigma) were dissolved and diluted with buffer. Stock solutions of the reagents obtained in liquid suspensions, including human insulin (Peptide Institute, Inc.), anti-porcine insulin (Cambridge Medical Diagnostics), anti-human insulin (Serotec), fluorescein-labelled anti-human insulin (Serotec) and rhodamine-labelled anti-human insulin (Serotec) were all diluted with buffer. According to the manufacturer, the anti-porcine insulin had the same biological activity as the anti-bovine insulin.

Samples were prepared by successive dilutions of the stock solutions. Blanks were prepared with the same constituents, except that the labelled reagents were omitted. Measurements were made after 15–20 min incubation. The sample compartment was maintained at 25 ± 0.1° with a Haake A81 temperature-control unit.

*Author for correspondence.

Several types of cuvettes were investigated, including silica cuvettes and disposable cuvettes made of polyethylene (Precision Cell), polystyrene (Evergreen) and poly(methyl methacrylate) (Spectrocell).

Apparatus

All fluorescence measurements were made with an SLM 48000S spectrofluorometer (SLM Instruments, Inc., Urbana, IL), with a 450-W xenon lamp source and Hamamatsu R928 photomultiplier tube detector. An IBM PC-XT microcomputer was used for on-line data acquisition and for data analysis. Fluorescence lifetime determinations were made at an excitation modulation frequency of 30 MHz, with a scattering solution as the reference. Details of the phase-modulation instrumentation and technique have been described elsewhere.[9,10] Phase and modulation measurements were made in the "100-average" mode, in which each measurement is the average of 100 samplings, performed internally by the instrument electronics over a period of approximately 25 sec. The excitation monochromator slits were set to give 16 and 1 nm band-pass for the entrance and exit, respectively. The emission monochromator slits were set at 16 nm band-pass. Some lifetime measurements were made with a band-pass interference filter (530 nm, 10 nm half-width, Oriel) instead of a monochromator for emission wavelength selection.

Steady-state excitation and emission spectra were obtained in the "10 average" mode, with all of the slits set at 2 nm band-pass. Fluorescence intensity and polarization measurements were made in the "25 average" mode, and reported as the average of five measurements. The excitation monochromator slits were set to 4 nm band-pass and the band-pass filter was used for emission wavelength selection. Polarization measurements were made by using the "L-format".[11] Polarization (P) was calculated as:

$$P = (I_{VV} - CI_{VH})/(I_{VV} + CI_{VH}) \quad (1)$$

The subscripts to the fluorescence intensity values (I) refer to the orientations of the excitation and emission polarizers, in that order (V = vertical, H = horizontal). The correction factor C ($C = I_{HV}/I_{HH}$) is required for the L-format and was experimentally determined along with I_{VV} and I_{VH}. Each of the intensity values used to calculate P was the average of five measurements performed in the "50 average" mode.

RESULTS AND DISCUSSION

The excitation and emission maxima of the labelled reagents did not change on binding. The fluorescein- and rhodamine-labelled antibodies from human antisera did not show any change in fluorescence intensity and lifetime when bound to either bovine or human insulin, possibly because the fluorescent label was located at a site far from the antibody binding sites. The non-competitive labelled antibody system was not investigated further. A small increase in fluorescence intensity of the fluorescein-labelled bovine insulin (Ag*F) on binding to anti-porcine insulin antibody (Ab) was observed. The intensities of both free and bound Ag*F increase with increasing pH in the range 7.0–8.4, but the intensity increments of the two are similar at each pH value. The differences in polarization and lifetime between free and bound Ag*F change only slightly with pH.

Effects of cuvette material

Disposable plastic cuvettes are widely used in chemical and clinical experiments. For the insulin system, we found that the signal from the fluorescent label when the plastic cuvettes are used decreases rapidly as a function of time. Plots of fluorescence intensity of Ag*F in pH 7.4 buffer as a function of time for different types of cuvette are shown in Fig. 1. The relative intensities for the curves in Fig. 1 are all normalized to an initial value of 1.00. All the disposable plastic cuvettes show a very rapid rate of intensity decrease. The rates of decrease appear to be correlated with the polarity of the cuvette surface. Polyethylene has a nonpolar surface and shows the fastest rate of decrease. Polystyrene, which contains no polar groups but does have an aromatic ring, gives a slightly slower rate than polyethylene. Poly(methyl methacrylate) cuvettes have the highest polarity and show the slowest rate among the plastic cuvettes. The decrease in intensity is probably due to adsorption of the fluorescent labelled insulin on the solid cuvette surfaces, which can reduce the amount of fluorescent label in the light path and enhance intermolecular quenching of the label on the surface. Silica cuvettes showed a much lower rate of decrease than the plastic cuvettes, and were used in the remainder of the experiments described here.

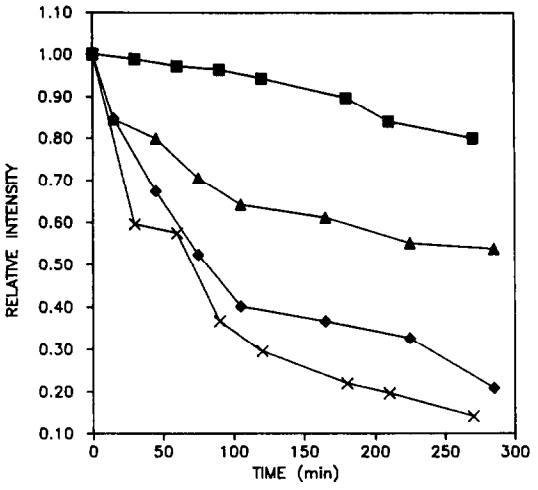

Fig. 1. Relative fluorescence intensity of Ag*F ($2.0 \times 10^{-8}M$) in pH 7.4 TRIZMA buffer, in different cuvettes, as a function of time. (×) Polyethylene, (■) silica, (◆) polystyrene, (▲) poly(methyl methacrylate).

In addition to using silica cuvettes, we attempted to minimize the error due to adsorption of insulin on solid surfaces by adding several kinds of chemicals, including RTX, ethanol and NaSy, to the buffer solutions. Figure 2 shows the effects of the chemicals on the stability of the fluorescence intensity of Ag*F over a period of several hours. The relative intensities for the curves in Fig. 2 are all normalized to an initial value of 1.00. However, it is worth noting that ethanol and RTX increased the intensity of the Ag*F fluorescence, whereas NaSy decreased it. The RTX, at a concentration of 0.19mM (about three-quarters

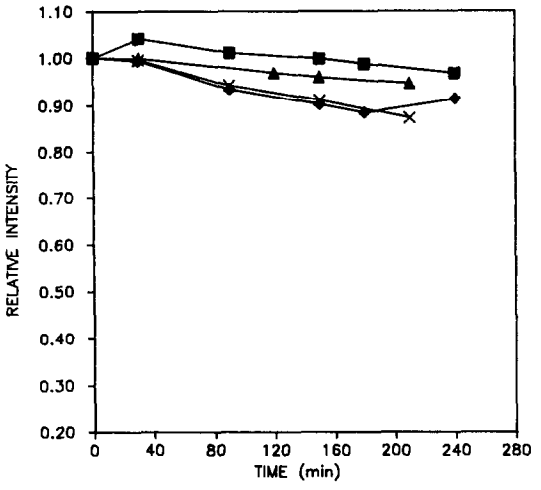

Fig. 2. Relative fluorescence intensity of Ag*F ($1.6 \times 10^{-8} M$) in pH 7.6 TRIZMA buffer, in silica cuvettes, as a function of time. (◆) Buffer only, (▲) 10% ethanol, (×) 0.19m*M* RTX, (■) 0.025*M* NaSy.

of the critical micelle concentration) did not significantly improve the stability of the fluorescence intensity, but both ethanol and NaSy did improve it. Interestingly, NaSy caused a slight increase in intensity at the beginning of the time interval (see discussion below). Sodium salicylate was used rather than ethanol in the FIA because it provided greater sensitivity for the calibration curve.

*Effects of additives on the fluorescence of free and bound Ag*F*

Table 1 shows the fluorescence characteristics of free and bound Ag*F in buffer and in the presence of several additives. In all cases, binding of Ag*F to Ab enhances the fluorescence intensity and increases the polarization. The fluorescence lifetime increases on binding in buffer alone, and in the presence of NaSy with or without Zn^{2+}. Binding causes a decrease in lifetime in the presence of Zn^{2+} alone. Sodium sulfate and urea, both of which have been reported to increase the fluorescence intensity of 6-carboxyfluorescein,[12] enhance the fluorescence intensities of both free and bound Ag*F and decrease the intensity ratio. The polarization change [$\Delta P = P$(bound) $- P$(free)] is about the same in sodium sulfate medium as in buffer, and slightly lower in the urea medium.

It has been reported that Zn^{2+} increases the specific binding of insulin to its receptor.[13] We found that Zn^{2+} quenches the fluorescence intensity of both free and bound Ag*F, with an intensity ratio of approximately 1.40. Although Zn^{2+} causes a large difference in fluorescence intensity, it also causes precipitation in the systems containing a high protein concentration, and is therefore not a practicable reagent for the homogeneous immunoassay. The ΔP in presence of Zn^{2+} is less than that in the buffer solution, and the fluorescence lifetimes of both free and bound Ag*F are shorter in Zn^{2+} medium than in buffer. An interaction between the fluorescein label and Zn^{2+} must exist in the system, because the changes in polarization and lifetime relative to the buffer system cannot otherwise be explained. The decrease in lifetimes indicates that the interaction may involve collisional and/or heavy-atom quenching. In the latter case, the proximity of Zn^{2+} to the fluorescein label in the bound Ag*F may be responsible for shortening the lifetime relative to that of free Ag*F.

Sodium salicylate has been used to increase solubility and minimize molecular self-association of insulin[12] and dyes.[12,14] The effects of NaSy on the fluorescence intensity and polarization of free and bound Ag*F are shown in Figs. 3 and 4, respectively. Small amounts of NaSy cause a small enhancement of the fluorescence intensities of both free and bound Ag*F. Higher concentrations of NaSy result in

§Intensity ratio of antibody-bound Ag*F to free Ag*F.
‡Polarization difference between antibody-bound Ag*F and free Ag*F [P(bound) $- P$(free)], per cent relative differences in parentheses.
¶Difference in lifetime between antibody-bound Ag*F and free Ag*F [τ(bound) $- \tau$(free)], per cent relative differences in parentheses. Lifetimes were calculated from phase-shift measurements of $1.6 \times 10^{-8} M$ Ag*F and a 10^3 dilution of Ab. Maximum standard deviation for the lifetime measurement was 50 psec, and the lifetime of free Ag*F in buffer was 2.99 nsec.

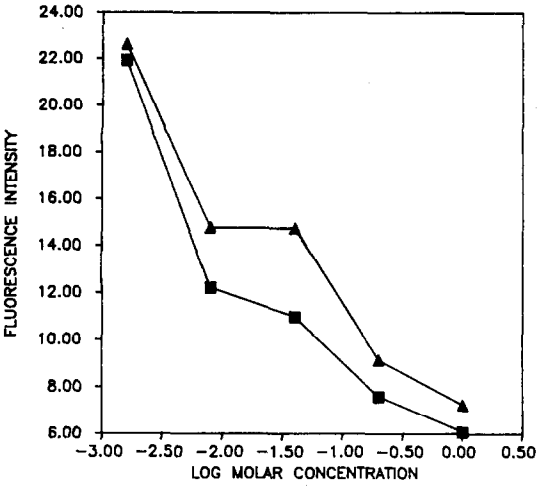

Fig. 3. Fluorescence intensity of Ag*F ($7.8 \times 10^{-10} M$) in pH 7.6 TRIZMA buffer as a function of NaSy concentration. (■) Free Ag*F, (▲) Ab-bound Ag*F (10^4 dilution of Ab used).

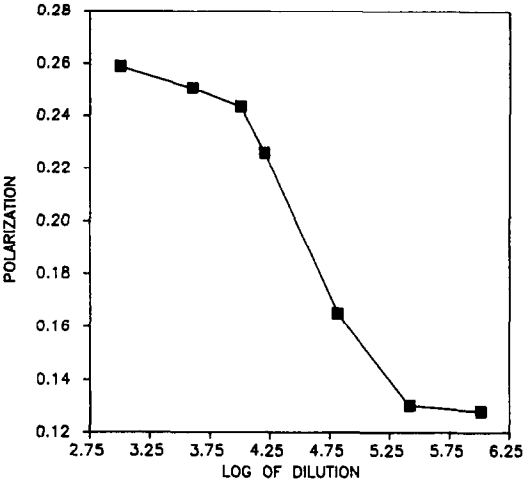

Fig. 5. Plots of the changes in polarization of Ag*F ($5.2 \times 10^{-10} M$) as a function of Ab dilution in pH 7.6 TRIZMA buffer and $0.025 M$ NaSy.

decreasing intensities. The changes in intensity shown in Figs. 3 and 4 do not appear to result from the change in pH of the solutions (pH = 7.4–7.9 in this NaSy concentration range); the intensity decreases with increasing NaSy concentration (and, therefore, with increasing pH), whereas the expected effect of increasing pH would be to increase the fluorescence intensity. The largest difference in fluorescence intensity was observed in the concentration range 0.010–0.10M NaSy. The polarization of both free and bound Ag*F increases in NaSy medium, but ΔP decreases as the concentration of NaSy increases. In NaSy medium the fluorescence lifetime of bound Ag*F is similar to the lifetime in buffer, whereas the lifetime of free Ag*F is shorter than in buffer, indicating a strong interaction between NaSy and free Ag*F. The difference in lifetime between free and bound Ag*F in NaSy is 280 psec (Table 1).

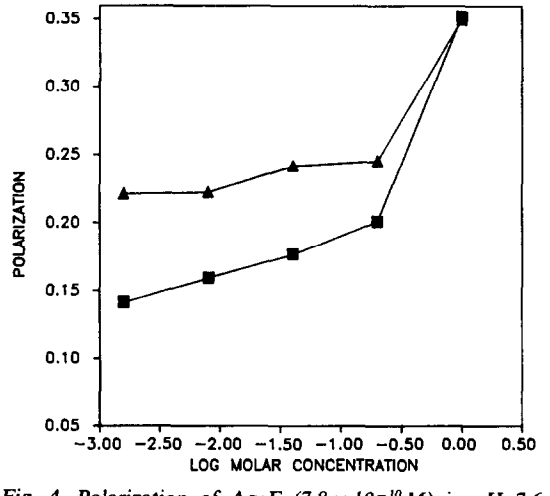

Fig. 4. Polarization of Ag*F ($7.8 \times 10^{-10} M$) in pH 7.6 TRIZMA buffer as a function of NaSy concentration. Symbols as for Fig. 3.

The combination of Zn^{2+} and NaSy yields the highest intensity ratio, with polarization and lifetime differences falling between those for the individual Zn^{2+} and NaSy systems. The Zn^{2+}/NaSy combination is not suitable for the homogeneous immunoassay, however, owing to the tendency of the proteins to precipitate in the presence of Zn^{2+}.

Polarization FIA

We chose to use NaSy (25mM in the cuvette) in the homogeneous FIA for several reasons, based on the studies described above. It provides adequate discrimination between free and bound Ag*F without precipitation problems and it stabilizes the fluorescence intensity of the Ag*F in the cuvette. The polarization difference, ΔP, was judged, from the results shown in Table 1 and related experiments, to be a more reproducible and selective parameter than the fluorescence intensity ratio or lifetime difference, and was used as the basis of the FIA.

Dilution curves. The Ab was obtained as a serum with unknown protein content. A dilution curve for a fixed amount of Ag*F with different dilution factors of Ab is shown in Fig. 5. Each point in the curve is the average of the polarization for two sets of standard solutions. The amounts of Ab used in subsequent experiments were chosen from the region of the curve with the highest slope.

Bovine insulin. The polarization difference as a function of bovine insulin concentration is shown in Fig. 6. Each data point is the average ΔP for three different sets of solutions. A competitive homogeneous immunoassay requires that concentrations of reagents (especially the antibody) be kept low in order to obtain high sensitivity and low detection

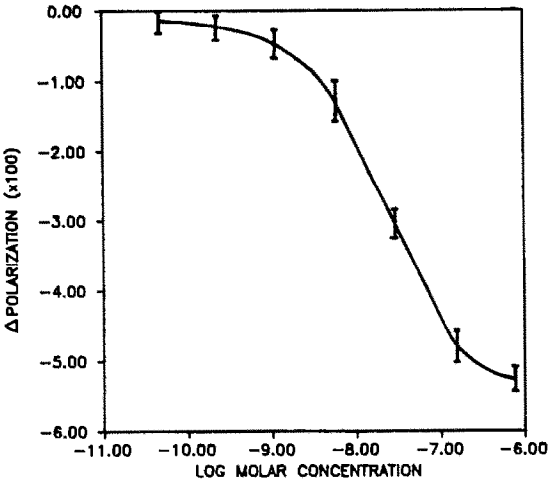

Fig. 6. Calibration curve for bovine insulin, with Ag*F ($5.2 \times 10^{-10} M$) and Ab (1.7×10^4 dilution) in pH 7.6 TRIZMA buffer with 0.025*M* NaSy.

limits for the analyte. This will, however, limit the dynamic range and lower the signal-to-noise ratio of the measurements. Background interference and scattered light are often a major problem when low reagent concentrations are used, because of the low signals that must be measured. In this study, a 490 nm excitation wavelength and a 530 nm band-pass filter were used to minimize the scattered light signals. Background interference was corrected by blank subtraction.

Human insulin. We were able to use the same reagents that were used for bovine insulin (bovine Ag*F and anti-porcine insulin Ab) to determine human insulin because of the similarity between insulins from different species. The ΔP as a function of the concentration of human insulin is shown in Fig. 7. Each data point is the average obtained for three different sets of solutions. The curve indicates that the human insulin can successfully compete with the bovine Ag*F for Ab, causing a decrease in polarization. The detectability appears to be at least as good as for bovine insulin. A slightly higher sensitivity was observed for human insulin than for bovine insulin and may be due to the lower amounts of Ab used.

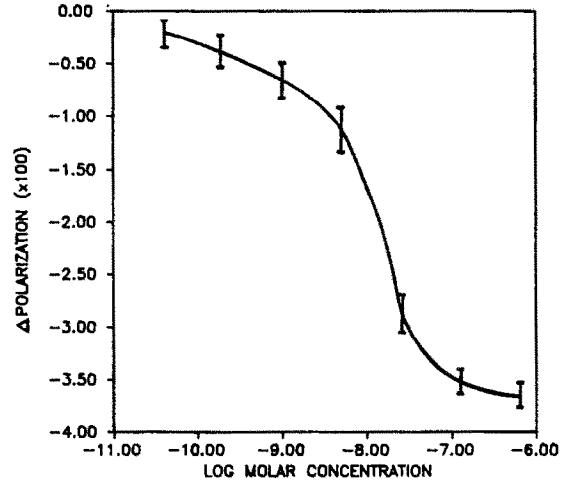

Fig. 7. Calibration curve for human insulin, with Ag*F ($5.2 \times 10^{-10} M$) and Ab (4.0×10^4 dilution) in pH 7.6 TRIZMA buffer with 0.025*M* NaSy.

CONCLUSIONS

The results of these studies indicate that: (1) fluorescence polarization provides better discrimination between free and bound Ag*F than do fluorescence intensity and lifetime, despite the relatively high molecular weight of insulin compared to that of small hapten molecules; (2) sodium salicylate can be used in combination with silica cuvettes to stabilize the intensity of Ag*F, probably by reducing adsorption on the cuvette walls; (3) the same reagents (bovine Ag*F and anti-porcine insulin Ab) can be used to determine both bovine and human insulin.

Summary—A pulsed continuum xenon flash-tube is used as an excitation source in ICP–AFS. The simultaneous excitation of many elements is attractive and avoids the one source per element as in conventional ICP–AFS. In this study, the pulsed continuum flash-tube is evaluated as an excitation source for multielement atomic fluorescence spectrometry in an ICP. Analytical figures of merit are given for the elements studied.

The most commonly used multielement atomic spectroscopy technique is inductively-coupled plasma atomic-emission spectrometry (ICP–AES), which achieves ng/ml detection limits, linear calibration over a wide range, excellent precision, and measurements free from matrix effects for most elements.[1–3] More recent techniques include the multielement hollow-cathode lamp–inductively-coupled plasma–atomic-fluorescence spectrometer (HCL–ICP–AFS), inductively-coupled plasma–mass spectrometer (ICP–MS), and continuum source–furnace–atomic-absorption spectrometer (CSF–AAS) combinations.[1–3] The fluorescence approach results in lower detection limits, greater spectral selectivity, and a reduced emission background;[4,5] the furnace atomic-absorption approach is applicable to smaller sample amounts than the ICP–AES approach. In our present study, we decided to capitalize on the simplicity of the atomic-fluorescence spectra of virtually all elements, as well as the possibility of exciting all atoms (and/or ions) simultaneously by means of a spectral-continuum light-source.[6–8] To increase the source spectral irradiance,[9] especially in the ultraviolet, we used a repetitively pulsed xenon flash-tube, and a gated detector to increase the measured signal-to-noise ratio. Here, we describe the experimental system and give some initial analytical figures of merit.

EXPERIMENTAL

Instrumentation

A schematic diagram of the system used is shown in Fig. 1. The experimental components and manufacturers are listed in Table 1. Source radiation from the pulsed flash-tube was focused into the ICP by using two lenses, L1 and L2 (both with diameter and focal lengths of 50 mm): L_1 collimated the light from the flash-tube and L_2 focused the collimated light onto the center of the ICP, above the load coils. The diameter of the focused beam was approximately 8 mm. Several precautions were taken to reduce the amount of scattered light reaching the monochromator. A light-trap was placed opposite the ICP, and blackened baffles were set up around the ICP. The collection lens, L_3 (focal length 178 mm), was also enclosed within a blackened tube to further reduce scattered light. The limiting noise of the system was due to scattered light from the excitation source.

The 300-W xenon flash-tube was enclosed within a fan-cooled housing having a front-surface spherical mirror (focal length 31.5 mm) and collimating lens (L_1). The lamp was operated from a pulsed 5-kV power supply. A 0.2-μF discharge capacitor provided an input energy of 5 J per flash, a flash half-width of *ca.* 680 nsec, and a peak power of 4.2 kW. The lamp was pulsed at 20 Hz. To help reduce radiofrequency (rf) noise, the entire lamp housing was surrounded and grounded with copper wire cloth acting like a Faraday cage. The fluorescence radiation was collected at 90° to the excitation beam and a 1:1 image of the ICP was focused onto the entrance slit of the monochromator (focal length 350 mm, reciprocal dispersion 20 Å/mm, and aperture *f* 6.8). So as to not overfill the monochromator collimator, an iris diaphragm was placed between L_3 and the monochromator. A small fraction of the excitation light from the flash-tube was reflected to a photodiode which triggered the boxcar averager. The photocurrent pulse produced by the photomultiplier tube (PMT) was passed through a 1000-Ω load resistance directly into the boxcar input. The resulting signal pulse had an FWHM of *ca.* 1.5 μsec. The boxcar gate delay time (the time between the trigger pulse and the start of the measurement) was 700 nsec. The gate width (the time during which fluorescence was measured) was 1.8 μsec for all cases. Thirty signals (*i.e.*, 30 lamp flashes) were averaged for each output signal. The "busy out" of the boxcar averager triggered the Stanford analog-to-digital (A/D) system to measure the output signal.

Horizontal and vertical movement of the ICP torch was accomplished with two single-axis mounts allowing horizontal translation up to *ca.* 100 mm and vertical translation up to *ca.* 80.mm. The ICP concentric pneumatic nebulizer was fed by peristaltic pump to permit a lower sample uptake rate and thus reduce salt encrustation in the torch. The plasma operating conditions are listed in Table 2.

Reagents and procedure

All components of the experimental system were operated according to the directions given in the manufacturers' manuals. The stock solutions were made with reagent-grade compounds recommended by Parsons *et al.*,[10] and

diluted as required. Distilled demineralized water was used throughout.

For each element studied, the optimal ICP rf power, observation height above the ICP load coil, monochromator slit-width, and ICP gas flows were determined. Calibration graphs and limits of detection were also determined for each element. For measurement of the synthetic mixture containing five elements, compromise values of the operating parameters were necessary. A comparison was also made of the results obtained with an extended ICP torch and the conventional torch used for most parts of this study. An extended ICP torch has an outer sleeve that is 40 mm longer than that of the conventional torch. Finally, we looked at the possibility of double resonance excitation of Ca by use of the flash-tube.

RESULTS AND DISCUSSION

Molecular species of non-refractory elements typically have low molecular dissociation energies and are easily atomized by the plasma at lower rf powers, whereas those of the refractory elements typically have high molecular dissociation energies and are atomized by the plasma at higher rf powers. Also, the atomic and ionic populations of the sample species in the plasma are often greatly affected by the choice of rf power and observation height.[9,10] For these initial studies, the dependences of the fluorescence on the rf power and observation height were examined independently, as shown in Figs. 2 and 3 respectively.

Figure 4 shows the variation in fluorescence signal-to-noise with monochromator slit-width for each element (at optimal rf power and observation height). Table 2 lists the optimal conditions (found by univariate search) for each element, based on Figs. 2–4.

Typical calibration plots obtained under the optimal conditions are shown in Fig. 5. Table 3 lists the analytical figures of merit. The detection limit is defined as the concentration in μg/ml of the element in pure aqueous solution resulting in a signal that is three times the standard deviation of the blank

measurements. The electronic band-width for all measurements was *ca.* 1 Hz. Previously reported ICP–AFS detection limits for the same elements are also listed in Table 3. All the log–log calibration plots have slopes between 0.96 and 1.06.

The effect of using a long torch was examined for cadmium as model element. The results are shown in Figs. 2–5 and the corresponding curves are labeled Cd(L). With the long torch, the fluorescence signal was practically constant at observation heights 45–60 mm above the load coil, whereas with the standard torch the signal rapidly decreased with increase in observation height (Fig. 2). The variation in signal with increase in rf power was similar in pattern for both torches, but the signal was significantly larger with the standard torch (Fig. 3). A similar difference was observed for the effect of monochromator slit-width on the signal-to-noise ratio, and again the standard torch gave much the better performance (Fig. 4). Despite this, the detection limits for cadmium were essentially the same with both torches (Table 3).

Figure 6 shows a multielement scan of a synthetic mixture of the five elements (20 μg/ml each), with a standard torch. The most intense fluorescence line of each element except vanadium was excited and observed (see Table 2). The most intense fluorescence signals for vanadium are at 309–310 nm, *i.e.*, in the middle of a strong OH band.[12] Therefore, the next most intense fluorescence line of vanadium at 292.4 nm, was observed.

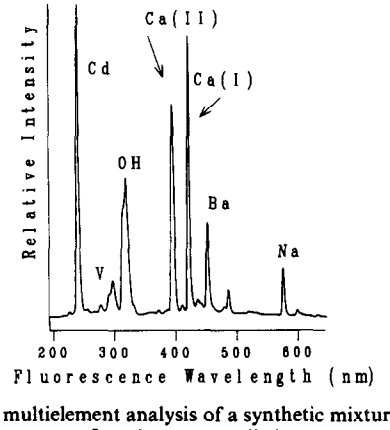

Fig. 6. A multielement analysis of a synthetic mixture of the five elements studied.

We were unable to detect any instances of double resonance fluorescence of calcium as described by Omenetto *et al.*,[13] who observed double resonance excitation of Ca with two different dye lasers (pumped by an excimer laser), one laser giving excitation at 396.847 nm and the other at 370.603 nm, the fluorescence being observed at 373.690 nm.

CONCLUSION

The work presented thus far shows promising results for the use of a flash-tube in ICP–AFS. The present system would appear to have considerable use in multielement analysis even though the detection limits for each element were at least an order of magnitude poorer than the best reported in the literature. Future work on this project will involve studies to improve the detection limits so as to be competitive with the present commercial atomic spectrometry systems. Improvements could be made by better rf shielding, decreased excitation source scatter, and better and more efficient collection of the fluorescence signal. Since the limiting noise in our system was due to scattered light from the flash-tube, efforts will also be made to reduce scattered light by using non-resonance fluorescence emission filters and better light-traps. An ultrasonic nebulizer will also be used for the more efficient sample uptake into the ICP.

TEMPERATURE EFFECTS ON THE SOLID-MATRIX LUMINESCENCE PROPERTIES OF 4-PHENYLPHENOL ADSORBED ON FILTER PAPER

S. M. RAMASAMY and R. J. HURTUBISE*
Chemistry Department, University of Wyoming, Laramie, WY 82071, U.S.A.

(*Received* 6 *April* 1988. *Revised* 17 *August* 1988. *Accepted* 7 *September* 1988)

Summary—Experimental values of fluorescence quantum yield, phosphorescence quantum yield, and phosphorescence lifetime were obtained at temperatures from 23° to −180° for 4-phenylphenol adsorbed on filter paper. From the experimental values, rate constants for phosphorescence and radiationless transition from the triplet state were calculated along with the triplet formation efficiency. The data revealed several important aspects that are responsible for the room-temperature fluorescence and phosphorescence of 4-phenylphenol adsorbed on filter paper.

Solid-matrix room-temperature fluorescence (RTF) and solid-matrix room-temperature phosphorescence (RTP) are important analytical techniques in organic trace analysis.[1,2] Relatively little research has been done to clarify the interactions needed for RTF and RTP. In particular, the interactions needed for strong RTP signals have not been fully elucidated. It has been shown by a variety of spectral techniques that the anion of *p*-aminobenzoic acid can be held by two sodium acetate molecules, which allows strong RTP signals to be observed.[3] Recent reports have discussed the physicochemical interactions of *p*-aminobenzoic acid adsorbed on sodium acetate[4–6] and on an α-cyclodextrin/sodium chloride mixture.[7]

Filter paper is the matrix most widely used for obtaining RTP from adsorbed compounds. Nevertheless, little is understood about the interactions needed with filter paper for RTP to occur. Schulman and Parker[8] postulated that hydrogen bonding of ionic organic compounds to hydroxyl groups on filter paper was the primary mechanism giving a rigid sample matrix for RTP. Andino *et al.*[9] used X-ray photoelectron spectroscopy to study the surface processes in RTP in the presence of heavy atoms. They observed that the extent of penetration of the heavy atoms or ions seemed to exceed that of the organic compound. Su and Winefordner[10] also used X-ray photoelectron spectroscopy to study heavy atom–analyte–substrate interactions in RTP. Suter *et al.*[11] considered hydrogen-bonding properties involved in RTP with a cellulose substrate. They also reported that totally symmetric vibrational bands are predominantly enhanced for dibenzo[*f*, *h*]quinoxaline adsorbed on filter paper with a heavy atom present.[12] Their results led to improved spectral assignments which would permit more accurate identification of compounds in mixtures. Other workers have proposed various interactions that are important in understanding solid-matrix RTP.[13–15]

In this work, a somewhat different approach has been undertaken to study solid-matrix luminescence interactions. The fluorescence quantum yield, phosphorescence quantum yield, and phosphorescence lifetime values for 4-phenylphenol adsorbed on filter paper were obtained over a wide temperature range.

EXPERIMENTAL

Reagents

Absolute ethanol was purified by distillation. 4-Phenylphenol (Aldrich) was recrystallized from ethanol. Sodium salicylate (Gold Label, Aldrich) and sodium acetate (anhydrous, Baker Analyzed Reagent) were used as received. The filter paper (Whatman No. 1) was eluted with ethanol to collect impurities at one end prior to use. Nitrogen was purified as reported earlier;[5] it was used to cool the sample to the desired temperature, and was passed into the cell compartment.

Apparatus

The instrumental setup used for the quantum yield and phosphorescence lifetime studies was that described previously.[5]

Procedures

Powdered samples of sodium acetate (blank), and sodium salicylate/sodium acetate (1:75) (standard) were prepared as reported earlier.[5] For filter paper, a solution of 250 ng of 4-phenylphenol in 2 μl of ethanol–water (80:20 v/v) saturated with sodium chloride was spotted onto the top of a pack of five $\frac{3}{8}$-in. diameter filter paper circles. The filter paper circles were held in the depression of the Delrin sample holder and treated as described previously.[16]

The procedures used to determine the quantum yields and phosphorescence lifetimes for 4-phenylphenol adsorbed on filter paper along with sodium chloride were essentially the same as those outlined earlier,[5] except for the following modifications made to improve the procedure for the determination of quantum yields.

For the measurement of reflectance bands, 1-nm band-pass slits were used in the entrance and exit ports of the excitation monochromator, instead of the beam-aperture reducer and 2.5-nm band-pass slits in the excitation mono-

*Author for correspondence.

chromator used previously.[16] This change eliminated the need to check the position of the beam-aperture reducer whenever the slits were changed in the excitation monochromator or the phosphoroscope was turned on and off. This change also allowed the thermopile reading of the corrected-excitation unit to be set to 80 at 467 nm, instead of the previously used setting of 30,[16] resulting in use of a lower gain in the electronic amplification and hence a less noisy signal. Furthermore, in the absence of the beam-aperture reducer, even weak phosphors could be excited to yield emission spectra of measurable intensity. The fluorescence emission spectra of the standard and the blank were also recorded with the same slits so that the quantum yield of the standard could be calculated by an absolute method.[16]

The standard, analyte and the corresponding blanks were used on the same day for recording their spectra at a given temperature. This minimized the error associated with changes in source intensity of the xenon lamp from day to day.

The background phosphorescence of the filter paper blank was subtracted from the phosphorescence of the 4-phenylphenol adsorbed on the filter paper. The standard, analyte and the blanks were all excited with 270 nm radiation.

RESULTS AND DISCUSSION

Solid-matrix luminescence quantum yields as a function of temperature

We have recently reported the effects of temperature on the fluorescence and phosphorescence properties of *p*-aminobenzoic acid adsorbed on sodium acetate.[5] Using methods similar to the ones developed earlier,[5,16] we have obtained the fluorescence quantum yield (ϕ_f) and phosphorescence quantum yield (ϕ_p) values for 4-phenylphenol adsorbed on filter paper from ethanol solutions saturated with sodium chloride. Sodium chloride was used because relatively strong RTP signals had been obtained from 4-phenylphenol present with this salt on filter paper.[15] 4-Phenylphenol was chosen as a model compound because some of its solid-matrix luminescence properties had previously been investigated on filter paper.[15] Table 1 lists the quantum yield values obtained for 4-phenylphenol. The samples were dried prior to quantum yield measurements and all measurements were made with the samples in a nitrogen atmosphere so there would be little, if any, quenching from water and oxygen. The data in Table 1 show that ϕ_f increased by 54.5% between 23° and −180°. This is in contrast to the ϕ_f values for 4-phenylphenol adsorbed on 80:20 w/w α-cyclodextrin/sodium chloride, which showed no increase when the temperature was changed from 23° to −180°.[7] The ϕ_p values given in Table 1 for 4-phenylphenol show a dramatic increase, changing from 0.020 at 23° to 0.53 at −180°. For 4-phenylphenol adsorbed on the α-cyclodextrin/sodium chloride mixture, the ϕ_p values increased from 0.08 (23°) to 0.34 (−180°C).[7] Changes in the ϕ_f and ϕ_p quantum yields at 23° and −180° have also been reported for *p*-aminobenzoic acid adsorbed on sodium acetate[5] and for *p*-aminobenzoic acid, benzo(*f*)quinoline, and phenanthrene adsorbed on α-cyclodextrin/sodium chloride mixtures.[7,17]

Table 1. Fluorescence and phosphorescence quantum yields from 23° to −180° for 4-phenylphenol adsorbed on filter paper

Temperature, °C	Fluorescence quantum yield, ϕ_f*	Phosphorescence quantum yield, ϕ_p*
23	0.33	0.020
0	0.47	0.072
−40	0.46	0.12
−80	0.45	0.25
−120	0.50	0.36
−180	0.51	0.53

*Average of duplicate runs. The pooled standard deviations for the fluorescence and phosphorescence quantum yields were 0.04 and 0.01, respectively.

The very large increase in the ϕ_p values on cooling to −180° indicates that 4-phenylphenol is not as strongly held on filter paper at room temperature as at low temperature. This is most likely due to the phenyl ring of the molecule not strongly interacting with the surface. In related experiments, the ϕ_f values for 4-phenylphenol in ethanol were found to be 0.17 at 23° and 0.26 at −196°. Comparison with the ϕ_f values in Table 1 shows that the solid-matrix ϕ_f values are all higher than the solution phase ϕ_f values. The fact that the ϕ_f values are higher on filter paper are thus important analytically. The room-temperature ϕ_p value for 4-phenylphenol on filter paper (Table 1) is low, as is normally the case for room-temperature phosphorescence quantum yields for compounds adsorbed on solid matrices. However, lowering the temperature to −80° gives a ϕ_p value on filter paper that is greater than the ϕ_p value of 0.18 obtained in ethanol at −196°C. This could prove to be important analytically because it is experimentally easier to obtain a temperature of −80° than one of −196°.

The effects of temperature on phosphorescence lifetime

The change in phosphorescence lifetime (τ_p) with temperature for *p*-aminobenzoic acid adsorbed on sodium acetate has already been reported.[5] The graph of τ_p as a function of temperature showed a linear portion with a negative slope between 23° and about −140° and then a plateau region from about −140° to −196° with essentially no change in lifetime. Oelkrug and co-workers[18–20] have reported similar solid-matrix phosphorescence lifetime curves for polycyclic aromatic hydrocarbons adsorbed on γ-alumina. However, for 4-phenylphenol adsorbed on filter paper impregnated with sodium chloride, τ_p decreased linearly as the temperature was increased from −180° to 23° (Table 2) and was essentially the same as for 4-phenylphenol adsorbed on filter paper alone, at the same temperatures, with ±0.1 sec reproducibility. Also only one decaying component was found, at all temperatures. Two decaying components were reported for *p*-aminobenzoic acid adsorbed on sodium acetate.[5]

Table 2. Phosphorescence lifetimes of 4-phenylphenol adsorbed on filter paper

Temperature, °C	Lifetime (τ_p)*, sec
23	1.38
0	1.53
−40	1.69
−80	1.96
−120	2.22
−180	2.53

Luminescence parameters

To help in understanding the interactions responsible for solid-matrix luminescence from organic compounds, it is important to know the fundamental luminescence parameters. Ramasamy and Hurtubise[5] summarized the calculation of the rate constants for phosphorescence (k_p), for the radiationless transition from the triplet state (k_m), and of the triplet formation efficiency (ϕ_t) for *p*-aminobenzoic acid adsorbed on sodium acetate. In this work, a similar approach was used to calculate k_p, k_m, and ϕ_t for 4-phenylphenol adsorbed on filter paper.

Equation (1) gives ϕ_t in terms of unimolecular rate constants, where k_{is} is the rate constant for intersystem crossing, k_f is the rate constant for fluorescence, and k_{ic} is the rate constant for internal conversion from the singlet state.

$$\phi_t = \frac{k_{is}}{k_f + k_{is} + k_{ic}} \tag{1}$$

The approach used to calculate ϕ_t for compounds adsorbed on solid matrices has been discussed previously.[5,6] Because the ratio ϕ_p/τ_p for 4-phenylphenol on filter paper was not constant with temperature, equation (2) was used to calculate ϕ_t.[5,6,21] The primed terms in equation (2) refer to the low-temperature values (−180°).

$$\phi_t = \frac{\phi_p \tau_p'}{\phi_p' \tau_p} \phi_t' \sim \frac{\phi_p \tau_p'}{\phi_p' \tau_p}(1 - \phi_f') \tag{2}$$

The substitution of $1 - \phi_f'$ for ϕ_t' in equation (2) should be reliable because ϕ_f' is measured at low temperature (−180°),[5,6,21] and the expression thus obtained was used to calculate the ϕ_t values, which are listed in Table 3 and varied over a wide range, with the smallest value obtained at 23°.

Equation (3) was employed to calculate the k_p values,[6] which are given in Table 3,

$$\phi_p = \phi_t k_p \tau_p \tag{3}$$

The average k_p values are the same at all temperatures, which would be expected because k_p is considered a fundamental molecular parameter. The radiationless transition rate constants from the triplet state (k_m) were calculated from equation (4) with the experimental τ_p values and the calculated k_p values, and are given in Table 3.

$$\tau_p = \frac{1}{k_p + k_m} \tag{4}$$

They decrease from the largest value at room temperature to essentially zero at −180° (the negative value at −180° is due to experimental error). Because the measurements were made with the samples protected by a nitrogen atmosphere and under dry conditions, quenching effects due to water and oxygen would be minimal. However, if quenching impurities were present in the filter paper, the value of k_m calculated from equation (4) would not be correct. The term $\Sigma k_q[q]$ would have to be added to the denominator of equation 4, where k_q is the rate constant for bimolecular quenching and [q] is the concentration of quencher, and the value obtained for k_m would in fact be $k_m + \Sigma k_q[q]$. Under the conditions of the experiment, quenching impurities in the filter paper were not determined. Thus, there was no simple way of assessing whether the nonradiative loss of energy from the triplet state was described by k_m or by $k_m + \Sigma k_q[q]$. Nevertheless, the value of k_m calculated from equation (4) gives a measure of the nonradiative loss of energy.

Interpretation of luminescence parameters

As mentioned earlier, k_p was constant with temperature, which indicates that it is mainly a function of the molecular structure of the model compound. The rate constant for the radiationless transition from the triplet state, k_m, decreased with temperature. This suggested that k_m depends on how rigidly the 4-phenylphenol is held in the matrix. A similar

Table 3. Luminescence parameters for 4-phenylphenol adsorbed on filter paper*

*The results are the average of duplicate runs. The numbers in parentheses are the absolute differences between the results for the duplicate runs.

conclusion was reached for the k_m values for *p*-aminobenzoic acid adsorbed on pure sodium acetate and on mixtures of sodium acetate with sodium chloride.[5,6] However, as also mentioned above, there may be impurities in the filter paper that would cause quenching of the phosphorescence signal. As the temperature is lowered, the quenching impurities could be inhibited from interacting with the phosphor as the matrix becomes more rigid. It would be necessary to evaluate $\Sigma k_q[q]$ to assess the magnitude of quenching and this information is not yet available. However, Table 2 shows that τ_p is a linear function of the temperature. It would seem that if both k_m and $\Sigma k_q[q]$ were a function of temperature then a more complicated relationship would be obtained between τ_p and temperature. Thus, the term $\Sigma k_q[q]$ probably had a minimal influence on τ_p [see equation (4) and discussion under *Luminenscence parameters*].

The linear relationship in Table 2 is somewhat anomalous compared to the earlier results for *p*-aminobenzoic acid adsorbed on sodium acetate[5] and the results reported by Oelkrug and co-workers[18-20] for compounds adsorbed on solid matrices. Normally a plateau is obtained at lower temperatures and τ_p becomes independent of temperature. From graphs of this type, an activation energy (E_a) can be obtained which is an approximate measure of how strongly a compound interacts with the matrix.[18-20] Table 1 shows that ϕ_p is very sensitive to temperature, and Table 3 shows that ϕ_t is also very sensitive to temperature. Neither ϕ_p nor ϕ_t reached a constant value over the temperature range investigated, which suggests that the flexibility of 4-phenylphenol is a factor in giving a relatively low ϕ_p at room temperature. To estimate the activation energy of the 4-phenylphenol adsorbed on filter paper, the value at which τ_p became independent of temperature was

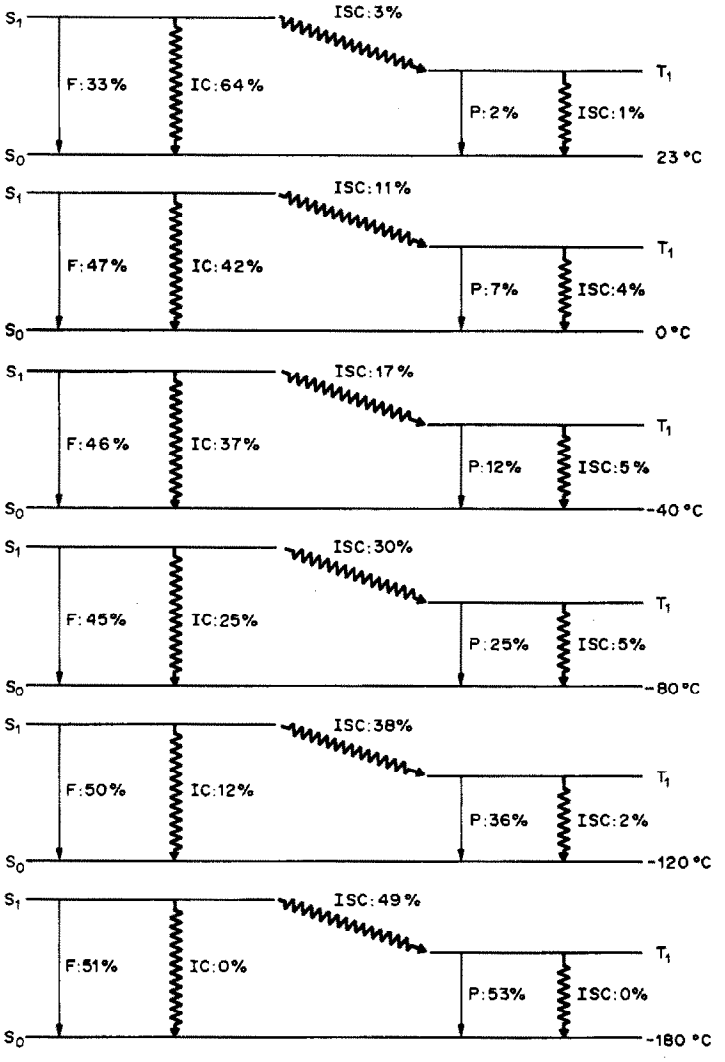

Fig. 1. Energy diagrams for 4-phenylphenol adsorbed on filter paper at different temperatures. S_0—ground state, S_1—singlet state, T_1—triplet state, F—fluorescence, IC—internal conversion, ISC—intersystem crossing, P—phosphorescence.

calculated by arbitrarily selecting values of τ_p° so that a plot of $\ln[1/\tau_p - 1/\tau_p^\circ]$ against the inverse of the absolute temperature gave the best straight line.[5,22] The term τ_p° is the value of τ_p at which the lifetime becomes independent of temperature. From the slope of the line, E_a was calculated to be 371 cm^{-1}. For *p*-aminobenzoic acid adsorbed on sodium acetate, the average E_a for the rapidly and slowly decaying components of *p*-aminobenzoic acid was 392 cm^{-1},[5] which is similar to the calculated value for 4-phenylphenol adsorbed on filter paper. The activation energy can be considered as a measure of how strongly a compound interacts with the matrix.[18,19] However, the exact meaning of E_a is not yet fully elucidated.[23]

Because it was not possible under the experimental conditions to obtain all the rate constants for the various radiative and nonradiative processes for adsorbed 4-phenylphenol, the fractions of absorbed photons involved in radiative and nonradiative transitions were calculated.[6,24] By use of the ϕ_t, ϕ_f and ϕ_p values in Tables 1 and 3, the diagrams in Fig. 1 were constructed.[6] From the diagrams, it is observed that the percentage internal conversion decreases with temperature, and becomes zero at $-180°$. It was earlier observed that the degree of internal conversion was zero at $-180°$ for 4-phenylphenol adsorbed on 80% α-cyclodextrin/sodium chloride mixture and 0.05% α-cyclodextrin/sodium chloride mixture.[7] Also the extent of intersystem crossing from the S_1 state to the T_1 state increased significantly for 4-phenylphenol as the temperature was lowered (Fig. 1). At $-180°$ the intersystem crossing yield was 16.3 times greater than that at room temperature. For 4-phenylphenol adsorbed on 80% α-cyclodextrin/sodium chloride, the intersystem crossing yield increased by a factor of about two when the temperature was lowered from room temperature to $-180°$. Interestingly, the intersystem crossing from the triplet state to the ground state did not vary much with temperature. It was calculated that there was no intersystem crossing to the ground state at $-180°$. In previous work, a relatively high degree of intersystem crossing to the ground state was observed for 4-phenylphenol adsorbed on 80% α-cyclodextrin/sodium chloride at 23° and $-180°$.[7] It is clear from Fig. 1, that at room temperature a large fraction of the energy absorbed is lost by internal conversion. This most likely results from the adsorption of 4-phenylphenol on filter paper being relatively weak because the only polar group in the molecule is the hydroxyl function. Also, the nonrigid structure of 4-phenylphenol can result in several vibrational modes in the ground state and excited singlet state which could provide channels for the nonradiative loss of absorbed energy. As the temperature is lowered, the ϕ_t values increase significantly, and this is mainly a result of the decreasing degree of internal conversion with temperature. Generally, the results in Fig. 1 support the postulate that a rigid analyte–substrate structure is responsible for the RTP from 4-phenylphenol; this is mainly deduced from the large decrease in internal conversion with temperature and the increase in intersystem crossing with temperature, from the S_1 state to the T_1 state. Apparently, 4-phenylphenol is held strongly enough at room temperature by hydrogen bonding of the hydroxyl groups of the filter paper to both the hydroxyl group of 4-phenylphenol and the phenyl ring of the molecule to permit the rigidity needed for RTP. As mentioned earlier, moisture and oxygen would not cause a quenching problem, because of the conditions of the experiment.

CONCLUSIONS

Both the triplet formation efficiency and phosphorescence quantum yields for 4-phenylphenol are very sensitive to temperature. This indicates that the RTP of 4-phenylphenol is a function of how rigidly the molecule is held to the filter paper surface. Because the rate constant for the radiationless transition from the triplet state is essentially zero at $-180°$, it can be concluded that nonradiative loss of energy from the triplet state does not occur at this temperature. However, the energy level diagrams for 4-phenylphenol reveal the relative complexity of the luminescence processes for solid-matrix luminescence analysis and indicate that several phenomena have to be considered in explaining the interactions for RTF and RTP.

3-BENZOYL-2-QUINOLINECARBOXALDEHYDE: A NOVEL FLUOROGENIC REAGENT FOR THE HIGH-SENSITIVITY CHROMATOGRAPHIC ANALYSIS OF PRIMARY AMINES

STEPHEN C. BEALE, YOU-ZUNG HSIEH, JOSEPH C. SAVAGE, DONALD WIESLER and MILOS NOVOTNY*
Department of Chemistry, Indiana University, Bloomington, IN 47405, U.S.A.

(*Received* 30 *June* 1988. *Revised* 12 *September* 1988. *Accepted* 23 *September* 1988)

Summary—3-Benzoyl-2-quinolinecarboxaldehyde has been synthesized and characterized for use as a precolumn fluorogenic reagent for the ultrahigh sensitivity determination of primary amines by microcolumn liquid chromatography with laser-induced fluorescence detection. The reaction conditions and the spectral properties of the derivatives were investigated with standard amino-acids. The detection limits, with an He–Cd laser operated at 442 nm, are in the low femtogram range. The linear dynamic range is at least three orders of magnitude. The separation of a standard amino-acid mixture and the high-sensitivity analysis of a hydrolyzed protein sample are demonstrated.

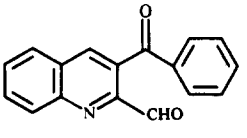
Determination of primary amines (*e.g.*, amino-acids and peptides) resulting from the controlled degradation of proteins is an important area in modern biochemical research. In conjunction with precolumn or postcolumn derivatization, high-performance liquid chromatography (HPLC) is the most common method of analysis for such compounds. A number of fluorogenic reagents specific for the amino-group, such as fluorescamine,[1] 7-chloro-4-nitrobenzene-2-oxa-1,3-diazole (NBD-chloride),[2] *o*-phthalaldehyde (OPA),[3,4] ninhydrin,[5] and naphthalene-2,3-dicarboxaldehyde (NDA),[6] have been developed for the purpose, and will give detection of primary amines at picomolar concentrations.

OPA has become the most popular fluorogenic reagent for pre- and post-column derivatization in chromatographic determination of amino-acids. OPA, itself non-fluorescent, reacts with primary amines to form an intensely fluorescent isoindole with an absorption maximum at 430 nm, but its use, particularly in a precolumn, is somewhat restricted by its sensitivity to auto-oxidation and attack by light and acids.[7]

De Montigny *et al.*[6] have recently described another fluorogenic reagent, NDA, which forms a more stable isoindole derivative than the OPA product from a primary amine. The improvement in stability results, in part, from the use of cyanide instead of a thiol as a nucleophilic reagent, resulting in substitution of a nitrile group instead of a thiol group on the isoindole ring.

The reagents so far developed usually display detection limits in the picogram range when used with conventional chromatographic systems and detection schemes. Sensitivity on this scale is inadequate for the analysis of protein hydrolysates resulting from state-of-the-art protein microisolations. Such microisolation strategies, based on packed-capillary LC, feature detection limits in the low picogram range for proteins, with nearly 100% recovery.[8,9] When hydrolyzed, picogram amounts of bovine insulin, for example, will yield only trace quantities of the free amino acids. Our goal in the development of fluorogenic reagents is the capability for routine analysis of the degradation products from femtomole, or smaller, protein samples, by micro-LC with laser-induced fluorescence (LIF) detection.

We have recently described a general approach to synthesis of fluorogenic reagents containing a variety of functional moieties so that the absorption maxima of their derivatives may be tuned to fit in with the desired detection scheme.[10] Through this strategy, we have developed 3-(2-furoyl)quinoline-2-carboxaldehyde (FQCA),[11] a reagent which reacts with amines to yield isoindoles with absorption maxima at 490 nm, and hence is ideal for use with the argon-ion laser, and also 3-benzoyl-2-quinolinecarboxaldehyde (BQCA),[10] a fluorogenic reagent yielding derivatives with absorption maxima compatible with the 442 nm line of the He–Cd laser. Here we extend the description of the latter reagent (structure shown below).



BQCA

*Author for correspondence.

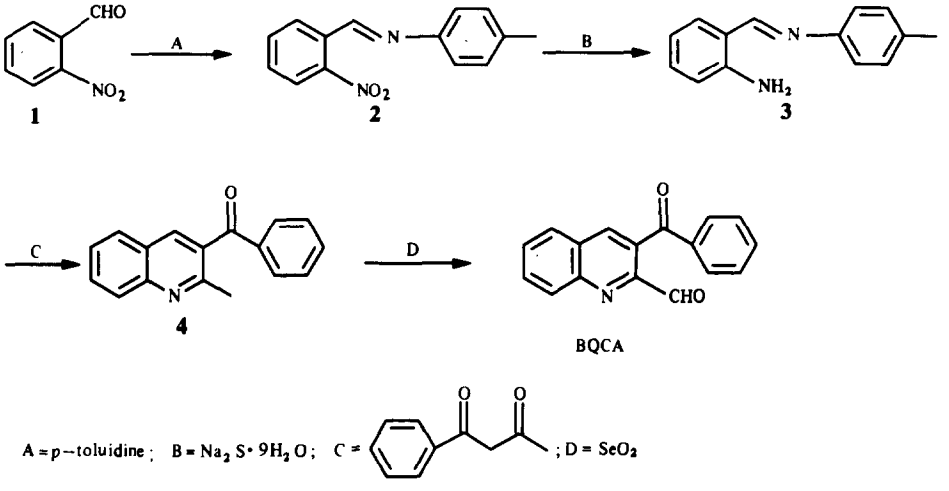
Implementation of a laser as an excitation source for fluorimetric LC detection has provided greatly reduced detection limits in a variety of experiments.[12-17] Excitation in the visible range eliminates many interferences from species present in biological samples (many of these species have excitation maxima in the ultraviolet region). Here we will show how this can be exploited with BQCA in analysis of protein hydrolysates.

EXPERIMENTAL

Chemicals

2-Nitrobenzaldehyde was obtained from Aldrich Chemical Co. (Milwaukee, WI). A set of L-amino-acids (kit # LAA-21) from Sigma (St. Louis, MO) was used without further purification. The hydrochloric acid was "sequanal" grade (Pierce Chemical Co., Rockford, IL). All other solid chemicals were analytical reagent grade from Fisher Co. (Fairlawn, NJ). Acetonitrile from Burdick & Jackson (Muskegon, MI) was used without purification. The water used was distilled and demineralized. The identity of all intermediates was established by NMR and/or mass spectral data.

Synthesis of BQCA



A mixture of 9.69 g (90.5 mmole) of *p*-toluidine and 10.89 g (72.1 mmole) of *o*-nitrobenzaldehyde (**1**) in 25 ml of ethanol was allowed to react for 5 min, then the yellow precipitate was filtered off, washed with cold ethanol, and air-dried. Additional solid was obtained by adding water to the ethanol wash; total yield 16.0 g (66.7 mmole, 93%). The 2-nitro-*N*-(*p*-tolyl)benzaldimine (**2**) thus formed was reduced to 2-amino-*N*-(*p*-tolyl)benzaldimine (**3**) by the procedure outlined by Borsch *et al.*[18] A mixture of 3.23 g (15.4 mmole) of this compound (**3**), 2.40 g (15.4 mmole) of benzoylacetone and 300 μl of piperidine in 25 ml of ethanol was heated under reflux for 20 hr, under nitrogen. After addition of water, the solution was distilled to remove excess of starting materials. The residue was washed with 3*M* sodium hydroxide and dried. The total yield of 3-benzoyl-2-methylquinoline (**4**) was 3.31 g (13.4 mmole, 87%). A mixture of 80 mg (0.32 mmole) of (**4**) and 40 mg (3.6 mmole) of selenium dioxide in 2 ml of glacial acetic acid was heated for 12 hr at 82°, then cooled to 5°, and finally 0.5 ml of 1*M* potassium hydroxide was added. The mixture was extracted with diethyl ether. The extract was washed with water, and dried with anhydrous sodium sulphate, then evaporated to yield 72 mg (0.28 mmole, 86%) of yellow crystals of BQCA.

Derivatization procedure

Individual amino-acids were dissolved in water to give 10m*M* solutions. For the preliminary fluorescence studies 20 μl of the amino-acid solution, 50 μl of BQCA solution (10 mg/ml in ethanol), and 100 μl of 10m*M* potassium cyanide were added to 200 μl of methanol and mixed. One ml of a 0.2*M* phosphate buffer, adjusted to the required pH, was also added for the pH studies. Except for the study of the development of the fluorescence, the mixtures were allowed to react for at least an hour before measurement.

Chromatographic instrumentation

The micro-LC system consisted of a Varian 8500 syringe pump (Walnut Creek, CA) modified to operate at constant pressure. Injections were made by the stopped-flow method. The laser-based detection system, shown schematically in Fig. 1, utilizes an Omnichrome (Chino, CA) He–Cd laser, with 50 mW output at 442 nm. The microcolumn was prepared by slurry-packing a 500 × 0.25 nm fused-silica capillary (Polymicro Technologies; Phoenix, AZ) with 5-μm C_{18} particles (Shiseido Co., Yokohama, Japan).

Spectrometric measurements

A Hewlett-Packard (Palo Alto, CA) model 5980A mass spectrometer was used for identification of the synthesis intermediates and products, by means of the direct insertion probe. Static fluorescence measurements and spectral data were obtained with a Perkin-Elmer (Norwalk, CT) 650 spectrofluorimeter equipped with xenon arc lamp, powered by a Perkin-Elmer 150 xenon power supply.

RESULTS AND DISCUSSION

It has been shown that isoindoles are extremely sensitive to electrophilic attack[19] or auto-oxidation[7] at the two positions adjacent to the nitrogen atom of the indole system. Consequently, we have chosen to investigate keto-aldehydes rather than dialdehydes as fluorogenic reagents. Use of a keto-aldehyde leads to replacement of the hydrogen atom on one of the carbon atoms adjacent to the isoindole nitrogen atom, with a concomitant increase in stability. We can also take advantage of the keto-aldehyde type of reagent to introduce various substituents into the

product, thereby "tuning" its absorption maximum. It has been reported by de Montigny *et al.*[6] that the use of cyanide instead of a thiol as the nucleophilic substituent in the derivative formation increases both the fluorescence intensity and stability of the isoindoles relative to OPA, presumably because of its electron-withdrawing characteristics. We have done the same, thus replacing the other hydrogen atom in the isoindole grouping by a nitrile group. We assume that the reaction mechanism is similar to that for use of a thiol.[20]

The excitation and emission spectra, obtained at a scan-rate of 60 nm/min, for the glycine derivative of BQCA are shown in Fig. 2. The excitation maximum, which is representative of the other amino-acid derivatives, is at 455 nm, sufficiently close to the 442 nm line of the He–Cd laser for this to induce a fluorescence intensity that is about 90% of the maximum attainable. The emission maximum is at 545 nm.

It has been previously shown[10] that isoindoles derived from BQCA are more stable than the corresponding OPA derivatives. Once a stable fluorescence intensity is reached, that level is maintained for several hours. We have found that if the derivatives are stored dry (in a freezer) they do not decompose for at least two weeks.

Several factors that influence the yield of derivative have been studied. These included the amount of

reagent and cyanide present, as well as the pH. Figures 3 and 4 show at least a 4-fold molar excess of BQCA and a 5-fold molar excess of cyanide is required for the fluorescence intensity to be independent of the amounts of these two reagents.

The corresponding influence of pH is presented in Fig. 5. For this investigation, equimolar amounts of methionine and lysine were reacted in 1 ml of 0.2*M* phosphate buffer, adjusted to the appropriate pH. The mixture was diluted to 3 ml with 50% aqueous methanol and the fluorescence intensity at 550 nm was plotted as a function of pH. The results indicate that the fluorescence is maximal when a pH of about 8 is used. This pH can be realized by means of the

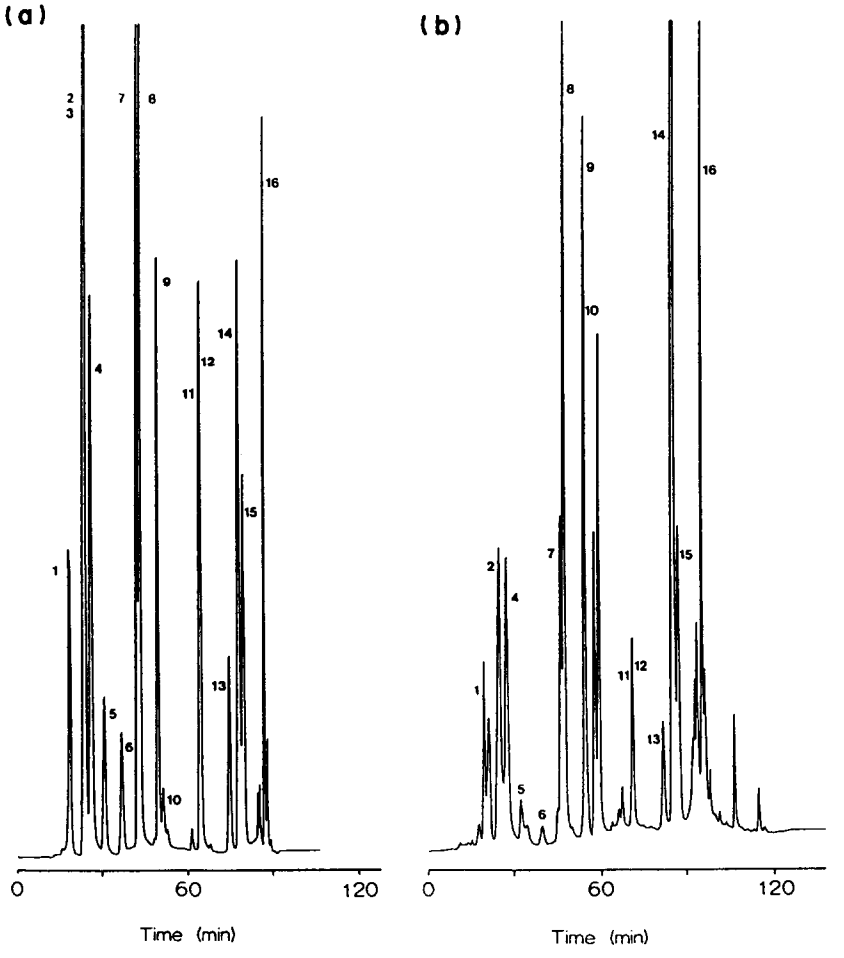

Fig. 6. (a) Chromatogram of standard amino-acid mixture (15 ng of each) (b) Chromatogram of hydrolysis products from 171 fmole of myoglobin. Peaks: (1) His; (2) Glu; (3) Gln; (4) Thr; (5) Asp; (6) Ser; (7) Tyr; (8) Gly; (9) Ala; (10) Arg; (11) Met; (12) Val; (13) Ile; (14) Leu; (15) Phe; (16) Lys.

cyanide added, without addition of a buffer, so the methanol/water solvent system can be used as the reaction medium. It should be noted that at this pH the cyanide will be extensively hydrolysed, and mainly in the free acid form (HCN).

The utility of BQCA for amino-acid analysis is demonstrated in Fig. 6, which shows the micro-LC separation of the BQCA-derivatives of the amino-acids. The upper trace is a chromatogram of a standard amino-acid mixture (15 ng of each acid) and the lower is the chromatogram of the products from acid hydrolysis of 171 fmole of myoglobin. This amount of myoglobin was hydrolyzed in a few hundred μl of acid, and the free amino-acids were then derivatized with BQCA. The solvent was removed by lyophilization, and the residue was taken up in 2–3 μl of methanol. The whole of this was injected onto the column by the stopped-flow method, and the amino-acids were eluted with a stepwise gradient from 25 to 50% acetonitrile in water, at a constant concentration of 0.1% v/v acetic acid and 0.2% v/v triethylamine in the mobile phase. Calibration graphs for glycine and serine were linear over at least three orders of magnitude.

In summary, we have synthesized a useful reagent for producing fluorescent derivatives of primary amines, suitable for analysis by micro-LC with LIF detection at 442 nm. The reagent, in the presence of a primary amine and an appropriate nucleophile (we have chosen cyanide) forms an intensely fluorescent isoindole with an absorption maximum which is close to the 442 nm line of the He–Cd laser. The reaction proceeds reproducibly under mild conditions (pH ~8, room temperature), and the products are stable for several hours in solution. Through the use of micro-LC/LIF, we have reduced the routinely achievable mass detection limits to the femtomole range, with few interferences. Moreover, we have demonstrated that a complete analysis, from hydrolysis to separation and detection, can be achieved with as little as 171 fmole of a protein, which is on the scale of the protein micro-isolations recently reported by this laboratory.[8,9] Micro-LC/LIF is ideally suited for this type of sample-limited trace analysis. The inherently small volume and hence greater mass sensitivity featured in micro-LC make it the separation mode of choice in this case. In addition, LIF with proper derivatization can further enhance the sensitivity. Thus, micro-LC/LIF may be a very suitable tool for use by chemists and biochemists interested in extremely small biological objects and their trace analysis.

LIQUID CHROMATOGRAPHY STUDIES OF SOLUTE–CHAIN INTERACTION UNDER REORDERING/RESOLVATION CONDITIONS—I

CORRELATIONS BETWEEN SOLUTE STRUCTURE AND CHANGES IN RETENTION FOR HYDROXYLATED ALIPHATIC AND AROMATIC COMPOUNDS

S. S. YANG and R. K. GILPIN*
Department of Chemistry, Kent State University, Kent, OH 44242, U.S.A.

(*Received* 12 *July* 1988. *Accepted* 9 *September* 1988)

Summary—The current investigation is an extension of previous liquid chromatography studies involving conformational changes of n-alkyl-bonded phases under totally aqueous mobile phase conditions. Relative changes in retention, $\Delta k'$, before and after reordering/resolvation of an octyl phase have been studied with various linear, branched, cyclic and aromatic compounds. The magnitude of $\Delta k'$ can be correlated to structural features in the solute, such as size, shape, rigidity and substitution. The largest values of $\Delta k'$ were obtained for rigid solutes with multiple hydroxy groups.

Reversed-phase liquid chromatography is perhaps the most important means of separating thermally labile low molecular-weight compounds. In a majority of cases, separations are done with linear alkyl phases. Hence developing a better understanding of such bonded materials and the fundamental processes controlling solute retention and selectivity continues to be important.

A number of theories have been proposed to explain the nature of the bonded microlayer.[1–9] A common view is that the immobilized chains are surrounded by intercalated solvent, the composition of which may or may not be close to that of the bulk mobile phase. Further, the microlayer can swell or shrink depending on the solvent composition—this phenomenon has been discussed in terms of a "breathing" model.[9]

Previously we have systematically investigated thermally induced reordering/resolvation of both polar and nonpolar bonded phases in contact with water[1,10–12] Likewise, the influence of solvent entrapped during preconditioning of the surface has been examined.[13] Although separations are not usually performed with totally aqueous mobile phases, results from such studies have been useful in developing a better understanding of the orientation and dynamics of the bonded chains. The surface immobilized chains assume a folded conformation (an aggregated state) when the mobile phase is changed from an organic solvent to a totally aqueous solution. However, the bonded chains may be reoriented to an extended state when heated. Water molecules penetrate into the bonded phase and form hydrogen bonds with unreacted surface silanol groups. For nonpolar chains, this behavior can be explained by differences between the two conformations in terms of (*a*) cohesive interactions between bonded chains, (*b*) hydrophobic interactions between bonded chains and the contact solvent, water, and (*c*) specific interactions resulting from hydrogen bonding between the aqueous mobile phase and unreacted surface silanol groups.[11] However, for bonded alkyl chains containing a polar functional group, the specific interactions between this and the aqueous mobile phase must also be considered.[12]

The onset temperature (T_0) for reordering/resolvation can be obtained from a plot of $\ln k'$ *vs.* $1/T$. This is illustrated in Fig. 1 for a silica with immobilized octyl chains. The experimental details of this procedure have already been described.[4] T_0 values have been determined for a number of polar and nonpolar phases. For a particular homologous series of anchored groups, a linear correlation exists between the reordering/resolvation onset temperature and the boiling point of corresponding nonimmobilized compounds.[11,12] A similar experiment was performed to examine the influence of bonding chemistry on resolvation.[14] Reordering has been found to begin at approximately the same temperature, irrespective of the bonding chemistry.

The relative changes in retention, caused by resolvation, have been shown to be a function of surface coverage and solute structure.[10] The current investigation is an extension of these earlier surface resolvation experiments and is a systematic attempt to examine what differences in ordering occur when molecules interact with the bonded phase. Relative

changes in retention, following resolvation, have been determined for various linear, branched, cyclic and aromatic compounds.

EXPERIMENTAL

Chemicals and instruments

All compounds listed in Table 1, and the HPLC grade acetonitrile, were purchased from the Aldrich Chemical Co. Demineralized water was purified with a Milli-Q reagent water system and used as the mobile phase. Octyldimethylchlorosilane was obtained from Petrarch System Inc., (Levittown, PA) and used as received. LiChrosorb Si60 (particle size 10 μm and surface area 550 m^2/g) was from E. Merck (Darmstadt, West Germany).

All chromatographic studies were made with a Laboratory Data Control (Riviera Beach, FL) model constametric II G liquid chromatographic pump equipped with ultraviolet and refractive index detectors. Column temperature was controlled by a water-bath with a Tempunit (Techne, Princeton, NJ) model TU-14 zero cross-over proportional controller and a Neslab (Neslab Instruments, Portsmouth, NH) model EN-350 flow-through liquid cooler. The flow-rate was monitored with a model F1080A liquid flowmeter (Phase Separations Ltd., Queensferry, Clwyd, UK). Retention data were recorded and processed with an IBM Instruments model 9000 data-system.

Column preparation

LiChrosorb Si60 (3.0 g) was slurried with demineralized water and allowed to stand for 3 hr. Excess of water was removed and the material dried at 110° for 3 hr. The dried silica was refluxed overnight with 50 ml of a 15% solution of n-octyldimethylchlorosilane in toluene. During this process, a stream of dry nitrogen was continuously bubbled through the solution. After this reaction, the modified silica was washed with five 50-ml portions of toluene and two 50-ml portions of diethyl ether. The material was dried at 110° for 4 hr to remove the solvent. The surface coverage (w/w%, carbon/silica), determined by microcombustion analysis, was 11.2%.

Empty 5-cm long columns were prepared from 4.6 mm I.D. stainless-steel tubing, and thoroughly cleaned with nonpolar and polar solvents and then rinsed with acetone. The modified materials were packed into the columns by a dynamic procedure.[15]

Chromatographic studies

Solute retention was measured before and after resolvation of the bonded phases.

Initial studies. The column was first conditioned with 100 ml of acetonitrile followed by 100 ml of demineralized water at 20.0 ± 0.1°. Acetonitrile was chosen as the conditioning solvent to minimize entrapment problems.[13] The flow-rate was 4.0 ml/min and the retention of each compound was measured at least twice. The void volume was determined by use of D_2O.

Thermal treatment. The pump was switched off and the column temperature increased to 70°. The column was maintained at this temperature for 20 min to ensure themal equilibrium. The pump was then restarted and allowed to run for 15 min (passage of 60 ml of water) with the column maintained at 70°. The pump was again switched off and the column cooled to 20.0°.

Studies following thermal treatment. The pump was restarted and all compounds injected as in the initial studies.

These three steps were repeated three times.

Calculations

The capacity factors (k') for all solutes were calculated and $\Delta k'_r$ (the relative change in retention as a result of reordering/reorientation) was determined from

$$\Delta k' = 100(k'_a - k'_b)/k'_a \quad (1)$$

where k'_a is the capacity factor measured at 20.0° before thermal treatment, and k'_b is the capacity factor measured at the same temperature after heating and cooling.

RESULTS AND DISCUSSION

Representative plots of $\ln k'$ *vs.* $1/T$ for phenol chromatographed on an octyl phase before and after thermal treatment are shown in Fig. 1. In the presence of a totally aqueous mobile phase, the bonded chains may be in either an aggregated or an extended state at a given temperature.[10-12] At temperatures lower than T_0 (*i.e.*, 40° for an octyl phase), the

cyclohexanol	39.0	32.0	0.198	18.0 ± 2.0

*Average of values from three cycles.

bonded chains are in an aggregated state (line A) and following thermal treatment at temperatures above T_0 the chains are in an extended state (line B). The difference in retention before and after resolvation, $\Delta \ln k'_r$, is illustrated in Fig. 1 by line C.

Listed in Tables 1 and 2 are k', $\ln k'_a/k'_b$ and $\Delta k'_r$ values for the solutes studied. These solutes were chosen on the basis of small differences in size (*i.e.*, addition of methylene groups), shape (linear, branched, cyclic, *etc.*), position of hydrophilic substitution, and aliphatic *vs.* aromatic character. They cover a k' range from <1 to >200 and thus represent different degrees of solute–phase interaction. Interestingly, the trends to be discussed are independent of overall differences in retention but depend rather on structural features of the solutes. The relative magnitude of both $\ln k'_a/k'_b$ and $\Delta k'_r$ for the solutes decreased in the following order: (*a*) dihydroxy compounds > monohydroxy compounds > nonpolar compounds; (*b*) aromatic compounds > cyclic or branched aliphatic compounds > linear aliphatic compounds. The largest values of $\ln k'_a/k'_b$ and $\Delta k'_r$ were found for rigid solutes with multiple polar functional groups. The smallest values of $\Delta k'_r$ were obtained for small flexible solutes.

Plots of $\ln k'$ *vs.* carbon number are shown in Fig. 2 for three homologous series of solutes. These were linear alcohols (● and ○), branched alcohols (■ and □) and alkyl phenols (▲ and △). The data shown are the values before and after thermal treatment. For a given homologous series, the slopes of the lines are related to the incremental change in selectivity per methylene group added. Values for the slopes are given in Table 3. The incremental change was smaller for branched alcohols than for linear alcohols, which is reasonable on steric grounds. The 35–40% reduction in slope reflects a decrease in interaction per carbon atom in the more hindered system.

The two linear regression lines for a given series of solutes were parallel, with similar slopes before and after reordering/resolvation, indicating a similar degree of solute–chain interaction regardless of the conformation of the bonded chain. The relative

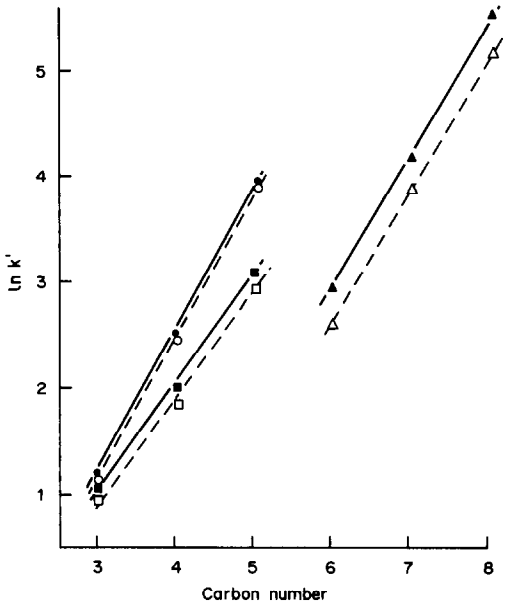

Fig. 2. Plots of $\ln k'$ *vs.* carbon number, showing changes in retention with addition of methylene groups. Solid line and filled symbols: data obtained before surface reordering/resolvation. Dashed line and open symbols: data obtained after surface reordering/resolvation. ●, ○: propanol, butanol, pentanol. ▲, △: phenol, *p*-methylphenol, *p*-ethylphenol. ■, □: 2-propanol, *tert*-butyl alcohol, *tert*-pentyl alcohol.

changes in retention appear to indicate the increased orientation necessary (*i.e.*, decrease in ΔS) for a solute to have the same degree of interaction (ΔH) regardless of the conformation of the phase. Thus, $\Delta k'_r$ can be correlated to the hydrophobicity of the solute and the way in which the substitution and rigidity influence solute–chain interaction. For rigid molecules with the hydrophobic portion more sterically hindered, $\ln k'_a/k'_b$ was largest, whereas for flexible solutes or for solutes where the polar group was at one end of the molecule, it was smallest. For example, a relatively small value of $\ln k'_a/k'_b$ was observed for benzene (0.0785), and only a slightly higher value for toluene (0.0944). These values represent only a small change in retention, of 7.5 and 9.0% respectively. However, the $\ln k'_a/k'_b$ values for phenol and the dihydroxybenzenes were significantly larger (0.333 and 0.391–0.413 respectively).

Plots of $\ln k'$ *vs.* number of hydroxy groups on the aromatic ring are given in Fig. 3. Two linear relationships are observed, with slopes of -1.04 and

Table 3. Effect of additional methylene groups on $\ln k'$ for various homologous series of solutes before/after reordering/resolvation

Compounds	Slope*	*Y*-intercept	Correlation
linear	1.38/1.37	−2.94/−2.99	0.999/0.999
branched	1.04/1.02	−2.15/−2.17	0.994/0.993
aromatic	1.30/1.27	−4.86/−5.05	1.000/1.000

*Calculated from plots of $\ln k'$ *vs.* carbon number (Fig. 2).

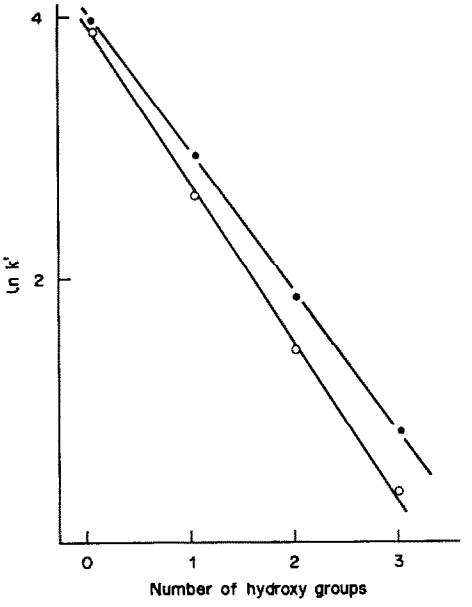

Fig. 3. Plots of $\ln k'$ *vs.* number of hydroxy groups on an aromatic ring. ●: data obtained before thermal treatment. ○: data obtained after thermal treatment. solutes: benzene, phenol, resorcinol and pyrogallol.

-1.14 for retention measurements made before and after reordering/resolvation of the surface. These lines are nonparallel and show that increasing hydrophilic substitution on the ring results in increasing values of $\ln k'_a/k'_b$. However, for substituted aromatic solutes where the hydrophobicity and rigidity are similar (*e.g.*, chlorophenols and methylphenols), the $\ln k'_a/k'_b$ values are not significantly different (for the chlorophenols 0.347 ± 0.004 and for the methylphenols 0.333 ± 0.020: means $\pm$ s.d).

The rigidity of the solutes studied is in the order aromatic compounds > branched or cyclic aliphatic compounds > linear aliphatic compounds. The data in Tables 1 and 2 also show a good correlation between solute rigidity and $\ln k'_a/k'_b$. For example, phenol (0.333) > cyclohexanol (0.198), cyclopentanol (0.179) or tert-pentyl alcohol (0.173) > 1-pentanol (0.123) *etc.* These data further support the idea that $\ln k'_a/k'_b$ is a measure of the conformational changes of the solute necessary for similar solute–chain interaction to occur.

Changes in retention and selectivity for a pair of solutes before and after surface reorientation, $\Delta k'_r$, have been correlated to structural features in the solutes such as size, shape, rigidity and substitution. The magnitude of $\ln k'_a/k'_b$ and $\Delta k'_r$ for a pair of structurally similar solutes falls within a narrow range and there are only small changes in selectivity between conformational states of the bonded phase. For a pair of solutes with different features the retention changes may be relatively large and the elution order and selectivity may change.

CONCLUSION

The types of measurements made in the current study provide a means of examining the influence of the structure of a solute and the conformation of the bonded phase on the mechanism governing reversed-phase separations. Additional studies are now in progress on solutes which contain different functional groups, in an effort to characterize the influence of functionality on retention and selectivity.

EVIDENCE FOR THE ROLE OF MYOGLOBIN IN FACILITATING OXYGEN TRANSPORT

BERTHA C. KING and FRED M. HAWKRIDGE*
Department of Chemistry, Virginia Commonwealth University, Box 2006, Richmond, VA 23284, U.S.A.

(*Received* 12 *May* 1988. *Accepted* 6 *August* 1988)

Summary—Cyclic voltammetric studies of the heterogeneous electron-transfer reactions of myoglobin under aerobic and anaerobic conditions are reported. Evidence for a role of myoglobin that has not been previously measured directly, namely, facilitation of oxygen transport, is presented. It is suggested that one molecule of oxygen can be contained within the structure of the oxidized form of myoglobin, but is not co-ordinated to the heme iron. Reduced myoglobin binds one molecule of oxygen to the heme iron but no reports have been found that suggest that the oxidized form of myoglobin binds to, or contains a molecule of, oxygen.

Myoglobin is a medium size heme protein (m.w. 17800) that functions as an oxygen storage site in muscles.[1] Its structure[2,3] is known from high-resolution X-ray diffraction data and the polypeptide sequence has been determined for 24 species.[1] Though an extensive body of literature has been published describing the structure and function of myoglobin, many important features remain to be elucidated. Several groups are currently pursuing research in this area, and new insights into the mechanisms by which myoglobin binds oxygen are evolving.[4–9]

Frauenfelder *et al.*[4] have calculated the mean-square displacement of the amino-acid residues in the semiliquid regions of myoglobin through which oxygen must travel. Their results indicated displacements of 0.2–0.5 Å, too small to permit entry and exit of an oxygen molecule (diameter 2.8 Å). More recent work has shown evidence of several cavities within the myoglobin molecule, inside the heme pocket, that could accommodate an oxygen molecule.[5] Xenon atoms (diameter of 4.2 Å) were used as probes in this X-ray crystallographic study. Up to four xenon atoms may be accommodated within each myoglobin molecule when myoglobin crystals are subjected to xenon pressure $\geqslant 7$ atm.

Using computer simulations, Case and McCammon[6] and Karplus and McCammon[7] have shown evidence for two possible paths for oxygen to travel through the myoglobin molecule to reach the heme pocket binding site.

An additional function that has been ascribed to myoglobin is facilitating oxygen transport in muscles.[10–12] However, there is little direct evidence that myoglobin increases the rates of oxygen transport in muscles or *in vitro*. Moreover, little is known about the mechanism that enables myoglobin to enhance oxygen transport.

In an earlier study of the heterogeneous electron-transfer kinetics for myoglobin at indium oxide optically transparent electrodes,[13] it was shown that electrochemical methods enable the dynamics of the myoglobin/oxygen ligand-binding reaction to be studied directly. The reaction mechanism is an EC mechanism (an electrode reaction followed by a chemical reaction that consumes the product of the electrode reactions) as shown below:

$$\text{Electrode: } \mathrm{Mb(III)} + e^- \rightleftharpoons \mathrm{Mb(II)} \quad (1)$$

$$\text{Solution: } \mathrm{Mb(II)} + \mathrm{O_2} \rightleftharpoons \mathrm{Mb(II)\cdot O_2} \quad (2)$$

where Mb(III) and Mb(II) are the oxidized (met-myoglobin) and reduced forms of myoglobin, respectively. As is the case for hemoglobin, myoglobin only binds to oxygen when in the reduced state.[1]

In an attempt to quantitatively model the cyclic voltammetric results for the reaction of myoglobin at an indium oxide electrode under anaerobic conditions and under conditions of varying oxygen concentration, background cyclic current–voltage curves (CVs) were acquired under various conditions of myoglobin and oxygen concentrations.[13] CVs for anaerobic solutions containing buffer/electrolyte in the presence and absence of myoglobin were acquired and stored, and digital subtraction of the background from the total CVs yielded currents that were due only to faradaic reactions. These CVs were then fit to digitally simulated CVs to determine how well the myoglobin electrode reaction conforms to the model used to describe it, namely the Butler–Volmer theory.[14–16]

EXPERIMENTAL

Sperm whale myoglobin was obtained from Sigma Chemical Company (Type II, lots 93F-04971 and 36F-0353) and from Fluka Chemical Corporation (lot 263014-187). In

previous work[13] myoglobin samples were further purified by ion-exchange chromatography with carboxymethylcellulose (Whatman CM-52) by published procedures.[17,18] This was shown to be necessary in order to observe cyclic voltammetric responses for myoglobin. In this study samples of myoglobin as received were dissolved in tris/cacodylic acid buffer, pH 7.0, and then filtered through a 30000 molecular weight filter (YM30, Amicon Div., W. R. Grace and Co.) just before each experiment.

The tris/cacodylic acid buffer (ionic strength 0.20*M*) was used to avoid binding of phosphate to myoglobin.[19,20] The tris(hydroxymethyl)aminomethane (Trizma Base, Reagent grade, Sigma) was used as received, and the cacodylic acid (hydroxydimethylarsine oxide, 98% pure from Sigma) was recrystallized twice from 2-propanol. Oxygen was removed from solution by passage of nitrogen (grade 4.5 from Airco, Inc.) that had been passed over hot copper turnings in a Sargent–Welch furnace to scavenge any oxygen in it. A gas-dispersion trap containing water was placed between the furnace and the sample solution to cool the nitrogen and saturate it with water.

The electrochemical and spectroelectrochemical methods and procedures have been described previously.[13] In all experiments the working electrode was tin-doped indium

oxide deposited on glass (Donnelly Corp.) and a new electrode was used in each experiment. These electrodes were cleaned by a published procedure[21] consisting of a 5-min sonication in Alconox detergent solution, ethyl alcohol and twice in distilled water. The reference electrode was Ag/AgCl (1.0*M* KCl) and the auxiliary electrode was a platinum wire. All potentials in this work are referred to the normal hydrogen electrode and all measurements were made at room temperature, $22 \pm 1°$. Data-acquisition and handling have been described in detail.[13]

RESULTS

Cyclic current–voltage curves for metmyoglobin and different concentrations of oxygen are shown in Fig. 1(A). Only at the lowest concentration of oxygen is there evidence of an oxidative wave. No oxidative wave is observed, at higher concentrations of oxygen, because there is a succeeding ligand-binding reaction between the electrochemically formed reduced myoglobin and the oxygen present in solution [see equation (2)]. However, at higher oxygen concentrations the reductive current, at voltages more negative than the peak potential, increases with increasing oxygen concentration. Figure 1(B) show the CVs of buffer alone at the same oxygen concentrations as the myoglobin solutions studied in Fig. 1(A). Clearly, the extent of oxygen reduction is much smaller than in the myoglobin solutions [Fig. 1(A)]. This difference is more clearly illustrated in Fig. 1(C) by subtracting the background currents and the direct oxygen reduction currents shown in Fig. 1(B) from the corresponding CVs in Fig. 1(A).

