(Received 6 April 1990. Accepted 28 June 1990)

Summary—Recent trends in the use of chemically modified electrodes (CMEs) in electrochemical detection systems used in flow-injection analysis or high-performance liquid chromatography are reviewed, with the objective of indicating the most promising approaches for practical CME applications. Four specific application areas of CMEs are identified: (1) those using perm-selective coatings to enhance selectivity and inhibit surface fouling, (2) those using immobilized electron-transfer mediators to catalyse slow electrode reactions, (3) those using enzymes as modifiers to provide biological activity on the electrode surface and (4) those using ion-exchange coatings for the electrochemical detection of non-electroactive anions and cations. By virtue of these approaches, the judicious use of CMEs has already had a significant impact on the performance and scope of electrochemical detection in flow systems. The most important improvements have been in CME selectivity, which produces simpler assay procedures with less need for sample treatment, and increased usefulness for complex samples, and in CME reactivity, which expands the range of analytes amenable to electrochemical monitoring.

Although the idea of chemically modified electrodes (or CMEs) was first demonstrated systematically only in the early 1970s, this approach has assumed a dominant position in modern electrochemistry. These electrodes, which are made by incorporating specific chemical groupings or "microstructures" on otherwise conventional electrode surfaces, are of interest because their responses have two completely separate components: the usual electrochemical component determined by the potential at which the electrode is maintained instrumentally and an additional chemical component determined by the reactivity of the attached group. Consequently, CMEs offer not only easily variable redox characteristics but also the possibility of adjustable physical and chemical properties (such as charge, polarity, chirality, permeability). Therefore, to a much greater extent than is possible with classical or "unmodified" electrodes, CMEs can be targeted for a specific application or investigation and rationally designed to provide an optimal environment for that task.

Pioneering studies demonstrating the varied synthetic approaches by which modifiers can be

incorporated and the useful properties and applications that can result from modification have been the subject of several reviews.¹⁻⁵ In addition, hundreds of papers per year are published on CMEs. Of the disciplines directly affected by these developments, analytical chemistry is certainly one of the foremost; and virtually all the important analytical properties of electrodes—sensitivity, selectivity, reproducibility and even applicability—have been shown to be capable of enhancement by the judicious use of chemical modification. For example, CMEs capable of extremely selective binding and preconcentration of trace metals have been developed by utilizing well-known chelating agents such as EDTA and dimethylglyoxime as modifiers. Alternatively, effective rates of electron transfer have been improved for numerous compounds by attachment of electrocatalytic functional groups to the electrode surface. A few specific modifications—for example, the deposition of a polymer film such as Nafion—have been so successful that their use has become nearly routine. However, most modifications, although often well-conceived, offer advantages which have not yet been exploited in practical analysis.

*Author for correspondence.

The applications in which CMEs are probably closest to success in solving practical analytical problems are as amperometric detectors in flow-injection analysis (FIA) and liquid-chromatography (LCEC) systems. Over the past 20 years, the use of conventional electrodes for this purpose has become well established as an analytical technique offering extremely high sensitivity for analytes that are electroactive at modest potentials.⁶ For example, LCEC with glassy-carbon electrodes has become the method of choice for the determination of many easily oxidized biochemical compounds such as catechols, phenols and aromatic amines. As a result, LCEC instrumentation has become commercially available from several companies and is commonly used in analytical and clinical laboratories throughout the world.

Recently a diverse range of CMEs has begun to be applied in both flow-injection and liquid-chromatography systems to achieve impressive enhancements in electrode performance. The most important of these studies to date have involved the use of perm-selective coatings to enhance selectivity or inhibit electrode fouling, the use of bound electron-transfer mediators to catalyse slow electrode processes, the use of protein and enzyme modifiers to provide biological activity and the use of ion-exchange coatings for the electrochemical detection of non-electroactive ions. In this survey we will review some of the most interesting recent work and attempt to indicate some of the most important directions which the field is likely to take. We will begin by briefly examining the fabrication of CMEs and the most important CME characteristics for quantitative flow-stream applications, and then summarize specific applications from the past few years. As will be seen, the capabilities of CMEs can be imaginatively employed to enhance the analytical performance and scope of electrochemical detection in flow systems.

CONSTRUCTION OF THE ELECTRODES

Over the past 15 years, dozens of individual procedures have been reported for the immobilization of hundreds of different species on various electrode materials.^{1,2} However, virtually all these procedures are based on only a few approaches:

(1) direct adsorption of the modifier onto the bare electrode surface;

- (2) covalent binding of the modifier to a specific surface site;
- (3) physical coating of the electrode surface with a polymer that contains the modifier grouping;
- (4) mixing of a slightly soluble modifier with a conductive matrix (such as a carbon paste).

Each of these general approaches has been well characterized experimentally and thoroughly reviewed and discussed in the literature, so detailed description is not necessary here. Suffice it to say that several synthetic routes are likely to be available for the surface attachment of most modifiers and that some flexibility in choosing or designing an attachment method should usually be possible. This is especially important in usage of CMEs in analytical applications, because of the stringent demands on electrode stability and reproducibility if the electrode is to be of use in routine determinations.

The ideal CME for analytical applications involving continuous, long-term operation in a flow system should possess most of the following characteristics: good mechanical and chemical stability of the electrode substrate, the modifier and the electrode-modifier linkage; good short-term reproducibility and long-term stability of the modifier's activity towards the analyte; flexible modifier loading levels; a wide dynamic range (ideally linear) of response; low and stable background currents over the potential range required; compatibility with a wide range of aqueous and organic matrices; simple and reliable fabrication that results in consistency of response from one electrode to another. These properties are mainly those desired for a conventional electrode, plus the requirements regarding the attachment and activity of the modifier. Obviously, a CME that takes longer to prepare than it lasts in use, or has an activity which is fleeting or irreproducible, possesses very limited appeal for the analyst.

Of the four methods listed above, the last two—mixing with carbon paste and coating with a functionalized polymer—seem to approach most closely this set of ideal characteristics. The carbon-paste approach is undoubtedly the easiest method of fabrication and provides for rapid and acceptably reproducible generation of fresh modified surfaces. Relatively large batches of modified paste can be prepared in a few minutes by

simply hand-mixing appropriate portions of modifier, graphite powder and organic binder. Moreover, such mixtures can be packed into an electrode assembly, used and then provided with a new surface by extrusion and repolishing to give the same reproducibility (2–5% variation) as ordinary carbon paste. In practice, this method is limited to use in predominantly aqueous solvents (to keep the carbon paste intact) and to use of modifiers possessing only slight solubility in water. An interesting variation, suggested initially as a means of overcoming the solubility limitation, involves mixing the modifier with solid matrices such as graphite epoxy⁹ and polystyrene containing either carbon particles¹⁰ or carbon fibres.¹¹ Although this method for the construction of solid composite CMEs has not yet become widely used, its potential utility for flow applications in both aqueous and organic solvent systems is readily apparent.

The polymer-based approach is somewhat more difficult to execute, because it requires a means of including the modifier group in the polymer to be deposited on the electrode. However, once this has been accomplished, the CMEs can usually be formed from the bare electrode and functionalized polymer by simple and straightforward procedures such as dip-coating and evaporative deposition. In some instances, the polymerization and modification steps can be conveniently combined in a single electro-polymerization operation involving oxidation or reduction of the monomer at the bare electrode. The resulting polymer CMEs often have much greater chemical and mechanical stability than analogous carbon-paste CMEs and are able to operate in a wider range of aqueous and organic matrices. Furthermore, it is usually possible to control the thickness of the modifying polymer film, and thus the loading level of the modifier on the electrode surface, by relatively straightforward procedures. However, the ease and reproducibility of regeneration of polymer surfaces are likely to be somewhat less than for carbon-paste CMEs. When the modifier of interest (*e.g.*, metal particles^{12,13} or enzymes^{14,15}) can be stably trapped inside the polymer network, polymer-based CMEs can be constructed by simply depositing the polymer onto the electrode surface from a solution containing a dispersion of the modifier.

We have employed both these approaches with considerable success for making CMEs to be used for detection in flowing streams. Incorporation of the modifier into carbon paste can

often be used for evaluation of modifiers; but once optimization has been completed, the polymer method may be preferred for long-term applications.

APPLICATIONS

The principal improvements resulting from application of CMEs in FIA and LCEC have generally involved the use of (1) perm-selective coatings that restrict access of solute to the electrode surface, (2) electrocatalytic redox modifiers that activate the electrode toward solutes that exhibit substantial overpotentials, (3) enzymes and related biomolecules as modifiers as a means of incorporating specific biological activity and (4) electroactive polymer films for the electrochemical detection of non-electroactive ionic analytes. Each of these application areas will be considered in turn. While striving for a degree of completeness in this survey, our primary goal has been to focus on very recent CME applications that appear to have immediate potential for use in practical analysis. With this emphasis in mind, we have chosen to omit consideration of several CMEs which, despite exhibiting interesting properties, seem unlikely to offer useful FIA or LCEC applications.

Perm-selective mass transport

Two related ideas, both of which derive from coating the electrode with a thin semi-permeable membrane, form the basis of the applications included under this classification. First, this kind of modification may improve the selectivity of response if the membrane coating preferentially excludes some electroactive species from the electrode surface. Secondly enhanced stability and reliability can be obtained if the solutes excluded would otherwise be adsorbed on the bare surface and foul it; in these cases, electrochemical methods may be applied directly to samples which would normally require extensive pretreatment for removal of the adsorbable material.

The membranes concerned consist of polymer films coated onto electrodes made from conventional materials. The films themselves must be relatively thin (a few μm in thickness) so that transport of the analyte to the electrode surface is not too restricted. However, as even monolayers will decrease transport of the analyte to some degree, the optimal thickness

always reflects a compromise between the efficient exclusion of interfering species and the free and rapid diffusion of the analyte that is required to avoid peak broadening and tailing effects detrimental to practical analysis in flow systems. Most important, of course, are the particular structural features of the membrane that determine its permeability and, therefore, the CME selectivity. Most commonly, these include the presence of fixed anionic or cationic sites in the membrane, the existence of well defined hydrophobic or hydrophilic regions and the maximum pore size available for internal diffusion through the film. As a result, the selectivity of transport at the CME can normally be related to solute charge, polarity and molecular size or shape. Thus, the frequently studied Nafion, which is a non-crosslinked perfluorinated polymer containing strongly acidic sulphonate groups, is permeable to cationic and neutral species and excludes anions rather well. This capability, which has most notably been taken advantage of to facilitate the *in vivo* determination of catecholamines in the presence of high levels of ascorbate,¹⁶ has been thoroughly studied in terms of the effects of buffer cation and concentration, pH, polymer film thickness and concentration of organic solvent in the medium.¹⁷ Conversely, the use of cationic polymers such as polyvinylpyridine (protonated at $\text{pH} < 6$) has been shown to alter the CME selectivity to favour negatively charged analytes.¹⁸

Perhaps the most interesting CMEs in this category are those utilizing a coating of cellulose acetate. This polymer, initially suggested for use in LCEC applications by Sittampalam and Wilson¹⁹ and subsequently exploited extensively by Wang and co-workers^{18,20-22} is uncharged and therefore shows no preference for anions or cations. However, it undergoes slow hydrolysis and pore formation when exposed to alkaline media. Thus, by variation of the pH and duration of the hydrolysis, the pore size of the polymer coating can be controlled so that access to the electrode surface is restricted to molecules smaller than a limiting size (or with suitable shape). For example, only small species such as H_2O_2 may be able to pass an unhydrolysed cellulose film efficiently,¹⁹ whereas substantially larger analytes such as phenol, acetaminophen and ascorbic and uric acids are able to reach the electrode surface and contribute to the current through a coating hydrolysed for 30 min in dilute potassium hydroxide solution.²⁰ In both

cases, however, the ability of the cellulose polymer to resist fouling by macromolecules is sufficiently preserved in a flow-stream for repeated exposure of the coated electrode to the levels of proteins found in physiological matrices to result in little or no decrease in sensitivity. In a very recent report²³ it was shown that a poly(3-methylthiophene) coating formed by electro-polymerization of the monomer onto glassy carbon largely eliminated the electrode fouling problem that occurs upon electro-oxidation of phenols. Two explanations for the success of this CME were offered. One was that the polymeric products formed by oxidation of phenols tend to be less adsorbed than on a bare metal or carbon electrode. Alternatively, the structure of the coating might be such that processes leading to dimerization (and eventual polymerization) of the initially formed phenoxy radicals are substantially hindered. In either case, extremely stable responses to relatively high concentrations of phenol were obtained at this CME in static and flow experiments.

Selectivity can be enhanced by combining charge, size and other CME effects in bi- and multilayer electrode systems. For example, the size selectivity of a cellulose acetate coating can be supplemented by the activity of additional catalyst- or enzyme-containing layers similar to those discussed below. Examples of these and other perm-selective CME applications are given in Table 1.