To demonstrate this point further only the negative sweeps of the CVs from Fig. 1(C) are shown in Fig. 2(A). Similarly Fig. 2(B) shows the reduction

currents that occur in the presence of myoglobin. Figure 2(C) shows the corresponding oxygen reduction currents that occur in the absence of myoglobin. Experiments were also conducted on a 106μM solution of myoglobin and the results were the same as those shown in Fig. 2. A solution of myoglobin at a concentration of 23μM was also studied but the faradaic current due to myoglobin reduction was small. The same trend as in Fig. 2 was evident but with poorer precision.

Another experimental approach used in this research is shown in Fig. 3. The results of background-subtracted double potential-step chronocoulometry experiments for solutions containing myoglobin and various concentration of oxygen are shown. Trace (a) is due to the reduction of both myoglobin and oxygen when the applied overpotential is stepped to −426 mV in the first 10 sec. A small reoxidation is observed during the reverse potential step in the next 10 sec. Background charge for buffer alone has been subtracted from each of the traces shown. As the oxygen concentration is increased, the reductive charge increases until the oxygen concentration is about the same as the myoglobin concentration (about 82μM in these experiments). No further increase in reductive charge is observed when the oxygen concentration is increased further. The reverse potential-step chronocoulometry results are the same in each case, showing no reoxidation of the myoglobin.

DISCUSSION

The results presented above suggest that the oxidized form of myoglobin, metmyoglobin, may contain at least one oxygen molecule within its molecular structure. Moreover, this molecule of oxygen can be released from the myoglobin molecule and reduced when the diffusing metmyoglobin molecule arrives at the electrode. Since the heme iron in metmyoglobin does not bind to the oxygen molecule, this molecule may reside in one of the cavities that exist along the channel between the surface of the metmyoglobin molecule and the heme pocket, as described by Austin *et al.*[22] The oxygen molecule could have penetrated the hydration layer surrounding the myoglobin surface and possibly entered the heme pocket. Similar results have been reported by Barboy and Feitelson[23] who showed that the "gating" action of the myoglobin and not the size of the ligand controlled the rate of entry to the heme pocket.

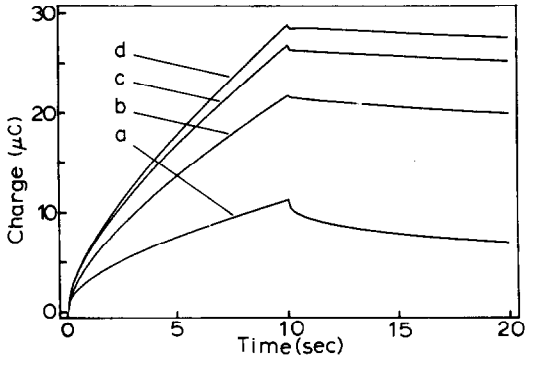

Fig. 3. Double potential-step chronocoulometry of metmyoglobin in the presence of various concentrations of oxygen. Metmyoglobin 81 μM, potential steps from +0.520 V to −0.380 V (an overpotential of −426 mV). Oxygen concentration (μM): (a) 16, (b) 63, (c) 78 and (d) 94.

The electrochemical results presented here provide new insights into the nature of the association of myoglobin with oxygen molecules. These *in vitro* experiments may have physiological relevance to the role of myoglobin in facilitating oxygen transport.

SYNTHESIS AND ANALYTICAL CAPABILITIES OF FLUOROGENIC RING-SUBSTITUTED CROWN ETHERS

H. FORREST and G. E. PACEY
Department of Chemistry, Miami University, Oxford, OH 45056, U.S.A.

(*Received* 4 *May* 1988. *Revised* 1 *October* 1988. *Accepted* 12 *October* 1988)

Summary—Fluorogenic crown ethers do not generally produce enough signal to be analytically useful. The incorporation of fluorogens in the crown ether ring can considerably increase the fluorescence intensity obtained on complexation, to 2–6 times that of the blank. The disadvantage is a loss of selectivity, all the alkali metals being complexed by the fluorogenic compound obtained.

Crown ethers, cryptands, and open-chain polyglycol compounds are effective complexation reagents for alkali-metal ions. Most of the research in this area has centered around the use of these compounds as phase-transfer catalysts in synthesis, and the synthesis of new macrocylic compounds with emphasis on structures which mimic naturally occurring compounds responsible for membrane transport.

The analytical application of these compounds has been limited. They have been used, for example, as electrode ionophores,[1,2] functional groups on chromatographic packings,[3] and to produce a cationic alkali-metal complex that can be extracted as an ion-pair with anionic dye.[4]

The demand for alkali-metal ion determination comes from the clinical diagnostics field. The determinations are to be made on whole blood (possibly *in vivo*) or in serum, urine or other body fluids. Therefore, the reagent must exhibit high selectivity and detection limits adequate to deal with current therapeutic levels. The macrocyclic compounds must be usable in current diagnostic systems as well as with newer techniques such as use of optrodes.

The first attempts to modify crown ethers by incorporation of a chromophoric group were reported by Dix and Vögtle,[5] Ueno and co-workers[6–15] and this research group.[16–25] The unique feature of these chromogenic crown ethers was that a red shift was produced in the absorption spectrum, on complexation. The shift could be as large as 150 nm. In the work of Ueno's group and ours, the compounds (*e.g.*, Fig. 1a) formed an intramolecular ion-pair between the trapped alkali-metal ion and the anionic functional group of the singly deprotonated chromogenic crown ether. This approach provides stable complexes and enhanced selectivity.

The next logical step was the synthesis of fluorogenic crown ethers. Unfortunately, success with these compounds was more difficult to obtain. By utilizing the same approach as with the chromogenic crown ethers, but with fluorogenic tags, several compounds were synthesized and tested[25] (Fig. 1b). However, the change in fluorescence on complexation was not sufficient for analytical application. Increases of only 2–10% relative fluorescence were observed.

The phenyl ring which separates the fluorogenic tag and the crown ether was believed to be the limiting factor for the change in fluorescence intensity. Therefore, fluorogenic compounds where the tag was directly attached to the crown ether ring were synthesized (Fig. 1c). These compounds exhibited improved fluorogenic activity, but were also considerably less stable, decomposing in less than 2 hr.[25]

Several other approaches were attempted. The most successful was Ueno's use of the coumarin type fluorogenic tags attached through a CH_2 group to an amine-substituted crown ether (Fig. 1d).[15] These compounds did exhibit some signal change, but the details were not given. A comparable compound produced by our group also produced an increase in fluorescence intensity on complexation but there was a high degree of fluctuation in the signal.

It was clear that a new approach was needed if analytically useful fluorogenic crown ethers were to become a reality. It has been hypothesized that the lack of fluorescence change is due to the fact that the crown ether cavity and the subsequent complexation are too far removed from the fluorogenic tag. It would be optimal if the tag and the crown ether were both involved in the complexation process. It has been the experience in this laboratory that intramolecular ion-pairs offer the best overall analytical performance. An easily deprotonated group, either an amine or phenol, is ideal for this purpose. Therefore, the fluorogenic tag/crown ether compound should have such a group.

The compounds reported in this study achieve this aim by the incorporation of the tag (carrying the easily deprotonated group) in the ring of the crown ether (Fig. 1e).[26–29] This paper describes the synthesis and analytical capabilities of this type of compound.

EXPERIMENTAL

Synthesis

The first step was to synthesize 2,6-dimethylanisole from 2,6-dimethylphenol. The phenolic oxygen atom needed to be protected from the alkyl bromination step. Sodium hydride (0.157 mole) and tetrahydrofuran (THF) as solvent were placed in a three-necked round-bottomed flask equipped with a condenser, constant-pressure dropping funnel, heating mantle and magnetic stirrer. 2,6-Dimethylphenol (0.157 mole) dissolved in 100 ml of THF was added dropwise at ambient temperature over a period of 1 hr to the well stirred reaction mixture, which was then stirred and heated to reflux for approximately 1 hr, after which methyl iodide (0.157 mole) dissolved in THF was dripped into the reaction mixture. A color change from gray to white was apparent after 6 hr, but to ensure that it was complete, the reaction was allowed to proceed for a total of 12 hr. The solution was then cooled and filtered by suction. The filtrate was concentrated in a rotary evaporator* to yield a tan oil and an inorganic salt. Water (250 ml) was added and the mixture was repeatedly extracted with chloroform. The chloroform extracts were combined, then dried over anhydrous magnesium sulfate, filtered, and evaporated (rotary evaporator), until reduced to a tan oil. The desired product was separated by distillation at 29%/0.2 mmHg. A yield of 75–90% was routinely obtained.

The second step was the preparation of 2,6-bis(bromomethyl)anisole. In a 500-ml three-necked round-bottomed flask, equipped with a reflux condenser, magnetic stirrer and heating mantle, 2,6-dimethylanisole (0.093 mole) and excess of *N*-bromosuccinimide (NBS; 0.22 mole) and a catalytic amount of benzoyl peroxide were combined in carbon tetrachloride. The solution was stirred and refluxed for 24 hr until all the NBS was converted into succinimide, which floated on top of the carbon tetrachloride. The solution was filtered and evaporated to a light orange-red oil. The oil was allowed to cool in a recrystallizing dish, where the desired product crystallized within 48 hr. The light yellow-orange crystals were sufficiently pure for the next reaction step after simple collection by filtration under suction. The typical yield was 50–60%.

The third step was nitration. 2,6-Bis(bromomethyl)-anisole (0.018 mole) was dissolved in 40 ml of tetramethylene sulfone in a two-necked 100-ml round-bottomed flask. The solution was stirred as a solution of nitronium tetrafluoroborate (0.019 mole) in 30 ml of tetramethylene sulfone was added. The mixture immediately changed from orange-yellow to dark brown-orange in color. The mixture was stirred at ambient temperature for 40 min to ensure complete reaction. Water (25 ml) was added and the mixture was stirred for 15 min. The solution was transferred to a separatory funnel, 50 ml of water were added, and the mixture was repeatedly extracted with chloroform. The chloroform solution was dried over anhydrous magnesium sulfate, filtered, and evaporated to a dark reddish-brown oil. The oil was washed with water until it became a tan solid.

The fourth step was to form the crown ether, 4-nitroanisole 18-crown-5. To a 500-ml three-necked flask equipped with a constant-pressure dropping funnel, reflux condenser, magnetic stirrer and heating mantle, an excess of sodium hydride (0.5 mole) was added to 75 ml of freshly distilled THF, and a solution of tetraethylene glycol (0.21 mole) in 50 ml of THF was slowly added to the reaction mixture, which was stirred at ambient temperature for 90 min. Then a solution of the 4-nitro-2,6-bis(bromomethyl)anisole (0.21 mole) in 75 ml of THF was added. The mixture was warmed until it refluxed, and was stirred for five days to ensure reaction. The solution was cooled, filtered under suction, and evaporated to a thick, dark brown oil. The oil was placed in a liquid–liquid extraction apparatus, and the crown ether was extracted from the oil with hot hexane. The hexane solution was evaporated to yield white crystals, which were then recrystallized from hexane. The yield was 15–30%.

The final step was removal of the phenol protection group. The 4-bromoanisole-18-crown-5 (1 g) dissolved in freshly distilled dimethylformamide (DMF) and 0.5 g of sodium ethyl sulfide were added to a round-bottomed flask equipped with a reflux condenser, heating mantle and magnetic stirrer. The solution was refluxed under nitrogen for 3 hr, then cooled, acidified with 4*M* hydrochloric acid, and repeatedly extracted with diethyl ether. The ether layers were washed with 1*M* sodium hydroxide and these washings were combined, acidified, and extracted with chloroform. The chloroform solution was evaporated to a brown liquid. This extraction procedure was repeated until the compound

*All evaporations of organic solvents were conducted in a rotary evaporator.

Table 1. Partition coefficients for the untagged crown ethers (Cr)

Crown	Concentration, M	Partition coefficient (S.D.), $[Cr]_{aq}/[Cr]_{org}$
4-Bromoanisole-18-crown-5	1.1×10^{-2}	3.25×10^{-4} (0.06×10^{-4})
	5.5×10^{-3}	3.63×10^{-4} (0.04×10^{-4})
4-Bromophenol-18-crown-5	6.8×10^{-3}	8.29×10^{-4} (0.08×10^{-4})

crystallized as a brown solid. The product was purified by dissolving the brown solid in chloroform, filtering, evaporating the solvent, and drying under vacuum until crystallization was complete. The resulting dark yellow crystals were dissolved in diethyl ether and the solution was washed repeatedly with water until light yellow crystals were obtained on evaporation of the ether.

The crown ether was tagged by dissolving 0.5 g of the 4-nitrophenol-18-crown-5 in 100 ml of freshly distilled DMF. A catalytic amount of 10% Pd on carbon was added to the mixture. An initial 35 psig hydrogen pressure was applied in the Parr hydrogenator. After hydrogenation for 4 hr, the solution was filtered to remove the catalyst and the DMF was evaporated. Water (200 ml) was added and the mixture was extracted with chloroform. The dried chloroform solution was evaporated, producing a brown oil that solidified upon standing.

This solid was dissolved in methanol and placed in a round-bottomed flask equipped with a constant-pressure dropping funnel, and magnetic stirrer. An equivalent amount of a solution of 4-chloro-7-nitrobenzo-2-oxa-1,3-diazole (DNB) chloride in methanol was dripped into the reaction mixture, which was stirred for 2 hr and then filtered. Evaporation yielded a residue, which was dissolved in chloroform, washed with slightly acidic water, and dried with anhydrous magnesium sulfate. After filtration and evaporation a dark red oil was obtained. This oil solidified after 48 hr and the solid was recrystallized from hot hexane. The purified product was an orange-yellow powder.

Extraction

The degree of extraction for the nontagged crown ethers was determined by placing in a 50-ml round-bottomed flask an aliquot of an alkali-metal chloride solution for low pH studies or the hydroxide for high pH studies, and picric acid, the final concentrations being 6.65×10^{-2} and $9.66 \times 10^{-5}M$ respectively and the final volume 10 ml. Then 10 ml of 1×10^{-3}–$1 \times 10^{-2}M$ organic crown ether solution were added. The mixture was shaken mechanically for 15 min at room temperature (22°), then allowed to stand until the layers had separated. The concentration of the extracted complex was determined spectrophotometrically.

The partition coefficients of the crown ethers were determined by using various crown ether concentrations and equal phase volumes, and equilibrating for 1 hr. The aqueous layer was then analysed for crown ether by extraction after addition of potassium and picrate ions.

The extraction constant was determined in a similar manner to the degree of extraction except that the crown ether, alkali-metal ion and picric acid concentrations were all varied. The chlorides used gave an aqueous pH of 3.8, and the hydroxides gave an aqueous pH of 11.9–12.2.

For the fluorogenic crown ethers similar procedures were followed, except that the extraction with picric acid was not used, since the complexation could be followed by observing the fluorescence.

In both cases the physical constants could be determined from these experiments by using the equilibrium equations developed in previous studies.[20–28] The new compounds created no additional problems that needed to be considered by incorporation of other equilibrium expressions.

RESULTS AND DISCUSSION

Two precursors to the final tagged crown ether, 4-bromoanisole-18-crown-5 and 4-bromophenol-18-crown-5, were tested in picrate ion-pair studies. The results for the partition coefficients are shown in Table 1. The phenolic compound is slightly more soluble than the anisole crown ether in water.

The pH was kept low, at about 3.0, for the phenolic crown ether extractions. This was necessary since a crown ether with a deprotonated phenol group would act as its own counter-ion in ion-pairing and inhibit the formation of the picrate ion-pair used for the determination. Table 2 gives the extraction constants for the two compounds. In both cases the compound extracted potassium and rubidium ions. The anisole crown ether was a more efficient extraction reagent than the phenol, and displayed some selectivity towards potassium. The different pH conditions did not affect the extraction. The selectivity observed is not a problem, since in clinical samples the selectivity that is needed is for potassium relative to sodium, or the reverse. It appears that tagging this type of compound would produce a reagent with the desired selectivity for potassium.

The data above suggest that the fluorogenic crown ether with a phenol group in the crown ring should

complex alkali-metal ions. The tag itself usually produces improved selectivity.

The absorption spectrum for the tagged compound is shown in Fig. 2. There is a surprising blue shift of the absorption peak and the usual increase in molar absorptivity for the more highly deprotonated species. The appearance of the 325 nm peak was accompanied by disappearance of the 350 nm peak. With increase in pH, the peak at 270 nm slowly shifted into the shoulder observed between 240 and 250 nm. The tagged crown ethers examined earlier usually exhibited red shifts in the absorption spectrum. There is no easy explanation for this observation. Emission was observed at 395 nm at pH 5.2 and 375 nm at pH 11.6. Tables 3–5 show the relative fluorescence intensity at the different pH values. On complexation, the intensity was increased to 3.7–6.7 times that of the blank, depending on the wavelength of measurement. With exception of cesium, the compound appears to complex the alkali-metal ions somewhat equally.

These data definitely demonstrate that incorporating an anionic moiety in the crown ether ring significantly increases the fluorescence that occurs on complexation. One explanation of this is that the phenolic group is deprotonated and forms the intended intramolecular ion-pair. The crown ring itself

is therefore restricted in movement, since the oxygen atoms in the ring interact with the alkali-metal ion. Before complexation the crown ring was free to rotate about the phenol moiety linkage, so that the phenolic OH-group could lie inside or outside the crown cavity. This was confirmed as possible, by use of molecular models.

On the other hand, it is possible that the deprotonated phenol might attract the alkali-metal ion first, and that the crown ether would then stabilize the complex. Therefore, some experiments were done at pH 4.9, at which the phenol in the compound was not deprotonated. Table 6 shows that the selectivity of the compound did not significantly change from that observed at high pH, which suggests that only the crown ether ring attracts the alkali-metal ion.

The apparent detection limits for the alkali-metal ions range from 1×10^{-3} to $1 \times 10^{-2} M$, depending on the ion tested. The reproducibility of the extractions was 2–6%. No quenching effects were observed. The solutions was not degassed.

The new compound gives a large fluorescence intensity change, but is usable only when a single alkali metal is present in the sample. The alkaline-earth metal ions and ammonium ion do not interfere when present at concentration equal to that of the alkali-metal ion. Improvements in selectivity are needed in the next generation of compounds.

Conclusions

Although this new method of producing a fluorogenic crown ether improves the signal obtained by interaction with alkali-metal ions, the overall complexation selectivity is altered. The untagged compound is selective for potassium and rubidium, but the tagged compound seems to complex the first four alkali-metal ions (lithium–rubidium) equally well, and cesium to a lesser extent.

Further studies are needed to see whether the selectivity can be improved. It is believed that this will not be achieved by simple size changes in the cavity, but by a delicate balance between the apparent size of the cavity in the free ligand and that of the cavity made rigid by complexation.

ANNOTATION

ON THE NATURE OF IMMOBILIZED TRIS(CARBOXYMETHYL)ETHYLENEDIAMINE

MARIAN F. MCCURLEY and W. RUDOLF SEITZ
Department of Chemistry, University of New Hampshire, Durham, NH 03824, U.S.A.

(*Received* 4 *May* 1988. *Revised* 10 *August* 1988. *Accepted* 24 *August* 1988)

Summary—Immobilized tris(carboxymethyl)ethylenediamine (TED) (also known as ethylenediamine-*N,N,N'*-triacetic acid) serves as a stationary phase for fractionation of proteins and the preparation of metal-free proteins by immobilized metal-ion affinity chromatography. The Cu(II) complex of commercially available immobilized TED has been characterized by elemental, electrochemical and spectroscopic techniques. There is a large discrepancy between the theoretical capacity determined from the nitrogen content and the experimental capacities determined by atomic-absorption spectroscopy and anodic stripping voltammetry (ASV), indicating that a substantial portion of the immobilized ligand is not binding Cu(II). In addition, the titration of immobilized TED with Cu(II), monitored by ASV, suggests that more than one ligand is involved in binding Cu(II). A comparison of the EPR spectrum for immobilized Cu(II)–TED with spectra for various model complexes shows that the major immobilized ligand is ethylenediamine-*N,N'*-diacetic acid (EDDA) with immobilized TED present only as a minor component. The complexation constant for Cu(II) is close to the value for Cu(II)–EDDA in solution. The formation of EDDA is consistent with the method for synthesizing immobilized TED.

The immobilization of tris(carboxymethyl)ethylenediamine (TED) (also known as ethylenediaminetriacetic acid) on a carbohydrate support was first described in 1975.[1] The first step in the procedure is to react the carbohydrate with epichlorohydrin. The modified surface is then reacted with an excess of ethylenediamine. The final step is to react the immobilized ethylenediamine with monobromoacetic acid.

It was shown that the Ni(II) and Cu(II) complexes of immobilized TED could serve as stationary phases for separating proteins by ligand exchange, a technique christened immobilized metal-ion affinity chromatography.[1-3] This technique is now well established, with diverse applications reported in the literature.[4] Immobilized TED is commercially available from Pierce Chemical Company.

In addition to serving as a stationary phase for ligand exchange chromatography, immobilized TED is potentially useful for other analytical applications such as preconcentrating heavy metal ions for determination by other techniques. Our interest in immobilized TED arises from the possibility of developing ligand-selective indicators for optical sensing.

Although the interaction between immobilized metal–TED complexes and proteins has been described,[5] the immobilized ligand has yet to be completely characterized. Equilibrium constants for metal ion binding have not been measured, nor has the putative structure been confirmed. This report describes the characterization of the interaction between commercially available immobilized TED and Cu(II), by a variety of techniques, including elemental analysis, metal-ion binding-capacity measurements and EPR spectroscopy. The results suggest that the commercial material is actually a mixture of ligands, the major component being ethylenediaminediacetic acid. In contrast, the EPR spectrum of the Cu(II) complex with an immobilized TED sample provided by the referee was that expected for TED, indicating that the commercial material differs from the immobilized TED described in the literature.[1-3,5]

EXPERIMENTAL

Apparatus

Nitrogen was determined with a Perkin-Elmer 240B Elemental Analyzer after the sample had been dried at 120° to constant weight.

Cu(II) was determined by atomic absorption with an Instrumentation Laboratory 951 AA/AE spectrophotometer with a Jarrell Ash copper hollow-cathode lamp and the manufacturer's recommended instrument settings.

An IBM Instruments EC220^{1A} Stripping Voltammeter with SCE reference, Pt ring auxiliary and mercury thin-film working electrodes was used for anodic stripping voltammetry.

Electron paramagnetic resonance (EPR) spectra were measured on a Varian E-4 spectrometer interfaced with a Digital Equipment Corporation MINC 11-23 computer.

Reagents

Immobilized tris(carboxymethyl)ethylenediamine (TED), batch numbers 850510086 and 860617089, was purchased from Pierce Chemical Co. Batch number 850510086 was used in most experiments. In addition, the referee sent us a sample of immobilized TED prepared in his laboratory.

Other reagents included nitrilotriacetic acid (NTA), ethylenediamine-*N,N'*-diacetic acid (EDDA), *N*-(2-hydroxyethyl)ethylenediaminetriacetic acid (HEDT), mercuric chloride (all from Aldrich Chemical Co.), iminodiacetic acid

(IDA) from Eastman Kodak, ethylenediaminetetra-acetic acid (EDTA) and Cu(II) AA standard from Fisher Scientific, and 2-[*N*-morpholino]ethanesulfonic acid (MES) buffer from Sigma Chemical Co.

A 0.0103*M* mercuric chloride solution was prepared by dissolving 0.0280 g of $HgCl_2$ in a small amount of dilute hydrochloric acid and diluting to 10.0 ml with distilled water. Phosphate buffer (pH = 7.0) was prepared by dissolving 5.38 g of sodium dihydrogen phosphate and 16.35 g of sodium monohydrogen phosphate in 1000 ml of distilled water. Acetate buffer (pH = 5.0) was prepared by combining 2.34 g of sodium acetate and 0.34 ml of glacial acetic acid and diluting to 200 ml with distilled water. MES buffer (pH = 5.48) was prepared by mixing 0.976 g of MES and 1.6 ml of 0.5*M* sodium hydroxide and diluting to 100.0 ml with distilled water. Unless otherwise indicated, the pH 5.0 acetate buffer was used for all experiments.

Procedures

Immobilized TED was prepared for all experiments in the same manner. Initially the immobilized TED was rinsed with two or three 10-ml portions of distilled water to remove the preserving solution in which it was stored. Next the gel was protonated by washing with two or three 10-ml portions of 1*M* hydrochloric acid, followed by rinsing with 10 ml of distilled water and two or three 10-ml portions of buffer or sodium hydroxide solution, as appropriate. Between washings, the TED gel was suction-dried on a fritted glass filter.

Samples for atomic absorption analysis were prepared by equilibrating the immobilized TED in buffer with 10.0 ml of 1000 ppm Cu(II) solution. The gel was subsequently rinsed with distilled water. The solution containing unbound copper was combined with the washings and diluted to 100.0 ml with distilled water. Bound copper was removed from the TED gel by treating it with two 10-ml portions of 1*M* hydrochloric acid. The immobilized TED was neutralized with three 10-ml portions of buffer, which were then combined with the bound copper fraction. This mixture was diluted to 100 ml with distilled water. Both fractions were further diluted with buffer to ensure that the final concentrations were in the appropriate linear working range for copper. Samples were analysed in triplicate and the absorbance of each sample was measured five times.

Anodic stripping voltammetry was performed on a slurry of 3.3 ml of immobilized TED diluted to 100.0 ml with pH 5.0 acetate buffer. The sample was deaerated by bubbling nitrogen through the slurry. A blanket of nitrogen bathed the surface throughout the experiment. A 0.400-ml aliquot of 0.0103*M* mercuric chloride was the source of the mercury film.[6] Successive 0.100-ml increments of a 1000 ppm Cu(II) standard solution were added to the slurry and allowed to equilibrate for 10 min, with stirring. Copper was deposited during a period of 3 min at a potential of −1.000. V *vs.* SCE, and then stripped at a scan-rate of 20 mV/sec. Deposition and stripping were repeated three times for each addition of Cu(II). Between additions of Cu(II), the mercury film on the electrode was removed and an additional 0.400-ml portion of 0.0103*M* mercuric chloride was added.

Competition experiments involved successive additions of 0.120*M* IDA to 3.3 ml of TED gel complexed with 1.000 mg of Cu(II) and buffered to pH 5.0, in a total volume of 51.0 ml. After each aliquot of IDA was added, the solution was equilibrated by stirring for 10 min. The fractions containing bound and free Cu(II) were removed and collected as described above.

EPR spectra were taken for 1.0 g of immobilized TED samples which had been equilibrated for 10 min, with stirring, with various amounts of 200 ppm Cu(II) standard solution. The slurries were buffered with acetate at pH 5.0 and 5.5 and with MES at pH 5.5. After equilibration with Cu(II) the slurry was transferred to an EPR tube and slowly frozen in a dry ice/acetone slush, then cooled in liquid nitrogen for EPR measurement. Samples of Cu(II) equilibrated with other complexing agents were prepared similarly.

RESULTS

Cu(II) binding capacity

A theoretical Cu(II) binding capacity for the TED gel was determined by measuring the nitrogen content of the gel. This calculation was based on the manufacturer's suggested structure for immobilized TED, shown in Fig. 1, and assumes that one Cu(II) ion is bound per two nitrogen atoms. Immobilized TED batch number 850510086 contained 0.875% nitrogen, which corresponds to 284 μmoles of Cu(II) per ml of dried TED gel. The density of the dried gel was found to be 0.91 g/ml. Immobilized TED batch number 860617089 was found to contain 1.93% nitrogen, which corresponds to 626 μmoles of Cu(II) per ml of dried gel. This batch also had a density of 0.91 g/ml.

In addition to the twofold difference in Cu(II) binding capacity, the two batches of immobilized TED also differed greatly in their water content prior to drying. Batch number 850510086 lost 95.5% of its total weight on drying, whereas batch number 860617089 lost only 77.0%. Batch 860617089 thus has over an order of magnitude greater capacity for

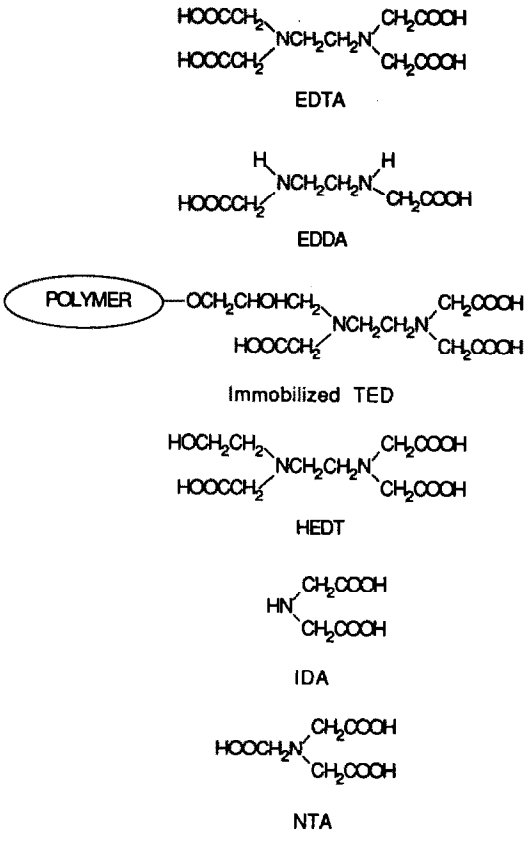

Fig. 1. Structures of immobilized TED and model ligands.

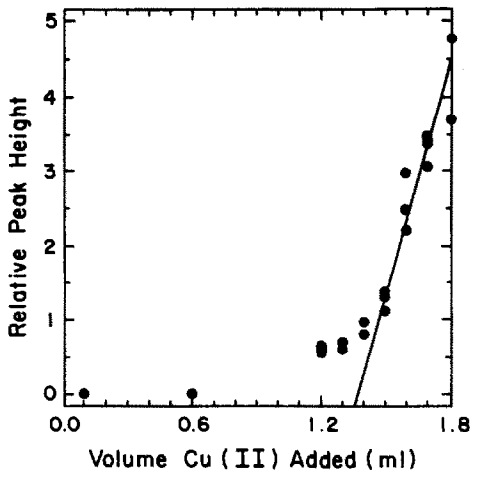

Fig. 2. Relative peak current measured by ASV as a function of the volume of Cu(II) solution added to a slurry of immobilized TED.

Cu(II) than does batch 850510086, if the capacity is based on the volume of undried gel.

Experimental Cu(II) binding capacities were measured for immobilized TED batch number 850510086 by both flame atomic absorption (AA) and anodic stripping voltammetry (ASV). The ASV titration was performed on samples buffered to pH 5.00 with acetate. The results are shown in Fig. 2. The end-point was determined by extrapolating the two straight-line portions of the curve to the point where they intersected. This end-point corresponded to a capacity of 0.015 μmole of Cu(II) per ml of dried gel.

For volumes less than 1200 μl of added Cu(II) solution, the ASV experiment did not indicate a measurable amount of free Cu(II). However, for between 1200 and 1400 μl Cu(II) was observable, indicating that the Cu(II) binding equilibrium is not complete in this region.

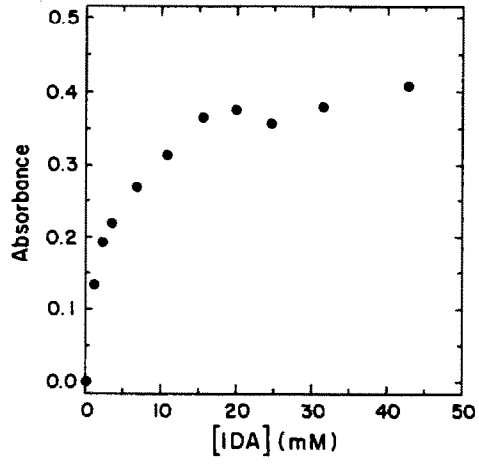

Fig. 3. Absorbance due to free copper, measured by AA, as a function of the amount of IDA added to a slurry of immobilized TED.

The binding capacities measured by AA were 0.017 μmole of Cu(II) per ml of dried TED gel at pH 7.0 and 0.013 μmole of Cu(II) per ml of dried gel at pH 5.0.

Complexation constant

Initially, we attempted to determine the equilibrium constant for binding of Cu(II) to immobilized TED, by potentiometric titration with Cu(II) monitored with a Cu(II) electrode. However, the response was sluggish and satisfactory results were not obtained. Although Cu(II) electrodes respond to trace concentrations of free Cu(II) in the presence of dissolved Cu(II) complexes, this was not the case for immobilized TED, which is in a separate phase.

Accordingly, the complexation constant was measured by a competition experiment. The procedure involved titrating immobilized Cu(II)–TED with iminodiacetic acid (IDA) at pH 5.0 and measuring the amount of Cu(II) removed by the IDA, by atomic absorption spectrometry. The results of this experiment are shown in Fig. 3.

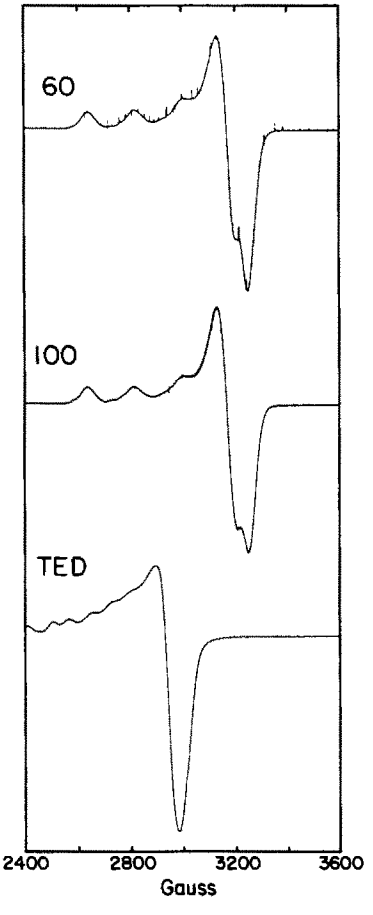

Fig. 4. EPR spectra for batch 860617089 of immobilized TED with Cu(II) equivalent to 60% and 100% of the experimental binding capacity. The spectrum designated TED is for the Cu(II) complex of the immobilized TED sample provided by the referee. Spectra recorded in MES buffer at a frequency of 9.15 GHz.

The conditional complexation constant at pH 5.0 for Cu(II) with immobilized TED was calculated to be 1.6×10^8. It is based on the point at which sufficient IDA has been added to complex half of the Cu(II). The calculation procedure has been described previously.[7]

EPR spectra

EPR spectroscopy is an effective tool for elucidating the structure of Cu(II) complexes.[8] Figure 4 shows EPR spectra for batch 860617089 of immobilized TED containing 60% and 100% of the theoretical capacity for Cu(II), and also for the Cu(II) complex of the immobilized TED provided to us by the referee. The EPR spectrum for the Cu(II) complex of batch 850510086 is not shown but was identical to the spectrum for batch 860617089. The spectra for immobilized Cu(II)–TED were compared with spectra for Cu(II) complexes with a series of model ligands, including EDDA, HEDT, EDTA, NTA and IDA. Figure 5 shows the spectra of the model complexes, and Fig. 1 shows the structure of the ligands. The EPR spectrum of Cu(II)–EDDA most closely resembles the EPR spectrum of the commercial immobilized Cu(II)–TED. The spectrum for the immobilized TED provided by the referee is very similar to the spectrum of Cu(II)–HEDT.

The spectrum of HEDT indicates that two species are present. One of these matches the EDDA spectrum. The other is the HEDT spectrum. Because Cu(II) has a strong tendency to be four-coordinate, the third acetate group is only partially coordinated to Cu(II) under the conditions used for taking the EPR spectra. Careful inspection of the spectra for the commercial samples of immobilized TED indicates a small but detectable signal which corresponds to the HEDT spectrum.

DISCUSSION

The experimental evidence shows that commercial TED does not have the structure indicated by the manufacturer. Instead, it appears to be a mixture of ligands, with EDDA predominant. The EPR spectra provide the most direct evidence for this. However, the other experimental data are also consistent with this interpretation. The fact that the experimental capacities are lower than the theoretical capacities calculated from the nitrogen content indicates that some of the nitrogen is in a form that does not complex with Cu(II).

The observation that the experimental capacities are lower at pH 5.0 than at pH 7.0 suggests that there are ligands present which bind Cu(II) only at pH 7.0.

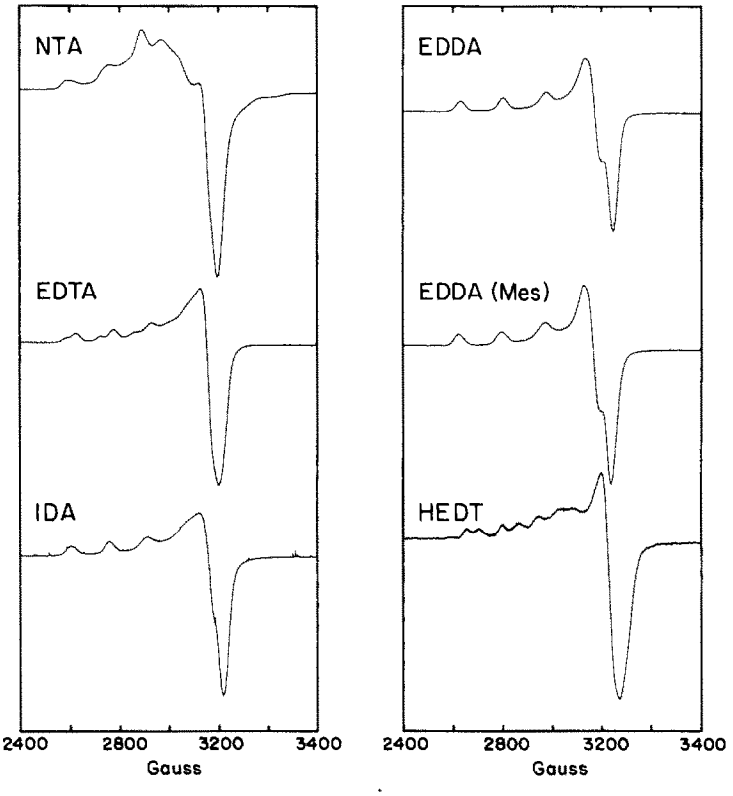

Fig. 5. EPR spectra of the Cu(II) complexes of NTA, EDTA, IDA, EDDA and HEDT recorded at a frequency of 9.15 GHz. All spectra were recorded in acetate buffer, except the EDDA spectrum designated EDDA (Mes). This spectrum was run to confirm that the spectra obtained for EDDA in Mes and acetate buffers were identical.

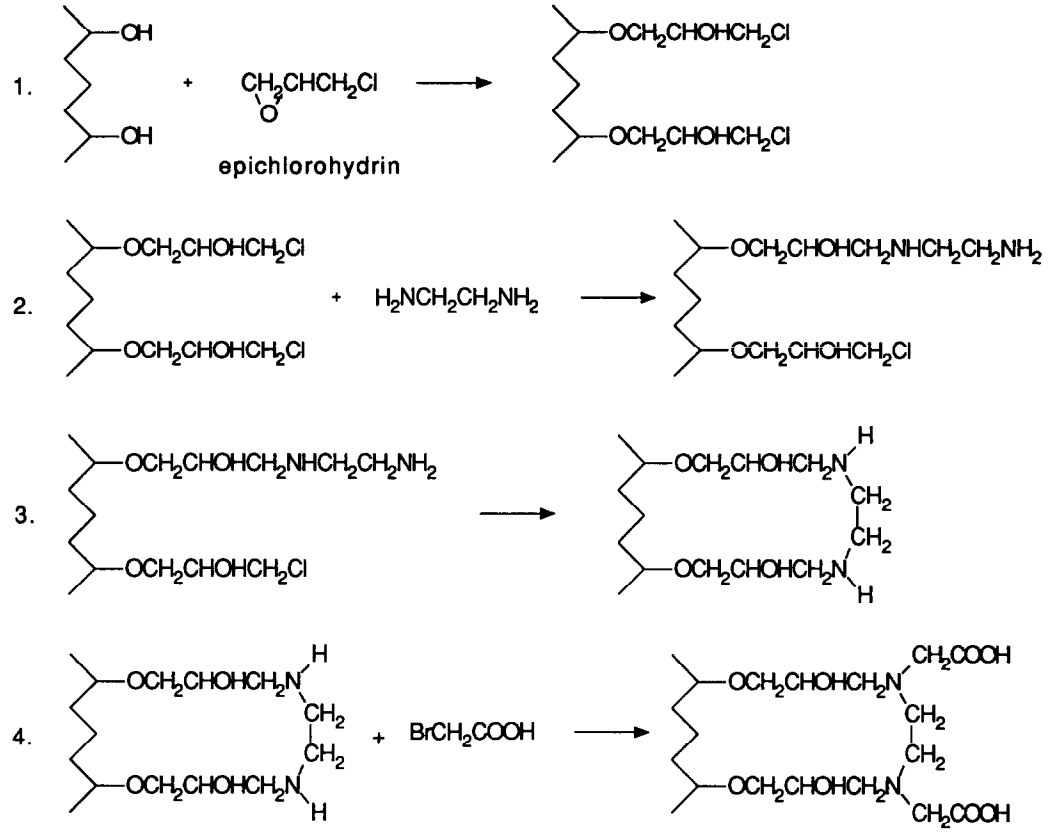

Fig. 6. Proposed reaction sequence for formation of immobilized EDDA.

From the measured complexation constant, EDDA would be expected to contribute to the Cu(II) binding capacity at both pH values. Thus the discrepancy suggests that a weaker ligand is present. The ASV titration shows a significant amount of free copper in solution before the end-point, which is also consistent with the presence of weaker ligands in addition to EDDA.

There is no evidence for weaker ligands in the EPR spectra. Since the spectra were run at pH 5.0 and 5.5, there should be no Cu(II) complexes of those ligands which bind Cu(II) at pH 7.0 but not at 5.0. The amount of weaker ligands that bind Cu(II) at pH 5.0 may be too small to show up on the EPR spectrum.

The conditional complexation constant at pH 5.0 is somewhat less than 6.0×10^9, the value calculated for Cu(II)–EDDA in solution at pH 5.0. This is certainly reasonable, since steric constraints imposed by the immobilization are likely to reduce the stability of the complex.

The formation of EDDA is consistent with the method for preparing immobilized TED.[1] The first step is to react the surface of a carbohydrate with epichlorohydrin. The modified surface is then reacted with ethylenediamine. A very large excess of ethylenediamine is employed, to reduce the probability that a given ethylenediamine molecule will react with the surface at more than one site. In practice, this measure does not seem to be effective. Instead, once initially bound to the carbohydrate surface, the ethylenediamine seems to give preferential reaction at the other nitrogen atom. Thus when monobromoacetic acid is added to form the carboxymethyl groups on the nitrogen atoms, only two positions are available. The reaction sequence that we propose is represented in Fig. 6.

The weaker ligands that seem to be present could arise from ethylenediamine molecules that bind to three sites on the surface. Alternatively, they could form if the reaction with monobromoacetic acid does not go to completion.

Because the EPR spectrum of the Cu(II) complex of the immobilized TED sample provided by the referee is essentially identical to the spectrum of HEDT, we believe that this material is immobilized TED without a significant component of EDDA. The procedure for preparing both batches of the commercial material presumably differs from the literature procedure for preparing immobilized TED, in a manner which promotes EDDA formation.[1]

Acknowledgement—NSF Grant CHE85-02061 provided partial financial support for this research. The authors express their appreciation to John Grady for running the EPR spectra and Professor Dennis Chasteen for helping in their interpretation. The authors also thank the referee

(Professor L. Andersson, University of Uppsala) for donating a sample of immobilized TED for comparison with the commercial samples.

SHORT COMMUNICATION

ELECTROCHEMICAL STUDY OF THE MECHANISM OF LANTHANIDE EXTRACTION WITH THENOYLTRIFLUOROACETONE

WEI-HUA YU and HENRY FREISER
Strategic Metals Recovery Research Facility, Department of Chemistry, University of Arizona, Tucson, AZ 85721, U.S.A.

(*Received* 27 *July* 1988. *Accepted* 13 *September* 1988)

Summary—Current-scan polarography at the ascending-water electrode (AWE) was used to examine the electrochemical behavior of HTTA and La^{3+}, both in the absence and presence of neutral ligands, TOPO or MBDPO, and the light this sheds on the mechanism of extraction of lanthanides with HTTA, as well as the role played by mixed-ligand chelate formation.

This work is a part of our continuing study of metal-ion extraction systems, by means of their electrochemical behavior.[1-7] We have recently described the electrochemical behavior of lanthanide complexes with neutral ligands as well as with acylpyrazolones, which are similar to β-diketones. Here we examine thenoyltrifluoroacetone (HTTA), a β-diketone which is a widely used metal extractant.

EXPERIMENTAL

Apparatus

Current-scan polarography at the ascending-water electrode (AWE) was employed. The electrolytic cell, apparatus and experimental procedures were as described earlier.[1,6]

Materials

Sodium acetate solution (0.2*M*) is used as the aqueous supporting solution. The organic phase is 1,2-dichloroethane (DCE) containing 0.01*M* tetraheptylammonium tetraphenylborate (THA·TPB) as electrolyte, prepared as previously described.[5] Thenoyltrifluoroacetone was purchased from Aldrich, and TOPO from Alfa. Methylbisdiphenyloxide (MBDPO) was synthesized and purified in the laboratory.[8] A 0.1*M* lanthanum solution was prepared by dissolving lanthanum oxide (Alfa, 99.99% pure) in a minimum quantity of sulfuric acid or acetic acid then diluting to volume with water.

RESULTS AND DISCUSSION

There is a well defined cathodic wave at the AWE when 0.4m*M* HTTA in DCE 0.01*M* THA·TPB as supporting electrolyte is in contact with 0.2*M* sodium acetate aqueous solution with pH > 6.2 (Fig. 1). The limiting current of this cathodic wave is proportional to the concentration of HTTA in the organic phase and is independent of the pH of the aqueous solution. The half-wave potential is shifted by +52 mV/pH over the pH range 6.2–7.0, but at pH > 7.0 there is much less change in the half-wave potential (Fig. 2). The appearance of the cathodic wave indicates that some anion enters the organic phase from the aqueous solution. The limiting current depends on the initial concentration of HTTA in the organic phase. Therefore, the anion of HTTA is assumed to be the species transferred. This is supported by the pH-dependence of the half-wave potential. The logarithm of the limiting current is proportional to the logarithm of the height of the hydrostatic head of the aqueous phase in the AWE, with a slope of 0.35 rather than the 0.5 expected for a diffusion-controlled process. This suggests that the process may be at least partially kinetically controlled,[9] which may reflect the relatively slow keto–enol tautomerism of HTTA in

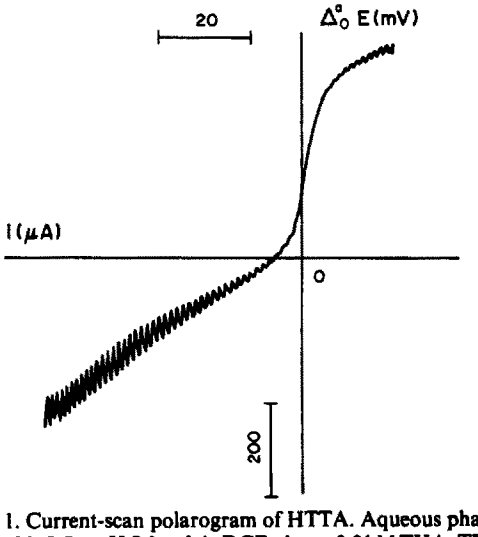

Fig. 1. Current-scan polarogram of HTTA. Aqueous phase: 0.2*M* NaOCa, pH 7.0 ± 0.1. DCE phase: 0.01*M* THA·TPB, 0.4m*M* HTTA.

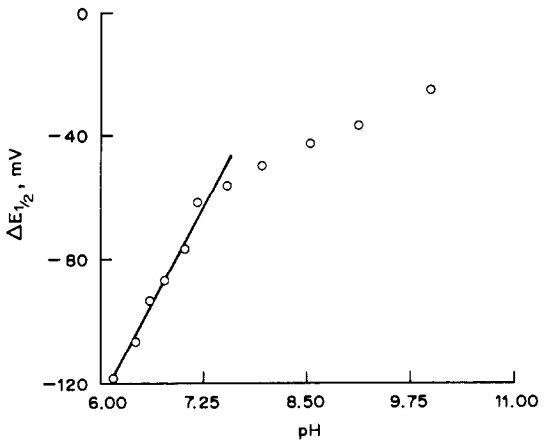

Fig. 2. Effect of pH on the half-wave potential of the TTA^- wave. Aqueous-phase: 0.2*M* NaOAc. DCE phase: 0.01*M* THA·TPB, 0.4m*M* HTTA.

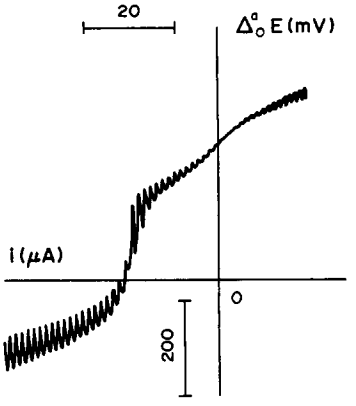

Fig. 3. Polarogram of the chelate La–HTTA. Aqueous phase: 0.2*M* NaOAc, 0.3m*M* La, pH 7.0 ± 0.1. DCE phase: 0.01*M* THA·TPB, 4m*M* HTTA.

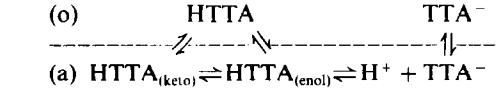
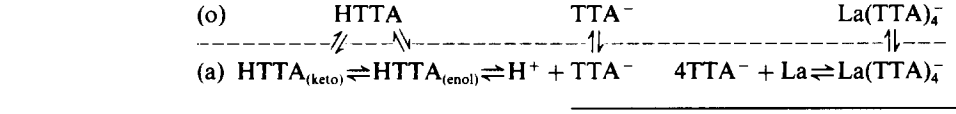
that the enol form of HTTA (*i.e.*, the acidic form of the compound) can dissociate,[10] and at higher pH HTTA may be converted completely into the enol form. The dependence of the half-wave potential on pH is supportive of this explanation. The following diagram demonstrates this ion-transfer process:



A well defined cathodic wave completely different from that of deprotonated HTTA appears when an organic phase containing HTTA at concentrations $>0.001M$ is in contact with aqueous 0.002*M* lanthanum solution in 0.2*M* sodium acetate in the pH range 5.7–7.2 (Fig. 3). The half-wave potential of this new wave depends on the pH of the aqueous solution: in the pH range 5.7–6.2, the half-wave potential shifts by +256 mV/pH, but changes more slowly at higher pH values (Fig. 4). This trend is similar to that for the wave of the deprotonated species. A tenfold increase in the concentration of HTTA in DCE results in a shift of +258 mV in the half-wave potential, whereas a comparable increase in the lanthanum concentration yields a shift of only +62 mV. Thus, the new cathodic wave would seem to be derived from the transfer of an anion which consists of 4 TTA^- ions and one La^{3+} ion, *i.e.*, $La(TTA)_4^-$. The relationship between the limiting current and the hydrostatic head of the aqueous reservoir is the same as that for the wave of deprotonated HTT. The transfer of the chelating ion can be depicted as follows:



When TOPO is present in the organic solution, the limiting current of the cathodic wave decreases. A neutral mixed-ligand chelate of La and TTA with TOPO can be supposed to be formed.[11–13] If i_1 stands for the limiting current caused by $La(TTA)_4^-$ in the absence of TOPO, and i_2 represents the limiting current with TOPO present, the following relationship is obtained:

$$i_1 = K[La(TTA)_4^-]$$

$$i_2 = K[(La(TTA)_4^-] - K'[La(TTA)_2^+ (TOPO)_n]$$

$$\Delta i = K'[La(TTA)_2^+ (TOPO)_n]$$

The plot of log Δi *vs.* log [TOPO] gives a slope of 0.93, indicating that one molecule of TOPO is involved in the new chelate.

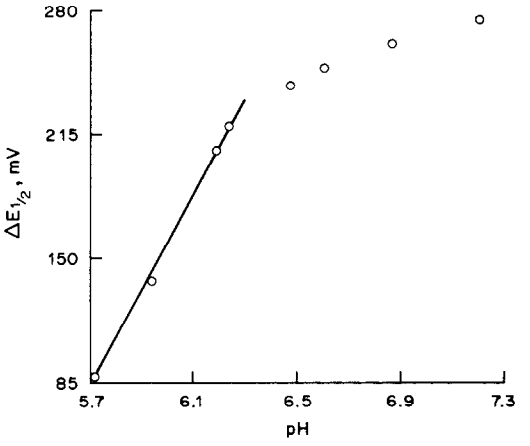


Fig. 4. Effect of pH on the half-wave potential of the wave from the La–HTTA chelate. Aqueous phase: 0.2*M* NaOAc, 0.2m*M* La, pH 7.0 ± 0.1. DCE phase: 0.01*M* THA·TPB, 4m*M* HTTA.

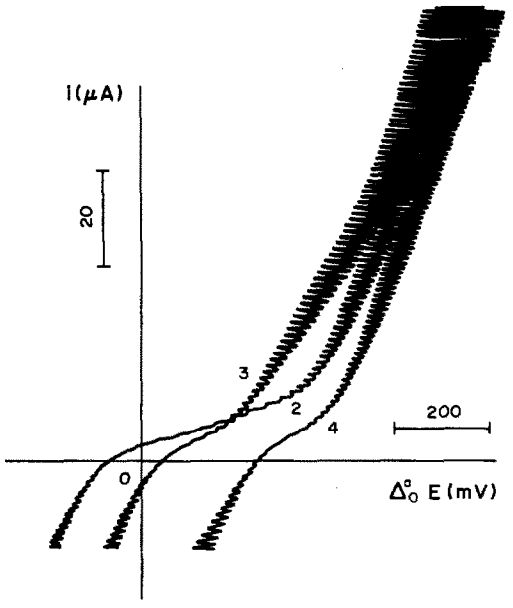

Fig. 5. Polarogram of the HTTA–La–TOPO adduct. Aqueous phase: 0.2*M* NaOAc, 0.4m*M* La, pH 6.0 ± 0.1. DCE phase: 0.01*M* THA·TPB; (1) 5m*M* HTTA, (2) 2.8m*M* TOPO, (3) 5m*M* HTTA, 2.8m*M* TOPO.

The limiting current of the cathodic wave decreases with increase in [TOPO], finally disappearing, while an anodic wave appears (Fig. 5), which is caused by transfer of a cation involving La, TOPO and TTA. The limiting current is proportional to the concentration of TOPO in the organic phase when [HTTA] is constant and in large excess, and is dependent on the square root of the height of the hydrostatic head of the aqueous solution at the AWE, indicating a diffusion-controlled process. The logarithmic analysis exhibits a slope of 64 mV. The ion transferred is therefore a singly charged cation. The half-wave potential shifts by −64 mV/pH, but by +64 mV when the concentration of HTTA in the organic phase is increased tenfold. Only one TOPO molecule is involved in the complex, as seen from the slope of the plot of the half-wave potential *vs.* log [TOPO] when TOPO is present in large excess. No wave is observed in sulfate solution unless acetate is also present, so the chemical reaction can be described as follows:

$$La(TTA)_2(OAc) + TOPO + H^+ = La(TTA)(OAc)(TOPO)^+ + HTTA$$

$$\beta = \frac{[La(TTA)(OAc)(TOPO)^+][HTTA]}{[La(TTA)_2(OAc)][TOPO][H^+]}$$

The half-wave potential is expressed by the equation:

$$\Delta_o^a E_{1/2} = \Delta_o^a E^0 + \frac{RT}{2F} \ln \frac{D_{La(TTA)_2(OAc)_{(a)}}}{D_{La(TTA)(OAc)(TOPO)_{(o)}}} + \frac{RT}{F} \ln \frac{K_{TOPO}}{K_{D_{HTTA}}} + \frac{RT}{F} \ln \frac{[HTTA]_{(o)}}{[TOPO]_{(a)}[H^+]_{(a)}\beta}$$

where D is the diffusion coefficient for the species and phase indicated by subscript and K_D is the distribution coefficient for the species indicated.

TOPO and MBDPO were found to exhibit similar electrochemical behavior, indicating a similar ion-transfer process, but MBDPO is a stronger extractant than TOPO, and there is a shift of the anodic wave to more negative values when MBDPO is used instead of TOPO.

PREDICTION OF FORMATION CONSTANTS FOR ACTINIDE COMPLEXES IN SOLUTION

PAUL L. BROWN
Australian Nuclear Science and Technology Organisation, Lucas Heights Research Laboratories, Private Mailbag No. 1, Menai 2234, NSW, Australia

(*Received* 1 *June* 1988. *Revised* 11 *August* 1988. *Accepted* 4 *November* 1988)

Summary—A numerical treatment for predicting the formation constants of actinide complexes from the properties of the metal ion and the ligand is presented. Comparison of predicted and averaged literature values of the formation constants shows excellent agreement, and the method will be most useful for modelling transport from radioactive waste repositories.

The modelling of radionuclide transport from high- and low-level radioactive waste repositories requires several types of fundamental input data, including the formation constants of complexes of the actinide elements present in the repository, and a number of data-bases[1–3] have been formulated for this purpose. The problem associated with these and other data-bases is that in many cases the data are limited, uncertain, or non-existent. The reason for this is that it is often extremely difficult, if not impossible, to make the necessary measurements, owing to the high radioactivity of the actinide concerned.

One approach to this problem, which has been attempted many times,[4–8] is to predict the formation constants from fundamental properties of the metal ion, such as charge and radius. These treatments, unfortunately, have had limited success since, at best, they could only predict the constants for a small range of complexes, or constants for complexes with ligands closely related in structure. More recently, Brown *et al.*[9,10] have developed a method which utilizes the properties of both the metal ion (charge, radius and electronic structure) and the ligand (ionic charge and pK_a of its parent acid). This new treatment allows the prediction of the formation constant of *any* metal ion–ligand complex and is extremely useful in obtaining constants for those complexes which cannot easily be studied experimentally. The use of the method for predicting the stability of actinide complexes is outlined.

The overall formation constant of an actinide complex produced by the reaction

$$p\mathrm{Ac} + q\mathrm{L} \rightleftharpoons \mathrm{Ac}_p\mathrm{L}_q \qquad (1)$$

is defined by

$$\beta_{pq} = \frac{[\mathrm{Ac}_p\mathrm{L}_q]}{[\mathrm{Ac}]^p[\mathrm{L}]^q} \qquad (2)$$

where Ac represents an actinide ion (for example, Am^{3+}, Th^{4+}, PuO_2^+, UO_2^{2+}) and L the ligand, and charges are omitted for simplicity.

Early studies[4–6] aiming to correlate the stability of the first mononuclear complex, β_{11}, with the ionic charge (z_M) and radius (r_M) of a metal ion, used various ratios of the two parameters. Williams[4] used the ionic potential, z_M/r_M, to explain the stability of alkaline-earth metal complexes, whereas Palmer[5] suggested that the ionic charge density, z_M/r_M^2, should be used. Davies[6] described the hydroxo-complexes of the Group 1A and 2A metals in terms of the ratio z_M^2/r_M, and proposed that the equation

$$\log \beta_{11} = 0.607 z_M^2 - 1.156 \qquad (3)$$

should be used to predict the formation constants of these complexes. Brown *et al.*[10] were able to show that these constants could equally well be predicted from the function z_M/r_M^2 by means of the equation

$$\log \beta_{11} = 0.556 z_M/r_M^2 - 0.40 \qquad (4)$$

i.e., for these ions a simple electrostatic model applies. However, for other ions this simple model has been shown[9,10] to be inapplicable since other effects are present which completely outweigh the electrostatic effect.

Brown and Sylva,[9] by considering the type of bonding orbitals available and the Slater screening constant,[11] have extended and generalized the simple electrostatic model. This "extended electrostatic model" may be represented by

$$\log \beta_{11} = \mathrm{Int}_1 + \mathrm{Slp}_1[g_1(z_M/r_M^2 + g_2)] \qquad (5)$$

where

$$g_1 = (1 + D + \epsilon_L^2 S)(z_M + 2) \qquad (6)$$

$$g_2 = g(n)(z_M - 1) - 0.05d[(\gamma - 1)(\epsilon_L^4 - 3) - 1] \times [n - (3 + 2\gamma)]^2[1 - \gamma z_M](1 - S) \qquad (7)$$

and Int_1 and Slp_1 are the least-squares intercept and slope of the linear equation for (1, 1) complexes. In equations (6) and (7), S is 0 for the absence and 1 for the presence of s-electrons in the outermost shell of the ion (exhibiting the inert pair effect); $D = 1$ if d-orbital electrons are available for bonding (otherwise $D = 0$); $g(n)$ is a Slater function[11] [$g(n) = 1$ when

n, the principal quantum number, is greater than unity, otherwise $g(n) = 0$]; d is the number of d-electrons in the outermost shell of the ion; γ is termed the ligand parameter and is 0 when the conjugate acids of the ligands are inorganic binary acids, and 1 when they are inorganic oxo-acids. These equations also introduce a new fundamental ligand property, ϵ_L, which with the corresponding metal property ϵ_M, is a unifying concept called the "electronicity" ("freeness" of the valence electrons). The concept describes quantitatively the ability of a ligand to complex a metal ion and, in the context of complex formation, quantifies a number of other concepts such as A- and B-character, "hard" and "soft" metal ions and ligands, and charge- and frontier-controlled reactions.[12-15]

Brown *et al.*[9,10] showed that for polynuclear, or further mononuclear species, an unknown formation constant β_{pq} can be determined from the known values of the first formation constant, β_{11}, and one other constant, β_{rs}, by using the generalized Sylva–Davidson equation[9,10,16]

$$\log \beta_{pq} + \log U_{pq} = q \log \beta_{11} + [(p-1)/(r-1)] \times [\log \beta_{rs} + \log U_{rs} - s \log \beta_{11}] \quad (8)$$

and

$$\log U_{pq} = \log[(q+1-p)!] - 0.5(q-p)(q-p+1)\log k \quad (9)$$

Log U can be considered as a measure of the intrinsic tendency of a metal ion (electron acceptor) to form a chemical (co-ordinate) bond with a ligand (electron donor) to produce a metal complex. It is a property associated with both the metal ion and the ligand and is manifested by the decreasing tendency of ML to form ML_2 relative to the tendency of M to react with L to give ML. That $\log U_{11} = 0$ follows automatically since the ML (1, 1) complex is formed from the reference states M (1, 0) and L (0, 1).[9] In equation (9), k is a proportionality constant relating two consecutive formation constants[9] and can be described by

$$\log k = -(2 - \theta_M)\exp[-(\epsilon_M - \epsilon_L)^2] \quad (10)$$

where θ_M is the number of metal ions bonded to each ligand molecule, and ϵ_M and ϵ_L are the electronicities of the metal ion and ligand, respectively. The electronicity of a ligand can be calculated directly from the first formation constant of a metal ion complex of that ligand.[9] However, the electronicity of a metal requires knowledge of at least one other stepwise formation constant for a mononuclear complex and the electronicity of the ligand involved in the complex. Thus, considering equations (8)–(10) for only the mononuclear stepwise formation constant, we obtain (since $\theta_M = p = 1$)

$$\log K_q = \log K_1 - \log_q - (q-1)\exp[-(\epsilon_M - \epsilon_L)^2] \quad (11)$$

which by rearrangement gives

$$\epsilon_M = \epsilon_L \pm [\ln\{(q-1)/(\log K_1 - \log K_q - \log q)\}]^{1/2} \quad (12)$$

Thus, by use of the first and second stepwise formation constants of a metal–fluoride complex (since $\epsilon_L = 0$ for fluoride), equation (12) is simplified to equation (13), since all electronicity values, by definition, are greater than or equal to zero:[9]

$$\epsilon_M = [2.303 \log(1/\{\log K_1 - \log K_2 - \log 2\})]^{1/2} \quad (13)$$

It is possible to obtain further values for comparison, by using equation (12) with other ligands, and when this was done satisfactory agreement was obtained. Furthermore, it is possible to obtain the values of both ϵ_M and ϵ_L from the concepts of Klopman[13] and of Parr and Pearson,[15] as was shown by Brown and Sylva.[9]

The condensation step (log C) for formation of the polynuclear species (r, s) can be expressed by

$$\log C = [1/(r-1)][\log \beta_{rs} + \log U_{rs} - s \log \beta_{11}] \quad (14)$$

and by analogy with equation (5), we can write

$$\log C = \mathrm{Int}_2 + \mathrm{Slp}_2[g_1(z_M/r_M^2 + g_2)] \quad (15)$$

where Int_2 and Slp_2 are the least-squares intercept and slope values of linear equations for the polymeric species. Substitution of equations (5) and (15) into (8) leads to

$$\log \beta_{pq} = [(p-1)(\mathrm{Int}_2) + q(\mathrm{Int}_1) + [(p-1)(\mathrm{Slp}_2) + q(\mathrm{Slp}_1)][g_1(z_M/r_M^2 + g_2)] - \log U_{pq} \quad (16)$$

which expresses β_{pq} solely in terms of properties of the reacting metal ion and ligand.

Zachariasen[17] showed that in the solid state the ionic radius of oxo-metal ions such as dioxouranium(VI) depends on both the nature and number of the ligands bonded to the metal ion. Brown and Sylva[9] demonstrated a similar dependence in aqueous solution; that is, the value of the function $g_1(z_M/r_M^2 + g_2)$ in equation (8) depends specifically on the nature of the ligand. Indeed, they were able to show that the value of $g_1(z_M/r_M^2 + g_2)$ was a function of the pK_a value of the acid form of the ligand. They described this dependence by

$$\log \beta_{11} = \mathrm{Int}_1 + \mathrm{Slp}_1[g_1(z_M/(r_o)_M^2 + g_2) + 1.125 z_M(pK_a + 4)] \quad (17)$$

where $(r_o)_M$ is defined as the maximum allowable ionic radius in the case of a ligand bound in the primary hydration sphere of the metal ion. However, as the ionic radius varies with the nature of the ligand it would be more appropriate to express this dependence in terms of an "apparent ionic radius" $(r_{app})_M$:

$$\log \beta_{11} = \mathrm{Int}_1 + \mathrm{Slp}_1[g_1(z_M/(r_{app})_M^2 + g_2)] \quad (18)$$

$$(r_{app})_M = (r_o)_M\{g_1/[g_1 + 1.125(r_o)_M^2(pK_a + 4)]\}^{1/2} \quad (19)$$

The argument for the use of equation (18) rather than (17) (from which it is derived), is that it demonstrates that the oxo-cations, like all other metal ions, can be treated in terms of equation (5): with the other metal ions the apparent ionic radius is the actual ionic radius, whereas with the oxo-metal ions the radius is given by equation (19). Table 1 gives the values of the maximum allowable ionic radius, $(r_o)_M$, of each dioxoactinide ion.

As might be expected, there are fundamental relationships between the intercept and slope of equation (16) and the properties of the ligand, since their values are solely ligand-dependent. The relationships have been described[9] by the equations.

$$\mathrm{Slp}_1 = 0.031 + 0.0078\,pK_a \quad (20)$$

$$\mathrm{Int}_1 = 0.11 - 4.10[1 + (3 - z_L)(z_L + 1)]\,\mathrm{Slp}_1 \quad (21)$$

$$\mathrm{Slp}_2 = 0.187\theta_L^2 - 0.814\theta_L + 0.78 \quad (22)$$

$$\mathrm{Int}_2 = 3.58 - 62.67\,\mathrm{Slp}_2 \quad (23)$$

where z_L is the charge of the ligand and θ_L is the number of ligand molecules bonded to each metal ion.

Use of these equations thus allows the prediction of the formation constants of actinide complexes at zero ionic strength and 25°. The usefulness of the method is illustrated by Tables 2 and 3, in which the agreement between the predicted and averaged literature formation constants of (*a*) hydroxo-actinide complexes (Table 2) and (*b*) complexes of dioxouranium(VI) (Table 3) are compared. The literature value is the average of the reported values quoted in a number of formation constant compilations.[5,18–21] Error limits for each complex have also been estimated on the basis of the number of formation constants cited and the stoichiometry of the species. Comparison of the averaged literature values (and their estimated errors) with the predicted values shows that 63 of the 67 predicted constants for the hydroxo-actinide complexes, and 28 of the 29 for dioxouranium(VI) complexes, fall within the estimated error limits. For actinide complexes in general, 247 of the 256 predicted formation constants are expected to fall within the error limits, thus demonstrating the value of the developed method. Never-

theless, it would appear that in a small number of cases the method gives predicted formation constants which are grossly inaccurate. In most (but not all) of these cases, however, the experimental value would seem questionable since (*i*) only one determination has been made, (*ii*) experimental difficulties resulting from reactivity and leading to precipitation (*e.g.*, Pa^{4+})[10] may give unreliable constants, (*iii*) the stepwise formation constant K_q is greater than K_{q-1} (*e.g.*, the stepwise formation constant of $UO_2(HPO_4)_2^{2-}$ is two orders of magnitude greater than that of $UO_2(HPO_4)$, whereas the opposite normally occurs,[9] and (*iv*) computational difficulties in determining the formation constant at zero ionic strength for oligonuclear complexes [*e.g.*, $Th_4(OH)_{12}^{4+}$ and $Th_6(OH)_{15}^{9+}$] can lead to inaccurate formation constants. In other cases though, it is possible that assumptions made in the present theory are inaccurate. For example, the large deviations for the (3,5) and (4,7) species of dioxoactinide ions may be a result of assuming that all the bonds in the complexes are of hydroxo-actinide type, when it is likely that oxo-actinide bonds may be involved.[10] All these deviations are currently being investigated.

Conclusion

A new unifying theory for prediction of complex formation constants for actinide complexes has been described. The overall agreement between predicted and averaged literature values demonstrates the accuracy of the numerical method. The theory will be of great value in obtaining formation constants for compounds for which such data are limited, uncertain, or non-existent. Its usefulness to actinide chemists is enhanced further since many of the data cannot be directly determined in the laboratory, owing to the radioactive nature of the parent actinide.

PERIODATE DETERMINATION BY FIA WITH CHEMILUMINESCENCE EMISSION DETECTION, AND ITS APPLICATION TO ETHYLENE GLYCOL

N. P. EVMIRIDIS*
Laboratory of Analytical Chemistry, Department of Chemistry, The University, Hull, England

(*Received* 1 *April* 1987. *Revised* 30 *September* 1988. *Accepted* 27 *October* 1988)

Summary—A method for periodate determination is given which combines the rapidity of flow-injection analysis and the sensitivity of chemiluminescence (CL) detection. It is based on the CL emission generated during oxidation of pyrogallol by periodate, and gives a relative standard deviation of 3% and a detection limit of 350 ng with the instrumentation used. The method has been applied to determination of ethylene glycol, with a detection limit of 0.5 μmole. The accuracy of the method is quite good when the ethylene glycol is oxidized in unbuffered solutions, and the interference due to formaldehyde produced can be halved by prior addition of an appropriate amount of iodate. A throughput of 15 samples/min is possible, and the method is suitable for automation and remote control.

Determination of periodate is almost exclusively related to analysis of organic compounds that have vicinal —CH_2OH, —CHO, >CO, or —COOH groups, especially polyhydroxy compounds. The consumption of periodate is determined by measurement of the periodate concentration before and after oxidation of the organic compound; titrimetric methods[1–3] are usually used.

The Müller–Friedberger method[1] is based on addition of iodide and titration of the iodine produced, but has the disadvantage that the iodine may react further with some of the products of oxidation. Some workers[4–6] have reported doubts of the reliability of the Fleury–Lange method[2] for determination of excess of periodate in analysis of carbohydrates. Other workers,[7–10] dealing with specific carbohydrate compounds, have found errors due to iodination or further oxidation by iodine formed during the determination procedure, or to incomplete reaction between iodine and arsenite. In addition, all the procedures above are time-consuming and not applicable in flow systems.

A spectrophotometric method[11] is also used for the determination of very small quantities of periodate by monitoring of the absorbance at about 222.5 nm, but it suffers serious interference from iodate and the probability of oxidation of HCHO and HCOOH in the light-beam. Pons[12] employed H-acid as a spectrophotometric reagent for periodate but the method is time-consuming and needs further statistical validation.

It has recently been reported[13,14] that chemiluminescence (CL) is generated during the oxidation of pyrogallol with periodate, and this forms the basis of the method reported here.

EXPERIMENTAL

Reagents

All chemicals were of analytical-reagent grade and demineralized distilled water was used throughout. The reagent solutions were prepared as described earlier.[13]

Ethyleneglycol (EG) aqueous solution, 0.5M. Dissolve 31.04 g of ethylene glycol in 1 litre of water, and dilute further as required for lower concentration solutions.

Phosphate buffer, pH 8.0. Dissolve 13.6 g of potassium dihydrogen phosphate in water, adjust the pH with 1*M* sodium hydroxide and dilute to 1 litre.

Apparatus

The flow manifold (Fig. 1) and detector[15] used have already been described.[13]

Method

A sample (40 μl) of periodate solution or the reaction mixture of excess of periodate with ethylene glycol is injected into the carrier stream of buffer solution, and then mixed with the reagent (either pyrogallol solution or pyrogallol-hydroxylamine solution).

For periodate determination the reagent stream is $[Pg]_0 = [Hx]_0 = 1.0 \times 10^{-3}M$ in pH 8.0 phosphate buffer.

RESULTS AND DISCUSSION

The CL emission generated during oxidation of pyrogallol with periodate is rather weak and relatively insensitive to changes in periodate concentration, but can be enhanced by the addition of hydroxylamine to the system.[13]

Optimization of conditions

The reagent is a buffered solution of pyrogallol (Pg) and hydroxylamine (Hx), which are considered to form a condensation product

$$Pg + Hg \overset{K_f}{\rightleftharpoons} Pg\text{–}Hx$$

*Present address: Laboratory of Analytical Chemistry, Department of Chemistry, University of Ioannina, Ioannina, Greece.

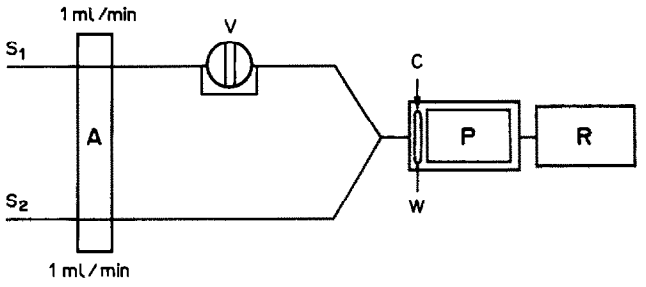

Fig. 1. Manifold and instruments used for the mixing and for monitoring the generated CL emission. (S1) carrier stream; (S2) reagent stream; (V) sample valve; (W) waste; (C) cell; (A) pump; (P) photomultiplier; (R) recorder.

that acts as a sensitizer in the oxidation of Pg with periodate.[13] However, any free hydroxylamine acts as an inhibitor by reduction of periodate.

The effect of the concentration of each reactant on the overall CL emission was studied by varying the concentration of either Pg or Hx (keeping the concentration of the other fixed) at two levels of periodate concentration, $1.0 \times 10^{-3}M$ (low) and $1.0 \times 10^{-2}M$ (high).

Figure 2 shows that for $[IO_4^-] = 10^{-3}M$ and $[Hx] = 10^{-3}M$ the CL is maximal at $[Pg] = 5 \times 10^{-4}M$, and that for $[IO_4^-] = 10^{-2}M$ and $[Hx] = 10^{-3}M$ the maximum is at $[Pg] = 10^{-3}M$. The decrease in CL with increase in [Pg] after the maximum is presumably a consequence of an inner filter effect of the Pg.

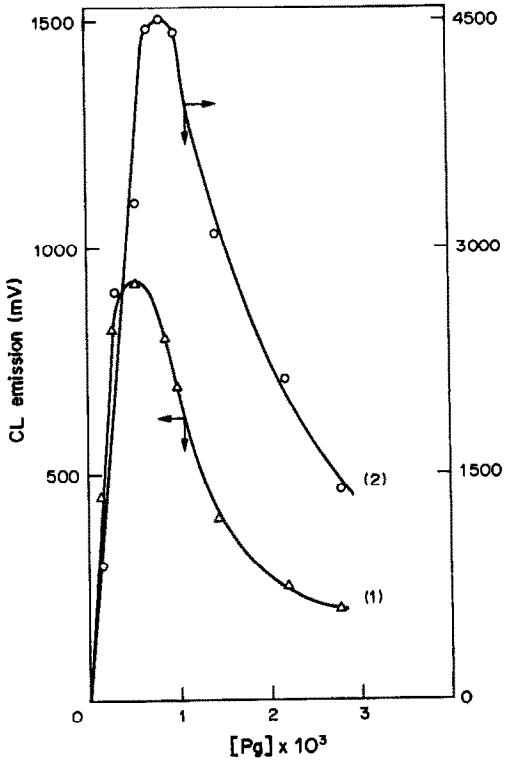

Fig. 2. Effect of pyrogallol concentration at $[Hx]_0 = 1.0 \times 10^{-3}M$. Conditions: pH 8.0; $[IO_4^-]_0$ $1.0 \times 10^{-3}M$ (1), $1.0 \times 10^{-2}M$ (2).

Effect of hydroxylamine concentration

This was examined at two concentration levels of Pg, 5.0×10^{-4} and $1.0 \times 10^{-3}M$ and two periodate concentrations, 1.0×10^{-3} and $1.0 \times 10^{-2}M$, Fig. 3.

At the lower periodate level ($10^{-3}M$) the CL obtained from $5 \times 10^{-4}M$ Pg is maximal at $5 \times 10^{-4}M$ Hx concentration, and is higher than that for $1.0 \times 10^{-3}M$ Pg, which occurs at $2 \times 10^{-3}M$ Hx. This suggests competition between Hx and the Pg–Hx complex for oxidation by periodate, and this is substantiated by the results for the $1.0 \times 10^{-2}M$ periodate system, where the larger excess of periodate can accommodate the competitive reduction by Hx.

Analysis of effects and interactions

It was obvious that the system was complicated, so a 2^3 factorial experiment was performed at two levels of each reactant, 1.0×10^{-2} and $1 \times 10^{-3}M$ periodate, 5.0×10^{-3} and $5.0 \times 10^{-4}M$ Hx and 2.5×10^{-3} and $5 \times 10^{-4}M$ Pg. The residual variance found for 12 measurements under identical conditions was $s_0^2 = 379.5$. Table 1 clearly demonstrates that all the effects and interactions of the analytical concentration levels are significant at the 95% level, especially the interaction between Pg and Hx. The next most significant are the effect of periodate and the ternary interaction between all three reactants.

Effect of reagent concentrations on periodate calibration curves

The concentrations of the reactants at equilibrium were calculated for an analytical Hx concentration of $1.0 \times 10^{-3}M$ and analytical Pg concentrations of 5.0×10^{-4}, 1.0×10^{-3} and $2.5 \times 10^{-3}M$, on the basis of reaction (1) and the assumption that $K_f = 1 \times 10^3$, and are given in Table 2 together with $[Pg–Hx]_{eq}/[Pg]_{eq}$ which represents the ratio of [sensitizer]/[CL generator].

Calibration curves for periodate over the range 0–0.01M, for each of the [Pg], [Hx] combinations, are shown in Fig. 4. It is clear that the equimolar mixture

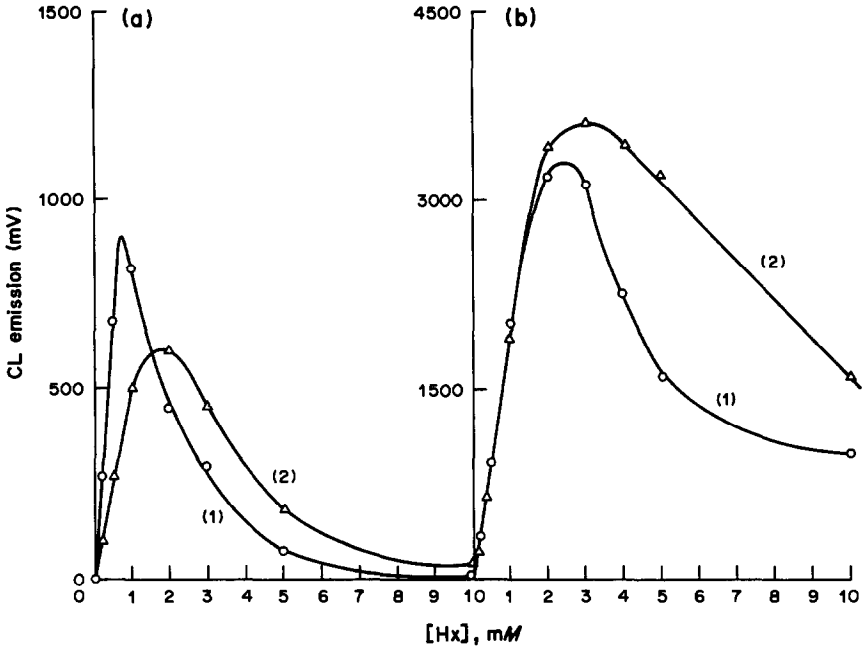

Fig. 3. Effect of hydroxylamine concentration at (a) $[IO_4^-]_0 = 1.0 \times 10^{-3}M$ and (b) $[IO_4^-]_0 = 1.0 \times 10^{-2}M$. Conditions: pH 8.0; $[Pg]_0$ $5.0 \times 10^{-4}M$ (1), $1.0 \times 10^{-3}M$ (2).

of Pg and Hx gives the greatest sensitivity and widest useful range.

Optimization of the sensitivity

The shape of the calibration curve is dependent on both [CL generator] and the ratio [sensitizer]/[CL generator]. Since it is not possible to adjust $[Pg–Hx]_{eq}$ independently of $[Pg]_{eq}$, it is necessary to find the analytical concentrations $[Pg]_0$ and $[Hx]_0$ which optimize the CL emission. As an equimolar mixture seemed best (Fig. 4), the effect of varying $[Pg]_0$ $(= [Hx]_0)$ was examined. Figure 5 shows that $[Hx]_0 = [Pg]_0 = 1.0 \times 10^{-3}M$ gives the best result overall. The crossing of curves 2 and 3 at low periodate concentration is due to the competitive oxidation of Hx by periodate when the $[Hx]/[IO_4^-]$ ratio is high, resulting in less CL.

For low periodate concentration ($<0.0125M$) the $[Pg]_0 = [Hx]_0 = 5.0 \times 10^{-4}M$ combination gives the highest sensitivity (Fig. 5), with a relative standard deviation of 3% for ten measurements in the middle of the steep part of the calibration curve.

For high periodate concentrations the calibration curve with $[Pg]_0 = [Hx]_0 = 1.0 \times 10^{-3}M$ is more convenient, and gives the same r.s.d. value.

Table 1. Analysis of significance of effects and interactions (F-test)[19–21]

Effects and interactions	Effect on CL signal height, mV	B = mean* square	$C = S_0^2 \times F_{11}^1$	B/C	95% Significance

Application to determination of organic compounds

Periodate is almost exclusively used in analysis of organic compounds that have vicinal hydroxyl, carbonyl or carboxylic acid groups, which are oxidized to aldehyde, carboxylate or carbon dioxide respectively.

The most important group determined by periodate oxidation is that of polyalcohols. Excess of periodate is added and the surplus determined. This can be done by the method proposed here. The application has been tested with ethylene glycol.

Ethylene glycol oxidation in buffered solution (pH 8.0). Ethylene glycol was treated with excess of periodate in aqueous solution buffered at pH 8.0 and after the end of the reaction a small volume of the reaction mixture was injected into the FIA manifold for periodate determination.

Table 3 gives the results for a series of 5.0-ml volumes of $1.0 \times 10^{-2}M$ periodate to which 0.05 ml of $0.5M$ ethylene glycol plus 0–0.30 ml of $0.05M$ ethylene glycol had been added.

The residual periodate concentration in each sample was calculated and compared with the value expected from the reaction stoichiometry. Comparison of columns 3, 5 and 7 of Table 3 shows there is over-consumption of periodate by low quantities of ethylene glycol, but lower consumption than expected at the higher quantities. This may be explained by the fact that with high excess of periodate there is oxidation of the formaldehyde formed[16-19] but with low excess of periodate the oxidation of ethylene glycol reaches completion very slowly.

Ethylene glycol oxidation in unbuffered solution. The results in Table 4 for oxidation with 5 ml of $2.5 \times 10^{-3}M$ periodate mixed with ethylene glycol show an improvement, but the reaction is still slow to reach completion when the excess of periodate is small.

The recommended method is addition of a fixed volume of sample solution, (*e.g.*, 0.05 ml) containing not more than 10 μmole of ethylene glycol, to 5.0 ml of $2.5 \times 10^{-3}M$ periodate, and measurement of the periodate excess as already described.

A linear calibration graph for the amount of ethylene glycol added is obtained over the range 0–10 μmole.

Selectivity

Oxidation of ethylene glycol by periodate leads to the formation of formaldehyde and iodate:

$$HOCH_2CH_2OH + IO_4^- \rightarrow 2HCHO + IO_3^- + H_2O$$

Table 3. Excess of periodate, calculated from CL emission after oxidation of ethylene glycol with periodate in pH 8.0 buffer solution

Ethylene glycol added, μmole	Calculated periodate excess, μmole	[Periodate] excess, mM	Experimental signal peak height: 30 min after mixing CL, mV	30 min after mixing [Periodate] excess, mM	60 min after mixing CL, mV	60 min after mixing [Periodate] excess, mM
25	25	5.0	850	3.10	780	2.80
30	20	4.0	820	3.05	750	2.70
35	15	3.0	720	2.70	670	2.50

Table 4. Excess of periodate calculated from CL emission after oxidation of ethylene glycol with periodate in unbuffered aqueous solution

Ethylene glycol added, μmole	Calculated periodate excess, μmole	[Periodate] excess, mM	Experimental signal peak height: Immediately after mixing CL, mV	Immediately after mixing [Periodate] excess, mM	90 min after mixing CL, mV	90 min after mixing [Periodate] excess, mM
0.0	12.5	2.5	690	2.55	680	2.50
2.5	10.0	2.0	555	2.10	530	2.02
5.0	7.5	1.5	410	1.55	350	1.40
7.5	5.0	1.0	290	1.25	210	1.00
10.0	2.5	0.5	175	0.85	60	0.52
12.5	0	0	165	0.82	25	0.25
15.0	0	0	150	0.77	0	0

The formaldehyde is a reductant and the iodate an oxidant, so both may interfere in determination of the periodate excess. Table 5 shows the effect of some products from periodate oxidation of polyalcohols.

The interference from formaldehyde and formic acid is rather high, but can be decreased by the presence of an equimolar amount of iodate.

Application of the method to aqueous samples

Sample solutions were prepared by dissolving a known volume of ethylene glycol (analytical-reagent grade) or commercial antifreeze (containing fluorescent dyestuff) in water, or by diluting the water/antifreeze mixture from a car radiator. The samples were analysed by the Fleury–Lange and CL-emission methods. The results are shown in Table 6. There was good agreement for the pure ethylene glycol solutions, and fairly good agreement for the other samples. No problems were caused by the fluorescent dyestuffs.

Conclusions

The method is rapid, and reasonably accurate and reproducible. When the oxidation reaction used in

the application is fast, the whole determination can be performed in the flow-injection system by merged flow of separate solutions of the sample and the periodate, followed by passage of the mixture through the sampling valve, and injection of a sample into the carrier stream. The system could even be used for continuous monitoring of a process stream. The kinetics of oxidation of a specific polyhydroxy-compound with periodate can also be followed fairly easily with appropriate arrangement of the stream which leads to the sample loop. Such systems can be automated and are suitable for remote control.

Summary—A method for the differential-pulse polarographic determination of nifedipine has been developed, based on the electrochemistry of the aromatic nitro group in the drug. Polarography has also been used in studies of the photodegradation of nifedipine, which is highly light-sensitive under ultraviolet light and artificial daylight.