Electrocatalysis by bound mediators

The basic principle involved in CME electrocatalysis by a surface-confined electron-transfer mediator is illustrated in Fig. 1 for a generalized oxidation process. In this sequence, the analyte diffuses from the bulk solution to the electrode surface, where it is oxidized in a purely chemical reaction with the oxidized form of the mediator (M_{ox}). However, the potential of the electrode is maintained at a value sufficiently positive for M_{ox} to be the stable state of the mediator and its reduced form (M_{red}) to be rapidly re-oxidized to the catalytically active form. Thus the heterogeneous electron transfer takes place between the electrode and mediator and not directly between the electrode and analyte. In essence, then, the mediator can be considered to function

Fig. 1

Table 1. CME applications based on perm-selective coatings

CME	Analyte	Summary
Cellulose acetate on platinum ¹⁹	H ₂ O ₂	The cellulose film prevented adsorption of proteins and other surface-active substances. Although the currents observed were only a twentieth of those for an equivalent bare electrode, the calibration curve for H ₂ O ₂ at the CME remained essentially constant in the presence of bovine serum albumin or undiluted serum, compared to a 50% decrease over time with an uncoated Pt electrode. In addition, the H ₂ O ₂ oxidation current was not affected by the presence of glucose and ascorbic acid at physiological levels.
Cellulose acetate on glassy carbon ²⁰	Various small electroactive compounds	The permeability of the cellulose membrane toward analytes of different molecular size was varied by hydrolysis in KOH for different times up to 50 min. In FIA the detection of phenol and acetaminophen at a partially hydrolysed cellulose film was virtually unaffected by the presence of nitrophenols and ferrocyanide, respectively. Urine samples, pretreated only by filtration and dilution, gave simplified chromatograms suitable for the direct determination of ascorbic and uric acids. In addition, the cellulose coating improved the stability of the electrode towards exposure to bovine serum albumin and passivation by phenol oxidation products.
Cellulose acetate on glassy carbon ²¹	Various small electroactive compounds	One of a pair of glassy-carbon electrodes was coated with a cellulose acetate polymer film, the permeability of which was varied by alkaline hydrolysis for different times. When both electrodes were held at the same potential and operated in the parallel-opposed configuration, the CME detection gave simplified chromatograms, showing a response for only the smaller analyte species in diluted urine samples and beer extracts. Ratios of the peak current from the coated and uncoated surfaces were used to increase selectivity and aid in peak identification.
Nafion on glassy carbon ²⁴	Catecholamine neurotransmitters	Coating the electrode with a layer of the cation-exchanger Nafion caused it to favour cationic analytes rather than anionic or neutral ones, <i>e.g.</i> , catecholamine neurotransmitters relative to ascorbic and uric acids, bilirubin and chlorpromazine. In addition to this charge selectivity, the CMEs had a decreased flow-rate dependence and therefore less noise. By combining the Nafion film with an outer cellulose acetate coating, a bilayer electrode offering both cation preference and antifouling properties was obtained. The CME was applied to the analysis of urine samples.
Nafion on glassy carbon ²⁵	Catechols and related compounds	The response of dual glassy-carbon electrodes, one bare and the other coated with a Nafion film, was examined with respect to selectivity for charged and neutral analytes and stability in flow systems. The current observed for cationic species (dopamine and epinephrine) was only slightly diminished at the Nafion CME, while that for neutral molecules (catechol and hydroquinol) was decreased to a greater extent and that for anions (3,4-dihydroxybenzoate and ascorbate) was very small. Signal dependence on Nafion film thickness, flow-rate and pH was characterized. The Nafion CME was stable in methanol (30%) and CH ₃ CN (10%) and showed no passivation from exposure to albumin.
Poly(4-vinylpyridine), PVP, on glassy carbon ¹⁸	Chlorpromazine, uric and ascorbic acids, acetaminophen	PVP films, which are cationic at pH < 6, showed highly attenuated responses to catecholamines and other positively charged species, but still exhibited large currents for anionic and neutral analytes. This effect was illustrated by LCEC of ascorbic and uric acids in human urine. Bilayer CMEs containing both PVP and cellulose films rejected both cations and large surfactant molecules such as gelatin.
Cobalt phthalocyanine and cellulose acetate on glassy carbon ²	Oxalic and ascorbic acids, N ₂ H ₄ , cysteine	A CME exhibiting both size-selective and electrocatalytic response was obtained by co-depositing sparingly soluble cobalt phthalocyanine and a cellulose film. The bifunctional CME retained the electrocatalytic activity of the cobalt complex for the oxidation of N ₂ H ₄ , oxalic acid, and cysteine, while the permeability of the modifier coating was determined by the extent of alkaline hydrolysis of the cellulose. In FIA, lower potentials could be used for detection; decreased fouling by surface-active agents such as gelatin and albumin was observed), and increased selectivity to small analytes was confirmed. As the detection limit estimated for N ₂ H ₄ was 1 μM, the presence of the coating did not significantly affect the trace analysis capabilities of the system.
Poly(ester sulphonic acid) on glassy carbon ²⁶	Catechols and related compounds	Films of the poly(ester sulphonic acid) cation-exchanger Eastman-AQ55D excluded anions while allowing and sometimes enhancing transport of cationic and neutral compounds. Stable response was obtained in FIA for acetaminophen in the presence of an excess of bovine serum albumin.
Bilayers of Nafion and collagen on gold ²⁷	Glucose	The determination of glucose at physiological levels was possible by FIA and pulsed amperometric detection at polymer-coated Au electrodes. An inner Nafion layer acted to retain OH ⁻ at the Au surface while excluding normal levels of Cl ⁻ , amino-acids and ascorbic and uric acids. An outer collagen film prevented protein penetration and adsorption. Excellent glucose response was obtained for blood serum samples.
Poly(3-methylthiophene) on glassy carbon ²³	Phenols	These CMEs exhibited good resistance to the fouling normally caused in FIA by high concentrations of phenol.

simply as an electron shuttle between the electrode and the analyte. Of course, this sequence of events represents an idealized picture, that may often be more complex in practice. For example, if the CME has a thick or multilayered modifier coating, electron transport may take place either by direct conduction through the film or by "hopping" from one modifier group to another; in either case, the mediator group specifically reacting with the analyte does not need to be in the immediate vicinity of the electrode surface. Finally, it should be apparent that corresponding, but converse, processes would be involved in an electrocatalysed reduction.

The need for mediation of this sort arises whenever the rate of direct electron transfer is slow. When this happens at an ordinary electrode, a potential in excess of the analyte's thermodynamic potential, *i.e.*, an overpotential, must be applied in order for the desired redox process to proceed at an appreciable rate. Unfortunately, in flow-injection and liquid-chromatography applications, the use of more extreme potentials affects both the selectivity and the detection limit, to an extent depending on the overpotential required. With an electrocatalytic CME, however, the oxidation (or reduction) of the analyte is made to take place at the redox potential of the mediator. This must, of course, be higher than the analyte's thermodynamic potential, but in favourable cases can be 500 mV or more lower than that needed when the bare electrode is used. Decreases of this magnitude in the applied potential can substantially improve the analytical performance. In particular, decreased detection potentials can be expected to result in improved detection limits and greater selectivity, because of the lower noise levels and restricted range of sample components electrolysable at the lower potentials. More important, however, are the instances where the changes in potential made possible by electrocatalytic effects permit electrode processes that would normally occur at potentials near or beyond those for solvent breakdown to be shifted to a practically useful range of applied potential. In these cases, the advantages of LCEC can be extended by electrocatalytic CMEs to new groups of compounds that give no analytically useful response at ordinary electrodes.

The solution-phase electrocatalysis of many important substrates has been studied quite extensively, and a great deal of chemical

information relevant to the selection of electrocatalytic mediators as electrode modifiers is available. Certainly, CMEs applied to electrocatalysis studies in static media have successfully employed mediators of all varieties, both organic and inorganic.^{1,2} However, studies involving FIA or LCEC have been much more limited, primarily employing a few well-known metal-based catalysts as modifiers. These include, most notably, cobalt phthalocyanine in carbon paste²⁸⁻³⁷ and inorganic ruthenium polymer electro-deposited onto either platinum or glassy carbon.³⁸⁻⁴² These particular modifiers have been the most frequently used because, in addition to their catalytic activity towards a wide variety of analytes, both possess very limited solubility and therefore can be placed very stably onto electrode surfaces for flow applications. For the cobalt phthalocyanine CME, the response of which is initiated by electro-oxidation of the Co(II) centre to Co(III), analytes determined by FIA or LCEC have included hydrazine, thiols, oxalic acid, α -keto-acids, carbohydrates (mono- and polysaccharides), ribonucleosides, alditols and aldonic, uronic and aldaric acids. At the ruthenium-based CME, where the mediator redox process is the oxidation of Ru(II) to Ru(III), analytes have included As(III), thiocyanate, hydrazine and, most recently, several thiols, including cysteine, glutathione and the 50-amino-acid hormone insulin. A strength of all the electrocatalytic CME systems summarized in Table 2 is that they typically offer very low detection limits, usually in the nanogram range.

Finally, some mention should be made of a group of metal oxide electrodes which, although not technically CMEs, bear some similarity to them in their very extensive LCEC applications. The metals of interest here include Pt,⁴⁸⁻⁵⁰ Au,⁵¹⁻⁵⁴ Ni,⁵⁵⁻⁵⁸ Cu⁵⁹⁻⁶² and Ru.⁶³ With the noble metals Pt and Au, the major function of the oxide or hydroxide layer is thought to be to provide a catalytic surface capable of dehydrogenation or oxygenation reactions with the analyte species. Invariably, the products of these anodic processes are strongly adsorbed on the metal and lead to a rapid loss of signal by blocking the surface sites necessary for further oxidations. Removal of the passivating film and re-activation of the electrode is most easily accomplished by applying an oxidizing potential. Thus, stable long-term operation of Pt and Au electrodes nearly always requires the use of regularly pulsed potential waveforms that must

be supplied by the control instrumentation. With Ni, Cu and Ru, the oxide layer apparently serves both electrocatalytic and passivating functions and allows the operation of the electrode at potentials where the bare metals would undergo rapid oxidation. Fouling by oxidation products is generally not a significant problem here, and detection can be done at constant potential. Thus, in a very broad sense, these oxide films, generated *in situ* by a combination of potential and solution conditions, might be considered as electrode modifications designed to impart catalytic and passivating properties. Inclusion of these "CMEs" in this survey is justified for this reason and because of the impressive success of this approach in producing highly sensitive amperometric detection for several families of compounds not otherwise amenable to electrochemical monitoring. The most notable analytes detectable with the metal oxide electrode systems are the carbohydrates and related chemical families. However, attractive detection capabilities for other important analytes (*e.g.*, amino-acids) have also been observed.^{49,50,54,56,59} Metal oxide electrodes nearly always provide their optimum performance in strongly basic solution, often giving detection at or below the nanogram level.

Biological activity

Recent advances in the study of biological molecules and processes have had an enormous impact on many areas of chemistry, not the least of which is electroanalysis. First, there is an immediate need to devise and develop analytical methods suitable for the identification and quantification of a vast array of biologically important molecules. At the same time, there is a great opportunity for improving the analysis by taking advantage of the unique reactivity and recognition properties possessed by these same biomolecules. Thus, it is not surprising that recent years have witnessed a great deal of activity related to the design and application of electrochemical sensors, often incorporating biologically active molecules or structures, for use in a wide variety of bio-assays. The principal approaches, including those utilizing CMEs, have been reviewed by Frew and Hill.⁶⁴

The focus of virtually all CME utilization for bioanalysis has been the development of electrodes exhibiting improved electrochemical activity towards biomolecules, especially enzymes. When coupled with FIA or LCEC, this "improved reactivity" has been directed to

the determination of either the enzymes themselves or their substrates. These studies, listed in Table 3, will be considered in this section.

In the simplest approach, a CME with a surface-bound moiety capable of promoting or catalysing the oxidation or reduction of the protein of interest is used to determine it. Modification is necessary because, in spite of the fact that many enzymes and proteins contain functional groups that can readily be oxidized or reduced by purely chemical agents, most such molecules do not undergo facile oxidation or reduction at conventional electrodes. The electroactive centre is often shielded within the protein's extended three-dimensional structure and cannot gain access to the electrode surface. Alternatively, strong adsorption of the protein can occur and cause the electrode surface to become passivated. In both cases, the problem may often be solved by the use of CMEs. For example, in an extension of work on static systems by Eddowes and Hill⁶⁵ and Taniguchi *et al.*,⁶⁶ Schlager and Baldwin⁶⁷ showed that a gold electrode coated with a 4,4'-dipyridyl disulphide film can be used at very low potentials for the LCEC of cytochrome *c*. Apparently, the pyridyl groups on the CME can promote the protein redox reaction by interacting with positively charged lysine residues on cytochrome *c* and orienting the protein's haem group favourably for direct electron transfer to the electrode surface. The same research group later demonstrated that incorporation of traditional organic electron-transfer mediators can be used to make electrocatalytic CMEs for the haem-containing proteins myoglobin and haemoglobin⁶⁸ and for the copper protein ceruloplasmin.⁶⁹ In these studies, stable and sensitive detection with limits in the 1–10 pmole range was generally obtained. On the basis of these results, it would appear that CMEs tailored for other redox proteins might be similarly conceived and constructed for flow applications. A straightforward approach to protein detection would be to employ the dozens of electron-transfer mediators already in use for solution-phase oxidation or reduction of these biomolecules.⁷⁰

Apart from the above-mentioned work, which was focused on detection of the proteins themselves, several other studies have attempted to incorporate the enzymes into CME systems for the purpose of detecting the enzyme substrate. The principal attraction of this approach is that it allows the inherently high *sensitivity* of electrochemical detection to be combined with

Table 2. CME applications using electrocatalytic modifiers

CME	Analyte	Summary
Cobalt phthalocyanine (CoPC) in carbon paste ²⁸	N ₂ H ₄	The catalytic oxidation of hydrazine at this electrode was employed in FIA. Detection was performed at -0.1 V vs. Ag/AgCl in 0.20 M NaOH, which is several hundred mV less than that required at an unmodified carbon electrode. Linear response was observed for N ₂ H ₄ concentrations from 10^{-8} to 10^{-3} M, giving a detection limit of less than 1 pmole. The CME response in NaOH was stable for 7–8 hr and was not seriously degraded by operation in 10% CH ₃ OH or CH ₃ CN.
CoPC in carbon paste ^{29,30}	Thiols, including cysteine, homocysteine, N-acetylcysteine and glutathione	The CME catalysed the electro-oxidation of thiols at $+0.75$ – 0.85 V vs. Ag/AgCl. Used in conjunction with reverse-phase chromatography, the CME exhibited linear response for cysteine from 2.7 to 270 pmole. Individual electrodes were sufficiently stable for a full day of continuous use and surfaces could be reproduced with a relative standard deviation of 7%. LCEC assay procedures using the CME were developed for cysteine and glutathione in whole blood and plasma. The levels of these compounds determined by the CME approach fell within the expected ranges for normal blood samples. The only sample treatment steps required were protein precipitation and filtration.
Glassy carbon coated with (a) a ruthenium oxide/hexacyanoruthenate film or (b) a poly(4-vinylpyridine) film containing hexachloroiridate ^{31,43}	(a) As(III) (b) NO ₂ ⁻	In (a) the CME catalysed the oxidation of As(III). In FIA, linear calibration from 5×10^{-6} to 2×10^{-4} M and a detection limit $< 1 \mu$ M were obtained. Excellent reproducibility and stability were observed. In (b), NO ₂ ⁻ oxidation at CMEs containing a quaternized poly(4-vinylpyridine) film impregnated electrochemically with hexachloroiridate catalyst was examined. Short-term instability due to surface passivation was improved at the CME. However, day-to-day stability and reproducibility were less than desired.
CoPC in carbon paste ³¹	Thiopurines	Assay procedures were developed for 6-mercaptopurine, 6-thioguanine and related thiopurines in blood plasma. Sample preparation was minimal and total analysis time (including reversed-phase chromatography) was less than 10 min. Detection limits were 1.5–8 pmole, approximately an order of magnitude better than those obtained with UV absorption or fluorescence detection.
CoPC in carbon paste ^{32,33}	Oxalic acid and α -keto-acids including pyruvic, phenylpyruvic, α -ketobutyric, α -ketoglutaric, and α -ketoisocaproic acids.	The CME catalysed the oxidation of oxalic acid and α -keto-acids over the range $+0.75$ – 0.9 V vs. Ag/AgCl, which represents a roughly 500 mV decrease in overpotential compared with use of an unmodified electrode. At $+0.75$ V, the response for oxalic acid was linear from 10^{-7} to 2×10^{-3} M and gave a detection limit of 0.3 pmole. The detection limits for the α -keto-acids varied from 0.15 to 1 nmole. Assay procedures using the CME in reverse-phase chromatography were developed for oxalic acid and pyruvic acids in plasma and urine samples. Results for samples from healthy volunteers and kidney-stone patients fell within the expected ranges for both analytes. The assay procedures were attractive because relatively low detection limits were possible, and the only sample treatment required was dilution and filtration.
CoPC in carbon paste ³⁴	Carbohydrates	The electro-oxidation of sugars occurred at low potentials in strongly basic solution. The carbohydrates examined included mono- and disaccharides, pyranose and furanose rings, and reducing and non-reducing sugars. Use of this phenomenon in LCEC required that the applied potential was pulsed between $+0.4$ V (for detection) and -0.3 V (for electrode re-activation) vs. Ag/AgCl. Coupled with anion-exchange chromatography in 0.15 M NaOH, the CME provided detection limits of 100–500 pmole. The stability of the pulsed detection was such that the relative standard deviation for 40 injections over 5 hr was only 2%.
Nickel hexacyanoferrate electrochemically deposited on glassy carbon ⁴¹	Fe(III)	Fe(III) reduction, which is generally irreversible and irreproducible at bare glassy carbon, was catalysed at a CME and used for the determination of Fe(III) following separation on a chelate-loaded anion-exchange column. Because detection was at $+0.2$ V vs. SCE, there was no interference from dissolved O ₂ . The separation prevented interferences from most metal cations and common anions. The detection limit was 4×10^{-8} M, and the linear range extended from 2×10^{-7} to 9×10^{-4} M.
CoPC in carbon paste ³⁵	Carbohydrates and other polyhydroxy compounds	Electrocatalysis of carbohydrates was extended to include oligosaccharides, deoxy sugars and simple polyalcohols. Detection (with pulsed applied potential) was performed in strongly basic solution following anion-exchange chromatography. Detection limits were in the 10–50 pmole range. Sample matrices included soft drinks, beer and urine.

(a) Pt with adsorbed I ⁻ and coated with cellulose and (b) glassy carbon coated with a ruthenium cyanide film. ³⁹	SCN ⁻	Both CMEs catalysed the oxidation of SCN ⁻ at +0.7-0.8 V vs. Ag/AgCl and prevented fouling of the electrode surface by oxidation products and sample constituents. The Pt-CME had a linear response for SCN ⁻ from 5×10^{-6} to 1×10^{-4} M and was stable for several days. The Ru-based CME gave a response that was linear only over $0.2 - 4 \times 10^{-6}$ M, but was stable for more than 300 injections over 3 months. FIA of urine samples was evaluated at both CMEs; interferences by uric and ascorbic acids had to be eliminated by prior controlled potential electrolysis of the sample at +0.55 V.
Tris(4,7-diphenyl-1,10-phenanthroline)iron(II) in carbon paste ⁵	NO ₂	Attempts were made to incorporate several iron complexes into a carbon-paste CME. Of the complexes examined, tris(4,7-diphenyl-1,10-phenanthroline)iron(II) formed the most stable and reproducible CME and was chosen for further study. When used in FIA, the CME yielded anodic peaks for air samples doped with gaseous NO ₂ . The NO ₂ response, which was only 3-4 times greater than that observed at an unmodified surface, occurred at potentials more positive than +0.6 V vs. Ag/AgCl and was assigned to an electrocatalytic process involving redox mediation by the modifier. NO ₂ concentrations as low as 15 nl/l were reproducibly detected.
Glassy carbon coated with an Ru-containing poly(4-vinylpyridine) polymer ⁴⁶	NO ₂ and Ni dithiocarbamate	The CME was made by wetting a glassy-carbon surface with a solution of [Ru(bipy) ₂ (PVP) ₂ Cl]Cl and allowing the solvent to evaporate [PVP = poly(4-vinylpyridine) and bipy = 2,2'-bipyridyl]. In FIA, the CME was able to promote the oxidation of NO ₂ and several metal dithiocarbamates at high positive potentials. Although it is unclear whether simple electrocatalysis occurred, 4-10 times larger currents were obtained at the CME than at an uncoated electrode. Problems included poor electrode-to-electrode reproducibility and slow loss of the polymer in the flow-stream.
CoPC in carbon paste ⁴⁶	Ribonucleosides	The CMEs were able to catalyse the oxidation of the ribonucleosides cytidine, uridine, adenosine and guanine in strongly basic solution. Neither the purine and pyrimidine bases themselves nor 2-deoxyribonucleosides such as thymidine gave similar activity. When used in LCEC with a pulsed applied potential, the activity of the CME was very stable and reproducible. Detection limits were at the nmole level and roughly comparable to those for detection by UV absorption. Because of the selectivity of the CME, chromatograms of an RNA hydrolysate were much simpler with electrochemical detection than with UV detection at 280 nm.
CoPC in carbon paste ³⁷	Carbohydrates, alditols and acidic sugars	CoPC CMEs catalysed the oxidation of alditols and aldonic, uronic and aldaric acids similarly to that of simple carbohydrates. ^{34,35} For LCEC, detection was at +0.42 V vs. Ag/AgCl, but the potential was continually pulsed to -0.3 V to regenerate the active form of the CoPC catalyst. For anion-exchange chromatography in strongly alkaline solution, detection limits ranged from 10 pmole for the alditols up to the nmole level for some of the aldaric acids.
A mixed-valence Ru(II,III) cyanide film electro-deposited onto glassy carbon ⁴⁶	N ₂ H ₄ and mono- and dimethylhydrazines	The oxidation of hydrazine and mono- and 1,2-dimethylhydrazine was catalysed at +0.9-1.0 V vs. Ag/AgCl. For N ₂ H ₄ , FIA response was linear for concentrations from 5 to 50 μM and gave a detection limit of 2×10^{-7} M. Compared to detection of N ₂ H ₄ at CoPC-CMEs, the operation of the Ru-CME was not restricted to strongly alkaline solution and appeared to be much longer-lived. When polyaniline was co-deposited with the Ru cyanide film, the resulting CME exhibited size-selective as well as electrocatalytic properties.
Glassy carbon coated with an Ru cyanide film ⁴¹	Insulin	The CME catalysed the electro-oxidation of insulin by a mechanism presumably involving oxidation of one or more of the disulphide bonds. The catalysis, which occurs at potentials more positive than +0.9 V vs. Ag/AgCl, permitted FIA detection at or below the 10 ⁻⁷ M level.
Mn(III) meso-tetraphenylporphyrin adsorbed onto glassy carbon ⁴⁷	Ascorbic acid, acetaminophen, hydralazine, epinephrine and other biologically relevant compounds	The Mn porphyrin coated on glassy carbon promoted the oxidation of several compounds. Because the effect occurred at different potentials for different analytes, the catalysis probably involved specific interactions between analyte and modifier rather than direct charge-transfer mediation. In FIA, the primary effect of the CME consisted of 50-360 mV decreases in the potential required for oxidation of the compounds examined (relative to the unmodified electrode). A 5% decrease in response occurred over 60 injections of acetaminophen, and a linear response was obtained for hydralazine between 5 and 40 μM. The CME was used for the analysis of urine samples, where its lower operating potential should be advantageous.
Glassy carbon coated with a mixed-valence Ru oxide/cyanide film ⁴²	Cysteine and glutathione	The CME catalysed the oxidation of cysteine and glutathione between +0.9 and +1.0 V vs. Ag/AgCl. In FIA, detection limits for these compounds were below the μM level and the response was linear over about three orders of magnitude. Long-term stability was excellent, with no change in sensitivity for > 200 injections over a 2-week period.

Table 3. CME applications involving bio-active molecules

CME	Analyte	Summary
Reticulated vitreous carbon with covalently attached glucose oxidase ⁷⁷	Glucose	Glucose oxidase was immobilized onto the surface of a flow-through reticulated vitreous carbon electrode by reaction with a water-soluble carbodi-imide. In FIA, injections of glucose samples resulted in the enzymatic production of H ₂ O ₂ at the CME surface. By holding the CME at +0.9 V vs. SCE and monitoring the anodic current due to oxidation of the H ₂ O ₂ , so produced, glucose could be quantified over the 10 ⁻⁴ -10 ⁻¹ M range. The CME response was linear for glucose concentrations from 2.5 to 10mM, with a relative standard deviation of less than 2%.
Meldola Blue adsorbed on graphite ⁷¹	Glucose	NADH was oxidized electrocatalytically at the CME at 0 V vs. SCE, which was at least 300 mV less than the potential required at a bare graphite electrode. Glucose was quantified by inserting a packed-bed glucose dehydrogenase reactor ahead of the CME in a flowstream containing NAD ⁺ and measuring the NADH produced upon sample injection. The detection limit was 0.25mM, and the response was linear up to 1mM. Because of the low potential possible with the CME, potential interferences, such as ascorbic acid, uric acid and catechols, posed no problem.
4,4'-Dipyridyl disulphide adsorbed on polyvinyl-ferrocene-treated gold ⁶⁷	Cytochrome c	By use of the promoting effect of 4,4'-dipyridyl disulphide, cytochrome c could be oxidized and reduced almost reversibly. LCEC following size-exclusion chromatography gave a detection limit of 3 pmole for the reduced form of cytochrome c and a linear response over three orders of magnitude. Both redox forms of the protein were detected in human plasma pretreated only by dilution and filtration.
Meldola Blue adsorbed on graphite ⁷²	L-Lactate	The CME was used to oxidize NADH electrocatalytically at 0 V vs. Ag/AgCl. L-Lactate was determined by placing an enzyme reactor containing immobilized lactate dehydrogenase and glutamic-pyruvic transaminase ahead of the CME in the FIA flow-stream and monitoring the NADH generated upon sample injection into a mobile phase containing NAD ⁺ and glutamate. Linear response was observed in the concentration range 10μM-1.5mM. System response was rather stable, the limiting factor being the slow loss of modifier from the CME surface over the course of a few days.
Nile Blue adsorbed on graphite ⁷³	Xylose and xylulose	In the presence of xylose or xylulose, NAD ⁺ could be converted into NADH by means of a mixed-bed enzyme reactor containing xylose isomerase, mutarotase and glucose dehydrogenase. The NADH so generated was detected by oxidation to NAD ⁺ at 0 V vs. SCE at the electrocatalytic CME. In FIA, this system exhibited a linear response to both sugars from 5μM to 2mM and gave a maximum throughput of 30 samples/hr.
Carbon paste containing banana pulp ⁷⁹	Dopamine	A carbon-paste CME constructed by mixing a measured amount of banana tissue into the paste matrix illustrates a simple and effective approach for building enzymatic activity into an electrode surface without the use of isolated enzymes. Polyphenoloxidase in the banana catalysed the conversion of dopamine into dopamine quinone, which was detected amperometrically by its reduction to dopamine. In FIA, a detection limit of 1.3 × 10 ⁻⁹ M was realized, and the response was linear over nearly two orders of magnitude. In addition to its high selectivity, the principal strength of this CME was that, by incorporating the biocatalyst so intimately at the electrode surface, analyte diffusion requirements were greatly reduced compared to those with conventional tissue-based electrodes; therefore, response times were of the order of seconds rather than minutes.