Nifedipine, methyl-1,4-dihydro-2,6-dimethyl-4-(2-nitrophenyl)-3,5-pyridine dicarboxylate (Fig. 1), is one of a class of drugs known as calcium antagonists, which have recently become available for clinical use[1,2] as coronary vasodilators. The drug is usually given orally or intravenously, and the therapeutic range in plasma is 25–100 μg/l. It is extensively metabolized before it is excreted. The drug is also light-sensitive, especially in solution. When exposed to ultraviolet light it is converted into 4-(2′-nitrophenyl)pyridine and under visible light it is oxidized to the 4-(2′-nitrosophenyl)pyridine homologue (Fig. 2).[3–5] Because of this, special care must be taken in determining it. Methods available are based on fluorescence,[6] gas chromatography with flame ionization,[7] mass spectrometric[8] or electron capture[9] detection, liquid chromatography,[3] HPLC with electrochemical detection,[10] and polarography.[11]

There is a pressing need for improved techniques for determination of nifedipine in biological fluids and in pharmaceutical preparations. HPLC appears to be the best method for use with biological fluids, and polarography for pharmaceutical preparation. This paper describes the reduction of nifedipine and its photodecomposition products by differential pulse polarography (dpp), and a method for determination of its stability in pharmaceutical preparations.

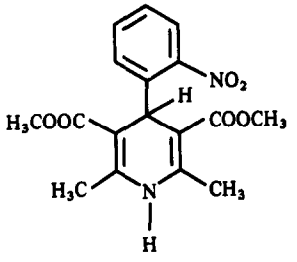

Fig. 1. Molecular structure of nifedipine.

EXPERIMENTAL

Chemicals

Nifedipine was obtained from Laboratorio Bayer (Santiago, Chile). McIlvaine and Sörensen buffers were used. The ionic strength was kept constant at 0.3*M* with potassium chloride. The drug and its photodecomposition products were dissolved in buffer–ethanol mixtures. All other chemicals were of analytical reagent grade. The solutions were polarographed after deoxygenation by passage of a

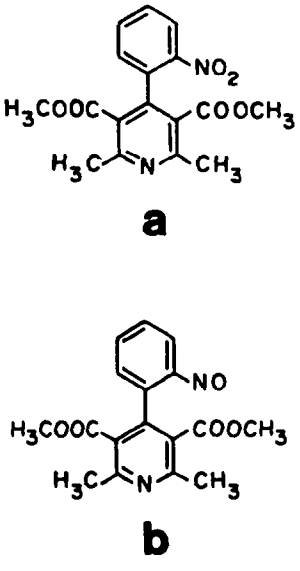

Fig. 2. Molecular structure of photodecomposition products obtained on exposure to (a) ultraviolet light; (b) daylight.

stream of purified nitrogen for 10 min. Peak potentials (E_p) were measured against an Ag/AgCl reference electrode.

Apparatus

A Tacussel EPL-3 recorder equipped with a TI-PULS module was employed. A Tacussel CPRA thermostatic polarographic cell with a dropping mercury electrode (drop-time 1.0 sec), an Ag/AgCl reference electrode and a platinum wire counter-electrode were used. Polarograms were recorded starting from an initial potential of −0.1 V at a scan-rate of 10 mV/sec in the cathodic direction. The pulse modulation was 60 mV and the current range was varied from 0.25 to 12.5 μA as required. For degradation studies of the drug an ultraviolet lamp (366 nm, 250 W) was used. A Varian Anaspect EM-360 NMR spectrometer and a Leitz Model III G infrared spectrometer were used in elucidation of the photodecomposition.

RESULTS AND DISCUSSION

Nifedipine contains two redox centres, a dihydropyridine ring and an aromatic nitro group. For reduction studies the second is the more important. The electrochemical reduction of aromatic nitro compounds has attracted considerable attention in the past and has been reviewed.[12] Nifedipine exhibits only one polarographic wave throughout the whole pH range. This wave is due to the four-electron reduction of the nitro group to a hydroxylamine derivative and is electrochemically irreversible. The peak potential is a linear function of pH, with a slope (−63.1 mV/pH at 30°) that is consistent with the four-electron four-proton electrode reaction typical of the nitro group:

$$RNO_2 + 4H^+ + 4_e^- \rightarrow RNHOH + H_2O$$

The peak current remains practically unchanged between pH 3 and 11.

For analytical purposes we have selected the peak obtained at pH 6 in a 70:30 v/v phosphate buffer–ethanol mixture, mainly from considerations of the solubility and stability of nifedipine. The linear relation of the limiting current to the square root of the mercury column height (corrected for back-pressure) and a value of 2.3%/deg for the temperature coefficient indicate that the limiting current is diffusion-controlled. The diffusion current is a linear function of the nifedipine concentration. The smallest detectable concentration was $0.5 \times 10^{-8} M$. The analytical procedure involves calibration over the concentration range from 0.7×10^{-4} to $1.1 \times 10^{-3} M$.

One of the most important advantages of the present method is that nifedipine remains stable under daylight conditions during the analysis. Furthermore, the proposed dpp method is an adequate tool for studying the photodecomposition of nifedipine. Several authors have reported that nifedipine is very light-sensitive in solution and special care must be taken in analysis for it. However, all studies related to the photodecomposition have been performed with purely organic solutions of the drug. Our studies have been made with aqueous alcohol solutions under three different conditions of light exposure: (*a*) artificial daylight (with a 400–600 nm range, (*b*) ultraviolet light (366 nm) and (*c*) room daylight.

Artificial daylight

A $1 \times 10^{-3} M$ solution of nifedipine at pH 6 in phosphate buffer–ethanol (70:30 v/v) at 29° was irradiated with light from a lamp. The degradation was monitored by means of the polarographic peak at about −700 mV. The irradiation was continued until total disappearance of this peak. During this time, two new peaks at −1370 and −10 mV appeared. Figure 3 shows the differential pulse polarograms of a $1 \times 10^{-4} M$ solution of nifedipine before

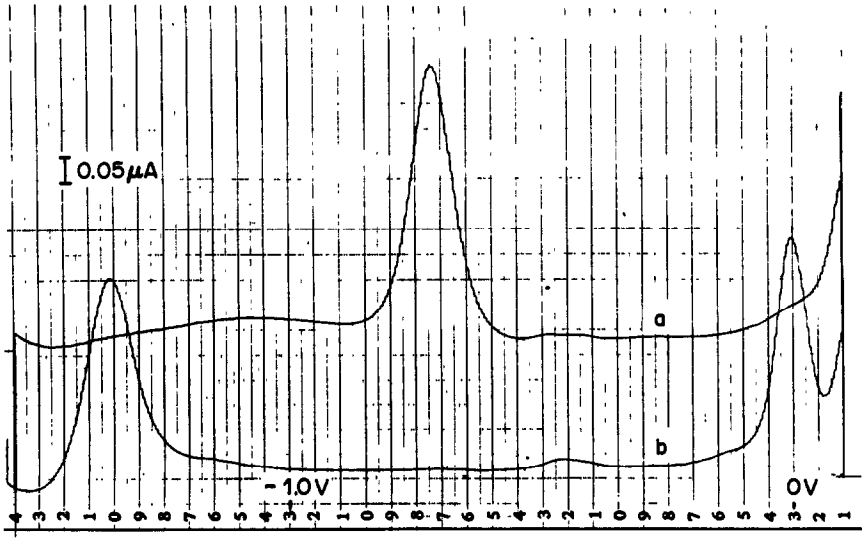

Fig. 3. Differential pulse polarograms obtained for (a) nifedipine solution at pH 6 in ethanolic phosphate buffer (30:70 v/v), (b) a nifedipine solution after irradiation.

and after the degradation. The more cathodic peak shows that strong adsorption takes place. The dpp peak current was used to estimate the degradation parameters. From the decrease in peak current with irradiation time, and assuming first-order kinetics, we have calculated a degradation rate constant of 0.036 min^{-1} with $t_{1/2} = 19.4$ min. The degradation product was obtained quantitatively by irradiation of an ethanol solution (10 mg/ml) of nifedipine for about 24 hr, and was isolated as described by Testa *et al.*[4]

The yellowish green crystals obtained were assayed by NMR and infrared spectroscopy and from the results summarized in Table 1 it is easy to deduce that the product is 4-(2′-nitrosophenyl)-2,6-dimethyl-3,5-dicarbomethoxypyridine (Fig. 2), in agreement with earlier work.[3-5] This compound shows two dpp peaks, at −1370 and −10 mV (pH 6, 29°), similar to the peaks that appear during the degradation process. The reaction that accounts for the peak at −10 mV is the two-electron two-proton reduction of the aromatic nitroso group. The peak at −1370 mV is due to the two-electron two-proton reduction of the azomethine group in the pyridine ring of the degradation product.

Ultraviolet light

Two different kinds of behaviour in the course of irradiation at 366 nm can be distinguished, depending on the irradiation time. First, at relatively short times, there is a decrease in the nifedipine dpp peak and the appearance of two new peaks at −1370 and −10 mV; the degradation parameters, assuming first-order kinetics, are a rate constant of 0.095 min^{-1} and $t_{1/2}$ 7.29 min. Secondly, at longer irradiation times, the dpp peak at −10 mV decreases and a new peak appears at −540 mV. The peak at −1370 mV remain unchanged. Once the degradation is complete (total disappearance of the peak at −10 mV and a steady peak at −540 mV) the polarogram shows two major peaks at −540 and −1370 mV. Another broad

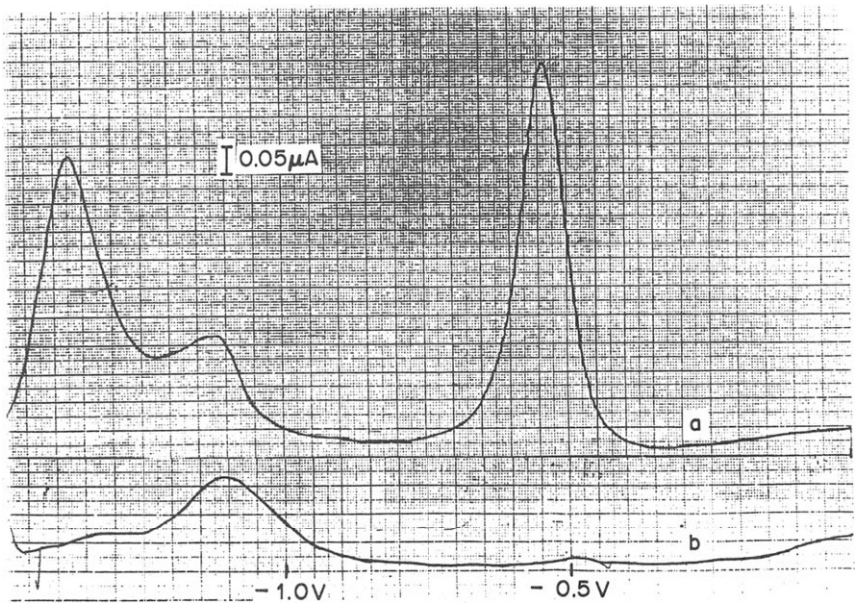

Fig. 4. Differential pulse polarograms of (a) nifedipine solution at pH 6 in ethanolic phosphate buffer (30:70 v/v) after irradiation with ultraviolet light for 24 hr, (b) ethanolic phosphate buffer (30:70 v/v), after irradiation as for (a).

peak, due to irradiation products from the ethanol, appears at −1120 mV (Fig. 4). The degradation product was obtained according to Testa *et al.*[4] and examined by NMR and infrared (Table 1). It was found to be 4-(2′-nitrophenyl)-2,6-dimethyl-3,5-dicarbomethoxypyridine (Fig. 2a) and was responsible for the peaks at −540 and −1370 mV. The reaction that accounts for the peak at −540 mV is the four-proton, four-electron reduction of the aromatic nitro group, and the peak at −1370 mV is due to reduction of the pyridine ring.

The degradation thus takes place in two consecutive steps with the "daylight product" as the intermediate. This can explain the disagreement in the literature concerning the product from ultraviolet irradiation. Jakobsen *et al.*[7] and Testa *et al.*[4] found that the nitro derivative was produced (Fig. 2a), whereas Ebel *et al.*[13] obtained only the nitroso derivative. Our study concludes that both derivatives can be obtained, depending on the duration of irradiation.

Room daylight

No degradation was observed during up to 580 min exposure to room conditions of daylight. This result is important, because it eliminates a precaution otherwise necessary in the analytical procedure.

MULTIELEMENT PRECONCENTRATION OF TRACE METALS FROM NATURAL WATERS BY SOLVENT EXTRACTION WITH AN ALKYLATED OXINE DERIVATIVE

VICTOR PAVSKI and ALFIO CORSINI*
Department of Chemistry, McMaster University, Hamilton, Ontario, Canada

SHELDON LANDSBERGER
Department of Nuclear Engineering, University of Illinois at Urbana-Champaign, Urbana, IL 61801, U.S.A.

(*Received* 17 *August* 1988. *Accepted* 20 *October* 1988)

Summary—Kelex 100, a commercially available alkylated oxine derivative, is shown to be effective, in purified form, for the simultaneous extraction of trace levels of Cd(II), Co(II), Cu(II), Mn(II), Ni(II), Pb(II), and Zn(II) from natural waters into toluene. The high lipophilicity of the extractant and its chelates affords large preconcentration factors in a single batch-extraction. Back-extraction with a small volume of nitric acid provides additional enrichment for subsequent determination of total (soluble) metal by graphite-furnace atomic-absorption spectrometry (GFAAS). Calibration with standard solutions can be used, which has advantages over the method of standard additions.

Within the last decade, numerous techniques have been developed for multielement preconcentration of trace metals from natural waters. Among the most widely applied are ion-exchange chromatography and solvent extraction.[1–6] The former generally affords larger preconcentration factors since the degree of enrichment is limited only by the volume of sample available and the volume of eluent required to strip the sorbed metal-ions from the resin. Solvent extraction procedures have been limited to practical preconcentration factors of 100 or less in a single batch-extraction,[7] owing to limited metal-chelate distribution ratios and the volume of organic phase that can readily be separated from the aqueous phase.

Extractions involving highly lipophilic chelating agents ("liquid cation-exchangers") have been extensively used in hydrometallurgy[8,9] and have been the subject of fundamental investigations,[10–12] but their application to environmental analytical chemistry has received very little attention[13] despite their high distribution ratios.

We therefore decided to investigate the potential of a proprietary alkylated derivative of oxine (8-quinolinol), 7-(4-ethyl-1-methyloctyl)-8-quinolinol (HL), the active component of the commercial product Kelex 100, as a group extractant for environmentally significant trace metals in natural waters. In addition to possessing unselective complex-forming characteristics similar to those of its parent compound, the enhanced lipophilicity of HL relative to oxine should make higher distribution ratios attainable. The efficiency of HL in toluene for extraction of nine trace metals from artificial and natural sea-water as well as natural lake-water matrices, has been studied with radioisotopes, as a function of pH. The optimized preconcentration procedure has been applied to the sea-water reference material, CASS-1.

EXPERIMENTAL

Reagents

Barnstead "NANOpure" distilled demineralized water (DDW) was used throughout. Baker Ultrex or Instra-Analyzed acids and bases were used for the adjustment of pH and the preparation of buffer solutions. To remove associated trace metal impurities, buffer solutions were passed through a Chelex 100 resin column (200–400 mesh, Bio-Rad). All other chemicals used were reagent grade. Metal-ion solutions were prepared by appropriate dilution of Fisher 1000 μg/ml atomic-absorption standard solutions.

Kelex 100 (lot number 3349–72, manufactured by the Sherex Chemical Company, Dublin, Ohio) was kindly supplied through Henley Chemicals (Scarborough, Ontario). A previous study[14] and an internal document[15] reveal that Kelex 100 contains approximately 15% of organic impurities and by-products, specifically a C_{22} alkylated oxine derivative (~3%), oxine (≤0.5%), and C_2 and C_9 alkylated furoquinolines (~12% total). The commercial product was purified from traces of oxine by washing with 1*M* hydrochloric acid.[16] The remaining organic impurities were removed by repeated fractional distillation at 134–136°/0.1 mmHg. The initial distillation removed the C_{22} alkylated oxine and some of the C_2 and C_9 alkylated furoquinolines, leaving a fraction composed of approximately 90% HL, 7% C_2 and 3% C_9 alkylated furoquinolines. A further three distillations removed most of the non-chelating furoquinoline impurities, resulting in a final product which consisted of 98% HL and 2% C_2 alkylated furoquinoline, as determined by gas chromatography. The purified Kelex 100 still contained trace-metal impurities, most of which were removed

*Author for correspondence.

by washing a solution of the extractant in toluene with 10% v/v nitric acid, then DDW, and finally four times with 0.1*M* EDTA (free from trace metals) at pH 7, the phase volume ratios being 1:1 for each step.

The artificial sea-water was 0.77*M* sodium chloride, 0.053*M* magnesium chloride and 0.010*M* calcium chloride, prepared in DDW, to simulate the salinity and major inorganic ions found in sea-water. Natural water samples consisted of a National Research Council of Canada Nearshore Sea-water Reference Material, CASS-1, a coastal sea-water sample from Sandy Cove, Nova Scotia, and an offshore fresh-water sample from Lake Ontario (Station 302, Western Basin). All samples were passed through a 0.45-μm filter to remove particulates and were acidified to pH 1.6 to minimize trace metal losses during storage.

Radiotracers were prepared by irradiation of the metal nitrates in the McMaster Nuclear Reactor.

Apparatus

Polypropylene and Teflon ware was used where appropriate. Prior to use, all laboratory ware was soaked in 10% v/v nitric acid and rinsed thoroughly with DDW.

Measurements of γ-radiation were made with an APTEC Ge(Li) coaxial detector interfaced to a Canberra Series 90 multichannel analyser. The radiotracers were analysed in the following groups: ^{60}Co, ^{65}Zn, ^{115}Cd, ^{59}Fe, ^{203}Hg, ^{110m}Ag (long-lived, $t_{1/2} \geq 20$ hr); and ^{64}Cu, ^{56}Mn, ^{65}Ni (short-lived, $t_{1/2} \leq 13$ hr). Samples were counted until a minimum of 10,000 counts (background-corrected) was obtained for each isotope. Typical counting times were 3000 sec.

Atomic-absorption measurements were made with a Perkin-Elmer Model 373 instrument equipped with an HGA-2200 graphite furnace atomizer/controller. The wavelengths, slit-widths, lamp currents and temperature programmes were those recommended in the applications manual.[17] Sample volumes (20 μl) were manually injected.

Gas chromatographic analysis of Kelex 100 distillates were made with a Varian Model 3700 gas chromatograph equipped with a flame-ionization detector and a Hewlett-Packard Series 530 μ fused-silica column (DB-1 stationary phase). A temperature programme from 100 to 300° was used.

A Fisher Accumet 520 digital pH/ion meter equipped with a Ross model 81–55 combination electrode and standardized with appropriate buffers was used for pH measurements.

A Burrell Model 75 wrist-action shaker was used for phase equilibration.

Procedures

Extraction. The radiotracers ^{60}Co, ^{115}Cd, ^{65}Zn, ^{64}Cu, ^{65}Ni, ^{56}Mn, ^{59}Fe, ^{203}Hg, and ^{110m}Ag were used to determine extraction efficiencies with HL as a function of pH. The aqueous phase was 95 ml of artificial sea-water containing the radiotracers in the groups previously noted, at concentrations of 5–50 ng/ml for each ion. The aqueous phase was adjusted to the desired pH with the appropriate buffer solution (0.6 ml), presaturated with toluene (100 μl) and then extracted with 5.0 ml of the organic phase. Initial tests employed organic phases of 0.025, 0.25 and 0.50*M* HL in toluene. Because extraction of the radiotracers was incomplete at [HL] < 0.25*M*, this concentration was employed in all subsequent extractions. Preliminary tests showed that equilibrium was achieved in 15 min of mechanical shaking. After complete clarification of the phases (2–3 hr), a 4.0-ml volume of each was counted. The degree of extraction of a metal-ion was obtained as the ratio of the counting rate found for the organic phase (corrected to 5.0 ml) to that of a 4.0-ml standard representing the activity added to the aqueous phase before extraction. For each radiotracer, the sum of the activities in the organic and aqueous phases was 100 ± 5% of the original activity in all cases. The γ-ray energies used and the concentration of each radiotracer are given in Table 1. A radioisotope of Pb could not be generated by (n, γ) reactions in the reactor and the extraction efficiencies for this metal-ion with HL were obtained by GFAAS.

Table 1. Radiotracers used and γ-rays monitored

Radiotracer	Concentration employed, *ng/ml*	γ-Ray energy, *keV*
^{115}Cd	5	527.7, 492.5
^{60}Co	5	1173.1, 1332.4
^{65}Zn	5	1115.4
^{59}Fe	20	1098.6, 1291.5
^{203}Hg	20	279.1
^{110m}Ag	5	657.8
^{64}Cu	5	511.0, 1345.5
^{56}Mn	5	846.9
^{65}Ni	50	1481.7, 1115.4

Stripping. After extraction of the aqueous phase containing the radiotracers, a 4.0-ml portion of the organic phase was stripped with 2.0 ml of a number of aqueous acids, including those listed in Table 3. The phases were shaken for 15 min. After clarification of the phases (which took 1 hr), 1.0 ml of each was counted and the degree of back-extraction was determined as above (lead by GFAAS).

Effect of phase ratio. The volume ratio of artificial sea-water to organic phase was varied to determine the practical preconcentration factors attainable. The aqueous phase (100, 250 or 500 ml) containing the radiotracers was buffered to pH 9.3 (the optimal pH) with 4*M* ammonia/0.4*M* ammonium acetate, presaturated with toluene, and extracted as above with 1.0 ml of 0.25*M* HL in toluene. After clarification, a suitable volume of each phase was counted to determine the extraction efficiency.

Recovery of radiotracer spikes from natural waters. Coastal sea-water and a Lake Ontario water sample (95 ml each) were spiked with radiotracers, buffered to pH 9.3, equilibrated for at least 2 hr, presaturated with toluene and extracted with 5.0 ml of 0.25*M* HL in toluene. Extraction efficiencies were obtained as before.

Application to CASS-1 sea-water by GFAAS. The aqueous phase (95 ml) was adjusted to pH 9.3, presaturated, and extracted with 5.0 ml of 0.25*M* HL in toluene. A 4.0-ml portion of the organic phase was stripped with 2.0 ml of 16% v/v nitric acid, a portion of which was stored in 1.5-ml capped polypropylene tubes until ready for measurement by GFAAS. Calibration was done with standard metal-ion solutions made up in 16% v/v nitric acid. Blanks were run by applying the whole procedure to DDW.

RESULTS AND DISCUSSION

Up to 1976, the active component in Kelex 100 was 7-(1-ethenyl-3,3,5,5-tetramethylhexyl)-8-quinolinol and various studies based on this (purified) component have been reported.[11,13,18,19] Of particular interest is the report of Isshiki *et al.*[13] in which XAD-4 resin was impregnated with the compound for use in the extraction/preconcentration of trace metals from sea-water. After a change in the manufacturing process in 1976, the active agent in Kelex 100 was identified[14,15] as 7-(4-ethyl-1-methyloctyl)-8-quinolinol (HL) and no applications of the purified component to the preconcentration of trace metals in natural waters have been reported, although the compound has been adsorbed on XAD-7 resin for the

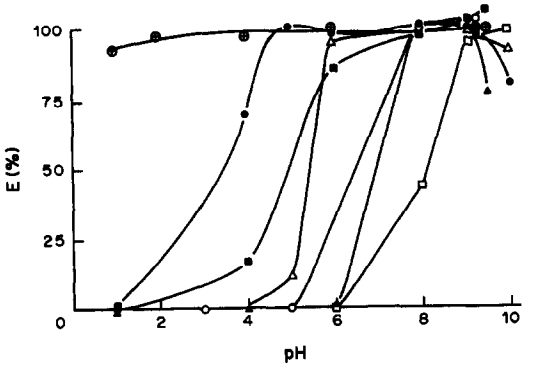

Fig. 1. Efficiencies for extraction of ^{64}Cu (⊕), ^{60}Co (●), ^{65}Ni (■), ^{65}Zn (△), Pb (○), ^{56}Mn (▲), and ^{115}Cd (□) with 0.25*M* HL in toluene, as a function of pH.

recovery of Ga(III) from aqueous solution.[20] For analytical studies, the present-day Kelex 100, like its predecessor, requires considerable purification. This was accomplished by the procedure described above. A purification procedure[20] involving precipitation of the Pb(II) complex of HL was avoided because the removal of trace metal-ion contaminants from HL is tedious and difficult. Even with stripping of toluene solutions of HL with 10% v/v nitric acid, DDW, and 0.1*M* EDTA (see above), the level of Cu(II) contamination was still sufficient to give appreciable blank values (30% of the sample absorbance signal) in the determination of Cu(II) in sea-water by GFAAS, although the blank levels for the other trace metals were low ($\leqslant 10\%$ of the final signal).

Extraction efficiencies and preconcentration factors

The efficiencies for extraction of the radiotracers with 0.25*M* HL in toluene as a function of pH are given in Figs. 1 and 2. Nearly quantitative extraction of ^{115}Cd, ^{64}Cu, ^{65}Ni, ^{56}Mn, ^{65}Zn and ^{60}Co from artificial sea-water was achieved over the pH range 9.0–9.5. Pb, determined by AAS, was also extracted quantitatively in this pH range. For subsequent extraction work, the pH was set to 9.3. Of the nine radiotracers tested, only ^{110m}Ag, ^{59}Fe, and ^{203}Hg were not extracted quantitatively at the desired pH. Extraction of ^{110m}Ag was not observed at any pH, owing to the large concentration of chloride in the artificial sea-water matrix and consequent formation of silver

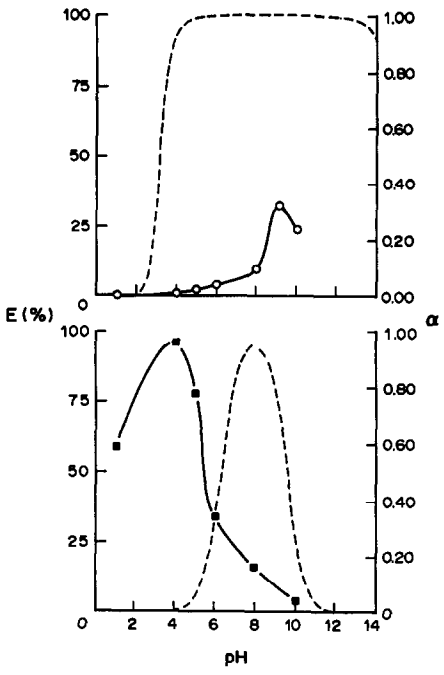

Fig. 2. Efficiencies for extraction of ^{203}Hg (○) and ^{59}Fe (■) with 0.25*M* HL in toluene, and fraction (α) of uncharged hydroxides (---), as a function of pH.

chloride complexes. The incomplete extraction of ^{59}Fe and ^{203}Hg at pH 9.3 can be ascribed to hydrolysis of the metal-ions; specifically, to formation of the uncharged insoluble hydroxides. Figure 2 shows the per cent extraction and the fraction (α) of these ions present as uncharged hydroxide,[21] as a function of pH. The formation of chloride complexes in the saline aqueous phase also cannot be ruled out. Chiang[22] reported a similar decrease in the distribution ratio of Fe(III) adsorbed on XAD-7, at $pH \geqslant 5$, and the incomplete extraction of Hg(II) with 0.1*M* oxine in chloroform at $pH \geqslant 3$ was observed by Starý.[23]

The values of per cent extraction (%E) for the six extractable radiotracers from artificial sea-water (95 ml) at pH 9.3 and $V_{aq}/V_o = 19$ are given in Table 2. Because the extractions at this phase volume ratio are quantitative within experimental error, the efficiencies for single batch-extraction were also de-

^{60}Co	98 ± 3	97 ± 3	96 ± 5	91 ± 4	(5.0 ± 0.3) × 10^3

*Mean ± standard deviation of 3–5 determinations; ionic strength of artificial sea-water = 0.96*M*.
†Calculated for $V_{aq}/V_o = 500$.

termined at phase ratios of 100, 250 and 500, with $V_o = 1.0$ ml. In all cases, the extraction efficiencies are greater than 90% and are, in fact, essentially quantitative for phase ratios of 100 and 250.

The enrichment or preconcentration factor, F, in solvent extraction has been defined[24] as

$$F = (\%E)V_{aq}/100\,V_o$$

When the extraction is essentially quantitative, $F \approx V_{aq}/V_o$. In Table 2, the lowest extraction efficiency (91%) represents a 455-fold enrichment for the extraction into toluene. GFAAS measurement of an aliquot of the organic phase (*e.g.*, 20 μl) is readily accomplished, if desired, although even with background correction, direct measurement of the laden organic phase may present a problem. A practical consideration that may limit use of the higher range of preconcentration factors reported in this work is the consumption of large volumes of water samples, particularly if the organic phase is directly analysed.

Therefore, to deal with these problems and simplify the final matrix for GFAAS measurement, a procedure for back-extraction into an acidic aqueous phase was developed. Back-extraction of 4.0 ml of the 5.0-ml organic phase with 2.0 ml of 16% v/v nitric acid afforded an additional enrichment factor of 2 as well as quantitative recovery of all the radiotracers with the exception of ^{60}Co (Table 3). The incomplete stripping of cobalt after extraction of Co(II) with 7-(1-ethenyl-3,3,5,5-tetramethylhexyl)-8-quinolinol has also been reported[16,25,26] and has been ascribed to rapid oxidation of Co(II) at the phase interface, resulting in the formation of the stable and non-labile Co(III)-chelate.[25,26] The Cu(II) complex of HL is also very stable (as evidenced by its quantitative extraction into toluene at pH 1, Fig. 1) and is not quantitatively decomposed and stripped by the more dilute acids listed in Table 3. Pb(II), determined by AAS, was found to be quantitatively stripped by 16% v/v nitric acid.

The benefits of incorporating a back-extraction step in the overall preconcentration procedure outweigh the inconvenience of the additional manipulation and the small attendant risk of contamination.[4] First, an additional two-fold enrichment is obtained, permitting high overall preconcentration factors to be attained with relatively small sample volumes (*e.g.*, 95 ml), thus conserving the supply of sample. Secondly, the aqueous matrix thus obtained is easily matched, which is one of the requisite conditions for use of calibration with standard solutions in place of the more tedious and sample-consuming method of standard additions.[1]

^{60}Co	2.1 ± 0.5	2.3 ± 0.4	4.8 ± 0.6

*Mean ± standard deviation of 3–5 determinations; $V_o/V_{aq} = 2$.

The high values of $\%E$ obtained even at $V_{aq}/V_o = 500$ are quite extraordinary (Table 2). Brooks *et al.*[5] have illustrated graphically the relationship between $\%E$ and V_{aq}/V_o for various values of D_C, the distribution ratio of the extracted chelate species. For example, to achieve 90%E at $V_{aq}/V_o = 500$, D_C must be 4.5×10^3, an unusually high value. In Table 2, the calculated values for D_C range from 1.62×10^4 for the extraction of Cd(II) to 5.0×10^3 for Co(II), at $V_{aq}/V_o = 500$. It can be assumed that the extraction of bivalent metal-ions (M) by HL can be described by the fundamental equation

$$D_C = \frac{\beta_2 K_{ML_2} K_a^2 [HL]_o^2}{K_{HL}^2 [H^+]^2}$$

where β_2 is the stability constant of ML_2, K_{ML_2} and K_{HL} are the distribution constants of the chelate and reagent respectively, and K_a is the dissociation constant of HL.[27,28] Bag and Freiser[11] have used this equation to characterize the extraction of Cu(II) into chloroform with 7-(1-ethenyl-3,3,5,5-tetramethylhexyl)-8-quinolinol, and estimated a value of $10^{9.5}$ for the chelate distribution constant, K_{ML_2}. This is in fair agreement with the value of $10^{10.3}$ which they calculated on the basis of the linear free energy correlation proposed by Hansch and Leo.[29] In view of the structural similarity of HL to the ethenyl derivative, it is reasonable to expect similarly high values of K_{ML_2} for the HL chelates and, therefore, enhanced D_C values. High K_{ML_2} and D_C values are to be expected from the fact that HL and its ethenyl derivative are highly lipophilic and so it is likely that their metal chelates are also.

Recovery of radiotracer spikes from natural water samples

Data for the recovery of radiotracer spikes from natural waters are provided in Table 4. With the exception of ^{60}Co, for which the recovery is nearly 90%, the data show that the spikes are quantitatively recovered. In general, in dealing with spiked natural water samples, it is difficult to state with certainty that the spikes have equilibrated with the analyte metal-ions in the sample. In the present work, the samples had been passed through 0.45-μm filters to remove particulate matter, but colloidal species may still have been present, with which the spikes would have to equilibrate, even at the storage pH of 1.6. With regard to organic complexes, however, previous work[1] has shown that at pH 1–2, organic complexes such as humates are dissociated. Thus, as the spikes are added before the pH is raised to 9.3, it is reasonable to assume that the spikes and the analytes behave in exactly the same way towards organic

Table 4. Extraction of radiotracers from natural waters at pH 9.3 with 0.25*M* HL in toluene*

complexing components in the matrix. If so, then the data in Table 4 suggest that HL is an effective extractant for metal-ions in free and variously bound forms in both sea-water and freshwaters.

Application to analysis of sea-water (CASS-1) by GFAAS

The optimized extraction and stripping procedure was applied to the determination of five trace metals in the sea-water reference material, CASS-1, by GFAAS and calibration with matrix-matched standard metal-ion solutions, on the assumption that the recovery of the analytes is quantitative. The results for the determination of total (soluble) metal in CASS-1 are given in Table 5.

In general, the experimental data are in reasonable agreement with the reference values within the limits of experimental error. Cobalt and zinc were excluded from the group of metals determined by GFAAS, cobalt because it could not be quantitatively stripped from the organic phase, and zinc because of atmospheric contamination which resulted in irreproducible analytical blank values for this element. Considering the low concentrations dealt with, the results are certainly satisfactory and suggest that the extraction efficiencies of HL for metal-ions in natural sea-water are very similar to those obtained for artificial sea-water spiked with radiotracers.

Finally, impregnation of macroporous resins such as XAD-4 and XAD-7 with HL for column preconcentration of trace metals could provide an alternative to solvent extraction. Indeed, Isshiki *et al.*[13] described such a method based on the ethenyl derivative of HL immobilized on XAD-4. The procedure involved loading the column with the metal-ions, stripping them, evaporation of the effluent, and mineralization of the organic residue before GFAAS analysis. It offers no advantages in time or simplicity over the solvent extraction procedure outlined in this work and, furthermore, is complicated by the fact that resins such as XAD-4 and XAD-7 have low but significant cation-exchange capacity due to the presence of impurity sites.[1,30]

CONCLUSIONS

Purified Kelex 100 is a useful group extractant for Cd, Co, Cu, Mn, Ni, Pb, and Zn from natural waters, and large preconcentration factors are possible. All these metal-ions except cobalt can be quantitatively back-extracted into aqueous acid and readily determined by GFAAS, with use of easily matrix-matched calibration standards; high atmospheric background levels of Zn may preclude its determination, however.

(*Received* 28 *June* 1988. *Accepted* 20 *October* 1988)

Summary—Conventional reversed-phase HPLC conditions have been optimized for resolution of a mixture containing prostaglandins PGE_1, PGE_2, $PGF_{1\alpha}$ and $PGF_{2\alpha}$. Electroactive derivative-forming reagents, such as *p*-nitrobenzyloxyamine, 2-bromo-2′-nitroacetophenone, and 2,4-dinitrophenylhydrazine have been evaluated for use as precolumn reagents for forming prostaglandin derivatives. The results indicate that detection limits of 120 pg are achievable with amperometric detection. The utility of the procedures developed is illustrated by the detection of prostaglandins in human urine and plasma.

Prostaglandins are derivatives of arachidonic acid. They function as "local hormones", allowing communication between cells by modifying the plasma membrane responses.[1] Prostaglandins are found in almost all mammalian cells and tissues and are among the most potent physiologically active substances known.[2] The determination of prostaglandins in different biological matrices has been the subject of intense research in both the medical and pharmaceutical fields.[3,4] A number of analytical methods, such as bioassay,[5–7] radioimmunoassay (RIA),[8–10] and gas chromatography–mass spectrometry (GC–MS),[11–13] have been successfully used for the determination of prostaglandins. High-performance liquid chromatographic (HPLC) methods using ultraviolet absorption and fluorescence detection for prostaglandin derivatives have been reported.[14–17] The HPLC methods utilizing ultraviolet detection were found to be relatively insensitive, whereas fluorescence detection yielded excellent sensitivity for endogenous prostaglandins in biological materials.[15–17]

The sensitivity and selectivity of the electrochemical detector for detection of electroactive analytes in complex matrices is well documented.[18–20] The present study is an evaluation of the use of nitroaromatic compounds for the derivatization of prostaglandins. Various papers have described the use of nitroaromatics in precolumn derivatization methods.[21–24] In addition, the use of nitroaromatics as derivative-forming reagents for electrochemical detection has been extensively discussed by Jacobs.[25] We have applied this technique to the detection of prostaglandins in biological matrices, and have evaluated the use of nitroaromatic derivatization reagents such as 2-bromo-2′-nitroacetophenone (NPA), 2,4-dinitrophenylhydrazine (DNPH), and *p*-nitrobenzyloxyamine hydrochloride (PNBA) for electrochemical detection of prostaglandins in biological matrices.

EXPERIMENTAL

Apparatus

The high-performance liquid chromatograph used was fitted with a model M6000 dual-piston pump (Waters Assoc., Milford, MA.) and a model 70-10 injection valve equipped with a 50-μl injection loop (Rheodyne Inc., Berkeley, CA). Equipment used for detection included a model 5100A amperometric/coulometric controller with an amperometric glassy-carbon electrode wall-jet cell (ESA, Inc. Bedford, MA), and a model 440 fixed wavelength ultraviolet detector (Waters Assoc., Milford, MA). A mainframe integrator system was used to integrate the output of the ESA amperometric controller and the model 440 detector simultaneously. Modifications of the chromatography system described by Jacobs[25] were used to ensure the removal of oxygen from the system. This included the use of helium to deaerate the mobile phase thoroughly, and the use of stainless-steel tubing throughout the entire system to prevent oxygen from re-entering by diffusion through tubing walls.

Reagents

Prostaglandins PGE_1, PGE_2, $PGF_{1\alpha}$ and $PGF_{2\alpha}$ were purchased from Sigma (St. Louis, MO). *p*-Nitrobenzyloxyamine hydrochloride and pyridine (Regis Chemical, Morton Grove, IL), 2-bromo-2′-nitroacetophenone, *N*,*N*-di-isopropylethylamine, sodium acetate, cyclopentanone, hexanoic acid, cyclopentanol, *N*-methyl-*N*-nitroso-*p*-toluenesulphonamide and trichloroacetic acid (Aldrich, Milwaukee, WI), and dry 2,4-dinitrophenylhydrazine, (Eastman, Rochester, NY), were used as received. Other chemicals used were the best grade commercially available.

Procedures

Derivatization. 2-Bromo-2′-nitroacetophenone (NPA) prostaglandin esters were prepared by the method of Zoutendam *et al.*[26] for derivatization with the similar reagent 2-bromo-4′-nitroacetophenone. The oximes formed by *p*-nitrobenzyloxyamine hydrochloride (PNBA) with prostaglandins and the internal standard (cyclopentanone) was made according to Fitzpatrick *et al.*[27] Before hydrazone formation with 2,4-dinitrophenylhydrazine (DNPH) the carboxyl group of the prostaglandins was esterified. Prostaglandin methyl esters were made by reaction with excess of ethereal diazomethane solution for 5 min. The surplus reagent was evaporated under a stream of nitrogen, and the prostaglandin methyl esters were then converted into the hydrazones according to Treiber and Oertel.[28]

Extraction. Prostaglandins were extracted from human plasma by a modification of the method of Krakauer and Williamson.[29] A sample of 0.5 ml of plasma and internal standard (hexanoic acid or prostaglandin E_2) was mixed with 0.5 ml of 0.1*M* dipotassium hydrogen phosphate and loaded onto a Waters C-18 Sep-Pak cartridge. Two ml of dimineralized water were passed through the column and discarded. The prostaglandins and internal standard were then eluted from the cartridge with 1.0 ml of acetonitrile. Prostaglandins were extracted from human urine by a modification of the method of Yamada *et al.*[17] Human urine was collected during the morning (7–10 a.m.) from normal adult human volunteers, and immediately stored in dry-ice until analysis. Prior to analysis, the urine sample was warmed to room temperature. A 10-ml volume of sample was placed in a 25-ml sample tube and the internal standard was added. The pH of the solution was adjusted to 4 with formic acid, and the mixture was extracted with 5 ml of ethyl acetate. The extract was applied to a 500-mg silica solid phase extraction column (J.T. Baker Chemical Co., Phillipsburg, NJ). The prostaglandins and internal standard were eluted with 3 ml of ethyl acetate, and the eluate was evaporated to dryness under a stream of nitrogen at room temperature.

RESULTS AND DISCUSSION

Characterization of prostaglandin derivatives

Prostaglandin structures are shown in Fig. 1. Prostaglandin carboxyl[14,30] and carbonyl[17,27] functional groups have been derivatized prior to HPLC analysis. The derivative-forming reagents used in the present study are also shown in Fig. 1. Nitroaromatic deriva-

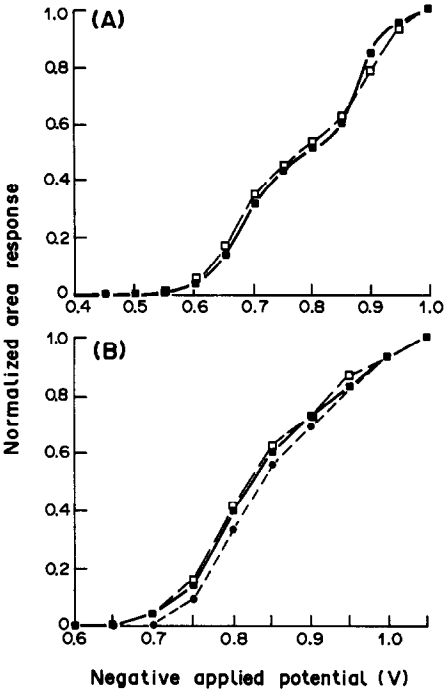

Fig. 2. Hydrodynamic voltamperograms of (A) DNPH and (B) NPA derivatives: (■) PGE_2, (□) PGE_1, (●) hexanoic acid.

tives of prostaglandins, made with these reagents, were first investigated for applicability in electrochemical detection. Hydrodynamic voltamperograms for derivatives of DNPH and NPA are shown in Fig. 2. The plots indicate that potentials more negative than −0.90 V would be suitable.

Prostaglandin concentrations found in biological samples have been reported to vary widely.[9,17,31,32] A study of the electrochemical detector response over the concentration range typically found in urine (2–20 pmole/ml) was implemented. The amount of derivatized prostaglandin, made by the procedures described, was varied. Calibration data and detection limits for these derivatives are listed in Table 1. The regression data were found to be relatively invariant for the derivatives of the different prostaglandins with a given reagent. The detection limits with PNBA were 4–5 times those with NPA. The difference was due to impurities from the reaction mixture that interfere with the amperometric detector. Pyridine is eluted slowly from the analytical column and produces a signal at the amperometric detector. In general, the detection limits achieved were comparable to those obtained with other HPLC derivatization methods.[14,15,17]

(B) HPLC–UV; detection, 254 nm.

Application of derivatization procedures to urine and plasma

Extraction procedures were evaluated for removal of biological interferences and recovery of prostaglandins before derivatization. Recovery of 3 μg of prostaglandin PGE_1 from 1 ml of human plasma was found to be 90–93%, in the described plasma extraction and DNPH derivatization procedures. A chromatogram of the prostaglandins extracted from plasma is shown in Fig. 3.

Human urine contains measurable amounts of prostaglandins which could interfere with the evaluation of the extraction procedure. Therefore a 10-fold dilution of urine with HPLC-grade water was used as the matrix for evaluation. Samples of this diluted urine were doped by addition of all four types of prostaglandins (2 nmole/ml). A chromatogram of the extracted prostaglandins derivatized with NPA is shown in Fig. 4, for both amperometric and ultraviolet detection. Lack of specificity precluded the use of DNPH for determination of urinary prostaglandins. Recoveries of the prostaglandins were variable, ranging from 60 to 84%. The differences in the recoveries may be due to differences in polarity. The PGF prostaglandin series is more polar than the PGE series and is not extracted with the same efficiency. The recoveries obtained are comparable to those reported previously.[32,34,35]

PNBA method			2.2 ± 0.4	ND

[b]PNBA method not suitable.

Endogenous urinary prostaglandins

Urine samples from two subjects were collected, extracted and derivatized with NPA and PNBA to compare the results achieved with these two reagents. The extracted urinary prostaglandins were quantified by an internal standard method with height-ratio measurements. In addition, because of the degree of variability of prostaglandin recovery with this method, samples derivatized with NPA were also quantified by a standard-addition method. For the standard-addition experiments, another set of urine samples was prepared as before, except that 50 pmoles of each prostaglandin were added to an aliquot of extract. Table 2 lists the endogenous levels of prostaglandins found in the urine samples by both methods. The levels obtained by the two methods of quantification were similar. The endogenous levels

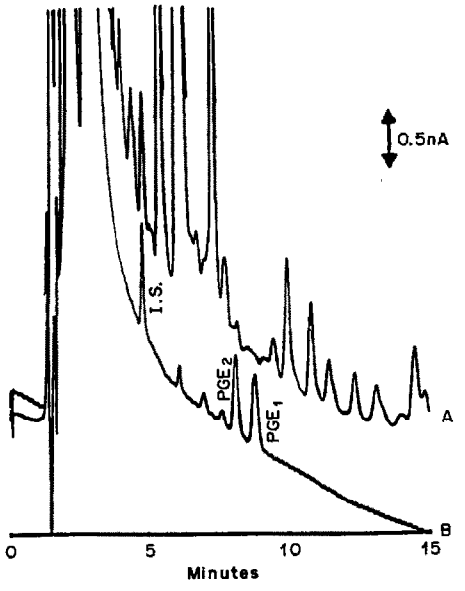

Fig. 5. Chromatograms of urinary prostaglandins derivatized with PNBA. found for prostaglandin PGE_1 and PGE_2 in these samples by derivatization with PNBA are also shown in Table 2. The levels of prostaglandins PGE_1 and PGE_2 found by both derivative procedures were in close agreement. Chromatograms of the urinary prostaglandin PNBA derivatives are shown in Fig. 5.

CONCLUSIONS

This work indicates that precolumn derivatization with electroactive reagents is a viable approach for trace prostaglandin determination. The use of different derivatizing reagents allows for choice of the electroactive moiety to be introduced and can be used to differentiate the classes of prostaglandins by their functional groups. The techniques have been shown to be sufficiently sensitive to detect endogenous levels of urinary prostaglandins.

NON-AQUEOUS TITRATION OF A FULVIC ACID SAMPLE, WITH USE OF AN INTERNAL REFERENCE COMPOUND

JAMES H. EPHRAIM
Institute of Theme Research, Department of Water and Environmental Studies, Linkoping University, S-581 83 Linkoping, Sweden

(*Received* 12 *May* 1988. *Revised* 20 *September* 1988. *Accepted* 18 *October* 1988)

Summary—The use of an internal reference compound in non-aqueous acid–base titrations as a relatively simple, reliable and accurate means of obtaining information on the acidity spectrum of natural organic acids is reported. Acid–base titrations in dimethylformamide, DMF, with tetrabutylammonium hydroxide as the titrant and *p*-hydroxybenzoic acid as an internal reference compound have been performed to determine the carboxylic acid and the acidic hydroxyl components of a fulvic acid sample isolated from surface water in the Bersbo area, south-east of Sweden. A carboxylic acid capacity of 4.78 ± 0.05 meq/g and an acidic hydroxyl group capacity of 1.35 ± 0.03 meq/g were found for the aquatic fulvic acid.

In studies with humic substances, the only fact of consensus is the heterogeneity of the substances. Gamble[1] tackled the problem by introducing an equilibrium function which was a weighted average, and Perdue and co-workers[2,3] considered humic materials as a continuum of acids with overlapping dissociation constants. The review by Flaig *et al.*[4] shows that from as few as one to as many as four types of acid can exist in humic substances. Paxeus[5] described the acidic properties of eight aquatic humic substances and one soil fulvic acid, in the pH range 2.4–10.0, by using a six-group model, and Ephraim *et al.*[6] used a four-group model to describe the acidic behaviour of an Armadale soil fulvic acid.

Acid–base titrations in non-aqueous medium have been employed by earlier workers[7] in an attempt to distinguish between different acid groups in humic substances, but such attempts yielded negative results. In their titrations of humic and fulvic acid preparations from the A_0 and Bh horizons of a Spodosol with sodium aminoethoxide, in pyridine, dimethylformamide and ethylenediamine as media, Wright and Schnitzer[7] observed a single inflection corresponding to the total –COOH and phenolic –OH content of their sample.

Recently,[8] non-aqueous titrations in dimethylformamide and dimethylsulphoxide have been employed in an attempt to gain insight into the acidic spectrum of a fulvic acid sample. The use of potassium hydroxide as a titrant is reported to be promising, despite the formation of a slight precipitate in DMF.

Over the past few years,[9–11] internal reference compounds have been employed in non-aqueous titrations with promising results. Non-aqueous titrations with internal reference compounds were first performed by Nakajima and Tanobe.[9] They added benzoic acid and phenol to bitumen to resolve the inflections and to group the acids into weak and very weak categories. Yonebayashi and Hattori[10] used non-aqueous titrations with benzoic acid and phenol as internal standards to determine acidic functions in humic acid samples. Pobiner[11] has similarly employed internal reference standards in non-aqueous titrations to quantify two different acidic functions in lignin samples.

This communication is intended to support the case for the use of internal reference compounds in non-aqueous titrations when information on the acidic spectrum of natural organic acids is being sought. Use of *p*-hydroxybenzoic acid as an internal reference compound in non-aqueous titrations of monomeric acids and of fulvic acid samples is reported.

EXPERIMENTAL

Reagents

Bersbo fulvic acid, BFA, was extracted from Bersbo river near Linkoping, Sweden by a combination of the methods of Thurman and Malcolm,[12] and Paxeus.[5] A detailed description of the method is given elsewhere.[13] Tetrabutylammonium hydroxide, tetraethylammonium chloride, 2-propanol, *p*-hydroxybenzoic acid, benzoic acid, and *N*,*N*-dimethylformamide were obtained from Kebo Laboratories AB and used without further purification.

Apparatus

A Radiometer pHM84 research pH-meter and ABU 80 autoburette were employed in conjunction with a Radiometer G2040C glass electrode and K401 calomel electrode which had been modified by replacing the internal reference solution of saturated potassium chloride with 1.0*M* tetraethylammonium chloride, to eliminate diffusion of potassium ions into the solution. When not in use, the modified calomel electrode was stored in 1.0*M* tetraethylammonium chloride, and the glass electrode in 0.10*M* hydrochloric acid.

Procedure

Approximately 0.05*M* tetrabutylammonium hydroxide, TBAH, was prepared in 2-propanol under a blanket of

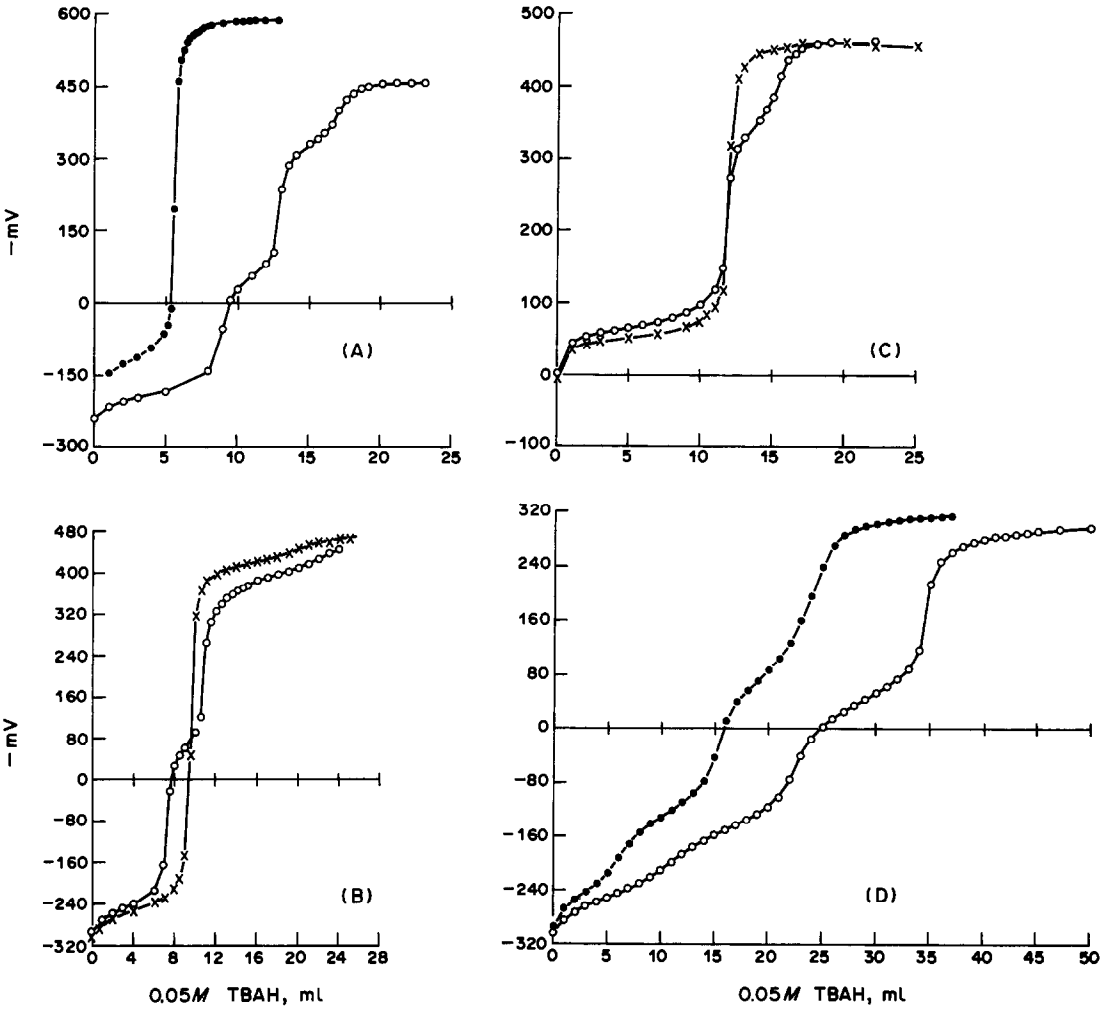

Fig. 1. (A) Non-aqueous titrations of salicylic acid in the presence and absence of *p*HBA: ● 31.7 mg of salicylic acid; ○ 54.7 mg of salicylic acid + 18 mg of pHBA. (B) Non-aqueous titrations of phthalic acid in the presence and absence of *p*HBA: × 66.8 mg of phthalic acid; ○ 54.7 mg of phthalic acid + 18 mg of *p*HBA. (C) Non-aqueous titrations of anthranilic acid in the presence and absence of *p*HBA: × 67.5 mg of anthranilic acid; ○ 48.6 mg of anthranilic acid + 18 mg of *p*HBA. (D) Non-aqueous titrations of citric acid in the presence and absence of *p*HBA: ○ 121.2 mg of citric acid; ● 69.5 mg of citric acid + 18 mg of *p*HBA.

nitrogen and stored in the refrigerator when not in use. The TBAH solution was standardized against benzoic acid dissolved in *N,N*-dimethylformamide, DMF. The standard solution of TBAH was then used to obtain a calibration (standardization) curve for *p*-hydroxybenzoic acid, *p*HBA. The already titrated *p*HBA solution in DMF was then added quantitatively to an aliquot of the fulvic acid solution and the mixture was titrated with the standard TBAH solution.

For the mixture of fulvic acid and *p*HBA, the titrant volumes corresponding to the two inflection points permitted computation of the separate contributions of the two major acid components in the fulvic acid.[11] Similar experimental runs were performed with monomeric acids (salicylic, phthalic, citric and anthranilic) instead of fulvic acid.

Potentiometric measurements were made with the same precautions as for measurements in aqueous media.[14]

RESULTS AND DISCUSSION

The capability of the non-aqueous technique to determine quantitatively acidic functions with different dissociation constants was investigated by using monomeric acids, *e.g.*, salicylic, phthalic, anthranilic and citric. These monomeric acids, with pK_a values ranging from 2.10 to 13.34, were believed to resemble the acidic functions present in the fulvic acid molecule. The non-aqueous titration curves for the monomeric acids are shown in Fig. 1.

For the salicylic acid system, Fig. 1A, only the carboxylic acid group ($pK_a = 2.99$) was observable in the potentiometric titration of the acid alone. The phenolic group ($pK_a = 13.4$) was not observed. When *p*HBA was added to the system, three inflection points were observed. The first corresponded stoichiometrically to the carboxylic group of the salicylic acid while the second corresponded to the carboxylic acid of the *p*HBA ($pK_a = 4.57$). The third inflection point corresponded to the phenolic OH of the *p*HBA.

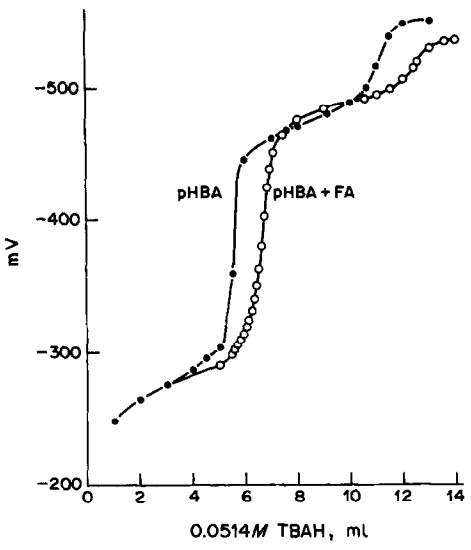

Fig. 2. Non-aqueous titrations of *p*HBA in the presence and absence of Bersbo fulvic acid: ● 38.53 mg of *p*HBA; ○ 38.53 mg of *p*HBA + 13.3 mg of Bersbo FA.

For the phthalic acid system, Fig. 1B, two inflection points were observed in the titration curve when no *p*HBA was present. The first corresponded to the carboxylic acid group with pK_a 2.95 while the second, not easily discernible, corresponded to the carboxylic acid group with pK_a 5.41. In the presence of *p*HBA, three inflection points were obtained. The first corresponded to the first carboxylic acid group of the phthalic acid, the second was due to the carboxylic acid group of the *p*HBA (pK_a = 4.57) while the third inflection represented the combination of the second carboxylic acid group (pK_a = 5.41) of the phthalic acid and the phenolic OH group (pK_a = 9.46) of the *p*HBA.

Figure 1C shows the non-aqueous titration curves of anthranilic acid in the absence and presence of *p*HBA. In the case of anthranilic acid alone, only one inflection point was detected, while for the mixture of anthranilic acid and *p*HBA, two inflection points were observed. The first inflection point corresponded to the combined acid capacity contributed by the carboxylic acid groups of anthranilic acid and *p*HBA, while the second inflection point corresponded to the phenolic OH group of the *p*HBA.

Non-aqueous titration of citric acid alone, Fig. 1D, yielded three inflection points corresponding to the three acid groups present in citric acid (*p*K 3.13, 4.76 and 6.39). In the presence of *p*HBA, three inflection points were again observed, at the same potential values as before. The inflection characteristics of the *p*HBA had completely merged with those of the citric acid molecule. This observation is believed to be a consequence of intermolecular hydrogen bonding between citric acid and *p*HBA.

The analytical recovery of the monomeric acids in the non-aqueous titrations of 30–120 mg of the acid plus 18 mg of *p*-hydroxybenzoic acid, ranged from 99.3 to 100.4%.

Figure 2 shows typical titration curves for *p*HBA alone and *p*HBA with FA present. The inflection points of the two systems (*p*HBA with and without FA) lie within the same mV range, thus corroborating the assertion[14] that no molecular interaction takes place between the two molecular species and that the acidic functions present in both molecules have similar characteristics.

In Table 1, the results of functional group analysis of Bersbo FA with *p*HBA as internal reference compound are presented. These results show a carboxylic acid capacity of 4.78 ± 0.05 meq/g and an –OH capacity of 1.35 ± 0.07 meq/g of FA. The acid capacity of Bersbo FA determined in aqueous medium is 4.65 ± 0.15 meq/g. This makes the total non-aqueous acid capacity of 6.13 meq/g greater than the total detectable aqueous acid capacity by 1.48 meq/g. This difference may be explained by the probable existence in Bersbo FA of hydroxyl or very weak carboxylic acid/phenolic groups with pK_a values greater than 6.0 but lower than 10.0. This pK_a distribution explains why such acidic functions would be detectable by titration in non-aqueous medium but not in aqueous medium. Results obtained with Armadale FA[6] show that the total acidity detectable in aqueous medium is only 7% less than the total acidity

†After subtraction of *p*HBA contribution.

detected in non-aqueous medium. It may therefore be inferred that the Bersbo FA has a larger hydroxyl group component than Armadale FA has. The total acidities observed in non-aqueous medium for both FA samples are close to each other, differing by only 2%.

The resolution of –COOH and –OH functions by the use of an internal reference compound in non-aqueous titrations offers the capability of gaining insight into the heterogeneity of humic substances. This experimental technique also offers a simple means of comparing humic substances from different sources.

ETUDE DU POUVOIR OXYDANT DU PENTOXYDE DE VANADIUM EN MILIEU NON AQUEUX

APPLICATION A L'OXYDATION DE MOLECULES ORGANIQUES OXYGENEES MONOFONCTIONELLES

D. PRADEAU* et M. HAMON

Résumé—L'oxydation par le pentoxyde de vanadium en milieu sulfurique aqueux présente certaines limites, principalement en raison de l'instabilité des complexes sulfovanadiques dans l'eau. C'est la raison pour laquelle les auteurs ont étudié la possibilité de préparer des solutions dans des solvants moins dissociants que l'eau, susceptibles de favoriser la stabilité des complexes sulfovanadiques et donc de renforcer le pouvoir oxydant. L'étude porte sur des molécules oxygénées simples dont certaines ont fait l'objet de travaux en milieu aqueux sulfurique en particulier les alcools, aldéhydes, cétones et acides. Certaines autres molécules (acétals ou esters), qui étaient difficiles à étudier en milieu aqueux en raison de leur nature hydrophobe, ont elles aussi été soumises à l'oxydation. Les résultats montrent que les alcools sont plus résistants en milieu anhydre qu'en milieu aqueux. Cependant, l'allongement de la chaîne facilite l'oxydation. En ce qui concerne les dérivés carbonylés, comme en milieu aqueux, les aldéhydes réagissent plus difficilement que les cétones. Cependant, ils s'oxydent plus intensément que les alcools correspondants. Par ailleurs, l'étude a permis d'étendre le domaine de l'oxydation vanadique à des substances insolubles dans l'eau, comme les étheroxydes (oxyde d'éthyle) dont la réactivité n'est pas négligeable. Les acides, quant à eux, ne réagissent que très faiblement.

Summary—Oxidation with vanadium pentoxide in aqueous sulphuric acid has certain limitations, mainly because of the instability of vanadosulphate complexes in aqueous media. Hence the possibility of use of less strongly dissociative solvents than water has been examined with a view to enhancing the stability and oxidizing power of these complexes. Some simple organic oxygen compounds (alcohols, aldehydes, ketones and acids) have been examined as reductants, together with some others (acetals and esters) which are difficult to study in aqueous media because of the hydrophobic character. The results show that alcohols are more resistant to attack in non-aqueous medium than in water, and that the longer-chain alcohols are more easily oxidized. The aldehydes are more difficult to oxidize than ketones, as is also the case in water. The acids, also as in water, react only very feebly. The use of non-aqueous media extends the range of oxidation with vanadate to some substances insoluble in water (such as epoxides) which display sufficient reactivity.

L'oxydation vanadique en milieu sulfurique aqueux de molécules oxygénées a été largement étudiée notamment par l'équipe de Guernet et Malangeau[1] pour des acides-alcools, des acides cétoniques et des sucres, par Dauphin[2] dans le cas des polyoxyéthylèneglycols et par Hila[3] pour des dérivés du chromanne.

Au cours d'autres travaux Waechter,[4] Tsitini,[5,6] Postaire[7] et Assamoi[8] ont étendu ces recherches à des molécules azotées appartenant à des séries intéressantes sur le plan thérapeutique telles que les quinoléines et isoquinoléines. Cependant, bien qu'en milieu sulfurique concentré, il se forme des complexes sulfovanadiques dont le caractère oxydant est augmenté par rapport à l'ion VO_2^+ libre, en phase aqueuse, dans les conditions d'acidité 2,5 et 5*M* et jusqu'à 8*M*, ces complexes ne sont pas stables. Ils subissent une hydrolyse quasi totale. Par ailleurs, les réactions sont rarement instantanées, même en milieu très acide, et il est souvent nécessaire d'opérer à chaud, soit à la température du bain-marie bouillant, soit même, dans le cas des polyoxyéthylèneglycols de poids moléculaire élevé, à la température d'ébullition du mélange.

C'est pourquoi nous avons étudié la possibilité de préparer des solutions dans des solvants moins dissociants que l'eau et qui pourraient favoriser la stabilité des complexes sulfovanadiques, et donc renforcer le pouvoir oxydant. Outre l'amélioration de la stabilité de ces derniers, ce caractère peu dissociant pourrait favoriser la formation de complexes initiaux entre la molécule organique et le vanadium, accélérant ainsi la réaction d'oxydation. Par ailleurs, maintes molécules oxygénées ne sont pas suffisamment

*Laboratoire de Contrôle de Qualité, Pharmacie Centrale des Hôpitaux de Paris, 7 rue du Fer à Moulin, 75221 Paris Cedex 05, France

hydrosolubles pour permettre une réaction en phase homogène. C'est la raison pour laquelle nous avons envisagé de réaliser l'oxydation de telles molécules n'ayant souvent que peu d'affinité pour l'eau, en remplaçant ce milieu par des solvants plus adéquats. Notre choix s'est tout d'abord porté sur l'acide acétique anhydre. La légère oxydabilité de ce solvant à chaud nous a conduit à en chercher un autre dépourvu de tout caractère réducteur. L'acide phosphorique a été retenu en raison de son aptitude à dissoudre de nombreuses molécules organiques peu hydrophiles, et de la possibilité de préparer un réactif totalement anhydre.

Malgré les avantages que semblait apporter, comme solvant, l'acide phosphorique par rapport à l'acide acétique, ces derniers ont été étudiés parallèlement.

Nous avons tout d'abord envisagé le comportement de quelques acides α-carbonylés et α-hydroxylés.[9] Les résultats quelque peu suprenants observés avec les acides glycolique et lactique nous ont conduit à étudier des molécules oxygénées simples dont certaines ont fait l'objet de travaux en milieu aqueux sulfurique, en particulier des alcools, aldéhydes, cétones et acides.[10-13] Ce travail a été ensuite étendu à certaines autres molécules, acétals ou esters qui n'avaient pu être étudiées en milieu aqueux en raison de leur caractère hydrophobique.

PARTIE EXPERIMENTALE

Réactifs

Solutions sulfovanadiques 0,05*M* [en vanadium(V)] dans l'acide acétique anhydre, l'acide phosphorique à 85%, et l'acide phosphorique à 100%.[14] Ces trois solutions sont étalonnées par titrage avec une solution de sulfate de fer(II) et d'ammonium 0.125*M* (sel de Mohr).[15]

Mode opératoire

Lors de la réalisation d'une cinétique d'oxydation, et afin de déterminer le nombre de moles de vanadium(V) consommé par mole de produit initial, le procédé expérimental suivant est appliqué.

Préparation de la solution "blanc" des réactifs. Dans un bécher de 100 ml, introduire 20 ml de la solution vanadique acétique ou phosphorique à 85 ou 100%.

Préparation de la solution "essai". La prise d'essai choisie doit correspondre à la réduction attendue d'environ 0,02 à 0,2 mmole de réactif vanadique. Si cette masse est trop faible pour obtenir une pesée exacte, il est nécessaire de préparer une solution mère dans l'acide acétique anhydre ou dans l'acide phosphorique, à 85 ou à 100% selon les cas. La prise d'essai est introduite dans un bécher de 100 ml où sont ensuite ajoutés 20 ml de solution vanadique dans le solvant adéquat. Les récipients qui doivent être portés à l'étuve à 100° sont recouverts d'un entonnoir pour limiter l'évaporation.

Les solutions "blanc" des réactifs et "essai" sont ensuite maintenues soit à température ambiante, soit à l'étuve pendant le temps prescrit. Au bout de ce temps, 50 ml environ de la solution aqueuse d'acide sulfurique 5*M* y sont ajoutés pour obtenir une phase suffisamment aqueuse pour le titrage. L'excès de vanadium(V) non consommé est dosé par la solution ferreuse avec indication potentiométrique du point d'équivalance.

Isolement et dosage de composés formés au cours de l'oxydation. Les quantités de monoxyde et de dioxyde de carbone libérées au cours de l'oxydation ont été déterminées par chromatographie en phase gazeuse par espace de tête et transformation en méthane.[16]

L'identification des acides formique, acétique, succinique, maléïque, et benzoïque ainsi que du benzile est réalisée par chromatographie en phase gazeuse après méthylation ou sylilation et détection par spectrométrie de masse.[15]

RESULTATS ET DISCUSSION

Des observations réalisées en milieu sulfurique aqueux sur les composés monofonctionnels, il ressort un certain nombre de conclusions. Bien que ces dérivés soient assez difficilement oxydables par le vanadium(V) leur oxydation met probablement en jeu la formation d'un complexe linéaire initial puis un mécanisme radicalaire. La réaction débute par la formation rapide d'un complexe linéaire avec une molécule d'oxydant. Elle se poursuit ensuite en donnant l'acide correspondant, probablement par l'intermédiaire de radicaux libres.

Molecules hydroxylées et derivés

Alcools. En milieu aqueux, ils ne s'oxydent qu'à chaud sauf le butanol tertiaire. Cependant, ce dernier se déshydrate facilement pour donner l'isobutène qui, lui, est oxydable.

Le premier essai d'oxydation sur le méthanol et l'ethanol, réalisé en milieu acétique anhydre, nous a permis de constater une absence de réactivité de ces alcools. En revanche, le comportement de ces derniers vis à vis d'un réactif en milieu phosphorique utilisé à chaud (100°) varie en fonction de la teneur en eau.

Le réactif, préparé en milieu phosphorique à 85%, contient, en effet, des concentrations presque équimoléculaires d'eau et d'acide ortho-phosphorique (8,3 moles d'eau pour 8,7 moles d'acide).

L'oxydation des alcools dans ce milieu aboutit à une consommation de vanadium(V) (0,25 mole par mole) qui n'est pas négligeable. Alors qu'en milieu phosphorique à 100%, donc rigoureusement anhydre, aucune oxydation n'est détectable.

En conclusion, ce travail préparatoire permet d'entrevoir que le comportement des alcools est différent en milieu légèrement aqueux et en milieu strictement anhydre. Cependant, l'étude a été poursuivie en milieu non aqueux pour envisager l'influence de la classe de l'alcool ainsi que celle de la longueur de la chaîne.

La solution acétique a été retenu en raison de sa plus grande facilité d'emploi par rapport à la solution phosphorique à 100%.

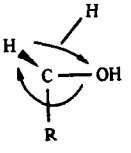
Dans la figure 1 sont regroupées les cinétiques d'oxydation des différents alcools étudiés.

Le fait que les alcools secondaires soient beaucoup plus oxydables que leurs isomères primaires (Fig. 1), pourrait être rapproché du fait observé en milieu aqueux de la nette oxydabilité de la proline (acide aminé cyclique) contrairement à la résistance pratiquement totale à l'oxydation des acides α aminés

Fig. 1. Cinétique d'oxydation de quelques alcools.

aliphatiques.[17] Une hypothèse d'explication avait alors été émise, fondée sur la plus grande difficulté à former des complexes dans ce dernier cas. En effet, la mobilité du groupement aminé par rapport au groupement carboxylique est plus importante dans le cas d'une amine primaire.

Il est possible d'envisager, dans le cas des alcools primaires, une rotation libre du groupement hydroxyle et des deux atomes d'hydrogène autour de l'axe formé par le carbone vicinal et celui du groupement fonctionnel:



Cette rotation pourrait entraver la formation d'un complexe et donc la cession d'un doublet de l'oxygène au vanadium.

Cependant, il devrait en être de même en milieu aqueux. Or, nous avons montré une légère oxydabilité du méthanol et de l'éthanol dans un milieu partiellement ou totalement aqueux. Dans ce cas il existe, du fait de la faible taille des molécules, de multiples liaisons hydrogène entre alcool et eau qui conduisent, de ce fait, à un blocage partiel des rotations facilitant alors la réaction avec le vanadium.

L'influence de la longueur de la chaîne a été examinée. Dans le cas des alcools primaires, si le propanol résiste, comme le méthanol et l'éthanol, à toute oxydation, à partir du butanol une oxydation non négligeable apparait. La figure 1 montre que l'oxydabilité croit avec la longueur de la chaîne. Ceci conduit à émettre l'hypothèse que l'allongement de la chaîne permet un don d'électrons plus important. La facile complexation des alcools par un chélate du vanadium(V) et de l'oxine[18] nous parait étayer cette hypothèse.

En ce qui concerne les alcools aryl aromatiques, l'exemple de l'alcool benzylique montre que l'oxydation est nette malgré le caractère attracteur du groupement phényle. Ceci parait confirmer le caractère donneur d'électrons du reste benzyle. La réaction, dans ce cas, conduit à la formation presque stoechiométrique d'acide benzoïque comme le montre l'identification et le dosage de cet acide par chromatographie en phase gazeuse après sylilation et détection par spectrometrie de masse. L'acide benzoïque, en effet, n'est pas oxydé en milieu acétique comme nous le verrons lors de l'étude des acides.

Dans le cas des alcools secondaires aliphatiques, l'absence de réactivité du propanol-2 confirme les résultats obtenus avec les alcools primaires. La présence des seuls groupements méthyle en α de l'alcool ne permet pas l'oxydation. Il faut que l'une des chaînes hydrocarbonées possède au moins deux atomes de carbone pour voir apparaître un début de réaction. C'est le cas du butanol-2. Le fait que celui-ci subisse une oxydation plus poussée que l'alcool primaire isomère étaye l'hypothèse faite précédemment sur la rotation libre du groupement hydroxyle. Enfin, la nette oxydation de l'octanol-2 par rapport à l'octanol-1 nous parait confirmer encore cette hypothèse et conduit comme pour les alcools primaires à l'observation que l'allongement de la chaîne augmente la réactivité.

La réactivité du cyclohexanol se situe entre celle du butanol-2 et de l'octanol-2. Elle montre l'influence prépondérante de la longueur de la chaîne sur l'oxydabilité et l'absence d'une éventuelle intervention de la position du groupement hydroxylé sur la chaîne.[19]

Etheroxyde. La réactivité du vanadium(V) en milieu sulfurique aqueux, étudiée sur les groupements étheroxyde et en particulier sur les méthoxyles de divers hétérocycles[7] ainsi que sur les polyoxyéthylèneglycols, n'avait pas pu être étendue aux étheroxydes simples pour des raisons de solubilité. En revanche, en milieu acétique anhydre, l'oxydation

d'un éther de phénol, le diméthoxy-1,2 benzène, a été étudiée.[20] Ainsi, la miscibilité totale de l'acide acétique ou de l'acide phosphorique et de l'oxyde d'éthyle a été exploitée pour envisager l'oxydation de ce dernier.

En milieu acétique, il reste stable, ce qui nous a conduit à étudier sa réactivité en milieu phosphorique. Dans ce dernier milieu, l'étude de la cinétique d'oxydation met en évidence une augmentation régulière de la consommation de vanadium(V) par mole jusqu'à 5 hr où elle se stabilise autour de 1 mole/mole. Cette réactivité faible mais notable de l'oxyde d'éthyle doit être comparée à l'absence de réaction de l'éthanol. Ceci confirme l'hypothèse émise dans ce dernier cas que la complexation était entravée par la libre rotation du groupement hydroxyle autour de l'axe formé par les deux carbones. Dans le cas de l'oxyde d'éthyle, une telle rotation est génée et l'oxygène se trouve donc partiellement stabilisé et donc plus susceptible de céder son doublet au vanadium.

Molécules à groupement carbonyles et dérivés

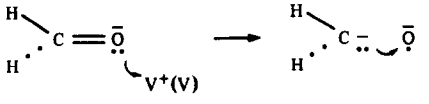
Aldéhydes et dérivés. Le formaldéhyde étant un produit intermédiaire dans de nombreuses réactions d'oxydations, il a été étudié en premier. Son comportement est comparé à celui de l'homologue supérieur aldéhyde acétique.

Par ailleurs, la lipophilie des acétals interdisait, jusqu'à maintenant, l'étude de leur comportement vis à vis du vanadium(V). Seuls les hémiacétals dérivés des sucres avaient pu être étudiés. L'oxydation du premier de ces composés le méthylal (acétal du formaldéhyde et du méthanol) a donc été envisagée.

Parallèlement, le trioxyméthylène, polymère du formaldéhyde, a été étudié car il présente l'intérêt d'être l'un des constituants du mélange de polymères classiquement utilisés pour générer du formaldéhyde gazeux.

Il ne nous a pas paru nécessaire, en revanche, d'oxyder le benzaldéhyde puisque l'alcool benzylique subit, comme nous l'avons vu, une oxydation en acide benzoïque qui doit passer par cet intermédiaire.

En milieu acétique, l'observation, dans la figure 2, d'une consommation d'environ 2 moles de vanadium(V) par mole de formaldéhyde après 5 hr de réaction, et qui n'évolue pas ultérieurement, même après 24 hr, fait proposer l'hypothèse que le formaldéhyde serait attaqué dans un premier temps par le vanadium(V) selon le mécanisme suivant:



pour donner dans un premier temps soit un carbocation formyle H—C⁺=O et un atome d'hydrogène radicalaire, soit un radical formyle H—Ċ=O et un proton. Dans un deuxième temps, ce dernier conduit à son tour au carbocation. En présence de traces d'eau, celui-ci peut conduire à l'acide formique.

L'absence de réactivité de l'acide formique dans ce milieu étaye cette hypothèse. Cependant, il n'a pas été possible de la mettre en évidence en raison de l'interférence du solvant acétique. En revanche, en milieu phosphorique 100%, l'acide formique a pu être identifié par chromatographie en phase gazeuse couplée à la spectrométrie de masse après oxydation du formol pendant 24 hr à température ambiante.

L'acétaldéhyde est plus résistant à l'oxydation que son homologue inférieur comme le montre la figure 2, et ceci est, à première vue, surprenant en raison du caractère donneur d'électrons du méthyle. Nous pensons rapprocher ce comportement des observations faites dans le domaine spectral d'un effet hypsochrome du groupement méthyle de l'acétaldéhyde par rapport au formaldéhyde.[21] Ce comportement pourrait être dû à un effet mesomère plus important que l'éventuel effet inducteur.

Le mécanisme réactionnel d'oxydation est probablement le même que celui du formaldéhyde et conduit, dans ce cas, à la formation d'acide acétique en consommant 2 moles de vanadium(V).

La quantité déterminée expérimentalement étant de 1,6 mole/mole en 24 hr, il est possible d'imaginer que la réaction est ralentie ou que l'oxydation ne touche qu'une partie des molécules comme cela a déjà été observé en milieu aqueux sur des molécules difficilement oxydables.[21] L'explication possible de ce phénomène pourrait être que la faible stabilité du complexe formé initialement laisse libre un certain nombre de molécules et que seules les molécules complexées réagissent.

Le comportement du méthylal vis à vis de l'oxydation vanadique est très proche de celui du formaldéhyde, comme le montre la figure 2. Cette étude confirme l'absence de réactivité des groupements méthoxylés comme cela a été vu pour le méthanol lui-même. Elle permet également de constater que la disparition de la double liaison du carbonyle n'entrave pas l'oxydation. Cette observation est à rapporter à celle faite en milieux aqueux et non aqueux sur la réactivité des étheroxydes.[2]

Dans le cas de trioxyméthylène (trioxanne-1,3,5) la cinétique d'oxydation est considérablement ralentie. Au bout des 5 premières heures d'oxydation, alors que pour le formaldéhyde la transformation en acide formique est totale, la consommation, exprimée en "chaînon formaldéhyde" correspond seulement à 0,5 mole de vanadium(V) (Fig. 2). Il existe donc une résistance importante à l'oxydation. Celle-ci pourrait être due à la structure symétrique du cycle dans laquelle les atomes d'oxygène alternent avec les groupements méthylène. Il en résulte une certaine mésomérie, contrairement à ce qui se produit avec le méthylal où les groupements méthyle ont un caractère donneur. En effet, la formation de trimère à partir du formaldéhyde provient de la création de liaisons par un transfert concerté et la dépolymérisation peut se faire par un mécanisme inverse. Au bout de 24 hr, la consommation en

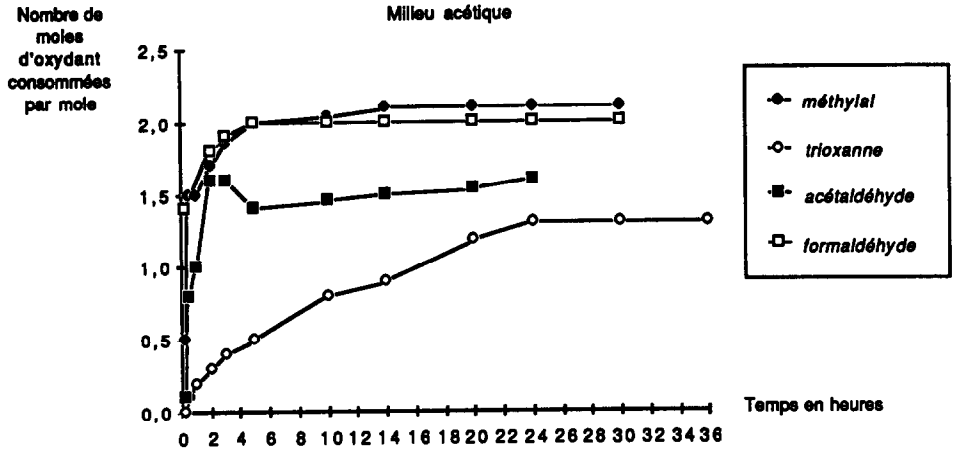


Fig. 2. Cinétique d'oxydation d'aldéhydes et de derivés.

vanadium(V) atteint 1,3 mole/mole et se stabilise. L'oxydation n'est donc pas complète dans ce milieu. L'hypothèse qui peut être émise consiste à envisager la création d'un complexe initial de faible stabilité qui entraîne une difficulté d'oxydation.

Cétones. En milieu aqueux, l'acétone s'oxyde selon Gaudefroy[22] en donnant les acides acétique et formique selon:

$$CH_3COCH_3 + 6VO_2^+ + 6H^+ \rightarrow CH_3COOH + HCOOH + 6VO^{2+} + 3H_2O$$

En milieu acétique, comparée à la réactivité du formaldéhyde et de l'acétaldéhyde que nous venons d'étudier, celle de l'acétone est encore plus faible (< 1 mole/mole en 36 hr) (Fig. 3). Ceci étaye l'hypothèse faite pour le cas de l'acétaldéhyde, puisqu'ici la présence de deux groupements méthyle diminuent la réactivité d'une manière plus importante que celle de l'unique méthyle de l'acétaldéhyde.

Par ailleurs, il faut noter que cette oxydation s'accompagne d'une libération importante de dioxyde de carbone (0,9 mole/mole en 24 hr). Dans les mêmes conditions, aucune trace de monoxyde de carbone n'a pu être détectée.

En fonction de ces premiers résultats nous avons envisagé pour d'autres cétones, comme pour les alcools, l'influence de la longueur de la chaîne, de la conformation spatiale et de la ramification.

L'oxydation de la butanone en milieu acétique confirme les résultats obtenus pour les alcools secondaires. En effet, par rapport à l'acétone, la consommation passe de 0,4 à 2,4 mole/mole en 24 hr. La présence au voisinage du groupement fonctionnel d'une chaîne comportant au moins deux atomes de carbone favorise l'oxydation. Cette observation est confirmée par l'étude de l'oxydation de la cyclopentanone et celle de la cyclohexanone qui réduisent respectivement 6 et 8 moles de vanadium(V) par mole (Fig. 3). Cependant la différence de réactivité entre ces deux cyclanones qui ne diffèrent que par un chaînon méthylène, nous fait envisager l'existence d'un autre paramètre que l'allongement de la chaîne.

Nous avons déjà émis, à propos de la différence de réactivité entre le formaldéhyde, l'acétaldéhyde et l'acétone, la possibilité de l'existence de formes méso-

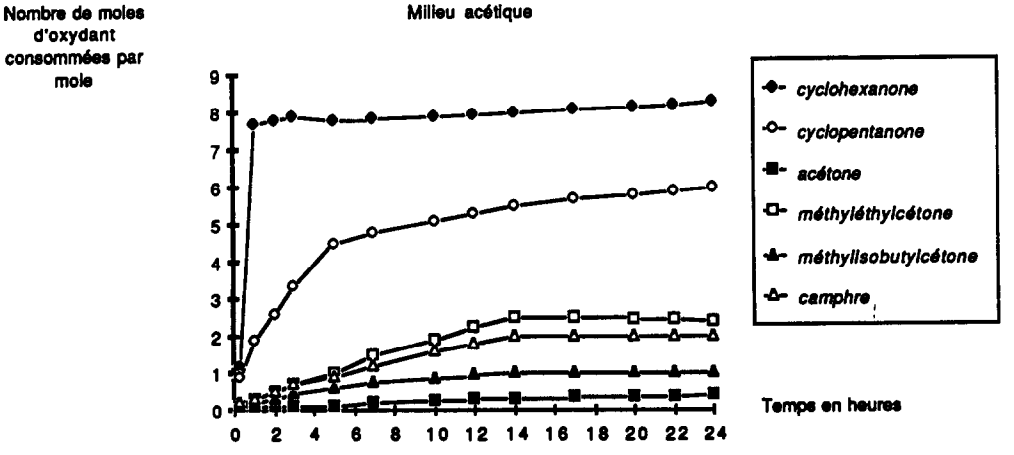

Fig. 3. Cinétique d'oxydation de quelques cétones.

mères par hyperconjugaison. Pour qu'existe une telle mésomérie la planéité de la molécule est nécessaire. Cela est le cas de la cyclopentanone, du fait de la tension du cycle. En revanche, une telle conformation est impossible dans le cas de la cyclohexanone. Cette absence de planéité peut être responsable de la réactivité plus importante de cette dernière.

L'étude de la méthylisobutylcétone pouvait, à priori, laisser envisager une augmentation de la vitesse et de l'intensité de l'oxydation en raison de l'augmentation du nombre d'atomes de carbone de la molécule. Or les résultats expérimentaux infirment cette hypothèse puisque qu'après 24 hr une seule mole de vanadium(V) est réduite par mole de cétone.

L'influence négative de la ramification est ainsi mise en évidence. Elle est confirmée par l'étude réalisée sur le camphre dont la structure voisine de la cyclohexanone pouvait laissé espérer un comportement analogue. Or nous constatons une évolution parallèle à celle de la méthylisobutylcétone, puisqu'en 24 hr la consommation n'est que de 2 mole/mole. Or cette molécule comporte trois groupements méthyle. Même si après 48 hr la réaction évolue vers une consommation plus importante, la résistance à l'oxydation n'en demeure pas moins évidente. Les raisons de cette influence négative des ramifications par des groupements méthyle pourraient correspondre à l'existence d'un certain encombrement stérique ou à la structure tertiaire ou quaternaire de certains carbones.

La plus grande oxydabilité des cétones que des alcools secondaires correspondants est un phénomène général puisque déjà l'acétone est légèrement oxydée alors que le propanol-2 résiste. Cette observation est encore plus nette pour le butanol-2 et la butanone et surtout pour le cyclohexanol et la cyclohexanone. La cession au vanadium de l'électron venant de l'oxygène est logiquement plus grande dans le cas du carbonyle, en raison de la double liaison qui facilite la mobilisation, que dans celui de l'hydroxyle.