Methylene Blue adsorbed on graphite ⁶⁸	Myoglobin and haemoglobin	Phenothiazine mediators, including Methylene Blue and thionine, were adsorbed on spectroscopic graphite electrodes and used to catalyse the reduction of haem-containing proteins at potentials from -0.1 to -0.2 V <i>vs.</i> Ag/AgCl. In FIA, the detection limit for myoglobin was 10 pmole, and response was linear between 20 and 2800 pmole. For haemoglobin, the limit of detection was slightly higher and the linear range somewhat smaller. In size-exclusion chromatography, detection with the CME, which maintained 90% of its activity over an 8-hr period of use, was comparable to that by UV absorption.
Carbon paste containing horseradish root tissue ⁶⁹	H ₂ O ₂	Mixing horseradish root into carbon paste produced an electrode surface that could perform the horseradish-peroxidase-catalysed reduction of H ₂ O ₂ . The reaction also requires the presence in solution of a suitable reducing agent such as <i>o</i> -phenylenediamine. In FIA, H ₂ O ₂ levels were determined by amperometric reduction of the di-imine oxidation product at 0.2 V <i>vs.</i> Ag/AgCl. A detection limit of 3×10^{-7} M H ₂ O ₂ and a linear range up to 1.2×10^{-4} M were observed. Excellent reproductibility and response times of the order of 10 sec were obtained.
Anthracene-ferrocene ester and glucose oxidase adsorbed on graphite ⁷²	Glucose	The modifier had a dual function: the anthracene group was strongly adsorbed on the graphite substrate to immobilize the modifier, while the ferrocene moiety was able to mediate the electron transfer with glucose oxidase. Subsequently, glucose oxidase itself was adsorbed on top of the anthracene-ferrocene derivative. In FIA, the CME exhibited an anodic response for glucose at the redox potential of the ferrocene compound. This response was suitable for glucose detection from 50 μ M up to 1.5 mM. Because the enzyme itself was electroactive at this CME surface, detection could be performed without the addition of an oxidizing agent or co-factor to the mobile phase.
Bis(benzophenoxazine) derivative adsorbed on graphite ⁷⁴	Mono- and oligosaccharides	A CME containing an immobilized phenoxazine gave electrocatalytic oxidation of NADH at 0 V <i>vs.</i> Ag/AgCl. Carbohydrate samples were first separated on a Ca-loaded ion-exchange column and then passed through two enzyme reactors containing amyloglucosidase and glucose dehydrogenase/mutarotase. NADH formed in the latter enzymatic process was detected at the CME located downstream. Sugars up to maltohexose were quantified at the 100–300 ng level in samples including soft drinks, beer and fermentation broths.
Polyaniline electro-deposited onto glassy carbon ⁶⁹	Ceruloplasmin	The similarity of the structure of polyaniline to that of several phenylenediamine compounds used as solution-phase electron-transfer mediators for redox proteins suggested that a CME containing this easily formed polymer might display useful electrocatalytic behaviour in FIA and LCEC. This prediction was upheld for the copper protein ceruloplasmin, which underwent reduction at approximately 0 V <i>vs.</i> Ag/AgCl. The reduction, which was greatly enhanced by the addition of modest Fe ²⁺ concentrations to the mobile phase, permitted quantification of as little as 2 pmole of ceruloplasmin. In conjunction with size-exclusion chromatography, the CME was able to determine physiological levels of the protein in human serum.
Glucose oxidase and platinum particles co-deposited onto carbon fibres ⁸¹	Glucose	This CME was constructed by electrochemically reducing hexachloroplatinate from a solution also containing glucose oxidase. In the presence of glucose, the enzymatic reaction at the CME resulted in the production of H ₂ O ₂ , which was oxidized with low overpotential at the platinum metal. Glucose concentrations as low as 1.3×10^{-7} M were accessible with a relative standard deviation of 3%, and continued monitoring with the same surface was possible for at least 20 days.
Horseradish peroxidase adsorbed on spectroscopic graphite ⁷³	H ₂ O ₂	Horseradish peroxidase was adsorbed strongly onto a spectroscopic graphite surface to form a functional CME. Upon addition of H ₂ O ₂ , broad reduction at peak potentials from $+0.6$ to -0.2 V <i>vs.</i> Ag/AgCl were observed at the CME without the addition of any solution-phase mediator. From this, it was concluded that efficient reduction of the oxidized form of the peroxidase must be possible at the bare graphite surface. In FIA, linear response was obtained at 0 V for H ₂ O ₂ concentrations from 0.5 to 250 μ M. After an initially rapid decline in activity, the CME lost its response only slowly as H ₂ O ₂ injections continued.
Horseradish peroxidase covalently attached to tin oxide ⁷⁸	H ₂ O ₂	H ₂ O ₂ was reduced at the CME in the presence of a dissolved ferrocene or ferrocyanide mediator. In FIA, determination of H ₂ O ₂ was possible down to 10^{-7} M.

the unparalleled *selectivity* of enzyme reactions in a single relatively simple sensing unit. In the simplest of these approaches, the enzyme is immobilized in a packed-bed reactor placed in the flow-stream ahead of the CME. When the enzyme substrate passes through the reactor (along with appropriate co-factors), the products of the enzymatic reaction are carried to the sensing electrode for detection. The role of the CME is to provide an electrocatalytic response to the product or co-factor, that will be related to the initial substrate concentration. Most commonly, the species detected has been the co-enzyme nicotinamide adenine dinucleotide (NADH) which exhibits a large overpotential at ordinary carbon electrodes. In particular, β -D-glucose has been detected by use of immobilized glucose dehydrogenase and a CME containing the phenoxazine dye Meldola Blue,⁷¹ L-lactate by use of immobilized L-lactate dehydrogenase and a Meldola Blue CME,⁷² xylose and xylulose by use of immobilized xylose isomerase, mutarotase, and glucose dehydrogenase and a CME containing the phenoxazine Nile Blue,⁷³ and glucose, xylose and several maltose oligomers by use of immobilized amyloglucosidase, glucose dehydrogenase and mutarotase and a bis(benzophenoxazinyl)-containing CME.⁷⁴

A similar, but more sophisticated, approach has been explored in several studies in which the enzyme is bound directly on the CME surface instead of separately in a preceding reactor bed. This is directly analogous to the numerous "enzyme electrodes" that have been developed and have become commercially available over the past 10–15 years.^{75,76} In both cases, a bio-active component, initially an enzyme but more recently an intact organism or tissue sample, is used to transform the analyte with a high degree of selectivity into a product that is easily measured potentiometrically or amperometrically. The primary differences in the CME approach are that the detection mode is always amperometric and that the enzyme or organism is always incorporated as an integral part of the active electrode surface and not just held in the vicinity of the electrode by a membrane or polymer sheath. The earliest example of the CME method, reported by Yacynych, involved the determination of glucose by oxidation of the H_2O_2 produced at a CME with covalently attached glucose oxidase.⁷⁷ Subsequently, Tatsuma *et al.* were able to detect H_2O_2 with a tin oxide electrode coated with covalently

attached horseradish peroxidase. Wang and Lin described stable, easily fabricated carbon-paste CMEs with added banana⁷⁹ and horseradish root⁸⁰ tissues, which were suitable for the FIA detection of dopamine and H_2O_2 , respectively; these electrodes, analogous to the bacteria- and tissue-based probes developed by Rechnitz's group⁷⁶ made use of the enzyme systems present naturally in the plant tissues to metabolize the target analytes and generate electroactive products. Finally, Wang *et al.*⁸¹ have recently reported a glucose-responsive micro-CME constructed by co-depositing glucose oxidase enzyme and platinum particles onto 7- μ m diameter carbon fibres.

The ultimate enzyme-based CME would combine these two approaches by not only immobilizing the enzyme at the sensing electrode surface but also incorporating an electrocatalyst capable of mediating the enzyme's own redox process. This arrangement would not only provide a relatively rapid measurement procedure but, more importantly, would eliminate the need for addition of any co-enzyme or solution-phase redox agent to the mobile phase. Such CME systems, suitable for glucose and H_2O_2 detection, have been developed by Gorton and his group.^{82,83} These electrodes consist of the familiar glucose oxidase adsorbed onto graphite along with a ferrocene/anthracene adduct that serves to mediate the enzyme's charge transfer reaction at the graphite surface,⁸² and horseradish peroxidase also adsorbed onto graphite but with no added mediator.⁸³

Detection of non-electroactive analytes

In these detection schemes, the analytes are ions which are electrochemically inactive but can, under properly controlled conditions, influence the electrochemical behaviour of redox pairs attached to a CME surface. Anions, for example, can be detected at polymer films containing fixed redox centres which acquire a positive charge upon oxidation. For oxidation of the polymer to occur to an appreciable extent, the associated build-up of positive charge in the film must be counterbalanced by the migration of anions across the electrode-solution interface. This ion-doping process and the corresponding undoping that occurs when the oxidized sites are reduced are shown in Fig. 2 for a polypyrrole film.

Application of this phenomenon in FIA or LCEC is straightforward. If such an electrode is

Fig. 2

placed in a flow-stream and an oxidizing potential is applied, oxidation of the film occurs only when anions capable of penetrating it are present in the surrounding solution. Thus, a transient anodic current, or chromatographic peak, results upon passage of a sample containing such anions. In the ideal case, the magnitude of this current is related directly to the concentration of the anion concerned. Furthermore, if the film exhibits unequal permeability toward different anions, its response may provide some selectivity; this is often the case, with small singly-charged ions generally giving the best sensitivity. In order to ensure that oxidation of the film does not take place prematurely, the mobile-phase electrolyte should not be capable of effectively penetrating the film. This is normally accomplished by using electrolytes with anions that are either zwitter-ions or very bulky.

For this purpose, CMEs formed with two different polymers, polypyrrole^{84,85} and polyaniline,⁸⁶ have been utilized for anion detection. Both of these CMEs enable the quantification of micromolar levels of common anions, including halides, acetate, carbonate and phosphate. However, the polyaniline-based system appears preferable in that it is more stable, operates at a considerably lower potential, and allows the undoping process to take place spontaneously without application of a strongly reducing potential.

The detection of non-electroactive cations can be realized by the analogous scheme involving the formation of negatively charged sites in a reducible polymer film and the subsequent migration of cations from solution. In fact, the first demonstration of the potential analytical utility of the ion doping/undoping process utilized an Ag(I)-Mo(CN)₈ film for the determination of potassium by cyclic voltammetry.⁸⁷ Very recently, electrodes coated with zeolite-like hexacyanoferrate deposits have been shown to be very effective for the uptake and detection of alkali-metal and ammonium ions in both static and flow experiments.⁸⁸⁻⁹¹ On reduction of the hexacyanoferrate, these films act as cation-exchangers and preferentially incorporate cations with the smallest hydrated radii. This

coupling between ion-exchange and the redox state of the film allows sensitive detection of passing cations when the electrode is placed in a flow-stream. A unique aspect of these systems is that the nature of the incorporated cation noticeably alters the redox potential of the hexacyanoferrate centres, most likely because of changes in the microstructure of the film induced by intercalation of specific ions.⁸⁸ Thus the potential required for detection is less negative for Cs⁺ than for K⁺ and a significant degree of selectivity among these ions can be achieved in flow systems by control of the potential.^{90,91}

Examples of this approach for both anion and cation detection are summarized in Table 4. Its most attractive application appears to be in ion-chromatography, as a simple alternative to conductivity detection. Although not yet able to match the highest sensitivities reported for the conductivity method, the amperometric CME-based approach described here clearly renders unnecessary the use of secondary suppressor columns ordinarily recommended for optimum conductivity detection. Furthermore, any selectivity in ion uptake demonstrated by the CME should clearly have the effect of minimizing possible interferences and easing somewhat the demands on the chromatographic separation.

CONCLUSIONS

It is clear that the development and popularization of practical CMEs has created a variety of new and potentially powerful detection opportunities in FIA and LCEC. As our ability to manipulate precisely and imaginatively the chemical nature of the electrode/solution interface continues to grow, it can be expected that applications in the areas considered above will expand and completely new applications be developed.

The most intriguing possibilities for new work are the detection of analytes not readily sensed at conventional electrodes and the detection of conventional analyte with increased selectivity. Many of the CME studies above had these objectives as their driving force and the continued use of biologically active agents as electrode modifiers will undoubtedly have increased selectivity as a principal focus. In this regard, recent work by Wang and Lin^{79,80} in which plant tissues are used intact for electrode modification is noteworthy in that it offers a simple and successful route for fabricating biologically-derived CMEs. In addition, complex

Table 4. CME applications involving the detection of non-electroactive ions

CME	Analyte	Summary
Polypyrrole on platinum ⁸⁴	Acetate, carbonate and phosphate	Oxidation of the polypyrrole film at +0.9 V vs. Ag/AgCl was accompanied by formation of positively charged sites in the film and migration of anions from solution. In FIA with the glycine zwitter-ion as the mobile phase electrolyte, injection of sample plugs containing anions such as CH ₃ COO ⁻ , CO ₃ ²⁻ and PO ₄ ³⁻ produced transient anodic currents related to oxidation of the film and uptake of the anion. After each injection, the anions were expelled from the film by application of a reducing potential (-0.3 V). The doping current was linearly dependent on anion concentration from 10 ⁻⁵ to 10 ⁻³ M. The CME response was stable as long as O ₂ was excluded from the flow-stream.
Polypyrrole on platinum ⁸⁵	Halides and other non-electroactive anions	Anodic doping of polypyrrole enabled the detection of halides, particularly Cl ⁻ , over the range 10 ⁻⁶ -10 ⁻³ M. Of various electrolytes containing bulky anions, glycine buffer gave the best response and lowest background current. Variations in applied potential indicated two linear regions, one on either side of the polypyrrole oxidation potential.
Polyaniline on platinum ⁸⁶	Non-electroactive anions in general	Polyaniline CMEs were able to give responses to anions by an anodic doping mechanism involving uptake of the anions upon oxidation of the polymer film. The anions examined were classified according to the responses obtained in mobile phases of different composition. Cl ⁻ , Br ⁻ , NO ₃ ⁻ and ClO ₄ ⁻ gave large signals in acetate buffer and even larger signals in glycine buffer. SO ₄ ²⁻ , CO ₃ ²⁻ and PO ₄ ³⁻ gave small responses in acetate and large responses in glycine. Thus some selectivity was possible by appropriate choice of mobile-phase electrolyte. The potential dependence was sigmoidal in shape and centred at the polyaniline redox wave. Undoping of the film, indicated by the presence of a shallow cathodic trough immediately following the initial anodic peak, was effected by operating at a potential (e.g., +0.2 V vs. Ag/AgCl) where the film was neither fully oxidized nor fully reduced. For NO ₃ ⁻ , linear response was obtained from 10 ⁻⁶ to 10 ⁻⁵ M. The same CME surface could be used for 2 weeks without loss of activity.
Ferric hexacyanoferrate (Prussian Blue) on the quartz crystal of a piezoelective microbalance ⁸⁹	K ⁺ and NH ₄ ⁺	Reduction of the Prussian Blue required the availability of cations, such as K ⁺ and NH ₄ ⁺ , with hydrated radii small enough to permit migration into the film and counterbalancing of the negative sites associated with the reduction process. Thus, this CME was useful for the FIA of these ions by following their uptake into the Prussian Blue film either amperometrically or by the change in mass (or frequency) of the quartz crystal. Both the current and mass responses for reduction of the film in dilute HNO ₃ gave non-linear calibrations from 10 ⁻⁴ to 10 ⁻² M for both K ⁺ and NH ₄ ⁺ .
Cupric hexacyanoferrate on glassy carbon ⁹⁰	K ⁺ and NH ₄ ⁺	Reduction of the cupric hexacyanoferrate deposit was facilitated by the availability of K ⁺ , NH ₄ ⁺ and other ions capable of transport into and out of the film. In FIA and cation-exchange chromatography, this phenomenon gave rise to transient signals at the CME, consisting of cathodic peaks for the uptake of the cations, followed by anodic troughs corresponding to their release back into solution. At an applied potential of only +0.45 V vs. Ag/AgCl, detection limits of 5 × 10 ⁻⁷ M and linear ranges over three orders of magnitude were obtained for both K ⁺ and NH ₄ ⁺ . Reproducibility (1-5% relative standard deviation) and stability (several hours) in the flow-stream were improved by adding a layer of Nafion to the CME surface. The electrode operation was fully compatible with the low ionic-strength mobile phases typically employed in ion-chromatography.
Cupric hexacyanoferrate on glassy carbon and nickel(II) hexacyanoferrate on nickel ⁹¹	K ⁺ , NH ₄ ⁺ , Rb ⁺ and Cs ⁺	Both Ni and Cu hexacyanoferrate CMEs exhibited responses in FIA and LCEC for the alkali-metal and NH ₄ ⁺ ions, but only the latter electrode was sufficiently stable for routine use. The response of the Cu-CME to K ⁺ , NH ₄ ⁺ , Rb ⁺ and Cs ⁺ was rather selective. Within this group, the selectivity could be controlled from general to almost specific for Cs ⁺ by adjusting the applied potential (from +0.4 to +0.7 V vs. Ag/AgCl). The CME gave detection limits of 2 × 10 ⁻⁷ M and was tested for determination of K ⁺ and NH ₄ ⁺ in urine and K ⁺ in blood serum.

CMEs incorporating more than one level of modification may prove extremely interesting. Several examples of such multifunctional CMEs have been reported. Most notably, Wang's group has explored bilayer cellulose/Nafion and cellulose/poly(vinylpyridine) CMEs which offer both size and charge selectivity^{18,24} and cellulose/cobalt phthalocyanine CMEs which combine both perm-selective and electrocatalytic properties.²²

As CME systems continue to develop, completely new kinds of applications can be expected. Perhaps the best illustration of this is provided by recent innovations that have demonstrated how electrochemical detection may be used in gas chromatography (GC) and supercritical fluid chromatography (SFC). The central idea behind these approaches is the use not simply of a single chemically modified or controlled electrode, but of an entire chemically controlled electrochemical cell. For GC, Pons and co-workers^{92,93} employed a micro-assembly consisting of two concentric ring electrodes separated by a thin insulating film of epoxy resin. When this cell was placed at the outlet of the GC column, eluted electroactive species were electrolysed at the inner microelectrode (either carbon or gold). Because the currents involved were only of the order of 10^{-16} – 10^{-10} A, the corresponding flow of charge to the auxiliary electrode could be sustained by the limited number of charge carriers present naturally in the epoxy resin. Applied potentials from +3.0 to -3.0 V (*vs.* the auxiliary electrode) were employed and a wide variety of organic analytes could be oxidized or reduced. However, the linear response range and sensitivity varied considerably with sample type. Subsequently, Parcher *et al.*⁹⁴ reported the use of a micro-electrode assembly coated with a solid poly(ethylene oxide) film made conductive by the addition of lithium trifluoromethanesulphonate and containing a fixed concentration of an electroactive probe such as a ferrocene. Partition of the analyte (in the GC eluate) into the polymer film altered its degree of plasticization and hence the diffusion coefficient of the probe and the resulting microelectrode current. Note that unlike the Pons technique, which requires the analyte to be electroactive, detection by this approach was also possible for non-electroactive species. Finally, in an attempt to adapt amperometric detection to SFC, Michael and Wightman^{95,96} were able to deal with the requirement of a non-conductive

mobile phase in SFC by using a cell consisting of a pair of platinum microelectrodes coated with a Nafion overlayer. In this system, ferrocenes, catechols and other electroactive substrates eluted in the supercritical fluid were partitioned into the ionically conducting Nafion film, where diffusion to the working electrode produced the expected redox current.

(Received 6 November 1989. Accepted 26 February 1990)

Summary—A novel method for the simple and cheap manufacture of microband and multiple microband electrodes is described. The construction technique is based entirely on the screen printing of the surface of alumina tiles with conducting and insulating ink materials. The range of potentials over which the electrodes may be used has been determined by basic electrochemical studies. These electrode systems have been used successfully for the measurement of vitamin C, vitamin B₁ and paracetamol, which illustrates their potential as useful tools in the field of electroanalysis.

Microelectrodes have attracted much interest from workers in the field of electroanalysis. Their physical size allows both the exploration of microscopic domains¹⁻³ and the analysis of very small volumes of solution.⁴⁻⁶ In addition, microelectrodes exhibit a number of electrochemical properties that offer advantages over their macroscopic counterparts, namely, enhanced rates of mass transport of electroactive species to the electrode surface, reduced double layer capacitance (surface area greatly diminished) and, because of the small size of the faradaic currents that are passed, less susceptibility to ohmic losses.⁷ These characteristics make it possible to perform analyses on short time scales (μsec),^{8,9} under time-independent conditions, or in highly resistive media.¹⁰⁻¹³ Also, the increased rates of mass transport provide a greater sensitivity in the electrochemical measurements.

The only drawback, a slight one, of microelectrodes is that the currents obtained are very small. For measurement purposes this places high demands on instrumental precision. Nowadays, however, circuitry of the required sensitivity can be constructed fairly routinely. Much larger current responses are observed at electrodes that are macroscopic in one direction (*e.g.*, microband or microcylinder electrodes) and at closely spaced arrays of micro-

electrodes.¹⁴⁻²⁶ With regard to electrochemical properties, these electrodes possess many of the same advantages over macroscopic electrodes as described above, although the currents observed at microband and microcylinder electrodes do not approach a steady-state value. One advantage associated with the use of microelectrode arrays is the possibility of operating groups of electrodes separately, allowing simultaneous detection of a number of different species or "ring-disc" type electrochemical measurements^{22,27} to be performed.

Despite all the advantages that microelectrodes offer in the area of electroanalysis they have not yet been used on a large scale, owing to the problem of their fabrication, especially the sealing around the electrode. Although the methods of manufacture have improved considerably over the last 10 years, these electrodes are still, in general, hand-made one at a time by researchers who have by necessity become skilled in the art. The recent application of lithographic techniques^{16,18,20-25} to solve the fabrication problem shows promise, but there is still a need for novel approaches that will allow identical microelectrodes, either singly or in arrays, to be manufactured quickly, easily and at low cost.

Recently, Bond and co-workers^{23,28} described a method for the production of microband and microelectrode arrays which was based on a screen printing process²⁹ which

*Author for correspondence.

involves squeezing a specially prepared ink through a masked thin metal gauze onto the surface of a substrate beneath. This substrate is then fired in a furnace at high temperature to leave a thin pattern ($\sim 10 \mu\text{m}$ thick) of an insulating or conducting material on its surface. The technique used by Thormann and Bond involved organically based gold and platinum ink materials which were printed and fired on the surface of a pyrex glass plate. Conversion into microelectrodes was achieved by gluing a glass slide on top of the printed metal pattern. In this paper we describe a new method for the cheap and simple mass production of microband and multiple microband electrodes, which, unlike the process above, utilizes screen printing in all stages of manufacture.

Screen printing methods and materials have been highly developed for the manufacture of capacitors, resistors and conductors on alumina substrates for use in hybrid electronic circuits. Formulations are also available for printing onto glass, steel and plastic substrates, for making decorative patterns and electrical components. Their use in the fabrication of electrical components means that the multilayer patterns deposited are repeatable in thickness and geometry in mass production. In conjunction with the fact that screen printing is a simple process which does not require expensive specialist equipment, it would seem that the idea of adapting materials and methods to mass-produce electroanalytical tools and particularly microelectrodes is very attractive. For example, since the analytical response of a microelectrode is determined only by its geometry, any method of manufacture which gives repeatable geometry would lead to devices which did not require individual calibration. Of the inks available, conductor (Au, Pt, Ag, Pd/Ag, Cu) and resistor (C, RuO_2) formulations would seem suitable for electrodes, and dielectric formulations (typically lead-containing glasses filled with barium titanate) seem suitable for insulation and masking. Because these inks have been highly developed, problems of mutual compatibility, sealing at the interface and adhesion to substrates should already have been solved. In this paper the electrochemical behaviour of electrodes fabricated by these methods is discussed, and their potential for electroanalysis is demonstrated.

EXPERIMENTAL

Electrodes were made by screen-printing patterns of conductors and insulators on the

surface of an alumina tile. For this purpose a DEK65 (DEK Ltd, Weymouth, UK) printer was used, with the different patterns defined by precision screens which were also obtained from DEK. The alumina tiles (50 cm^2 ; NGK, Japan) used as the substrates for the screen-printing processes were cleaned prior to use by boiling in demineralized water (Milli Q) for 10 min. The inks were purchased from Agmet Ltd (Reading, UK) and are described in Table 1. Each ink was applied separately, with the appropriate pattern of screen. Between each printing step the tiles were passed through an infrared drier (DEK 1209) at about 120° for 10 min, and then fired in a belt furnace (DEK 840). The firing time (entry into the furnace at 15 mm/min and removal at 70 mm/min) and the temperature of the furnace varied according to the type of ink (see Table 1). In most cases the screens were 220-mesh made of stainless-steel wire ($45 \mu\text{m}$ thickness) with the print mask patterned in a layer of emulsion ($50 \mu\text{m}$) added on the underside. The print thickness is the sum of the mesh and emulsion layer thicknesses. The resulting patterns had a thickness of about $10\text{--}15 \mu\text{m}$ after firing (except for the organogold ink: thickness $\sim 2 \mu\text{m}$). In some of the experiments involving platinum ink electrodes the fabrication process utilized 325-mesh stainless-steel screens with a $23\text{-}\mu\text{m}$ thick layer of emulsion (resulting electrode thickness $< 10 \mu\text{m}$).