Acides. Comme nous l'avons vu précédemment, l'acide formique résiste à l'oxydation tant en milieu acétique que phosphorique. Quant à l'acide acétique, dans le seul milieu où son étude soit possible, c'est à dire le milieu phosphorique, il est également résistant aussi bien à l'acide phosphorique 85% qu'à 100%.

Comme pour le séries précédentes (alcools, dérivés carbonylés), l'influence de la longueur de la chaîne a été envisagée. Ceci nous a amené à étudier les cinétiques d'oxydation des acides propionique, butyrique, caprylique et caprique. Nous avons constaté que le milieu acétique n'est pas adapté à une oxydation d'homologues du solvant. En effet, leur comportement doit être analogue à ce dernier. Les premiers essais entrepris en milieu acétique avec les acides formique, dipropylacétique (valproïque), benzoïque et phénylacétique confirment l'absence de réactivité. En outre, l'insolubilité des acides saturés à longue chaîne, tels que l'acide stéarique, est un argument supplémentaire pour abandonner ce solvant. L'étude a donc été réalisée pour ces dérivés exclusivement en milieux phosphoriques.

L'acide propionique subit une très légère oxydation (0,7 mole/mole en 24 hr). En ce qui concerne les acides supérieurs, la consommation semble se stabiliser à 24 hr vers 2,5 mole/mole au moins jusqu'à C_{10} (Fig. 4). Au delà, la diminution de la solubilité rend l'étude impossible. Cependant, les acides semblent réagir d'une façon un peu plus intense que les alcools primaires correspondants.

En ce qui concerne l'influence de la ramification de la chaîne, étudiée dans le cas des cétones, nous retrouvons un phénomène analogue puisque l'acide valproïque ne consomme que 1,8 mole/mole en 24 hr.

En ce qui concerne les esters, aucune étude n'avait été réalisée en milieu aqueux en raison de leur insolubilité. Un essai réalisé sur un ester (l'acétate de méthyle) en milieu acétique a montré qu'il est insensible à l'oxydation au moins jusqu'à 24 hr. Ceci n'est pas surprenant si nous considérons l'analogie avec

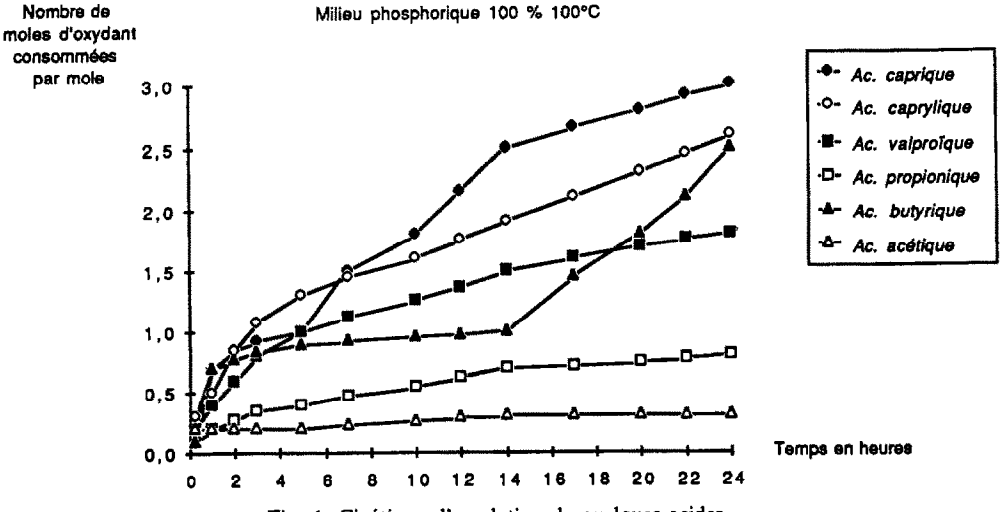

Fig. 4. Cinétique d'oxydation de quelques acides.

l'acide, mais il était possible d'envisager un comportement voisin de celui des étheroxydes.

L'acide benzoïque a été envisagé en sa qualité d'acide aromatique, et en raison du fait qu'il peut être également l'intermédiaire ou le terme de nombreuses réactions d'oxydation.

En milieu acétique, il est insensible à l'oxydation au moins pendant les 20 premières heures. En milieu phosphorique à 85% et à 100°, il ne commence à s'oxyder qu'à partir de 24 hr (environ 0,1 mole de V(V) par mole). En milieu phosphorique à 100% et à 100°, il s'oxyde plus nettement puisqu'en 24 hr, il consomme 1,6 mole de V(V) par mole. Cependant, l'absence pratique d'oxydation de l'acide benzoïque dans des conditions classiques confirme les observations déjà remarquées en milieu vanadique aqueux.

L'acide phénylacétique permet d'étudier l'éventuelle réactivité du méthylène benzylique. Aucune oxydation ne se produit en milieu acétique jusqu'à 5 hr et ensuite une consommation de 0,35 mole de V(V) par mole apparait à 24 hr. En revanche, en milieu phosphorique à 100% et à 100°, il consomme 8,5 moles de V(V) par mole en 24 hr.

L'étude de l'acide phénylacétique avait pour but d'envisager le comportement d'un dérivé portant le groupement benzyle. En effet, il a été possible de mettre en évidence, lors de l'oxydation vanadique en milieu aqueux de la benzyl-1 isoquinoléine, la résistance inattendue du méthylène du substituant qui dans d'autres types d'oxydation est transformé en cétone. Parmi les produits réactionnels, a été isolée une quantité importante d'acide benzyl-2 pyridine dicarboxylique-3,4.[6] Nous constatons, ici encore en milieu anhydre, la même résistance de ce groupement.

CONCLUSION

L'emploi de réactifs partiellement ou totalement anhydres a permis d'explorer un nouveau domaine d'oxydation par le pentoxyde de vanadium. Il était important d'envisager l'oxydation de molécules unifonctionnelles simples dans la mesure où les mécanismes réactionnels d'oxydation de dérivés plurifonctionnels conduisent fréquemment à un dérivé hydroxylé, carbonylé ou carboxylique.

Cependant, en milieu acétique anhydre, la réactivité du vanadium(V) ne parait pas supérieure à celle observée en milieu aqueux. Ceci peut être dû à l'existence dans le réactif de complexes sulfo-acétovanadiques.[14]

Dans le cas des alcools, les premiers termes sont moins oxydables en milieu acétique qu'en milieu aqueux. L'emploi de l'acide acétique comme solvant a toutefois permis d'étudier le comportement d'alcools supérieurs peu solubles dans l'eau et de constater que l'allongement de la chaîne facilite l'oxydation. En outre, les alcools secondaires sont plus facilement attaqués que les primaires comme le montre la comparaison entre les comportements de l'octanol-1 et de l'octanol-2.

En ce qui concerne les dérivés carbonylés, comme en milieu aqueux, les aldéhydes réagissent plus difficilement que les cétones. Cependant, ils s'oxydent plus intensément que les alcools correspondants.

Pour les acides, nous confirmons l'absence de réactivité en milieu acétique comme en milieu aqueux.

Par ailleurs, cette étude permet d'étendre ici encore le domaine de l'oxydation vanadique à des molécules hydrophobes, comme les étheroxydes (oxyde d'éthyle). En effet, par opposition à la résistance des esters, l'oxydabilité des étheroxydes permet de confirmer que ce groupement fonctionnel, souvent réputé inerte, réagit d'une façon non négligeable avec le vanadium(V).

En revanche, l'acide phosphorique concentré, qui possède lui aussi un bon pouvoir solvant vis à vis de nombreuses molécules organiques et qui permet, en outre, d'opérer à température élevée, nous a permis d'observer une oxydation non négligeable des acides aliphatiques.

EXTRACTION–SPECTROPHOTOMETRIC DETERMINATION OF GERMANIUM(IV) WITH MANDELIC ACID AND MALACHITE GREEN

SHIGEYA SATO and HIROYUKI TANAKA
Faculty of Education, Kumamoto University, 2-40-1, Kurokami, Kumamoto 860, Japan

(*Received* 1 *June* 1988. *Revised* 22 *August* 1988. *Accepted* 7 *October* 1988)

Summary—A method has been developed for determination of germanium, based on complexation with mandelic acid and extraction of the ion-associate formed with Malachite Green (MG) into chlorobenzene. A weakly acidic aqueous solution (pH 2.5–3.5) at room temperature is used and indirect determination is achieved by measuring the absorbance of MG in the extract, at 628 nm. The calibration graph is linear over the range $(0.17–8.63) \times 10^{-6}M$ (0.05–2.50 μg of germanium); the apparent molar absorptivity is 1.33×10^5 l.mole^{-1}.cm^{-1}. The interferences from Fe, Ti, Sn(IV), Mo, and Sb(III) can be eliminated by addition of *trans*-1,2-diaminocyclohexanetetra-acetic acid and sodium diethyldithiocarbamate.

Germanium has been determined by several spectrophotometric methods and a variety of reagents.[1–6] Of these, the highly sensitive phenylfluorone (9-phenyl-2,3,7-trihydroxy-6-fluorone; PF) method is most commonly used in spite of its poor selectivity, poor reproducibility and the slow formation of the Ge(IV)–PF complex. The PF method also requires the addition of gelatin, gum arabic or poly(vinyl alcohol) as a dispersing agent because of the low solubility and stability of the complex in water. Recently, highly sensitive and selective determinations, based on the colour reaction between germanium and PF-derivatives in the presence of cationic surfactants, have been reported.[7,8] These non-extractive methods are simple and rapid but a highly acidic medium (15*M* phosphoric acid or 6*M* sulphuric acid) is necessary for complete formation of the coloured complex. Methods for extraction and spectrophotometric determination have also been reported.[9–12] These methods are, however, based on the colour reaction of germanium and PF, and a pre-extraction step to separate the germanium from interfering ions is necessary because of the poor selectivity of PF, which is a major drawback of the method. It is difficult to obtain high sensitivity and good reproducibility by using flame atomic-absorption spectrophotometry, because GeO volatilizes without undergoing atomization, on account of the high dissociation energy of the Ge–O bond, and there is also serious interference from concomitant ions.[13,14]

We have found that α-hydroxy-acids are very useful complexing agents, especially for metals which form oxo-ions in solution, and highly sensitive and selective methods for their determination have been reported.[15–22] In further work on these systems, it was found that germanium reacted rapidly with mandelic acid to form a complex that could be extracted into chlorobenzene with Malachite Green as counter-ion, from weakly acidic media (pH 2.5–3.5) at room temperature, and that the resulting ion-association complex with Malachite Green is very stable. The proposed method is highly sensitive, selective and reproducible, and less troublesome than others, since only a single extraction is needed. There is no requirement for dispersing agents such as gum arabic or surfactants, or strongly acidic media, or pre-separation of germanium from other ions or back-extraction into aqueous solution. Interferences from molybdenum(VI) and antimony(III) can be effectively eliminated by the use of sodium diethyldithiocarbamate (DDTC). Interferences from iron(III), titanium(IV) and tin(IV) are prevented by addition of *trans*-1,2-diaminocyclohexanetetra-acetic acid (DCTA).

EXPERIMENTAL

Apparatus

UVIDEC-660 (Japan Spectroscopic Co.) and Hitachi Model 181 spectrophotometers were used, with 10-mm glass cells. An Iwaki Model V-DN type KM shaker and a Hitachi 03P centrifuge were also used. The pH values were measured with a Hitachi–Horiba M-8 pH-meter.

Reagents

All reagents and solvents used were of analytical grade. All aqueous solutions were prepared with demineralized water.

Standard germanium(IV) solution. A commercially available germanium standard solution (1000 ppm Ge) was used and working solutions were made by suitable dilution as required.

Malachite Green (MG) solution (2.0×10^{-3}M). Prepared from guaranteed grade MG oxalate.

Mandelic acid (MA) solution (1.0×10^{-2}M).

Acetate buffer (pH 3.0). Prepared from 0.1*M* sodium acetate and 0.5*M* sulphuric acid.

*DCTA solution, 0.1*M.

*DDTC solution, 0.1*M.

Standard procedure

Transfer a suitable volume of standard germanium solution (containing up to 2.50 μg of germanium) into a 10-ml test-tube equipped with a stopper, and add 1.0 ml of acetate buffer, 0.6 ml of MA solution and 1.0 ml of MG solution.

Dilute to 4.0 ml with water and shake the solution with 4.0 ml of chlorobenzene for 5 min. Separate the phases and measure the absorbance of the organic phase at 628 nm, using 10-mm glass cells, against chlorobenzene as reference.

RESULTS AND DISCUSSION

Selection of complexing agent, cationic dye and extraction solvent

We have examined the reactions between germanium and α-hydroxy-acids such as lactic, glycollic, 2-hydroxyisobutyric, 2-hydroxy-2-methylbutyric, 2-hydroxyisocaproic, mandelic and *p*-chloromandelic, along with extraction of the products into chlorobenzene, benzene, toluene, carbon tetrachloride and cyclohexane, with the dyes Ethyl Violet, Crystal Violet, Brilliant Green and Malachite Green as counter-ions. With each acid, different combinations of extraction solvents and dyes were examined, and optimal experimental conditions were established. The germanium complexes with lactic and glycollic acids could not be extracted into any of the solvents. Carbon tetrachloride and cyclohexane did not extract any of the ion-association complexes. With both benzene and toluene as extractant, the most appropriate combination of complexing agent and dye was *p*-chloromandelic acid and Brilliant Green, and the apparent molar absorptivities obtained were 6.2×10^4 and 5.4×10^4 $l.mole^{-1}.cm^{-1}$, respectively. Similarly, the effectiveness of β-hydroxy-acids as complexing agents for germanium has been examined. The acids tested were 5-amino-2-hydroxybenzoic, 2,4,6-trihydroxybenzoic, 2,5-dihyroxybenzoic, 2-amino-2-hydroxybutyric, 2-amino-3-hydroxypropionic and 2-phenylhydroxyacrylic. However, none of the ion-association complexes thus obtained could be extracted into chlorobenzene. Table 1 shows the reagent blank and apparent molar absorptivity for germanium complexes with α-hydroxy-acids and dyes, extracted into chlorobenzene. It is clear that the MG–MA–chlorobenzene system is the most suitable for determination of μg amounts of germanium.

Absorption spectra

The absorption spectra of the reagent blank and the ion-association species formed between the germanium–MA complex and MG in chlorobenzene are shown in Fig. 1. MG is not extracted into chlorobenzene. The wavelength of maximum absorption in each spectrum is 628 nm.

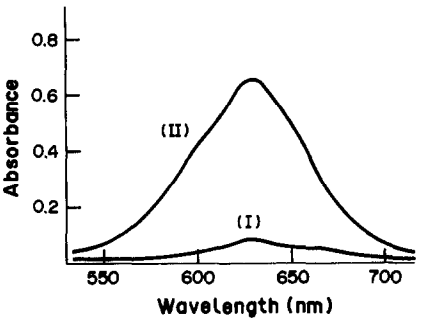

Fig. 1. Absorption spectra: (I), reagent blank; (II), $4.1 \times 10^{-6}M$ Ge (1.2 μg). Malachite Green, $5.0 \times 10^{-4}M$; mandelic acid, $1.5 \times 10^{-3}M$; pH, 3.0; reference, chlorobenzene.

Experimental variables

Maximum and constant absorbance of the organic phase was obtained over the pH range 2.5–3.5, and pH 3.0 was chosen as optimal. Phosphate buffer ($0.1M$, pH 3.0) can be used instead of acetate buffer, but not tartrate or citrate buffer, because the sensitivity will be lowered.

The absorbance of the reagent blank increases gradually with increase in MG concentration, but the net absorbance for a fixed germanium concentration ($4.1 \times 10^{-6}M$) reaches a constant value at MG concentrations exceeding 4.5×10^4M in the aqueous solution. The concentration of MG was fixed at $5.0 \times 10^{-4}M$. Figure 2 shows that maximal and

constant net absorbance is obtained when the MA concentration in the aqueous phase is at least $1.0 \times 10^{-3}M$. The concentration of MA was therefore fixed at $1.5 \times 10^{-3}M$.

A shaking time of about 3 min was necessary to attain a constant absorbance, and for routine work 5 min is recommended.

Composition of the complex

The molar absorptivity of MG in aqueous solution is *ca.* 6.8×10^4 $l.mole^{-1}.cm^{-1}$, and the apparent molar absorptivity for germanium in the extract is about twice that. It is thus suggested that the molar ratio of MG to germanium in the complex is 2:1 and that a doubly charged anionic germanium complex is formed. The composition of the extracted species cannot be determined by the continuous-variation or mole-ratio methods, because of the large excess of MA and MG required for its formation. It is, however, suggested that $[Ge(MA)_3]^{2-}$ is formed and extracted as its ion-association complex with MG.

Calibration graph

The calibration graph obtained by the standard procedure was linear over the range $(0.17–8.63) \times 10^{-6}M$ (0.05–2.50 μg of germanium) in the aqueous phase. The apparent molar absorptivity calculated from the slope of the graph was 13.3×10^4 $l.mole^{-1}.cm^{-1}$, and the absorbance of the reagent blank was 0.11. These figures were independent of temperature in the range 10–25°. The coefficient of variation was 1.8% (8 replicates, $4.1 \times 10^{-6}M$ germanium) and the absorbance of the organic phase remained constant for at least 60 min.

Effect of diverse ions

The effect of various ions on the determination of $4.1 \times 10^{-6}M$ germanium was examined (Table 2). Iodide, perchlorate and thiocyanate, which are bulky anions with low surface-charge density, cause positive errors even at low levels, whereas fluoride, chloride, and sulphate do not interfere even at high concentrations. Most cations tested do not interfere when present in 100-fold w/w ratio to the germanium. The interference from iron(III), lead or aluminium is due to the adsorption of germanium by the metal hydroxide. Chromium(VI) gives a positive error when present at the same concentration as germanium, owing to the extraction of an ion-association complex ($[MG^+][HCrO_4^-]$), but chromium(III) does not interfere even at 1000-fold amounts. Interference by these ions, except for Cr(VI), can be eliminated by the addition of DCTA ($2.5 \times 10^{-3}M$). The permissible amounts of foreign metal ions which strongly interfere with the determination of germanium are shown in Table 3. These ions react with mandelic acid to form extractable complex anions, but antimony(V) does not interfere, owing to its slow reaction rate at room temperature. The tolerance limits obtained by

addition of masking agents are also given in Table 3. Those for titanium(IV) and tin(IV) can be improved somewhat by masking with DCTA ($2.5 \times 10^{-3}M$), and those for molybdenum(VI) and antimony(III) with DDTC ($1.0 \times 10^{-3}M$). It is concluded that the proposed method is superior to conventional methods using phenylfluorone and permits the determination of germanium in the presence of large amounts of iron.

Applications

The proposed method was applied to carbon steel samples (NBS 362, JSS 169-3 and 171-3), to which known amounts of germanium were added because the samples were virtually free from germanium. The steel was dissolved along with the known amount of germanium, as previously reported,[22] and 100 ml of sample solution was prepared. Then 0.1 ml of 0.1*M* DCTA and 0.4 ml of 0.01*M* DDTC were added to 0.5 ml of the sample solution, and the germanium content was determined by the proposed method. The results are summarized in Table 4, together with the data obtained by a PF–CCl_4 extraction method[11]. The recovery was close to 100%, and the values obtained were in good agreement with those obtained by the PF extraction method.

Although the low tolerance level for certain elements is a drawback, the method is suitable for most types of sample.

(*Received* 9 *July* 1988. *Revised* 26 *August* 1988. *Accepted* 3 *October* 1988)

Summary—Decomposition methods based on fusion with alkali are discussed, with respect to the determination of iodine in biological material. It is shown that sodium hydroxide can be used for the decomposition of seaweed without loss of iodine. In spite of the oxidizing conditions, the iodine will be present as iodide in the final ash. The iodide can be determined by an indirect atomic-absorption method, based on the reaction between iodide and mercury(II), with determination of mercury by cold vapour atomic-absorption spectrometry. The basis of the method is discussed, and it is shown that the use of tin(II) as reductant is essential. The effect of the oxidation state of the iodine on the sensitivity of the method is pointed out. High concentrations of chloride interfere, but it is still possible to determine iodide in iodinated table salt.

The determination of iodine in biological material is complicated by the risk of loss of iodine during the decomposition step. Both acid digestion and fusion with alkali have been used with success, but losses are also frequently observed. Malvano *et al.*[1] found that an acid digestion was better than an alkaline attack, and Pauwels and Wesemael[2] and Kuldvere[3] also used an acid treatment, but Sun and Julshamn[4] found significant losses of iodine during acid digestion.

Fusion with alkali-metal hydroxide or carbonate seems to be the decomposition method preferred by most authors for the determination of iodine in biological material.[4–11] However, there are many different ways of performing the decomposition. The alkali may be added either as an ashing aid for dry ashing, or in larger amounts to facilitate an efficient alkaline fusion. Foss *et al.*[5] and Sun and Julshamn[4] found that it is better to use the alkali-metal hydroxides than the carbonates, and for some matrices the potassium compounds may be more suitable than the sodium compounds.[4–7] Recently Ayiannidis and Voulgaropoulos[8] found that addition of potassium chloride to the potassium hydroxide melt is advantageous. The experimental parameters used, such as amount of alkali added, temperature, time and type of digestion vessel, vary from one author to another, and so do the losses reported.

The oxidation state of the iodine after the treatment with alkali is commented on by few workers. Barakat *et al.*[9] state that the iodine will be present as potassium iodide after a digestion with potassium carbonate, and the presence of iodide is implicitly assumed by other workers using alkali, although the decomposition process involves oxidation of the organic material by atmospheric oxygen.[12] The subsequent method of determination often requires that the iodine is present as iodide. This is the case for the well-known Sandell and Kolthoff reaction,[13] which is based on the catalytic action of iodide on the arsenic(III)–cerium(IV) reaction. Iodide is also the reacting species in the indirect determination of iodine by atomic-absorption spectrometry,[3,4] which is the method used in this work. Both the Sandell and Kolthoff reaction and the atomic-absorption method involve the use of a reducing agent to produce iodide ions, if these are not already the only form of iodine produced during the decomposition step. This is probably the reason why some authors[3,4] suggest that the calibration curve can be prepared from *either* iodide *or* iodate salts. However, it has been pointed out[10] that erroneous results are obtained if iodate is used as the standard in the Sandell and Kolthoff method, and a similar dependence on the oxidation state is also to be expected for the atomic-absorption method.

In the present work the use of sodium hydroxide for the decomposition of seaweed has been investigated. It has been claimed that sodium compounds will more easily give a fully oxidized white ash,[12] but on the other hand losses of iodine have been reported when sodium hydroxide is used for the decomposition of biological matrices.[4,5] The iodine oxidation state after the fusion step and its effect on the sensitivity of the indirect atomic-absorption method has also been studied in some detail.

The indirect atomic-absorption method is based on the effect of iodide on the determination of mercury by the cold vapour technique. Mercury(II) is added

*To whom all correspondence should be addressed.

to the sample solution in a molar amount which is approximately one tenth of that of the iodide. The decrease in the atomic-absorption signal for mercury is proportional to the iodide concentration in the solution, within a certain concentration range. The theoretical basis for the method has not been well explained. The possible reactions involved are discussed in this paper.

It has been claimed that chloride does not interfere in this indirect atomic-absorption method.[3] However, in iodinated table salt the ratio of chloride to iodide is extremely large, and it was therefore of interest to check whether the method can be applied to this material. This is discussed at the end of the paper.

EXPERIMENTAL

Apparatus

A Perkin-Elmer 300 atomic-absorption spectrometer, an Omniscribe D-5000 recorder and a mercury hollow-cathode lamp were used. The all-glass mercury-generation system consisted of a vessel and lid (B45 joint) with inlet and outlet tubes for argon. The inlet tube had a glass sinter at the end immersed in the solution. The outlet tube was connected to a 10-cm long fused-silica absorption cell, which was placed in the light-path. A Naber N3P muffle furnace was used for the decomposition of seaweed.

Reagents

All reagents were of analytical grade. A 5μM mercury(II) stock solution was prepared from the chloride and stabilized by addition of 30 g/l. sodium chloride. A 0.3M tin(II) stock solution was prepared from $SnCl_2 \cdot 2H_2O$ and 2.4M hydrochloric acid. Standard iodide solutions were prepared from potassium iodide. The seaweed sample was a commercial nutrition supplementation product, Vitalia Taremel (Cederroth A/S, Norway), a dried powder produced mainly from the seaweed *Laminaria*. The iodinated table salt was a common commercial product. The argon used was 99.99% pure.

Decomposition of seaweed

Transfer 0.5 g of the seaweed powder to a nickel crucible, add 1 g of sodium hydroxide powder, and mix well with a glass rod. Cover the mixture with 1 g of sodium hydroxide, place the crucible in the muffle furnace, and heat according to the temperature programme shown in Fig. 1. Cool the melt and dissolve it in 10 ml of water, by heating at 90° for 15 min, transfer the solution to a 1-litre standard flask, and dilute it to volume with water.

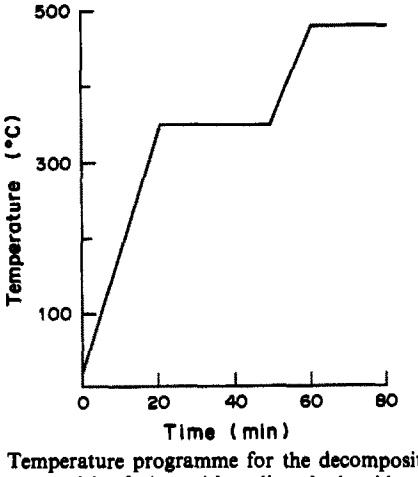

Fig. 1. Temperature programme for the decomposition of seaweed by fusion with sodium hydroxide.

Atomic-absorption procedure

To a 5-ml aliquot of the sample solution, add 50 ml of 60% perchloric acid and 2 ml of 5μM mercury(II) and dilute to 250 ml with water. The final concentrations should be *ca.* 0.5μM iodide, 2.3M perchloric acid and 0.05μM mercury(II). Transfer 50 ml of this solution to the reaction vessel and add 1 ml of 0.3M tin(II) solution. Put on the lid and pass argon through the solution at 1 l./min, and record the atomic-absorption signal. Calculate the concentration of iodine from the calibration curve, which is prepared by similar treatment of potassium iodide standards.

RESULTS AND DISCUSSION

Decomposition of seaweed

The decomposition of biological material by heating with alkali-metal hydroxide is referred to either as dry ashing with an ashing aid or as a fusion process. There is no clear distinction between the two terms. If the sample is heated at above 410° with an excess of the hydroxide, a melt is obtained, because of the low melting points of the alkali-metal hydroxides (321° for NaOH and 404° for KOH). However, the reaction is not a simple fusion, because the melt will react with atmospheric oxygen,[12] and the organic material in the sample will be oxidized. If the alkali-metal hydroxide is not added in excess, its function will probably be more that of an ashing aid in a dry ashing process.

The sample should be well mixed with the hydroxide. To this end the hydroxide is sometimes added as an aqueous solution.[8,10] The addition of alcohol has also been recommended.[4,14] In these cases the mixture must be dried at 100° before the ashing can commence. However, the sample can also be mixed directly with the solid hydroxide.[11] The ashing/fusion step is normally done by placing the crucible in a cold muffle furnace, which is then heated to 400–600°.

Preliminary experiments showed that the addition of alcohol prior to the ashing necessitated a prolonged drying step at a low temperature, to ensure that all the alcohol had been evaporated before the ashing was started. When traces of alcohol were present, ignition of the sample easily occurred in the furnace, but this could be prevented by covering the sample with a layer of alkali-metal hydroxide powder.

In this work the sample was mixed with sodium hydroxide powder, and the mixture was covered with a layer of the hydroxide. The crucibles were heated in a muffle furnace, according to the temperature programme shown in Fig. 1. After 75 min the melt was cooled and dissolved in hot water. The final solution was not filtered.

It was found that both sodium and potassium hydroxide could be used for the decomposition. However, the decomposition was more complete with sodium hydroxide than with potassium hydroxide, as indicated by a more homogeneous melt, and, after the

dissolution, by a colourless solution with few carbon particles. Even so, the same results were obtained for iodine in seaweed, whichever of the two hydroxides was used (see below).

Mercury(II) reactions

The indirect method is based on the effect of iodide on the generation of mercury vapour, which in turn is measured by atomic-absorption spectrometry. The mercury(II) is added in a molar concentration which is approximately one tenth of that of iodide, and tin(II) is used as reductant. The atomic absorption signal decreases with increasing concentration of iodide.

The effect of iodide on the mercury signal has not been well explained. Both complex formation and redox equilibria must be taken into consideration. Mercury(II) forms a series of complexes with iodide, the main species being HgI^+, HgI_2, HgI_3^- and HgI_4^-. The respective formation constants are $10^{12.9}$, $10^{23.8}$, $10^{27.6}$ and $10^{29.8}$.[15] For $1\mu M$ iodide and $0.1\mu M$ mercury(II), the predominating species is found to be HgI_2. The ratio $[HgI_2]/[Hg^{2+}]$ is $\sim 10^{11.6}$, and the concentration of non-complexed mercury will be only $10^{-18.6} M$. The most likely reduction reaction for mercury(II) is therefore

$$HgI_2 + 2e^- \rightarrow Hg + 2I^- \qquad (1)$$

although a two-step process involving Hg_2I_2 is also possible. In the absence of iodide the reaction would be

$$Hg^{2+} + 2e^- \rightarrow Hg \qquad (2)$$

The standard potential of reaction (1) is 0.150 V, and that of reaction (2) 0.854 V.[16] Thus, the complexation of mercury(II) by iodide shifts the standard potential of the mercury reduction by *ca.* 0.70 V. The value 0.150 V was calculated from the equation

$$E_1^0 = E_2^0 - \frac{0.05916}{2} \log K_{HgI_2}$$

where E_2^0 refers to reaction (2) and K_{HgI_2} is $10^{23\,8}$. With $0.1\mu M$ and $1\mu M$ for the total mercury(II) and iodide concentrations, respectively, the potential of reaction (1) becomes 0.304 V.

The reaction of tin(II) during the mercury reduction is

$$Sn(II) \rightarrow Sn(IV) + 2e \qquad (3)$$

The standard potential of the Sn(IV)/Sn(II) system is 0.133 V in $2M$ hydrochloric acid.[17] The potential is less well defined in perchlorate medium. Assuming that the concentrations of tin(II) and tin(IV) are $6mM$ and $0.1\mu M$, respectively, the potential of reaction (3) becomes -0.008 V, which indicates that tin(II) should still be able to reduce the mercury complexes.

The effect of iodide on the mercury generation may thus be explained by the shift in the potential for the mercury(II) reduction, which makes the reduction by tin(II) less effective. According to this explanation, the effect of iodide should be more pronounced when a lower concentration of reductant is used. This is observed experimentally. On the other hand, if a stronger reductant, such as tetrahydroborate is used, the method should no longer work. This was also confirmed experimentally. Thus, the indirect method for the determination of iodide by atomic-absorption spectrometry relies on the use of tin(II) as reductant.

Atomic-absorption measurements

For the indirect method a home-made mercury vapour generation system was found to be more suitable than the commercial system available (Perkin-Elmer MHS 10). Efficient mixing of the solution and flushing of mercury into the atomic-absorption cell was achieved by using a relatively high flow-rate of argon through the system. The optimal concentration of tin(II) was found to be $1–5mM$; at higher concentrations the decrease in the mercury signal as a function of the iodide concentration was less marked.

The acidity of the sample solution was adjusted to $2.3M$ in perchloric acid. The mercury generation was less efficient at higher concentrations of perchloric acid, although generally a high acidity improves the sensitivity of the method.[3,4] The choice of acid is not critical. Perchloric acid was mostly used in this work, to avoid possible interference from the redox properties of the anion of the acid used, but we obtained similar results with nitric acid, which was the acid used in previous studies. Hydrochloric and sulphuric acids are apparently less suitable for the indirect method.[4]

From Fig. 2, curve A, it can be seen that the method gives a non-linear calibration curve, although it has a middle part which is almost linear. The first, almost horizontal part of the curve determines the detection limit of the method.

Oxidation state of the iodine

The effect of the oxidation state of the iodine was studied by recording calibration curves for iodide, iodine and iodate standards. The three curves are shown in Fig. 2. The standard deviation of each point was *ca.* 0.002 absorbance. It can be seen that the method responds differently towards the three iodine species. The reason is that iodine and iodate must first be reduced to iodide by the added tin(II), before complex formation with mercury(II) can occur. Because of the differences in sensitivity illustrated in Fig. 2, the iodine should be present in a single oxidation state in the sample solution prior to the analysis, and the calibration curve must be prepared by use of this particular iodine species. Therefore, the suggestion by some authors[3,4] that the calibration curve can be prepared from *either* iodide *or* iodate salts is not justified for our present experimental conditions. However, the effect of the oxidation state of iodine will be less marked when the sample is

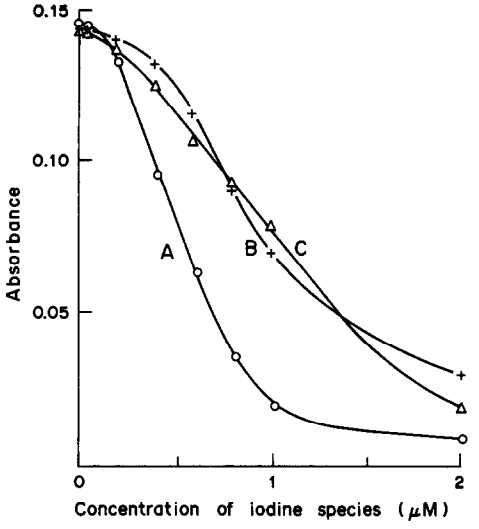

Fig. 2. Calibration curves for I^- (A), IO_3^- (B) and I_2 (C). For I_2 the molar concentrations were half the values indicated. The concentrations of Hg(II) and Sn(II) were 0.04μM and 6mM, respectively.

acidified with nitric acid instead of perchloric acid, since iodide would be oxidized to iodine by the acid. In our method the calibration curve is prepared from potassium iodide.

The different sensitivities obtained for the three iodine species allowed a check for the absence of iodine and iodate after the sample decomposition. To this end, sodium tetrahydroborate was added to the digest, to reduce any iodine and iodate present. The added tetrahydroborate was decomposed by acid prior to the addition of mercury(II), to prevent it from interfering with the subsequent measurements. The treatment with tetrahydroborate was found to have no effect on the results. This indicates that all the iodine had been converted into iodide during the fusion process, which is interesting, because of the oxidizing conditions during the decomposition. Iodide is probably stabilized as sodium iodide during the fusion process.

Evaluation of results for seaweed

The seaweed sample was found to contain 0.51% iodine. The relative standard deviation of the method was 2–4%. Multiple digestions were performed, and multiple parallel analyses made for each digested sample. To check the accuracy of the method, the seaweed sample was also analysed by the instrumental neutron-activation method.[18] A value of 0.50% was obtained by this method, with a relative standard deviation of 2.8%. The good agreement between the two methods indicates that sodium hydroxide can be used successfully for the decomposition of seaweed without loss of iodine, when the procedure outlined in this work is followed. This is interesting, because iodine losses have been reported when sodium hydroxide was used for other biological matrices.[4,5] Potassium hydroxide was found to be equally useful, but apparently the decomposition is less complete with this reagent. The results show that a final temperature of 480° is sufficient for oxidizing the organic material in the sample, when the temperature is increased gradually. The total time needed for the decomposition was greatly reduced by adding the sodium hydroxide as the powdered solid instead of as a solution. Ayiannidis and Voulgaropoulos[8] found that the decomposition with potassium hydroxide was only satisfactory when potassium chloride was also added to the sample in relatively high concentration, to minimize iodide adsorption. The seaweed analysed here contained 8.5% chloride, so there was no need for any addition of chloride in this work. In spite of the oxidizing conditions, the iodine will be present as iodide in the final ash. The response of the indirect atomic-absorption method was found to depend on the oxidation state of the iodine, and the calibration curve must therefore be prepared from iodide solutions.

Analysis of table salt

It has been claimed that chloride does not interfere in this indirect atomic-absorption method.[3] However, we found that the shape of the calibration curve depended on the concentration of chloride in the sample solution. The effect of a large excess of chloride is illustrated in Fig. 3, which shows the calibration curves in the presence of 0.01 and 0.15M chloride, respectively. The concentration of tin(II) was 4.4mM in these experiments. The effect of chloride was less pronounced when a lower concentration of tin(II) was used. Thus, a calibration curve similar to Fig. 3A was obtained for 0.15M chloride, when the concentration of tin(II) was 1mM. In general, the effect of iodide on the mercury generation became more pronounced when the concentration of reductant was decreased.

The iodinated table salt analysed had a declared content of 5 ppm iodide. The molar ratio of chloride to iodide was therefore 4×10^5. When 2 g of this salt

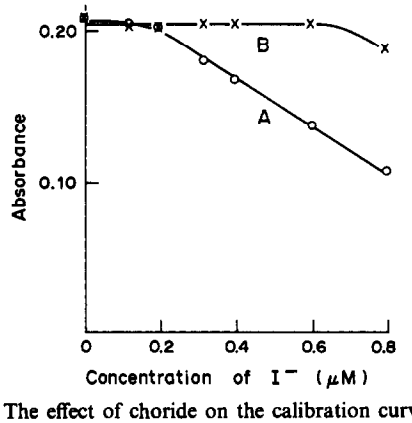

Fig. 3. The effect of choride on the calibration curve. The concentration of chloride was 0.01M in curve A, and 0.15M in curve B. The concentrations of Hg(II) and Sn(II) were 0.04μM and 4.4mM, respectively.

was dissolved to give 250 ml of solution, the resulting concentrations of chloride and iodide were *ca.* 0.14*M* and 0.3μM, respectively. Accordingly, iodide could be determined in iodinated table salt, provided that the concentration of tin(II) was 1m*M*, and that the calibration curve was prepared from standard solutions with the same concentration of chloride as the sample solution. In this work non-iodinated table salt from the same manufacturer was used for preparing the calibration curve. This allowed us to determine the amount of iodide added in the iodinated salt, which should correspond to the value declared by the manufacturer (the declared content did not include the iodide originally present in the salt). The amount of iodide obtained in this way was 4.9 ppm, which was close to the declared content of 5 ppm. The relative standard deviation of the results for eight 2-g samples of two different batches of the salt was 10.2%, whereas replicate analyses of each 2-g sample gave a relative standard deviation of *ca.* 2%, indicating that the iodide was somewhat inhomogeneously distributed in the table salt.

The content of iodide in non-iodinated table salt could not be determined by the present method, owing to the interference from chloride. According to Malvano *et al.*,[1] common salt contains from 0.06 to 1.1 ppm iodide.

SHORT COMMUNICATIONS

DETERMINATION OF ZIRCONIUM IN STEELS

C. S. P. IYER and T. P. S. ASARI
Analytical Chemistry Division, Bhabha Atomic Research Centre, Trombay, Bombay—400085, India

(*Received* 22 *April* 1988. *Revised* 20 *September* 1988. *Accepted* 7 *October* 1988)

Summary—The determination of zirconium in the range 0.01–0.20% is required for some special alloy steels. A method has been developed, based on initial removal of iron as its chloro-complex by extraction with methyl isobutyl ketone, followed by further extraction after addition of potassium thiocyanate, and determination of the zirconium left in the aqueous phase, with Arsenazo III. The absorbance is measured at 665 nm.

Zirconium is added to steels, in the range 0.01–0.20%, as a deoxidizer and a scavenger for nitrogen and sulphur.[1] The ASTM gravimetric method is based on initial precipitation of zirconium as cupferronate, followed by final weighing as the phosphate.[2] This is laborious and cannot be easily adopted for low concentrations of zirconium. Alternatively, zirconium can be determined spectrographically.[3]

Of the colorimetric reagents, pyridoxyl salicyloylhydrazone and Arsenazo III have been used for the determination of zirconium in steels.[4,5] Many ions interfere in the first case. In the second, where zirconium is first extracted with trioctylphosphine oxide (TOPO), the reproducibility is poor unless the experimental conditions are very closely adhered to. The method described here tries to overcome many potential interferences by the addition of potassium thiocyanate and extraction of the thiocyanate complexes into methyl isobutyl ketone (MIBK) prior to spectrophotometric determination of zirconium with Arsenazo III.

EXPERIMENTAL

Reagents

Standard zirconium solution (5 μg/ml). Dissolve 3.532 g of zirconyl chloride octahydrate and make up to 1 litre with 6*M* hydrochloric acid. Standardize the solution by precipitating zirconium hydroxide and igniting it to the oxide. Dilute the solution with 6*M* hydrochloric acid to give a concentration of 5 μg/ml. Prepare this working solution when required.

Standard molybdenum solution (1 mg/ml). Dissolve 0.2521 g of sodium molybdate dihydrate and make up to 100 ml with 6*M* hydrochloric acid.

Standard tungsten solution (1 mg/ml). Dissolve 0.1794 g of sodium tungstate dihydrate and make up to 100 ml with 6*M* hydrochloric acid.

Standard titanium solution (1 mg/ml). Fuse 0.1664 g of ignited titanium oxide with 2 g of potassium bisulphate. Cool and take up the melt in hydrochloric acid. Precipitate titanium hydroxide, filter it off and wash it with ammonium chloride solution. Dissolve the precipitate in hydrochloric acid, repeat the precipitation, and finally dissolve the hydroxide and make up to 100 ml with 6*M* hydrochloric acid.

Standard solution of niobium (20 μg/ml) in an iron-free steel-matrix. Dissolve 0.2 g of BCS steel 467 (Nb 1.06%) in 10 ml of concentrated hydrochloric acid and 1 ml of concentrated nitric acid. Evaporate the solution nearly to dryness on a boiling water-bath, add 10 ml of concentrated hydrochloric acid and evaporate to dryness. Repeat the addition and evaporation of hydrochloric acid, until all the nitrates are converted into chlorides. Take up the residue in 50 ml of 6*M* hydrochloric acid containing 1 g of tartaric acid. Transfer the solution to a 250-ml separating funnel and extract with two 50-ml portions of MIBK. Collect the aqueous layer in a 100-ml standard flask and make up to volume with 6*M* hydrochloric acid.

Arsenazo III solution. Dissolve 0.25-g of Arsenazo III [2,2′-(1,8-dihydroxy-3,6-disulphonaphthalene-2,7-diazodibenzenearsonic acid] in 95 ml of water containing 300 mg of anhydrous sodium carbonate, adjust the pH to 4.0 ± 0.1 with 6*M* hydrochloric acid and make up to 100 ml.

Procedures

Determination of Zr in steels. Weigh 1 g of sample and dissolve it in 25 ml of concentrated hydrochloric acid with the addition of a few drops of concentrated nitric acid. Evaporate the solution to dryness. Add 10 ml of concentrated hydrochloric acid and evaporate it. Repeat this operation twice. Take up the residue in 10 ml of 6*M* hydrochloric acid. Filter off the residue on a Whatman No. 540 paper with a little pulp and wash it with 6*M* hydrochloric acid. Transfer the filtrate and washings to a 200-ml separating funnel, rinsing with small portions of 6*M* hydrochloric acid. Adjust the volume to 50 ml with the same acid. Extract with two 50-ml portions of MIBK, rejecting the organic phase. Add 5 g of potassium thiocyanate dissolved in 6*M* hydrochloric acid and extract once more with 50 ml of MIBK. Transfer the aqueous phase to a 100-ml standard flask and make up to volume with 6*M* hydrochloric acid. Transfer an aliquot containing 5–20 μg of zirconium to a 50-ml standard flask. Dilute to approximately 40 ml with 6*M* hydrochloric acid, add 1 ml of Arsenazo III solution and make up to volume. After 5 min measure the absorbance at 665 nm. Run a blank determination, using the same reagents and procedure, except for the sample. Read the zirconium content from the calibration curve.

Calibration curve. Take portions of standard zirconium solution equivalent to 0, 5, 10, 15 and 20 μg of Zr, in 50-ml standard flasks, dilute each to approximately 40 ml with 6*M*

Table 1. Error caused by interfering elements in the determination of 5 μg of zirconium

Interfering elements	Quantity added	Absorbance at 665 nm
—	—	0.133
Mo	0.5–2.0 mg	0.133
Ti	0.1–0.4 mg	0.134
W	0.1–0.4 mg	0.134
Nb	20–50 μg	0.134
Nb	100 μg	0.143
Nb	200 μg	0.148
Mo + Nb	2 mg + 50 μg	0.133
W + Nb	0.4 mg + 50 μg	0.122
Ti + Nb	0.4 mg + 50 μg	0.128
Mo + W	2.0 mg + 0.4 mg	0.133
Mo + Ti	2.0 mg + 0.4 mg	0.133
Ti + W	0.4 mg + 0.4 mg	0.133
Mo + W + Ti	2.0 mg + 0.4 mg + 0.4 mg	0.133
Mo + Ti + W + Nb	2.0 mg + 0.4 mg + 0.4 mg + 50 μg	0.115

hydrochloric acid, add 1 ml of Arsenazo III solution, dilute to volume and measure as above.

Recovery of zirconium

It was thought possible that loss of zirconium could occur during the MIBK extraction, by entrainment of aqueous phase. This was examined by adding ^{95}Zr–^{95}Nb tracer to a solution of BCS 332 standard steel, applying the extraction procedure, combining all the organic phases and measuring the ^{95}Zr activity at 724.2 keV with a Ge(Li) detector. The activity in the organic phase was found to be about 0.4% of the initial activity, so the loss of zirconium is negligible at the levels used.

RESULTS AND DISCUSSION

Interferences

The elements which are found to interfere in the Arsenazo III method for zirconium are iron, molybdenum, niobium, titanium and tungsten. Iron can be quantitatively removed as the chloro-complex, by extraction with MIBK. In earlier methods the extraction was done with diethyl ether and residual traces of Fe(III) were reduced to Fe(II) with a precise amount of ascorbic acid (as excess causes serious interference). In the present case, there is no need to add any reducing agent after the extraction with MIBK.

The other interfering elements were examined by adding them to a solution of 1 g of standard steel BCS 332 (which does not contain Zr, Nb, Mo, W, Ti) in 6*M* hydrochloric acid. After extraction twice with MIBK, the aqueous phase was made up to 100 ml with 6*M* hydrochloric acid. Aliquots were taken, and different quantities of interfering element (Mo, Nb, Ti, W) were added along with a known quantity of Zr, followed by Arsenazo III, the acidity being maintained at 6*M* hydrochloric acid.

Mo, Nb, Ti and W were found to cause serious interference. All four are known to form thiocyanate complexes[6] which are extractable into MIBK.[7] Hence the method was modified by inclusion of addition of potassium thiocyanate and extraction with MIBK. The results given in Table 1 show that Mo, Ti and W can be tolerated individually or in combination up to a few mg. Nb can be tolerated only up to 50 μg in the aliquot taken, when present alone or in combination with Mo. However, in combination with Ti or W, Nb interferes even at the 50 μg level.

Table 2. Analysis of steels

Standard steel		Zirconium, % Certified value	Spectrographic value	Present method
DMRL	M–5		0.150	0.150
	M–10		<0.01	0.0005
	M–12		0.045	0.048
	M–13		0.100	0.114
	M–14		0.250	0.280
	M–15		0.035	0.036
BCS	459/1	0.072		0.070
	G/2	0.13		0.13

Application

The method was applied to a number of Defence Metallurgical Research Laboratory (DMRL) low-alloy steel standards and also to two BCS standards; 459/1 (Carbon steel) and G/2 (Standard steel). The values obtained were compared with the spectrographic values for the low-alloy steels and the certified values for the BCS standards, and found satisfactory. Standard additions of Zr were made to one of the solutions of the steel standards, along with Mo, Ti and W. The recovery was greater than 95%. The coefficient of variation for 5 μg of Zr was 7%. In conclusion, the method is reasonably simple and involves clean separations by solvent extraction instead of the cumbersome cupferron and phosphate precipitation. The sensitivity of the method is high enough for traces of Zr to be determinable. The accuracy and precision are reasonable. A set of six determinations takes about 6 hr.

SELECTIVE ION-EXCHANGER BEHAVIOUR OF NEUTRAL CARRIER ION-SELECTIVE ELECTRODE MEMBRANES

G. HORVAI, V. HORVÁTH, A. FARKAS and E. PUNGOR
Institute for General and Analytical Chemistry, Technical University, Gellért ter 4, 1502 Budapest XI, Hungary

(*Received* 16 *June* 1988. *Revised* 19 *August* 1988. *Accepted* 7 *October* 1988)

Summary—Radiotracer experiments confirm that neutral carrier ion-selective electrodes made from plasticized PVC are low-capacity selective ion-exchangers. The ion-exchange selectivity is closely correlated to potentiometric selectivity.

Neutral carrier ion-selective electrodes (ISEs) are widely used in analytical chemistry. The best known applications are in the clinical and biochemical field, where blood and urine electrolytes, *e.g.*, sodium, potassium and calcium, are routinely determined by means of neutral carrier ISEs.[1,2]

Electrode membranes are usually cast from a tetrahydrofuran solution of poly(vinyl chloride) (PVC), plasticizer and neutral carrier. A typical w/w composition would be 33% PVC, 66% plasticizer and 1% neutral carrier.

Neutral carrier ISEs usually give Nernstian response to the measurable ions. Their selectivity is mainly determined by the choice of neutral carrier, *e.g.*, valinomycin makes the electrodes highly selective for potassium relative to sodium and many other ions.

A formidable task for electroanalytical chemists has been to elucidate the mechanism of the selective potentiometric behaviour of neutral carrier ISEs. It is believed that the carrier (or a pair of carrier molecules) traps the cation to be measured, by co-ordinating electron-rich groups to it. The hydrophobic groups remain on the outer side of the complex, and thus the whole complex can be solvated by the organic phase.

The concentration of primary ions trapped in the membrane by carrier molecules can be measured by radiotracer techniques.[3,4] A membrane with a valinomycin concentration of $10^{-2}M$ has been found to trap potassium at a concentration of about $5 \times 10^{-4}M$ from a $10^{-3}M$ aqueous solution of potassium chloride. It was observed, however, that chloride ions were not exchanged at all between the membrane and the bathing solution, so it was concluded that the membrane behaved as a cation-exchanger.

The idea that neutral carrier ISEs are in fact selective low-capacity ion-exchangers was proposed a long time ago by Kedem *et al.*[5] Sufficient experimental evidence with respect to PVC-based membranes has been lacking, however. The purpose of the present work is to provide that evidence. Two aspects of ion-exchange have been investigated: the non-dependence of the ion-exchange capacity on the salt concentration in the bathing solution, and the selectivity of ion-exchange.

The radiotracer method was used. A thorough study of liquid ion-exchanger type ion-selective electrodes has been made by this method,[6–10] whereas similar studies related to neutral carrier membranes have been less extensive. It has been shown[3,4] that the latter type of membrane can exchange cations with the bathing solution, while anion-exchange is almost negligible. There have been no data presented for these membranes, however, to show whether the ion-exchange capacity is dependent on the solution concentration or not. Ion-exchange selectivity due to the presence of the neutral carrier has not been shown experimentally either.

EXPERIMENTAL

Plasticized PVC membranes were made as described by Craggs *et al.*[11] They contained 0.5% valinomycin (Fluka), 33% PVC (Corvic S 704, from ICI) and 66.5% bis(2-ethylhexyl) sebacate (Fluka). Disks 17 mm in diameter were cut from the 0.2–0.3 mm thick membranes. All other chemicals were analytical grade. Water was doubly distilled in fused silica apparatus.

^{137}CsCl tracer solutions were obtained by dilution of a $10^{-2}M$ solution of 0.32 MBq/l. activity. Beta radiation was detected with an ND 304 scintillation detector (Gamma Works, Hungary) attached to an NK 225/8 counter (KFKI, Hungary). The measured counts were corrected for the self-absorption of the membranes, which was determined experimentally by covering an active sample with an inactive membrane.

To study the ion-exchange behaviour of the membranes, individual membranes were soaked in the radioactive bathing solution held in a plastic container. The radioactivity of the membranes was checked from time to time until no more change occurred (this usually took two days of soaking). Activity measurements had to be made with dry membranes. Therefore the membranes were quickly washed with distilled water and dried on filter paper before counting.

Ion-exchange capacity was expressed as the number of moles of caesium taken up by 1 kg of membrane material. This is approximately equal to the molar concentration, because the membrane density is very close to 1 kg/l.

Membranes identical in composition to those used in this study have also been used in ISEs. The response to caesium chloride solutions was close to Nernstian and the selectivity for potassium relative to caesium was quite low (log $K^{pot}_{K,Cs} = -0.3$).

RESULTS AND DISCUSSION

Ion-exchange capacity

The membranes studied show a marked uptake of caesium from caesium chloride solution. To show that this uptake is due to ion-exchange we have determined the caesium uptake from a wide concentration range of bathing solutions, 10^{-5}–$10^{-2}M$. Ion-exchange materials are expected to have a constant exchange capacity over a wide concentration range. Figure 1 shows that the caesium uptake changes only very slowly with the caesium chloride concentration in the bathing solution. It changes by a factor of only 3 when the concentration of the bathing solution is changed by three orders of magnitude. This behaviour is not exactly what is expected from an ideal ion-exchanger but it is very close to it. The increase in capacity at high solution concentration may be attributed to breakdown of Donnan equilibrium.[12] The decrease in capacity at low solution concentration might be connected with the detection limit of the electrodes, which is between 10^{-5} and $10^{-6}M$ caesium chloride.

From earlier results[3] and those shown above it can be accepted that the neutral carrier ISE membrane is a low-capacity ion-exchanger. In a related recent work[13] it was shown that simple inorganic salts incorporated into plasticized PVC membranes can turn them into low-capacity ion-exchangers. It is believed that the ion-exchange behaviour found in this work can be attributed to ionizable contaminants in the membranes. Evidence for such contamination in the chemicals normally used for ISE membrane preparation is available.[14] The mechanism by which the ionizable contaminants work as ion-exchangers has not yet been clarified.

The data shown in Fig. 1 were obtained with a single membrane. Curves obtained with four other

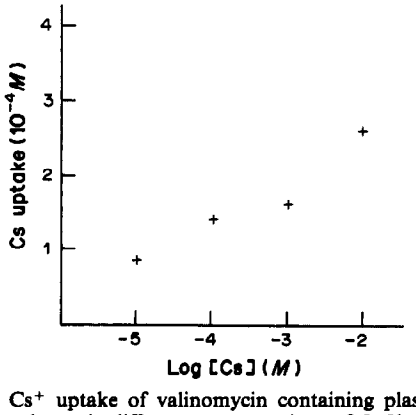

Fig. 1. Cs^+ uptake of valinomycin containing plasticized PVC membrane in different concentrations of CsCl soaking solution.

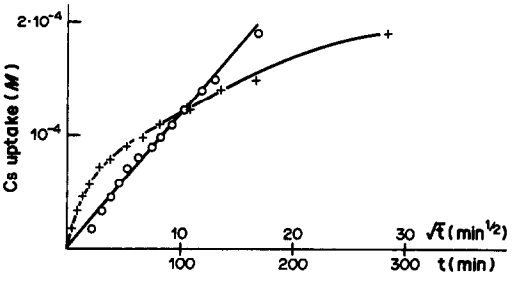

Fig. 2. Time dependence of Cs uptake of a valinomycin containing plasticized PVC membrane.

membranes were similar in character but the actual ion-exchanger capacities (at $10^{-3}M$ caesium chloride concentration) varied by a factor of 2.5. This again may be attributed to the ion-exchange capacity being due to uncontrolled contamination. The radiotracer measurements of the ion-exchange capacity cannot be blamed for the observed wide variation of the results. This has been proved by measuring the ion-exchange capacity of a membrane containing a deliberately added contaminating exchanger, potassium tetrakis-(*p*-chlorophenyl)borate. The estimate by the radiotracer method ($2.43 \times 10^{-3}M$) agreed fairly well with the true value of $2.56 \times 10^{-3}M$.

The rate of uptake of labelled Cs by a membrane is shown in Fig. 2. The linear relation to the square root of the time indicates a diffusion process.

Ion-exchange selectivity

Once it had been shown that neutral carrier ISE membranes are low-capacity ion-exchangers, it was of much interest to prove that they are also selective, and that their ion-exchange selectivity is closely related to their potentiometric selectivity.

Ion-exchange selectivity can be tested in a number of ways. We have adopted here a very simple test. A membrane was soaked in an aqueous solution containing equal molar concentrations of caesium chloride and another metal chloride, MCl. If the ion-exchange is non-selective, then half the exchange sites will be occupied by caesium and the other half by M ions. This means that the uptake of caesium will be only 50% of the caesium uptake from a pure caesium chloride solution. If caesium is preferred by the ion-exchanger then the apparent ion-exchange capacity for caesium will be more than 50% of that for a pure caesium solution; if the ion M is preferred it will be less than 50%.

Table 1 shows the measured apparent exchange capacity for caesium as a fraction of the total capacity. Three cations have been tested for ion-exchange selectivity: potassium, ammonium and sodium. Potentiometric selectivity coefficients for these ions are also shown in Table 1. It is seen that the valinomycin-containing membrane is a selective ion-exchanger. It prefers potassium to caesium on the one hand, and caesium to ammonium and sodium on the other. In fact the table also shows that the ion-exchange select-

Table 1. Apparent caesium exchange capacity in mixed solutions of chloride salts

MCl	C_{MCl}, mM	C_{CsCl}, mM	Exchange %*	log $K^{pot}_{Cs,M}$
KCl	1	1	41.9	0.3
NH_4Cl	1	1	86.3	−1.63
NaCl	0.1	0.1	100	−2.53

*Exchange % is the apparent exchange capacity for caesium, determined by the radioactive tracer method in a mixed salt solution, expressed as a percentage of the total exchange capacity found with pure CsCl solution.

ivity for caesium relative to ammonium is less than that for caesium relative to sodium. All this is in good agreement with the potentiometric selectivities.

Work in progress indicates that ISE membranes with different neutral carriers and with or without deliberately added ion-exchangers such as sodium tetraphenylborate are selective ion-exchangers and their ion-exchanger selectivity constant is equal to the potentiometric selectivity coefficient.

Conclusion

It has been confirmed that the widely used neutral carrier ISE made from valinomycin and plasticized PVC is a low-capacity selective ion-exchanger. The capacity is about $10^{-4}M$. The ion-exchange selectivity closely parallels the potentiometric selectivity.

ION-PAIR EXTRACTION OF Co(II) BY CROWN ETHERS FROM PERCHLORATE MEDIUM

SALAH M. KHALIFA and HISHAM F. ALY
Hot Laboratory Centre, Atomic Energy Authority, 13759 Cairo, Egypt

JAMES D. NAVRATIL

(*Received* 27 *July* 1988. *Accepted* 7 *October* 1988)

Summary—The extraction of cobalt(II) by chloroform solutions of the crown ethers (CE) 12C4, 15C5, 18C6, Db18C6, Dch18C6 or Dch24C8 from aqueous perchlorate medium was investigated. Slope analysis of the experimental data suggested that the extraction of Co(II) by these CEs takes place through ion-pair formation, and that the chemical formula of the main extracted species is $Co(OH)^+ClO_4^- \cdot CE$. The magnitudes of the extraction constants are in the sequence 18C6 > Dch18C6 > Dch24C8 > Db18C6 > 15C5 > 12C4, which is discussed in terms of the correspondence between the CE cavity size and the ionic radius of cobalt(II).

Crown ethers (CE) have been used for the extraction of univalent ions by ion-pair or adduct formation.[1–6] The cavity size of the crown ether plays a main role in the extraction; in many cases the metal ions are most easily extracted when there is a match in size between the metal ion and the cavity of the CE. This concept was found not to apply[7] when cobalt(II) was extracted synergically by crown ethers together with thenoyltrifluoroacetone. In this case, the stability of the extracted species increased with increase in the basicity of the crown ether used and the number of oxygen donor atoms. The present work aims to investigate the extraction of cobalt(II) by crown ethers alone from aqueous perchlorate medium and to find the effect of the cavity size of the CEs on the extraction constant.

EXPERIMENTAL

Materials

The crown ethers 1,4,7,10-tetraoxacyclododecane (12C4), 1,4,7,10,13-pentaoxacyclopentadecane (15C5), 1,4,7,10,13,16-hexaoxacyclo-octadecane (18C6), 2,5,8,15,18,21-hexaoxatricyclo(20,4,0,0)hexacosane (Dch18C6), 2,3,11,12-dibenzo-1,4,7,10,13,16-hexaoxacyclo-octadeca-2,11-diene (Db18C6) and 2,5,8,11,18,21,24,27-octaoxatricyclo(26,4,0,0)dotriacontane (Dch24C8) were Fluka products and used without purification. All the other reagents used were of analytical purity grade and obtained from BDH and Merck. Cobalt-60 was prepared locally by neutron activition of analytical grade cobalt carbonate.

Procedure

The aqueous phase was an acetate buffer solution having constant ionic strength of 0.1 (H^+, $NaClO_4$) and the pH was changed by varying the acetic acid–sodium acetate ratio. The metal concentration in the aqueous phase was less than $10^{-5}M$ Co(II) tracer. The organic phase was chloroform containing a known concentration of the crown ether being used.

Equal volumes (7 ml) of the aqueous and organic phases (each presaturated with the solvent medium of the other) were mixed and shaken for 25 min at 25 ± 1°. The concentration of the cobalt species in the two phases was assayed radiometrically with a gamma-counting system of a well-type NaI(Tl) detector and an Ortec single-channel analyser.

The distribution ratio (D) was determined by using the general equation;

$$D = \frac{\bar{A}V}{A\bar{V}}$$

where $\bar{A}$ and A refer to the activities in the organic and aqueous phases, respectively, and V and $\bar{V}$ are the aqueous and organic volumes.

For lower metal distribution ratios, the counting technique was adjusted by increasing the volume and counting time of the organic phase, as well as the number of determinations, to minimize the statistical error in the counting to $< \pm 2\%$.

RESULTS AND DISCUSSION

The different factors (f) affecting the extraction of Co(II) by the six CEs tested were investigated and presented as log D *vs.* log f relationships, Figs. 1–3. Slope analysis[6,8] gave slopes of −1 for the dependence on hydrogen-ion concentration, +1 for the dependence on CE concentration and +1 for the dependence on perchlorate concentration, for all the crown ethers investigated.

On the basis of this information, as well as the experimental conditions used (which justify assumption of the presence of $[Co(OH)]^+$),[9] the extraction equilibrium can be represented as

$$Co^{2+} + H_2O + ClO_4^- + \overline{CE} \rightleftharpoons \overline{Co(OH)^+ \cdot (ClO_4^-) \cdot CE} + H^+$$

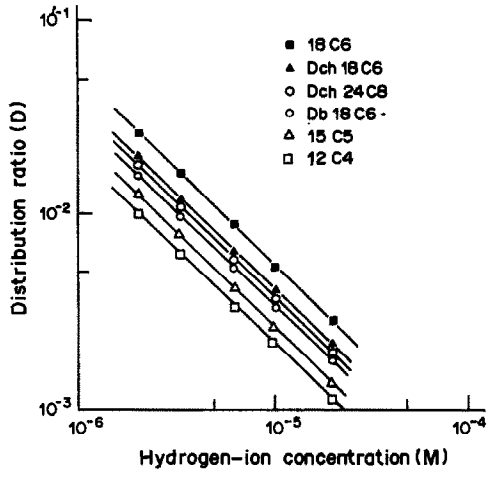

Fig. 1. Effect of the hydrogen-ion concentration on the extraction of Co(II) by crown ethers (0.05*M*) in chloroform from perchlorate aqueous media at constant ionic strength 0.1 (H^+, $NaClO_4$).

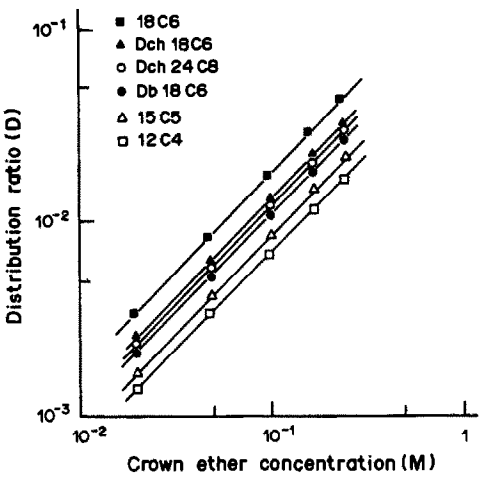

Fig. 2. Effect of crown ether concentration in chloroform on the extraction of Co(II) from perchlorate aqueous medium at constant ionic strength 0.1 (H^+, $NaClO_4$) and pH 5.2.

with an extraction constant (K_{ex}) given by

$$K_{ex} = \frac{D[H^+]}{[ClO_4^-][CE]}$$

where

$$D = \frac{\overline{[Co(OH^+)\cdot ClO_4^- \cdot CE]}}{[Co^{2+}]}$$

and the barred symbols refer to the organic phase.

The K_{ex} values calculated for the different CEs are given in Table 1, together with the cavity diameter of the crown ether used.[10]

The sequence of K_{ex} values obtained, as related to the CEs investigated, is 18C6 > Dch18C6 > Dch24C8 > Db18C6 > 15C5 > 12C4. This sequence indicates that the cavity size of the CEs plays the main role in the extraction, the highest extraction of cobalt being achieved with Dch18C6 and 18C6 (cavity diameter 2.6–3.2 Å).

Lower extraction constants were obtained for the smaller cavity crown ethers 12C4 and 15C5 (1.2–1.5 and 1.7–2.2 Å) and the larger cavity crown ether Dch24C8 (4.5–5.6 Å). This trend is different from that previously reported by us[7] for extraction of cobalt(II) as an adduct of its thenoyltrifluoroacetone (HTTA) complex with these CEs, where the extraction constants increased with increase in the number of oxygen donor atoms in the CE. Therefore, it might be concluded that when cobalt is extracted as an ion-pair, $Co(OH)^+ \cdot CE \cdot ClO_4^-$, the cavity size of the CE is a main factor in the extraction of the metal ion,[1-4] whereas when the extraction takes place through adduct formation, $Co(TTA)_2 \cdot CE$, the CE acts mainly as an electron-donor ligand and its cavity

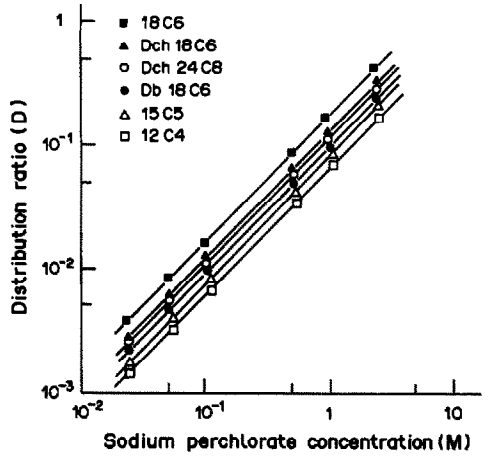

Fig. 3. Effect of sodium perchlorate concentration on the extraction of Co(II) by crown ethers (0.05*M*) in chloroform from aqueous perchlorate media at pH 5.2.

Table 1. Extraction of Co(II) by different crown ethers in chloroform from aqueous perchlorate medium at constant ionic strength, 0.1 (H^+, $NaClO_4$) and pH 5.2 (acetate buffer)

Species extracted	Extraction constant	Cavity diameter, Å
$Co(OH)^+ \cdot ClO_4^- \cdot 12C4$	$(4.16 \pm 0.11) \times 10^{-6}$	1.2–1.5
$Co(OH)^+ \cdot ClO_4^- \cdot 15C5$	$(4.92 \pm 0.13) \times 10^{-6}$	1.7–2.2
$Co(OH)^+ \cdot ClO_4^- \cdot Db18C6$	$(6.56 \pm 0.16) \times 10^{-6}$	2.6–3.2
$Co(OH)^+ \cdot ClO_4^- \cdot Dch24C8$	$(7.07 \pm 0.15) \times 10^{-6}$	4.5–5.6
$Co(OH)^+ \cdot ClO_4^- \cdot Dch18C6$	$(7.57 \pm 0.19) \times 10^{-6}$	2.6–3.2
$Co(OH)^+ \cdot ClO_4^- \cdot 18C6$	$(10.73 \pm 0.24) \times 10^{-6}$	2.6–3.2

size is of minor importance. However, the extraction constant for the Db18C6 ion pair seems anomalous, since Db18C6 has the same cavity size as Dch18C6 and 18C6. This decrease in K_{ex} for cobalt, in the order 18C6 > Dch18C6 > Db18C6, can be explained in terms of the electron-withdrawing and weak electron-donating abilities of the dibenzo and dicyclohexyl substituents, respectively, which affect the basic character of the adjacent crown-ether oxygen donor atoms.[7,11]

ANALYTICAL DATA

ON THE PROTONATION EQUILIBRIA OF SEPHADEX C-25 AND C-50

ERIK HÖGFELDT, TOHRU MIYAJIMA and MAMOUN MUHAMMED
Department of Inorganic Chemistry, The Royal Institute of Technology, S-100 44, Stockholm, Sweden

(*Received* 3 *March* 1988. *Revised* 16 *June* 1988. *Accepted* 27 *October* 1988)

Summary—The system H^+–Na^+ has been studied on Sephadex C-25 and C-50 at two ionic strengths by potentiometry. The data have been fitted by the Högfeldt three-parameter model. For ionic strength 0.100*M* (Na)ClO_4 an excellent fit is obtained with a standard deviation of ±0.013 for both gels. For ionic strength 0.010*M* (Na)ClO_4 a satisfactory fit could only be obtained by excluding the lowest and highest pH-value for each gel.

Recently Miyajima *et al.*[1] studied the neutralization of Sephadex gels at two ionic strengths and 298.2 K in order to apply an approach reported by Marinsky[2–11] for treating ion-binding in polyelectrolyte gels. The data obtained can also be used to test a recently developed three-parameter model for fitting thermodynamic and other molar properties of liquid and solid ion-exchangers.[12–15]

TREATMENT OF DATA

Free energy

The model is applicable to both solid and liquid binary mixtures. In the present case it will be applied to free energies in the system H^+–Na^+ on Sephadex C-25 and C-50.

Consider the reaction

$$H^+ + NaR \rightleftharpoons HR + Na^+ \quad (1)$$

where R^- is the cation-exchanging group in the gel.

The equilibrium quotient of reaction (1) is defined by

$$\kappa = \frac{[HR][Na^+]}{[NaR][H^+]} = \frac{(1-\alpha)[Na^+]}{\alpha[H^+]} \quad (2)$$

where α is the fraction of the gel phase in sodium form:

$$\alpha = \frac{[NaR]}{[NaR] + [HR]} \quad (3)$$

The concentration of sodium ions in the aqueous phase is obtained from

$$[Na^+] = I - 10^{-pH_c} \quad (4)$$

where I = ionic strength in the aqueous phase and $pH_c = -\log[H^+]$; $[H^+]$ is the hydrogen-ion concentration in the ionic medium used, obtained by calibrating the glass electrode in terms of $[H^+]$ instead of using the more or less uncertain estimates of proton activity in the actual solution that are obtained by calibrating with standard buffers in a very different ionic medium.

It is assumed that the ratio of the activity coefficients of the two cations in the aqueous phase is kept constant by the ionic medium. This is a fair assumption for singly charged ions. According to the model

$$\log \kappa = \log \kappa(Na)\,\alpha + \log \kappa(H)(1-\alpha) + \bar{B}\alpha(1-\alpha) \quad (5)$$

where $\kappa(Na)$ is the limiting value of κ when $\alpha = 1$ and $\kappa(H)$ that for $\alpha = 0$; $\bar{B}$ is an empirical constant related to the third parameter of the model, κ_m, by

$$\log \kappa_m = \tfrac{1}{2}[\log \kappa(H) + \log \kappa(Na) + \bar{B}] \quad (6)$$

The model implies that a binary mixture of components A and B can be regarded as divided into three parts, one with the properties of pure A, one with the properties of pure B and one with the properties of the mixture. The amount of each part is given by the number of A–A pairs, B–B pairs and A–B pairs in the mixture, assuming random distribution of the pairs, *i.e.* Guggenheim's zeroth approximation.[16]

In the present case $\log \kappa(Na)$ and $\log \kappa(H)$ refer to pure NaR and pure HR, and $\log \kappa_m$ refers to the mixture. By integration of equation (5) and use of equation (6) the following expression is obtained for the integral free energy expressed as a thermodynamic equilibrium constant, K,

$$\log K = \int_0^1 \log \kappa \, d\alpha = \tfrac{1}{3}[\log \kappa(H) + \log \kappa(Na) + \log \kappa_m] \quad (7)$$

Excess of free energy

The application of the model can be further illustrated by calculating the activity coefficients of HR and NaR in the gel phase. The concentration

scale is the ionic fraction, α. The standard and reference states are the pure ionic forms.

The second degree polynomial, equation (5), can also be written as

$$\log \kappa = a + b\alpha + c\alpha^2 \quad (8)$$

From this expression, the Gibbs–Duhem equation and

$$K = \kappa(f_{HR}/f_{NaR}) \quad (9)$$

the following expressions are obtained for the activity coefficients:

$$\log f_{HR} = -\tfrac{1}{2}b\alpha^2 - \tfrac{2}{3}\alpha^3 \quad (10)$$

$$\log f_{NaR} = -\tfrac{1}{2}(b+2c)(1-\alpha)^2 + \tfrac{2}{3}c(1-\alpha)^3 \quad (11)$$

It is interesting to note that for $c = 0$ (*i.e.*, $\log \kappa = f(\alpha)$ is a straight line) the activity coefficient expressions become those for a regular solution.

$$\log f_{HR} = -\tfrac{1}{2}b\alpha^2 \quad (12)$$

$$\log f_{NaR} = -\tfrac{1}{2}b(1-\alpha)^2 \quad (13)$$

It deserves to be mentioned that these equations (12) and (13) were used by Kielland[17] to obtain $\log K$ for systems where $\log \kappa$ could be approximated by a straight line as a function of $\bar{x}$, the ionic fraction used as the independent variable.

The two expressions (10) and (11) are easily obtained from the parameters of the model by using $a = \log \kappa(H)$; $b = 2[\log \kappa_m - \log \kappa(H)]$; $c = \log \kappa(Na) + \log \kappa(H) - 2 \log \kappa_m$.

These expressions are obtained by setting equation (5) equal to equation (8) and equation (6) to eliminate $\bar{B}$.

RESULTS

In Tables 1–4, experimental and computed pH_c-values are compared. The latter were obtained

from

$$pH_c(\text{calc}) = \log \kappa_{\text{calc}} - \log\left(\frac{1-\alpha}{\alpha}\right) - \log[Na^+] \quad (14)$$

$\log \kappa_{\text{calc}}$ was computed from equation (5), with the parameters given in Table 5 and obtained by a least-squares fit to the experimental data for $\log \kappa$, α. In Tables 1–4 some quantities obtained by statistical analysis of the residuals are also given.

In Figs. 1 and 2, experimental and calculated $\log \kappa$-values are compared. In Fig. 3 $\log f_{HR}$ and $\log f_{NaR}$ are plotted against α for Sephadex C-25 and $I = 0.100M$ (Na)ClO_4. From the data in Table 5 the following expressions were obtained:

$$\log f_{HR} = -(0.343 - 0.06\alpha)\alpha^2 \quad (15)$$

$$\log f_{NaR} = -(0.313 - 0.06\alpha)(1-\alpha)^2 \quad (16)$$

Figure 3 emphasizes the fact that the system behaves in a rather non-ideal manner because, in terms of the model, $\log \kappa$ is very different for each part of the mixture; $\log \kappa$(Na) and $\log \kappa$(H) differ by about one (see Table 5).

CONCLUDING REMARKS

The excellent fit to the model obtained for $I = 0.100M$ over a pH_c range of about 3.5 strongly supports the model. Moreover, it also supports the correctness of the Stockholm school definition of pH as $-\log[H^+]$ in the medium used; this has

been adopted by oceanographers for defining pH in sea-water.[18]

The poorer fit at $I = 0.010M$ and the need for exclusion of the first and last points in each data set is likely to be due to experimental difficulties at this lower ionic strength. An important feature of the model is that the limiting values log κ(H) and log κ(Na) are obtained from data for which the experimental uncertainty is small, *i.e.*, for data obtained at around $\alpha = 0.5$.

It should be mentioned that an equation equivalent to equation (5) has been obtained by Marton and Inczédy by applying electrolyte theory to the ion-exchange process.[19]

STUDIES ON FLUORESCEIN—VI*

ABSORBANCE OF THE VARIOUS PROTOTROPIC FORMS OF YELLOW FLUORESCEIN IN AQUEOUS SOLUTION

HARVEY DIEHL
Department of Chemistry, Iowa State University, Ames, IA 50011, U.S.A.

(*Received* 1 *April* 1987. *Revised* 20 *September* 1988. *Accepted* 21 *October* 1988)

Summary—The absorbance of yellow fluorescein in water, at ionic strength 0.10, as a function of pH at 437, 455, 464, 475 and 490 nm has been resolved into four components, the absorbances of the individual prototropic forms of fluorescein in water. The molar absorptivity of each species at each of the five wavelengths is reported. A novel type of isosbestic point is described.

The preceding paper of this series reported the absorbance of purely aqueous solutions of yellow fluorescein at ionic strength 0.10 over the pH range 0.15–8.70 at five different wavelengths, and the absorbance at 437 nm was used for calculating the molar absorptivity of each of the four fluorescein species present. Corresponding calculations and results for the measurements at the other wavelengths are now reported.

The calculation is based on the assumptions: (1) that four species (the prototropic forms H_3Fl^+, H_2Fl, HFl^-, Fl^{2-}) and only four are present; (2) that each species conforms to the Beer–Lambert law; (3) that the system conforms at each wavelength to the additivity law

$$A_{\lambda,pH} = \vec{A}_{H_3Fl}\alpha_{H_3Fl} + \vec{A}_{H_2Fl}\alpha_{H_2Fl} + \vec{A}_{HFl}\alpha_{HFl} + \vec{A}_{Fl}\alpha_{Fl} \quad (1)$$

Here the $\vec{A}$-quantities are the working absorptivities at a given total concentration of fluorescein, the superscript arrows being redundancy markers serving as a reminder that these are constants which must be evaluated. The α-quantities are the fractions of the prototropic forms as calculated from the dissociation constants. The symbolism used is that of our earlier papers, in which the charges on the subscripts have been dropped to avoid confusion. Thus, a set of three dissociation constants defines the equilibria of the system over the entire pH range, and at each wavelength a set of four working absorptivities establishes the absorbance.

For a given set of dissociation constants and a constant total concentration throughout, the α-values are calculated from

$$\frac{1}{\alpha_{H_3Fl}} = 1 + \frac{K_{H_3Fl}}{[H^+]} + \frac{K_{H_3Fl}K_{H_2Fl}}{[H^+]^2} + \frac{K_{H_3Fl}K_{H_2Fl}K_{HFl}}{[H^+]^3} \quad (2)$$

$$\frac{1}{\alpha_{H_2Fl}} = \frac{[H^+]}{K_{H_3Fl}} + 1 + \frac{K_{H_2Fl}}{[H^+]} + \frac{K_{H_2Fl}K_{HFl}}{[H^+]^2} \quad (3)$$

$$\frac{1}{\alpha_{HFl}} = \frac{[H^+]^2}{K_{H_3Fl}K_{H_2Fl}} + \frac{[H^+]}{K_{H_2Fl}} + 1 + \frac{K_{HFl}}{[H^+]} \quad (4)$$

$$\frac{1}{\alpha_{Fl}} = \frac{[H^+]^3}{K_{H_3Fl}K_{H_2Fl}K_{HFl}} + \frac{[H^+]^2}{K_{H_2Fl}K_{HFl}} + \frac{[H^+]}{K_{HFl}} + 1 \quad (5)$$

For a given set of dissociation constants, α_i was calculated for each species at the pH of each solution measured (Table 2 of the preceding paper). Multiple regression was applied to the absorbance at each wavelength and the α_i values; that is, a four-variable, least-squares treatment was applied in accordance with equation (1). This regression provided, at each wavelength, a set of working absorptivities, from which the total absorbance was calculated [equation (1) again]. The fit of each calculated absorbance *vs.* pH curve to the observed data was assessed by plotting (*e.g.*, Fig. 2), and more accurately by calculating, the difference between the two values at each pH. The standard deviation of these differences was then used as a criterion of fit.

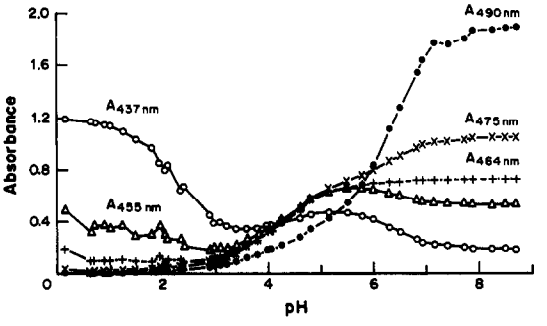

Fig. 1. Absorbance of yellow fluorescein in water solution at five wavelengths, as a function of pH, Ionic strength 0.10. Total concentration of fluorescein, $2.407 \times 10^{-5}M$.

*Part V—H. Diehl and N. Horchak-Morris, *Talanta*, 1987, **34**, 739.

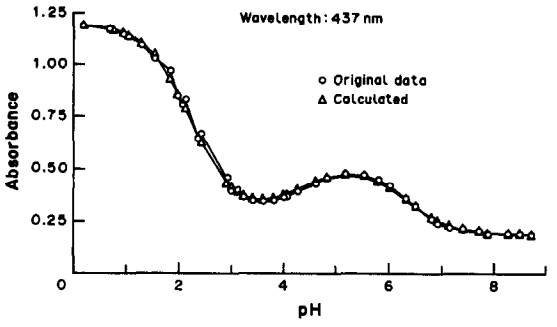

Fig. 2. Fit of observed and calculated absorbance *vs.* pH curves at 437 nm. Fluorescein, $2.407 \times 10^{-5}M$. Water only as solvent; $\mu = 0.10$. Calculation based on $pK_{H_3Fl} = 2.19$, $pK_{H_2Fl} = 4.24$, $pK_{Fl} = 6.33$.

The entire calculation was repeated with a new set of dissociation constants. With the second and third dissociation constants held constant, the first constant was varied, in steps of 0.02 over the range $pK_{H_3Fl} = 2.13$–2.25. A similar calculation was made with the second constant varied over the range $pK_{H_2Fl} = 4.20$–4.48, and another for pK_{HFl} varied over the range 6.30–6.38.

Minima were found in plots of the standard deviation of fit *vs.* the dissociation constant being varied. Variation in the first and second constants had a great effect on the fit of A_{437nm} and A_{455nm} but much less on the fit of A_{475nm} and A_{490nm}. On the other hand variation in the third dissociation constant had a great effect on the fit of A_{490nm} but very little on the fit of A_{437nm} and A_{455nm}. This is a consequence of the changing contribution of the absorbances of the individual prototropic forms to the total spectra.

The results of the numerous regressions led to a set of best values for the dissociation constants: $K_{H_3Fl} = 6.46 \times 10^{-3}$ ($pK_{H_3Fl} = 2.19$), $K_{H_2Fl} = 5.75 \times 10^{-5}$ ($pK_{H_2Fl} = 4.24$), $K_{HFl} = 4.68 \times 10^{-7}$ ($pK_{HFl} = 6.33$) and values for the working absorptivities of each of the four prototropic forms at each of the five wavelengths measured. The results are shown in Table 1, the working absorptivities ($A_{species,wavelength}$) having been converted into molar absorptivities by division by the concentration ($2.407 \times 10^{-5}M$).

The regressions were performed on the Iowa State University VAX computer (Digital Equipment Corporation) with the Minitab Statistical Computing System developed at Pennsylvania State University.[2] The Minitab multiple regression routine ("Noconstant" option) is directly applicable to equation (1) and provides not only the standard deviation of the differences ("the fit") between the observed and calculated curves but provides various other related statistical quantities (not reported here) and apportions the standard deviation between the four constants and the regression itself. For the best values of the dissociation constants ($pK_{H_3Fl} = 2.19$, $pK_{H_2Fl} = 4.24$, $pK_{HFl} = 6.33$) the fits for the five wavelengths were

Wavelength, *nm*	Standard deviation of the mean absorbance (40 lines of data)
437	0.0022_1
455	0.0041_1
464	0.0023_6
475	0.0011_7
490	0.0026_4

The Minitab multiple regression routine also automatically identifies data which have a large standard deviation or are given a large influence by their x-values. This provides an excellent warning that certain data may bear a large probable error or fall outside the range of assumptions made in the theoretical development. After deletion of those data which are in error by more than 2.5 times the standard deviation (some 14 of the 200 absorbance readings taken), and recalculation, the new standard deviations were smaller than those reported just above, by a factor of 2. Re-examination of the experimental work and the recorded spectra showed no justification for such deletions and all the data were used in preparing the curves shown here and the results in Table 1.

The extent to which each of the four prototropic forms of yellow fluorescein contributes to the absorption as a function of pH at the various wavelengths is shown in Fig. 3.

It is apparent that at very low pH the absorption at 437 nm, Fig. 3a, is primarily that of the cation, but in the middle pH range there is significant absorption by the neutral molecule and the singly charged anion.

The small shoulder at ~pH 3 in the plot of the absorbance at 455 nm is associated primarily with the

Table 1. Calculated molar absorptivities ($l.mole^{-1}.cm^{-1}$) of the prototropic forms of yellow fluorescein in aqueous solution: ionic strength, 0.10; total concentration, $2.407 \times 10^{-5}M$; $K_{H_3Fl} = 6.46 \times 10^{-3}$, $K_{H_2Fl} = 5.75 \times 10^{-5}$, $K_{HFl} = 4.68 \times 10^{-7}$

Wavelength, *nm*	ϵ_{H_3Fl}	ϵ_{H_2Fl}	ϵ_{HFl}	ϵ_{Fl}
437	4.98×10^4	1.16×10^4	2.13×10^4	7.79×10^3
455	1.60×10^4	5.54×10^3	2.93×10^4	2.20×10^4
464	4.78×10^3	3.81×10^3	2.84×10^4	3.03×10^4
475	821	3.51×10^3	2.89×10^4	4.37×10^4
490	20.8	2.28×10^3	1.53×10^4	7.89×10^4

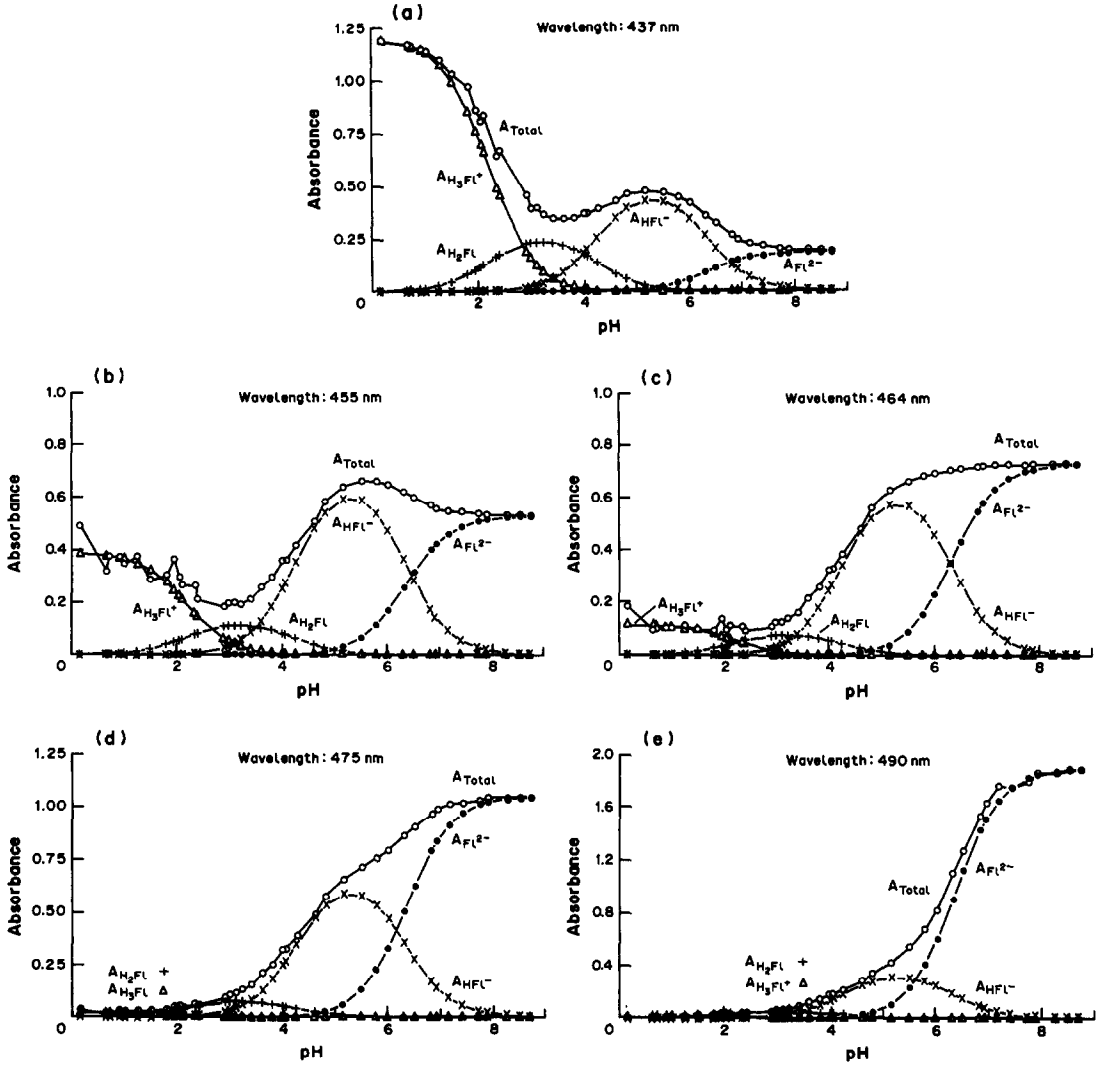

Fig. 3. Absorbance *vs.* pH curves for the four prototropic forms of yellow fluorescein at five wavelengths (a)–(e). For each wavelength and at each pH the four component absorbances sum to the observed absorbance. Symbols are the same on all five graphs. Total A, original data ○; A_{H_3Fl} △; A_{H_2Fl} +; A_{HFl} ×; A_{Fl} ●.

neutral molecule, as shown by Fig. 3b, even though the neutral molecule has a relatively low molar absorptivity. The maxima in the absorbances of H_2Fl and HFl^- at all five wavelengths are (Fig. 3) at pH ~ 3.22 and ~ 5.26 respectively, as expected since α_i will be maximal at a pH midway been pK_{H_3Fl} and pK_{Fl} for H_2Fl, and between pK_{H_2Fl} and pK_{HFl^-}. Analogously, Fig. 3e, at pH above 7.5 the absorption is primarily that of Fl^{2-}. The shoulder at pH ~ 5 on the plot of absorbance at 475 nm is clearly due to HFl^- (Fig. 3d).

A number of isosbestic (equal absorbance) points are present in the absorbance *vs.* pH plots shown in Fig. 1. These points are related to the absorptivities and alpha-values for the various forms of fluorescein in accord with equation (1). There are also iso-absorbance points in the individual absorbance *vs.* pH curves for the four prototropic forms of fluorescein at a given wavelength (Fig. 3). The positions of these points agree with calculations made by using equations (1)–(5) and the molar absorptivities given in Table 1.

STUDIES ON FLUORESCEIN—VII

THE FLUORESCENCE OF FLUORESCEIN AS A FUNCTION OF pH

HARVEY DIEHL† and RICHARD MARKUSZEWSKI§
†Department of Chemistry and §Ames Laboratory, Iowa State University, Ames, IA 50011, U.S.A.

(*Received* 21 *October* 1987. *Accepted* 21 *October* 1988)

Summary—The relative fluorescence of fluorescein over the pH range 3–12 has been measured at 516 nm, with excitation at 489 nm. The relative fluorescence is essentially zero at pH 3, increases slowly between pH 4 and 5, rises rapidly between pH 6 and 7, reaches a maximum at pH 8, and remains constant at above pH 8. The curve of relative fluorescence as a function of pH lies somewhat above the corresponding curve describing the fraction of fluorescein present as the doubly charged anion, Fl^{2-}, indicating much weaker fluorescence of the singly charged anion, HFl^{-}, and very much weaker fluorescence by the neutral species, H_2Fl. The fluorescence data have been used to calculate a value for the third dissociation constant. Because of the complexity of the system, one unknown dissociation constant and three (relative) fluorescence constants, a series of three variable regressions on the data was made. The final values were $K_{HFl} = 4.36 \times 10^{-7}$ ($\mu = 0.10$) for the third dissociation constant and $\kappa_{H_2Fl} = 0.8$; $\kappa_{HFl} = 5.7$; $\kappa_{Fl} = 100.0$ for the relative fluorescence constants.

The primary interest in fluorescein lies in its fluorescence, and it is therefore surprising that the relation of this to the nature of the prototropic forms of fluorescein in water solution has not been unequivocally established. Some workers have proceeded on the basis that the doubly charged anion Fl^{2-} is responsible for the fluorescence, inasmuch as alkaline solution is necessary for the fluorescence to appear, but this assumption has been made without knowledge of the values of the acid dissociation constants and the range of pH over which the various prototropic forms exist and the fluorescence occurs.

An extensive study of the fluorescence was made by the flash photolysis method by Lindqvist.[1] Finding a knowledge of the dissociation constants of fluorescein necessary, he determined them by the spectrophotometric method, by the procedure described by Zanker and Peter,[2] but in purely aqueous solution. Because of the difficulties posed by the closeness of the second and third dissociation constants, a difference of only 2.12 in pK, the Lindqvist value for the third dissociation constant, $K_{HFl} = 1.99 \times 10^{-7}$ ($pK_{HFl} = 6.7$), is probably too small. Although Lindqvist was concerned with the dissociation constants of the excited states and the decay rates as a function of pH, nowhere in the paper did he report the observed relative fluorescence as a function of pH.

We have now measured the fluorescence of highly purified fluorescein in water as solvent, at ionic strength 0.10, pH 3–12, with excitation at 489 nm and emission measurement at 516 nm (Table 1 and Fig. 1, curve F′).

The fluorescence is essentially zero at pH < 3, increases slowly between 4 and 5, rises rapidly between pH 6 and 7, reaches a maximum at pH 8, and remains constant at pH ⩾ 8. Visual inspection shows the point of inflection of the curve to be at pH 6.35.

Figure 1 also shows the distribution of the four prototropic forms of yellow fluorescein, the only form present in aqueous medium. The curve for the fluorescence lies slightly above that for the fraction of Fl^{2-} present, especially at lower pH. It is apparent that Fl^{-} also fluoresces, but not as strongly as Fl^{2-}, and that quite possibly the undissociated species also fluoresces but even more weakly than Fl^{-}.

EXPERIMENTAL

Chemicals

Fluorescein was prepared and purified through the diacetyl compound described in an earlier paper.[3]

Buffers covering the pH region 1.5–13 at intervals of 0.5 were prepared from 0.1M hydrochloric acid, potassium hydrogen phthalate, boric acid and potassium hydroxide, as appropriate, with addition of 0.1M potassium chloride to maintain the ionic strength constant at $\mu = 0.1$. After the fluorescence measurement the pH of the solution was determined with a Corning Model 10 pH-meter and a Beckman glass electrode and SCE.

Standards

A stock solution of fluorescein was prepared by dissolving 100.0 mg of pure red fluorescein in 1 litre of 0.1M potassium hydroxide. A 1.00-ml aliquot of the stock solution was placed in a 50-ml standard flask, 1 ml of 0.1M hydrochloric acid was added, and the mixture was diluted to the mark with the appropriate buffer. The concentration of fluorescein in all the solutions tested was $6 \times 10^{-6}M$.

*Part VI—H. Diehl, *Talanta*, 1989, **36**, 413.

Table 1. Relative fluorescence of fluorescein as a function of pH [F'_m = observed relative fluorescence normalized to maximum fluorescence (pH ≥ 8) set equal to 100.0; ionic strength $\mu = 0.10$; concentration $6.0 \times 10^{-6} M$]

pH	3.11	3.56	4.05	4.34	4.65	4.84	5.11	5.28
F'_m	0.92	1.67	3.00	4.16	5.80	7.10	10.0	11.6
pH	5.35	5.50	5.51	5.69	5.85	6.05	6.35	6.63
F'_m	13.5	17.4	16.7	21.7	27.1	38.2	52.5	67.5
pH	6.99	7.48	7.73	8.20	8.40	9.10	10.45	12.40
F'_m	82.7	95.8	99.2	100.0	100.0	100.0	100.0	100.0

Procedure

The excitation and emission spectra of fluorescein as a function of pH were obtained by use of a Bowman–Kiers Spectrophosphorimeter with an attached Mosely Autograf X–Y Recorder. The path-length of the fused-silica cell was 1.00 cm. The emission at 516 nm was recorded over the pH range 3.11–12.4, with excitation at 489 nm.

RESULTS AND DISCUSSION

For the prototropic forms and dissociation constants of fluorescein, we employ the same symbolism as in the earlier papers.[3-7] For definition of K_{H_3Fl}, K_{H_2Fl} and K_{H_3Fl}, see reference 4. For calculation of the distribution of the four prototropic forms (H_3Fl^+, H_2Fl, HFl^-, Fl^{2-}) see reference 7.

We now assume that the fluorescence intensities, F_i, of the individual prototropic forms are additive to give the total fluorescence F_m:

$$F_m = F_{H_2Fl} + F_{HFl} + F_{Fl} \quad (1)$$

The individual fluorescence intensities are given by

$$F_{H_2Fl} = 2.303\, \phi_{H_2Fl}\, \varepsilon_{H_2Fl}\, b[H_2Fl] = k_{H_2Fl}[H_2Fl] \quad (2)$$

$$F_{HFl} = 2.303\, \phi_{HFl}\, \varepsilon_{HFl}\, b[HFl^-] = k_{HFl}[HFl^-] \quad (3)$$

$$F_{Fl} = 2.303\, \phi_{Fl}\, \varepsilon_{Fl}\, b[Fl^{2-}] = k_{Fl}[Fl^{2-}] \quad (4)$$

where ϕ is the fluorescence efficiency, ε is the molar absorptivity, b the path-length, and k the fluorescence constant. In equations (2)–(4) the fluorescence efficiency and the molar absorptivity for a given form are assumed to be constant and the path-length to be 1.00 cm. Combination of equations (1)–(4) yields

$$F_m = k_{H_2Fl}[H_2Fl] + k_{HFl}[HFl^-] + k_{Fl}[Fl^{2-}] \quad (5)$$

The concentration terms are eliminated by substi-

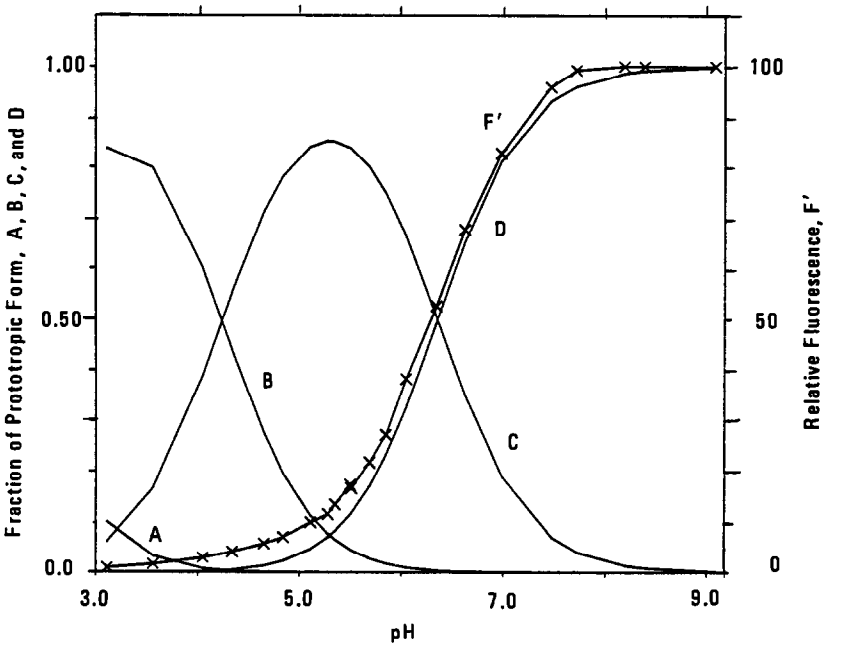

Fig. 1. Normalized relative fluorescence F'_m of $6.0 \times 10^{-6} M$ fluorescein as a function of pH; excitation at 489 nm, emission at 516 nm, ionic strength $\mu = 0.10$. A, B, C and D are the fractions of fluorescein present as H_3Fl^+, H_2Fl, HFl^- and Fl^{2-} respectively as calculated from $pK_{H_3Fl} = 2.19$, $pK_{H_2Fl} = 4.24$, $pK_{HFl} = 6.36$.

tution of the equations defining the concentrations of the individual prototropic forms as fractions (α_i) of the total concentration C:

$$\alpha_{H_2Fl} = \frac{[H_2Fl]}{C} \quad (6)$$

$$\alpha_{HFl} = \frac{[HFl^-]}{C} \quad (7)$$

$$\alpha_{Fl} = \frac{[Fl^{2-}]}{C} \quad (8)$$

giving

$$F'_m = k_{H_2Fl}\alpha_{H_2Fl}C + k_{HFl}\alpha_{HFl}C + k_{Fl}\alpha_{Fl}C \quad (9)$$

the prime indicating that the values of F_i have been normalized. With C constant throughout a series of measurements, a new term, κ, the "working fluorescence constant", where $\kappa = kC$, is introduced for each of the prototropic forms, giving

$$F'_m = \kappa_{H_2Fl}\alpha_{H_2Fl} + \kappa_{HFl}\alpha_{HFl} + \kappa_{Fl}\alpha_{Fl} \quad (10)$$

It is apparent that the system involves six constants: the three dissociation constants, K_{H_2Fl}, K_{H_2Fl}, K_{HFl}, and the three working fluorescence constants, κ_{H_2Fl}, κ_{HFl} and κ_{Fl}. Our present approach to this problem has been to assume values for the three dissociation constants, calculate the fractions of the various prototropic forms present, as functions of pH, substitute these in equation (10) and apply regression to evaluate the three working fluorescence constants, and then to repeat the process with a slightly different set of dissociation constants until an optimum fit of observed and calculated fluorescences is obtained.

The values assumed for the first and second dissociation constants, $pK_{H_3Fl} = 2.19$ and $pK_{H_2Fl} = 4.24$, obtained from the ultraviolet absorption studies reported earlier,[6,7] were held constant throughout the calculation. The third dissociation constant was varied in a series of regressions: $pK_{HFl} = 6.330$, 6.350, 6.355, 6.360, 6.365, 6.370, 6.390. As a criterion of fit, the differences between the observed and calculated values for the total fluorescence were calculated; the standard deviations and sums-of-squares showed pronounced minima at $pK_{HFl} = 6.360$, at which the standard deviation of an individual observation ($n = 22$) was 0.694 and the standard deviation of the mean was 0.151 (both in terms of relative fluorescence normalized to 100.0). At this point $\kappa_{H_2Fl} = 0.804$, $\kappa_{HFl} = 5.819$, and $\kappa_{Fl} = 101.45$.

We conclude that the third dissociation constant K_{HFl} is equal to 4.36×10^{-7} ($pK_{HFl} = 6.36$), and normalizing to $\kappa_{Fl} = 100.0$ gives the working fluorescence constants as $\kappa_{H_2Fl} = 0.8$, $\kappa_{HFl} = 5.7$, and $\kappa_{Fl} = 100.0$.

SPECTROPHOTOMETRIC STUDY OF THE COMPLEX FORMATION OF 3-(1-NAPHTHYL)-2-MERCAPTOPROPENOIC ACID WITH NICKEL(II), PALLADIUM(II) AND HYDROGEN IONS

ALVARO IZQUIERDO* and JOSÉ LUIS BELTRAN
Departament de Química Analítica, Universitat de Barcelona, Diagonal 647, 08028 Barcelona, Spain

(*Received* 21 *April* 1987. *Revised* 11 *August* 1988. *Accepted* 21 *October* 1988)

Summary—The equilibria between 3-(1-naphthyl)-2-mercaptopropenoic acid (H_2NMP) and nickel, palladium and hydrogen ions at 25° in aqueous 0.1*M* $NaClO_4$ solution containing 1–2% ethanol have been studied spectrophotometrically. Protonation constants for the ligand and formation constants for the complexes Ni(NMP), $Ni(NMP)_2^{2-}$, Pd(NMP) and $Pd(NMP)_2^{2-}$, refined by the SQUAD program, are reported.

The complexation of metal ions by some 3-aryl-2-mercaptopropenoic acids has recently been studied.[1–4] These compounds are of biological interest because of their effect on trace metal metabolism, being potent inhibitors of some copper- and zinc-dependent enzymes,[1] and showing antibacterial activity.[5]

The reactions of arylmercaptopropenoic acids are of two main types: formation of insoluble compounds with metal ions such as Ag(I), Pb(II) and Hg(II), and soluble complexes with transition metal ions, which are readily extractable with organic polar solvents. Some of the reagents have been used for spectrophotometric determination of nickel,[6] titanium[7] and manganese[8].

Studies of metal complexation by arylmercapto-acids[1–4] have shown the formation of ML and ML_2 complexes with Mn(II), Co(II), Zn(II) and Ni(II), and demonstrated that the 3-aryl-2-mercaptopropenoic acid complexes are more stable than the 3-aryl-2-mercaptopropanoic acid complexes.[2] In contrast to the saturated aliphatic mercapto-acids such as mercaptoacetic[9] or mercaptopropanoic,[10] the 3-aryl-2-mercaptopropenoic acids do not form polynuclear complexes with nickel or zinc. This difference can be attributed to the conjugated system formed between the aryl substituent and the carbonyl and mercapto groups through the unsaturated chain.

However, comparison between the potentiometric studies of the different complexes is not satisfactory because different media had to be used owing to the low solubility of 3-aryl-2-mercaptopropenoic acids in water, which necessitated use of mixed solvents such as ethanol–water or dioxan–water.

This problem can be overcome by the spectrophotometric determination of the stability constants, which can be done at a concentration level at which the ligand and the complexes formed are soluble in water.

In this work we studied the protonation equilibria of 3-(1-naphthyl)-2-mercaptopropenoic acid (H_2NMP) and its complexes with nickel and palladium. Earlier qualitative studies of H_2NMP[11] had shown that nickel forms a yellow-green soluble complex in acetate buffer, and palladium a red complex in hydrochloric acid. The systems were studied at 25° in 0.1*M* sodium perchlorate solution in water containing 1–2% ethanol. The formation constants were determined by the SQUAD program.

EXPERIMENTAL

Apparatus

Beckman Acta M-VII and DU-7 spectrophotometers were used with 10-mm silica cells. The pH-meter was a Radiometer PHM 84 in conjunction with a Radiometer G 202 B glass electrode, and a Radiometer K 801 Ag/AgCl reference electrode, the latter filled with saturated sodium chloride solution, instead of saturated potassium chloride solution, to prevent clogging of the reference electrode frit by precipitation of potassium perchlorate.

The electrode system was first calibrated with pH 4.008, 6.863 and 9.183 buffer solutions at 25°, according to DIN 19266. After equilibration, the electrode response was checked against pH 2.00, 4.00, 6.00, 7.00 and 8.00 buffer solutions (Carlo Erba and Crison). The temperature of the solutions was kept constant at 25 ± 0.1° with a Selecta model Tectron thermostatic bath.

Reagents

H_2NMP was synthesized as described earlier,[11] and its purity was checked frequently by iodometric titration.[12] In all experiments freshly prepared ethanolic solutions were used.

Nickel perchlorate was prepared by dissolving nickel carbonate in perchloric acid (1 + 1), evaporation, and recrystallization from water. Palladium perchlorate was obtained from the pure metal as described by Burger and Dyrssen.[13] The stock solutions of metal perchlorates (about

Table 1. Experimental conditions of spectrophotometric measurements

Equilibrium system	Wavelength range, *nm*	Number of spectra	C_L, 10^{-5}M	C_M, 10^{-5}M	pH range
NMP–H^+	275–415	39	3.0–8.0	—	1.1–11.7
NMP–Ni^{2+}	275–505	33	0.2–16.2	0.8–7.2	3.2–7.3
NMP–Pd^{2+}	275–505	37	0.1–4.0	0.1–0.9	1.1–5.6

0.03–0.05*M*) were standardized gravimetrically with dimethylglyoxime.[14] The ionic strength of the medium was kept constant at 0.1*M* by addition of 0.5*M* sodium perchlorate. All reagents were of analytical grade.

Procedures

For each equilibrium system, several series of solutions were prepared, by adding 0.1% ethanolic solution of H_2NMP to 25- or 50-ml standard flasks, containing the buffer or buffer and metal solutions. After equilibration, the absorbance was measured at 10-nm intervals over the spectral range required, and finally the pH of the solution was measured and converted into pC_H units according to the Davies equation[15] (the calculated activity coefficient for the hydrogen ion was 0.778 at 25° and 0.1*M* ionic strength). In the pC_H range 1–2 and at $pC_H > 11$ the pH of the solutions was not measured, because the pC_H value was obtainable directly from the dilution of 0.2*M* perchloric acid and 0.1*M* sodium hydroxide.

The effect of the ethanol present in the working solutions (from the ligand solution) on the activity coefficient was neglected because of the smallness of the change in the dielectric constant of the medium (the amount of ethanol in all solutions was less than 2% v/v).

Table 1 lists the experimental conditions. The upper limit of ligand and metal concentrations was set by the solubility of the ligand and the metal complexes under the experimental conditions.

In the determination of the two protonation constants of the ligand, equilibrium solutions covering the pH ranges 2.1–3.7 and 7.7–9.2 were used. Solutions in 0.1*M* perchloric acid ($pC_H = 1$), phosphate buffer ($pC_H = 5.7$) and 0.01*M* sodium hydroxide ($pC_H = 11.71$) with ionic strength 0.1*M* ($NaClO_4$) were used to determine the spectra of the pure species H_2L, HL^- and L^{2-} respectively. Figures 1A and 1B show the variation in spectra on changing the pH of the solutions.

The Ni(II)–NMP system was buffered with acetic acid–sodium acetate because of the low formation constant of nickel(II)–acetate complexes.[16,17] In the Pd(II)–NMP system, the pH of the equilibrium mixtures was adjusted with sodium hydroxide and perchloric acid (to avoid interference from buffer components). Figures 2 and 3 show some of the spectra obtained.

DATA TREATMENT

The general equilibria studied can be written as:

$$lL + mM + hH \rightleftharpoons L_lM_mH_h$$

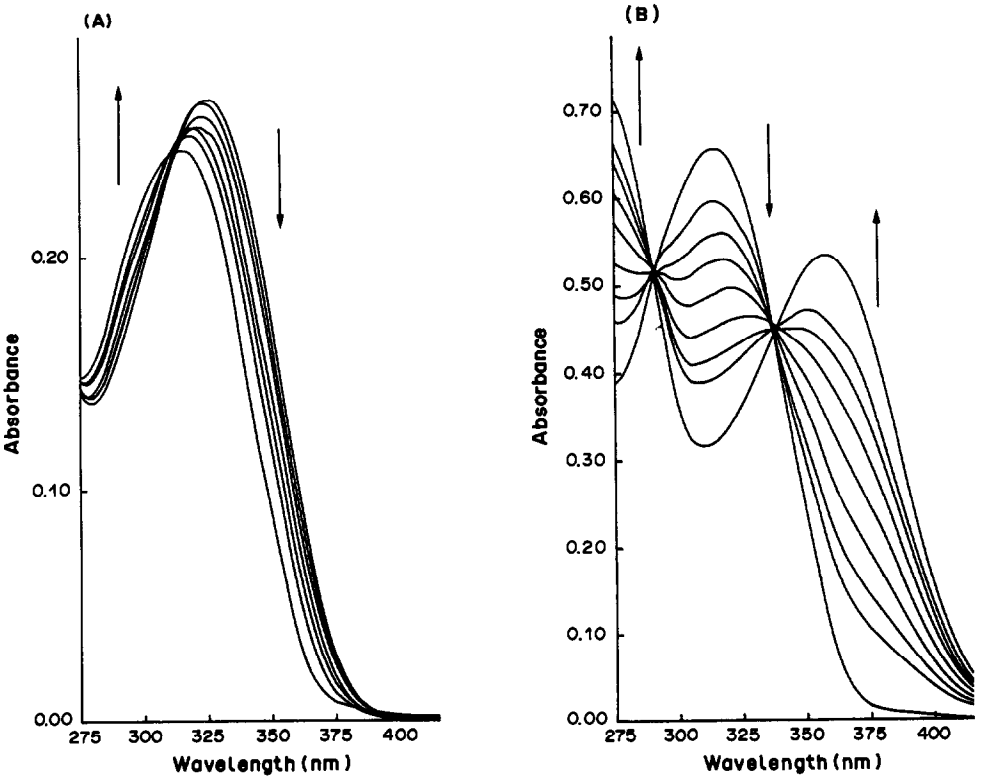

Fig. 1. Spectra of two series of solutions used to determine the protonation constants of H_2NMP. Arrows indicate the spectral trends in changing the pH (A) from 1.11 to 5.72, $C_L = 3.03 \times 10^{-5}M$; (B) from 5.66 to 11.74, $C_L = 7.98 \times 10^{-5}M$.

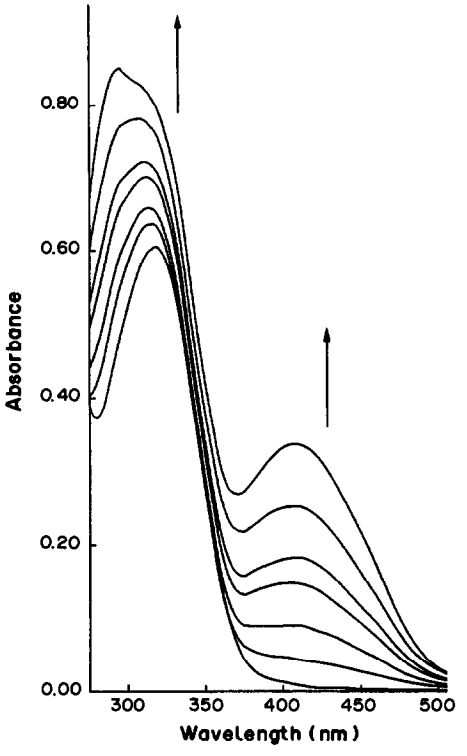

Fig. 2. Absorption spectra of the system Ni(II)–NMP at different pH values. Arrows indicate the spectral trends in changing the pH from 3.27 to 4.98. $C_L = 7.04 \times 10^{-5} M$, $C_M = 3.22 \times 10^{-5} M$.

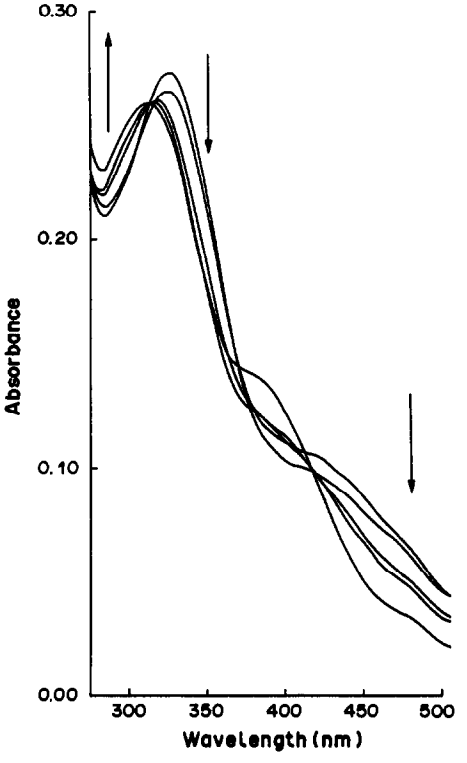

Fig. 3. Absorption spectra of the system Pd(II)–NMP at different pH values. Arrows indicate the spectral trends in changing the pH from 1.11 to 5.46. $C_L = 2.70 \times 10^{-5} M$, $C_M = 9.81 \times 10^{-6} M$.

and the overall formation constants are defined by:

$$\beta_{lmh} = [L_l M_m H_h]/[L]^l[M]^m[H]^h$$

where L = ligand (charges are omitted for simplicity).

For the protonation equilibria, initial estimates of the formation constants were determined analytically[18] at several wavelengths (315, 355 and 375 nm for the first protonation constant, and 335, 345 and 355 nm for the second). The values found were $\log \beta_{101} = 8.21$, and $\log \beta_{102} = 11.23$.

In the complex formation studies, the predominant species in equilibrium were determined before the numerical calculations. For the Ni(II)–NMP system, the continuous variations method indicated an ML_2 complex, but for the Pd(II)–NMP system, the stoichometry obtained by this method was about $ML_{1.4}$, suggesting overlap of the equilibria for the ML and ML_2 species, which was confirmed by a molar ratio plot (Fig. 4). Consequently, taking into account the formation of only mononuclear complexes between metal ions and 3-aryl-2-mercaptopropenoic acids,[1-4] the formation of ML and ML_2 species was assumed for the two systems.

Initial estimates of the formation constants for the Ni(II) complexes were taken from the corresponding literature values of the 3-(2-furyl)-2-mercaptopropenoic acid complexes[2] ($\log \beta_{110} = 7.5$, $\log \beta_{210} = 16.4$). Although this system was studied in ethanol–water (1:9 v/v) at ionic strength 0.1M (KNO_3), the protonation constants of the ligand were similar ($\log \beta_{101} = 8.097$ and $\log \beta_{102} = 11.490$ for the 2-furyl derivative) to those obtained for H_2NMP in our experimental conditions.

There were no previous references for formation of palladium complexes with mercapto-acids, so the initial estimates for the constants were made by comparing the pH range of complex formation with that for the nickel complexes. Formation of the latter begins at about pH 3.3–3.8 (Fig. 2), but the palladium complexes show very high absorbance even at pH 1. From this, we can consider that the formation constant for the PdL complex is about 3–4 orders of magnitude greater than for NiL, so an initial estimate of 12 for $\log \beta_{110}$ would be reasonable, and 24 for $\log \beta_{210}$ (calculated as twice $\log \beta_{110}$).

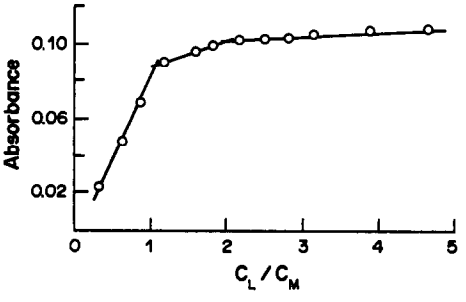

Fig. 4. Molar ratio plot for the Pd(II)–NMP system measured at 415 nm. $C_M = 9.37 \times 10^{-6} M$; pH = 3.5.

All the experimental data were processed by the least-squares program SQUAD,[19] on an IBM 3083 mainframe computer. This program refines the formation constants, and the molar absorbances for each species at all wavelengths. The function minimized (U) is defined in terms of the absorbance of the solutions:

$$U = \sum_{i=1}^{s} \left[\sum_{j=1}^{w} (A_{i,j,\text{calc}} - A_{i,j,\text{exp}})^2 \right]$$

where s and w mean the number of solutions measured and the number of wavelengths, respectively.

As already mentioned, complexation by the buffer solution was neglected in treatment of the Ni(II) complexes, and the hydrolytic nickel species can also be neglected under the experimental conditions. For palladium, the complexes $Pd(OH)^+$ and $Pd(OH)_2$ were found the main hydrolytic species in the pH range considered,[16,17] and their formation constants ($\log \beta_1 = 12.4$, $\log \beta_2 = 25.2$) were used as input data for the program.

RESULTS AND DISCUSSION

The formation constants obtained are shown in Table 2, together with the standard deviations of the absorbance residuals obtained by the program SQUAD.

The formation constants for the nickel–NMP complexes are similar to those for the 3-(2-furyl)-2-mercaptopropenoic acid complexes, as shown in Table 3, as can be expected from the protonation constants of the two ligands. Figure 5 shows the distribution of Ni(II) species for metal and ligand concentration levels similar to those in the experimental working range.

Table 2. Calculated formation constants (at 25°C, $I = 0.1M$ $NaClO_4$)

Metal ion	Species (lmh)	$\log \beta_{lmh}$	σ†
H^+	101	8.22 ± 0.01	0.004
	102	11.20 ± 0.02

†Standard deviation of absorbance data.

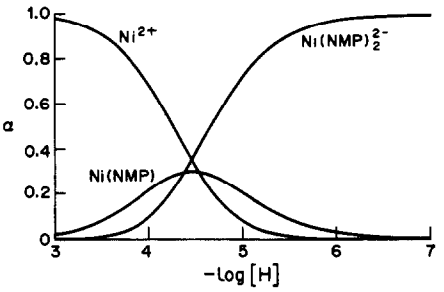

Fig. 5. Distribution of Ni(II) species in the Ni(II)–NMP system as a function of pH. $C_L = 5 \times 10^{-5}M$, $C_M = 1 \times 10^{-5}M$.

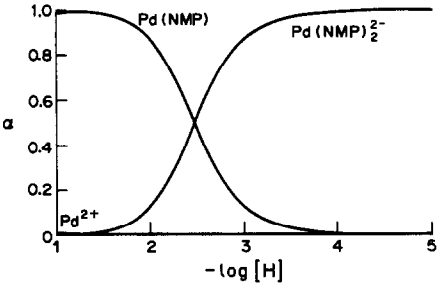

Fig. 6. Distribution of Pd(II) species in the Pd(II)–NMP system as a function of pH. $C_L = 5 \times 10^{-5}M$, $C_M = 1 \times 10^{-5}M$.

The palladium–NMP complexes have very high formation constants. The species distribution for the Pd(II)–NMP system is shown in Fig. 6. The most sensitive reaction is the formation of the neutral Pd(NMP) complex in acidic medium, which is extractable by organic polar solvents, such as isoamyl alcohol or methyl isobutyl ketone. Although these results might be interpreted as suggesting formation of mixed hydrolytic species, such as Pd(NMP)$(OH)_2^{2-}$, to be compatible with the square-planar configuration of most palladium(II) complexes, tentative calculations by the program SQUAD showed that this would not be the case.

Table 3. Literature values of formation constants of Ni(II) complexes with 3-aryl-2-mercaptopropenoic acids

Aryl group	$\log \beta_{110}$	$\log \beta_{210}$	Ionic medium	Reference

POTENTIOMETRIC STUDIES OF INDIUM(III) AZIDE COMPLEXES IN AQUEOUS MEDIUM

MAURO BERTOTTI and ROBERTO TOKORO
Instituto de Química USP B-8-Sup, Caixa Postal 20780, São Paulo-SP, 01498-Brazil

(*Received* 20 *January* 1988. *Revised* 18 *March* 1988. *Accepted* 7 *October* 1988)

Summary—The stability constants of indium–azide complexes were determined by the potentiometric method (glass electrode). The effect monitored was the change in pH of a solution of azide and hydrazoic acid (N_3^-/HN_3) when indium(III) cations were added. The azide concentration was varied from close to zero to 90m*M*, the ionic strength being kept at 2.000*M* with sodium perchlorate and the temperature at 25.0°. Evaluation of experimental data showed only mononuclear species, and the global constants found were $\beta_1 = (2.0 \pm 0.1) \times 10^3$, $\beta_2 = (7 \pm 2) \times 10^5$, $\beta_3 = (5 \pm 1) \times 10^7$ and $\beta_4 = (7 \pm 3) \times 10^8$.

Complex formation between azide and various cations has been studied in our laboratories for some time.[1] For the present study, indium(III) was selected because of its electrochemical properties. Azide acts as a catalyst in the polarographic conditions in which In^{3+} is electroactive.[2] Many ligands, such as halides, carboxylates and oxy-anions, form complexes with indium(III) but the results are not always reliable.[3] A pseudohalide, thiocyanate, has received special attention.[4] Thiocyanate and azide are isosteric[5] and there is strong evidence for complex formation between azide and indium(III). Potentiometry is a suitable method for these studies because hydrazoic acid and its conjugate anion azide form a buffer solution. The change in pH of this buffer solution when metal ion is added can be monitored with a combination glass electrode. The complex formation constants were evaluated by standard methods.[6]

EXPERIMENTAL

Reagents

A standard solution of indium(III) perchlorate was prepared by dissolving 0.6950 g of the primary standard oxide In_2O_3 (Johnson & Matthey) in enough concentrated perchloric acid (Merck) to give a final acid concentration of around 30m*M*. Gentle heating was needed to dissolve all the oxide. Excess of acid is necessary to prevent hydrolysis of In(III). The solution was diluted with water to a final volume of 500.0 ml to give $C_{In} = 9.832 \times 10^{-3}M$ and $C_{H^+} = 3.405 \times 10^{-2}M$ (the acid was determined by a standard addition method[7]). Sodium perchlorate and azide (Merck) solutions were standardized gravimetrically.

Apparatus

pH was measured with a Micronal B375 potentiometer and a Metrohm EA121 combination glass electrode. The supporting electrolyte was 2.00*M* sodium perchlorate. The temperature was kept at 25.0 ± 0.1°. The microburette was a Metrohm E274 (5 ml), with a plastic capillary on the tip to control the droplets.

Procedure

The ionic strength was adjusted to 2.000*M* with sodium perchlorate to minimize variation of the activity coefficients,[8] so that the operational pH[9] measurements correspond to H^+ concentrations rather than H^+ activities. Thus, 0.01000*M* perchloric acid with $I = 2.000M$ ($NaClO_4$) gave a conditional pH of 2.000 as read by the glass electrode. The response of the electrode was determined for 2.000*M* sodium perchlorate to which successive additions of 0.0400*M* perchloric acid [$I = 2.000M$ ($NaClO_4$)] were made. In the pH range 2–3, the measured potential varied linearly with the calculated pH, with a slope of 0.06065 V/pH. Above pH 3 linearity was no longer observed and the curve deviated upward. This has been explained in terms of slight dissolution of the glass wall of the electrode or of adsorption of H^+ on the membrane.[10] Once the slope was known all measurements could be corrected.[7]

The working solutions used for the equilibrium measurements were prepared as follows.

(1) To known volumes of 2.000*M* sodium perchlorate, V_i, different volumes of N_3^-/HN_3 buffer [$I = 2.000M$ ($NaClO_4$)] were added with a microburette and the pH values were measured. A series of pH-values for different buffer concentrations in the absence of indium(III) was thus obtained.

(2) To known volumes of 2.000*M* sodium perchlorate, V_i, containing indium at concentration C_M, N_3^-/HN_3 buffer containing In^{3+} at the same concentration C_M [$I = 2.000M$ ($NaClO_4$)], was added and the pH-values were measured [the buffer constituents were at the same concentration as in (1)]. Comparison of the pH-values for the various buffer concentrations with those in the first series yields ΔpH; then $\bar{n}$ can be evaluated[6] from:

$$\bar{n} = \frac{\Delta[N_3^-] - C_H + \Delta[H^+]}{C_M}$$

The buffer solutions with and without metal were prepared directly in the cylinder of the microburette, because transfer of the solutions in the open air would result in loss of HN_3 by volatilization. The number of data points is the number of increments of buffer solution used. Good reproducibility was obtained only if the concentration of hydrazoic acid did not exceed 0.2000*M*. Volatilization of HN_3 caused unavoidable errors. Large volumes (~2.0 ml) of the solutions of the buffer constituents ($NaClO_4$, $HClO_4$ and NaN_3) had to be used in preparing the buffers, to reduce the relative errors in the volumetric measurements and to obtain better reproducibility. The order in which the solutions are added is important: the sodium azide solution has to be added to the acid to prevent volatilization of HN_3. Two sets of experiments were performed: (*a*) N_3^-/HN_3 in the ratio 0.020*M*/0.180*M*, $I = 2.000M$ ($NaClO_4$), $C_{In^{3+}} \approx 3.0 \times 10^{-4}M$, pH varied from 2.5 to 3.0; (*b*)

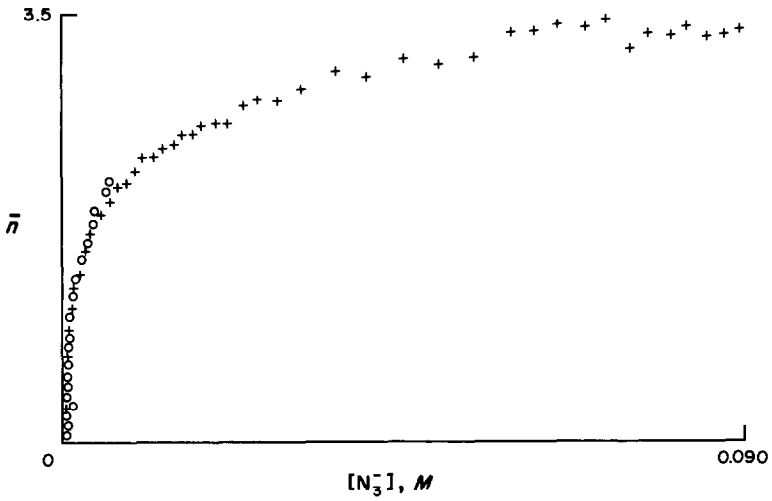

Fig. 1. Formation curve for the indium(III)–azide-system. $C_{In^{3+}}$: ○, $3.69 \times 10^{-4}M$; +, $9.83 \times 10^{-4}M$.

N_3^-/HN_3 in the ratio $0.180M/0.180M$, $I = 2.000M$ ($NaClO_4$), $C_{In^{3+}} \approx 1.0 \times 10^{-3}M$, pH varied up to 4.5.

MEASUREMENTS AND RESULTS

Influence of ionic strength on pH measurements

It is well known that pH depends on ionic strength. However, the dependence observed was unexpected, showing a continuous decrease as the ionic strength was increased. The mechanism by which a glass electrode responds to changes in H^+ activity is not clear. For the present work the concentration of H^+ was needed rather than the activity. To determine this, the slope of the glass electrode had to be measured carefully and the ionic strength held constant to ±0.1%.

Hydrolysis of In^{3+}

To check that the cell was tightly closed the pH of the buffer was monitored for a period. After this, a small amount of indium solution was added. The pH decreased owing to protonation and complexation reactions. The pH then stayed constant for 30 min, showing that no hydrolysis occurred. In a non-complexing medium In^{3+} hydrolyses slowly, but up to pH 3 no hydrolysis is observed. In complexing media, hydrolysis does not occur.

Bjerrum function ($\bar{n}$) for the system $In^{3+}/N_3^-/HN_3$

The working solutions with and without metal were prepared repeatedly. The corresponding Bjerrum functions are shown in Fig. 1. It can be observed that the curves for different metal concentrations superimpose well. This is evidence that no polynuclear species are formed.

Evaluation of stability constants

From the Bjerrum function, $\bar{n}$, and the Fronaeus equation[11] the values of $F_0(x)$ were obtained. By Leden's graphical method[12] four different complexes were found.

The $F_0(x)$ data can also be analysed by a computational method[13] based on solving simultaneous equations such as:

$$F_0(x) = 1 + \beta_1[x] + \beta_2[x]^2 + \cdots + \beta_n[x]^n$$

The main limitation of this method is that the values of $F_0(x)$ are obtained indirectly, and thus have large deviations.

Another way to evaluate the stability constants from experimental $\bar{n}$ and [L] data is to use the least-squares method.[14] Here, a non-linear method[15-17] was used which allowed estimation of the variance.

Table 1 compares the three methods of evaluation. The best set of constants was that found by the non-linear regression method.

The best values obtained for the stability constants of the In^{3+}/N_3^- aqueous system (with their standard

Table 1. Stability constants and standard deviations for the In^{3+}/N_3^- system found by the three methods ($I = 2.000M$; 25.0°); and values obtained by Avsar[18] ($I = 1.0M$; 25.0°)

Method	β_1	β_2	β_3	β_4	Standard deviation*
Leden	4.04×10^3	8.50×10^5	6.74×10^7	1.08×10^9	0.09
Simultaneous equations	3.68×10^3	6.84×10^5	8.46×10^7	8.42×10^8	0.08
Non-linear regression	2.05×10^3	6.76×10^5	5.15×10^7	7.24×10^8	0.05
Avsar[18]	$(1.54 \pm 0.05) \times 10^3$	$(4.1 \pm 0.1) \times 10^5$	$(1.8 \pm 0.1) \times 10^7$	$(2.9 \pm 0.3) \times 10^8$	

*Standard deviation was found by comparison of experimental $\bar{n}$ and evaluated $\bar{n}$ using the set of constants.

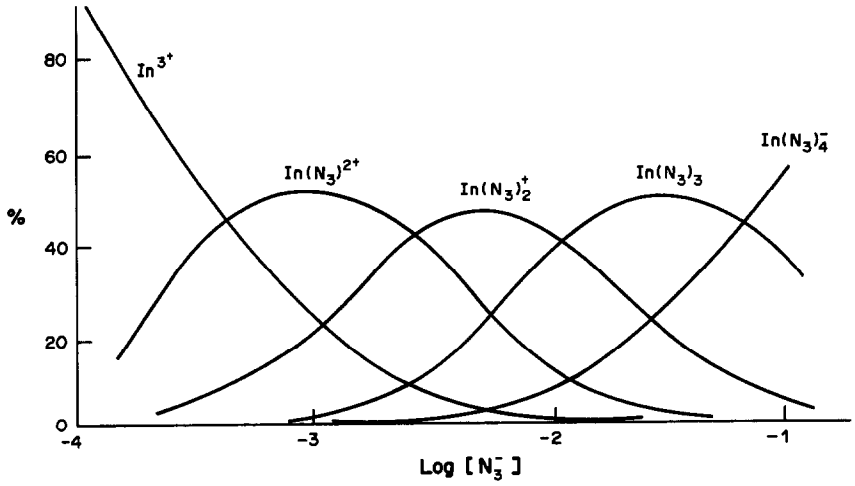

Fig. 2. Fraction of indium(III) in its various forms, as a function of free azide ion concentration.

deviations) are: $\beta_1 = (2.0 \pm 0.1) \times 10^3$; $\beta_2 = (7 \pm 2) \times 10^5$; $\beta_3 = (5 \pm 1) \times 10^7$; $\beta_4 = (7 \pm 3) \times 10^8$.

From the stability constants found, the distribution diagram was calculated (Fig. 2).

DISCUSSION

The results obtained in this work are comparable to those of Avsar[18] who also used a potentiometric method at $I = 1.0M$ and 25.0°, and found four complexes were formed. Despite the different ionic strengths, the values agree.

The driving force for the complex formation between In^{3+} and N_3^- comes from an entropy change in the system, since the interaction is ionic in character (In^{3+} is a hard acid and N_3^- is a borderline base). However, Avsar's thermodynamic data show that, in the case of the first two complex species, the enthalpy and entropy changes lead to complexation, whereas in the case of the third and fourth species only the enthalpy change is relevant.

According to Tuck's observations,[3] the four species found in the N_3^-/In^{3+} system should have octahedral structure. The tetrahedral configuration of In^{3+} is rare and exists only under special conditions.

From the kinetics of substitution of water molecules by azide ions it appears that the complexes are labile. For d^{10} ions undergoing dissociative substitution reactions there is no loss in stabilization energy of the crystal field when a complex of octahedral configuration changes into an activated state with a square-base pyramidal structure.[19] The lability of In^{3+} and N_3^- complexes can be analysed in the light of Eigen's work,[20] where the reaction

$$[In(H_2O)_x] + xH_2O^* \rightleftharpoons [In(H_2O^*)_x]^{3+} + xH_2O$$

was found to have a half-life of less than 10^{-2} sec.

The stepwise constants (K_i) are important parameters to be considered in complex formation between In^{3+} and N_3^-: $K_1 = \beta_1 = 2.0 \times 10^3$; $K_2 = \beta_2/\beta_1 = 3.5 \times 10^2$; $K_3 = \beta_3/\beta_2 = 7.1$; $K_4 = \beta_4/\beta_3 = 1.4$, and confirm the statistical model for successive complex formation, whereby each ligand added decreases the probability for co-ordination of the next.

CORRECTION FACTORS FOR GLASS ELECTRODES IN AQUEOUS DIMETHYLSULPHOXIDE SOLUTIONS

APARECIDO DONIZETI GALVÃO and NELSON RAMOS STRADIOTTO
Department of Chemistry, Faculty of Philosophy, Sciences and Letters of Ribeirão Preto, University of São Paulo, 14049—Ribeirão Preto, SP, Brazil

(*Received* 8 *February* 1988. *Revised* 10 *August* 1988. *Accepted* 19 *September* 1988)

Aqueous dimethylsulphoxide (DMSO) is used as a cryoprotective agent in chemistry[1] and biology, and as a physiological substrate.[2] It has also been proposed as a pharmaceutical or pharmacological substrate. Correction factors for the glass electrode in aqueous dimethylsulphoxide solutions have now been obtained by the method of van Uitert and Haas.[3]

The relationship used in this method is $-\log C_H = B + \log U_H$ where C_H is the stoichiometric concentration of acid, B is the reading of the pH-meter and $\log U_H = \log U_H^0 - \log 1/\gamma_\pm$, in which $\gamma_\pm$ is the mean activity coefficient of the acid and U_H^0 is the correction at zero ionic strength.

The measurements were made with a Metrohm E500 pH-meter equipped with a Metrohm EA121 combination glass electrode. The pH-meter was standardized with aqueous buffers. All measurements were made at $25 \pm 0.1°$ and a hydrochloric acid concentration of $0.0057M$.

The values of B were the averages of three independent experiments on solutions of the same nominal composition. Log $\gamma_\pm$ was calculated by using the relationships reported by Reynaud,[4] and Morel's dielectric constant data.[5] For $-\log C_H$, the value of 2.20 ($B - \log 1/\gamma_\pm$ for aqueous solution) was used instead of the stoichiometric value 2.24.

The results obtained are given in Table 1. A minimum value for log U_H^0 is observed at a DMSO mole fraction of 0.5. In this behaviour, it is analogous to other properties that show an extremum at around that composition, and can be mainly attributed to strong interaction between water and DMSO molecules.[6-8]

CALIBLOT

Concentration calculation with the aid of calibration curves, with use of "LOTUS 1-2-3"

Contributors: M.J. Gomez, C. Ceccarelli and Z. Benzo, Centro de Quimica, I.V.I.C., Apartado 21827, Caracas 1020-A, Venezuela; and J. Coella, Departamento de Quimica, Quimica Analitica, Universidad Autonoma de Barcelona, E-08193 Bellaterra, Spain.

Brief description: CALIBLOT can be used to handle data in most techniques where a calibration curve is required. However, it was designed with AAS and AES particularly in mind. In these techniques, the usual experimental procedure is to measure the response of some standards (3, 4 or 5), then the response of the samples, and finally check the standards again.

The main advantage of the CALIBLOT approach is the easy management of all the information, including the initial data, the intermediate steps, and the results, which can be displayed and printed in a neat table. When a solid is analysed, the concentration of each element is calculated as a percentage by weight, and as ppm, from the weight of the solid and the volume of solvent used. This information is also stored to allow easy checking of the results of the analyses. The final result is averaged over the number of replicates for the sample (2 or 3). The table is formatted in advance. A graph with the two calibration curves is generated, and optionally printed, to permit checking for changes in the slope with time. Additional calculations are easily implemented if necessary. The program is user-friendly and includes specific help on-line. It is suitable for routine use by untrained personnel.

Potential users: scientists.

Fields of interest: calibration and data handling.

This application has been developed for the IBM-PC and compatibles, to run under DOS 3.2 or later. It involves use of the commercial package LOTUS 1-2-3, Version 2.0 (Lotus Development Corp., 161 First Street, Cambridge, MA 02142). Several macros have been written, to erase old data (\E), to calculate calibration curves and determine the concentrations (\C), to average the replicates (\D or \T), to plot curves (\G), to print data and results in a compact table (\P), and to create help screens (\O and \H). The program has extensive external documentation about use, design and macros.

The application is fully operational, and is in use in several research laboratories at I.V.I.C. A formatted worksheet, including macros, can be made available on 5.25-in double-sided floppy discs, from the Technologic Center at I.V.I.C. The contributors are willing to deal with enquiries.

Software package TAL-009/88

POLYMER CHARACTERIZATION (GPC) SOFTWARE

Contributor: A. Ravve, Chemical Associates, Inc., 7235 N. Keating, Lincolnwood, Illinois 60646, USA.

Brief description: The software calculates molecular weights of polymers (Mw, Mn, Mz) and the molecular weight distributions (MWD) from size-exclusion chromatography (SEC) or gel-permeation chromatography (GPC) data. The user enters information on four points from the calibration curve, and then data on the peak heights. The computer then reconstructs the calibration curve, corrects the data for instrument spreading, and

calculates molecular weights and the molecular weight distribution. The data and the results are then shown on the CRT and printed out by the printer. This is followed by an analysis of the curve, and mean, variance, skew and kurtosis are reported.

Potential users: Users of size-exclusion chromatography (GPC).

Fields of interest: Analysis of polymeric materials.

This program has been developed for the Apple II computer, and is written in UCSD Pascal. The source code is available. It is available on 5.25-in single-sided floppy disc. The memory required is 128K. A version for the IBM PC and compatibles will be available soon.

Distributed by: Chemical Associates, Inc. (Tel. 312 677 5493). The cost is $300.00; a demonstration disc is available.

The Apple requires an 80-column card. The program is easy to use, and there is extensive external documentation. The contributor is willing to deal with user enquiries.

KINETIC STUDY OF THE DETERMINATION OF HYDRAZINES, ISONIAZID AND SODIUM AZIDE BY MONITORING THEIR REACTIONS WITH 1-FLUORO-2,4-DINITROBENZENE, BY MEANS OF A FLUORIDE-SELECTIVE ELECTRODE

ELENI ATHANASIOU-MALAKI and MICHAEL A. KOUPPARIS*
Laboratory of Analytical Chemistry, Department of Chemistry, University of Athens, 104 Solonos Street, Athens 10680, Greece

(*Received* 25 *July* 1988. *Revised* 14 *November* 1988. *Accepted* 30 *November* 1988)

Summary—A kinetic potentiometric method is described for the determination of hydrazines (hydrazine, phenylhydrazine, hydralazine and procarbazine), isoniazid and sodium azide, based on monitoring their reactions at 25° and pH 9.0 with 1-fluoro-2,4-dinitrobenzene by means of a fluoride-selective electrode. Initial-rate and fixed-time methods were used to construct calibration graphs, generally over the range 1×10^{-4}–$1 \times 10^{-2} M$. Hydralazine, procarbazine and isoniazid were determined in commercial formulations with a precision and error of 2–3% and the results were comparable with those of the official methods. The presence of common excipients and concomitant drugs in combination products do not interfere and the method can be used for coloured and cloudy sample solutions. A kinetic study of the reactions was made and the overall second-order rate constants are given. Base catalysis was observed. The fluoride-selective electrode is shown to be a valuable tool for monitoring fluoride-liberating organic reactions in kinetic studies and kinetic analysis.

1-Fluoro-2,4-dinitrobenzene (FDNB), the so-called Sanger reagent, has been used in structural analysis as a label for the terminal amino-acid group in the determination of the amino-acid sequence of proteins,[1] for active-site labelling of enzymes, and for studying protein tertiary structures.[2] FDNB has also been used for the spectrophotometric determination of amino-acids and primary and secondary amines,[3–9] amino-acid nitrogen in plasma and urine (Goodwin's method),[10,11] isoniazid,[12] various aminoglycoside antibiotics,[13] phenols[14] and the enzyme amidase.[15] It has also been used in the gravimetric determination of morphine[16] and other phenols[17] and as a derivative-forming reagent for determination of phenols[18] and amines[19] in GLC, for amines and aminoglycosides in HPLC[20–22] and for amines in TLC and mass spectrometry.[23]

The spectrophotometric methods above have inherent disadvantages as the reactions are slow and heating is needed to speed them up. Additional steps are also required for hydrolysis of the excess of FDNB and for the extraction and measurement of the DNB product. Also, the methods cannot be applied to coloured or turbid samples. All these drawbacks can be eliminated, with a slight decrease in sensitivity, by using a kinetic potentiometric method based on monitoring the FDNB–analyte reaction with a fluoride-selective electrode. The combination of the selectivity, sensitivity and simplicity of kinetic methods of analysis and ion-selective electrodes, produces a versatile technique.[24]

Recently, we reported a systematic kinetic study of the reaction of FDNB with amino-acids and primary and secondary alkyl and aryl amines.[25,26] The reaction was found to be first-order with respect to the amino-compound and second-order rate constants at pH 9.0 and 25° were reported. Based on this kinetic study, a kinetic potentiometric method (initial-rate and fixed-time procedures) was proposed for the determination of these compounds. The method is simple, relatively selective, sufficiently sensitive and applicable to turbid and coloured samples. It was validated by determining various drugs in commercial pharmaceutical formulations.

In this work we extend the method to three other classes of nitrogen compounds, *viz.* hydrazines, hydrazides and azides. As far as we know, no kinetic data have been reported in the literature for these reactions. Pool and Meyer[12] reported only the spectrophotometric determination of isoniazid in serum, by measuring the absorbance of the DNB product at 500 nm; the reaction was performed at 80°. The reaction of sodium azide with *p*-nitrofluorobenzene (an analogue of FDNB) in an aprotic solvent has been studied spectrophotometrically.[27,28] The reaction was found to be first-order with respect to azide and involves a stable intermediate complex which releases fluoride in the presence of a protic solvent which can solvate it.

EXPERIMENTAL

Apparatus

A combination fluoride electrode (Orion Model 96-09) and a conventional analogue electrometer (Corning Model 12 pH-meter) with 0.1 mV resolution, connected to a multi-speed variable-span recorder, were used. All measurements were made at $25.0 \pm 0.2°$ in a thermostatically controlled plastic double-wall reaction cell, with continuous magnetic stirring. The electrode was stored in $1 \times 10^{3}M$ fluoride solution overnight and between measurements.

Reagents

All reagents were of analytical grade and demineralized distilled water was used throughout.

Analyte standard solutions. Working standard solutions of the test compounds in the range 1×10^{-5}–$5 \times 10^{-2}M$ were prepared daily from $0.1000M$ stock standard solutions made from the analytical-reagent or USP grade substances in water.

FDNB working solution, 5.0% (0.269M) in acetone. Prepared by dissolving 1.25 g of FDNB (Sigma) in 25.0 ml of acetone, stored in a sealed amber glass vial in the refrigerator and kept sealed except when being used. It is stable for at least one month, and should be carefully handled as it is vesicatory.

Mixed borate (0.0300M)–fluoride (3.0×10^{-5}M)–DCTA (0.005M) buffer, pH 9.0. Prepared by dissolving 11.4 g of $Na_2B_4O_7.10H_2O$ and 1.73 g of *trans*-1,2-diaminocyclohexane-*N,N,N',N'*-tetra-acetic acid (DCTA) in 800 ml of water, adjusting the pH to 9.0 (pH-meter) adding 300 μl of $0.1000M$ sodium fluoride and diluting to 1 litre.

Standard fluoride solutions. Working standard solutions were prepared by dilution of $0.1000M$ stock sodium fluoride solution. All fluoride solutions were stored in polyethylene bottles.

Procedure

Pipette 10.00 ml of a working standard or sample analyte solution and 5.00 ml of the mixed buffer into the reaction cell. Start the stirrer and after the potential has stabilized (about 20 sec) adjust the recorder pen to the high potential side of the chart, set to 20 mV full scale, and start recording. Initiate the reaction by the injection of 100 μl of FDNB working solution with a micro-syringe and record the reaction curve for about 2–3 min. Empty the cell, wash it twice with water and proceed to the next sample. Include a water blank with each set of measurements. Estimate graphically the initial slope $\Delta E/\Delta t$ (mV/sec) for the kinetic study and analytical determinations by the initial-rate procedure, or the potential change ΔE (mV) for the stated time interval for each analyte, for determinations by the fixed-time procedure. Using the standard analyte solutions, construct a calibration graph of $\Delta E/\Delta t$ *vs.* concentration (initial-rate method) or $(10^{\Delta E/S} - 1)$ *vs.* concentration (fixed-time method). Subtract ΔE for the blank from the ΔE values for the standards and samples. Determine S, the electrode response slope, by successive additions of 100 μl of 1.5×10^{-3} and $1.5 \times 10^{-2}M$ standard fluoride solutions to 10.0 ml of water mixed with 5.00 ml of buffer and measurement of the potentials.

Sample preparation

The sample solutions should be neutralized to phenolphthalein if necessary. For assays of drug formulations the official USP procedures for sampling and treatment are followed and a suitable portion of the homogenized sample is dissolved or diluted with water to give a concentration within the range of the calibration graph. Sample dissolution can be assisted with a vortex mixer and the clear supernatant liquid is used for measurements.

RESULTS AND DISCUSSION

Selection of experimental conditions

The rate of the FDNB reaction with hydrazines, hydrazides and azide is drastically affected by pH because of base catalysis of the liberation of fluoride from the intermediate complex. FDNB is also hydrolysed in alkaline solutions. A borate buffer of pH 9.0 was chosen as optimum for the proposed kinetic method with the fluoride electrode as this ensured a moderate reaction rate, low interference from hydroxide, and a low FDNB hydrolysis rate. A final borate concentration of $0.0100M$ in the reaction mixture was chosen as a compromise between the requirements for low ionic strength and sufficient buffer capacity. A preliminary pH adjustment of very acidic or alkaline sample solutions is therefore necessary.

The electrode was found capable of producing reliable kinetic measurements in the chosen buffer, providing that an addition of fluoride equal to the lower linear concentration limit ($1 \times 10^{-5}M$) is first made to the reaction mixture.[25]

DCTA was added to the mixed buffer to mask any Fe^{3+} and Al^{3+} present in the samples. The kinetic study and the analytical determinations were performed at 25°. At higher temperatures the rate of both the main reaction and the FDNB hydrolysis is accelerated. Acetone was used as solvent for the reagent because it produces negligible solvolysis, mixes rapidly with the buffered sample solution and in the amount used has no practical effect on the electrode response.

Kinetic study of the reactions

The reaction of amino-compounds with FDNB is a nucleophilic aromatic substitution, with formation of an intermediate complex. The same mechanism is believed to be followed in the reactions with hydrazines and azide.[28] Its scheme is:

$$\mathrm{RNHNH_2} + (\mathrm{NO_2})_2\mathrm{C_6H_3F} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} (\mathrm{NO_2})_2\mathrm{C_6}\overset{\ominus}{\mathrm{H}}_3(\mathrm{F})\overset{\oplus}{\mathrm{N}}\mathrm{H_2NHR} \xrightarrow{k_2} (\mathrm{NO_2})_2\mathrm{C_6H_3NHNHR} + \mathrm{H^+} + \mathrm{F^-} \quad (1)$$

Assuming a steady state, the rate of fluoride formation is described by

$$d[\mathrm{F^-}]/dt = \frac{k_1 k_2}{k_{-1} + k_2}[\mathrm{RNHNH_2}]_f[\mathrm{FDNB}]_f = k_{\mathrm{exp}}[\mathrm{RNHNH_2}]_f[\mathrm{FDNB}]_f \quad (2)$$

where k_{exp} is the overall experimental second-order rate constant. By differentiation of the Nernst equation for the fluoride electrode with respect to time, we have

$$dE/dt = S'(1/[\mathrm{F^-}])\,(d[\mathrm{F^-}]/dt) \quad (3)$$

where S' is the slope of the E *vs.* $\ln[F^-]$ calibration graph. Equation (3) is valid in the linear part of the electrode response graph, *i.e.*, for $[F^-] > 1 \times 10^{-5}M$.

Combining equations (2) and (3), at the start of the reaction where the initial slope is measured, we have

$$(\Delta E/\Delta t)_0 = S'(1/[F^-]_0)\, k_{exp}[RNHNH_2]_0\,[FDNB]_0 \quad (4)$$

Since the pK_a values of the conjugated acids of the compounds tested are <9.0, it is assumed that the molar concentration of the unprotonated reactive hydrazine or azide group is equal to the stoichiometric concentration $C_{0,RNHNH_2}$.

As FDNB is also subject, to a small extent, to hydrolysis and reaction with hydroxide at pH 9.0 (with rate constants $k_h = 6 \times 10^{-6}$ sec^{-1} and $k_{OH^-} = 0.05$ l.mole^{-1}.sec^{-1} at 35° respectively), the initial $(\Delta E/\Delta t)_0$ for the FDNB reactions must be corrected. A blank of $(\Delta E/\Delta t)_{0,hydrolysis}$ can easily be measured or considered as equal to the intercept of the plots of $(\Delta E/\Delta t)_0$ *vs.* C_{RNHNH_2}.

From experiments in which the FDNB concentration was varied over the range 1.8×10^{-4}–$7.2 \times 10^{-4}M$ with constant hydrazine concentration ($6.7 \times 10^{-4}M$), the reaction order for FDNB was found to be 1.03 ± 0.02. From experiments with various concentrations of the test substances and a constant concentration of FDNB, k_{exp} and the reaction order with respect to the substance can be obtained.

Figure 1 shows typical E–t curves for the FDNB–azide reaction, used for the calculation of the kinetic parameters. The experimental results and the calculation of the kinetic parameters according to equation (4) are shown in Table 1. It is shown that the reaction is first-order with respect to azide, that the precision of the kinetic parameters obtained

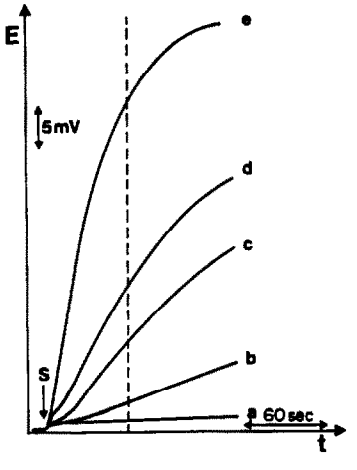

Fig. 1. Typical E–t curves of the FDNB–azide reaction for the calculation of the kinetic parameters and calibration graphs at 25° and pH 9.0. $[NaN_3]$, *m*M	$(\Delta E/\Delta t)_0$, *mV/sec*	$(\Delta E/\Delta t)_0'$ (corrected), *mV/sec*
0.667	0.160	0.018
3.333	0.222	0.080
6.667	0.336	0.194
33.33	1.05	0.908

$(\Delta E/\Delta t)_{0,\,hydrolysis} = 0.142$ mV/sec
Reaction order for azide = 1.04 ± 0.08, $r = 0.9995$
$k_{exp} = 0.0129 \pm 0.0006$, l.mole^{-1}.sec^{-1}, $r = 0.9994$

is sufficient for such a kinetic study, and that the regression coefficients are greater than 0.999. Figure 2 shows the effect of pH on the rate of the FDNB–azide reaction. Since pK_a of hydrazoic acid is 4.65, the azide ion will be the reactive species at pH 8 and 9, and so the pH effect on the reaction rate can be explained only by base catalysis in the second step of the reaction [equation (1)]. This differs from the behaviour of amino-acids and amines, where the pH affects the protonation of the reacting group.

Figures 3 and 4 show typical E–t curves of the FDNB–isoniazid reaction and the effect of pH on the reaction rate, respectively. Since pK_a of the conjugated acid is 3.85, as in the case of azide, base catalysis by hydroxide must be assumed. As shown in Table 2, the reaction is also first order with respect to isoniazid. Table 3 shows the results of the kinetic study. The reaction is seen to be first order with respect to all the analytes studied. Unfortunately, no kinetic data for these reactions could be found in the literature for comparison. Hydrazine was found to be the most reactive, followed by procarbazine and isoniazid. The rate constants of the hydrazine derivatives show that the reactivities increase with the basicity of the hydrazine group, as shown by pK_a for the conjugated acid: hydrazine 7.96 > hydralazine 7.1 > phenylhydrazine 5.20.

Analytical applications

From equation (4), the initial slope of the reaction curve is linearly related to the analyte concentration, since the reaction is first order (Table 3). The reaction rates at pH 9.0 are suitable for use of the fluoride electrode for monitoring a kinetic method of analysis. The base catalysis by hydroxide requires the reaction pH to be controlled. The shape of the reaction curves in Figs. 1 and 3 suggests that the initial-rate and fixed-time methods can be used for construction of the calibration graphs, but the so-called reciprocal time method cannot.[24]

For the determinations by the fixed-time method, a Δt value of 60 or 120 sec was selected, depending on the relative rate of the individual reaction. Table 4 shows the results obtained by the initial-rate (IR) and fixed-time (FT) methods. It also summarizes the performance data. The detection limit depends on the relative reaction rate of each substance, the lowest being for hydrazine, and the highest for azide. The precision of the measurements was reasonable for kinetic potentiometric determinations, RSD 1.8–3.5%. The total measurement time, for both kinetic methods, ranged from 2 to 3 min, depending on the reaction rate.

To evaluate the operative life of the fluoride-selective electrode in a working medium different from its optimum one (*viz.* borate buffer pH 9.0, in the presence of FDNB and a small concentration of acetone), the same electrode was used throughout the whole study of the FDNB reactions with amino and hydrazino compounds. This four-year study showed that the slope of the electrode response was the expected Nernstian one (59 mV/pF) in the first two years of its use, decreasing slowly to about 49 and 36 mV/pF in the third and fourth year respectively. The decreased slope of about 36 mV/pF used in this work has no effect on the kinetic parameters calculated, but

*Calculated by range method ($n = 3$).

higher sensitivities and lower detection limits for the analytical methods are expected when an electrode less than two years old is used.

The proposed method was applied to the determination of those substances of pharmaceutical interest, in commercial formulations, *viz.* hydralazine, procarbazine and isoniazid. The results are shown in Table 5. Good precision (1–2% RSD, 3 samples each measured three times) and good agreement with the reference methods were obtained. The excipients in the formulations analysed had no effect on the determination. FDNB reacts only with primary and secondary amines, phenols, mercaptans, hydrazines and hydrazides, so a selective determination of the drug, in the presence of other drugs or excipients having other functional groups, is possible by the proposed method. The very simple and selective determinations of hydralazine in the presence of hydrochlorothiazide and of isoniazid in the presence of the highly coloured rifamycin are particular advantages over the usual analytical procedures. Most of the sample solutions in the assays were coloured or cloudy, and for such cases the superiority of ion-selective potentiometry is obvious.

Table 5. Comparison of results obtained by the proposed kinetic potentiometric (initial-rate) and established methods for the determination of drugs in commercial formulations

†Contains 15 mg of hydrochlorothiazide.

§Contains 150 mg of rifamycin.

‡Contains 300 mg of rifamycin.

Semicarbazide and the cyclic hydrazide luminol were found not to react with FDNB.

CONCLUSIONS

This work shows the usefulness of ion-selective electrodes in kinetic studies of reactions, in which an ion that can be monitored by the electrode is produced. Furthermore it demonstrates that ion-selective electrodes can be used to provide simple, rapid and selective kinetic methods of analysis. The application of the proposed method in routine pharmaceutical control, and especially in the assay of drug combinations, shows the advantages of ion-selective electrodes in the analysis of coloured and cloudy sample solutions.

COMPLEX-FORMING PROPERTIES OF NATURAL ORGANIC ACIDS

FULVIC ACID COMPLEXES WITH COBALT, ZINC AND EUROPIUM

(*Received* 30 *March* 1988. *Revised* 11 *November* 1988. *Accepted* 29 *November* 1988)

Summary—The complex-forming properties of a fulvic acid sample have been studied by an ion-exchange distribution method. The results have been analysed by a novel physicochemical approach which attempts to take into account complications introduced by the polyelectrolyte nature and functional heterogeneity of the fulvic acid molecule. These studies with trace level concentrations of cobalt, zinc and europium show that these metal ions are selectively complexed by the weakly acidic enol grouping of the fulvic acid molecule. The logarithms of the stability constants (β_1) for the cobalt, zinc and europium chelates are 6.5, 6.4 and 10.3 respectively.

The complex-forming properties of natural organic acids have been examined by scientists[1–7] whose major concerns have been to determine the binding capacities of these acids. Attempts to determine the stability constants of the metal complexes formed with these humic materials have been thwarted by the complexity of these natural organic acids in solution. Considerable interest in the problem has developed over the past few years, and though some progress has been made, the capability for achieving this goal has developed only slowly.

Recently, a new physicochemical approach to the problem was developed.[8] This approach has led to a better understanding of the two complicating factors, the polyelectrolyte nature and functional heterogeneity of the natural organic acid molecule, that have disturbed analysis of the data obtained in studies of proton and metal-ion binding to humic substances.[9] Its contribution to elucidation of the observed properties of aqueous solutions of these natural organic acids is the major asset of this approach. It makes it possible to give an adequate description of the binding patterns of various metal ions to these natural organic acids.[10]

This unified physicochemical approach is used in this paper to examine the complexation of cobalt, zinc and europium by an Armadale Horizons Bh fulvic acid. The distribution of these metal ions at trace level concentrations between a cation-exchange resin and fulvic acid in simple salt solutions has been measured to facilitate this study.[11]

THEORY

The distribution coefficient, D_0, characterizing the partition of a trace metal ion between 1 g of resin in the counter-ion (Na^+) form and 1 g of a sodium salt (NaX) in the solution phase can be expressed as

$$D_0 = \frac{[\overline{M}^{z+}]}{[M^{z+}]} \tag{1}$$

In equation (1) and the equations which follow, a bar represents the resin phase.

The equilibrium quotient, Q_0, for the ion-exchange reaction between the trace metal ion and Na^+

$$M^{z+} + z\overline{Na}^+ = \overline{M}^{z+} + zNa^+ \tag{2}$$

may be represented by

$$Q_0 = D_0([Na^+])/([\overline{Na}^+])^z \tag{3}$$

In experiments with trace metal ions (10^{-12}–$10^{-7}M$), $[\overline{Na}^+]^z$ is constant. Since $Q_0[\overline{Na}^+]^z$ is also constant, the logarithmic form of equation (3) yields:

$$\log D_0 = \log K - z \log[Na^+] \tag{4}$$

where K is a constant. When a ligand L is added to the system, some of the trace metal ion is sequestered and the distribution coefficient is lowered to D, given by

$$D = [\overline{M}^{z+}]/\sum[M] \tag{5}$$

where $\sum[M] = [M]_{free} + [M]_{bound}$, subsequently denoted by M_f and M_b respectively. The relationship of

D_0 and D to the complexation property of the system under investigation is readily obtained:

$$\frac{(D_0 - D)}{D} = \frac{M_b}{M_f} = \sum_{i=1}^{n} \beta_i [L]^i \qquad (6)$$

where β_i is the stability constant of the ith complex and [L] is the effective ligand concentration. If [L] can be measured, one or more of the complex formation constants, β_i, can be resolved by this experimental approach. Two major assumptions are made in the development of equation (6), *viz.* that positively charged complexes with FA as the ligand do not exchange with Na^+, and that physical sorption of the FA molecule by the resin is practically non-existent.

EXPERIMENTAL

Reagents

Triply distilled water was used in preparation of all solutions. Analytical grade Bio-Rad cation-exchange resin, Ag 50WX8, 50–100 mesh, in the hydrogen-form, was converted into the sodium form and allowed to equilibrate with water vapour in desiccators containing saturated ammonium nitrate solution, for a period of one week before transfer to polyethylene bottles for storage. Sodium hydroxide solutions were prepared from "Dilut-it" concentrates (J. T. Baker). The freshly prepared solutions were transferred to polyethylene bottles and stored in desiccators containing "Ascarite" to ensure a CO_2-free atmosphere. Before use, the sodium hydroxide solutions were standardized with potassium hydrogen phthalate.

The radioisotopes ^{154}Eu, ^{65}Zn, ^{22}Na and ^{60}Co, in 0.50*M* hydrochloric aicd, and with a purity of 99%, were purchased from New England Nuclear Corporation. Armadale fulvic acid was obtained from C. H. Langford of Concordia University, Canada and D. Gamble of the Soil Research Institute, Ottawa, Canada.

The water content of the resin was determined by drying 0.10–0.50 g samples under vacuum at a temperature of about 60° to constant weight. The resin exchange capacity was determined by an isotope dilution technique employing ^{22}Na. This was done to check that the resin was totally converted into the Na-form.

Procedure

The pH and metal ion uptake by the resin from fulvic acid solutions were measured as a function of degree of fulvic acid neutralization, for varied fulvic acid and bulk electrolyte concentrations.

In a typical experiment, about 1–2 μCi of the radioactive nuclide was added to the fulvic acid (FA) solution of the desired FA concentration, pH and defined ionic strength. Two weighed aliquots of the solution were then added to two previously weighed (0.10–0.50 g) samples of wet sodium-form resin in polyethylene bottles, which were then shaken for at least 24 hr in a water-bath at 25 ± 0.5°. After equilibrium had been reached, the pH of the solution was determined and duplicate aliquots of the solution phase were removed for radioactivity measurement. Parallel experiments were performed for the same ionic strength in the absence of fulvic acid. These distribution measurements were also performed over a fairly wide range of bulk electrolyte concentration in order to define the distribution (D_0) of the trace metal ion between the resin and solution phases in the absence of the fulvic acid.

In a number of experiments, because of removal or uptake of protons by the resin, the pH of some of the samples had to be readjusted with additional base until the required pH was obtained in a final equilibration of the resin, salt, fulvic acid and trace metal ion mixture. Fairly widely differing amounts of resin were used with aliquots of the same original solution to check the reproducibility of the measurement from the values of the $(D_0 - D)/D$ ratios found for each set of experimental conditions.

Radioactivity measurements were performed with a Canberra multichannel analyser equipped with a 3 × 3 in. NaI(Tl) crystal as the detector. The size of the samples for measurement was kept identical within a few per cent to ensure reproducibility in the geometry of the active source. To ensure high statistical precision, at least 10^5 counts were accumulated. The observed sample counts were corrected for background, measured over a sufficiently long time interval to ensure its accurate assessment.

RESULTS AND DETERMINATION

Background information

In our earlier potentiometric examination of the Armadale FA, the apparent pK of the acid was determined at various neutral salt concentrations to relate this property to pH and the degree of neutralization, α. The distribution studies were conducted over the same salt concentration range so that the extent of neutralization as well as the electrostatic contribution to pK^{app} could be estimated. To resolve the electrostatic deviation term, the following method was employed. The pH at equilibrium was related to the degree of neutralization of the fulvic acid molecule, α, and hence to the apparent dissociation constant, pK^{app}. From plots of degree of neutralization, α, and the electrostatic contribution, obtained earlier for the experimental ionic strength, the electrostatic contribution of each sample could be estimated.

It was in the course of this metal–humate interaction study that the selective removal of Zn(II), Co(II) and Eu(III) ions from solution was linked directly to the weakly acidic enol site of the Armadale FA. The extent of complexation through chelation by the dihydroxy assembly initially proposed for this acidic site[10] required much too large a formation constant to be considered as the principal reaction path. Formation constants reported in the literature for such chelates (*e.g.*, catechol)[12] were orders of magnitude smaller than the constants needed to correlate the ion-exchange distribution data. It was necessary to suggest that carbonyl groups replaced 10% of the phenolic part of the dihydroxy group.[10] The magnitude of the formation constant calculated for such a chelate with this estimate is in reasonable enough agreement with the constants reported for analogous chelates (*e.g.*, acetylacetonates) to justify this rationalization.[12]

Unambiguous identification of the weakly acidic hydroxyl group as the site responsible for the selective complexation of Zn(II), Co(II) and Eu(III) by the Armadale FA was effected in the following way. Literature values for the stability constants of the complexes formed by these metal ions with the functional groups assigned to the Armadale FA[12] were employed in the procedure developed in the Cu(II)–FA study[10] to predict the amount of bound

metal ion for each experimental condition. Because of free-energy considerations as discussed earlier,[9] the only chelation path considered in these computations as accessible to the metal ion was chelation by the dihydroxy grouping associated with the weakly acidic OH site. Comparison of such estimates of the ratios of bound metal, (M_b), to free metal, (M_f), with the experimentally observed ratios $(D_0 - D)/D$ showed that the experimentally determined bound metal to free metal ratio, $(M_b/M_f)_e$, was always much larger than the corresponding calculated ratio, $(M_b/M_f)_c$. This difference was treated as shown below. To identify the acidic FA site responsible for the extra complexation the $(M_{b(e)} - M_{b(c)})/M_f^{z+}$ ratio was first divided by $\gamma_M(\exp)^z \alpha A$ and equated to β_{MA} to give

$$\frac{M_{b(e)} - M_{b(c)}}{M_f^{z+}\gamma_M(\exp)^z \alpha A} = \beta_{MA} \qquad (7)$$

where γ_M represents the single-ion activity coefficient assigned by Kielland[13] to the ion M^{z+} at the experimental ionic strength, $(\exp)^z$ corresponds to the electrostatic correction term applicable to M^{z+} at the experimental pH and ionic strength (Fig. 24 in ref. 9), and α and A are respectively the degree of dissociation and the abundance of the acidic group involved in the complexation reaction and unaccounted for in the earlier summation of metal-ion binding reactions. In the experiments at 20 ppm FA concentration level the electrostatic correction term was increased by 0.15–0.20 to account for the displacement of $pK^{app}_{(FA)_v}$ observed at this FA concentration level.[9] The values of α, A and β were not then available, of course, and experimental points treated by equation (7) had to be expressed as the products $\alpha A \beta_{MA}$. By dividing one such experimentally based product by the next as shown below:

$$\frac{\{M_{b(e)1} - M_{b(c)1}\}M_{f2}(\exp_{(2)})^z}{\{M_{b(e)2} - M_{b(c)2}\}M_{f1}(\exp_{(1)})^z} = \frac{\alpha_{(1)}A\beta_{MA}}{\alpha_{(2)}A\beta_{MA}} = \frac{\alpha_{(1)}}{\alpha_{(2)}} \qquad (8)$$

the α could be obtained as a function of pH. The constant terms, A and β_{MA}, cancel to leave $(n-1)$ relationships between the $n\alpha$-values. Suitable assignment of a value to α, on a trial and error basis, quickly resolved the intrinsic pK of the acidic unit responsible for the selective complexation reaction. When the α_n values, so resolved, were combined with the corresponding experimental pH value and the appropriate electrostatic correction term in equation (9) the most suitable assignment of α_1 resulted in a pK^{int}_{HA} value of 5.65 ± 0.2:

$$pK^{int}_{HA} = pH - \log\left(\frac{\alpha}{1-\alpha}\right) + \exp \qquad (9)$$

This pK value is close enough to the pK value of the enol group that has already been assigned to the Armadale Horizons Bh fulvic acid on the basis of our earlier investigation of its protonation in aqueous media,[9] for it to be identified with the selective complexation of Zn(II), Co(II) and Eu(III).

Computation procedure

It was observed that correction for the binding of Eu(III) by the other sites was small enough to be neglected and the ion-exchange distribution data were used directly in equation (10), below, to compute the formation constant of the chelate formed by its interaction with site IV, the carbonyl–enol assembly.[9]

$$[Eu^{2+}_{IV}] = \frac{(D_0 - D)}{D(\exp)^3\gamma_{Eu}[FA_T]\alpha_{IV}A_{IV}f} \qquad (10)$$

In this equation FA_T refers to the molarity, calculated on a monomer basis, of the FA source, A_{IV} is equal to 0.3, the fractional abundance of the weakly acidic OH site,[9] α_{IV} is the degree of dissociation of this site and f, equal to 0.10, is the fractional frequency of substitution of carbonyl groups for the phenolic OH groups *ortho* to the weakly acidic OH group of the fulvic acid molecule.

With the Zn(II) and Co(II)–FA systems, however, correction for binding of these ions to the sites had to be made. Even though the magnitude of this correction term was also much smaller than the total binding experienced, it was usually still too large to be neglected. Literature-based constants for the uni- and bidentate complexes considered to be formed by these trace metal ions with the various acidic groups of the FA molecule were used to facilitate the series of computations involved.

For the computation of the quantity of metal ion bound in the unidentate mode to each of the four acidic sites assigned to the Armadale FA molecule in an earlier study,[9] single β_{uni} values of 50 for the Zn(II) complex and 30 for the Co(II) complex were assigned from the literature[12] for use in equation (11):

$$\sum_{n=1}^{n=IV} M_{b(uni)}/M_f = \beta_{uni}\gamma_M(\exp)^2 \sum_{n=1}^{n=IV} [FA_T]A_n\alpha_n \qquad (11)$$

Unlike that of Cu(II), the degree of interaction of these ions with a weakly acidic carboxylic or hydroxy group is, because of the much lower covalency in the bond formed, much less susceptible to the acidic strength of the group. This justifies the assignment of a single literature-based formation constant to the series of unidentate complexes in accounting for the metal-ion binding.

The sequence of computations presented below was made for estimation of the quantity of metal ion complexed by the more weakly acidic groups (amino and phenol) positioned *ortho* to the acidic groups identified in our earlier study.[9] The carboxylic acid group, with a fractional abundance of 0.30 and an intrinsic pK of 3.40, on the basis of our earlier study,[9] was presumed to have both –OH and $-NH_2$ groups *ortho* to it. The resultant salicylate-like group was presumed to have a fractional abundance of 0.23, the remainder ($A = 0.07$) being assigned to the proposed aminocarboxylic acid assembly. The respective contributions to the removal of metal ion from solution

were determined with equations (12) and (13)

$$(M_b/M_f)_{Sal} = K^{Exch}_{MSal} \frac{0.23\,\gamma_M(exp)\alpha_{II}[FA_T]}{[H^+]\gamma_H} \quad (12)$$

$$(M_b/M_f)_{amino} = K^{Exch}_{Mamino} \frac{0.07\,\gamma_M(exp)\alpha_{II}[FA_T]}{[H^+]\gamma_H} \quad (13)$$

Values of 7.1×10^{-7} and 5.2×10^{-7} for K^{Exch}_{MSal} for Zn(II) and Co(II) were arrived at by using the literature values[13] of β_{MSal} (7.1×10^6 and 5.2×10^6 respectively). Values of 3.4×10^{-4} and 3.7×10^{-4} assigned to K^{Exch}_{Mamino} for Zn(II) and Co(II) were arrived at by using the literature values[13] (3.4×10^6 and 3.7×10^6) for β_{Mamino}. The pK_2 values for the salicyclic and amino groups (13 and 10 respectively) were used to describe the dissociation of OH and NH_2 in the corresponding assemblies in the FA molecule.

Estimation of the M_b/M_f contribution by 90% of the dihydroxy sites (site IV) used a similar approach. The K^{Exch}_{Mdihyd} value of 1.6×10^{-2} assigned to Zn(II) and Co(II) was based on the value used to predict the binding of the Cu(II)–dihydroxy complex[10] and the observation that complexes of Co(II) and Zn(II) were significantly similar.[13]

$$(M_b/M_f)_{dihyd} = K^{Exch}_{Mdihyd} \frac{0.9\,\gamma_M(exp)\alpha_{II}[FA_T]A_{IV}}{[H^+](\gamma_H)} \quad (14)$$

Results

To test the validity of the distribution measurements, the log D_0 values obtained as a function of salt concentration with trace level concentrations of Eu(III), Co(II) and Zn(II) are plotted in Fig. 1 *vs.* the logarithm of the activity of the Na^+ ion at the various salt concentration levels examined in the experimental programme. Such a plot, according to equation (3), should yield a straight line with a slope numerically equal to $-z$, where z, as noted earlier, is the charge of the trace cation under investigation.

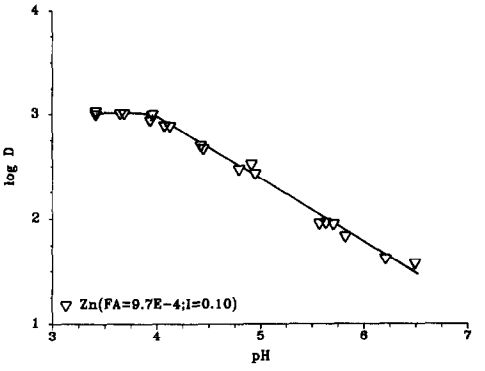

Fig. 2. The variation of the distribution coefficient (D) of Zn(II) in the presence of fulvic acid, as a function of pH.