Investigations of the electrochemistry of the various ink materials were performed on macroscopic electrodes which were produced by first printing a line of a conducting ink and then defining the active area with one of the dielectric materials (Fig. 1a). To fabricate a microband electrode, a line of the conducting ink $2\text{--}8 \text{ mm}$ wide and $\sim 10 \mu\text{m}$ thick was printed on the surface of the tile. This was then coated with a layer of a dielectric material. An electrode $2\text{--}8 \text{ mm}$ long and approximately $10 \mu\text{m}$ wide could then be exposed by cutting the tile perpendicularly to the direction of the line, with a diamond saw. Multiple band arrangements were

Table 1. Inks and firing conditions

Ink material	Catalogue number	Firing temperature, $^\circ\text{C}$	Firing time, <i>min</i>
Platinum	5545	1200	15–60
Gold (fritted)	8836	850	15
Organogold	8081-A	850	15
Carbon	1116-S	300–500	10
Silver	9912	850	15
Dielectrics	4905	850	15

Fig. 1. Schematic diagram of two types of screen-printed electrodes: (a) a macroscopic electrode achieved by successive printing of metal and dielectric patterns and (b) a triple-band electrode (side view) made by successive printing of metal and dielectric layers and then cutting across the tile to reveal a cross-section.

prepared in a similar way: a series of alternating layers of conducting ink lines and dielectrics was printed prior to cutting the tile. The lines of the conductors were arranged so that they overlapped as illustrated in Fig. 1b. It was found that two separate layers of the insulating material had to be printed between each of the individual electrodes to prevent them from shorting together. The electroanalysis experiments involved the use of band electrodes in conjunction with a silver/silver chloride³⁰ reference/counter electrode (two-electrode arrangement). The latter electrodes were prepared by first printing a high surface-area silver electrode on the opposite side of the alumina tile. Subsequent conversion of these into silver/silver chloride electrodes was achieved by anodization in 3.5M potassium chloride.

Electrochemical measurements were performed with a potentiostat (PAR, type 173) in

conjunction with a triangular wave generator or by use of a simple 2-terminal arrangement in which the counter-electrode was powered directly from the output of the waveform generator and the working electrode was returned to ground through a sensitive current-follower (Keithley, type 427). Unless otherwise stated, all potentials are quoted with respect to a standard calomel electrode (SCE). Aqueous solutions were made up with demineralized water (Milli Q). All chemicals were obtained commercially and used without further purification. To prevent excessive oxidation, ascorbic acid solutions were prepared immediately prior to use.

RESULTS AND DISCUSSION

Electrochemistry of the ink materials

Electrodes fabricated by screen-printing processes are by their nature less pure than those constructed from base metal because the inks used contain components that facilitate interparticle binding and attachment to a substrate. This point is illustrated in Table 2, which shows surface analysis data obtained for Au and Pt screen-printed electrodes. In these cases, the native metal accounts for less than 80% of the bulk composition. It might be expected that the presence of these high levels of impurities would cause the electrochemistry of these materials to be radically altered, but this is not the case and within certain potential regions the electrochemical behaviour of the screen-printed and "pure" metal electrodes are practically identical. Taking first the example of platinum, Fig. 2 shows typical cyclic voltamperograms (CV) of printed ink and wire electrodes in phosphate buffer (pH 7.4). Here the only differences between the CVs are that for the printed electrode; a small anodic peak is present at the onset of oxide formation (approx. +350 mV) and the resolution of the hydrogen adsorption and desorption peaks is slightly poorer. This similarity in the CVs extends to those for solutions of a

*Surface refers to values obtained after 1–2 nm of the material had been removed by argon ion beam bombardment.

Fig. 2. Cyclic voltamperograms obtained with platinum screen-printed (a) and platinum wire (b) electrodes in 0.1M phosphate buffer (pH 7.4): sweep rate 200 mV/sec area of the printed electrode approximately 0.04 cm².

lower pH (*e.g.*, 0.1M sulphuric acid). The electrode impurities do not appear to hinder oxidation and reduction of electroactive species in solution. This is demonstrated by the cyclic voltamperogram (Fig. 3) obtained for phosphate buffer containing 5mM potassium ferrocyanide. A reversible peak is obtained at the

Fig. 3. Cyclic voltamperogram obtained with an ~0.04 cm² Pt printed ink electrode in phosphate buffer (0.1M, pH 7.4) containing 5mM potassium ferrocyanide: sweep rate 10 mV/sec.

Fig. 4. Cyclic voltamperograms obtained with a gold fritted ink electrode [(a) initial scan, (c) steady-state voltamperogram obtained after about 10 scans] and a gold wire electrode (b) in 0.1M phosphate buffer (pH 7.4): sweep rate 200 mV/sec; area of the printed electrode approximately 0.04 cm².

thermodynamic potential of the redox couple, the same as that observed when a "pure" platinum electrode is used. Similarly, in the case of the gold fritted-ink electrodes (Figs. 4a and b) in the anodic region (>0 mV), the electrochemistry is virtually the same as that obtained on gold wire electrodes. In both cases the only observable features are an oxidation wave (at +700 mV) representing the formation of gold oxide and the associated reduction peak for the reverse process at between +300 and +400 mV. The kinetics of the ferricyanide/ferrocyanide redox couple is also reversible on these gold electrodes. The electrochemical behaviour, at potentials above 0 mV, of organogold electrodes in background electrolyte solutions is much the same as that observed for the fritted-ink electrodes.

In contrast to the anodic region, at potentials below -500 mV the CVs of the gold wire and gold fritted-ink electrodes are very different (Figs. 4a and b). For example, the hydrogen evolution wave is suppressed by as much as 500 mV with the printed electrodes, compared to the

gold wire. Moreover, whereas the CV obtained with the gold wire is relatively featureless, many peaks are observed with the printed electrodes between around -500 and -800 mV. These peaks appear to contain contributions from four or more different redox processes, which, because of their similarity in E^0 , are difficult to resolve. The very sharp oxidation peak at about -550 mV is not observed unless the potential is swept beyond the stable solvent limit in the cathodic direction. This probably represents the desorption of hydrogen from sites on the electrode surface. A further peculiarity regarding the cathodic electrochemistry of the gold fritted-ink electrodes is that initially the CV varies between repeated potential scans. Figure 4a represents the final CV obtained after several tens of cycles. The first potential scan is shown in Fig. 4c and is characterized by the presence of two very large reduction peaks at -650 and -850 mV. On subsequent scans both of these peaks are absent.

The voltamperograms in Fig. 4 were obtained for phosphate buffer (pH 7.4). Similar measurements were also made for solutions containing other background electrolytes (KCl, Na_2SO_4 , CH_3COONa) at neutral pH. In all cases the electrodes exhibited slow kinetics for hydrogen evolution and gave a large number of peaks in the cathodic region. It was hoped that changing the background electrolyte from one which forms insoluble salts of some of the impurity metals (*e.g.*, phosphate) to one forming soluble salts (*e.g.*, chloride) would result in a reduction in the number of peaks. This, however, was not the case and thus a more rigorous analysis of the electrochemistry of the electrodes is required to identify the nature of the electroactive impurities.

Most of the impurities present in the gold printed electrodes are electroactive only at potentials below about -500 mV. Hence, for the conditions of Fig. 2, if electroactive species with similar values of E^0 are present on the surface of the printed platinum electrodes their electrochemistry will be masked by the current associated with hydrogen evolution.

In terms of analysis, these results suggest that screen-printed electrodes can be used effectively to determine concentrations of redox-active species that can be either reduced or oxidized at potentials more anodic than -500 mV *vs.* SCE. At more cathodic potentials than this, certainly in the case of the gold fritted-ink electrodes, any technique involving stepping or sweeping

of the potential will not be feasible, because of the large currents associated with the redox properties of the electrode impurities.

In the case of the screen-printed carbon electrodes, if the firing temperature is the same as that recommended by the manufacturer, the electrodes have a high internal resistance and hence the electrochemistry is dominated by iR effects. At firing temperatures above 300° the resistance of the electrode is greatly reduced and normal electrochemical behaviour is observed. Electrodes of this type give practically featureless CVs in solutions of background electrolytes when the potential is scanned between the solvent limits. These CVs are characterized by high capacitive currents, which suggests that the electrodes are porous in nature, with a correspondingly large surface area. The dramatic increase in electrode conductivity at higher firing temperatures is most likely due to the decomposition of the epoxy-based polymer which is present as a binder for the carbon particles. A natural consequence of this decomposition is that the electrodes show poor adhesive properties and are mechanically weak. If these two problems could be overcome, the carbon ink would provide the added bonus of allowing electroanalysis to be performed at reducing potentials.

Microband electrodes

Single-band electrodes. Microband electrodes have been constructed with both gold and platinum printing inks. In the absence of electroactive species in the surrounding environment these electrodes exhibit electrochemical behaviour identical to that of their macroscopic counterparts described above. They also exhibit the general characteristics of microelectrodes (having low capacitive currents, which allows use at high sweep rates and in media of high electrical resistance). The gold microbands showed no sign of leakage around the seal with the insulator, but the platinum microbands did, evidenced in solution by a gradual increase in the observed capacitive currents with time (faradaic currents over the same period remained constant) and indicating a need for further attention to detail in the choice of materials and preparation conditions.

Figure 5 shows cyclic voltamperograms obtained with fritted gold and organogold electrodes (band length 6.5 mm in each case) in a solution containing ferrocyanide ions. The thicknesses of the bands (estimated by

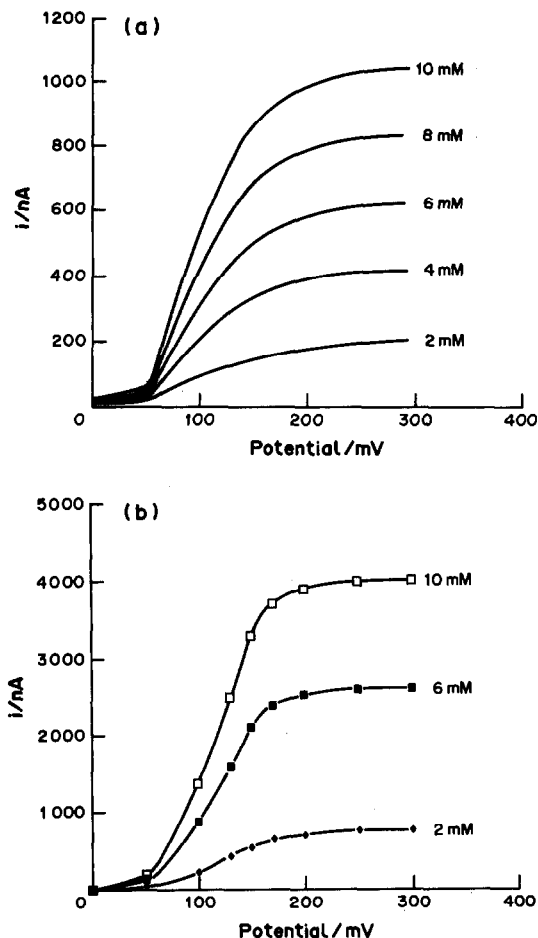

Fig. 5. Cyclic voltamperograms obtained with (a) an organogold-based microband electrode and (b) a fritted ink microband electrode in $0.1M$ KNO_3 containing $K_4Fe(CN)_6$ (concentrations indicated). Sweep rate 20 mV/sec.

inspection under a high-power optical microscope) were approximately 12 and $2 \mu m$ for the fritted and organogold electrodes respectively. The shape of the voltammetric curve, shown in Fig. 5, is characteristic of that obtained at microband electrodes, *i.e.*, at sufficiently low sweep rates the oxidation wave levels off to a quasi-steady-state limiting current and the corresponding reduction peak is greatly reduced. For both of these band electrodes the magnitudes of the limiting current are proportional to the concentration of the electroactive species.

The quasi-steady-state current (A) is given by²⁷

$$i = nFDCl \left[\frac{5.553}{\ln \theta} - \frac{6.791}{(\ln \theta)^2} \right] \quad (1)$$

where n is the number of electrons, F the Faraday constant, D the diffusion coefficient (cm^2/sec), C the bulk concentration ($mole/cm^3$)

of the electroactive species and l the length of the band (cm), and θ is $4Dt/W^2$, t being time (sec) and W the width of the band (cm).

By use of this equation, theoretical values for the steady-state currents of $0.43C$ (fritted gold) and $0.29C$ (organogold) can be calculated for the experimental conditions described in Fig. 5 ($D = 6.3 \times 10^{-6} cm^2/sec$, $t \sim 1.25$ sec ($\sim RT/Fv$, where v is the scan rate)). From Fig. 5, a value of $0.4C$ is obtained for the fritted gold electrode, which is in good agreement with theory. For the organogold ink electrode a value of $0.1C$ is obtained, which is much less than would be expected from purely theoretical considerations. However, examination of this band electrode under an optical microscope indicated that it was not continuous and hence this low value is not unexpected. The reason for the discontinuous nature of these electrodes is not known, but is likely to be due to smearing of the dielectric layer over the surface of the electrode during the cutting process (see Experimental).