The slopes of the lines drawn through such plots of the distribution data are −3.01, −2.02 and −2.05 for Eu(III), Co(III) and Zn(II), in agreement with expectation. This shows that in the salt concentration range examined, the assignment of a constant Na^+ content to the resin in the development of equation (3) is indeed justifiable.

In Figs. 2–4, the log D values measured for the three trace metal, FA, NaCl, NaR systems investigated is plotted *vs.* the pH measured concurrently. The value of log D decreases with increasing pH in these plots, showing that the degree of complexation increases with pH as expected. With the Zn(II) system (Fig. 2) plateaus in log D appear to be reached at low (~3.5) and high (~6.3) pH-values. With the Co(II) system (Fig. 3) a plateau in log D occurs at the same low pH but no second plateau is observed in the high pH region, even above pH 7. Since evidence for a log D plateau at pH > 6.3 is based on only one point in the Zn distribution study, whereas the many data points obtained in the Co(II) distribution experiments at pH > 6.3 and up to and exceeding pH 7 provide no corroborating support for

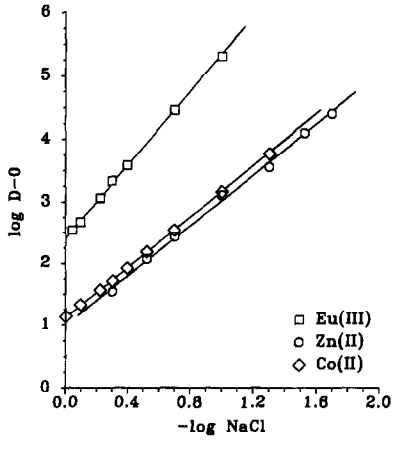

Fig. 1. The dependence of the distribution coefficients (D_0) of Eu(III), Co(II) and Zn(II) on the concentration of bulk electrolyte.

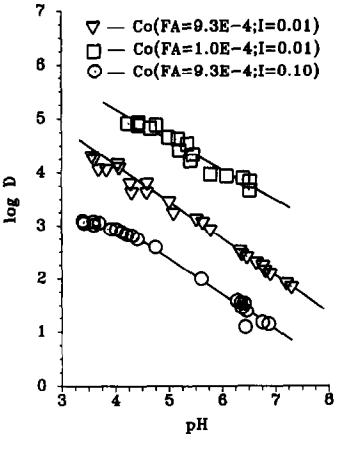

Fig. 3. The variation of the distribution coefficient (D) of Co(II) in the presence of fulvic acid, as a function of pH and ionic strength.

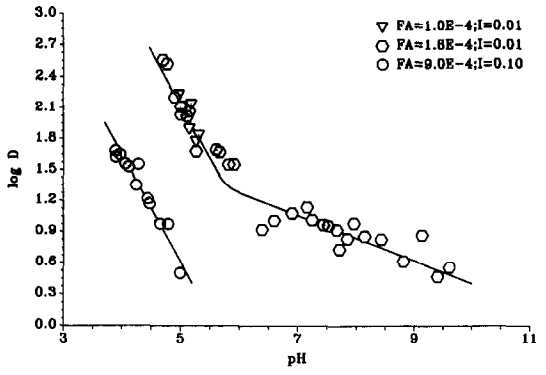

Fig. 4. The variation of the distribution coefficient (D) of Eu(III) in the presence of fulvic acid, as a function of pH and ionic strength.

the appearance of this plateau, it is reasonable to question the validity of this lowest log D value in Fig. 2; the curve drawn in Fig. 2, therefore, ignores the log D value obtained for Zn(II) at the highest pH.

In the Eu(III)–FA system a plateau in log D is reached at a pH value of about 6.3. The experimental pH never reaches a low enough value to develop the plateau in log D that is expected to occur in the low pH range.

The appearance in the Zn(II)- and Co(II)–FA, NaCl, NaR systems of a plateau in log D at pH values below 4 (Figs. 2 and 3) is to be expected. Over this pH range the dissociation of the group responsible for their selective complexation is small. Since the formation constant of these metal ions with the (–R–CO–COH)$_v$ group is too low to affect removal of the trace ions from solution, under these conditions the value of D must approach D_0, to yield the observed plateau. For Eu(III), which binds much more strongly to the (–R–CO–COH)$_v$ grouping, it is obvious that the pH at which the value of D levels off must be even lower than for Zn(II) and Co(II).

The appearance in the Eu(III)–Fa, NaCl, NaR system of a plateau in the plot of log D *vs.* pH (Fig. 4) at pH > 6.3, whereas no such plateau is observed for the Co(II) system (Fig. 3) is more difficult to explain. A plateau at high pH is expected for both systems since the availability of the ligand (–R–CO–CO–)$_v$ in this high pH range can increase by not more than a factor of about 2, limiting the change in log D to approximately 0.3, as observed with the Eu(III) system. This unexpected contrast in behaviour of the two systems may be a consequence of the difference in the complexation and hydrolysis properties of these two ions. In the case of Eu(III) the tendency for complexation of this metal ion by the (–R–CO–COH)$_v$ grouping may be large enough to keep the quantity of tervalent ion present in solution low enough to minimize formation of $Eu(OH)^{2+}$ and $Eu(OH)_2^+$ even when the pH is raised significantly. With Co(II), hydrolysis may be the controlling factor because of the lower formation constant of $Co(–R–CO–CO–)_v^+$; the value of D in this instance is apparently lowered by the competitive formation of hydroxo-complexes of Co(II). For example the reaction $Co^{2+} + 2H_2O \rightleftharpoons Co(OH)_2 + 2H^+$, has a reported constant of 3.16×10^{-11}.[14] At pH 7.0, the ratio of $Co(OH)_2$ to Co^{2+} is thus 3.16×10^3. This competitive formation of hydroxo-complexes of Co(II) at high pH values may account for the absence of a plateau in the log D *vs.* pH plots for the Co(II)–FA, NaCl, NaR system.

Finally, the effect of ionic strength and initial FA concentration levels on log D as a function of pH was briefly surveyed in Fig. 3. Examination of this figure shows that these variables have little effect on the general shape of the three curves; their slopes are approximately the same, 0.7. Lowering the ionic strength (lower two curves) or the initial FA concentration (upper two curves) by a factor of 10 while keeping the second variable unchanged lifts the curves by about the same factor ($\Delta \log D \geqslant 1$).

Any quantitative assessment of the significance of these observed properties of D has to wait for analysis of the distribution data with equation (7). The results of such analyses are summarized for Zn(II), Co(II) and Eu(III) in Table 1.

Table 1. Stability constants ($\beta_{M(-R-CO-CO-)_v^{(z-v)+}}$) for the selective binding of zinc, cobalt and europium by the enolic grouping of the Armadale Horizon Bh fulvic acid

Metal ion	Fulvic acid, M	Ionic strength, M	pH range	Stability constant
Zn^{2+}	9.70×10^{-4}	0.100	3.4–6.5	$(2.51 \pm 0.92) \times 10^6$
Co^{2+}	9.31×10^{-4}	0.010	3.6–4.5	$\sim 2 \times 10^7$
			5.0–7.3	$(5.0 \pm 1) \times 10^6$
Co^{2+}	9.97×10^{-5}	0.010	4.3–6.7	$(2.0 \pm 0.9) \times 10^6$
Co^{2+}	9.28×10^{-4}	0.100	3.4–6.8	$(2.9 \pm 0.8) \times 10^6$
Eu^{3+}	9.00×10^{-5}	0.010	4.9–5.3	$(2.7 \pm 0.4) \times 10^{11}$
Eu^{3+}	1.80×10^{-4}	0.010	4.7–5.3	1.2×10^{11}
			5.6–9.6	$(5 \pm 2) \times 10^{10}$
Eu^{3+}	1.30×10^{-4}	0.050	4.3–4.9	$(1.1 \pm 0.4) \times 10^{10}$
Eu^{3+}	9.00×10^{-4}	0.100	3.9–5.0	$(3.5 \pm 0.7) \times 10^{10}$
Eu^{3+}	9.00×10^{-5}	0.300	3.6–3.8	$(2.9 \pm 0.5) \times 10^{10}$

The evaluation of D and consequently of $(D_0 - D)/D$ and β is susceptible to greatest error at low and high pH values, where propagation of errors in the evaluation of D becomes sizable. At low pH the amount of radioactivity left in solution approaches the background. Even as small an error as 1% in measuring the gross activity (which includes the background) can yield an absolute error of about 50–100% in some cases. The danger of error propagation at high pH is attributable to the fact that most of the radioactivity is left in solution and the computation of the distribution coefficient involves the difference between two large numbers that can be very nearly the same and have practically the same variance. Again a 1% error in the counting can produce a much larger error in the computation of the distribution coefficient.

The ion-exchange distribution data compiled in the studies carried out with ^{65}Zn in $0.10M$ sodium chloride and $9.7 \times 10^{-4}M$ FA over the equilibrium pH range from 3.4 to 6.5 (Table 1) yield consistent values for $\beta_{Zn(-R-CO-CO-)_v^+}$. They lead to the value $2.5 \pm 0.9 \times 10^6$ for the formation constant.

The ion-exchange distribution data for ^{60}Co as a function of pH were obtained in three separate experiments. One of these mimicked the conditions of the study with trace ^{65}Zn ($9.28 \times 10^{-4}M$ FA and $0.10M$ sodium chloride) and the $\beta_{Co(-R-CO-CO-)_v^+}$ value of $2.9 \pm 0.80 \times 10^6$ obtained is quite close to the β value obtained for the Zn compex with the keto-enol grouping proposed as a chelating site in the Armadale Horizons Bh fulvic acid molecule.

In the two additional experiments run at the lower ionic strength of $0.010M$ the one with more dilute FA ($9.97 \times 10^{-5}M$) yields results ($\beta = 2.0 \pm 0.9 \times 10^6$) consistent with those obtained at the higher ionic strength. The second low ionic-strength experiment, with FA concentration raised almost 10-fold, produces a set of data which, in the same pH range, yield β values much too large and inconstant. Between pH 3.5 and 4.5 the β value falls from 3×10^7 to 1.1×10^7. In the higher pH range (5–7.5) the β value found levels off at $5 \pm 1 \times 10^6$.

The discrepancy between these results can be partially rationalized. The Na^+ concentration of $0.01M$ is raised to almost $0.011M$ in the system where the higher concentration of FA is employed. This leads to an overestimate of D_0 by approximately 30%. This in turn results in a 30% overestimate of β. On this basis the β value may be reduced from 5×10^6 to 3.8×10^6, and then falls on the upper boundary of the earlier $2.9 \pm 0.8 \times 10^6$ estimate. The anomalous distribution behaviour for ^{60}Co in the low pH range is much more resistant to rationalization. At the lowest pH values encountered the quantity of Na^+ in the resin during the D_0 measurements has to be reduced by the square of the factor $[Na^+]/([Na^+] + [H^+])$ for calculation of D_0. At the lowest pH encountered this amounts to $(0.01/0.01032)^2$ and produces only a 6% reduction in D_0 and $\beta_{Co(RCOCO)_v^+}$. This perturbation of the system is obviously not responsible for the rejection of ^{60}Co by the resin.

The second set of data were compiled for a tenfold higher concentration level of FA. The value of D, which is close to D_0 in the low pH region, should have been somewhat less susceptible to the potentially large error possible in that region as a consequence of the higher fulvic acid concentration. The numbers obtained in the low pH region for $\beta_{Co(RCOCO)_v^+}$, though error prone, could not possibly be the source of the discrepancy between the two sets of data.

It is well known that at low pH fulvic acid is adsorbed on uncharged polystyrene spheres. It is this property of fulvic acid that is the basis for its recovery from aquatic sources.[15] It might be suspected that this could lead to some adsorption of fulvic acid by the polystyrene sulphonated resin in the distribution studies. However, such a tendency should lead to low estimates of the metal-ion binding to FA at low pH rather than the higher binding tendencies actually encountered at low pH.

The other explanation for the extra interaction of ^{60}Co with FA in the low pH range when the FA concentration is raised from $10^{-4}M$ to $10^{-3}M$ seems to involve the dipole character of the fulvic acid molecule at low pH, which has been invoked in explaining its potentiometric properties during neutralization with base in non-aqueous media[10] and is expected to lead to metal-ion adsorption through ion–dipole interaction. This phenomenon can be expected to be most noticeable at low pH and low ionic strength, where screening of such dipole interaction would be small.

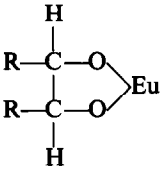
Results of the ion-exchange distribution studies made with solutions of ^{154}Eu and FA at four different salt concentrations are also presented in Table 1. In $0.30M$ sodium chloride the β value obtained from a limited number of points measured at low pH (3.6–3.8) is $2.9 \pm 0.5 \times 10^{10}$. The average value obtained for $\beta_{Eu(-RCOCO)_2^{2+}}$ in $0.10M$ sodium chloride over the pH range from 3.9 to 5.0 is $3.5 \pm 0.7 \times 10^{10}$. The measurements of D in $0.05M$ sodium chloride give a β value of $1.1 \pm 0.4 \times 10^{10}$ over the pH range 4.35–4.90. The FA concentrations in these separate experiments were 9.0×10^{-5}, 9.0×10^{-4} and $1.3 \times 10^{-4}M$, respectively.

Once again the two series of distribution measurements at the lowest ionic strength examined yield anomalous results. An average β value of $2.7 \pm 0.4 \times 10^{11}$ was obtained when the FA concentration was $9.0 \times 10^{-5}M$ and the pH ranged from 4.95 to 5.31. In the second series of experiments, where the FA concentration was doubled to $1.8 \times 10^{-4}M$, the β value over the pH range from 4.7 to 5.3 averaged 1.2×10^{11}. Extending the pH range to 5.6–9.6 lowered the β value to $5 \pm 2 \times 10^{10}$.

Such sensitivity of the formation constant to ionic strength and pH in this study of Eu(III) complexation by FA is comparable to the sensitivity of $\beta_{Co(RCOCO)_v^+}$

in the corresponding experiments with trace concentrations of Co^{2+}. Once again low pH and low ionic strength appear to interfere with this kind of study, because of ion–dipole interaction at the charged surface of the fulvic acid molecule. At high pH such interaction becomes less important, and high ionic strength screens the charged surface of the molecule more effectively. Selective exclusion of counter-ions from the hydrophobic fulvic acid molecule might account for the sensitivity of the formation constants to ionic strength and pH. Use of the previously determined electrostatic correction term (Fig. 24 of ref. 9) becomes uncertain because the different counter-ions experience different potentials relative to the charged surface of the hydrophobic FA molecule.

On this basis of our interpretation of the results in Table 1, the best formation constant value for the proposed Eu(III) complex,



is $\sim 2.0 \times 10^{10}$, and the β values for the Zn(II) and Co(II) complexes are 2.5×10^6 and 2.9×10^6, respectively.

The stability constant obtained for the europium–fulvic acid system is consistent with the value obtained by Berta and Choppin[16] in their studies of the interaction of europium(III) with humic and fulvic acids.

THE EFFECT OF pH ON THE ROOM-TEMPERATURE PHOSPHORESCENCE PROPERTIES OF SEVERAL PURINE AND PYRIMIDINE DERIVATIVES

M. D. GAYE and J. J. AARON*
Institut de Topologie et de Dynamique des Systèmes, de l'Université Paris VII, associé au CNRS, 1, rue Guy de la Brosse, 75005 Paris, France

(*Received* 12 *July* 1988. *Revised* 11 *October* 1988. *Accepted* 17 *November* 1988)

Summary—Room-temperature phosphorescence (RTP) spectra of eleven purines and pyrimidines adsorbed on Whatman No. 40 filter paper have been determined in acidic, neutral and basic media. RTP excitation and emission wavelengths do not vary significantly with pH. For most compounds, use of basic (pH ~13) solutions yields stronger RTP signals than use of neutral or acidic (pH ~1.6) solutions. Exceptions are adenine, theobromine and theophylline, which give larger RTP signals when in neutral than in basic conditions. The existence of differences in phosphorescence quantum yields between the various ionic species as well as of specific pH-related interactions with the substrate is discussed. Absolute limits of detection, ranging between 0.4 and 38 ng for selected compounds, depend on the pH of the analyte solution.

Purine and pyrimidine derivatives constitute a class of compounds of great importance in biochemistry, clinical chemistry, and pharmacology, and their photochemical reactions have been the object of several investigations.[1–10] Their photophysical characteristics have also been extensively examined.[11–24] There are also several reports on the effect of pH on the luminescence of purine and pyrimidine derivatives.[25–33] Borresen[25,26] and Longworth *et al.*[28] found that the acidities of the excited singlet and triplet states of adenine and several other purines and pyrimidines were significantly higher than those for the ground states. Aaron and Winefordner[29] determined the excited triplet state dissociation constants of several purines at 77 K, and observed pK differences ranging between 0.6 and 3.8 from the ground-state values. The pH-related shifts of the fluorescence and phosphorescence bands of sixteen purines and pyrimidines were also interpreted by Parkanyi *et al.*[31] in terms of excited state equilibria. In the equilibria between cation and neutral species, the basicity of most derivatives increased in the excited singlet and triplet states relative to the ground state. In the equilibria between neutral and anion species, all purines and pyrimidines were found to be more acidic in the excited singlet state.[31] Al-Mosawi *et al.*[32] investigated the phosphorescence of 6-mercaptopurine and its derivatives in acidic, neutral and alkaline ethanol glasses at 77 K and also of these compounds adsorbed on cellulose thin-layers at 77 K and at room temperature. A simple, pH-controlled fluorimetric method has been proposed for the determination of purines and pyrimidines.[33] More recently, pH effects on the low-temperature and room-temperature fluorescence and phosphorescence spectra and intensities of caffeine and theophylline have been studied by Andino *et al.*[24]

In a recent paper,[34] we reported the interest in using room-temperature phosphorescence (RTP) for the determination of biologically important purines on filter paper. The presence of heavy ions such as Tl^+, Pb^{2+} and I^- leads to a significant enhancement of RTP signals. We found absolute limits of detection ranging from 400 pg (purine) to 19 ng (theophylline).

In the present study, the effect of pH on the room-temperature phosphorescence properties of selected purines and pyrimidines, on filter paper as substrate, is evaluated. Its potential usefulness for the determination of these compounds is also demonstrated.

EXPERIMENTAL

Apparatus

All excitation and emission RTP spectra were obtained with a Perkin–Elmer model LS-5 luminescence spectrophotometer. Delay and gate times of 0.1 and 9 msec respectively were used. Band-widths of 10 and 2.5 nm were chosen for the excitation and emission monochromators respectively. A laboratory-constructed sample holder was placed in the sample compartment of the LS-5 spectrophotometer and allowed the use of 80-mm^2 filter paper rectangles. During all RTP measurements, the sample compartment was flushed with dry nitrogen.

Reagents

The chemicals used were adenine, caffeine, 6-chloropurine, cytosine, 5-fluorouracil, guanine, 6-mercaptopurine, 6-methylpurine, purine, theobromine, theophylline, 2-thiouracil, thymine and uracil (Aldrich).

Potassium iodide (Normapur) was obtained from Prolabo (Paris). An ethanol–water (70:30 v/v) mixture was used as solvent. Whatman No. 40 filter paper was utilized as substrate.

Procedure

Portions (3 μl) of sample solution (or solvent) and 2 μl of 1*M* potassium iodide were added successively by means of 5-μl Hamilton syringes onto the filter-paper rectangles which were held in the sample holder. The samples were then dried in a stream of hot air for 1 min. Immediately afterwards, the samples were allowed to dry for between 3 and 15 min, depending on the compound, under a flow of dry nitrogen in the sample compartment of the spectrophotometer. RTP measurements were then made. Ethanol–water (70:30 v/v) solutions of purines were freshly prepared. Acidic solutions were approximately 0.1*M* in hydrochloric acid (pH ~1.6) and basic solutions were approximately 0.1*M* in sodium hydroxide (pH ~13).

RESULTS AND DISCUSSION

RTP spectral characteristics

Except for uracil, 5-fluorouracil and cytosine, all the purine and pyrimidine derivatives under study

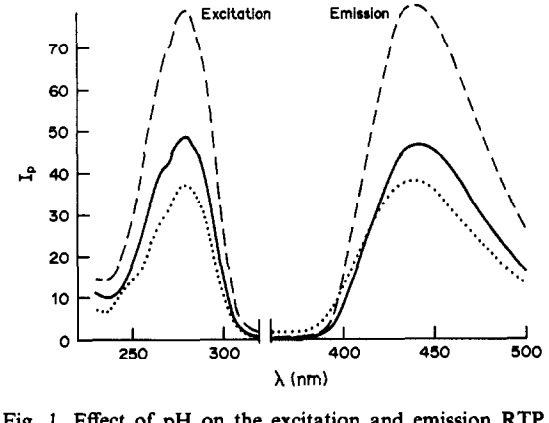

Fig. 1. Effect of pH on the excitation and emission RTP spectra of theobromine ($10^{-3}M$) on W-40 filter paper, in the presence of 1*M* KI: ---- neutral solution (sensitivity ×0.8); —— acidic (0.1*M* HCl) solution (sensitivity × 1); ····· basic (1*M* NaOH) solution (sensitivity × 5).

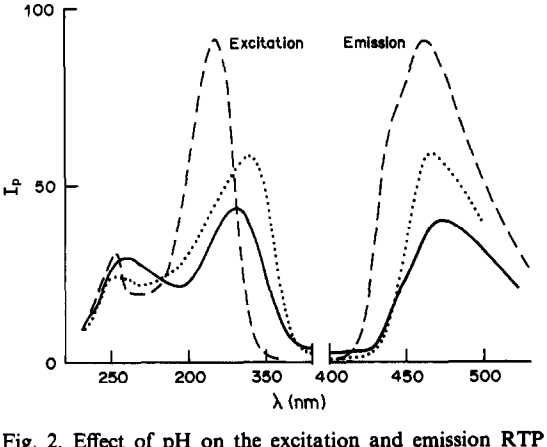

Fig. 2. Effect of pH on the excitation and emission RTP spectra of 6-mercaptopurine ($10^{-3}M$) on W-40 filter paper, in the presence of 1*M* KI: ····· neutral solution (sensitivity × 1); —— acidic solution (sensitivity ×4); ---- basic (1*M* NaOH) (sensitivity × 1).

presented RTP spectra when adsorbed on Whatman No. 40 filter paper in the presence of 1*M* potassium iodide. The RTP excitation and emission wavelength maxima under neutral, basic and acidic conditions are given in Table 1.

The RTP spectra did not vary appreciably with the pH of the sample solution (Fig. 1), with the exception of 6-mercaptopurine and 2-thiouracil, which produced a moderate red-shift of their emission maxima on going from pH 7 to 1.6 for the former (Fig. 2) and from pH 13 to 7 for the latter (Table 1). However, the poor resolution of RTP spectra did not allow us to detect small pH-related changes which might occur in the spectra. Our results are in agreement which those of Andino *et al.*[24] who also found that the RTP spectra of caffeine and theophylline did not change significantly with pH.

pH effects on RTP intensity

Table 2 gives the net RTP relative intensities measured for the purine derivatives in the three media used.

It can be seen that the pH of the sample solution has a marked but variable effect on the phosphorescence signal, depending on the compound under study (Table 2). With the exception of uracil, 5-fluorouracil and cytosine, all purines and pyrimidines are phosphorescent at room temperature in alkaline media. In contrast, purine, 6-chloropurine, guanine and thymine do not phosphoresce in neutral or acidic media, and adenine 6-methylpurine and 2-thiouracil do not given an RTP signal in acidic media, but are phosphorescent at pH 7. Except for adenine, theobromine and theophylline, the use of

*Evaluated on W-40 filter paper, with 1*M* KI solution.

†LDR = linear dynamic range, corresponding to the ratio of the upper concentration limit of linearity (within 5%) and the LOD.

§LOD = limit of detection, defined as the amount of analyte giving a signal-to-noise ratio of 3, for a 3-μl sample.

basic solutions yields stronger RTP signals than those from acidic or neutral media. Since the excited triplet-state pK_a^T values of purines range between about 5.0 and 11.1,[31] only anionic species can be present on the surface of the paper when basic sample solutions (pH ~ 13) are used. Therefore, larger phosphorescence quantum yields of anionic species could cause the higher emission intensities observed from most alkaline purine solutions. There may also be a polar interaction between the negative charge of the anionic species and the hydroxyl groups on the paper, resulting in an increase in the phosphorescence intensity.

Adenine, theophylline and theobromine seem to be more sensitive than caffeine to the pH of the sample solution. The RTP intensities obtained from basic solutions of the three compounds adsorbed on Whatman No. 40 paper are 48.5, 17 and 37%, respectively, of their values in neutral medium, whereas the intensity for a neutral solution of caffeine is about 92% of that for a basic medium. It is highly probable that caffeine, because of its high ground-state pK_a of 14, is mainly present as the neutral form, on the surface of the paper, in both cases. Consequently, the RTP signal does not vary strongly in this region of pH. In contrast, as expected from the pK_a values of adenine, theophylline and theobromine (9.8, 10 and 8.7, respectively), either neutral or anionic species would be present on the paper, depending on whether the solution is neutral or basic. The RTP intensity would then depend on the respective phosphorescence quantum yields and/or specific interactions between the substate and the neutral and anionic forms. Similar observations were made by Andino *et al.*[24] on the RTP of basic and neutral caffeine and theophylline solutions adsorbed on Whatman No. 1 and DE-81 filter papers.

In the case of 6-mercaptopurine, the effect of pH is especially striking, since the RTP intensity is about 80 and 500 times higher in basic than in neutral and acidic solutions, respectively (Table 2). This behaviour can be attributed to the formation of a doubly-charged anion resulting from the successive deprotonation of the mercapto and NH-9 groups at neutral and moderately basic pH values. Strong hydrogen-bonding type interactions would be expected to take place between the double negative charge of the anionic species and the hydroxyl groups of cellulose, provoking a considerable enhancement of the RTP signal in basic medium.

Acidic solutions of caffeine, 6-mercaptopurine, theobromine and theophylline, spotted on W-40 paper, present weak, but significant RTP intensities, corresponding respectively to 66, 16, 39.8 and 39.9% of their values in neutral media. In contrast, Andino *et al.*[24] observed that acidic solutions of caffeine and theophylline gave no phosphorescence when spotted on Whatman No. 1 paper, but did on DE-81 and P-81 papers. These substrate-related discrepancies may be due either to acid–base neutralization reactions, or to protonation of the organic molecules and/or protonation of the active sites of the cellulose polymer, depending on the kind of papers.[24] Both phenomena should cause considerable changes in the substrate–analyte interactions and consequently in the phosphorescence emission intensities. Analogous filter-paper substrate effects on RTP intensity of indole-carboxylic acids have been noted recently.[35]

Quantitative considerations

Our results show that the choice of pH is important for improving the sensitivity of room-temperature phosphorescence in the determination of purines and pyrimidines. The RTP analytical figures of merit for selected compounds in basic and neutral media are given in Table 3. The log–log calibration curves are characterized by relatively large linear ranges, between 25 and 10^3 in basic, and 10 and 500 in neutral solutions, but the slopes range from about 0.7 to about 1.5; no reason for this has yet been found. The correlation coefficients are larger than 0.97, so the precision is satisfactory. As expected from the change in RTP intensity with pH, the absolute limits of detection (LOD) are lower for basic (ranging between 0.4 and 15 ng) than for neutral medium (between 1.2 and 38 ng). Our LOD of 0.4 ng for 6-mercaptopurine in alkaline solution is one order of magnitude lower than that reported for the same compound by Al-Mosawi *et al.*[32] for RTP on a cellulose thin-layer. An LOD of 0.05 ng for

6-mercaptopurine has also been obtained by thin-layer phosphorimetry at 77 K.[32] Thus RTP provides a simple and very sensitive method for determination of purines and pyrimidines, but correct choice of pH and of paper type is critical for improving sensitivity.

SEPARATION OF ^{203}Pb BY ION-EXCHANGE CHROMATOGRAPHY ON CHELEX 100 AFTER PRODUCTION OF ^{203}Pb BY THE Pb(p, xn)^{203}Bi $\xrightarrow{EC.\beta+}$ ^{203}Pb NUCLEAR REACTION*

TJAART N. VAN DER WALT† and PAUL P. COETZEE
Department of Chemistry, Rand Afrikaans University, P.O. Box 524, Johannesburg 2000, Republic of South Africa

(*Received* 21 *June* 1988. *Revised* 21 *October* 1988. *Accepted* 17 *November* 1988)

Summary—Bismuth radioisotopes, produced by 50-MeV proton bombardment of a lead target in a cyclotron, are separated from the lead target material by ion-exchange chromatography on a column containing 5.0 ml of Chelex 100. After a decay period of 24 hr, the ^{203}Pb formed *in situ* is eluted from the column and then separated from ^{200}Tl and ^{201}Tl on a second ion-exchange column containing 0.5 ml of Chelex 100. Separations are sharp and carrier-free ^{203}Pb is obtained.

Although ^{203}Pb has not so far found wide application in nuclear medicine, its usefulness has been demonstrated in a few cases. It has been used for skeletal imaging,[1] in the form of an EDTA chelate for cisternography,[2,3] as a label for red blood cells,[4] and for imaging bleomycin in tumours.[5] Wider applications seems to lie in investigations on the effects of lead pollution, entailing biological, biochemical and ecological studies.[6] Cyclotron methods for production of the ^{203}Pb isotope include the following reactions: ^{203}Tl(p, n)^{203}Pb, ^{205}Tl(p, 3n)-^{203}Pb, ^{203}Tl(d, 2n)^{203}Pb, ^{205}Tl(d, 4n)^{203}Pb, ^{203}Tl(^{3}He, 3n)-^{203}Bi $\xrightarrow{EC.\beta+}$ ^{203}Pb, and Pb(p, xn)^{203}Bi $\xrightarrow{EC.\beta+}$ ^{203}Pb.

Various methods have been described for separation of ^{203}Pb from the thallium target material. Qaim *et al.*[7] suggested co-precipitation of ^{203}Pb with ferric hydroxide, and removal of the carrier iron from the ^{203}Pb by anion-chromatography. Carrier-free ^{203}Pb was prepared by Chackett *et al.*[8] by the ^{203}Pb(^{3}He, 3n)^{203}Bi $\xrightarrow{EC.\beta+}$ ^{203}Pb reaction. The target was dissolved in nitric acid, 1–2 mg of bismuth was added (as nitrate solution) and bismuth was precipitated with disodium hydrogen phosphate. The bismuth phosphate was filtered off and washed to remove the thallium solution. After a decay period of 24 hr the ^{203}Pb (produced *in situ*) was eluted from the precipitate with 0.3*M* hydrochloric acid. Neirinckx[9] co-precipitated ^{203}Pb with ferric hydroxide but separated the carrier iron by solvent extraction. Levin *et al.*[10] separated ^{203}Pb from thallium by dissolving the latter in sulphuric acid and isolating ^{203}Pb by co-precipitation from the solution. The procedure of van der Walt and Strelow[11] involves cation-exchange chromatography in hydrochloric acid and hydrochloric acid–acetone mixtures. Further purification was obtained by anion-exchange chromatography in nitric acid–hydrochloric acid mixtures.

It seems that the production of ^{203}Pb through the Pb(p, xn)^{203}Bi $\xrightarrow{EC.\beta+}$ ^{203}Pb reaction has attracted little attention. An attempt was made to produce ^{203}Pb by this nuclear reaction at the separated sector cyclotron of the National Accelerator Centre of the CSIR at Faure. After proton bombardment of a lead target, the ^{203}Bi produced has to be separated immediately from the lead target material, otherwise the ^{203}Pb (formed by decay of ^{203}Bi) will be severely contaminated by lead originally used as the cyclotron target. Once the ^{203}Bi has been separated from the lead target, it is set aside for 24 hr to decay to the desired ^{203}Pb. The ^{203}Pb produced *in situ* has to be separated from the remaining ^{203}Bi.

Lead-201, -202m, -202, -203m, -204m and -204, and thallium-200 and -201 are also formed by proton bombardment of natural lead, by decay of bismuth-200, -201, -202, -203 and -204. The corresponding half-lives of the lead and thallium isotopes are 9.4 hr, 3.62 hr, 3×10^5 yr, 6.2 sec, 66.9 min, 1.40×10^{17} yr, 26.1 hr and 73.5 hr, respectively. Thus, the lead isotopes have to be set aside for at least one ^{203}Pb decay period (*ca.* 52 hr), and ^{203}Pb is then finally separated from the thallium isotopes. The only lead isotopes remaining with ^{203}Pb will be ^{202}Pb and ^{204}Pb, both having very long half-lives and no gamma-ray emission. Radionuclidically pure ^{203}Pb should thus be obtained.

Adsul *et al.*[12] separated bismuth from other elements by ion-exchange chromatography on a column of Chelex 100, eluting the other elements with 0.25*M* nitric acid. Bismuth was retained on the resin column, and finally eluted with 2.0*M* nitric acid. The method was adapted to separate the bismuth radioisotopes from a lead target after proton bombardment in a cyclotron, and later also from the lead radioisotope formed by decay of the bismuth radioisotopes.

*This paper represents part of an M.Sc. Thesis by T. N. van der Walt, submitted to the Rand Afrikaans University, Republic of South Africa.

†Present address: Isotope Production Centre, Atomic Energy Corporation of South Africa, P.O. Box 582, Pretoria 0001, Republic of South Africa.

^{200}Pb and ^{201}Pb decay respectively to ^{200}Tl and ^{201}Tl and these thallium radioisotopes have to be separated from ^{203}Pb. Iyer *et al.*[13] separated thallium from zinc and other elements on Dowex A-1 (H^+). Tl^{3+} was sorbed from a hydrochloric acid solution at pH 2.0 and finally reduced (to Tl^+) and eluted with 2.0*M* hydrochloric acid containing sulphurous acid (1.2%). The non-sorption of Tl^+ was used to separate ^{203}Pb from the thallium radioisotopes on Chelex 100 (H^+) in an ascorbic acid medium.

EXPERIMENTAL

Reagents

Analytical reagent grade chemicals and demineralized water were used throughout. The chelating exchange-resin Chelex 100, of 100–200 mesh particle size, was used in the hydrogen form. The resin (in the sodium form) was supplied by Bio-Rad Laboratories, Richmond, California.

Apparatus

Two types of ion-exchange columns were used: one column (type A) was prepared by joining a borosilicate glass tube (11 mm bore and 60 mm long) to a wider upper part (18 mm bore and 110 mm long). The column was fitted with a No. 1 porosity sintered-glass disc and a burette tap at the bottom, and a B19 ground-glass sleeve at the top to hold a dropping funnel as an eluent reservoir. The other type of column (type B) was similarly made but with a 50 mm long borosilicate glass tube (8 mm bore) joined to the wider upper part (15 mm bore and 80 mm long).

The ion-exchange column (type A) was filled with a slurry of Chelex 100 resin until the settled resin had a volume of 5.0 ml in water. The resin was equilibrated by passage of 50 ml of 0.10*M* nitric acid. The other column (type B) was filled with Chelex 100 resin to a mark at 0.5 ml volume. The resin was equilibrated by passage of 20 ml of 0.005*M* ascorbic acid.

Atomic-absorption measurements were made with a Varian Techtron 475 atomic-absorption instrument. An ISCO model 1220 automatic fraction-collector was used to collect fractions for construction of the elution curve.

A Cicero 8K Multichannel Analyzer with a germanium detector was used to identify the radioisotopes and to measure their activities.

Elution curves

Pb–Bi. $Bi(NO_3)_3.5H_2O$ (*ca.* 4.6 mg) was dissolved in 10 ml of 1.0*M* nitric acid, and the solution was diluted to *ca.* 70 ml with water. $Pb(NO_3)_2$ (*ca.* 16.0 g) was dissolved in this solution with continuous stirring and gentle heating on a hot-plate fitted with a magnetic stirrer. The solution was cooled and diluted with water to *ca.* 100 ml, and passed through an ion-exchange column of type A, prepared and equilibrated as described above. The elements were washed onto the resin with small portions of 0.1*M* nitric acid (40 ml in total). Lead was eluted with 300 ml of 0.25*M* nitric acid. Bismuth was then eluted with 80 ml of 2.0*M* nitric acid. A flow-rate of 3.8 ± 0.3 ml/min was maintained and 10-ml fractions were collected from the beginning of the sorption step. The amounts of the elements were determined in each fraction (after suitable dilution when necessary) by atomic-absorption spectrometry, under the conditions in Table 1. The elution curve is presented in Fig. 1.

Pb–Tl. $TlNO_3$ (*ca.* 6.5 mg) and $Pb(NO_3)_2$ (*ca.* 4.0 mg) were dissolved in 5 ml of 0.005*M* ascorbic acid (pH 3.2). The solution was adjusted to pH 4.0 with dilute ammonia solution, and then passed through an ion-exchange column of type B, prepared and equilibrated as described above. The elements were washed onto the resin with small portions of 0.005*M* ascorbic acid and thallium was eluted with more 0.005*M* ascorbic acid (245 ml in total), followed by 100 ml of 0.01*M* ascorbic acid. Finally, lead was eluted with 50 ml of 1.0*M* nitric acid. A flow-rate of 3.5 ± 0.3 ml/min was maintained throughout and 10-ml fractions were collected from the beginning of the sorption step. The amounts of the elements were determined in each fraction (after appropriate dilution) by atomic-absorption spectrometry (conditions as in Table 1). The elution curve is presented in Fig. 2.

Table 1. Conditions used for atomic-absorption spectrometry

Bi	Air–acetylene flame; 223.1 nm; slotted silica tube[14] for low concentrations of Bi.
Pb	Air–acetylene flame; 217.0 nm; slotted silica tube[14] for low concentrations of Pb.
Tl	Air–acetylene flame; 276.8 nm.

Separation of the bismuth radioisotopes from lead target material after 50-MeV proton bombardment

A lead cyclotron target was prepared from three circular lead discs (diameter 15 mm, thickness 0.4–0.5 mm, total mass 2.63 g). The lead target was bombarded with 50-MeV protons in a separated sector cyclotron for 2 hr at a beam current of 100 nA. At the end of the bomdardment the lead target was dissolved in 9.1 ml of hot 5*M* nitric acid. The solution was then diluted with water to *ca.* 100 ml and passed through an ion-exchange column of type A [prepared as above, but equilibrated by passage of 50 ml of 0.20*M* nitric acid (solution I)]. The eluate was collected from the beginning of the sorption step (eluate A).

The elements were washed onto the resin with four 10-ml portions of solution I (eluate B). Lead was eluted with 80 ml of 0.25*M* nitric acid (eluate C), and the nitric acid with 50 ml of 0.01*M* ascorbic acid (eluate D). The radioisotopes in each fraction were identified from their gamma-energies (Table 2), and their activities measured by means of the strongest gamma-energies. The results are listed in Table 3. The ion-exchange column was set aside for 24 hr and the lead and thallium radioisotopes, formed *in situ*, were eluted with two 25-ml portions of 0.01*M* ascorbic acid (eluates E and F). The radioisotopes were identified and their activities measured in each eluate fraction. The results are shown in Table 4.

Separation of ^{203}Pb on an ion-exchange column containing 0.5 ml of Chelex 100

Eluates D and E from the separation above were combined and left for 24 hr to let the shorter lived lead radioisotopes decay. The solution was then evaporated just to dryness, the isotopes were dissolved in 2.0 ml of 0.10*M* ascorbic acid, and the solution was diluted with 40 ml of water. The isotopes were then sorbed on an ion-exchange column of type B, prepared and equilibrated as described above (eluate 1). The isotopes were washed onto the resin with four 5-ml portions of 0.01*M* ascorbic acid (solution J) (eluate 2). ^{201}Tl was eluated with two 30-ml portions of solution J (eluates 3 and 4). Finally, ^{203}Pb was eluted with 25 ml of 1.0*M* nitric acid (eluate 5). The eluates were collected separately, and the radioisotopes identified and their activities measured in each fraction, and on the ion-exchange column. The results are presented in Table 5.

Determination of the amounts of lead in the "bismuth" and "^{203}Pb" eluates

Four g of lead foil (thickness *ca.* 0.5 mm) were weighed out (in triplicate) and the lead was dissolved in 12.0 ml of hot 5*M* nitric acid. The solution was diluted to *ca.* 100 ml with water, and passed through an ion-exchange column of type A, and the procedure described under "Separation of the bismuth radioisotopes from lead . . ." was applied. The "^{203}Pb" eluate (eluate C) was collected. Bismuth was finally eluted with 80 ml of 2.0*M* nitric acid and the eluate collected

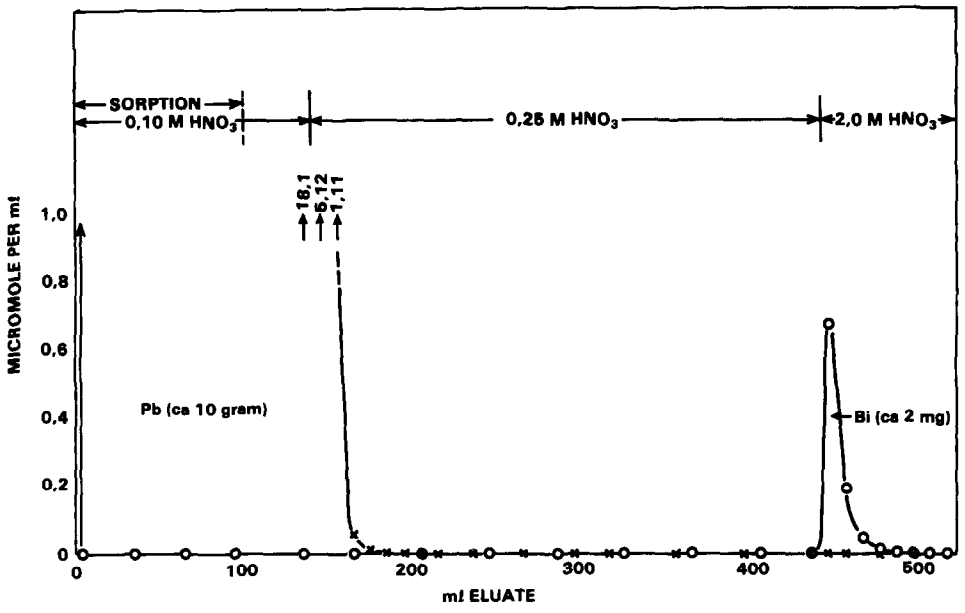

Fig. 1. Elution curve for Pb(II)–Bi(III): 5.0 ml of Chelex 100, H^+-form, 100–200 mesh; column length 53 mm, diameter 11.0 mm; flow-rate 3.8 ± 0.3 ml/min.

in a beaker ("bismuth" eluate). The eluates were evaporated to *ca.* 1 ml and made up to volume with water in 10-ml standard flasks. The amounts of lead were determined in each eluate by atomic-absorption spectrometry as described above. The results are presented in Table 6.

RESULTS AND DISCUSSION

Figure 1 shows that a sharp separation of bismuth from lead is obtained on an ion-exchange column containing 5.0 ml of Chelex 100, with 0.25*M* nitric acid as eluent. Less than 0.1 μg of bismuth per ml was found in all of the fractions collected prior to the elution of the bismuth with 2.0*M* nitric acid. The method described provides an excellent means for the separation of bismuth from up to 10 g of lead.

Figure 2 shows that an excellent separation of microgram amounts of lead and thallium is obtained on Chelex 100, with 0.005*M* and 0.01*M* ascorbic acid as the eluents. However, *ca.* 40 μg of lead was found in the effluent from the sorption step, when the solution used for that step had an ascorbic acid concentration of 0.01*M* (at pH 3.1). However, when

*Average of triplicate analyses.

the pH of the solution was adjusted to *ca* 4.0, no lead was found in effluent from the sorption step.

The lead target has to be dissolved immediately after the end of the bombardment, and a rapid separation of the bismuth radioisotopes from lead (originating from the cyclotron target) is essential. If these conditions are not met, the ^{203}Pb will either be

severely contaminated by lead from the target or the yield of ^{203}Pb will drop sharply owing to losses which will occur during the separation of the bismuth isotopes from the lead target material.

The separation of the bismuth isotopes from the lead target (measured from the means of the activities of the lead radioisotopes) is sharp, as illustrated by Table 3. No activity originating from bismuth radioisotopes was observed in the lead eluates. Table 4 shows that ^{203}Pb, ^{204m}Pb, ^{200}Tl and ^{201}Tl, produced *in situ* during a 24-hr decay period, were eluted with 0.25*M* nitric acid from the original ion-exchange column (type A), and the bismuth isotopes were retained by the resin. The ^{202m}Pb activities of eluates A, B, C and D apparently indicate differential behaviour of ^{202m}Pb, but the increase in the activity of ^{202m}Pb in eluate C is perhaps due to the

$$^{202}Bi \xrightarrow[1.8\ hr]{\beta+} {}^{202m}Pb$$

decay.

Table 5 indicates that ^{200}Tl and ^{201}Tl losses occurred during the evaporation step, probably by adsorption on the glass surface, because little or no thallium radioactivity was found in the eluates and on the column. Lead was finally almost completely eluted from the resin with 1.0*M* nitric acid.

According to Table 6, less than 5 μg of lead was found in the "^{203}Pb" eluate when 4 g of lead was originally present. The separation is thus very suitable for the preparation of carrier-free ^{203}Pb.

The two-column separation scheme presents an ideal separation of ^{203}Pb from bismuth and thallium radioisotopes. No other lead radioisotopes were found in the ^{203}Pb fraction 60 hr after the end of the bombardment. The final eluate can be evaporated to dryness and the ^{203}Pb dissolved in a suitable solvent, providing a carrier-free product of high purity. The method is well suited for the separation of ^{203}Pb from lead cyclotron targets.

Less than 5 μg of lead was found in the "bismuth" eluate when 4 g of lead was originally present (Table 6). Thus, by use of an ion-exchange column of type A, containing 5.0 ml of Chelex 100, ^{206}Bi can also be separated from the lead target after deuteron bombardment in a cyclotron. Carrier-free ^{206}Bi of high purity can be obtained in the desired solvent after evaporation of the nitric acid.

DERIVATIVE SPECTROPHOTOMETRIC DETERMINATION OF MERCURY(II) WITH PAN IN THE AQUEOUS PHASE

RATTAN LAL SHARMA and HAR BHAJAN SINGH*
Department of Chemistry, University of Delhi, Delhi-110007, India

(*Received* 25 *July* 1985. *Revised* 10 *April* 1988. *Accepted* 14 *November* 1988)

Summary—The Hg–PAN complex can be made soluble in water by addition of surfactant, and this can be made the basis of a spectrophotometric determination of Hg at ppm level. The selectivity and sensitivity can be improved by use of derivative spectrometry. The method has been applied to mercury-containing pesticides.

PAN [1-(2-pyridylazo)-2-naphthol] forms coloured water-insoluble complexes with a large number of metal ions,[1] and these are suitable for extractive spectrophotometric determination. Mercury(II) forms an orange-red complex with PAN which has been made the basis of a number of titrimetric[2,3] and spectrophotometric[4–7] determinations of mercury. The composition of the complex formed is variously reported as ML and ML_2, and the existence of a mixture has been suggested.[8] In the present work the PAN–Hg system has been reinvestigated, with PAN and the PAN–Hg complex made water-soluble by use of a cationic surfactant. Derivative spectrophotometry was used to improve the sensitivity and selectivity.

EXPERIMENTAL

Instruments

Absorption spectra were recorded with a Shimadzu UV-260 recording spectrophotometer with a 1 nm bandwidth and 10-mm matched silica cells. First and second order derivatives were recorded with $\Delta\lambda = 2$ and 4 nm respectively.

Solutions

A stock 0.01*M* solution of mercuric chloride was prepared in 0.1*M* hydrochloric acid and diluted as required. A $5.0 \times 10^{-4}M$ solution of PAN was prepared daily by dissolving 0.01246 g of the reagent in 15.0 ml of concentrated hydrochloric acid and diluting with water to 100 ml.

A 0.01*M* solution of cetyltrimethylammonium bromide (CTMAB) was prepared by dissolving the required quantity in the appropriate volume of hot water. Since the solution becomes hazy at temperatures below 20°, it was heated to 30° before use.

Solutions of metal salts and auxiliary reagents were prepared from suitable analytical grade chemicals.

Procedures

Study of pH effect. Two sets of solutions, one of which contained the metal ion, were prepared. Each solution in a set contained 1.0 ml of $5.0 \times 10^{-4}M$ PAN, 1.0 ml of 0.01*M* CTMAB and 0.25 ml of 10% ammonium acetate solution; 0.1 ml of $1 \times 10^{-3}M$ mercury(II) solution was added to each solution of the set containing the metal ion. The pH was adjusted in the range 2.0–12.5 with sodium hydroxide or hydrochloric acid, then the solutions were made up accurately to 10.0 ml with water and the spectra were recorded.

Beer's law study. Two sets of solutions were prepared with increasing amounts of mercury(II) added to solutions containing either 5.0 ml of $2 \times 10^{-4}M$ PAN, 1.0 ml of 0.01*M* CTMAB and 0.5 ml of 10% ammonium acetate solution, or 5.0 ml of $5.0 \times 10^{-4}M$ PAN, 2.0 ml of 0.01*M* CTMAB and 0.5 ml of 10% ammonium acetate solution. The pH and volume of each solution were adjusted to the optimum values (pH 9.0 and 10.0 ml respectively) and the spectra recorded.

Study of composition, interference etc. Sets of test solutions were prepared with metal concentrations in the linear response range, except when lower or higher ligand concentration was required to complete the set. Other variables such as pH and volume were kept constant.

RESULTS AND DISCUSSION

Effect of pH

The absorption spectra of the complexes showed a pH-independent peak at 555 nm in addition to the pH-dependent ligand peak at around 400 nm. The difference in absorbance at 555 nm for the two sets of solutions was plotted against pH. The pH of maximum complex formation was thus found to be 9.0. Subsequent studies were, therefore, made at this pH.

Effect of surfactant concentration

This was determined by measuring the absorbance, at 555 nm, of a set of solutions containing increasing amounts of CTMAB (1×10^{-5}–$2 \times 10^{-3}M$), and fixed amounts of metal ion, PAN and ammonium acetate. The precipitate appearing in solutions containing an inadequate amount of CTMAB was discarded and the spectra of the supernatant liquids were recorded. The absorbance increased sharply with increasing [CTMAB] up to $0.8 \times 10^{-3}M$ and decreased slightly for [CTMAB] $> 1.4 \times 10^{-3}M$. In subsequent studies the concentration of CTMAB was kept close to the CMC (critical micelle con-

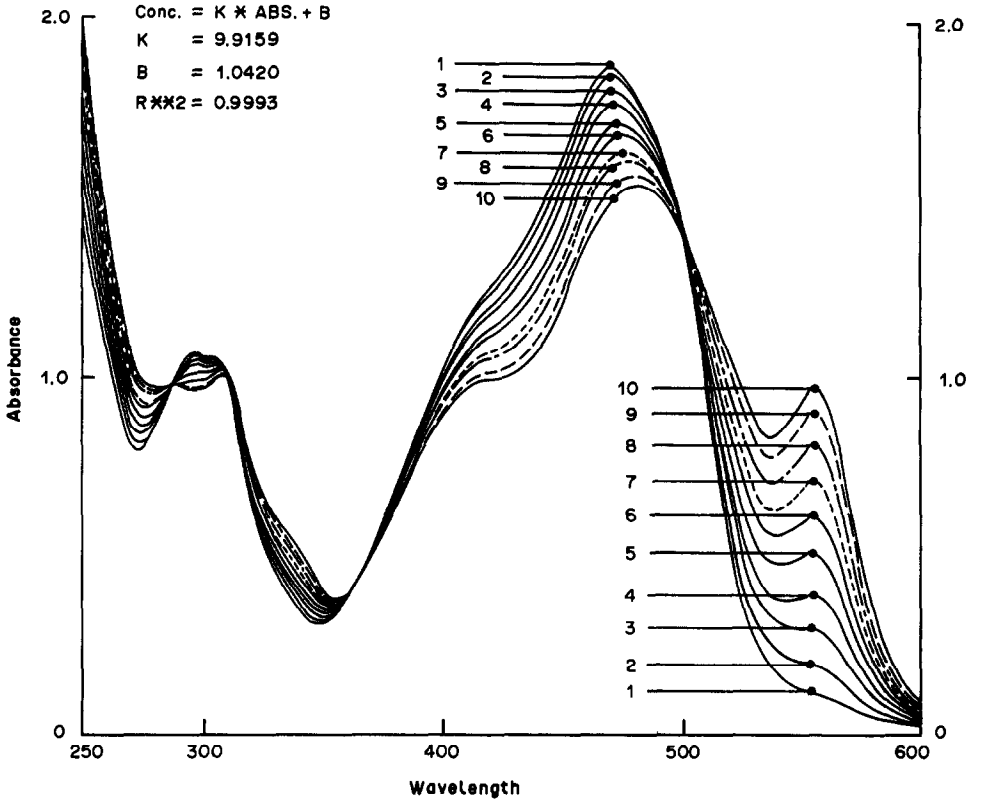

Fig. 1. Spectra of Hg(II)–PAN–CTMAB system: 1, reagent blank, 2–10, increasing Hg(II) concentration.

centration, *i.e.*, $1.3 \times 10^{-3}M$)[9] to obtain maximal absorbance.

Effect of PAN concentration

In the set of solutions containing $2.5 \times 10^{-4}M$ PAN and $2.0 \times 10^{-3}M$ CTMAB, a fine precipitate appeared about 45 min after sample preparation but when $9 \times 10^{-5}M$ mercury(II) was also present no precipitation occurred even after 3 hr. This suggests that the complex is more soluble than PAN in the micelles. At lower PAN ($1.0 \times 10^{-4}M$) and CTMAB ($1 \times 10^{-3}M$) concentration, the solutions were stable for longer and no precipitation took place even after 24 hr. The PAN concentration was kept at $< 2.5 \times 10^{-4}M$ in further investigations.

Effect of metal ion concentration

In the Beer's law study, there was significant curvature of the calibration plot at the higher metal ion concentrations when the overall PAN concentration was $1 \times 10^{-4}M$. Increasing the PAN concentration to $2.5 \times 10^{-4}M$ gave linear response for mercury(II) in the range 2×10^{-6}–$9 \times 10^{-5}M$, but there was a positive deviation in absorbance at mercury levels $< 2 \times 10^{-6}M$. The molar absorptivity at 555 nm was found to be 2.03×10^{4} l.mole^{-1}. cm^{-1}. The spectra are shown in Fig. 1.

First- and second-order derivative spectra of the test solutions were recorded (Fig. 2), and measured as shown in Fig. 3. The various heights were found to be linearly related to metal ion concentration.

Composition of the complex

The mole ratio and Job methods both indicated a 1:1 metal:PAN ratio in the complex. The following observations regarding the complex were made. (*a*) The complex is stabilized only by a cationic surfactant and not by a neutral one [such as Triton X-100 or poly(ethylene glycol) 4000], indicating that it is anionic in nature. (*b*) The complex is resistant to addition of a second PAN ion even at high PAN concentration, which suggests either that the free ligand is not able to react with the 1:1 complex or that any higher complex formed is unstable relative to the 1:1 complex. (*c*) An increase in the CTMAB concentration above $1.4 \times 10^{-3}M$ results in a slow decrease in the absorbance of the system.

On the basis of these observations we suggest that a negatively charged mixed-ligand complex of 6-co-ordinate mercury(II) is formed, of the type $[HgPANX_3]^{2-}$. A calculation of $[HgX_n]/[Hg^{2+}]$ ratios for the existing complexing anions in the solution, with due consideration of their concentration, showed X to be chloride. We also consider that the naphthalene moiety of the complex is held in the micelle (Fig. 4) and that formation of a 1:2 metal:PAN complex is prevented by electrostatic repulsion between micelles containing PAN and

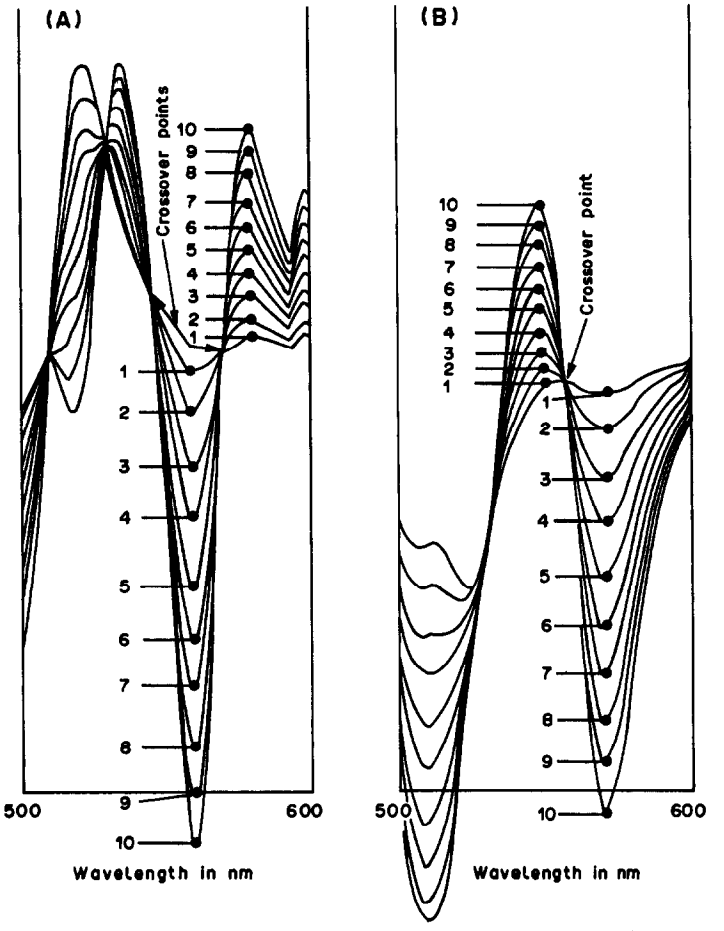

Fig. 2. First (A) and second (B) order derivatives of spectra in Fig. 1.

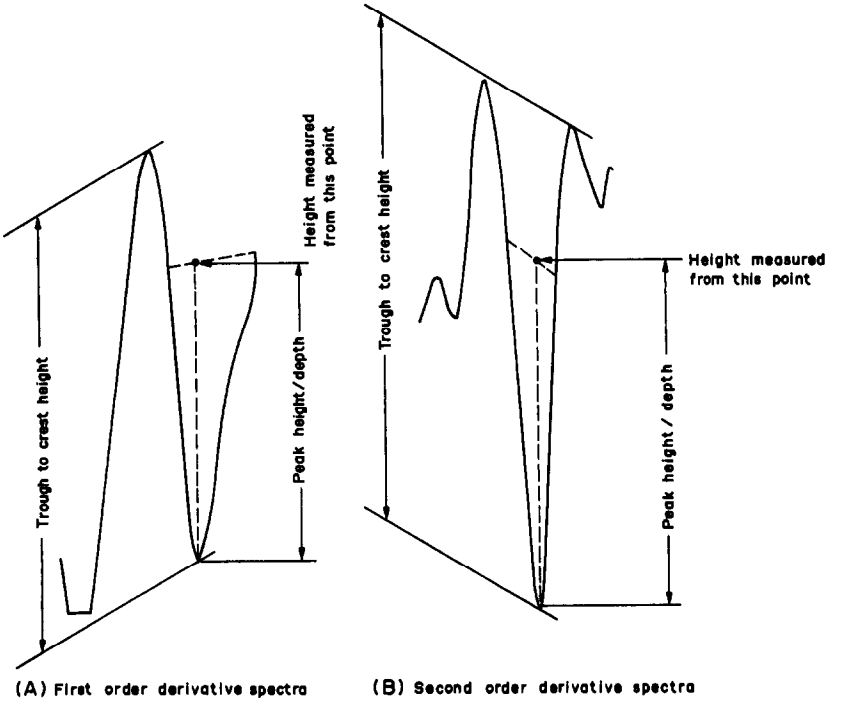

Fig. 3. Measurement of (A) first and (B) second order derivative spectra. In (A) the vertical distance from the crossover point to the trough is measured. In (B) a line is drawn between the crossover points and the vertical height from this line to the trough is measured.

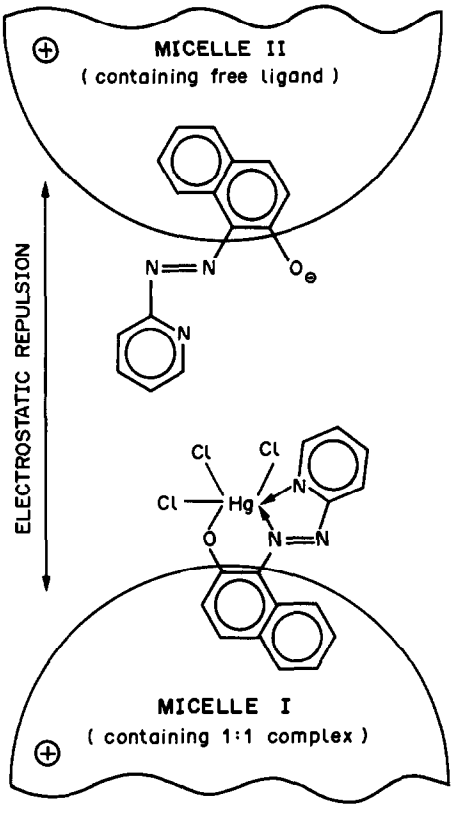

Fig. 4. Proposed reaction mechanism.

those containing the complex $[HgPANX_3]^{2-}$. This suggested orientation of PAN in the micelle allows interaction with mercury(II) ions in the bulk aqueous phase but inhibits its interaction with the 1:1 PAN:Hg complex. To obtain better insight into observation (*c*) above, cetyltrimethylammonium nitrate was used and the effect of adding increasing concentrations of Cl^-, Br^- and acetate was noted. These anions show a similar effect, indicating this to be a consequence of competing equilibria between the principal ligand (PAN) and the auxiliary ligand(s) (Cl^-, Br^- and/or acetate).

Stability constant of the complex

The conditional stability constant was calculated on the basis of the following equilibrium, paying due attention to the existence of the metal ion in various forms with auxiliary ligands and of the ligand in different protonated forms:

$$[HgCl_4]^{2-} + PAN^- \rightleftharpoons [HgCl_3PAN]^{2-} + Cl^-$$

The average of eight values (20°; $I = 2$) was found to be 3.5×10^7 with s.d. 1.2×10^7.

Interference by foreign ions

The effect of cations and anions was investigated. Serious interference was caused by Zn^{2+}, Cd^{2+}, In^{3+}, Ga^{3+}, Tl^{3+}, Ni^{2+}, Mn^{2+}, Cu^{2+}, Fe^{3+}, Fe^{2+} and others forming stable PAN complexes. The interference due to Zn^{2+}, Cd^{2+} and Ni^{2+} could be deduced from the

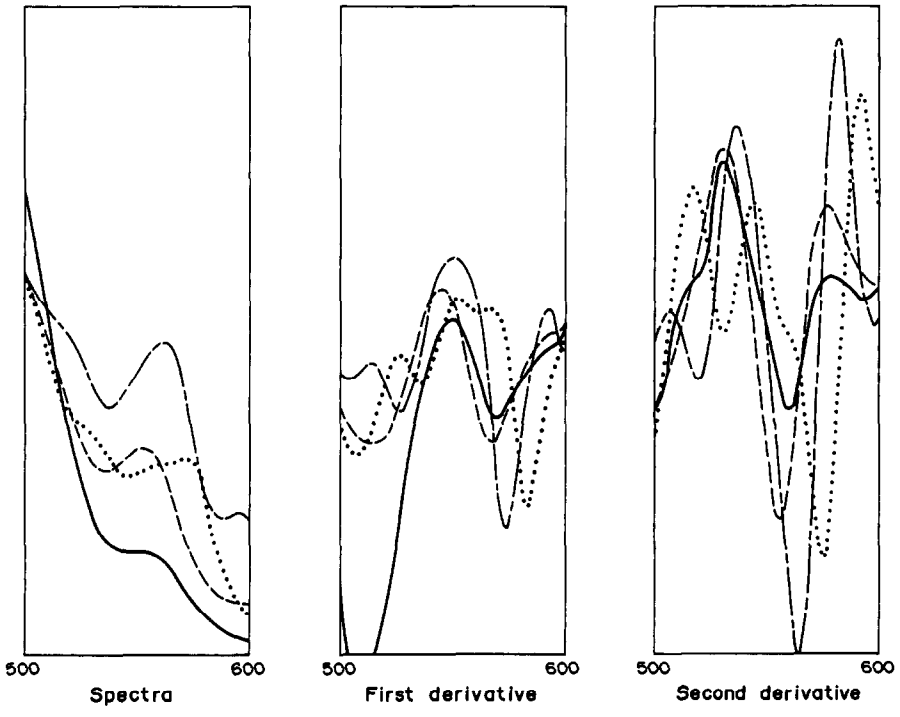

Fig. 5. Ordinary and first and second order derivative spectra of the Hg (——), Zn (– – –), Cd (–·–) and Ni (...) PAN–CTMAB systems.

first- and second-order derivative spectra for these three metal ions (Fig. 5). Mercury could be determined in the presence of these metal ions by means of the derivative spectra, but the error was rather high. Of the anions investigated, cyanide, EDTA and iodide interfered seriously. Alkali and alkaline-earth metal ions and lead did not interfere. The cobalt complex is precipitated quite soon on standing. This precipitate can be removed by centrifugation, and the absorbance of the supernatant liquid measured for determining mercury in presence of cobalt.

Application

The mercury content of a mercury-based pesticide (EMISAN 6), containing 6% mercury was determined by this method. The relative deviation was $<1\%$ for 10 determinations.

MIXED REAGENTS IN MULTICOMPONENT FLOW-INJECTION ANALYSIS

SIMULTANEOUS DETERMINATION OF IRON AND COPPER IN BLOOD SERUM WITH MIXED BATHOCUPROINEDISULPHONATE AND BATHOPHENANTHROLINEDISULPHONATE OR FERROZINE

V. KUBÁŇ, D. B. GLADILOVICH* and L. SOMMER
Department of Analytical Chemistry, J. E. Purkyně University, 61137 Brno, Czechoslovakia

(*Received* 15 *March* 1988. *Revised* 27 *May* 1988. *Accepted* 14 *November* 1988)

Summary—Mixtures of 0.6m*M* bathocuproinedisulphonate (BC) and 0.2m*M* bathophenanthrolinedisulphonate (BP) or 2m*M* BC and 0.2m*M* ferrozine (FZ) were used for a rapid determination of iron and copper in deproteinated blood serum in the presence of 0.1*M* formate buffer (pH 3.5), 10m*M* ascorbic acid and 0.3*M* trichloroacetic acid, by two variants of multicomponent FIA with a diode-array detector (MC–FIA). Merging zones MC-FIA is especially suitable for the determination of 0.7–33μM Fe and 0.4–35μM Cu, for Cu:Fe concentration ratios from 10:1 to 1:10 and with RSD <3 or 2% for Fe or RSD <6 or 5% for Cu in artificial mixtures and deproteinated standard blood sera, respectively, and relative errors of less than 3–5%. The concentrations of both elements were calculated according to a simple computer program (ORTHO) for overdetermined systems (10 or 11 wavelengths), but evaluation at the absorption maxima for the individual chelates (at 2 or 3 wavelengths) also gave satisfactory results.

The determination of iron in blood serum is important in differential diagnosis. An independent determination of copper in blood serum is less frequently required[1] but simultaneous evaluation of both elements gives complementary diagnostic information.[1,2] At present, ferrozine (FZ)[3,4] and bathophenanthrolinedisulphonate (BP)[5,6] or bathocuproinedisulphate (BC)[7,8] respectively, are the most popular reagents for iron and copper in clinical practice. Both elements are successively determined with BC and BP in saturated sodium acetate buffer medium with measurement at 492 and 446 nm.[9]

In this paper a rapid and accurate simultaneous determination of iron and copper in blood serum is described, based on use of a reagent mixture of BC and BP or of BC and FZ, and use of the single-channel and merging zones variants of multicomponent FIA, with a diode-array detector.[10–13]

EXPERIMENTAL

Reagents

Standard solutions of iron and copper [100.8m*M* Fe(III), 100.5m*M* Cu(II), and 86.6m*M* Fe(II) in 0.2*M* hydrochloric acid] were prepared by dissolving the pure chlorides (or "Specpure" metal for iron) in hydrochloric acid, and standardized gravimetrically or by chelometric titration.

Sodium 2,5-dimethyl-4,7-diphenyl-1,10-phenanthrolinedisulphonate (bathocuproinedisulphonate, BC), sodium 4,7-diphenyl-1,10-phenanthrolinedisulphonate (bathophenanthrolinedisulphonate, BP), and sodium 3-(2-pyridyl)-5,6-diphenyl-1,2,4-triazine-4′,4″-disulphonate (ferrozine, FZ) were materials from Merck (Darmstadt, F.R.G.) or Serva (Heidelberg, F.R.G.), and 1–5m*M* BC and 1–2m*M* BP and FZ aqueous solutions were prepared.

A 0.1*M* stock solution of ascorbic acid (Farmakon, Czechoslovakia) was prepared and 3.0*M* trichloroacetic acid (TCA) (Avondale Labs. G.B.) after purification by passage through a 6 × 200 mm column of Dowex 50W × 8 cation-exchanger in H^+-form (50–100 mesh).

Standard blood sera were samples of Lyonorm P and Lyonorm U (Lachema, Brno, Czechoslovakia) or EXA and EXAPAT (Serum and Vaccination Institute, Prague Czechoslovakia) dissolved in 3 or 5 ml of water, respectively, and allowed to stand for 20 min. Aliquots (0.5 ml) were transferred into micro centrifuge tubes (volume 1.5 ml) and mixed with 0.1 ml of 0.1*M* ascorbic acid, 0.1 ml of 3*M* TCA, and 0.3 ml of 0.33*M* formate buffer (pH 3.5). After 15 min incubation, the solutions were centrifuged for 5 min at 12000 rpm. Two 0.4-ml portions of the supernatant liquid were taken, one being diluted with 0.1 ml of 10m*M* EDTA and serving as the blank, and other diluted with 0.1 ml of water. These solutions were injected into the FIA system.

All the water used had been distilled twice in silica apparatus.

FIA manifolds

The arrangement for merging zones[14] multicomponent (MC) FIA consisted of an HPP 4001 linear plunger pump (Laboratory Instruments, Prague, Czechoslovakia), a multifunctional loop sampler giving samples in the range 10–100 μl, and a Y-piece merging module (cf. Fig. 1). The sampling loops were filled by a low-pressure diaphragm pump (Varian, Zug, Switzerland).

A multichannel PU 4021 UV–VIS diode-array detector (Pye Unicam, Cambridge, G.B.) equipped with an 8-μl

flow-cell was connected to a TZ 4200 twin-pen recorder (Laboratory Instruments, Prague, Czechoslovakia), and an on-line SAPI 1 microcomputer (Tesla Eltos, Prague, Czechoslovakia, 48 kbyte RAM). The "Autostore" mode was used, *i.e.*, fast (300 msec per record) automatic digital recording of the full absorption spectrum over the range 390–590 nm in 1-nm steps when the peak concentration of reaction product was passing through the flow-cell. All absorbance values were stored in the computer memory for subsequent data handlings.

A 20-μl volume of the reagent mixture and a 20-μl volume of the test solution containing Cu(I) and Fe(II) or the deproteinated blood serum were injected synchronously into two independent pulseless streams of carrier solution (1 mM nitric acid) flowing at 0.5 ml/min. The signals were maximal when a 27-cm PTFE capillary reaction coil (0.6 mm i.d.) was used.

A simple orthogonalizing program ORTHO was compiled for use with over-determined systems and used to evaluate the concentrations of both metal ions in solutions containing the reagent mixture in excess. The program is based on solution of a set of linear equations for the overall values of the absorbance of the reaction mixture, $A_{ij} = \Sigma \epsilon_{ij} c_j$, for the individual wavelength values by orthogonalization of the columns in the absorbance matrix. The number of linear equations employed in the data treatment varies from the number of components determined up to several doubled sets for overdetermined systems (up to a maximum of the 200 values for the full set of absorbances in the 390–590 nm spectral interval stored in the computer memory). The input data consisted of the values of the molar absorptivities, ϵ_{ij}, for all the absorbing components of the reaction mixtures determined in independent experiments, and the experimental total absorbance values for particular wavelengths, A_{ij}.

A standard linear least-squares procedure was used for evaluation of the calibration plots. The conditional molar absorptivities were obtained from calibration plots for the individual metal ions in the presence of the appropriate reagent mixture, and for binary metal ion mixtures in the presence of both mixed reagents. They were always calculated from absorbances at the peak maxima, as a function of the particular concentrations of Fe(II) and Cu(I) present and for the exactly linear parts of the calibration plots.

RESULTS AND DISCUSSION

Stationary systems

Copper(I) (50μM) gave a stable and intensely coloured CuL_2 chelate ($\lambda_{max} = 482$ nm, $\epsilon = 1.3 \times 10^4$ $l.mole^{-1}.cm^{-1}$) with an excess of BC (0.2mM) in chloride medium in the presence of 10mM ascorbic acid over a broad pH-interval of 2–10. With BP or FZ, weakly absorbing Cu chelates ($\lambda_{max} = 470$ nm,

*1–43μM Fe(II) or Cu(I).

†Single-channel FIA, $V_l = 30$ μl, $F_m = 1$ ml/min, $L_r = 40$ cm, i.d. = 0.6 mm PTFE, 4–30μM Fe(II) or Cu(I).

§Merging zones FIA $V_l = 20$ μl, $F_m = 0.5$ ml/min (dual channel), $L_r = 27$ cm, i.d. = 0.6 mm PTFE, 1–30μM Fe(II) or Cu(I).

$\epsilon = 2 \times 10^3$ l.mole^{-1}.cm^{-1} with FZ or $\lambda_{max} = 427$ nm, $\epsilon = 1 \times 10^3$ l.mole^{-1}.cm^{-1} at pH 3.5 or 4×10^3 l.mole^{-1}.cm^{-1} at pH 7 with BP) are formed only over the pH-intervals 2–8 or 3–8, respectively, under the same experimental conditions. Their formation is fast and the absorbance is constant from 1 min after mixing.

Iron(II) (50μM) forms red or red-violet FeL_3 chelates with BP or FZ in solutions (0.2mM reagent excess) under similar conditions at pH 1.5–10 ($\lambda_{max} = 535$ nm, $\epsilon = 2.25 \times 10^4$ l.mole^{-1}.cm^{-1} for BP and $\lambda_{max} = 562$ nm, $\epsilon = 2.62 \times 10^4$ l.mole^{-1}.cm^{-1} for FZ). The speed of chelate formation depends on the pH but is fast enough at pH $\geqslant 3$ with >3-fold reagent excess. Copper does not interfere even in 50-fold ratio to iron, at pH < 4.

The mutual interaction of Cu(I) or Fe(II) with both reagent mixtures depends on the concentration ratios, c(BC):c(BP) or c(BC):c(FZ). For c(Cu) or c(Fe) = 40μM there is practically no competition between the reagents in solutions containing more than 3-fold excess of BC relative to BP or 10-fold excess of BC relative to FZ at the optimum pH of 3.5 (0.1M formate buffer) and in the presence of 10mM ascorbic acid. The conditions are similar for c(Fe) = c(Cu) = 40μM in a binary mixture. The decrease of the reaction yield for Cu(I) with BC and for Fe(II) with BP or FZ is $<3\%$. For simultaneous determination in the concentration intervals c(Cu) = 0.4–35μM and c(Fe) = 0.7–33μM, reagent concentrations such as c(BP) = 0.2mM with c(BC) $\geqslant$ 0.6mM or c(FZ) = 0.2mM with c(BC) $\geqslant$ 2mM are satisfactory at pH 3.5 (0.1M formate buffer).

The molar absorptivities of the Cu(I) chelate with BC and of the Fe(II) chelates with BP or FZ are 1–2% lower for Fe(II) with FZ, 5% for Fe(II) with BP and ~8% for Cu(I) with BC, in the mixtures than those for solutions of the individual Cu(I) or Fe(II) chelates.[12] A further 5–10% decrease of these values for particular chelates follows from the additional competition of 0.3M TCA with the Cu(I) and Fe(II) chelates of BC, BP or FZ (see Table 1).

Flow systems

The molar absorptivity values of the FeL_3 chelates with BP or FZ and the CuL_2 chelate with BC for solutions containing the reagent mixtures and with or without 0.3M TCA, are 1.5–2 times higher in merging zones FIA than in the classical single-channel variant MC FIA with instant injection[12] (*cf.* Table 2). In the presence of TCA, the molar absorptivity of the Cu(I) chelate with BC [c(Cu) = 25μM] increases from 1.07 to 1.19×10^4 l.mole^{-1}.cm^{-1} at 482 nm (*i.e.*, by 10%) with increase of c(Fe) from 0–25μM, whereas in the absence of TCA it increases by only 2%. On the other hand the corresponding change in the molar absorptivities for the Fe(II) chelate with BP [c(Fe) = 25μM] with increasing c(Cu) from 0 to 25μM is $<3\%$ at 535 nm, but only $\leqslant 0.4\%$ in the absence of TCA.

If such changes are ignored during calculation of

the Fe(II) and Cu(I) concentrations, from absorbances at 11 or 3 wavelengths respectively, for test solutions containing c(Cu):c(Fe) = 1:5–6:1 ratios in the presence of 0.3M TCA and 10mM ascorbic acid, by the ORTHO program, the relative errors $\Delta c(\%) = 100\,(c_{th} - c_{calc})/c_{th}$ are lower than 5% for Fe and 6% for Cu, but only <15% for Cu at extremely low concentrations, c(Cu) < 3μM.

With the merging zones MC FIA systems the Δc(%) values are <3% for Fe or <4% for Cu with the reagent mixture BC and BP, or <3% for Fe or <6% for Cu with the reagent mixture of BC and FZ. The concentrations of both metal ions were usually calculated from data for 11 or 10 preselected wavelengths (440, 460, 480, 500, 510, 520, 530, 535, 550, 560, 580 nm for the BC and FZ mixture, or 460, 480, 490, 500, 505, 520, 530, 535, 550, 565 nm for BC and BP mixture), or for 2 wavelengths, *viz.* 535 and 480 nm or 560 and 480 nm for mixtures of BC with BP or BC with FZ, respectively.

Lower values of Δc(%) result for merging zones MC FIA even if wider concentration-ratio intervals, such as c(Fe):c(Cu) = 1:10–10:1, are present. No significant differences are obtained between the results for full sets, for all 11 or 10 wavelengths and for only 2 wavelengths in the absorption maxima of particular chelates (*cf.* Table 2).

Analysis of deproteinated blood serum

A 20 μl sample of deproteinated blood serum and 20 μl of the mixture of 0.6mM BC with 0.2mM BP or of 2mM BC with 0.2mM FZ, respectively, were simultaneously injected into two independent pulseless flows of 1mM nitric acid. The calculation of c(Cu) and c(Fe) always followed from absorbances measured at 11, 10, 3 or 2 wavelengths between 440 and 580 nm, after subtraction of the absorbance blank, which was that for deproteinated blood serum plus 0.1 ml of 10mM EDTA. Conditional molar absorptivities evaluated earlier for solutions of the individual chelates containing 0.3M TCA and the reagent mixtures, were used for the calculations.

The results for iron and copper in normal and pathological concentrations in tested standard blood sera differed from the declared values or those determined by atomic-absorption spectrometry with or without deproteination, by less than 5% for Fe and 4% for Cu in the single-channel MC FIA[12] and by <2% for Fe and Cu with BC and BP mixture or <1% for Fe and <4% for Cu with BC and FZ mixture in the merging zones MC FIA (*cf.* Table 3). The calculated concentrations never fell outside the declared confidence intervals.

CONCLUSIONS

When the 2mM BC and 0.2mM FZ reagent mixture is used the precision and accuracy for both elements is not influenced by the number of wavelengths used, and the measurements at the absorption maxima of the particular chelates, 480 and 560 nm, with a simple dual-wavelength detector are usually sufficient for the simultaneous determination of both metal ions.

Nevertheless, the accuracy is still better for iron than for copper even at the lower concentrations

[c(Fe) < 10μM] because of the larger conditional molar absorptivity of the FeL_3 chelates with BP ($\epsilon' \sim 2.25 \times 10^4$ l.mole^{-1}.cm^{-1}) or for FZ ($\epsilon' \sim 2.62 \times 10^4$ l.mole^{-1}.cm^{-1}) and of the lesser influence of increasing copper concentration in the sample compared with that of increasing iron concentration.

Comparable concentrations of Ni(II) and a 50-fold ratio of Co(II) interfere with the simultaneous determination of iron and copper with the BC and BP or BC and FZ mixtures, but this has no importance for deproteinated blood serum.

In the single-channel MC FIA system the resulting Δc(%) for the difference between the calculated and true values is also not greater than 5% for Fe or 10% for Cu under the same conditions but it increases for concentration levels down to 4μM. The precision and accuracy of the method are comparable to those for merging zones MC FIA, but the sensitivity of the latter is 1.5–2 times higher, owing to more effective and faster mixing of the reaction components, lower dispersion of the reaction mixture zone in the presence of limited reagent concentrations, and increased reaction yield in the merged zone. The considerable saving of reagents is also an important factor making merging zones MC FIA the method of choice.

EXTRACTION AND DETERMINATION OF ZINC IN PHARMACEUTICAL SAMPLES

BHANU RAMAN and V. M. SHINDE
Analytical Laboratory, Department of Chemistry, The Institute of Science, 15, Madam Cama Road, Bombay 400 032, India

(*Received* 15 *September* 1987. *Revised* 11 *May* 1988. *Accepted* 13 *November* 1988)

Summary—A systematic study of extraction of zinc salicylate is reported. Optimum conditions for the extraction and determination of zinc are evaluated from a critical study of the effect of pH, sodium salicylate concentration and triphenylphosphine oxide concentration. The effect of foreign ions on the extraction is also discussed. The probable composition of the species has been deduced from the extraction data. The method has been used to separate zinc from cadmium and mercury in binary mixtures and for the determination of zinc in various pharmaceutical products.

Zinc in trace amounts is essential for enzymatic reactions in animal nutrition. Its deficiency causes serious hazards, but overdosage results in poisonous effects. From this physiological point of view, the determination of zinc in pharmaceuticals is important.

Numerous reagents have been used for extraction of zinc. Amongst high molecular-weight amines, liquid ion-exchangers such as Amberlite LA-1,[1] Aliquat-336,[2–4] Alamine-336,[4,5] Alamine-308,[6] Primene JMT,[4,7] tribenzylamine,[8] Amberlite LA-2,[4] long-chain amines[9] and Versatic-9[10] have found considerable use. Neutral extractants such as tri-octylphosphine oxide,[11,12] mesityl oxide,[13,14] isobutyl methyl ketone[15] and tributylphosphate[16] have also been used. These methods, however, lack sensitivity,[9] or suffer interference from several cations.[1,10] The needs for longer extraction times[7,11] (15–30 min), pre-heating with sulphuric acid,[4] high temperature[3] for extraction, and/or multistage extractions[8] under different conditions are some other limitations of the reported methods.

The proposed method is relatively simple, rapid, and does not require a long extraction period or temperature control. The method finds a wide range of applications in the analysis of commercial drug samples containing zinc.

EXPERIMENTAL

Reagents

Analytical grade chemicals were used throughout. The stock solution of zinc was prepared by dissolving 5.49 g of $ZnSO_4.7H_2O$ in 250 ml of distilled water containing the minimum amount of sulphuric acid needed to prevent hydrolysis. The solution was standardized by a standard method[17] and test solutions of lower concentration were prepared by suitable dilution. A 5% solution of triphenylphosphine oxide (Fluka, m.p. 156–158°) in toluene was used for the extraction. Buffer solution of pH 10 was prepared with 142 ml of concentrated ammonia solution and 17.5 g of ammonium chloride made up to 250 ml with distilled water. Buffer solution of pH 5.8 was prepared from 0.1*M* acetic acid and 0.1*M* sodium acetate mixed in 1:9 ratio. A 0.1% methanolic solution of 1-(2-pyridylazo)-2-naphthol (PAN) was used for spectrophotometric determination of zinc.

General extraction procedure

To an aliquot of solution containing 1 mg of zinc, 2.0 ml of 0.5*M* of sodium salicylate were added, and the mixture was diluted to about 25 ml and adjusted to pH 5.5 with dilute hydrochloric acid and sodium hydroxide solutions. The solution was then transferred to a 125-ml separatory funnel and shaken for 2 min with two 5-ml portions of 5% triphenylphosphine oxide solution. From the combined organic phase, zinc was stripped with distilled water (3 × 10 ml) and determined complexometrically.[17]

For microgram amounts of zinc (5–40 μg), the determination was done spectrophotometrically in the organic phase itself as follows. To the organic layer 5 ml of acetate buffer (pH 5.8) and 1 ml of 0.1% PAN solution were added and the mixture was shaken for 2 min. The coloured organic layer was separated and diluted to 10 ml with toluene, and its absorbance measured at 555 nm against a reagent blank similarly prepared.

RESULTS AND DISCUSSION

Extraction conditions

The extraction of zinc was investigated at various pH values (4.2–10.0), salicylate concentrations (0.025–0.7*M*), and triphenylphosphine oxide concentrations (1–5%). It was found that a double extraction (2 min shaking) with 5 ml of 5% triphenylphosphine oxide solution was necessary for quantitative extraction of zinc at mg levels. However, for microgram amounts of zinc, a single extraction with 5 ml of 5% triphenylphosphine oxide solution is adequate. The optimum extraction conditions can be seen from Figs. 1 and 2.

Spectral characteristics

The extracted zinc may be determined spectrophotometrically in the organic phase with PAN. The orange Zn–PAN complex has maximum absorbance

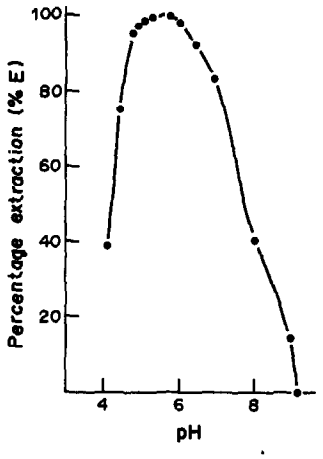

Fig. 1. Effect of pH on extraction of zinc.

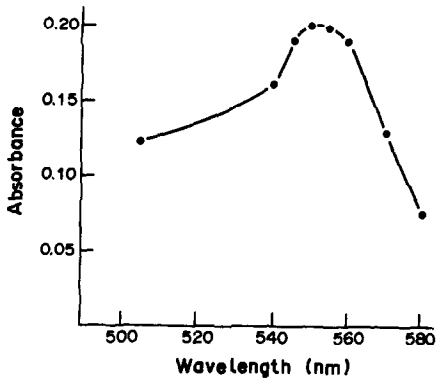

Fig. 3. Absorption spectrum of Zn–PAN complex in TPPO

at 555 nm (Fig. 3) and obeys Beer's law over the concentration range 5–40 μg per 10 ml of organic phase. The colour of the complex is stable for 24 hr. The molar absorptivity is 6.5×10^3 $1.mole^{-1}.cm^{-1}$ and the coefficient of variation is 3.8% for 20 μg of zinc.

Nature of extracted species

The log–log plots of distribution ratio *vs.* salicylate concentration [at fixed pH and triphenylphosphine oxide (TPPO) concentration] and *vs.* triphenylphosphine oxide concentration [at fixed pH and salicylate (Sal) concentration] indicate a molar ratio of 1:2 with respect to both extractant and salicylate. Thus, the species extracted is probably the solvated $ZnSal_2.2TPPO$.

Effect of foreign ions

An interference study showed that a large number of cations and anions offer no interference (as shown by less than 1% error in analytical recovery). The effect of foreign ions and their tolerance limits in the extraction of zinc are reported in Table 1.