One advantage of using screen printing methods with commercial inks is that the prints should be repeatable in thickness. The inter-electrode repeatability for a set of ten different microbands prepared with the fritted gold ink was checked by cyclic voltammetry of ferrocene in ethanol (containing $0.1M$ $LiBF_4$). The variation in the limiting current values obtained with the set of electrodes was less than $\pm 5\%$ around the mean.

Ascorbic acid sensors. Determination of vitamins in foodstuffs and biological fluids is generally time-consuming and expensive.³¹ Vitamin C can be measured electrochemically since it can be oxidized relatively easily to dehydroascorbic acid; the redox potential of this process is pH-dependent.

The system we have used for ascorbic acid determination consists of a fritted gold microband electrode with an associated printed silver/silver chloride auxiliary electrode (see experimental). A series of cyclic voltamperograms taken with one of these sensors in a solution containing ascorbic acid in phosphate-buffered saline at pH 7 ($0.1M$ phosphate buffer, $0.15M$ sodium chloride) is shown in Fig. 6a. The quasi-steady-state current was found to vary linearly with acid concentration. From the slope of this line a value of $5.7 \times 10^{-6} cm^2/sec$ (in good agreement with the literature value³²) can be calculated for the diffusion coefficient of ascorbic acid by equation (1).

Fig. 6. Cyclic voltamperograms obtained with a fritted gold microband electrode in phosphate-buffered saline (0.1M pH 7, 0.15M NaCl) for various concentrations of ascorbic acid. Sweep rate 20 mV/sec.

This electrode system was also placed in a proprietary orange drink. Figure 7 shows the linear sweep voltamperograms obtained with and without addition of ascorbic acid. Since the position of the oxidation wave is the same for both CVs, we conclude that the current for the orange drink alone is due to the presence of ascorbic acid. Analysis of the steady-state current gave a concentration of 1.6mM, which is within the limits quoted by the manufacturer.

The electrode has also been used to measure the concentration of ascorbate in apples (Granny Smith's). Figure 8 shows voltamperograms obtained at two separate locations: one at the surface, the other near the centre. The results indicate a decrease in concentration of ascorbate with depth, as reported previously.³³ The concentration at the surface was estimated

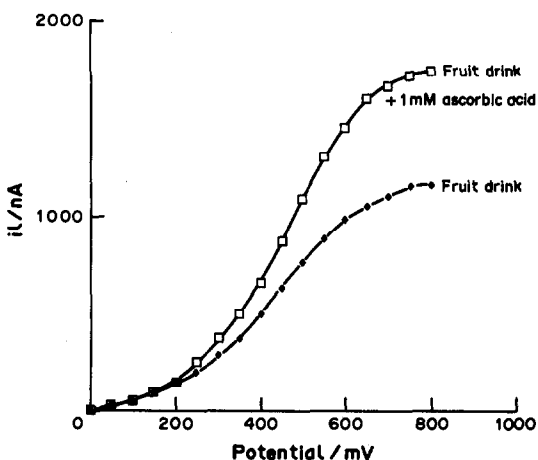

Fig. 7. Cyclic voltamperograms obtained with a fritted gold microband electrode in a proprietary fruit drink with and without added ascorbic acid. Sweep rate 20 mV/sec.

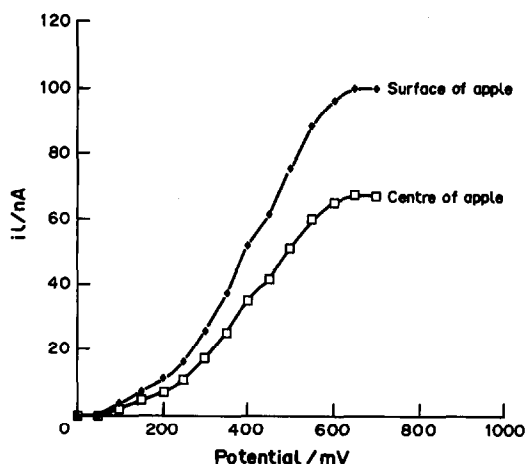

Fig. 8. Cyclic voltamperograms obtained with a fritted gold microband electrode in a Granny Smith's apple. Sweep rate 20 mV/sec.

to be approximately 3 mg/100 g of fruit, which is in line with results obtained by other techniques.³³ We have also used the method successfully for potatoes, oranges, strawberries and kiwi fruit.³⁴

Paracetamol sensor. Paracetamol can also be oxidized electrochemically. Figure 9 shows once again that a quasi-steady-state is observed, the magnitude of which is linearly dependent on the concentration of the electroactive species. Increasing the pH of the background electrolyte from 6.2 to 10.5 resulted in oxidation at a more cathodic potential. Linear calibration plots were also obtained at this higher pH.

Multiple band electrodes

In general it was found that multiple microband electrodes became less uniform as the

Fig. 9. Cyclic voltamperograms obtained with a fritted gold microband electrode in 0.1M NaClO₄ with various concentrations of paracetamol. Sweep rate 100 mV/sec.

Fig. 10. Current-time transient measured on a dual microband system. Ferricyanide electrogenerated on an organogold microband electrode is measured on an adjacent fritted gold microband electrode. Electrolyte used was 0.1M KNO₃ containing 12mM K₄[Fe(CN)₆]. The potential of the fritted gold microband electrode was maintained at -0.1 V (vs. SCE). The generating current on the organogold microband electrode was supplied from a dry-cell battery.

number of printed bands was increased. This is presumably due to problems associated with the repeated firing and cooling processes used in their manufacture.

Multiple band electrodes have been operated in ring-disc mode, where the product of the electrochemical reaction at one of the electrodes is measured on the others. Taking first the example of a dual-band system, Fig. 10 shows the results of experiments where one of the electrodes was made with the fritted gold ink and the other with the organogold material. Here the transient response is shown for the case where ferricyanide produced by the oxidation of ferrocyanide at the organogold electrode is measured on the fritted gold electrode. As can be seen, the current becomes constant after slightly less than 1 min. Increasing the generator current results in a corresponding increase in the current obtained at the fritted ink electrode. The proportion of current measured, defined by $\Phi = \text{collector current} / \text{generator current}$, is called the collection efficiency.

Figure 11 shows a plot of the collector current *vs.* the generator current for the same system as in Fig. 10. The collection efficiency was 42%. Figure 11 also shows data obtained with a dual-band electrode where both of the bands were made with the fritted ink. Here a reduced collection efficiency of 29% was observed. This is in line with the findings of Shea and Bard²⁷,

Fig. 11. Relationship between the generating current and the detected current for dual (1, 2) and triple (3) microband electrodes. Conditions as for Fig. 10. For the dual-band electrode systems a fritted gold collector microband electrode was used with both organogold (1) and fritted gold (2) generator microband electrodes.

who suggested that to maximize the collection efficiency the collector band should be much wider than the generator band.

Shea and Bard²⁷ used a computer simulation to calculate the collection efficiencies of this type of system. With θ_{gap} defined by

$$\theta_{\text{gap}} = 4Dt / (W_{\text{gap}})^2 \quad (2)$$

where W_{gap} is the width between bands (cm), the quasi-steady-state collection efficiency, Φ_{ss} , can be calculated from

$$\Phi_{\text{ss}} = 0.033 + 0.21 \log \theta_{\text{gap}} - 0.016 (\log \theta_{\text{gap}})^2 \quad (3)$$

With an average gap of 30 μm (estimated by inspection under an optical microscope), the collection efficiency for ferro/ferricyanide, for the case where the generator band was constructed from the organogold ink, was calculated to be 42%. This is in excellent agreement with the experimental value (42%).

Electrodes of triple-band configuration have been constructed with the gold fritted material (*i.e.*, all electrodes 12 μm thick). It was found that if adjacent electrodes were used in dual-band generator/collector mode then the collection efficiencies obtained were similar to those described above (29%). When both outer electrodes were used to measure the product electrogenerated at the inner electrode, the combined collection efficiency rose to 50% (Fig. 11). This is less than the sum of the individual collection efficiencies, which is again in agreement with the results obtained by Bard *et al.*²²

Thiamine sensor. For the purpose of analysis it is possible to measure non-electroactive species by monitoring their reaction with an electrogenerated reagent.³⁵ A convenient way of doing this is to use a multiple-band system where the reagent is generated at one electrode and measured at the others. In transit between the generator and collector electrodes this reagent can react with the substance of interest, which is present in the bulk solution. The reaction means that a smaller current than expected will be measured at the collector electrodes. This technique, which measures a reduction in the collection efficiency, can be operated as a type of amperometric titration.

Thiamine, vitamin B₁, when in its pyrophosphate form (cocarboxylase) is a cofactor which is utilized in a number of enzyme systems.³⁶ It is possible to oxidize this species in the presence of alkaline ferricyanide to thiochrome. The amperometric titration of thiamine, in a solution of ferrocyanide, has been performed by using triple-band electrodes. Here the central generator band is used to oxidize ferrocyanide to ferricyanide, which is subsequently measured at the two outer band electrodes. It was found that for a given current the collector current decreases with increasing thiamine concentration (an alternative method would have been to measure the collection efficiency as a function of generator current³⁶). Figure 12 shows a calibration curve which relates the collection efficiency to the concentration of thiamine.

Fig. 12. Calibration graph for thiamine; i_{col} is the collection current for electrogenerated ferricyanide reduction measured on the outer fritted gold microband electrodes (generator current 320 nA) and $i_{\text{col}, 0}$ is the collector current in the absence of thiamine. Experimental conditions as for Fig. 10.

CONCLUSIONS

A new simple and cheap method for the manufacture of microband and multiple-band electrodes has been described. Despite the presence of high levels of impurities, these electrodes demonstrate good electrochemical behaviour and are therefore suitable for use in electro-analytical applications. We believe that electrodes made in this way can be inserted into complex environments (both solid and liquid) to provide information on concentrations of chemical species. The potential in this area has already been demonstrated by the measurement of ascorbic acid levels in fruit and vegetables and an orange drink. Further investigations in this area are in progress. We are also extending our studies to look at new measurement techniques and to ascertain the different species that can be analysed by use of these electrode systems.

ANALYTICAL IMPLICATIONS OF ZEOLITES IN OVERLAYERS AT ELECTRODES

DEBRA R. ROLISON*, ROBERT J. NOWAK†, TIMOTHY A. WELSH and CATHERINE G. MURRAY
Code 6170, Surface Chemistry Branch, Naval Research Laboratory, Washington, DC 20375-5000, U.S.A.

(Received 30 May 1990. Accepted 6 July 1990)

Summary—A review is given of past and potential analytical and other applications of electrodes overlaid with zeolites.

The aluminosilicate zeolites, when incorporated into an electrochemical interphase, offer a number of chemical, physical, and structural characteristics of interest in the design of electro-analytical schemes. Several recent reviews cover the general interest in zeolites as materials useful in electrochemical environments.¹⁻³ The electro-analytically relevant characteristics of such zeolites will be described briefly below; the implications for electroanalysis inherent in these zeolite properties will be illustrated with examples from the literature and the work of our group. Potential zeolite-based electro-analyses will also be described.

The aluminosilicate zeolites

Many (but not all⁴) zeolites are formed from tetrahedrally oxygen-linked silicon and aluminum atoms in varying Al to Si ratios. The resulting crystalline aluminosilicate lattice has three predominant characteristics,⁵ each with electroanalytical and other implications. These characteristics are:

- (i) molecular sieve selectivity based on the size and shape of the molecules interacting with the zeolite;
- (ii) cation-exchange capacity;
- (iii) inherent catalytic properties due to the strong-acid nature of the zeolite as well as the ability to modify catalytic properties by cation-exchange with or without subsequent redox reactions.

Figure 1 summarizes the chemical/structural nature of the aluminosilicate zeolites. The two-

dimensional representation of the oxygen-linked tetrahedra (Fig. 1) illustrates characteristics (ii) and (iii). Every Al atom in the lattice results in a fixed negative charge; electroneutrality is achieved with mobile cations, frequently alkali-metal ions. These cations can be exchanged for others, depending on their specific site in the zeolite lattice and the size of the exchanging cation.⁵ The strong-acid nature of the aluminosilicate zeolites, responsible for their wide use in acid-catalyzed reactions of technological significance⁶ arises from the terminal hydroxyl groups at the crystal faces. The aluminum-rich aluminosilicate zeolites can decompose in the presence of strong acid, through removal of aluminum atoms from the lattice,⁵ so the pH of the medium needs to be considered when using these materials for electro-analysis.

The three-dimensional zeolite lattice, which arises from the linking of the various ring structures that can be formed from conjoining the oxygen-linked tetrahedra, offers a cage-and-channel architecture of molecular size; the molecular sieve character of zeolites is derived from the pore, void space, and cage aspects of this architecture. Figure 1b shows a framework representation for zeolite A, a synthetic zeolite with the ideal formula $(M^{(I)})_{12}(AlO_2)_{12}(SiO_2)_{12}$, and the zeolite of choice for our work.