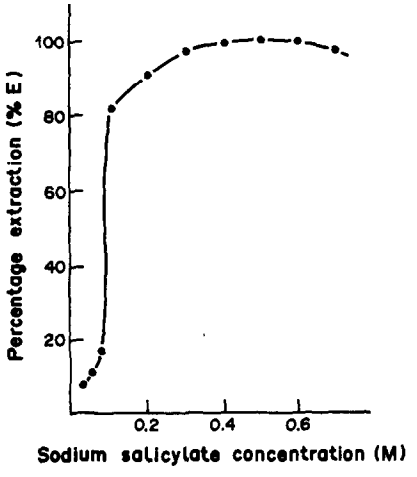

Fig. 2. Effect of sodium salicylate concentration for extraction of zinc.

Separation of Zn from Cd and Hg(II)

Zinc is not extracted into triphenylphosphine oxide (5% solution in toluene) from 0.5*M* sodium salicylate at pH 9.2 and remains quantitatively in the aqueous phase, whereas cadmium is extracted quantitatively under similar conditions. This facilitates the separation of zinc and cadmium in binary mixtures. The cadmium is scrubbed from the organic phase with distilled water and estimated complexometrically.[17] Both zinc and mercury(II) are quantitatively extracted at pH 5.5, but can then be separated by selective stripping of the zinc with water, which does not strip the mercury. The mercury is then stripped with acetate buffer (pH 4.7) and estimated complexometrically.[18] The recoveries of all three metals were > 99.0%. The results of the analysis of binary mixtures are given in Table 2.

Analysis of pharmaceutical samples

Zevit (capsules). A capsule was dissolved in *aqua regia*, and the solution was evaporated to dryness; the residue was taken up in the minimum amount of concentrated hydrochloric acid and the solution was evaporated to dryness again. The residue was taken up as before and the solution was diluted to 250 ml. An aliquot was taken for extraction and estimation of zinc by the recommended procedure.

Table 1. Effect of foreign ions on extraction and spectrophotometric determination of 20 μg of zinc

Tolerance limit, μg	Foreign ions
400	V(V), Cr(VI), Fe(III), Mo(VI), Mg(II), Ba(II), Ca(II), As(III), Sb(III), Bi(III), U(VI), F^-, Cl^-, SO_4^{2-}, PO_4^{3-}, NO_3^-, tartrate
200	Ag(I), Se(IV), Br^-, SO_3^{2-}, $S_2O_3^{2-}$, oxalate
150	Zr(IV), Pd(II), Au(III), Al(III), Th(IV), SCN^-, thiourea, citrate
50	Ascorbic acid
Ions not tolerated	Cu(II), Co(II), Ni(II)

Table 2. Separation of zinc from cadmium or mercury(II) in synthetic mixtures

Composition, *mg*	Recovery of Zn*, %	Recovery of added ion*, %
Zn(II) 1; Cd(II) 1	99.9	99.7
Zn(II) 1; Cd(II) 2	99.8	99.7
Zn(II) 1; Hg(II) 1	99.8	99.6
Zn(II) 1; Hg(II) 2	99.8	99.6

*Mean of six results.

Zad-G, Siloderm, Tineafax (skin ointments). A 0.1-g sample was digested with concentrated sulphuric acid and a few drops of concentrated nitric acid for about 10 min. The acid was neutralized with concentrated sodium hydroxide solution and the solution was made up to known volume. An aliquot of this solution was used for extraction and estimation of zinc by the proposed method.

Protostan-Z (health tonic). A 7.5-ml portion of the tonic was evaporated to dryness and the soluble salts were taken up in hydrochloric acid. The solution was filtered to remove the insoluble residue and the filtrate, was made up to volume in a standard flask. An aliquot was analysed for zinc.

Nycil (talc powder). The sample (20–25 mg) was treated with the minimum necessary amount of concentrated sulphuric acid, the solution was diluted a little with water, filtered to remove the white residue, then diluted to about 25 ml and analysed for zinc.

The results were in good agreement with the certified values and those of an independent analysis and are reported in Table 3.

SPECIFIC ROTATION MEASUREMENTS FROM PEAK HEIGHT DATA, WITH A GAUSSIAN PEAK MODEL

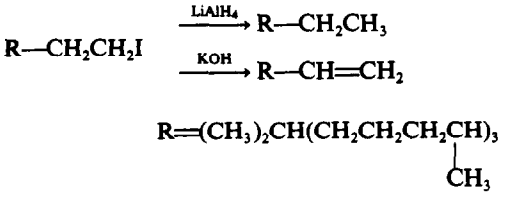
PATRICK D. RICE, YVONNE Y. SHAO*, STEVEN R. ERSKINE, TIMOTHY G. TEAGUE and DONALD R. BOBBITT†

Department of Chemistry and Biochemistry, University of Arkansas, Fayetteville, Arkansas 72701, U.S.A.

(*Received* 19 *July* 1988. *Revised* 28 *October* 1988. *Accepted* 11 *November* 1988)

Summary—A method is described whereby a sensitive laser-based polarimeter can be used to make very accurate and precise specific rotation measurements on microgram quantities of optically active materials. Flow-injection or liquid chromatography systems provide reproducible introduction of the sample into the polarimetric system. If a Gaussian distribution of the analyte concentration is assumed, the peak height can be used in the determination of specific rotation. This method provides a direct calibration with an absolute standard which yields more accurate and precise results than those obtainable by using peak area.

Optical activity is an extremely important property that is usually indicative of biological activity, past or present. The specific rotation is the parameter used to describe the magnitude of chirality possessed by a system and it can provide important and unique information about the arrangement of atoms at, or near the chiral centre. Small structural changes can, in some circumstances, produce large and pronounced changes in the specific rotation. For example, when 1-phytanyl iodide is subjected to reducing conditions, a product is formed that has a specific rotation of $+3.9\,deg.ml.dm^{-1}.g^{-1}$. However, the same starting material under conditions leading to elimination of hydrogen iodide yields a product[1] with a specific rotation of $-5.0\ deg.ml.dm^{-1}.g^{-1}$. This sequence is depicted in the reaction scheme below and it underscores the fact that subtle changes in the overall chemical structure of a molecule can produce large and significant changes in the specific rotation, even if the chemical changes take place several carbon atoms away from the chiral centre.



Specific rotation measurements can also be used to assess enantiomeric purity. This is particularly important considering the fact that only one enantiomer of an enantiomeric pair is usually biologically active. However, in spite of the usefulness of specific rotation measurements in answering a variety of important questions, the specific rotation is often an overlooked property. Part of the problem is the difficulty of making such measurements. Conventional polarimeters cannot detect a rotation of less than about 0.001°. Thus, for a sample with a specific rotation of $10\,deg.ml.dm^{-1}.g^{-1}$, the concentrations must be at the 0.1 mg/ml level or above, to be detectable. For a 10-ml detection cell, at least 1 mg of the optically active material must be available. Obviously, for routine analysis in situations where abundant sample is available, this is not a problem. However, when sample is limited, *e.g.*, in the analysis of a genetically engineered material, or in other trace-level situations, the poor sensitivity of conventional polarimetry precludes its use. However, it is precisely in these experimentally demanding situations that the information contained in the specific rotation could prove most useful.

Further, as the theory describing the basis for optical activity advances, experimental procedures must be developed to test these new concepts. For example, a recent theoretical study has shown that solvent molecules can influence the observed optical activity of a chiral system, inducing rotational changes at the 0.06°/cm level.[2] Obviously, to verify and use these new theories will require more sophisticated and precise polarimetric measurements than those available with conventional instrumentation.

Yeung *et al.* have described a laser-based polarimeter possessing rotational sensitivity substantially better than that of conventional polarimetric instrumentation.[3] This system has been used as a detector in HPLC to monitor for the presence of sugars in urine,[4] free and esterified cholesterol in blood,[5] and chiral components in shale oil[6] and coal.[7] Recently this system was modified for microcolumn detection[8,9] by using high-frequency polarization modulation of the laser light to extend the detection limit to less than 10^{-6} deg.[10]

The impressive quantitative capabilities of this instrument have not been directly translated into improvements in the ability to make specific rotation determinations. One application of this laser-based polarimeter in this context used chromatographic peak areas to determine specific rotations for a variety of derivatized amino-acids.[11] However, although peak area is relatively independent of chromatographic conditions, it is not always the most precise and accurate analytical parameter to use in certain experimental situations, particularly with respect to the measurement of specific rotation. It has been shown that for peak area to be accurate as analytical parameter, the baseline adjustment is critical.[12] Therefore, when an undulating baseline is present, peak area is not as accurate or precise as peak height for analytical description of the system under study. In addition, in chromatography peak area is much more sensitive than peak height to the resolution of closely eluted materials and requires nearly complete resolution of two components, so that each can be determined without interference from the other.[13] Finally, for highly accurate and precise trace-level specific rotation measurements it is necessary to calibrate the polarimetric system with a known rotational standard on an analysis-by-analysis basis to correct for instrumental changes from one measurement to the next. Such a standard is available in the Faraday effect. Faraday's law allows calculation, with a high degree of accuracy, of the rotation caused by the passage of a known current through a solenoid prepared with a specific number of turns. However, this rotation will then be observed as a deflection (height) above the baseline, and, although peak height can be directly calibrated by means of this signal, application to peak area is less straightforward.

This report will describe the use of a sensitive laser-based polarimeter similar to that of Yeung *et al.* to make highly accurate and precise specific rotation measurements on trace-level samples by using calibrated peak height data and a Gaussian peak model. Results obtained by this technique will be compared with those from both area data and direct measurements, and the capabilities for each method will be evaluated.

THEORY

Specific rotation, $[\alpha]$, is defined as

$$[\alpha]_T^\lambda = \frac{\alpha}{lc} \qquad (1)$$

where α is the rotation (deg) of the plane of polarization of plane-polarized light of wavelength λ by an optically active sample, T is the temperature (°C), l is the optical path-length (dm) and c is the sample concentration (g/ml). To apply equation (1) in conventional polarimetric measurements, the angular rotation induced by a sample of known concentration is measured. The angular rotation is obtained as the number of degrees through which the analyser must be mechanically rotated to re-establish the null condition (maximum extinction). There are two disadvantages to this approach. First, mechanical manipulation limits measurements to angles greater than approximately 0.010°. Secondly, static systems are not amenable to use for dynamic measurements such as those encountered in HPLC or flow-injection analysis (FIA). This is a significant limitation since these methods provide a precise and reproducible way to introduce microvolume samples into the polarimetric system.

The processes which shape the analyte profile in a flow system are many and complex. However, in the absence of secondary effects such as chemical interactions, or pre- or post-column broadening, mass transport by individual molecular motion is responsible for the characteristic shape of a chromatographic peak. These diffusive processes give rise to a Gaussian distribution of the analyte in the mobile phase.

Fick's second law is the fundamental equation for the mathematical treatment of diffusion processes, one solution of which describes the concentration *vs.* time or volume profile resulting from these processes in a flowing system.

$$c = \frac{M}{\sigma_V\sqrt{2\pi}} \exp(-\tfrac{1}{2}[(V - V_R)/\sigma_V]^2) \qquad (2)$$

where M is the mass injected, V_R is the mean retention volume, V is the eluate volume at which the concentration c is to be determined, and σ_V is the standard deviation of the distribution, in volume units. Conversion from volume into time units could be effected if desired, by division of the volume by the flow-rate.

To apply equation (1) with peak area data the concentration of the injected sample can be substituted for c since all of the injected mass (concentration × injection volume) will be accounted for in the total peak. However, to take advantage of the use of peak height as the analytical parameter, it is necessary to determine the *fraction* of the total injected mass that is in the cell when the maximum signal occurs. This mass fraction, divided by the cell volume (which can be determined very accurately) yields the concentration at the point of maximum signal.

For use of this technique equation (2) must be integrated symmetrically over the cell volume to find the fraction of the total injected mass that is in the cell.

$$c_{\text{cell}}^{\text{max sig}} = \frac{\text{mass inj. (g)}}{\text{cell volume (ml)}} \left\{ \frac{1}{\sigma_V\sqrt{2\pi}} \times \int_0^{V_{\text{cell}}} \exp -\frac{1}{2}\left[\frac{(V - V_{\text{cell}}/2)}{\sigma_V}\right]^2 dV \right\} \qquad (3)$$

In equation (3), the integration over the cell volume determines the analyte distribution in the cell when the maximum signal occurs. Multiplication of this term by the mass injected therefore enables the mass in the cell at maximum signal to be determined exactly.

The integral of equation (3) cannot be evaluated easily, because there is no analytical form for it. Equation (3) could be integrated by parts after expansion of the exponential in a power series, but even this approach is difficult to implement in practice, since a solution would have to be found for every Gaussian peak corresponding to different analyte retention times.

Fortunately, equation (3) can be transformed by substitution of the normal variable z according to the relation

$$z = \frac{V - V_{cell}/2}{\sigma_V} \tag{4}$$

and rewritten as

$$c_{cell}^{max\ sig} = \frac{\text{mass inj. (g)}}{\text{cell volume (ml)}} \times \left[\frac{1}{\sigma_V\sqrt{2\pi}}\int_{z_1}^{z_2} e^{-(z/2)^2}\,dz\right] \tag{5}$$

Equation (5) represents a transformed normal distribution and tables of the area under a standard normal distribution as a function of z can be used to evaluate the term in square brackets. To do this, the peak must be characterized by its standard deviation, σ_V. This is easily accomplished by measuring the width at half-height, $W_{0.5}$ and using the relation[14]

$$W_{0.5} = 2.354\sigma \tag{6}$$

Equation (1) can thus be modified to yield

$$[\alpha]_T^\lambda = \frac{R}{lc_{cell}^{max\ sig}} \tag{7}$$

where R (deg) is the rotation evaluated from the peak height calibrated against the Faraday response, and the concentration in the detection cell when the signal is maximal ($c_{cell}^{max\ sig}$) is determined by using the standard deviation of the peak (σ_V) as described above.

Therefore, if the assumption of a Gaussian model for the analyte distribution in a flowing stream is valid, peak height measurements can be used to determine specific rotations with high accuracy and precision.

EXPERIMENTAL

The laser-based polarimetric detection system has been described in detail elsewhere.[3,15] Glan–Thompson calcite polarizing prisms (Karl Lambrecht, Chicago, IL, model MGT-E8) serving as the polarizer and analyser were chosen by a procedure described previously.[4] In place of the large-frame argon-ion laser used in the earlier studies, a 5-mW helium-neon laser (Spectra Physics, Mountain View, CA, model 105) served as the source. Detection was accomplished with two cells constructed in-house with internal volumes of 101.5 μl (0.53 dm path-length) and 13.7 μl (0.10 dm path-length), respectively. A static Faraday cell filled with either acetonitrile or methanol was used to modulate the laser light at a frequency of 2 kHz. This frequency was found to produce the optimum signal to noise (S/N) ratio for this source laser. Light passing the analyser was detected with a red-sensitive photomultiplier tube (PMT) (Hamamatsu, Middlesex, NJ, model R928) powered by a high-voltage supply (Bertran Associates, Inc., Hicksville, NY, model 215). A lock-in amplifier (Stanford Research Systems, Palo Alto, CA, model SR510) demodulated, amplified and digitized the PMT signal. Data were digitized at a rate of 2 Hz, which permitted peak half-widths to be determined with 0.5 sec precision. Data were transferred to a PC computer by an IEEE interface (National Instruments Co., Austin, TX, model PC-2A) for subsequent storage and analysis.

Sample was passed into the detection cell by an ISCO syringe pump (Lincoln, NE model LC-5000) through a Rheodyne injection valve (Cotati, CA, model 7410) fitted with a 5-μl internal loop. Chromatographic studies utilized a 10-μm C-18 column to help shape the analyte distribution and ensure an approximately Gaussian profile. Alternatively, the column was replaced by a flow-injection configuration with delay line long enough to create sufficient dispersion for a Gaussian profile to be developed, resulting in a narrower but similarly shaped peak. The chromatographic system provided more reproducible results, however, and was used for the rest of these studies.

For the direct measurement of specific rotation, the 0.53-dm path cell was used and concentrations were chosen such that the measured rotation was approximately 2° for each compound. Thus, for example, the concentration of limonene ($[\alpha] \sim 90°$) was approximately 5.04×10^{-2} g/ml. For the chromatographic studies, the injected concentrations (g/ml) for the eight compounds studied were:

(R)-limonene	4.14×10^{-5}	(S)-limonene	4.98×10^{-5}
α-pinene	1.27×10^{-3}	β-pinene	4.23×10^{-4}
carvone	9.45×10^{-5}	nopol	3.83×10^{-5}
longifolene	9.14×10^{-5}	2-butanol	7.91×10^{-4}

The response of the polarimetric system was found to be linear over the range of concentrations used in the chromatographic studies. All specific rotation measurements were made with acetonitrile as the solvent.

The eight optically active compounds studied were obtained from Aldrich Chemical Co. (Milwaukee, WI). The acetonitrile was obtained from Fisher Scientific (Fairlawn, NJ). All reagents were filtered and degassed under vacuum with ultrasonic agitation prior to use.

Peak heights were calibrated by means of the rotation induced by a Faraday coil prepared by winding 8000 turns of 30AWG magnet wire (Beldon, Geneva, IL) around a 10 cm × 0.125 in. o.d. stainless-steel tube. Faraday's law gives the relationship between the angle of rotation, α (arc min) of plane-polarized light passed through a homogeneous magnetic field, B (gauss), of length L (cm) created in a medium with a Verdet constant v (which is medium- and wavelength-dependent).

$$\alpha = vBL \tag{8}$$

For the air-based solenoid used in this work, a current of 0.266 A produced a rotation of 2.86×10^{-4} deg at 632.8 nm. The laser-based polarimeter produced a baseline noise level (peak-to-trough) corresponding to 5×10^{-6} deg.

RESULTS AND DISCUSSION

To illustrate the method, consider the Gaussian peak produced by the injection of 9.30 μg of D-carvone into a reverse-phase HPLC system. As shown in Fig. 1 the goal is to calculate the concen-

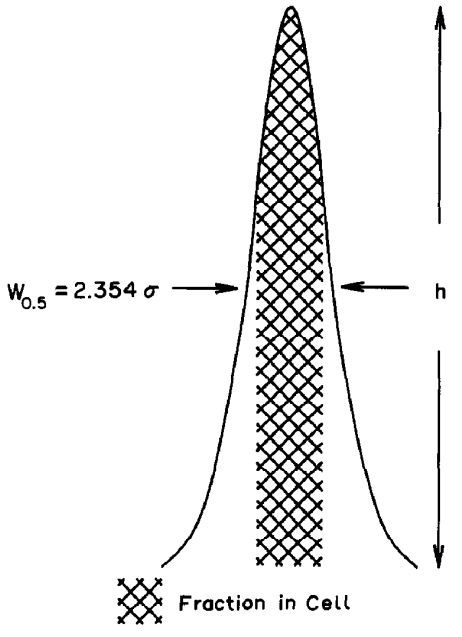

Fig. 1. Gaussian distribution characterized by width at half-height ($W_{0.5}$) equal to 2.345 σ; h is the maximum value of the distribution.

tration in the cell when maximum signal is reached, the region represented by the hatched portion of the figure. For the injection of D-carvone, the signal at the maximum of the peak was 6.51×10^{-5} V, and the Faraday coil produced a signal of 1.13×10^{-5} V. Since the Faraday coil was designed to produce a rotation of 2.86×10^{-4} deg, the half-width for the carvone peak was 12.0 sec, corresponding to 0.10 ml after multiplication by the flow-rate (0.5 ml/min). From equation (6), the standard deviation for this peak is thus 42.5 μl. If the peak is Gaussian, equations (4) and (5) can be used to determine the fraction of the inject mass that is present in the cell. For the carvone peak centred in a detection cell with a volume of 101.5 μl the transformed variable z is obtained from

$$z_1 = \frac{0 - V_{cell}/2}{\sigma_V} = \frac{-101.5/2}{42.5} = -1.194 \quad (9)$$

and

$$z_2 = \frac{V_{cell} - V_{cell}/2}{\sigma_V} = \frac{101.5 - 101.5/2}{42.5} = 1.194 \quad (10)$$

A table of the standard normal distributions[16] can then be used to find the area fraction under the peak over the range of z from -1.194 to 1.194. This fraction is 0.750, which signifies that 7.00 μg (0.750×9.30) of carvone was in the cell when the signal was at its maximum. For the 101.5-μl (0.53-dm path length) cell used in these studies, the concentration in the cell is therefore 6.87×10^{-5} g/ml. Substitution of this value into equation (7) yields a specific rotation of 45.4 deg.ml.dm^{-1}.g^{-1} for D-carvone.

The polarimetric system used for these studies is based on a 632.8 nm source. Since most literature tabulations of specific rotations refer to measurement with the sodium D line (590 nm), the polarimetric system was used in a conventional manner for the direct measurement of the specific rotations for the compounds studied. All measurements were repeated three times and were limited by the precision with which the degree scale on the analyser stage could be read (0.1°). The literature values for the eight compounds studied, as well as the results for the direct measurements are summarized as the first two entries in Table 1. As expected, there are small differences in the chirality of these compounds at the two wavelengths.

Since peak area has been used previously for specific rotation measurements, it seems appropriate to compare the peak area and peak height techniques to assess their relative capabilities. Application of equation (1) with the peak area data for the eight compounds studied produced the results summarized in the third column of Table 1. The peak-area results were, within experimental error, equivalent to the

¶Using equation (7).

direct measurements for six of the eight compounds. The results for β-pinene and carvone were outside the range predicted by experimental error.

Application of the new technique as described above for carvone led to the results in the fourth column of Table 1. From these results several conclusions can be drawn concerning the method. First, it should be noted that the values obtained from the chromatographic data correspond to the injection of approximately 10 μg of material. This differentiates the laser-based polarimetric system from conventional polarimetric measurements, especially considering that the detection limit for this polarimetric system has been shown to approach the 10 ng level.[17] Secondly, the peak-height method produces results that are, within experimental error, equivalent to those obtained by direct measurement for all eight compounds. The uncertainties listed in Table 1 were obtained by application of the rules of error propagation to the experimental data and this analysis shows that the precision of the peak height method is better than that of either the direct measurement or the peak-area techniques. The propagated error for longifolene is larger than for any of the other materials studied. This can be attributed to the fact that the retention time of longifolene under the chromatographic conditions used was substantially the longest, resulting in a much larger peak width. Thus the uncertainty in determining $c_{cell}^{max\ sig}$ will be larger, since a smaller fraction of the distribution is being sampled, *vide infra*. Thirdly, the method works equally well for either laevorotatory or dextrorotatory materials. Finally, the peak-height results are more comparable than the peak-area results to those obtained by direct measurement, for six of the eight cases studied. This suggests that the accuracy of the peak-height method is superior to that of the peak-area methods. One possible explanation for this may be the difference in calibrating the peak parameter in terms of rotation. For peak height, simple proportion between the Faraday signal and peak signal is used. For peak area, the Faraday signal must be integrated over a period of time and the rotation per unit time calculated before the calibration can be made. Thus the peak-height method is more straightforward.

Table 2 lists the relative standard deviations obtained for the two methods (five replications of each determination). The precision is good for each technique and close to the limits of chromatographic reproducibility, but the peak-height precision is better in 7 of the 8 test cases, which suggests that the peak-height method is not affected by the chromatographic conditions. To test this hypothesis, the peak-height technique was used to determine the specific rotation of D-longifolene under chromatographic conditions varied to change the capacity factor (k') over the range from 1 to 4; all the results agreed within experimental error. This underscores the fact that if the analyte distribution is characterized in terms of the fraction of the analyte present in the cell when the maximum signal is produced, comparisons of experiments will be meaningful whether the chromatographic conditions vary or not, making the method more robust.

Table 2. Experimentally determined relative precision for the peak-height and peak-area techniques*

Compound	RSD^{Area}, %	RSD^{Height}, %
(R)-Limonene	2.2	1.3
(S)-Limonene	2.1	0.9
α-Pinene	4.7	1.9
β-Pinene	8.9	4.9
Carvone	3.4	3.1
Nopol	3.9	2.0
Longifolene	4.8	3.0
2-Butanol	9.2	7.1

*Relative standard deviation for 5 determinations.

Since the fraction of the analyte distribution in the cell is a function of the cell volume as well as of the distribution parameters, the cell volume was tested as an experimental variable. The application of the peak height method to data obtained with a 13.7-μl detection cell is summarized for two of the test compounds in Table 3. With this cell, only a small fraction of the total injected mass is in the cell at any one time, yet the method produces results of the same quality as with the larger cell. Thus the method is not limited by the size of the detection cell. However, the uncertainties of the specific rotations in Table 3 are greater than those obtained with the larger cell. This is because the 2-Hz sampling frequency limits the precision with which the half-width can be determined to 0.5 sec. For the 13.7-μl cell, the relative precision with which the fraction in the cell can be determined is thus larger than with the other cell. This is not a serious limitation, since it can be overcome by increasing the data-sampling frequency to match the experimental configuration.

This method will obviously have its greatest application in the determination of specific rotations for materials available in pure form. Thus, either chromatographic or FIA systems could be used as the sample introduction techniques, and specific rotation measurements used, for example, to assess enantiomeric purity for known materials, identify unknown compounds, or follow changes occurring at a chiral centre during a biochemical reaction. It is also possible to apply the technique in a true chromatographic fashion to an unknown multi-

Table 3. Specific rotation as a function of cell volume (peak-height technique)*

Carvone	45.8 ± 2.3	45.2 ± 3.8
(S)-Limonene	92.9 ± 2.8	92.7 ± 3.6

*Units deg.ml.dm^{-1}.g^{-1}; at 632.8 nm.

component sample, providing another measurement is available to apportion the injected mass between the various components. This is what has been done previously with peak-area measurements in a chromatographic separation.[18] One possibility would be to monitor the effluent simultaneously with a refractive index detector, thereby ensuring a response for all components. Again, peak heights could be used, assuming that the refractive indices of the various components are similar under the extremely dilute conditions used in modern HPLC. Although both the peak-area and peak-height techniques require a second measurement to apportion the injected mass, the peak-height technique will give superior results when the chromatographic peaks are not fully resolved, and may give specific rotation information even when the peak-area method would not produce meaningful results.

The requirement that the analyte distribution should be Gaussian can be a limitation in certain chromatographic situations, since asymmetrical peaks, due to tailing or other effects, are common. However, this limitation can be overcome by the use of an exponentially modified Gaussian (EMG) function[19,20] to describe the distribution. Recent work[21] has shown that the EMG function is an accurate description of a tailed chromatographic peak.

In conclusion, a new method has been described and evaluated which permits specific rotation measurements to be made from peak-height data and statistical characterization of the peak moments. The method can produce accurate and precise results with microgram or smaller amounts of material, and is easier to implement and more precise than the peak-area method. Obviously, its precision will be a distinct advantage when changes in specific rotation are to be used to discern subtle differences occurring at or near a chiral centre. For example, the method has been used[22] to show that erythromycin A, with a specific rotation of 72.3 $deg.ml.dm^{-1}.g^{-1}$ can be distinguished from erythromycin C, with a specific rotation of 66.7 $deg.ml.dm^{-1}.g^{-1}$. The difference in structure between these two erythromycins consists of the substitution of a hydroxyl group (in erythromycin A) for a methoxy group (in erythromycin C), a change of only about 2% in the molecular weight. The method may also be modifiable for use with non-Gaussian peaks, as shown by recent work with exponentially modified Gaussian functions as models for tailed chromatographic peaks, and this warrants further investigation.

(*Received* 11 *September* 1987. *Revised* 17 *July* 1988. *Accepted* 9 *November* 1988)

Summary—The solvent effect on the photostability of Hg(II) dithizonate in daylight and under laser irradiation has been confirmed and benzene found to be the best solvent to use in photometric work with Hg(II) dithizonate. A 1:1 v/v mixture of benzene and carbon tetrachloride is recommended for use in the laser-induced photoacoustic spectrometric determination of Hg(II) dithizonate. A detection limit of 0.8 ng/ml has been attained, together with a linear dynamic range of 3 orders of magnitude. Coupled with a concentration factor of 50 obtained by extraction, the method shows promise for the detection of Hg(II) at the 5-pg/ml level in water.

Being toxic, mercury is regularly determined in a wide variety of samples such as air, waste-water, soil, food, human blood and urine. Ure comprehensively reviewed the literature up to 1973 on the analytical aspects of non-flame atomic-absorption and atomic-fluorescence methods for the determination of mercury.[1] Chilov compared the commonly used methods for the determination of trace amounts of mercury, in terms of sensitivity and ease of application.[2] Various new and improved methods have been developed recently, based on spectrophotometry,[3,4] potentiometry,[5,6] ion-selective electrodes,[7,8] polarography,[9] stripping voltammetry,[10–12] atomic-absorption spectrometry,[13–17] atomic-fluorescence spectrometry,[18–20] X-ray fluorescence,[21] photoacoustic spectrometry,[22] piezoelectric detection,[23] neutron-activation analysis,[24,25] proton-induced X-ray emission,[26] ion-chromatography[27] and liquid chromatography.[28,29] The most recent reviews are by Sun[30] and Krishnasamy and Ayyadurai.[31]

During the past decade, many new complexing and chromogenic reagents have been synthesized for the extraction–spectrophotometric determination of Hg(II),[4,32–35] but dithizone is still widely used because of its high selectivity for Hg(II) under specific conditions.[3,36–41] It has been reported that Hg(II) dithizonate in benzene, chloroform or carbon tetrachloride is light-sensitive.[3,37,42,43] When exposed to visible light, a solution of Hg(II) dithizonate in these solvents changes its colour from orange-yellow to royal blue; if the solution is then kept in the dark, its colour gradually returns to orange-yellow. This photochromism of Hg(II) dithizonate could cause a changing absorbance reading during a spectrophotometric measurement. Furthermore, it has also been observed that in these solvents Hg(II) dithizonate is decomposed irreversibly by daylight (in particular the ultraviolet component), with a resulting decrease in absorbance. Consequently, the extraction and spectrophotometric determination of Hg(II) as its dithizonate should be done under controlled dim light or in darkness, and the overall time should be minimized.[37]

This paper reports the use of dithizone in the extraction of Hg(II) from aqueous samples and the subsequent determination of Hg(II) dithizonate in the organic extracts by laser-induced photoacoustic spectrometry (LIPAS).[44] It examines the effect of the photostability of Hg(II) dithizonate in various solvents on the determination of trace mercury by LIPAS. The results are applied to developing an ultrasensitive method of dithizone extraction–photoacoustic spectrometry for the determination of Hg(II) in water at the ng/l. level.

EXPERIMENTAL

Reagents

ACS grade reagents and demineralized water were used.

Dithizone solution. The concentration was 0.001% in the solvent chosen for the experiment. The solution was covered with 0.5*M* sulphuric acid and stored in darkness.

Standard solution of Hg(II) sulphate. The mercury concentration was 2 μg/ml in 0.5*M* sulphuric acid.[45] This concentration should not change within a few days. Mercury(II) is more rapidly and completely extracted with dithizone from sulphuric or nitric acid than from hydrochloric acid.[3]

Apparatus

Spectrophotometers. Hilger 700 spectrophotometer and Perkin-Elmer Coleman 124 double-beam spectrophotometer.

Lux meter. International Light 1350 radiometer/photometer.

*Author to whom all correspondence should be addressed.

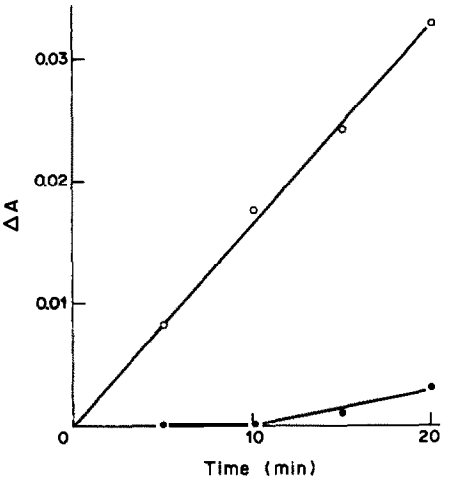

Fig. 1. Decomposition of Hg(II) dithizonate with time under 500-lux daylight irradiation. ●, $CHCl_3$; ○, CCl_4. Concentration of Hg(II) dithizonate = 1.4 μg/ml; initial absorbance = 0.098.

Power meter. Optikon 66XLA optical power/energy meter with an Optikon 400 broadband Si sensor head, calibrated by the U.S. National Bureau of Standards.

Laser. Lambda Physic F12000 dye laser pumped by an N2000 nitrogen laser.

Photoacoustic cell. An 8-mm diameter cylindrical borosilicate cell attached to a Vernitron 8-8031 piezoelectric ceramic tube transducer.[46]

Boxcar averager. Stanford Research Systems 250 gated integrator and boxcar averager.

Dithizone extraction

Sixty ml of 0.5*M* sulphuric acid, an aliquot of standard Hg(II) solution and 2.5 ml of organic solvent were placed in a separatory funnel. The mixture was shaken vigorously for 1 min to saturate the aqueous phase with the organic solvent. After separation from the organic phase, the aqueous solution was extracted with 5.0 ml of dithizone solution under weak fluorescent light for 1 min. Any excess of dithizone in the organic phase was removed by washing with dilute ammonia solution (1 + 1000);[37] This step was necessary because the presence of excess of free ligand increases the rate coefficient of photochromic relaxation of Hg(II) dithizonate.[47] If this step was omitted, irreproducible data were obtained. After separation of phases, aliquots of the organic phase were used for photostability studies and LIPAS measurements.

Photodecomposition

A 2.5-ml portion of the organic extract containing the Hg(II) dithizonate was sealed in a 1-cm path-length fused-silica cuvette, and its absorbance (A) was measured at 490 nm. It was then placed outdoors for a known time at daylight intensities measured with the lux meter. The absorbance was then monitored until a steady-state reading was obtained (*i.e.*, the photochromic relaxation had finished). The decrease in absorbance (ΔA) from the value before the irradiation was obtained by subtraction.

Photochromism

The photochromism of Hg(II) dithizonate in different solvents under irradiation by the light in the spectrophotometer, fluorescent light and sunlight was examined by eye. Quantitative measurement is complicated because the photochromic relaxation of the complex in some solvents is faster than the response of the spectrophotometer. A new technique for this measurement is being developed in our laboratory.

Photoacoustic spectrometry

The experimental arrangement for the LIPAS measurements was similar to that described elsewhere.[48] A 0.5-ml volume of sample solution was placed in the photoacoustic cell (the 8-mm diameter of which constituted the optical path-length. The dye laser was operated at a repetition rate of 25 Hz. The LIPAS signal detected by the piezoelectric transducer was amplified before it was processed by the boxcar averager. The boxcar gate was set at a delay time of 36 μsec to measure the amplitude of the first positive excursion of the pulsed signal.

RESULTS AND DISCUSSION

Photodecomposition

Hg(II) dithizonate in solution can be decomposed irreversibly by daylight, both during the transfer of samples[47] and when contained in ordinary glassware.[37] The photodecomposition is strongly dependent on the nature of the solvent. Under illumination by 500 lux of outdoor daylight for 20 min, the absorbance of an Hg(II) dithizonate solution in chloroform decreased by only about 3% whereas the absorbance of a carbon tetrachloride solution is decreased by about 40%, the decrease being directly proportional to illumination time (Fig. 1). As shown in Fig. 2, Hg(II) dithizonate in carbon tetrachloride was stable when the illumination intensity was less than 200 lux, but was decomposed rapidly at higher intensities. The steeper slope for the carbon tetrachloride solution shows that this solution is more light-sensitive than the chloroform solution. Benzene and methylene chloride solutions were also studied. The stability of the solutions decreased in the order $C_6H_6 > CHCl_3 > CH_2Cl_2 > CCl_4$. A suitable solvent

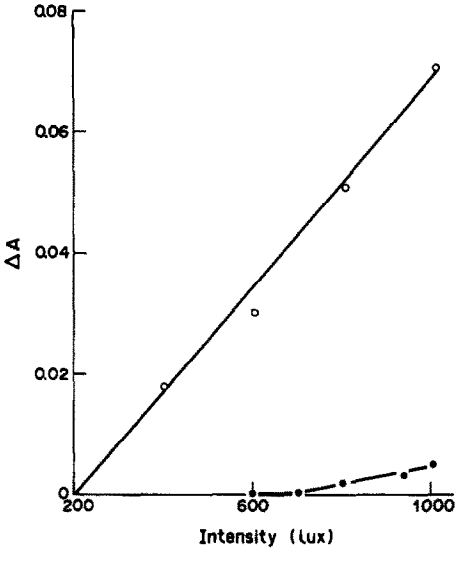

Fig. 2. Decomposition of Hg(II) dithizonate under daylight irradiation of varying intensities for 15 min: ●, $CHCl_3$; ○, CCl_4. Concentration of Hg(II) dithizonate = 1.4 μg/ml; initial absorbance = 0.098.

should, therefore, be selected for the dithizone extraction of Hg(II) before its determination by LIPAS or low results will be obtained.

The relevance of the data above to determination of Hg(II) by dithizone extraction and LIPAS is obvious. The light-sensitive region for the photodecomposition of Hg(II) dithizonate in the solvents mentioned has been found by us to extend up to 350 nm, with the sensitivity varying as a function of wavelength. Standard window glass of 3-mm thickness has 50% transmission at 330 nm, and borosilicate glass of 1.5-mm thickness 50% at 311 nm.[49] Since the integrated solar radiation flux (photons.cm^{-2}.sec^{-1}) at 311–350 nm is four times that at <311 nm,[50] the use of borosilicate separatory funnels and photoacoustic cell indoors will not exclude the possibility of photodecomposition. This is confirmed by the observation of Schmidt and Rautsche that under diffuse daylight the photodecomposition of dilute Hg(II) dithizonate solutions was nearly 65% complete after 3 hr.[51] It is also consistent with the report of Litman *et al.* that if solutions of Hg(II) in nitric or perchloric acid are extracted with dithizone in carbon tetrachloride, the complex is unstable and decomposes to a significant extent (30–60%) within 20 min.[36] Clearly, these effects can be avoided by proper choice of solvent *etc.*

Photochromism

The photochromism of Hg(II) dithizonate had been found to be very strong in dry non-polar (or weakly polar) solvents.[42] However, the photochromism of Hg(II) dithizonate in these solvents after extraction from 0.5*M* sulphuric acid differs considerably, increasing in the order $C_6H_6 < CHCl_3 < C_6H_5CH_3 < CH_2Cl_2 < CCl_4 < C_6H_5Cl$, as evidenced by the following observations. In chlorobenzene, the colour of the Hg(II) dithizonate solution is changed even by the light-beam passing through the sample compartment of the spectrophotometer. Under ordinary fluorescent light (approximately 140 $\mu W/cm^2$), the solution in carbon tetrachloride or chlorobenzene changes colour but not that in chloroform. There was no photochromism in benzene solution except under direct sunlight.

Marczenko[3] and Irving[37] reported that the yellow colour of Hg(II) dithizonate in organic extracts can be stabilized by shaking them with 2*M* acetic acid. However, our work has shown that though the photochromic effect is inhibited, acetic acid fails to prevent the photodecomposition of Hg(II) dithizonate.

Photoacoustic spectrometry

LIPAS has been proved useful for the trace determination of various metals and organic compounds, *e.g.*, cadmium has been determined by LIPAS after extraction as cadmium dithizonate into chloroform.[52] The detection limit was 0.02 ng/ml, which is two orders of magnitude lower than that for conventional

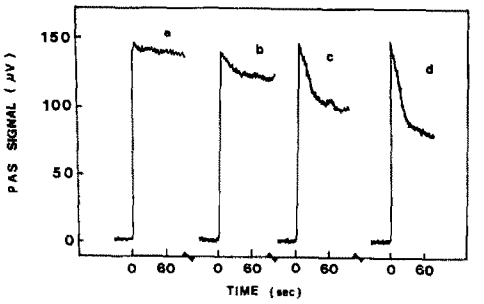

Fig. 3. Changes in photoacoustic signal amplitudes when a 460-nm laser beam was incident on Hg(II) dithizonate solutions in (a) benzene, (b) $CHCl_3$, (c) CH_2Cl_2 and (d) CCl_4.

spectrophotometry. However, if the sample solution exhibits photochromism when irradiated with a laser beam at the analytical wavelength, the LIPAS signal (which is directly proportional to absorbance) will decrease with time. This will seriously degrade the performance of the method, so a solvent which can prevent photochromism should be used.

The results discussed above have been utilized in LIPAS determination of Hg(II) dithizonate. A wavelength of 460 nm [at which the absorbance of Hg(II) dithizonate is only 70% of that at λ_{max}] and a laser power of 0.48 mW were used. Figure 3(a) show that the LIPAS signal for a benzene solution of Hg(II) dithizonate does not decrease significantly with time, whereas the signals for chloroform, methylene chloride and carbon tetrachloride do [Fig. 3(b)–(d)], the decrease indicating the extent of photochromism. For Hg(II) dithizonate, the best solvent among the four studied is undoubtedly benzene.

Determination of trace Hg(II)

A wavelength of 506 nm was selected for the next LIPAS experiment because it is the closest to the absorption maximum of Hg(II) dithizonate and the least likely to suffer interference from any residual dithizone after the extraction, and the absorptivity of Hg(II) dithizonate is still 84% of that at λ_{max}. Figure 4 shows the changes in photoacoustic signal when solutions of Hg(II) dithizonate in different solvents were suddenly exposed to irradiation by the 0.67-mW laser beam. Signals (a)–(c) were boxcar averages of 30 samples. Figure 4(a) shows that with chloroform as solvent the LIPAS signal becomes steady after irradition for 100 sec, whereas the signal for benzene solution [Fig. 4(b)] becomes steady within the first 16 sec of irradiation. In spite of this time-advantage, because the density of benzene is lower than that of water, a benzene-carbon tetrachloride mixture (1:1 v/v, density 1.2 g/ml) would be more convenient in practice for extractions from large volumes of aqueous solution, and gives as good an LIPAS signal as benzene does, Fig. 4(c). The undesirable spike due to the initial decay of the LIPAS signal can be suppressed electronically by

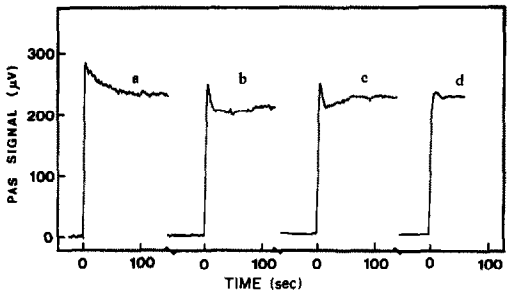

Fig. 4. Changes in photoacoustic signal amplitudes when a 506-nm laser beam was incident on Hg(II) dithizonate solutions in (a) $CHCl_3$, (b) benzene, (c) benzene–CCl_4 and (d) benzene–CCl_4 (with 100-sample boxcar averaging).

boxcar averaging of $\geqslant 100$ samples. The effect of 100-sample averaging is shown in Fig. 4(d); it provides a steady and less noisy signal after only 20 sec.

The determination of Hg(II) dithizonate in the mixed solvent by LIPAS was examined. A log-log calibration plot of the LIPAS signal (μV) *vs.* complex concentration from 3 to 2000 ng/ml was a straight line of unit slope, correlation coefficient 0.99. The limit of detection, calculated as the concentration giving a signal three times the background noise, was 0.8 ng/ml when 300-sample averaging was employed. If a concentration factor of 50 is assumed for the extraction process (from 50 ml to 1 ml),[39] then the technique can detect 20 pg/ml Hg(II) dithizonate, or 5 pg/ml Hg(II) in a water sample. This compares favourably with the detection limits of most other techniques, *e.g.*, 0.1 ng/ml for non-dispersive atomic fluorescence spectrometry (with an electrodeless discharge lamp and an argon–hydrogen–entrained-air miniflame)[53] and 40 pg/ml for ICP atomic fluorescence with a mercury vapour lamp operating in the pulsed mode.[19] Both these methods used cold vapour generation as the preconcentration technique. However, although the present method cannot compare, in terms of detection limit, with atomic-absorption spectrometry with amalgamation on gold to concentrate the Hg from a 500–1000 ml water sample,[15,16] it has a higher precision than the 10% for that method.

Interferences

There is little interference from other metal ions. Most of them will not be extracted along with Hg(II) by dithizone from 0.5*M* sulphuric acid, except Ag, Au, Cu, Pd and Pt.[3,45] These possible interferences can be eliminated by the addition of ethylenediaminetetra-acetic acid and/or potassium thiocyanate as masking agents,[45] or by means of kinetically-controlled selective extraction.[3,37,54]

The extraction of Hg(II) at trace concentrations with dithizone in the presence of various anions has been studied by Litman *et al.*,[36] who showed that the extraction is hindered by anions at the concentrations typically found in environmental samples. One reason for incomplete extraction of Hg(II) by dithizone is formation of $HgX_n^{(2-n)}$ complexes in the aqueous phase, where X stands for Cl^-, I^-, Br^- or CN^-. Hence hydrochloric acid should not be used as the sample medium for extraction. It was also observed that both the extraction efficiency and stability of the dithizone complex are dependent on the anion-to-mercury ratio, which may indicate possible participation of these anions in the formation of the Hg(II) dithizonate complex. However, in determination of Hg(II), this chemical interference by anions can be compensated for by applying the method of standard additions of Hg(II) to the environmental samples and using a stabilizing solvent such as benzene for extraction.

CONCLUSIONS

An extraction–LIPAS method based on dithizone has been developed for the determination of trace Hg(II). With a laser power of 0.67 mW at 506 nm, it offers a detection limit of 0.2 ng/ml Hg(II), without preconcentration by extraction, and a linear dynamic range of over three orders of magnitude. Both the photodecomposition of Hg(II) dithizonate under daylight and its photochromism under laser irradiation can affect the accuracy of the LIPAS determination, but this can be overcome by selecting a suitable solvent. The method may be extended to the determination of organomercury compounds in environmental and speciation studies.

ENERGY TRANSFER IN BENZALKONIUM CHLORIDE MICELLES

T. T. NDOU and R. VON WANDRUSZKA*
Department of Chemistry, University of Idaho, Moscow, Idaho 83843, U.S.A.

(*Received* 26 *August* 1988. *Accepted* 8 *November* 1988)

Summary—The energy transfer process from the excited phenyl group of micellar benzalkonium chloride (BAC) to solubilized anthracene is described. NMR studies show the solubilization site of the anthracene to be near the phenyl group in the BAC micelles. The system gives an energy transfer efficiency of 0.741 and the donor–acceptor separation is 41.4 Å.

Forster energy-transfer processes have been employed as "spectroscopic rulers" in the determination of interchromophore distances in macromolecules and microheterogeneous systems.[1] Energy transfer occurs when donor fluorescence and acceptor absorption bands overlap—the absorption spectra should be such that the donor can be excited without excitation of the acceptor.[2] The transfer competes directly with emission and non-radiative de-excitation of the excited donor[3] and the acceptor may or may not radiate part of the transferred energy. The extent of energy transfer can be monitored by observing the donor–acceptor emission intensity ratio. This ratio has been found to be relatively insensitive to the effect of light-scattering.[2]

This energy transfer between fluorescent molecules is revealed by the quenching of donor fluorescence and the appearance of sensitized fluorescence of the acceptor. In micellar solutions, it has been shown to occur between thionine and Methylene Blue solubilized in sodium lauryl sulphate (SLS) micelles.[4] The overall efficiency of the process was found to be related to the micellar aggregation number, the acceptor concentration and the intramicellar transfer efficiency. The energy transfer from diphenylacetylene to pyrene has been successfully employed to determine the aggregation number of SLS micelles.[2]

Surfactants that themselves contain donor groups can be used to observe energy transfer to associated species. Almgren[5] has studied the excitation energy transfer from the phenyl groups of sodium phenylundecanoate to solubilized naphthalene molecules. Similar work has been done for pyrene molecules solubilized in non-ionic micelles of Igepal CO-630.[6] The phenomenon has been advanced as evidence for the solubilization of aromatics inside the micelle, in close proximity to the phenyl group. Efficient energy transfer depends on several factors: the probability that acceptors have penetrated the micelle, intramicellar energy transfer efficiency, the orientation of the acceptor with respect to the donor, diffusion of acceptor species, and the solubilization site.

The mechanism incorporation of solutes in micellar solutions can be investigated by NMR spectroscopy. The chemical shifts and resonance line widths of surfactants and solutes can provide accurate information on solubilization sites, since these parameters are sensitive to the molecular environment. They are assessed by comparing the NMR spectrum of pure micellar surfactant with the spectrum of the surfactant containing the associated species. For instance, in surfactants containing a quaternary ammonium group, the binding shows itself most directly through changes in the widths and/or heights of the $-CH_2-$, $\alpha-CH_2$ and $(CH_3)_2N^+$ group resonances. Henrikson[7] has reported that relatively unrestricted motion of the group containing the proton leads to slow proton relaxation and narrow NMR lines. If the molecule is restrained and its motion is restricted in the vicinity of the group containing the proton, then the relaxation rate increases and the line broadens.

In the present study, the solubilization site of anthracene in micellar benzalkonium chloride (BAC) was determined. The energy transfer from the phenyl group of micellar BAC to solubilized anthracene was shown, and the distance between the phenyl group (donor) and anthracene (acceptor) in the micelles determined.

EXPERIMENTAL

BAC and anthracene (99 + % pure) were purchased from Sigma and used without further purification. Deuterium oxide (Aldrich, 99.8 atom% D), containing 0.75% sodium 3-(trimethylsilyl)-2,2,3,3-d_4 propionate was used as the solvent in the NMR studies.

High-resolution proton NMR spectra were obtained with an IBM/NR300 FTNMR spectrometer. All spectra were recorded at ambient probe temperature (35.0°). Absorption measurements were obtained with a Perkin-Elmer Lambda 4C spectrophotometer and fluorescence spectra were taken with a Perkin-Elmer MPF 66 fluorescence spectrophotometer equipped with a thermostatic cell housing. All optical measurements were made at 25.0°. Fluorescence was

measured in a 1-cm cell and all spectra were corrected for the blank.

RESULTS AND DISCUSSION

Proton NMR studies

The proton NMR spectrum of the surfactant (BAC) is shown in Fig. 1a. The peaks for the methylene protons merge at around 1.17 ppm, showing a broad peak with little splitting. The terminal methyl group gives a well resolved triplet with a maximum at 0.83 ppm. The α-CH_2 peak resonating at 2.99 ppm is very small; the singlet at 2.93 ppm is due to $(CH_3)_2N^+$.

The addition of anthracene alters the micellar properties and allows less motional freedom for both polar and non-polar groups. Figure 1b shows broadening and a loss of resolution of the major $(CH_2)_n$ signal. The $(CH_3)_2N^+$ resonance is also affected—the signal broadens and increases in height. This is accompanied by a slight upfield shift of 0.01371 ppm.

Okabayashi and Takahashi[8] found that the solubilization of large flat molecules in micelles reduces the mobility of the hydrocarbon segments of the micelles. Raman spectroscopy showed a significant increase in the rigidity of the hydrocarbon parts of lecithin on addition of cholesterol.[9] In the present case, restriction of segmental motion because of solubilization of anthracene appears to cause the line-width broadening of the $(CH_2)_n$ resonance. The

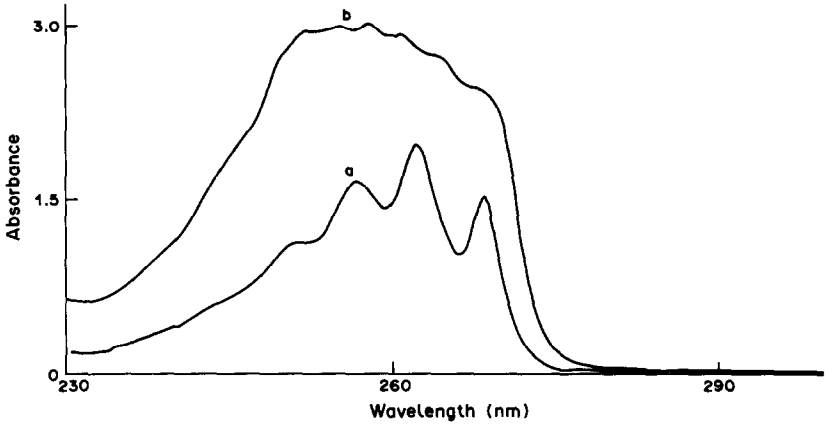

Fig. 2. The effect of concentration on the absorption spectrum of BAC. (a) Below the cmc; (b) above the cmc.

resolution of the α-CH_2 resonance of BAC is also influenced by the addition of anthracene. It is broadened and somewhat separated from the $(CH_3)_2N^+$ peak. This suggests that the anthracene resides at a site close to the α-CH_2 group.

The spectral features above indicate a preference for solubilization of anthracene at the polar end of BAC. This brings it into close proximity with the phenyl group of the micellar surfactant. The linewidth broadening of the methylene peak is attributable to those CH_2 groups in the chain that are located near the polar end of the detergent hydrocarbon chain. Although the local mobility at both the polar and non-polar ends of BAC is decreased on addition of anthracene, the effect seems to be most pronounced in the polar region. This suggests that anthracene comes into considerable contact with the $(CH_3)_2N^+$ group of BAC.

BAC absorption in the ultraviolet

Aqueous BAC solutions of low concentration show distinctive ultraviolet absorption spectra (Fig. 2). These change significantly when the surfactant concentration is raised above the critical micelle concentration (cmc). The three bands coalesce to form a single, broad blue-shifted peak when the cmc is reached (Fig. 2). Plots of molar absorptivity *vs.* BAC concentration (Fig. 3) show the dependence of absorption on surfactant concentration. The break at about $6 \times 10^{-3} M$ is interpreted as representing the cmc.

BAC fluorescence

The fluorescence spectrum of aqueous BAC is concentration-dependent (Fig. 4). At concentrations below the cmc, it consists of a broad band with a maximum at 317 nm. As the concentration is increased, the band shifts to longer wavelengths. This is due to premicellar interactions between individual surfactant species. At concentrations above the cmc, an additional band appears with a maximum at 340 nm. Kalyanasundaram and Thomas[6] have observed similar behaviour of Triton X-100 micelles. The new spectral band was attributed to dimeric species that appear at higher concentrations. In BAC, the mutual proximity of phenyl groups in the micelles gives rise to the observed excimer band. The monomer/excimer emission intensity ratio remains approximately constant when the BAC concentration is further increased.

Energy transfer

As discussed above, the proton NMR studies indicate that anthracene is solubilized at the polar end of micellar BAC and is located close to the surfactant phenyl group. The energy-transfer efficiency, E, between BAC and anthracene, is determined from the quenching of the donor fluorescence and the excitation spectrum of the acceptor.[10] The following relationship is employed:

$$E = [G(\lambda_1)/G(\lambda_2) - E_A(\lambda_2)/E_A(\lambda_1)] \times [E_A(\lambda_1)/E_D(\lambda_2)] \quad (1)$$

where $G(\lambda)$ is the magnitude of the corrected excitation spectrum of the energy acceptor excited at wavelength λ. The molar absorptivities of the energy donor (BAC) and acceptor (anthracene) at that wave-

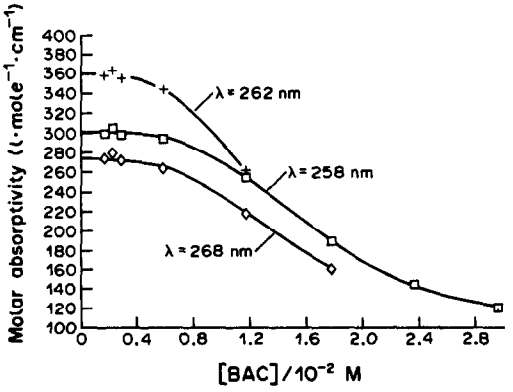

Fig. 3. Change in molar absorptivity of BAC with concentration.

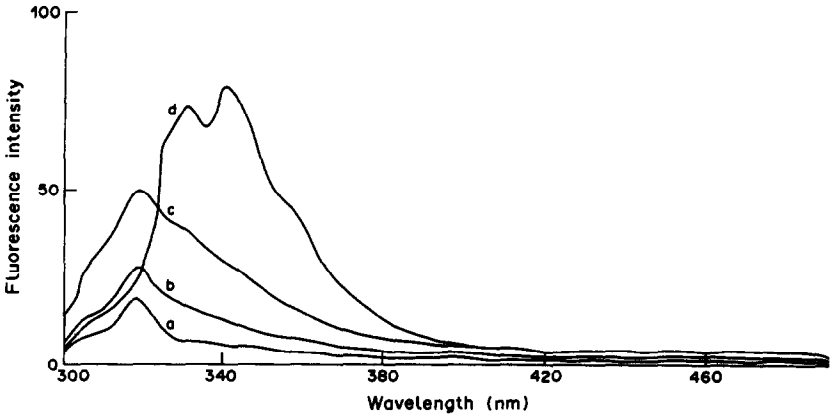

Fig. 4. Effect of varying concentration on the fluorescence emission spectrum of BAC: (a) $1.78 \times 10^{-3}M$; (b) $2.66 \times 10^{-3}M$; (c) $4.03 \times 10^{-3}M$; (d) $2.37 \times 10^{-2}M$.

length are $E_D(\lambda)$ and $E_A(\lambda)$, respectively. G is measured at two wavelengths: at λ_1, where the donor has no absorption, and at λ_2 where the absorptivity of the donor is large compared to that of the acceptor.

From $E_D(\lambda)$, $E_A(\lambda)$ and the concentrations of the donor (C_D) and acceptor (C_A), the fraction of light absorbed by the acceptor can be calculated.[2] This fraction is given by

$$X = E_A C_A / (C_A E_A + C_D E_D) \tag{2}$$

A value of 5.98×10^{-4} was found for anthracene.

The quantum efficiency, Q_D, of the fluorescence donor can be calculated by using the relationship of Lowey and Marsh:[11]

$$\frac{\text{(area under emission spectrum of BAC)}}{\text{(area under emission spectrum of quinine sulphate}} \times \frac{0.70\ (A_{252} \text{ for quinine sulphate})}{A_{252} \text{ for BAC}} \tag{3}$$

where 0.70 is the quantum efficiency of quinine sulphate in $0.05M$ sulphuric acid,[12] and A_{252} is the absorbance at 252 nm.

The quantum efficiency of BAC was found to be 0.348. This is comparable to the value obtained for Igepal CO-630 (0.34)[6] and for N-{[(iodoacetyl)amino]ethyl}-5-naphthylamine-1-sulphonic acid (0.30).[11]

The quantum efficiency is used in the calculation of the Forster radius, R_0, given by:

$$R_0 = \frac{9(\ln 10)\, k^2 Q_D J(\nu)}{128\, \pi^5 n^4 N} = 8.785 \times 10^{-25} k^2 Q_D n^{-4} J(\nu) \tag{4}$$

where n is the refractive index of the intervening medium, k^2 is the orientation factor, $J(\nu)$ is the overlap integral and N is Avogadro's constant. The overlap integral describes the relationship between the fluorescence emission of the donor and the absorptivity of the acceptor. It is given by:

$$J = \int \frac{F_D(\nu) E_A(\nu)\, d\nu}{\nu^4} \tag{5}$$

where F_D is the fluorescence intensity of the donor and ν is the frequency. J was calculated by a Simpson's rule integration of the function in equation (5).

The energy transfer efficiency for BAC/anthracene was found to be 0.741. This is in the range (0.5–1.0) predicted by Almgren[5] for the phenyl group of the sodium phenylundecanoate micelles and solubilized naphthalene. As given in equation (1), E is independent of the change in quantum yield of the donor as the acceptor is incorporated into the micelles. Thus, E is not affected by changes in the local environment of the donor in the presence or absence of the acceptor.

The anthracene molecules, solubilized near the phenyl groups of BAC, are expected to be homogeneously distributed within the micelles. It is assumed that the orientations of the donor–acceptor species are completely averaged within the lifetime of the transfer process, *i.e.*, the donor and acceptor are free to rotate during the excited state lifetime of the donor. In view of this, an average value of $k^2 = 2/3$ was used in these calculations.[3]

The rate of energy transfer is dependent on the donor–acceptor separation, R, which is given by:

$$R = R_0[(1/E) - 1]^{1/6} \tag{6}$$

The separation was found to be 41.4 Å, which is more than twice as large as the 15 Å obtained for Igepal CO-630 and pyrene.[6] However, Lowey and Marsh[11] have reported R-values in the range 26–46 Å, and Hillel and Wu[13] have indicated that energy transfer can be used to measure distances in the range 10–100 Å.

CONCLUSIONS

The red shift observed in the emission spectrum of BAC at concentrations above the cmc allows for strong overlap with the absorption spectrum of anthracene. This results in a relatively high energy-transfer efficiency (0.741). NMR studies show that the solubilization site of anthracene in BAC micelles

is near the polar end of the surfactant chain, close to the phenyl group. At concentrations below the cmc very little energy transfer is observed. The fluorescence emission of BAC at above the cmc is 77.6% quenched by anthracene, as compared to 5.8% at below the cmc. The calculated distance of 41.4 Å between the BAC phenyl group and the solubilized anthracene molecule is relatively large, but should only contain a minor uncertainty arising from the assumed value of k^2 (2/3). The phenyl group is part of the surfactant chain and the free rotation during its excited-state lifetime is not expected to have a major effect, since k^2 is averaged over the lifetime of the transfer process.

APPLICATION OF *p*-*N*,*N*-DIMETHYLPHENYLENEDIAMINE DIHYDROCHLORIDE FOR THE DETERMINATION OF SOME DIURETICS

C. S. P. SASTRY*, M. V. SURYANARAYANA and A. S. R. P. TIPIRNENI
Foods and Drugs Laboratory, School of Chemistry, Andhra University, Waltair 530 003, India

(*Received* 25 *November* 1987. *Revised* 20 *September* 1988. *Accepted* 8 *November* 1988)

Summary—A spectrophotometric method is described for the determination of acetazolamide, frusemide, polythiazide, benzthiazide, hydrochlorothiazide, hydroflumethiazide, trichlormethiazide and amiloride hydrochloride (AML) either in pure form or in pharmaceutical formulations. The method is based on the reaction with *p*-*N*,*N*-dimethylphenylenediamine dihydrochloride and chloramine-T, to give a coloured product having maximum absorbance at 660 nm (for AML) or at 540 nm for the others, and reproducible within ±1.0%.

Many of the reported visible-region spectrophotometric methods for the determination of diuretics such as amiloride hydrochloride (AMl),[1] frusemide (FRU),[2-4] acetazolamide (AZ)[5-7] and thiazides [benzthiazide (BZT), hydrochlorothiazide (HCT), hydroflumethiazide (HFT), polythiazide (PT) and trichlormethiazide (TCM)][8-10] suffer from lack of sensitivity or specificity. This paper describes the development of a simple, sensitive and inexpensive method using *p*-*N*,*N*-dimethylphenylenediamine dihydrochloride and chloramine-T, which is applicable to assay of these drugs in bulk samples and a wide variety of pharmaceutical preparations.

EXPERIMENTAL

Apparatus

A Systronics model spectrophotometer 105 (MK 1) with 1-cm matched glass cells was used for all the absorbance measurements. An Elico digital model LI-120 pH-meter was used for pH measurements.

Reagents

All solutions were prepared in doubly distilled water. Freshly prepared aqueous solutions of 0.05% *p*-*N*,*N*-dimethylphenylenediamine dihydrochloride (DMPDH, Fluka) and 0.2% chloramine-T (CAT, LOBA analytical grade) were always used.

Standard drug solutions

About 100 mg each of AZ, BZT, FRU, HCT, HFT, PT and TCM were accurately weighed and separately heated under reflux with 10 ml of 5*M* sodium hydroxide on a boiling water-bath for 30 min, and after cooling and adjustment to pH 7.0 with hydrochloric acid the solutions were diluted to volume with water in 100-ml standard flasks. These stock solutions were further diluted to give working solutions of AZ (125 μg/ml), BZT or HFT (250 μg/ml) and FRU, HCT, PT or TCM (500 μg/ml). For the AML solution the drug (25 mg) was dissolved in 100 ml of distilled water.

All chemicals used were of analytical or pharmacopoeial grade.

*Author for correspondence.

Analysis of bulk samples

Method A. Volumes of the standard AML solution ranging from 0.2 to 3.0 ml were placed in a series of 10-ml standard flasks, 1 ml of DMPDH solution and 1 ml of CAT solution were added to each and the mixtures were diluted to the mark with distilled water. The absorbances were neasured at 660 nm after not less than 10 or more than 50 min against a reagent blank prepared in a similar manner. The results were plotted in a calibration graph. Samples were analysed in the same way.

Method B. Volumes of the working standard solutions of the hydrolysed diuretics (AZ, BZT, HCT, HFT, FRU, PT or TCM) (to cover the calibration ranges given in Table 1) were transferred into a series of stoppered tubes graduated at 25 ml. One ml of CAT solution and enough distilled water to bring the volume to 5 ml were added to each, and the tubes were kept in a water-bath at 70° for 10 min, then cooled; 1 ml of DMPDH solution was then added to each flask and the solutions were diluted to the mark with distilled water. The absorbances were measured at 540 nm during the colour-stability period (1–8 min after this dilution for thiazides, 10–40 min for AZ and 10–75 min for FRU) against a reagent blank prepared in a similar manner. The results were plotted in calibration graphs. Samples were analysed similarly.

Analysis of pharmaceutical preparations

Single-component dosage forms. A weighed amount of powdered sample equivalent to 100 mg of the diuretic was extracted with acetone (4 × 10 ml). The residue from the acetone extracts was treated in the same way as for preparation of the corresponding standard drug solution and analysed by method B. In the case of AML–HCT tablets, an amount of powdered tablets equivalent to 25 mg of AML was extracted directly with distilled water (4 × 10 ml) and the extract was diluted to 100 ml and analysed by method A for AML. The water-insoluble residue, which contained the HCT, was extracted with acetone and processed and analysed as above.

Multi-component dosage forms. An amount of powdered sample equivalent to 100 mg of the diuretic to be determined was extracted successively with chloroform, water and acetone. The residue from the acetone extract was treated as described for the single-component dosage form. In the case of the HFT–propranolol hydrochloride combination, the HFT was selectively extracted into ethyl acetate (4 × 10 ml). The residue from evaporation of the combined ethyl acetate

*For regression equation $A = a + bc$ where A is the absorbance for concentration c (μg/ml).

extracts was treated as described for the corresponding standard drug solution and analysed by method B.

RESULTS AND DISCUSSION

Since the diuretics under investigation have either a free (AML) or a substituted (and releasable by hydrolytic cleavage thiazides, AZ and FRU) amino-group, the suitability of DMPDH for their estimation was examined. The applicability of DMPDH in conjunction with various oxidants [CAT, Fe(III), IO_4^-, $Fe(CN)_6^{3-}$, $S_2O_8^{2-}$, $Cr_2O_7^{2-}$, OCl^-] for the determination of each of the diuretics was examined and the DMPDH–CAT combination was preferred because of the sensitivity obtained. The effect of DMPDH and CAT concentrations, buffer (pH 1–13, if any), temperature, time, and order of addition of reagents was examined, to find the conditions giving maximum sensitivity, minimum blank, extended obedience to Beer's law and good stability. To ascertain the optimum conditions for complete hydrolysis, each diuretic (except AML) was hydrolysed with different concentrations (2–10M) of sodium hydroxide and times (5–180 min) in a boiling water-bath. The optimum conditions were incorporated in the procedure.

The optical characteristics such as Beer's law limits and molar absorptivity are given for each drug in Table 1, together with the regression equations for the calibration plots. The precision and accuracy were found by analysis of six separate samples containing known amounts of each drug, and the results are also summarized in Table 1. The values obtained by the proposed and reference methods for pharmaceutical preparations are compared in Table 2, and are in good agreement. The results of recovery

experiments by the proposed method are also listed in Table 2.

Excipients such as lactose, starch, magnesium stearate and talc were found not to interfere in the analysis. Clonidine, hydrochloride, dihydrallazine sulphate and methyl dopa, which are co-formulated with HCT, also had no effect. The possible interference by reserpine, propranolol hydrochloride, spiranolactone and metoprolol tartrate in combined dosage forms was avoided by use of the preferential dissolution of the diuretic in a suitable solvent.

The method suggested has the advantages of being simple and sensitive, with reasonable precision and accuracy when compared to many of the reported methods and may be considered as a general method for the spectrophotometric determination of these diuretics in various pharmaceutical preparations.

Mechanism

The mechanism for formation of the coloured species was postulated by analogy.[11] DMPDH undergoes a 2-electron oxidation in the presence of CAT to yield the less stable highly reactive *p*-*N*,*N*-dimethylbenzoquinonedi-imine. This species reacts with amino-compounds under the chosen experimental conditions by electrophilic attack on the most nucleophilic site of the substrate (*i.e.*, the position *para* to the amino group, or the *o*-position if the *p*-position is blocked). The resulting leuco-dye is oxidized to the indo-dye. In the case of AML and the acetazolamide hydrolysate the reaction might proceed by expulsion of the electron-withdrawing grouping (–Cl in AML; $-SO_3H$ in AZ hydrolysate) in the *p*-position, as in the case of DMPDH and amines.[11] The scheme is given in Fig. 1.

Comparison of λ_{max} and ϵ_{max} for the coloured species formed (Table 1) shows that there is considerable variation in ϵ_{max} even though λ_{max} is the same (530–540 nm) in all cases except AML (660 nm). One of the two hydrolysis products from benzothiadiazines is substituted 2,4-disulphamoylaniline, and the other is either a simple aldehyde (HCHO from HCT and HFT, $CHCl_2CHO$ from TCM) or a substituted dialkyl sulphide ($HOOCCH_2SCH_2C_6H_5$ from BZT, $OHCCH_2SCH_2CF_3$ from PT). The higher ϵ_{max} values of the final coloured species from BZT and PT may be due to the formation of another chromophore, with a similar λ_{max}, from the substituted

dialkyl sulphide, besides the expected oxidative coupling product of the substituted 2,4-disulphamoylaniline and DMPDH, and also due to the presence or absence of electron-withdrawing or -donating groups, with consequent inductive mesomeric or steric effects. This is supported by our observation that the amino-acid methionine slowly gives a colour (λ_{max} 530–540 nm) when treated by the proposed method B, but gives the colour reaction immediately if subjected to alkaline hydrolysis first. This suggests that cleavage at the sulphur atom takes place to yield a reactive thiol. In the case of BZT we suggest that the hydrolysis can lead to $C_6H_5CH_2SH$ and $CH_2OHCOOH$. The higher ϵ_{max} value for the thiadiazine derivative (hydrolysate of AZ) suggests the influence of the sulphide group in its cyclic structure. Finally the need to reverse the order of addition of CAT and DMPDH for determination of the two types of diuretic [AML, which has two *meta*-amino groups in the pyrazine moiety, and the others, the hydrolysates of which contain one amino-group attached to either an aromatic (BZT, HCT, TCM, PT, HFT or FRU) or a thiadiazine (AZ) nucleus] suggests that AML reacts more rapidly than the others with DMPDH in presence of CAT because it contains two amino-groups *meta* to each other.

Résumé—L'extraction de l'oxyde d'éthylène est réalisée par circulation d'eau distillée en circuit fermé à 37°. Le temps de circulation, le volume d'eau circulant et le début sont préalablement déterminés en fonction des caractéristiques de l'appareil. L'extrait est dosé soit par chromatographie gaz–liquide (injection directe avec étalon interne: oxyde de propylène), soit par spectrophotométrie. Cette dernière méthode consiste à réaliser, avec et sans hydrolyse acide, dans deux prises d'essai d'un même extrait, l'oxydation periodique de l'éthylène glycol et le dosage par l'acide chromotropique du formaldéhyde produit. La différence de l'absorbance entre ces 2 prises d'essai permet de connaître la quantité réelle d'oxyde d'éthylène présente dans l'extrait. Une bonne corrélation des résultats est observée ($r = 0{,}98$). Le choix entre ces 2 méthodes simples dépend donc du nombre d'échantillons et de l'équipement du laboratoire. La méthode spectrométrique est la plus longue.

Summary—Ethylene oxide is extracted by circulation with distilled water in a closed circuit at 37°. The circulation time, volume and flow of the water are previously determined as a function of the apparatus characteristics. The extract is analysed either by gas–liquid chromatography (direct injection with propylene oxide as internal standard) or by spectrophotometry. The latter method consists in the periodate oxidation of ethylene glycol in two samples of the same extract, with and without acid hydrolysis, followed by determination of formaldehyde with chromotropic acid. The difference between the absorbances of the two samples gives the quantity of ethylene oxide in the extract. A reasonable correlation of the two sets of results is observed, and the choice between these two simple methods depends on the number of samples to be analysed and on the equipment available. The spectrophotometric method is the longer of the two.

Grâce à ses puissantes propriétés biocides et sa grande diffusibilité dans les matériaux plastiques ou les élastomères, l'oxyde d'éthylène occupe une place importante dans la stérilisation du matériel médico-chirurgical. Cependant, la rémanence de résidus de ce gaz dans les matériels stérilisés est l'un des inconvénients majeurs de son utilisation en raison de divers effets toxiques.[1–9]

Ceci explique la nécessité du dosage de l'oxyde d'éthylène résiduel; la Pharmacopée Française a déterminé à la fois une méthode d'analyse et une limite tolérable.[10] La technique utilisée consiste en une extraction du gaz dans le matériel par entrainement à la vapeur d'eau. En effet, l'ouverture du cycle oxiranne par l'eau pure est lente et il est donc possible d'opérer un entrainement du produit en l'état. En revanche l'hydrolyse est rapide en milieu acide et conduit à l'éthylène glycol. Contrairement à l'oxyde d'éthylène, ce glycol est rapidement oxydé par l'acide periodique en conduisant à la formation de deux molécules de formaldéhyde. Le dosage spectrophotométrique de celui-ci est réalisé après réaction avec l'acide chromotropique.

De nombreuses autres techniques de dosage ont été proposées depuis.[11–21] La plupart des auteurs[12,13,15–17,19,21] ont utilisé la chromatographie gaz–liquide pour doser l'oxyde d'éthylène résiduel, après extraction par des solvants appropriés. La technique la plus employée est celle utilisant l'espace de tête. Cependant cette détermination présente un certain nombre de difficultés dans le cas de matériels de taille et de masse importantes tels que les oxygénateurs ou les appareils de circulation extracorporelle (CEC). Le poids de l'oxygénateur seul dépasse déjà souvent 1 kg et celui du circuit complet (CEC) est de l'ordre de 4 à 5 kg. C'est la raison pour laquelle nous avons été amenés à étudier une méthode dynamique de dosage dans ces types d'appareils.[22]

Nous rappelons qu'ils sont destinés à remplacer provisoirement les fonctions pulmonaire et cardiaque permettant ainsi une exclusion du cœur de plusieurs heures pendant une intervention chirurgicale.

Un circuit extracorporel complet est constitué par le matériel à usage unique suivant: un oxygénateur à bulles ou à membrane, un réservoir pour le sang, un filtre de perfusion, un filtre à gaz, éventuellement un filtre artériel, des tubulures, des connecteurs. Tous ces matériaux sont constitués de diverses matières plastiques (polycarbonate, polypropylène, polyuréthanne, polyester etc...). La circulation du sang dans ce système est assurée par une ou plusieurs pompe à galets.

PARTIE EXPERIMENTALE

Extraction

Matériels. Pompe à galets (Travenol). Etuve thermostatée. Tubulure en silicone (environ 2 m).

Conditions opératoires. L'extraction de l'oxyde d'éthylène est réalisée par circulation d'eau distillée en circuit fermé, à 37°. Le temps de circulation, le volume d'eau circulant et le débit ont été préalablement déterminés en fonction des caractéristiques de l'appareil et correspondent aux données suivantes:

—volume d'eau:
  oxygénateur pour adulte 3000 ml
  oxygénateur pour enfant 1500 ml
  ensemble du CEC pour adulte 5000 ml
—température de l'étuve: 37 ± 1°
—temps de circulation: 1, 3 ou 6 hr
—débit d'eau: 3 l./min

Procédé

Cas de l'oxygénateur. L'appareil rempli d'eau distillée est mis dans une étuve à 37°; les tuyaux d'entrée et de sortie sont reliés à une pompe à galets située à l'extérieur.

Cas du circuit extracorporel complet (CEC). Seuls l'oxygénateur et une partie des tuyaux de connection sont placés dans l'étuve; le filtre et le reste des tuyaux de connection restent à l'extérieur de l'étuve. L'eau distillée est versée dans l'oxygénateur. Tout le système est relié à une pompe à galets.

La circulation de l'eau dans les deux cas est réalisée en circuit fermé total pour éviter toute perte par volatilisation. Après 1, 3 ou 6 hr de circulation, une portion aliquote de liquide de circulation (20 ml) est prélevée pour le dosage qui doit être réalisé immédiatement.

Méthode chromatographique

Appareillage. Chromatographe GIRDEL Modèle 300 équipé d'un détecteur à ionisation de flamme. Colonne en acier inoxydable de 2 m × 1/8 pouce remplie de Carbopack C (80–100 mesh) + 0,8% THEED (tétrahydroxy éthyl éthylène diamine) (Supelco). La colonne doit être conditionnée d'abord à la température ambiante pendant une demi-heure avec l'azote (20 ml/min), puis chauffée progressivement à 120° toujours sous azote pendant une nuit.

Conditions chromatographiques. Température du four 80°, température de l'injecteur et du détecteur 120°. Débit d'azote 20 ml/min. Débit d'hydrogène 25 ml/min. Débit d'air 350 ml/min. Volume d'injection 5 μl.

Réactifs. Oxyde d'éthylène pur, Merck (O.E.). Oxyde de propylène pur, Baker (O.P.).

Prélèvement du gaz pur. Plusieurs méthodes ont été proposées[12,13,15,21,23] pour prélever l'oxyde d'éthylène pur; pour notre part, nous utilisons la technique suivante, modification de celle de Romano.[21]

L'opération doit se dérouler sous hotte bien ventilée à l'abri de toute flamme, car l'oxyde d'éthylène est un gaz très toxique et inflammable. Dans un flacon de 10 ml fermé par un bouchon à vis garni d'un septum en téflon, introduire à travers le septum deux aiguilles, l'une jusqu'au fond du flacon, l'autre près du septum. Relier la première aiguille au manodétendeur de la bouteille d'oxyde d'éthylène par un tuyau en téflon et l'autre aiguille de sortie par un autre tuyau plongé dans un bécher d'eau. Ouvrir la bouteille d'oxyde d'éthylène et purger l'air du flacon avec un débit de une bulle par seconde environ. Au bout de 12 min, retirer d'abord l'aiguille d'entrée, puis immédiatement après l'aiguille de sortie. La pression de l'oxyde d'éthylène dans le flacon est égale à celle de l'atmosphere.

Préparations des solutions étalon d'oxyde d'éthylène. Avec une seringue à gaz de précision de 250 μl, mesurer exactement 103 μl (200 μg) d'oxyde d'éthylène pur contenu dans le flacon précédent et l'injecter immédiatement dans un autre flacon étanche, de même type, contenant exactement 10 ml d'eau distillée. Par dilution, préparer des solutions à 2,5, 5 et 10 μg d'oxyde d'éthylène par ml d'eau. Les solutions aqueuses d'oxyde d'éthylène sont réparties par petites portions de 2 ml dans des petits tubes bouchés émeri, puis, soit réfrigérées à 4°, soit congelées à −20°. Les solutions réfrigérées doivent être utilisées dans un délai de 2 à 3 jours. Les tubes congelés peuvent être gardés plus longtemps, mais il faut les décongeler à 4° avant usage.

Préparation de la solution interne. Préparer une solution aqueuse d'oxyde de propylène à 0,2 μl/ml en dissolvant 100 μl d'oxyde de propylène liquide pur dans une fiole jaugée de 500 ml d'eau distillée. La conservation de cette solution est identique à la précédente.

Dosage. Le dosage est réalisé par injection de 5 μl du mélange de 50 μl de solution d'étalon interne et de 1 ml de solution d'oxyde d'éthylène (étalon et essai).

Méthode colorimétrique

Cette méthode est inspirée de la méthode du dosage de l'oxyde d'éthylène de la Pharmacopée Française,[10] mais n'utilise pas l'entrainement à la vapeur d'eau et comporte un dosage par différence. En effet l'échantillon aqueux à doser contient en général une certaine quantité d'éthylène glycol provenant de l'hydrolyse de l'oxyde d'éthylène au cours de la stérilisation, généralement réalisée en présence de vapeur d'eau.

Le principe de cette méthode consiste à hydrolyser quantitativement l'oxyde d'éthylène en éthylène glycol en milieu acide et à chaud. L'oxydation periodique de ce diol conduit au formaldéhyde qui donne avec l'acide chromotropique un dérivé violet rose qui est dosé par spectrophotométrie à 570 nm. Pour éviter l'interférence de l'éthylène glycol initialement présent dans l'échantillon, un dosage sans hydrolyse acide d'une autre prise d'essai d'échantillon est réalisé parallèlement. La valeur ainsi trouvée est soustraite de la précédente. Une courbe d'étalonnage est réalisée avec des solutions étalons d'éthylène glycol dans les mêmes conditions opératoires.

Matériel. Spectrophotomètre Gilford Star III à lecture digitale.

Réactifs. Solution d'acide sulfurique 0,5*M*: solution de soude 0,5*M*; solution aqueuse de periodate de sodium 0,1*M*; solution aqueuse de sulfite de sodium à 11%; solution d'acide chromotropique (préparée extemporanément en dissolvant 100 mg de chromotropate disodique dans 2 ml d'eau distillée, puis dans 50 ml d'acide sulfurique pur); solution mère d'éthylène glycol correspondant à 1 g d'oxyde d'éthylène (préparée avec 1,40 g d'éthylène glycol dans 1000 ml d'eau distillée); solution fille correspondant à 10 μg/ml d'oxyde d'éthylène, obtenue par dilution de la solution mère au 1/100 avec de l'eau distillée (elle doit être renouvelée tous les 2 jours).

Dosage de l'échantillon. Dans un erlenmeyer de 200 ml bouché émeri, introduire 5 ml du liquide d'extraction, 70 ml d'eau distillée et 1 ml d'acide sulfurique 0,5*M*. Porter au bain marie pendant 1 hr. Neutraliser ensuite avec 1 ml de solution d'hydroxyde de sodium 0,5*M*. Transvaser tout le liquide dans une fiole jaugée "E" de 100 ml en rinçant l'erlenmeyer deux fois avec environ 5 ml d'eau distillée. Faire parallèlement un témoin avec 5 ml de liquide

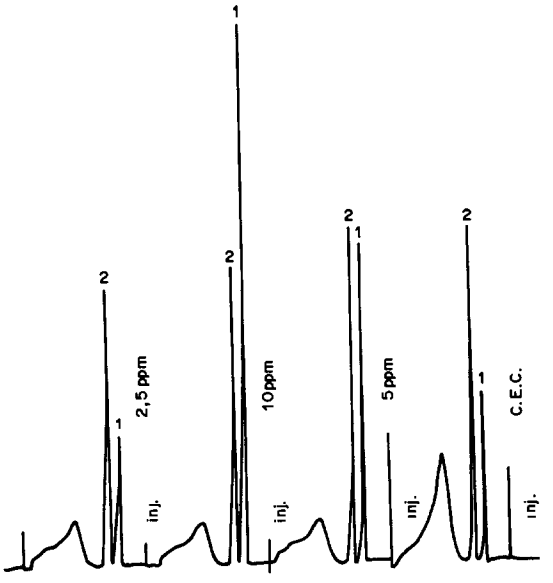

Fig. 1. Chromatogramme de l'oxyde d'éthylène (1, $t_R = 0{,}8$ min) en présence d'étalon interne: oxyde de propylène (2, $t_R = 1$ min).

d'extraction et 70 ml d'eau distillée dans une autre fiole "T" de 100 ml. Ajouter dans les deux fioles jaugées "E" et "T", 2 ml de periodate de sodium 0,1*M*. Laisser en contact 15 min en agitant fréquemment, ajouter ensuite 2 ml de sulfite de sodium à 11%. Compléter au volume avec de l'eau distillée.

Dans deux tubes gradués de 10 ml bouchés émeri, introduire respectivement 5 ml des solutions "E" et "T" précédentes, puis ajouter lentement 5 ml d'une solution d'acide chromotropique récemment préparée. Mélanger et porter les tubes au bain marie bouillant pendant 10 min. Refroidir à la température ambiante et compléter avec de l'acide sulfurique à 50%. Mesurer l'absorbance *A* des solutions "E" et "T" à 570 nm, dans une cuve de 1 cm en réglant le zéro du spectrophotomètre avec le blanc réactif. La teneur en oxyde d'éthylène de l'échantillon est obtenue par différence des valeurs trouvées pour les essais "E" et "T".

Faire parallèlement un étalonnage avec 0, 1, 2, 3, 4, 5 ml de solution fille d'éthylène glycol, réalisé dans les mêmes conditions opératoires que dans le témoin "T".

RESULTATS

La comparaison des méthodes chromatographiques et colorimétrique de dosage de l'oxyde d'éthylène a été réalisée sur:

—27 oxygénateurs, modèle adulte, avec 45 prélèvements correspondants à des temps d'extraction différents.

—18 oxygénateurs, modèle enfant avec 18 prélèvements après 3 hr d'extraction.

—18 circuits extracorporels modèle adulte, avec 34 prélèvements différents.

Dans le tableau 1, les taux d'oxyde d'éthylène résiduel ont été exprimés en μg/ml de liquide d'extraction et en mg total (ce chiffre représente la quantité totale d'oxyde d'éthylène contenue dans la totalité du liquide d'extraction).

DISCUSSION

Technique de dosage

Exactitude. D'après le tableau 1 ($n = 97$ analyses), ces résultats montrent une bonne corrélation (Fig. 2) entre les resultats des dosages chromatographique (y) et colorimétrique (x) en se fondant sur la droite de régression (méthode des moindres carrés) calculée suivant l'équation:

$$Y = 0{,}98X - 0{,}17$$

Le coefficient de corrélation r est de 0,98.

Reproductibilité. La déviation standard relative de la méthode chromatographique pour $n = 5$ est de 2,5% pour l'étalon 5 ppm et de 3,5% pour l'étalon 10 ppm. Celle de la méthode colorimétrique pour $n = 5$ est de 3,1% pour l'étalon 30 μg et de 3,8% pour l'étalon 50 μg.

Sensibilité. La limite de sensibilité de la méthode chromatographique est de 0,2 ppm, celle de la méthode colorimétrique est de 0,1 ppm.

Linéarité. La réponse chromatographique est linéaire de 0,5 ppm à 10 ppm d'oxyde d'éthylène, et la réponse colorimétrique de 0,5 μg à 2,5 μg d'oxyde d'éthylène.

Justification des conditions opératoires

Méthode chromatographique. L'usage de la phase Carbopack C + 0,8% THEED et de l'étalon interne oxyde de propylène, permet un dosage rapide de l'oxyde d'éthylène, car le temps de rétention de l'oxyde d'éthylène est de 0,8 min et celui de l'oxyde de propylène est de 1 min. En plus, cette phase permet une bonne séparation de ces deux pics et un dosage

Tableau 1. Comparaison des teneurs moyennes en oxyde d'éthylène trouvées par colorimétrie et par chromatographie

Nature du matériel	Nombre de matériels essayés	Nombre de prélèvements	Teneur moyenne en oxyde d'éthylène obtenue par: Colorimétrie $\mu g/ml$	Colorimétrie *mg* (total)	Chromatographie $\mu g/ml$	Chromatographie *mg* (total)
Oxygénateur modèle adulte	25	45	1,48	4,41	1,38	4,15
Oxygénateur modèle enfant	18	18	3,24	4,86	3,15	4,70
C.E.C. modèle, adulte	18	34	4,22	14,20	4,16	14,00

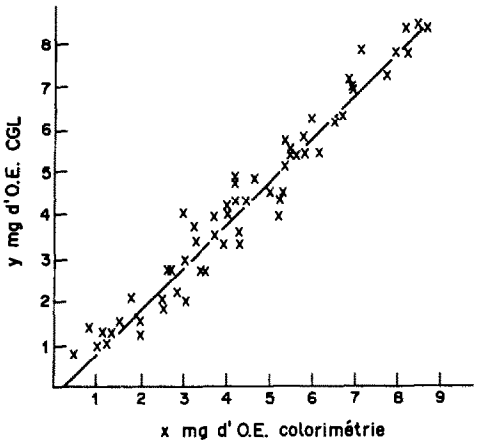

Fig. 2. Droite de corrélation entre les résultats obtenus par colorimétrie et par CGL ($y = 0{,}98x - 0{,}17$; $r = 0{,}98$).

simultané de l'éthylène glycol et du chloro-2 éthanol en élevant la température du four à 100°.[24,25] Cependant, il est important d'éviter tout contact de cette phase stationnaire avec l'oxygène de l'air et toute élévation de température dépassant 120° pour garder longtemps l'efficacité de la colonne. Cette méthode par injection directe est une technique très simple, rapide et sensible, car elle ne demande aucune extraction préalable. De plus, l'emploi de l'eau distillée comme solvant d'extraction permet d'éviter tout pic de solvant génant.

Méthode colorimétrique. Elle est de réalisation simple mais relativement longue. Elle évite les interférences dues à l'éthylène glycol ou au glycérol présent éventuellement dans les matériels. Pour vérifier l'absence des substances susceptibles d'interférer dans ce dosage, un essai direct de l'échantillon à doser avec l'acide chromotropique a été réalisé suivant une technique déjà publiée par l'un de nous.[18] Cet essai n'a montré aucune interférence. Pour vérifier la très faible transformation en éthylène glycol à 37° dans une solution aqueuse en fonction du temps, un témoin à 5 ppm d'oxyde d'éthylène dans l'eau a été dosé par chromatographie en fonction du temps.

Le tableau 2 montre que l'hydrolyse de l'oxyde d'éthylène dans l'eau distillée à 37° est pratiquement négligeable jusqu'à 6 hr.

Pour obtenir une bonne linéarité de la courbe d'étalonnage et une bonne reproductibilité des résultats de la méthode colorimétrique, il est important d'opérer avec de l'eau distillée (et non de l'eau déminéralisée par des résines échangeuses d'ions) et des réactifs de haute pureté, de respecter rigoureusement les conditions opératoires et d'utiliser un spectrophotomètre à lecture digitale de précision.

La méthode colorimétrique permet également de contrôler la teneur en oxyde d'éthylène dans les étalons aqueux pour la méthode chromatographique. Le coefficient de variation entre la valeur théorique de 10 ppm et celles obtenues par colorimétrie est de 1 à 5%.

Techniques d'extraction

En ce qui concerne la technique d'extraction, nous proposons une méthode dynamique pour des raisons suivantes.

—La méthode dynamique simule d'une manière assez proche les conditions opératoires d'une circulation sanguine extracorporelle. Les paramètres température (35–37°), débit (3 l./min), volume d'eau (3 l. pour l'oxygénateur adulte, 5 l. pour le circuit extracorporel) et durée (3 et 6 hr), correspondent à des conditions fréquemment rencontrées dans une circulation extracorporelle. La durée de 6 hr que nous proposons laisse une marge de sécurité, car une intervention chirurgicale dépasse rarement 3 hr. En réalité entre 3 et 6 hr, la libération de l'oxyde d'éthylène dans l'extrait devient plus lente; elle est plus importante entre 1 et 3 hr. En choisissant ces paramètres, nous pensons nous approcher le plus possible des conditions réelles de la circulation extracorporelle.

—Les méthodes classiques ou "statiques" telles que la méthode de la Pharmacopée Française, la méthode chromatographique gaz–liquide (CGL) avec platine de désorption[16] ou les méthodes d'extraction par espace de tête suivies d'une CGL ne sont applicables que pour les matériels de petit volume et de nature assez homogène. Elles ne sont pas réalisables dans le cas des matériels encombrants, de poids dépassant 1 kg et surtout constitués par des matériaux très divers. Ces méthodes classiques permettent d'extraire tout l'oxyde d'éthylène contenu dans l'échantillon, même si une partie du matériel n'est ni en contact avec le sang, ni avec les tissus.

Pour des matériels de petite taille dont les parois sont minces il est en effet utile de déterminer la teneur totale correspondant au risque potentiel de contaminant. Il n'en est plus de même pour les matériels étudiés dans ce mémoire, pour lesquels la partie la plus importante en masse correspond à des parois épaisses, dont la surface d'échange avec le sang (ou le liquide d'extraction) est très nettement inférieure à celle de la mousse de polyuréthane, qui ne représente pourtant qu'un dixième de la masse totale.

Par ailleurs, la libération de l'oxyde d'éthylène dépend largement de la température et de la durée de l'extraction. Klein[26] a montré que des raccords en polycarbonate placés en milieu aqueux à 37° pendant 6, 24 et 48 hr libèrent moins d'oxyde d'éthylène que ceux maintenus à 60° pendant le même temps. Par chauffage à ébullition, ou par désorption avec le

Tableau 2. Hydrolyse de l'oxyde d'éthylène en fonction du temps en solution aqueuse

Temps, *hr*	Oxyde d'éthylène, %	Ethylène glycol, %
0	100	0
1	99,3	0,7
3	98,8	1,2
6	98,5	1,5
24	96	4,0

platine[16] le polycarbonate libère facilement non seulement l'oxyde d'éthylène libre absorbé et dissous, mais aussi une grande partie de ce gaz qui semble combiné selon une réaction chimique réversible[13,19,27] et ne peut pas être libéré à la température d'utilisation.

D'autre part, l'expression en concentration (ppm) préconisée par la Pharmacopée Française, si elle permet une appréciation convenable des risques dans le cas des matériels de faible masse, ne permet pas d'en rendre compte d'une manière satisfaisante pour des appareillages de taille importante. Ainsi la même teneur de 2 ppm d'oxyde d'éthylène correspond à 2 μg dans un cathéter de 1 g et 10 mg dans un circuit extracorporel de 5 kg, c'est à dire 5000 fois plus. Il nous parait donc logique d'envisager une expression en masse totale d'oxyde d'éthylène extrait dans un volume de liquide utilisé comme certains organismes l'ont déjà proposé.[11]

CONCLUSION

En conclusion, la méthode dynamique que nous avons proposée permet de réaliser un dosage des résidus d'oxyde d'éthylène dans des conditions proches de l'utilisation clinique de l'oxygénateur et du circuit extracorporel et parait mieux refléter le risque toxicologique encouru par le patient. La détermination de ces résidus d'oxyde d'éthylène soit par colorimétrie soit par chromatographie gaz liquide est de réalisation simple et peut être facilement éxécutée dans tous les laboratoires.

(*Received* 18 *May* 1988. *Revised* 24 *October* 1988. *Accepted* 7 *November* 1988)

Summary—Adsorptive stripping voltammetry is used for the determination of trace levels of nifedipine. The conditions for preconcentration on the mercury drop electrode have been studied and the final measurements are made by differential pulse voltammetry. The response is linear from 2×10^{-9} to $1 \times 10^{-7}M$ and can be extended to $10^{-6}M$ by a change in conditions. The stripping peak has been used for determination of the drug in formulations, with a relative standard deviation of 0.8%. The method is applicable to the determination of nifedipine in blood-serum with a detection limit of 4.1 ng/ml.

Nifedipine [dimethyl 1,4-dihydro-2,6-dimethyl-4-(2-nitrophenyl)-3,5-pyridinedicarboxylate] is a calcium antagonist used in the prophylaxis of angina pectoris, the treatment of arterial hypertension, and especially of coronary artery disease. As it is very active, its therapeutic and toxic effects require very sensitive methods for determination of trace levels.

Various analytical methods have been employed for this purpose: gas chromatography with a nitrogen detector [detection limit (d.l.) 0.5 ng/ml in plasma][1] or with flame thermionic detection (d.l. 10 ng/ml in plasma);[2] HPLC with spectrophotometric detection (d.l. 10 ng/ml in serum)[3] or with electrochemical detection (d.l. 1 ng/ml in plasma).[4]

In this study low concentrations of nifedipine are determined by adsorptive stripping voltammetry. The analyte is preconcentrated by adsorption on the surface of the electrode and the surface-active species is then determined by a voltammetric scan method. Adsorptive stripping voltammetry has been shown to be a sensitive analytical method for a wide range of pharmaceutical compounds that can be adsorbed on the electrode surface,[5–7] and its applications have recently been reviewed by Wang.[8]

As the present study shows, submicromolar levels of nifedipine can be measured by this technique. As specific applications, the drug has been determined in human serum and in formulations.

EXPERIMENTAL

Apparatus

A Metrohm Polarecord coupled with a Metrohm 663 VA Stand was used. A multimode mercury drop electrode (Metrohm MME) which has a hanging mercury drop electrode (HMDE) served as the working electrode. The three-electrode system was completed by an SCE reference electrode and a platinum auxiliary electrode. A Metrohm VA 612 scanner and a fast X–Y recorder, Linseis LY 1800, were used to obtain the cyclic voltamperograms. All measurements were made at room temperature.

Reagents

Stock solutions ($1 \times 10^{-3}M$) of nifedipine (Sigma) were prepared daily by dissolution in demineralized water. The supporting electrolyte was Britton–Robinson buffer at an ionic strength of $0.25M$ ($NaClO_4$, pH 4.4). Human serum samples from five subjects were pooled.

Procedures

Adsorptive stripping voltammetry. The supporting electrolyte solution (20 ml) was added to the cell and deaerated by passage of nitrogen for 10 min. The preconcentration potential (usually −0.20 V *vs.* SCE) was applied to the electrode for a given time period, while the solution was stirred at 1500 rpm. After a 15-sec rest period, a negative-going scan was initiated, the resulting voltamperograms being recorded for different combinations of operational parameters.

Nifedipine assay in serum. A Waters Sep-Pak C_{18} extraction cartridge was wetted with 4 ml of methanol and 6 ml of water. For the nifedipine extraction, 1 ml of human serum was then passed through the cartridge, the drug being adsorbed on the Sep-Pak matrix. The matrix was rinsed with 5 ml of Britton–Robinson buffer and 4 ml of acetone–water (1:5 v/v). The nifedipine was eluted with 2 ml of acetone. The effluent was evaporated to dryness under a stream of nitrogen. The residue was dissolved in 20 μl of acetone and diluted to 20 ml with Britton–Robinson buffer (pH 4.4). The voltamperograms were recorded under the optimum instrumental conditions.

Nifedipine assay in formulations. The nifedipine content of a commercial capsule is transferred quantitatively into a 100-ml standard flask and diluted to volume with acetone. A 20 μl aliquot of this solution is diluted to 20 ml with Britton–Robinson buffer and transferred into the polarographic cell. The voltamperograms are recorded under the optimum instrumental conditions.

RESULTS AND DISCUSSION

The study by cyclic voltammetry confirms that nifedipine is spontaneously accumulated on the hanging mercury drop electrode, from the stirred solution, in 60 sec. Figure 1a shows the cyclic voltamperogram of a $1 \times 10^{-6}M$ solution of nifedipine at pH 4.4. A large well defined cathodic peak

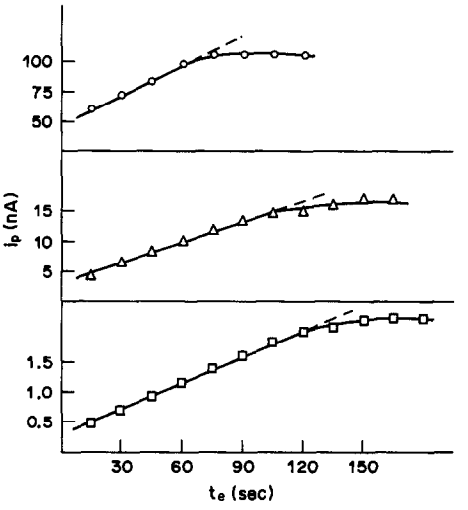

Fig. 3. Effect of preconcentration time on the stripping voltamperogram; ○, $10^{-6}M$; △ $10^{-7}M$; □, $10^{-8}M$ nifedipine. Scan-rate 8.3 mV/sec. Britton–Robinson buffer (pH 4.4) $0.25M$ in $NaClO_4$.

can be seen at −0.52 V, which in successive scans is markedly diminished, indicating rapid desorption from the electrode surface. Voltamperogram b in Fig. 1 shows the same pattern, but without use of a previous accumulation; the peak is much smaller than that obtained after accumulation. The largest wave is due to reduction of the nitro group to a hydroxylamine group and is electrochemically irreversible. This reduction process involves four electrons.[9]

Confirmation that we are dealing with an adsorption process on the electrode surface can be obtained by plotting log i_p *vs.* log (scan-rate). A slope of 1.0 would indicate adsorption. Figure 2 shows that a straight line with slope 0.8384 and correlation coefficient 0.9998 is obtained. Figure 2 also shows that the peak potential shifts when the scan-rate is increased.

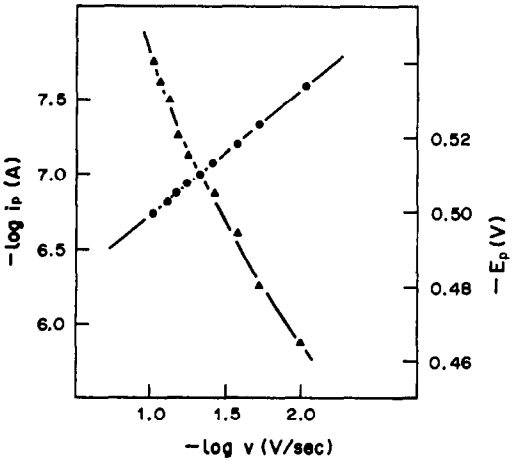

Fig. 2. Dependence of the logarithm of the peak current (●) and peak potential (△) on the logarithm of the potential scan-rate. Nifedipine concentration: $10^{-6}M$.

The spontaneous adsorption of nifedipine can be used for its voltammetric determination. In Fig. 3 the variation of peak current with preconcentration time is shown for 10^{-6}, 10^{-7} and $10^{-8}M$ nifedipine solutions. There is a linear relation up to 120 sec (slope 0.015 nA/sec) for $10^{-8}M$ nifedipine, 105 sec (slope 0.113 nA/sec) for $10^{-7}M$ and 60 sec (slope 1.064 nA/sec) for $10^{-6}M$. Thus the choice of optimum accumulation time depends on the range of concentration studied.

The influence of the accumulation potential on the peak stripping current is shown in Fig. 4. The current is maximal for stripping at −0.20 V.

The pH also affects the stripping current. Figure 5 shows that the optimum value is pH 4.4 (Britton–Robinson buffer) at an ionic strength of $0.25M$ ($NaClO_4$). The peak potential is displaced from −0.26 to −0.68 V with the rise in pH.

Various instrumental parameters directly affect the voltammetric response, and above all the shape and resolution, of the waves. Thus the peak current is linearly related to the pulse amplitude, between 20

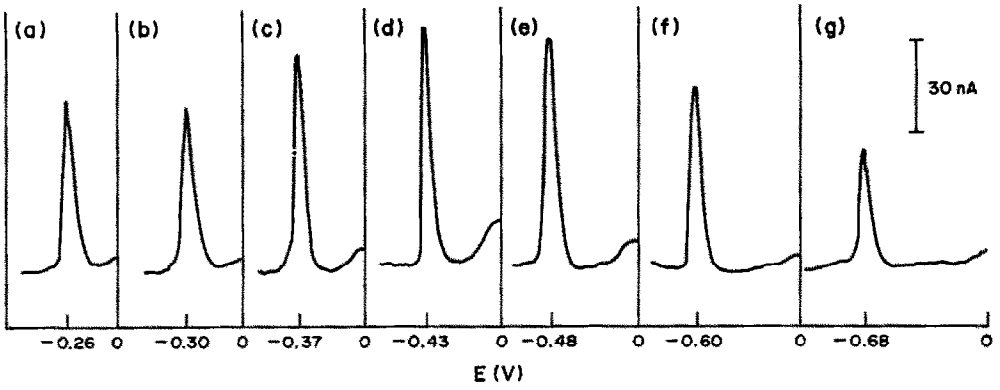

Fig. 5. Influence of pH on the voltamperogram peak current. Britton–Robinson buffer, 0.25M in $NaClO_4$. Nifedipine concentration $5 \times 10^{-8}M$. pH: a 1.48; b, 2.10; c, 3.05; d, 4.44; e, 5.60; f, 7.83; g, 9.70.

and 100 mV. A value of 70 mV was chosen as optimal for this variable, however, since there is a loss of resolution at higher values, as a result of excessive peak-broadening.

The peak current varies linearly with the area of the drop, between 0.25 and 0.52 mm^2; the latter value was chosen as the optimum. Increase in stirring speed during the accumulation has hardly any influence on the peak current. Tests were made at 500–3000 rpm, and 1500 rpm was chosen as giving the best results.

The determination is done on the basis of the linear dependence of the peak current on the nifedipine concentration. The calibration graph was linear from 2×10^{-9} to $10^{-7}M$ nifedipine, for 120 sec preconcentration, but the range can be extended to $10^{-6}M$ by use of preconcentration for 60 sec. The detection limit under the optimum instrumental conditions was estimated as $4 \times 10^{-10}M$.

The reproducibility of the method was determined by successive measurements on ten $10^{-8}M$ nifedipine solutions. The average peak current was 1.59 nA (range 1.45–1.77 nA) and the relative standard deviation (rsd) was 5.4%. Relative standard deviations of 1.9 and 0.9% were obtained for 10^{-7} and 10^{-6} M nifedipine, with preconcentration times of 90 and 60 sec, respectively.

The presence of other surface-active compounds which might affect the response was investigated, particularly those which might be present in biological samples. The effects of chloride, albumin and gelatin were studied with a $5 \times 10^{-7}M$ nifedipine solution. The addition of 2 ppm of albumin and 2 ppm of gelatin gives rise to a nifedipine peak depression of 47.1 and 56.6% respectively. The peak disappears completely in presence of 7 ppm of gelatine and 8 ppm of albumin. The addition of up to 450 ppm of chloride has no effect on the adsorption of nifedipine.

Application to determination of nifedipine in human serum

This determination is practicable by the proposed method and the standard additions method. The detection limit has been estimated as 4.1 ng/ml according to Caulcutt and Boddy,[10] with a mean recovery of 83% from spiked serum samples. This is much better than the 43% recovery reported for an extraction system,[11] and a correction can be applied for the loss.

For some types of serum it is necessary to change the preconcentration conditions in order to avoid the interferences previously mentioned. Good results have been obtained for cases in which there is near-disappearance of the wave under standard conditions, by changing the electro-deposition potential to −0.0 V, and/or reducing the accumulation time to 15 sec.

Application to analysis of formulations

A capsule containing 10 mg of nifedipine was taken and treated as described. The standard addition method was used, with a preconcentration time of 60 sec. The concentration found for the test solution was $2.92 \times 10^{-7}M$, which corresponded to 10.1 mg of nifedipine in the original capsule. Analysis of five different capsules gave a mean content of 10.1 mg, with a relative standard deviation of 0.8%, which indicates that the precision is adequate for quality control.

It can be concluded that the determination of nifedipine in human serum and formulations is practicable by adsorptive stripping voltammetry at the hanging mercury drop electrode. To avoid some interferences in serum analysis a solid–liquid extraction method with Sep-Pak C_{18} cartridges is necessary. To avoid certain other interferences a slight change in the analysis conditions is necessary.

(*Received* 6 *April* 1988. *Revised* 6 *September* 1988. *Accepted* 7 *November* 1988)

Summary—A new chemiluminescence system is described for selective determination of sulphide by a flow-injection method. The weak light emitted from the reaction between 7,7,8,8-tetracyanoquinodimethane and sulphide is efficiently sensitized by Rhodamine B in alkaline solution containing dioctadecyldimethylammonium chloride bilayer membrane aggregates and acetonitrile. The limit of determination is 0.05 ng (injection of 30 μl of $5 \times 10^{-8} M$ sulphide), the linear range is two orders of magnitude, the sampling rate is 240/hr, and the relative standard deviation is 3.0% for 0.3 ng of sulphide. Manganese(II), the strongest enhancing species after sulphide ion, provides a signal 1.1% of that for sulphide ion. Manganese(II), iron(II), and species forming precipitates with sulphide ion interfere, but other sulphur anions such as sulphite, sulphate, thiosulphate, and thiocyanate do not.

Determination of sulphide is very important in many connections. Sulphide has a wide variety of effects even at low concentrations,[1] including the corrosion of metal surfaces, degradation of concrete when oxidized to sulphate, and high toxicity (as hydrogen sulphide).

Various methods are available for its determination.[2] The gravimetric and iodometric methods are still widely used, but interference by other anionic sulphur species is often a problem. The *o*-hydroxymercuribenzoic acid method has the special advantage that sulphite and thiosulphate do not interfere, but a non-interfering indicator has to be used. The spectrophotometric method recommended as standard for trace amounts of sulphide requires strict control of conditions for reproducible results to be obtained. Molecular emission cavity analysis is also an excellent method, but its application is limited by the need for a special instrument.

In recent years, chemiluminescence (CL) methods have become increasingly important for analytical purposes, and use of the flow-injection technique makes CL methods more attractive.[3] Luminescent oxidative reactions with hypobromite[4] and hydrogen peroxide[5] have been reported for the determination of sulphide; the methods are very sensitive (detection limits 10^{-9}–$10^{-8} M$), but subject to interference from other sulphur anions. However, the utilization of organized surfactant assemblies as a CL reaction medium is currently of interest for improving analytical CL characteristics[6–9] and developing new CL reaction systems.[10–14] Its advantages stem from the possibility of enhancing the CL quantum efficiency or energy-transfer efficiency, of using of CL reagents and sensitizers that are insoluble in water, and of improving selectivity.

The aim of this work was to develop a new CL system for selective determination of sulphide by the flow-injection technique, free from interference by other sulphur anions. The results strongly suggest that the choice of reaction medium is critical for increasing the CL quantum efficiency. The present method is based on the measurement of CL arising from the reaction of 7,7,8,8-tetracyanoquinodimethane (TCNQ) with sulphide, the CL system being reinforced by use of organized surfactant assemblies and a sensitizer, in order to increase the light emission.

EXPERIMENTAL

Apparatus

A schematic diagram of the flow system is shown in Fig. 1. Reagent solutions (R_1 and R_2) are supplied by a dual-channel peristaltic pump (P) through two flow-lines; R_1 is the TCNQ solution, with a sensitizer and/or organic solvent added as required, and R_2 is an alkali or alkaline surfactant solution. A heating bath, in which the 1-m coils (M) are immersed, is placed as needed before a confluence of the two streams. Sample solution is injected by a 30-μl loop valve injector (S) that is placed as close as possible to the detection flow cell (D) to prevent loss of the emitted light, because the CL reaction used is fairly fast. Teflon tubing (1-mm i.d.) is used for the flow lines, except the pump tubes and detection flow-cell. The light emitted is detected by a photomultiplier tube (R453, Hamamatsu Photonics), placed opposite the spiral flow-cell made of a thin poly(vinyl chloride) tube as described by Nakahara *et al.*[15] The peak height of the CL signal was mostly measured.

Reagents

All chemicals were of analytical-reagent grade and used as received. Distilled and demineralized water was used throughout. Surfactant solutions were prepared by dissolving an appropriate amount of surfactant (a little more than needed to give the critical micelle concentration) by ultrasonic treatment. TCNQ surfactant and TCNQ acetonitrile solutions were prepared freshly. Standard sulphide solution was prepared from sodium sulphide and standardized by iodometry as needed.

RESULTS AND DISCUSSION

Reaction medium

The light emission comes basically from the reaction between TCNQ and sulphide in alkaline solution. However, its intensity is too weak for practical use. In such a case, modification of the reaction medium may be an effective means of enhancing the light emission. It is known that CL reactions can often be greatly accelerated in solutions containing organized surfactant assemblies[6-14] and/or an organic solvent.[10,16] In fact, several CL systems have been developed with the aid of such reaction media.[10-14] Thus surfactants and/or organic solvents were examined for use with the present CL system. First, the effect of cationic surfactant assemblies was explored by dissolving TCNQ in didodecyldimethylammonium bromide (DDAB) (*i.e.*, $1 \times 10^{-4}M$ TCNQ/$1 \times 10^{-3}M$ DDAB was used as R_1 and $1 \times 10^{-2}M$ sodium hydroxide as R_2). DDAB, one of the dialkyl type of surfactants, forms bilayer membrane assemblies (lamellae or vesicles)[17] in aqueous solution that are more organized and rigid aggregates than the micelles which monoalkyl type surfactants form. In a previous work, DDAB vesicular solution had been found to be an excellent reaction medium in another TCNQ CL system, for Mn(II) determination.[12] In the present work, however, only a low signal was obtained for the injection of $3 \times 10^{-3}M$ sulphide; no signal was observed when other cationic surfactant assemblies, such as dodecyltrimethylammonium bromide (DTAB), hexadecyltrimethylammonium chloride (HTAC), octadecyltrimethylammonium chloride (OTAC) and dioctadecyldimethylammonium chloride (DOAC) were used. Although DDAB did not produce a prominent effect, its use was not abandoned, because it was expected to function favourably in an energy-transfer reaction when a fluorescent compound was added as a sensitizer.[12,13]

Next, the participation of organic solvents in the CL system was investigated. TCNQ ($1 \times 10^{-4}M$) dissolved in the organic solvent (for reasons of ease of dissolution) was used as R_1 and the DDAB ($1 \times 10^{-3}M$) was dissolved in $1 \times 10^{-2}M$ sodium hydroxide to provide R_2. With 20% methanol or ethanol media, the signal for $3 \times 10^{-3}M$ sulphide remained low, but a 30-fold increase in signal was obtained with 20% acetone or acetonitrile media. In the absence of DDAB, the enhancement effects of both solvents were reduced by 75%. For subsequent experiments, acetonitrile was chosen as the organic solvent because it caused less damage to the flow-cell material (PVC). It was found that 40% acetonitrile was best, enhancing the signal about 40-fold.

Reaction temperature

Raising the reaction temperature may also enhance the light emission. As shown in Fig. 1, a heating bath was arranged for warming the two reagent solutions (to which Rhodamine B had not yet been added). The effect of reaction temperature on the signal is shown in Fig. 2, which also shows the effect of another vesicle-forming surfactant, DOAC. There is a maximum in each curve, and DOAC provides a much higher signal than DDAB at temperatures above 40°. This temperature effect is due to the properties of the surfactant assemblies formed, and is probably related to the phase-transition temperature (<10° for DDAB and 45° for DOAC). Bilayer membrane-forming surfactants such as DDAB and DOAC usually display the phase transition from gel to liquid-crystal at a certain temperature, at which their structures and hence photochemical and physicochemical properties dramatically change.[18] Below the phase-transition temperature the surfactant molecules in the bilayers are in highly organized states; accordingly, TCNQ dissolved in the hydrophobic region of the bilayers cannot diffuse readily to react with the sulphide, which is concentrated in the vicin-

ity of the positively charged head-groups of the surfactants because of its negative charge. Above the phase-transition temperature the surfactant molecules are in mobile liquid-like states; this enables TCNQ to diffuse easily into the bilayers. The decrease in signal appearing for DDAB at the higher temperatures is likely due to gradually increasing deterioration of the ordered bilayers and thus a decrease in their catalytic effect. However, the cause may be more complicated, because acetonitrile is also present in the system. The other surfactants mentioned above were also tested at elevated temperatures, but none of them surpassed DDAB and DOAC with regard to signal enhancement (Table 1). DOAC was selected for further experiments.

Concentrations of TCNQ, DOAC and alkali

The signal reached a maximum with use of $10^{-4}M$ TCNQ. The higher the DOAC concentration, the higher the signal. A DOAC concentration of $10^{-3}M$ was near the limit of solubility. A sodium hydroxide concentration of $10^{-3}M$ provided the highest signal with $10^{-3}M$ DOAC.

Selection of sensitizer

Under the conditions determined above, the limit of determination of sulphide was $10^{-5}M$, which was too high for practical use in trace analysis. We have made it clear in other CL systems that energy transfer to a fluorescent compound added as a sensitizer occurs efficiently in organized reaction media, especially in the presence of bilayer membrane assemblies, and results in an extreme enhancement of light emission.[12,13] Thus for further increase in sensitivity, the use of a sensitizer was examined. Among 12 sensitizers tested, Rhodamine B gave the highest sensitization factor, of ~ 100 (Table 2). In this case, no signal was observed in the absence of TCNQ. This means that the Rhodamine B acts only as a sensitizer. When DOAC was omitted from the system, the sensitized signal was reduced to about 0.9% of that in its presence, demonstrating that as expected, the energy transfer to Rhodamine B was tremendously increased by the presence of bilayer membrane assemblies. The effect of Rhodamine B concentration on the signal is shown in Fig. 3. Rhodamine B solution is deep red, and self-absorption may decrease the intensity of light emission if too concentrated a solution is used. Accordingly, a Rhodamine B concentration of $5 \times 10^{-4}M$ was used for subsequent experiments.

Our reasons for postulating the sensitization as due to energy transfer to the Rhodamine B are that CL still occurs (but less strongly) in the absence of Rhodamine B but not at all in the absence of TCNQ, and that some non-xanthene dyes also enhance the CL.

Flow-rates of the reagent streams

The highest signal for sulphide was obtained when the flow-rates of the reagent streams were both 7.5

Table 2. Effect of sensitizers on the CL signal for sulphide*

Sensitizer†	Relative CL signal	Sensitizer†	Relative CL signal
None	1	Erythrosin B	5
Rhodamine B	102	Eosin B	5
Methylene Blue	17	Uranine	4
Eosin Y	10	Acridine Red	3
Riboflavin	7	Brilliant Sulphoflavine	2
Pyronine B	6		

*Other conditions as for Fig. 1, except $[S^{2-}]$ is $2 \times 10^{-5}M$ and flow-rate is 6 ml/min.
†$10^{-4}M$.

Table 3. Effect of concomitant species (at $10^{-4}M$ level) on the CL signal for sulphide ion*

Species	Relative CL signal†	Species	Relative CL signal†
Mn(II)	560	Co(II)	78
Fe(II)	500	Al(III)	72
Fe(III)	180	Pb(II)	22
Ni(II)	120	Zn(II)	22
Sn(IV)	89	Cd(II)	17
Ag(I)	78	Cu(II)	17

*Conditions as for Fig. 1.
†Normalized with respect to the signal (=100) for $1 \times 10^{-6}M$ S^{2-}.
Other species examined in selectivity study did not interfere.

ml/min. At lower flow-rates some of the light emitted would not be detected because the CL reaction proceeds too quickly; on the other hand, at higher flow-rates the reaction cannot reach completion inside the flow-cell, which again leads to lower intensity.

Calibration graph

Under the conditions specified in Fig. 1, a log–log plot of peak area against sulphide concentration was a straight line with a slope of unity between 5×10^{-6} and $5 \times 10^{-8}M$ (the determination limit). The detection limit (S/N = 3) was 0.01 ng/ml (30 μl injection of $1 \times 10^{-8}M$ solution). When the concentration is higher than $5 \times 10^{-6}M$, the curve deviates from a straight line. This is a common phenomenon with CL signals and is due to light-absorption by the coloured solution. The sampling rate was 240/hr. The relative standard deviation was 3.0% for $3 \times 10^{-7}M$ sulphide ($n = 19$).

Selectivity and interference

For evaluation of the selectivity, solutions of various species ($1 \times 10^{-4}M$) were injected and the signals obtained were compared with that for sulphide ion ($1 \times 10^{-6}M$). The system is fairly selective. Only manganese(II) and iron(II) gave signals, and these were only 1.1 and 0.2% respectively, of that for the sulphide. This is as expected, because manganese(II) can be determined sensitively by means of another TCNQ CL system (TCNQ/OH^-/DDAB/eosin Y), where iron(II) and sulphide provide signals that are 6 and 0.01%, respectively, of that for the manganese(II).[12] The fundamental difference in the two systems is that in the present system acetonitrile is present, although its role is not clear. No signal was observed for other sulphur anions such as sulphide, sulphate, thiosulphate and thiocyanate, that often cause interference in sulphide determinations. In addition, the following species were found not to cause emission themselves: Fe(III), Ni(II), Zn(II), Pb(II), Cd(II), Al^{3+}, Cu(II), Ag(I), Co(II), Sn(IV), Mg^{2+}, Ca^{2+}, NH_4^+, F^-, Cl^-, Br^-, I^-, NO_3^-, NO_2^-, CO_3^{2-}, $H_2PO_4^-$, $C_2O_4^{2-}$, and CH_3COO^-.

To check the effect of concomitant species on the signal for sulphide, a $10^{-6}M$ sulphide solution containing one of the other species was injected. The results are shown in Table 3. In general, species giving signals *per se* show positive interference and species forming precipitates with sulphide show negative interference. When the concentration of the concomitant species was reduced to $10^{-5}M$, only manganese(II) and iron(II) still interfered, and then only slightly ($\sim 20\%$ increase in signal). No interference was observed from other sulphur-containing species. This is a special advantage for sulphide determination.

Determination of sulphide ion in hot-spring water

Hot-spring water was taken from Takayu hot spring (Fukushima prefecture). The sample solution was diluted 1000-fold with distilled water and this solution was injected. By the standard-addition method, the concentration of sulphide was found to be 51, 49, 51 mg/l., in agreement with the results (48, 50, 48 mg/l.) found by iodometry.

MEMBRANE ELECTRODE WITH A PSEUDOLIQUID POTENTIAL-DETERMINING PHASE FOR CLOXACILLIN DETERMINATION

RYSZARD DUMKIEWICZ
Department of Analytical Chemistry and Instrumental Analysis, Chemistry Institute, UMCS 20031 Lublin, Poland

(*Received* 10 *February* 1988. *Revised* 2 *May* 1988. *Accepted* 7 *November* 1988)

Summary—An ion-selective electrode with a pseudoliquid potential-determining phase for cloxacillin determination has been prepared. The basic electrode analytical parameters (measuring range, slope, detection limit, response time, lifetime, and selectivity coefficients in relation to penicillins and some inorganic ions) have been determined.

Determination of penicillin compounds proves to be very difficult because of their complex structure and the imprecisely stated chemical composition of medical preparation (*e.g.*, Penicillium Crystalisatum).

Penicillins have been determined by iodometric,[1-3] spectrophotometric[4-6] and polarographic[7] methods. Recently, indirect potentiometric methods with ion-selective electrodes[8-11] have been developed.

Penicillins that can be decomposed by enzymes have been determined by using enzymatic electrodes with penicillinase immobilized in polyacrylamide gel on the surface of a glass electrode.[12-17]

Better results are usually achieved with direct methods, but electrodes selective for penicillin have not yet been described.

The ability of quaternary ammonium salts to form ion-association complexes with cloxacillin anions has been used to prepare electrodes selective for cloxacillin (6-{([3-(2-chlorophenyl)-5-methyl-4-isoxazolyl]carbonyl)amino}-3,3-dimethyl-7-oxo-4-thia-1-azobicyclo-[3.2.0]heptane-2-carboxylic acid, monosodium salt). This complex may be an active substance in an ISE membrane phase. This paper presents the preparation and properties of the electrode.

EXPERIMENTAL

Reagent

Analytical grade salts (POCh, Gliwice) were used. Cloxacillin, potassium benzylpenicillin (Penicillium Crystalisatum) and ampicillin sodium, were obtained from POLFA, and amoxicillin from Laboratoires de Recherche Beecham, Sevigna. Aliquat 336 was obtained from General Mills, USA. Freshly prepared pencillin solutions were used, and were kept in the refrigerator (5°) between successive measurements.

Electrode construction

The electrode consists of a cylindrical Teflon container connected to the poly(vinyl chloride) (PVC) body by a screw-thread. The pseudoliquid potential-determining phase of the electrode, into which the Ag/AgCl electrode is introduced, is placed in a cylindrical PTFE container which acts as the sensor. The electrode structure is shown in Fig. 1.

The penicillin electrode potential can be described by the equation:

$$E = E_0 + \frac{2.303\,RT}{nF} \times \log[\text{penicillin}]$$

Electrodes of this type, which do not contain an inner internal reference solution, possess the same advantages as the coated wire electrodes but have longer lifetime[18] because the modified PVC plasticizer used is a reservoir of the active substances necessary for functioning of the electrode.

The liquid exchanger

The liquid exchanger was the Aliquat 336–cloxacillin complex, prepared by shaking 10 ml of Aliquat 336 and 20 ml of aqueous 0.1*M* penicillin solution in a separating funnel for 10 min. The extraction was continued until the aqueous phase was chloride-free. After drying, the Aliquat 336–cloxacillin complex was kept in a dry vessel at 5°.

Preparation of potential-determining phase

The potential-determining phase was prepared by mixing 0.2 g of the Aliquat 336–cloxacillin complex, 1.1 g of dibutyl phthalate, of 0.2 g of tributyl phosphate and 0.6 g of PVC. After deaeration, the mixture was used to fill the Teflon container of the electrode and was then gelled by heating at 80–90° for 30 min. After cooling, the electrode was mounted, and conditioned for 2 hr in 0.1*M* cloxacillin solution before use.

Potential measurement

The emf of the ion-selective pencillin electrode and reference electrode system was measured in a vessel kept at 25 ± 0.1°. The salt-bridge of the Orion 90-02 Ag/AgCl reference electrode was filled with 0.05*M* sodium acetate adjusted to pH 7.0 with 0.05*M* acetic acid. Measurements were made with an Orion 901 Ionometer and a Radiometer PHM 62 pH-meter.

RESULTS

Calibration graphs

The behaviour of the cloxacillin electrode in solutions of penicillins and interfering inorganic ions was studied over the concentration range 10^{-5}–$10^{-1}M$. The calibration plots are shown in Fig. 2. The slope

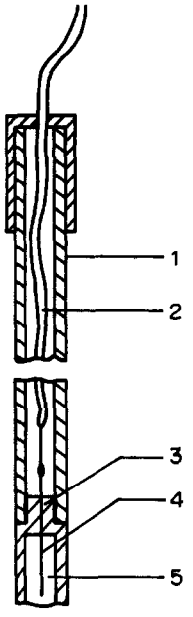

Fig. 1. Structure of the cloxacillin electrode: 1—body, 2—cable, 3—PTFE sensor, 4—Ag/AgCl electrode, 5—pseudoliquid potential-determining phase.

of the cloxacillin electrode response is 60 mV/decade, and the detection limit is $7 \times 10^{-6} M$. Other analytical parameters of the electrode are given in Table 1.

Selectivity

The selectivity coefficients of the cloxacillin electrode for a number of anions were determined by the separate solution method. The values found are given in Table 2. For penicilloate the electrode has a response slope of 30 mV/decade in the concentration range 10^{-3}–$10^{-1} M$. The selectivity coefficient $K^{pot}_{clox,pen}$ is 0.15. For 6-APA the electrode gives a response only in the range 0.01–0.1 M, with a slope of 26 mV/decade and a selectivity coefficient $K^{pot}_{clox/6\text{-APA}} = 0.005$.

Table 1. Analytical parameters of the cloxacillin electrode

Slope, mV/pc_{clox}	60.2
std. devn., *mV*	2.1
corr. coeff.	0.9991
Intercept, *mV*	238.2
Limit of detection, M	7×10^{-6}
μg/ml	3.5
Measurement range, M	10^{-5}–10^{-1}
μg/ml	0.00444–44
Response time, *min*	0.5
Lifetime, *months*	3

Response time

Response time was determined by measuring the change in the emf after injection of v_s ml of cloxacillin solution of concentration c_s into v_p ml of stock solution of concentration c_p, with vigorous stirring; the concentration and volume ratios were kept constant at $c_s/c_p = 100$ and $v_p/v_s = 20$. The solution was then diluted with an equal volume of water and the emf recorded as a function of time. The results obtained are shown in Fig. 3 and Table 1. During the stirring the emf changes by ~1 mV for 0.01–0.1 M solutions, but by up to 5 mV for more dilute solutions. The electrode is not suitable for use in flow-through systems, on account of washing away of the liquid exchanger.

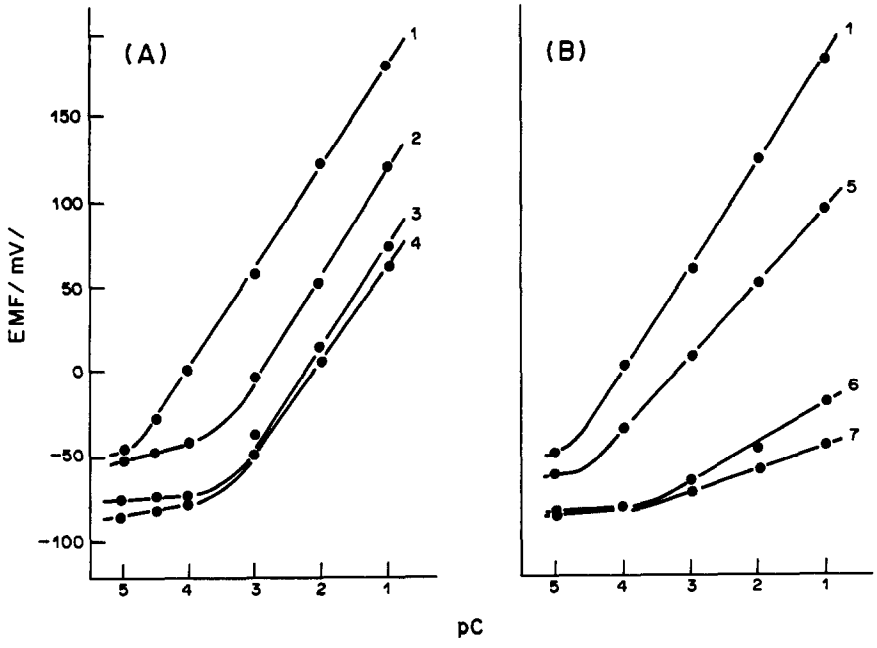

Fig. 2. Calibration curves of cloxacillin electrode. A: 1—cloxacillin; 2—benzylpenicillin; 3—ampicillin; 4—amoxycillin; B: 1—cloxacillin; 5—nitrate; 6—chloride; 7—acetate.

Table 2. Selectivity coefficients

Species x (0.01M)	$K^{pot}_{clox,x}$
Benzylpenicillin	0.096
Ampicillin	0.019
Amoxicillin	0.014
6-APA acid	0.005
Penicilloate	0.15
Nitrate	0.05
Chloride	0.0018
Acetate	0.001

Effect of pH

The dependence of the electrode potential on the pH of the solution was examined by adding 0.05M hydrochloric acid or sodium hydroxide dropwise to 20 ml of a stirred $10^{-3}M$ solution of cloxacillin. After each addition of acid or base, the electrode potential and pH were measured. The cloxacillin electrode is effective at pH 5–9 (Fig. 4).

Assay of pharmaceuticals

The standard addition technique was used, for samples at an ionic strength of 0.05M and a pH of 7.0. The results are given in Table 3.

DISCUSSION

As follows from Tables 1–3, the cloxacillin electrode is characterized by good analytical parameters. The response time of 30 sec, advantageous detection limit of $5 \times 10^{-5}M$ and relatively good selectivity coefficients for inorganic ions make it useful for cloxacillin determination.

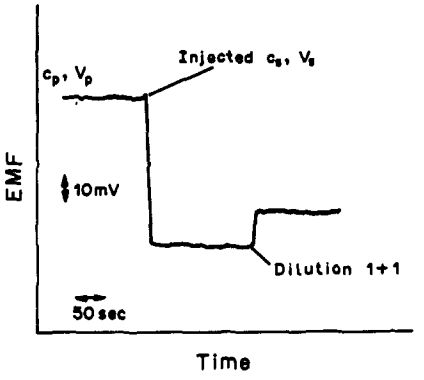

Fig. 3. Response time of cloxacillin electrode: $c_p = 10^{-3}M$; $c_s = 0.1M$; $v_p = 20$ ml; $v_s = 1$ ml; dilution 1:1.

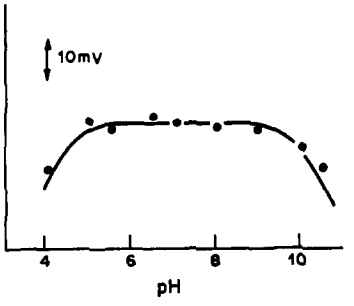

Fig. 4. Effect of pH on response of electrode to cloxacillin.

Table 3. Results of cloxacillin determination

Name of penicillin	Taken, mg/l.	n	Found, mg/l.	Cloxacillin std. devn., mg/l.
Cloxacillin	600.0	7	601	6
	400.0	7	399	5
	40.0	9	40.8	1.9
Cloxacillin Ampicillin	250 250	6	251	2
Cloxacillin Ampicillin	500 250	7	513	12
Cloxacillin Ampicillin	250 500	7	264	4

The selectivity coefficients of the cloxacillin electrode for penicillins decrease in the order cloxacillin > benzylpenicillin > ampicillin > amoxicillin, and this order can be explained in items of the change of substituent character in the penicillin side-chain.

Of the penicillins examined, cloxacillin has the strongest affinity for the ion-exchanger owing to the presence of a heterocyclic isoxazolyl substituent. Amoxicillin, which has amine and hydroxyl groups on the benzyl substituent, has the lowest affinity for the ion-exchanger; the affinity of ampicillin, which has only an amine group as the substituent, is slightly higher. The affinity of benzylpenicillin is only slightly smaller than that of cloxacillin.

Cloxacillin has been determined with the electrode (Table 3) in both pure preparations of the penicillin and in solutions corresponding to commercial formulations containing cloxacillin and ampicillin (Ampliclox and Ampiclox Neonatal, Beecham). The selectivity is sufficient for determination of cloxacillin in such mixtures.

The results show that the electrode can be employed for control analysis of antibiotics or for determinations made in hospital laboratories. The potentiometric determination of cloxacillin (a penicillin which is insensitive to enzyme action) creates new possibilities for application of ion-selective electrodes. It has been found to give satisfactory results for determination of cloxacillin in serum, and its use for control of cloxacillin production is being investigated.

DETERMINATION OF TIN AND TRIORGANOTIN COMPOUNDS IN SEA-WATER BY GRAPHITE-FURNACE ATOMIC-ABSORPTION SPECTROPHOTOMETRY

T. FERRI, E. CARDARELLI and B. M. PETRONIO
Dipartimento di Chimica, Università di Roma "La Sapienza", Piazzale Aldo Moro, 5-00185, Rome, Italy

(*Received* 26 *January* 1988. *Revised* 8 *June* 1988. *Accepted* 7 *November* 1988)

Summary—An analytical method based on graphite-furnace atomic-absorption spectrophotometry employing a suitable signal-enhancing medium for determination of inorganic tin and two of its trisubstituted organic derivatives in sea-water has been established. This method allows determination of triphenyltin and tributyltin compounds down to 2×10^{-12} and $2.8 \times 10^{-12} M$ respectively by means of enrichment by collection on graphitized carbon black (enrichment factor up to 8×10^4) and a separation on a small silica-gel column. Inorganic tin, which is not adsorbed on the graphitized carbon black, is isolated from the matrix by liquid–liquid extraction of its pyrrolidinedithiocarbamate complex into dichloromethane. The method gives good recovery (≥95%) and precision (≤5%) at the ng/l. level.

The determination of organotin compounds in the environment is becoming increasingly more important as their production increases.[1,2] Their use is strictly related to their degree of substitution.[3] In particular, trisubstituted derivatives are widely employed because of their biocidal properties as algicides, fungicides, molluscicides *etc.*[2,4] The introduction of such compounds into the environment could cause serious problems mainly due to their high toxicity and tendency to bio-accumulation.[2] In particular, bioassays with algae,[5] oysters,[6] crabs,[7,8] mussel larvae[9] and fish[10,11] have shown sublethal and lethal effects of tributyltin at levels even lower than 1 μg/l. In addition, these compounds can be accumulated by some organisms such as oyster[12] and fish[13] with factors up to 6000 for rather short exposure periods. However, as these organotin compounds in the environment are degraded into less toxic ones[14] at different rates, it is important to have highly sensitive (ng/l, level) analytical methods available for their determination, in order to control their concentration levels in the environment so as to prevent health risk.

Several techniques have already been employed to determine tin and/or its organic derivatives, including gas chromatography,[15,16] HPLC,[17,18] polarography[19–22] and especially atomic-absorption spectrophotometry.[23–28]

The objective of this work is to define an analytical method for determination of inorganic tin, tributyltin and triphenyltin in sea-water. The method, suitable for analyte determination at ng/l. concentration levels, should be very simple and require only the usual laboratory equipment and a graphite-furnace atomic-absorption spectrophotometer.

EXPERIMENTAL

Apparatus

A Perkin–Elmer model 2380 atomic-absorption spectrophotometer equipped with a Perkin–Elmer model R100 recorder, a deuterium-arc background corrector and a Perkin–Elmer model HGA 400 heated graphite atomizer was employed. Perkin–Elmer untreated graphite and pyrolytically-coated furnace tubes were used, but for no more than 100 determinations each.

Two GFAAS thermal programmes were utilized: the first, for inorganic tin, reported in Table 1, was defined on the basis of a preliminary study to determine the optimal ashing and atomization temperatures and the second, used for organotin compounds, was that defined by Pinel *et al.*[23]

Reagents

A 1 g/l. "Spectrosol" BDH standard solution for AAS was used as the primary standard solution for inorganic tin. All the less concentrated standard solutions obtained from it by dilution were made 1 *M* in hydrochloric acid. Standard solutions of both triorganotin compounds were prepared with Fluka products (>98% pure), and those of the di- and mono-organic derivatives were prepared with Aldrich products, all without further purification. The solutions (200 mg/l.) taken as standards were prepared by weight [triphenyltin chloride (TPT) and dibutyltin dichloride (DBT)] or by volume (and density) [tributyltin chloride (TBT) and monobutyltin trichloride (MBT)], in ethanol as solvent. The concentrated standard solutions were stored at 4°, and the dilute ones were prepared daily.

All the acids employed were "Suprapur" Merck products. All the other reagents were Carlo Erba products of analytical grade except for the ammonium pyrrolidinedithiocarbamate (APDC) which was from BDH. Ultrapure demineralized water (18 MΩ.cm) from a Milli-Q Millipore system was always used.

Artificial sea-water[21] with a salinity of about 36 g/kg was prepared from demineralized water and salts in the follow-

Table 1. Thermal programme utilized for inorganic tin; the Ar flow (50 ml/min) was stopped during the atomization step

Step	Time, *sec*	Temperature, °C	Heating rate, *deg/sec*
Drying	10	90	4.5
Drying	5	120	3.0
Ashing	10	550	21.5
Atomization	5	2100	max
Cleaning	3	2700	max

ing molar concentrations: NaCl 0.4106, $MgCl_2$ 0.0298, $MgSO_4$ 0.0284, KCl 0.0093.

Graphitized carbon black (GCB), Carbo-Pack B (Supelco) 80–100 mesh, with 100 m^2/g specific area was used for preconcentration of organotin compounds, and silica gel (70–230 mesh, ASTM, Merck) was used to prepare the column for their chromatographic separation.

Procedures

Sample treatment and storage. The collected samples were filtered through 0.45-μm acetate filters, acidified with 5 ml of concentrated nitric acid per litre and stored in polyethylene bottles at 4°.

Preconcentration. GCB (100 mg, previously washed with methanol) was put in a glass column (bore 7 mm) provided with a porosity-2 frit at one end (Bio-Rad). After passage of 5 ml of demineralized water to remove the methanol, a fixed volume (up to a few litres) of sample was passed through the column at a flow-rate of 20 ml/min, followed by 5 ml of demineralized water at the same flow-rate, to eliminate the matrix salts. The triorganotin compounds were then eluted with 2 ml of methanol/dichloromethane mixture (4:1 v/v) at 2 ml/min flow-rate. The GCB column, after washing with another 5 ml of demineralized water was then ready for further use. The eluate containing the triorganotins was evaporated to dryness under a stream of nitrogen and the residue was taken up in 1 ml of n-hexane.

Separation. The chromatographic column was prepared with 200 mg of silica gel between two frits in a Supelco column (bore 4 mm). First 20 ml of n-hexane were passed through the column (without draining it) to eliminate air bubbles. The 1 ml of hexane solution from the preconcentration step was then passed through the column at 0.5 ml/min flow-rate. The TBT was eluted with 3 ml of n-hexane/ethyl acetate mixture (2:1), and then with TPT 4 ml of ethyl acetate, at 0.5 ml/min.

Liquid–liquid extraction of Sn(IV). The sample (200 ml) was mixed in a 250-ml separatory funnel with 2 ml of 1*M* acetate buffer (pH 4.75) and 5 ml of 10% APDC solution. After 10 min the tin–APDC complex was extracted by shaking for 2 min with 10 ml of dichloromethane; the mixture was then let stand for 10 min for phase separation.

Spectrophotometric measurements. For all atomic-absorption measurements a 0.04% potassium dichromate/2% nitric acid medium[23] was used. The eluate from the chromatographic separation and the organic phase from the extraction step were evaporated to dryness under a stream of nitrogen and the residues were taken up in a suitable volume (usually 1 ml) of the acid dichromate solution. All measurements were made on 20-μl samples introduced into the furnace-tube by means of a high-precision Gilson micropipette. Each value used was the average of at least five different readings corrected for the blank absorption. In accordance with the recommendations of the ACS Committee on Environmental Improvement the signals used in the calculations were always at least ten times the standard deviation of the blank signal (*i.e.*, the limit of quantification). Unless otherwise specified, the values reported correspond to the average of four separate determinations, and refer to the tin content.

RESULTS AND DISCUSSION

Atomic-absorption determination of metals is particularly sensitive when electrothermal atomization is used.[25] The direct determinations in real matrices, however, are often subject to interference by matrix components, especially in determinations at ultra-trace levels. For tin determination, in particular, problems may arise during both the ashing and atomization steps, from formation of volatiles and interaction of tin with the carbon of the furnace walls.[26] Several approaches have been made into the solution of these problems, including isolation of tin from the matrix,[24,26–32] addition of a matrix modifier to the sample,[23,26,33–36] and pretreatment of the furnace walls.[37–39] Matrix modifiers should essentially prevent the tin from being lost by volatilization before it can be atomized, thus decreasing interference problems, but may also be used simply to obtain a signal enhancement.[24,40]

However, in the present case, the enrichment step should also avoid interference problems.

A short preliminary study was made to optimize some of the experimental conditions (kind of furnace, wavelength, medium). These results, summarized in Table 2, show that non-treated furnace tubes gave higher sensitivity than pyrolytically-coated ones. The sensitivity was also higher for the 224.6 nm line than the 286.3 nm line. The acid dichromate medium[23] was used whenever possible, as it enhanced the signal for all the analytes considered.

To allow speciation of the tin, at least two preconcentration steps were required, one for inorganic tin and one or more others for organic forms of tin.

Table 2. Evaluation of the influence of some experimental parameters on the recorded instrumental signal

Analyte	Medium	λ, *nm*	Tube	Sensitivity, *absorbance . ml . μg^{-1}*	*Y*-intercept, *absorbance* × 10^3	Correln. coeff.
$SnCl_4$	Demineralized water	224.6	Gr*	1.51	0.7	0.9981

Table 3. Preconcentration of inorganic tin from 200 ml of artificial sea-water by liquid–liquid extraction of its APDC complex into dichloromethane at pH 4.75

$SnCl_4$ added, *ng*	$SnCl_4$ found, *ng*	RSD, %	Recovery, %
4.0	3.9 ± 0.3	7.7	98
20.0	19.7 ± 0.5	2.6	98

For preconcentration of inorganic tin, co-precipitation with iron,[19] magnesium[41] or calcium,[42] and liquid–liquid extraction with cupferron,[43] tropolone[44] or APDC[45] are most frequently employed. Since sea-water contains a sufficient amount of magnesium, co-precipitation with this metal was tested on artificial sea-water spiked with tin. Unfortunately, the high magnesium content in the sample thus enriched strongly interferes in the tin determination. Therefore, liquid–liquid extraction of the tin–APDC complex at pH 4.75 into dichloromethane[45] was adopted. The results in Table 3 show that practically complete recovery of inorganic tin is obtained.

Triorganotin compounds have usually been preconcentrated from aqueous samples by liquid–liquid extraction with[18,35,45] or without[22,24,36-39] complexing agents. Toluene is one of the most commonly employed extractants, and dichloromethane also extracts these compounds.[39] Toluene and di-isopropyl ether were tested. The ether does not extract the test compounds sufficiently, and even though toluene extracts both triorganotin compounds practically quantitatively,[46] their total content cannot be directly determined by extraction because of the different AAS sensitivities for the two species.[46] At least one further step is necessary; either mineralization and determination of the resulting inorganic tin to give the sum of TBT and TPT, or a chromatographic separation. In this connection, the use of GCB seemed very promising for giving preconcentration and separation at the same time, since it had already been widely employed for chromatographic column preparation,[47] and preconcentration of pesticides from natural water[48] and of metabolites or catabolites from biological fluids.[49-51]

The complete retention of TBT and TPT by GCB was verified by passing 1 litre of 40 μg/l. TBT or TPT solution through it at 20 ml/min flow-rate, and testing the eluate for them. The maximum adsorption capacity (break-through) of GCB for the two organotin compounds was not determined, because of their extremely low concentration levels in sea-water. It was considered much more important to find and verify the lowest concentration levels at which these compounds may be determined by retention on GCB and subsequent elution and AAS determination. It must be stressed that the presence of inorganic tin in the sample does not interfere with the determination of the organotin compounds by this method, since it is not retained by GCB and thus can be separated from the organic forms.

The individual TBT and TPT elution curves with different eluents (methanol, acetonitrile and acetone) were determined. Although acetone and acetonitrile eluted TBT faster than TPT, and methanol eluted both simultaneously, the elution was not quantitative (Table 4), and other eluents were tested. A 2:1 v/v mixture of methanol and dichloromethane was found to be the best. Table 5 gives the data for the preconcentration of TBT and TPT (at two concentration levels) from both demineralized water and artificial sea-water with this eluent. To evaluate the lowest concentrations that can be determined increasing volumes of sample (in 1-litre steps) but always containing 1 ng (as total tin) of TPT or TBT were analysed by the procedure reported above, except that a final volume of 50 μl was used, which allowed only two spectrophotometric readings. The results, together with the relative factors, are reported in Table 6. Determination of TPT and TBT down to 0.25 and 0.33 ng/l. respectively is feasible, but it must be underlined that for more significant results to be obtained larger volumes (≥ 100 μl) of acid dichromate should be used to dissolve the final residue so that at least four readings can be made. This also means that either the limit of quantification will be doubled, or larger sample volumes must be treated.

Since the aim was determination of the individual analytes, a chromatographic separation of TBT and TPT after the preconcentration step was needed. Preliminary thin-layer chromatographic experiments showed that these two compounds could be separated on silica gel, with 2:1 v/v n-hexane/ethyl acetate mixture; in column work, however, the TPT (more strongly retained than TBT) gave a rather shallow and broad elution peak. It was therefore preferred to eluted the TBT with the solvent mixture, and then TPT with ethyl acetate alone.

No interference is caused by any less substituted phenyltin or butyltin compounds present in the sample. Although they may be at least partially

Table 7. Recovery tests on sea-water samples (200 ml)

Analyte	Natural content, ng	Added, ng	Found, ng	RSD, %	Recovery, %
Sn(IV)	3.0	12.5	15.1 ± 0.4	2.6	97
TPT	—	10.0	9.5 ± 0.5	5.3	95
TBT	—	10.0	9.5 ± 0.5	5.3	95

retained by GCB (only ~25% retention of the monosubstituted species) and co-eluted with the trisubstituted compounds by the methanol/dichloromethane mixture, the TBT and TPT are selectively eluted in the subsequent chromatographic step. The elution of DBT and MBT (which are more mobile than the corresponding phenyl derivatives) from the silica gel needs larger volumes of ethyl acetate than that needed for elution of TPT (the R_F values of DBT and MBT are a half and a fifth, respectively, of that for TPT).

The method was applied to a sea-water sample taken from the Roman coast. The inorganic tin concentration in the sample was only 15.0 ng/ml, and neither TBT nor TPT was detected. The reliability of the method was checked by recovery tests on the same sample suitably spiked. The results summarized in Table 7 confirm the adequate performance of the method, especially considering the very low concentration levels determined.

POTENTIOMETRIC STUDY OF END-POINT DETECTION IN THE COULOMETRIC DETERMINATION OF CARBON DIOXIDE

STANISLAW GŁAB and ADAM HULANICKI
Department of Chemistry, University of Warsaw, Warsaw, Poland

(*Received* 26 *August* 1988. *Accepted* 1 *November* 1988)

Summary—The coulometric determination of carbon dioxide is based on the alkalimetric titration of the product of absorption of carbon dioxide in an organic solution of monoethanolamine. The processes occurring in various solvents have been investigated and optimized for analytical application. The protolytic reactions of 2-hydroxyethylcarbamic acid have been investigated in 2-propanol + 2, 5 and 10% water, dimethylformamide + 2% water, dimethylsulphoxide + 5, 10 and 20% water. In coulometric generation of the base, 0.1*M* solutions of tetraethylammonium bromide in these solvents were used. The course of the titration was followed potentiometrically with glass and antimony indicator electrodes. From the titration curves the autoprotolysis constants of the mixed solvents and protonation constants of monoethanolamine in them were calculated. These constants and the concentration of monoethanolamine influence the size of the end-point break for the titrations. On this basis, optimal conditions for analysis have been selected and the total carbon content in samples of natural waters has been determined.

Determination of carbon dioxide presents an important analytical problem when its concentration should be directly evaluated or when carbon dioxide is the product of decomposition of samples containing inorganic as well as organic carbon. Methods of carbon dioxide determination can be divided into direct and indirect procedures. In the former the analyte is determined as carbon dioxide, *e.g.*, by infrared spectrometry,[1] gas chromatography, with a thermal conductivity detector,[2] or manometry.[3] In the indirect procedures the analytical signal relates to the product of a reaction between carbon dioxide and a component of the absorbing solution. Among indirect procedures the following may be noted: gravimetry as barium carbonate,[4] conductimetry, based on the decrease of solution conductance after absorption of carbon dioxide,[5] and pH-measurement, based on the change in pH of the absorbing solution (usually barium hydroxide).[6] The use of ion-selective electrodes sensitive to carbon dioxide may also be arbitrarily included in this group, because the diffusing carbon dioxide changes the pH of the hydrogen carbonate solution inside the sensor.[7] Titrimetric procedures are based on alkalimetric titration to restore the pH of the solution in which the carbon dioxide has been absorbed, to its initial value. Such titrations may be performed volumetrically with a standard alkali solution[8] or coulometrically with electrogenerated base.[9–13] The main difficulty is that the end-point is poor because hydrogen carbonate is a weak acid.

For several years, procedures for determining carbon dioxide have been based on its absorption in organic or mixed solvents in the presence of monoethanolamine (MEA). This amine reacts with carbon dioxide to form a stronger acid, which in turn is titrated with the standard base solution, *e.g.*, with tetraethylammonium hydroxide (thymolphthalein as indicator).[14–15] The coulometric version of this procedure, in which the base is electrogenerated at the cathode of the coulometric cell, is much more elegant. In such procedures different solutions have been used for carbon dioxide absorption. Boniface and Jenkins[16] used a 3.5% solution of MEA in dimethylformamide (96.5%) + water (3.5%) containing potassium iodide. Lindberg and Cedergren[17] used a similar solvent but containing only 2% water, and sodium perchlorate as an electrolyte. Metters *et al.*,[18] used 3% MEA in 2-propanol, along with tetraethylammonium bromide. In these methods the end-point of the coulometric titration was determined spectrophotometrically with thymolphthalein as indicator. Houde and Champy[19] used potentiometric end-point detection in dimethylsulphoxide (90%) + water (10%) solution containing 3% MEA and 0.2*M* tetrabutylammonium bromide.

Carbon dioxide reacts with MEA to give 2-hydroxyethylcarbamic acid:

$$CO_2 + HOC_2H_4NH_2 \rightarrow HOC_2H_4NHCOOH$$

Initially,[20] it was supposed that this compound is neutralized by the base. It is, however, a relatively strong acid[21] with log $K_H \ll 7$, and it reacts with an excess of MEA to give the monoethanolammonium ion, which, depending on the medium, may be associated with the 2-hydroxyethylcarbamate anion.[18,21] The coulometric titration of the monoethanolammonium ion as an acid is the basis of carbon dioxide determination. This suggestion was to some extent confirmed by Whymark and Ottaway,[22]

who isolated the corresponding carbamate from a solution of MEA in pyridine after carbon dioxide absorption.

The aim of this paper is to study the ionic equilibria in various solvents as an indication of the most reasonable choice of experimental conditions and to confirm whether potentiometric end-point detection can be used in this titration.

EXPERIMENTAL

Reagents

2-Propanol (POCh-Gliwice) was purified by distillation and the fraction distilling at 82° was collected. *N,N*-Dimethylformamide [DMF] (POCh-Gliwice) was purified by distillation under reduced pressure and the fraction distilled at 21° was collected. Dimethylsulphoxide [DMSO] (Reachim-USSR) was first purified by freezing and then doubly distilled. The fraction distilling at 38° was collected. Monoethanolamine [MEA] (POCh-Gliwice) was purified by distillation and the fraction distilling at 172° was collected. Tetraethylammonium bromide (Reachim-USSR) was dissolved in hot 2-propanol, cooled and precipitated with acetone. The precipitate was dried under reduced pressure at 40°. This procedure was repeated three times. The product had an m.p. of 274°. Sodium carbonate was obtained from sodium hydrogen carbonate by heating at 280°. Sulphuric acid, potassium persulphate and silver nitrate were of analytical reagent grade. In all cases the water used was doubly distilled. Argon was purified by passage through sodium hydroxide solution.

Apparatus

The arrangement is shown in Fig. 1. The coulometric analyser was a Radelkis OH-404 and the end-point was indicated by a Radiometer PHM 64 pH-meter, with either a Radiometer G-202 B glass electrode or a single-crystal antimony electrode of our own construction. The reference electrode was of the silver chloride type with an electrolytic bridge of 0.1*M* sodium chloride.

In the coulometric cell double compartment the cathodic and anodic parts were separated by two sintered-glass diaphragms (G4) with the intermediate space filled with 3% sodium perchlorate solution in agar gel. Both electrodes in the generating circuit were made of platinum, with a cathode surface area of approximately 0.8 cm^2.

In equilibrium studies the potentials were read directly from the potentiometer display. In analytical determinations the potentiometer output was recorded as a titration curve with a Radiometer REC 61 recorder and the end-point was evaluated graphically.

The mineralization vessel consisted of a three-necked 70-ml flask. The middle opening was fitted with an outlet tube for the gas evolved and its transport to the absorber. The two other openings were used for introduction of argon through a capillary tube and for addition of the sample.

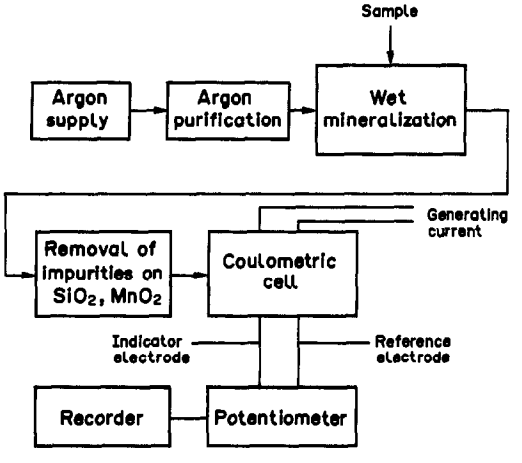

Fig. 1. Block diagram of the measuring set-up.

Procedure

In the determination of inorganic carbon the mineralization flask contains 10 ml of 3*M* sulphuric acid. The flask is first purged with argon and then the sample or a carbonate standard is added. The evolved gas is carried in a stream of argon flowing at 100 ml/min, and after passage through U-tubes containing silica gel and manganese dioxide is absorbed in the coulometric cell in the 1% solution of MEA in 0.1*M* tetraethylammonium bromide in a given solvent. After 15 min the contents of the cathodic compartment are titrated with base electrogenerated at 5 mA current.

When organic carbon is determined in samples of organic compounds or natural waters the mineralization flask contains 10 ml of 6*M* sulphuric acid, 5 ml of 10% silver nitrate solution and 25 ml of saturated potassium persulphate solution. After addition of the sample the flask is heated for 15 min, nearly to boiling, with continuous passage of argon. The carbon dioxide evolved is absorbed as before and coulometrically titrated at 5 mA current.

RESULTS AND DISCUSSION

Investigation of protolytic equilibria

The reaction between carbon dioxide and MEA may proceed in various organic solvents or aqueous organic solvent mixtures. Because the final determination is based on titration of the reaction product, which may be either 2-hydroxyethylcarbamic acid or the monoethanolammonium ion, the magnitude of the end-point break and consequently the precision of the titration depend primarily on the protonation constant of the relevant reaction product and on the autoprotolysis constant of the solvent. Such systems have not been investigated before and the choice of determination conditions had no firm theoretical basis. The solvents chosen for this study had either been used previously or had a composition similar to one mentioned in the literature. The solvents were 2-propanol containing 2, 5 or 10% water, DMSO containing 5, 10 or 20% water and DMF with 2% water. The last solvent was not studied with a higher water content because it is hydrolysed in the presence of more water.[17] The autoprotolysis constants of these seven mixed solvents and the corresponding protonation constants of monoethanolamine were determined.

The procedure for autoprotolysis constant determination was described previously[23] and is based on coulometric titration of a strong acid (perchloric) in a given solvent system (SH) with electrogenerated base. The potential of the glass electrode before the end-point (*i.e.*, in excess of acid) is

$$E = E_a^0 + 59.16 \log[SH_2^+]$$

$$= E_a^0 + 59.16 \log\frac{(Q_{E.P.} - Q)}{FV} \quad (1)$$

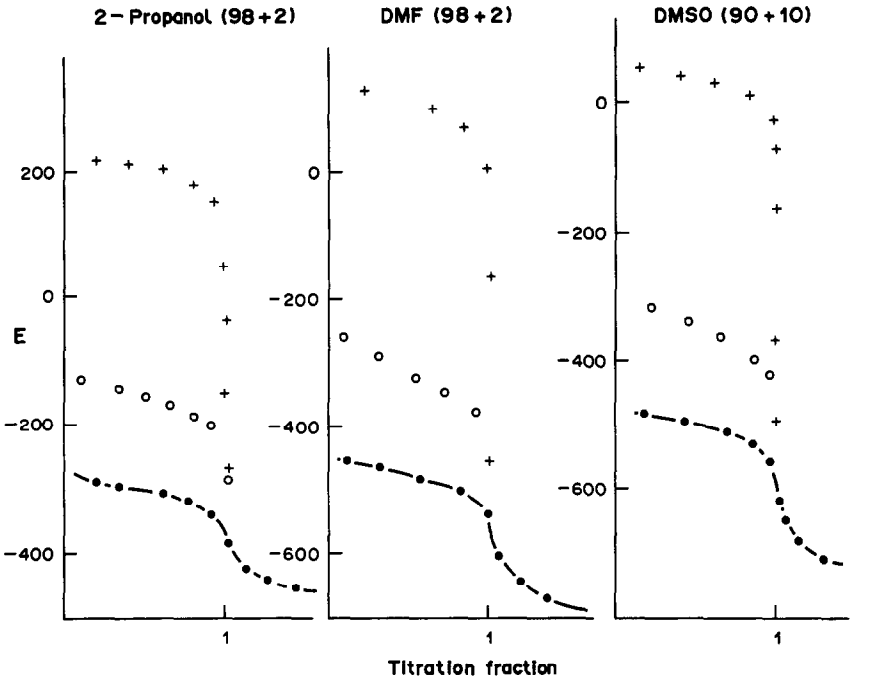

Fig. 2. Coulometric titration curves of $HClO_4$ (×), $MEAH^+$ (○), and the MEA + CO_2 reaction product (●) in various solvents. Solid line—curve calculated for $MEAH^+$ in presence of an excess of MEA.

where E_a^0 (mV) is a constant for the electrode-cell system in a given solvent for the acidic range, $Q_{E.P}$ (mC) is the charge consumed in reaching the titration end-point, Q (mC) is the charge corresponding to the potential E (mV), V (ml) is the solution volume and F is the Faraday constant. After the end-point (*i.e.*, in excess of strong base) the potential is given by

$$E = E_b^0 - 59.16 \log[S^-]$$

$$= E_b^0 - 59.16 \log\frac{(Q - Q_{E.P.})}{FV} \quad (2)$$

where E_b^0 (mV) is a constant for the basic range, and consequently

$$pK_i = -\log K_i = \frac{(E_a^0 - E_b^0)}{59.16} \quad (3)$$

The titration curves for three selected solvents are presented in Fig. 2 and values of the constants in Table 1.

The protonation reaction of monoethanolamine was also studied coulometrically according to the procedure described elsewhere.[24] The coulometric cell contained 40 ml of 0.1*M* tetraethylammonium bromide in the chosen solvent, containing 0.05 mmole of MEA and approximately 0.07 mmole of perchloric acid. The base was generated with a current of 5 mA. The logarithm of the protonation constant was calculated from the equation:

$$\log K_H^{MEA} = -\log[SH_2^+] + \log\frac{Q_{E.P.} - Q - FV([SH_2^+] - [S^-])}{Q + FV([SH_2^+] - [S^-])} \quad (4)$$

where $Q_{E.P.}$ (mC) is the charge equivalent to the amount of the monoethanolammonium ion. Q (mC) is the charge consumed in the course of titration corresponding to the potential E (mV) of the indicator electrode

$$E = E_a^0 + 59.16 \log[SH_2^+] \quad (5)$$

The curves for titrations in three of the solvent systems are shown in Fig. 2 and the calculated protonation constants for all the systems are given in Table 1, which also shows the equilibrium constant of the neutralization reaction; $\log K = pK_i - \log K_H^{MEA}$.

The reaction products obtained after absorption of carbon dioxide in 1% v/v solutions of MEA in

$\log K_H^{MEA}$	9.52	9.09	8.98	10.39	9.95	9.75	10.67
$\log K$	8.39	8.39	7.61	9.28	9.45	9.04	9.24

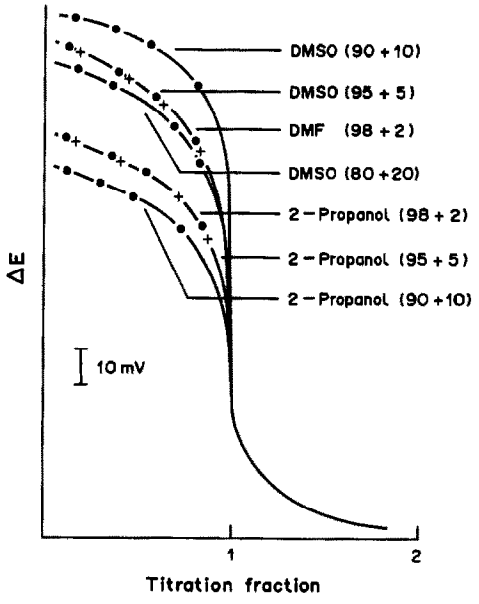

Fig. 3. Effect of various solvents on the titration end-point break in the determination of 0.05 mmole of CO_2. $C_{MEA} = 1\%$. Points—experimental; solid lines—calculated for $MEAH^+$ in the presence of an excess of MEA.

various solvents were examined. The samples contained 0.05–0.1 mmole of carbon dioxide and thus the amine was approximately 60–120-fold in excess. The titration curves (Fig. 2) show a significantly smaller end-point break than the titration curves for MEA alone, because a large excess of the non-protonated amine is present in the absorbing solution. When the fraction titrated is 0.5, log[MEA]/[$MEAH^+$] is close to 2.2, which means that the initial part of the titration curve should be shifted downwards by approximately 130 mV. [SH_2^+] at points on the titration curve was calculated from

$$[SH_2^+] = \frac{[MEAH^+]}{[MEA]K_H^{MEA}} = \frac{(Q_{E.P.} - Q)}{(C^0_{MEA}FV - Q_{E.P.} + Q)K_H^{MEA}} \quad (6)$$

where C^0_{MEA} (M) is the initial concentration of MEA; Fig. 2 shows that the calculated titration curve agrees with the experimental points within 2–3 mV. This supports the hypothesis that in such titrations the monoethanolammonium ion is titrated by the generated base.

The magnitude of the end-point break (Fig. 3) depends on the solvent and is largest for DMSO + water (90 + 10) and smallest for 2-propanol + water (90 + 10). This order is reflected in the value of log K, ($\log K = pK_i - \log K_H^{MEA}$), the equilibrium constant of the neutralization reaction (Table 1). The values of K_H explain the apparent anomaly that the titration curve has a larger break for the 90:10 DMSO–water mixture than for the 95:5 and 80:20 mixtures.

Conditions for carbon dioxide determination

An accurate determination requires complete absorption of the carbon dioxide in the MEA solution, as well as 100% current efficiency in the base generation. The latter condition was established (within experimental error) as holding for all the solvents investigated, by titration of perchloric acid samples of known concentration.

The time required for absorption of the carbon dioxide depends mainly on the rate of the mineralization process and for the samples used in this study 15 min from the beginning of mineralization was adequate.

The concentration of MEA also affects the absorption of carbon dioxide. The solutions used so far in this study contained 1% MEA, which was found sufficient for quantitative absorption. Nevertheless the concentration of MEA in the absorbing solution greatly influences the magnitude of the end-point break, shifting the initial part of the curve towards more negative potentials. Experiments were performed with MEA solutions having concentrations from 0.01 to 3.0% (Fig. 4), *i.e.*, starting from amounts of the amine that were nearly stoicheiometric relative to the amount of carbon dioxide. On the other hand, when the efficiency of absorption was evaluated for those solutions it was found to be only 50% for the lowest concentration studied (Fig. 5).

Table 2. Determination of total carbon in various samples

Sample	Sample size, *ml*	Total carbon, *mg*		R.S.D., % ($n = 5$)	Carbon content, *mg/l.*
		Taken	Found		
Sodium carbonate		0.546	0.543	0.1	
Potassium hydrogen phthalate		0.473	0.470	0.8	
		0.710	0.713	0.7	
		1.183	1.179	0.5	
River water (Wisla)	5		0.209	0.4	41.8
River water (Liwiec)	5		0.161	0.7	32.2
Well water	10		0.180	0.6	18.0
Pond water	10		0.385	0.4	38.5
Tap water	5		0.167	0.5	33.4
Paper mill effluent	5		0.468	0.3	93.6

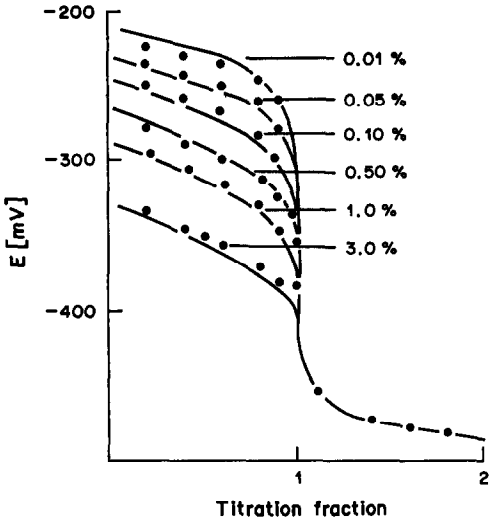

Fig. 4. Effect of MEA concentration on the titration curves of MEA + CO_2 reaction product in 2-propanol + water (98 + 2). The amount of carbon dioxide is *ca.* 0.05 mmole. Points—experimental; solid lines—calculated for $MEAH^+$ in the presence of an excess of MEA.

The lowest concentration of MEA that ensures complete absorption is close to 1% when the samples analysed contain approximately 0.1 mmole of carbon. In these conditions several samples may be analysed with the same absorption solution, but care must be taken not to fall short of the threshold MEA concentration necessary for complete absorption.

Potentiometric end-point detection

The study of the reaction mechanisms and of the determination procedure was mainly performed with a glass indicator electrode of good quality. The results indicate that it works properly in all the solvent systems over a wide range of acidity. In all cases the potential readings were taken with no current flowing in the generator circuit. An undesired coupling of the generator and indicator circuits is responsible for a systematic potential shift when the current in the generator circuit is switched on. This

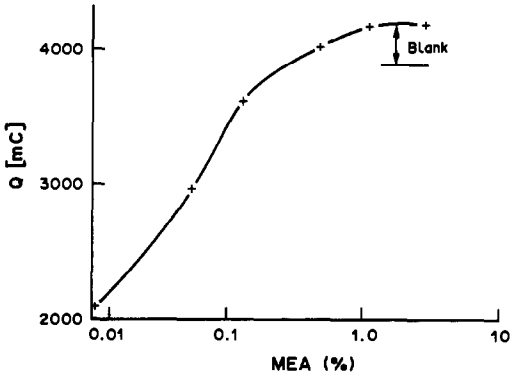

Fig. 5. Efficiency of carbon dioxide absorption at various concentrations of MEA in 2-propanol + water (98 + 2).

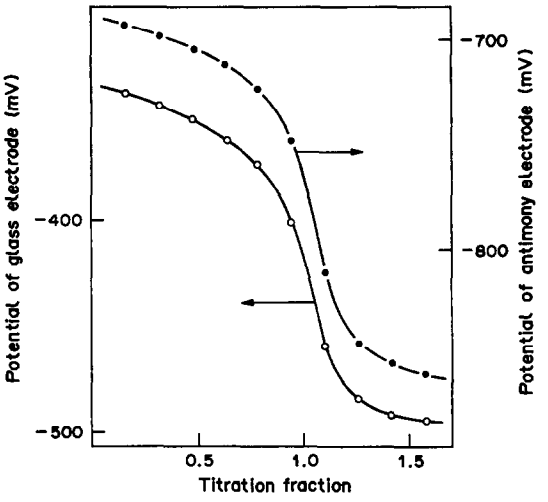

Fig. 6. Response of glass (○) and antimony/antimony oxide (●) electrodes in the titration of MEA + CO_2 reaction product in 2-propanol + water (98 + 2).

effect is probably mainly responsible for potentiometric detection being rarely used in coulometric procedures. Similar effects were also observed when the glass electrode was replaced by the low-resistance antimony pH electrode. Nevertheless, for both electrodes the shapes and the magnitudes of the titration curves were identical (Fig. 6), which suggests that the antimony electrode may be used with success. Its advantage is the possibility of miniaturization, which may be necessary if the equipment is adapted for analysing smaller samples.

Determination of carbon in natural samples

The procedure for carbon dioxide determination has been applied for analysis of sodium carbonate and potassium hydrogen phthalate. For the former, acid decomposition of the sample was used; for the latter mineralization was necessary, with an oxidizing mixture composed of sulphuric acid and potassium persulphate in the presence of silver ions as catalyst.[25] The same procedure was used for mineralization of water and sewage samples.

The study of the determination conditions indicated that the best solvent is DMSO + water (90 + 10), but in most routine determinations 2-propanol + water (98 + 2) was used. In this solvent the titration break is slightly smaller, but the solvent is cheaper and more easily purified. The stability of the potential response measured by the indicator electrode system was practically the same for all the solvents.

For all the reagents used in the mineralization it is necessary to find the blank value, which arises from carbon compounds present in the reagents and their solutions. For the sulphuric acid used for decomposition of sodium carbonate the carbon dioxide blank was usually close to 0.016 mg, whereas the reaction mixture for mineralization gave a blank of

0.124 mg. In spite of the good reproducibility of these values, there is doubtless a limit to the practicality of analysis of very small samples and of those with low carbon contents. The results obtained in this paper are satisfactory (relative standard deviation below 0.1%) over the total carbon range from 18 mg/l. for natural waters to 94 mg/l. for paper mill effluent.

SHORT COMMUNICATION

DETERMINATION OF FREE ELEMENTAL SULPHUR IN SOME PETROLEUM PRODUCTS

DODDABALLAPUR K. PADMA
Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore 560012, India

(*Received* 27 *May* 1987. *Revised* 14 *October* 1988. *Accepted* 14 *November* 1988)

Summary—Uncombined elemental sulphur in petroleum products such as kerosene, diesel, furnace and gear oil has been determined by conversion into copper(I) sulphide at 150–170°. The copper(I) sulphide can be weighed, or its sulphur content determined by the iodimetric method.

Recently a novel procedure for determination of elemental sulphur was reported.[1] It was then noted that though a similar procedure has been recommended for sulphur in cutting oils and cutting fluids,[2] no procedure has been recommended for the determination of free sulphur in petroleum distillates. This paper reports the application of the method to determination of elemental sulphur and other copper-reactive sulphur species in petroleum products, by converting the sulphur into Cu(I) sulphide by treatment with copper powder, filings or turnings.

EXPERIMENTAL

Reagents

The petroleum products were obtained locally. Pure copper powder (BDH) was used.

Determination of sulphur in kerosene

Reflux 200 ml of kerosene with 100 mg of copper powder in a 500-ml round-bottomed flask for about an hour. The sulphur present forms black Cu(I) sulphide, which separates out along with unused copper. Cool the mixture to room temperature, then distil off nearly all of the kerosene (150–170°), in a rotary evaporator, and let the slightly wet solid ($Cu + Cu_2S$) cool to room temperature. Retain the distillate for future use (see below). Fit an assembly having a nitrogen inlet, a dropping funnel and a reflux condenser to the flask. Attach the top end of the condenser to a bubbler holding 250 ml of a cadmium hydroxide suspension (30 ml of 2*M* sodium hydroxide + 10 ml of 10% cadmium acetate solution + 210 ml of distilled water). Pass nitrogen through the flask and then the bubbler. Add 10–15 ml of 67% hydriodic acid through the dropping funnel and heat the contents of the flask to reflux temperature. The hydrogen sulphide thus liberated is swept out by the nitrogen stream and trapped as cadmium sulphide in the suspension in the bubbler. After an hour, the flask is cooled and the yellow cadmium sulphide is determined after iodimetrically acidification of the solution.

Any polysulphides present will react similarly to elemental sulphur and the result will correspond to the sum of the two species.

Determination of sulphur in gear oil/lubricating oil

In a 100-ml round-bottomed flask place 50 ml of the kerosene that has been distilled during determination of its free sulphur content (as above), and add 20 ml of gear oil, 100 mg of copper powder and a Teflon-covered magnetic follower. Reflux the mixture for 1–2 hr. Distil off most of the petroleum oils and complete the analysis as already described.

Determination of sulphur in diesel and furnace oil

Analyse in the same way as gear and lubricating oils. The diesel oil mixture with Cu_2S/Cu froths during the refluxing with hydriodic acid, but this does not hinder the estimation.

RESULTS AND DISCUSSION

From the results in Table 1, for analysis of various samples, it can be seen that elemental sulphur dissolved in these petroleum oils can be completely removed and determined by treatment with copper. Secondly, kerosene has been found to be a very good solvent for sulphur, and copper reacts quantitatively with sulphur in this solvent. In the previously reported method,[1] benzene and acetonitrile were used as solvents. This study indicates that kerosene can also be employed, and kerosene free from copper-reactive sulphur is conveniently obtained in the course of its analysis for sulphur. Petroleum ether (b.p. 40–60°) can also be used as the solvent. To ascertain whether organic sulphur compounds react with copper in kerosene, experiments were done in which copper powder was treated with carbon disulphide, dimethyl sulphide, dimethyl sulphoxide, mercaptoacetic acid, thiourea and trimethylene thiourea. The samples were refluxed for 2 hr, cooled to room temperature and then treated with excess of hydriodic acid and boiled. It was observed that carbon disulphide, dimethyl sulphide and dimethyl sulphoxide underwent hardly any reaction with either copper or hydriodic acid, whereas thiourea, trimethylene thiourea and mercaptoacetic acid

Table 1. Determination of uncombined sulphur in some petroleum oils

Sample	Oil	Amount, *ml*	Sulphur, *mg* Present	Found
I	Kerosene Sample I	200	Not known	4.16
		200	Not known	4.20
	Kerosene Sample II	200	Not known	5.92
		200	Not known	5.98

†A saturated solution of sulphur in kerosene at 30°.

underwent partial reduction to hydrogen sulphide (20–30%) when heated with hydriodic acid, but gave no reaction with copper. It is important to note that elemental sulphur does not undergo reduction with hydriodic acid even on boiling. Thus, the results of reaction with and without copper could be followed by the hydriodic acid treatment, used as a differentiating test to detect and determine elemental sulphur (and or polysulphides) in a sample. Organic polysulphides underwent partial reaction with copper on boiling; presumably by reaction with the thermally cleaved sulphur.