Zeolite A belongs to the faujasite structure class, as do types X and Y; the channels and cages of these zeolites intersect in three dimensions, so that diffusion of sorbed species in such zeolites is three-dimensional. Figure 1b shows the supercages for the faujasitic zeolites A, X, and Y, with their pore openings in three dimensions, and as is evident from this figure, the size of the pore openings and the size of the supercages can differ as a function of the structure.

Fig. 1. The chemical and structural nature of aluminosilicate zeolites. (a) A two-dimensional representation of the Al-O-Si linkages that create the framework of aluminosilicate zeolites, illustrating the fixed anionic sites (one per Al atom), charge-compensating cations, and terminating hydroxyl groups (adapted from Rolison²); (b) three-dimensional representation of the faujasitic geometry for zeolites A (Al:Si = 0.7-1.2) and X (Al:Si = 1.0-1.5)/Y (Al:Si = 1.5-3).

Zeolites X and Y have pore openings of about 0.74 nm, whereas zeolite A has pore openings of about 0.4 nm. Zeolites in which diffusion is one- or two-dimensional along the channels also exist.^{3,5,7}

Zeolites and their electroanalytical possibilities

Combining a zeolite-containing overlayer on (or as part of) an electrode surface allows both electrochemical stimulus of the zeolite (*e.g.*, by electrogeneration of a reactant capable of interacting with the zeolite) and electrochemical detection (or reaction) of a zeolite-entrained reactant or a zeolite-reacted product. Electroanalytical consequences accrue from all of the zeolitic characteristics described above, in that any electroanalytical scheme which relies on ion-exchange, or analyte preconcentration, or size/shape/charge selectivity, or catalyst-assisted reactivity, or any combination of these features,

can be designed for use of a zeolite-modified electrode.

EXPERIMENTAL

All electrochemical experiments reported are for zeolite A, either in pure powder form (NaA, Linde; sized as less than 10 μm) or from ground and sieved 4A (NaA) or 3A (KA) molecular sieves (Linde, containing a clay extruder to form pellets or beads). The supporting electrolyte was 0.1M Et₄NClO₄ (Southwestern Chemicals, vacuum dried at 50°) in CH₃CN (Burdick & Jackson, high purity, used as received). Ferrocene, 1,4-dinitrobenzene and 1,4-benzoquinone were sublimed before use. Pyrrole (Aldrich) was purified before use, by passage through activated alumina.

Voltammetric experiments were performed with an EG&G PAR Model 173 potentiostat/

galvanostat. Pine Instruments Rotators, Models PIR and MSR, were used to electrodeposit zeolite overlayers on Pt and glassy-carbon disk electrodes (Pine Instruments) generally by a previously described procedure.⁸ Potentials are referred to a NaCl-saturated calomel electrode (SSCE), unless otherwise noted; platinum wire was used as the auxiliary electrode.

ELECTROANALYSIS WITH ZEOLITE-MODIFIED ELECTRODES

Preconcentration of electroactive solutes—amperometric detection

The molecular size and shape selectivity (and the high internal surface area⁵) of zeolites can be used for preferentially adsorbing appropriately sized neutral species or cations in the zeolite on the basis of the size of its pore openings. When a zeolite is coupled to an electrode (*e.g.*, by mixing with carbon paste or casting from a polymer suspension—see Rolison² for a summary of preparatory methods for zeolite-modified electrodes), species preconcentrated in it can be subsequently detected at their characteristic potentials or made available for coupled chemical and electron-transfer reactions.

An electroanalytical approach based on adsorption of cationic analytes by the zeolite in a zeolite-modified electrode, followed by electrochemical detection, has been applied in a number of instances; a few will be described here as examples. Zeolite-modified carbon pastes have been used to sorb cations such as Hg^{2+} ,⁹ or Ag^+ ,¹⁰ at $\mu\text{g/ml}$ levels from aqueous solution at open circuit and then, at a suitable applied potential, give a signal corresponding to the amounts adsorbed and hence (by calibration) to those present in the initial solutions.

Though zeolites can provide size and shape selectivity at an electrode interphase, they do not provide specificity; competing adsorbates in the analyte solution can affect the amperometric response, and this must be considered when performing electroanalysis with zeolite-modified electrodes. Wang and Martinez¹⁰ showed that the magnitude of the reduction current for Ag^+ adsorbed by zeolite-modified carbon-paste electrodes from $1 \mu\text{g/ml}$ Ag^+ solutions, was unaffected by the presence in the initial solution of $10 \mu\text{g/ml}$ amounts of Co(II) , Mn(II) , Ca(II) , Pb(II) , Cu(II) , and Ti(IV) , but completely suppressed by $10 \mu\text{g/ml}$ Fe(III) ; reduction currents were enhanced when the cationic interferents in solution were Bi(III) , U(IV) , Ni(II) , Zn(II) , and Tl(I) .

Shaw *et al.*¹¹ have explored competitive cation adsorption by zeolite Y of methylviologen (MV^{2+}) and $\text{Ru(NH}_3)_6^{3+}$ and by Cu(II)-Y for electrolyte cations of various hydrated sizes. Their work also highlights the importance of understanding the nature of the mass transport of electron-transfer species in the zeolite interphase in order to explain the observed voltammetry. Zeolite Y was shown to adsorb $\text{Ru(NH}_3)_6^{3+}$ preferentially, but the current response was greater with MV^{2+} -exchanged Y, indicating that the mobility into and out of Y was greater for MV^{2+} than for $\text{Ru(NH}_3)_6^{3+}$. The current observed for the reduction of zeolite-adsorbed Cu^{2+} increased when Cu(II)-Y was exposed to solutions of cations with small hydrated radius, showing that the smaller cations displaced the zeolite-adsorbed Cu^{2+} more readily.

The mechanism first proposed by Shaw *et al.*¹¹ to explain the amperometric response of a zeolite-modified electrode containing adsorbed electroactive solutes involves ion-exchange of the adsorbed electroactive cations with different cations in the electrolyte solution and the subsequent reduction of the liberated electroactive cations at the electrode, *e.g.*,

where E^{m+} is the electroactive cation, C^+ is the electrolyte cation, and the subscripts (z) and (s) refer to the zeolite and solution phases, respectively. The amperometric response observed for $\text{E}_{(s)}^{m+}$ thus depends on the mobility of E^{m+} within and out of the zeolite (the latter in turn being influenced by the mobility of the displacing cation) and the nature of mass transport of the species in the zeolite-electrode interphase. Zeolite overlayers at electrode surfaces provide edge effects and high interfacial concentrations of electroactive species, conditions which affect mass transport and have been shown to affect the voltammetric response of MV^{2+} -modified zeolite Y.^{11,12}

The ability of a zeolite-modified electrode to discriminate on the basis of the size of the sorbed analyte and the size of competing adsorbates can be a subtle effect, as we have shown for adsorption of oxygen by zeolite A electrodeposited as a compact coating on platinum or glassy-carbon rotating disk electrodes.⁸ In this system, both the sodium form of zeolite A (NaA , with pore openings of 0.4 nm) and the

potassium form (KA, with pore openings of 0.3 nm) sorb oxygen when the zeolite-coated electrode is exposed to air or an oxygenated solution. When these oxygen-loaded zeolite-modified electrodes were placed in deoxygenated acetonitrile/tetra-alkylammonium electrolyte, the reductive voltammetry was dominated by oxygen reduction. Attempting to purge oxygen from the coatings by bubbling nitrogen through the electrolyte solution worked only for the NaA coatings, as the nitrogen molecules were too large to enter into the pores of KA. The use of argon (with a diameter <0.3 nm) instead of nitrogen could purge oxygen from both coatings.⁸

Zeolites sandwiched between an anode and cathode have also been used to determine sorbed oxygen amperometrically, but in the dry state and at elevated temperatures (>200°).^{13,14} The voltammetric responses of adsorbed^{14,15} and occluded inorganic species^{13,16} in dry zeolite films have also been studied. Although it is not an example of amperometric detection, the work of Bein *et al.*¹⁷ is interesting: they used a mixed zeolite-silica thin film coated on a surface acoustic wave device to discriminate vapor-phase organic molecules that were small enough to be sorbed in the zeolite from those too large to penetrate it. The large surface area of the zeolite in the thin film resulted in a large change in the frequency of the device when adsorption occurred.

Preconcentration of electron-transfer interactive species—amperometric detection

Direct analytical application of zeolite-modified electrodes relies on adsorption of the electroactive analyte of interest by the zeolite but the zeolite can also act as a repository for reactants that can be used to affect the electrochemical response of a desired analyte. The loading of zeolite with a chemical reagent needed in an electroanalytical scheme is quite feasible and provides the reagent where it is most effective, *i.e.*, at the electrode interface during electron transfer. This aspect of electroanalysis with zeolites has yet to be exploited.

It should be remembered that a zeolite, by its inherent nature, provides an interactive electron-transfer species. The word zeolite derives from the Greek for "boiling stone" owing to the great uptake of water by a zeolite and its (reversible) release upon heating. Fully dehydrated zeolites will start to become hydrated upon exposure to ambient air, so the presence of

water in the zeolite-electrode interphase is ensured unless precautions are taken. For analyses in aqueous solutions, this would not be a primary concern, whereas in analyses for water-sensitive electroactive solutes in non-aqueous media, it could either cause difficulty or be an exploitable variable in the system. Also, as observed with regard to oxygen, the ability of zeolites to sorb appropriately sized gases can also influence the observed voltammetric response of zeolite-modified electrodes.

Another overlooked, but inherent reactive species in the zeolite is the mobile counter-ion, often Na⁺. Besides being replaceable by cationic reactants or analytes, such alkali-metal ions, when present in the zeolite-electrode interphase for a zeolite used in an aprotic electrochemical solvent of low donicity, will affect the electroreductive response to oxidants (designated as R), through ion-association reactions, *e.g.*,

The mobile counter-ions will be present in high concentrations in the zeolite-electrode interphase since zeolites are solid solutions of about 1 molal concentration and the cation-exchange reactions with electrolyte cations release these counter-ions into solution. The magnitude of their effect on organic reductions is related to the equilibrium constant for the ion-association reaction. This is the interaction which led to our discovery of the co-electrodeposition of organic oxidants and zeolite A as compact coatings on rotated Pt or glassy-carbon disk electrodes.^{8,18}

Zeolite overlayers on electrodes, however deposited, retain this ability to influence electroreductions of organic oxidants in low-donicity solvents by providing a high activity of strongly associating alkali-metal ions in the electrochemical interphase; this can be seen in Fig. 2 for the two one-electron reductions of 1,4-benzoquinone in 0.1M Et₄NClO₄/CH₃CN electrolyte. At an uncoated platinum electrode (Fig. 2a) the two reversible reductions are seen; scanning the potential at a platinum electrode with a compactly coated NaA/1,4-dinitrobenzene overlayer in the same solution shifts the second reduction (R^{•-} + e⁻ = R²⁻) to more positive voltages (see Fig. 2c), consistent with ion-pairing of the anion radical with a strongly associating cation, such as Na⁺.^{19,20} A similarly coated platinum electrode, but with visible regions of exposed metal, also shows a shift to more positive potentials for the second

Fig. 2. The two one-electron reductions for 1,4-benzoquinone in 0.1M $\text{Et}_4\text{NClO}_4/\text{CH}_3\text{CN}$ at (a) Pt; (b) Pt partially coated with a co-electrodeposited overlayer of NaA/1,4-dinitrobenzene; (c) Pt compactly coated with a co-electrodeposited overlayer of NaA/1,4-dinitrobenzene. The standard potential for the reduction of the anion radical is marked with a solid line to show the shift to more positive potentials when the reduction occurs through a zeolite overlayer.

reduction (Fig. 2b), but less than that occurring with a compactly coated electrode (Fig. 2c).

If ion-association reactions during electroanalysis in low-donicity electrolytes are undesirable, prior ion-exchange of the zeolite with a less strongly associating cation is necessary. Lithium and sodium type zeolites should certainly be avoided in such a situation.

One design involving zeolite-modified electrodes containing preconcentrated electron-transfer interactive species that could be applied to electroanalysis, but so far has not, is based on the manipulation of vectorial electron-transport chains. In this design concept, as pioneered by Mallouk and co-workers,^{21,22} the zeolite is used

as a size- and charge-discriminating support for spatial array of donor and acceptor pairs which can respond to light or electrochemical potential. This provides a rectifying interface with charge-trapping and untrapping characteristics.

For instance, MV^{2+} -exchanged zeolite Y was partially capped by ion-exchange of the bulky porphyrin derivative, cobalt(II) tetrakis(*N*-methyl-4-pyridyl)porphyrin chloride, for Na^+ ions on the external surface of zeolite Y; this modified zeolite was cast onto SnO_2 from a zeolite-polystyrene suspension. The porphyrin blocked direct reduction of the entrained viologen, but could itself be directly reduced at the electrode; in turn the reduced porphyrin ring could reduce the entrained viologen.²³ The proper choice of the sizes and standard potentials of redox species arranged on a zeolite for vectorial transport, could provide a detection system based on the electron-flow (charge untrapping) produced by exposure of such a zeolite-electrode interphase to an analyte of appropriate standard potential.

Conductive composites—amperometric detection

Zeolite-modified electrodes can be readily prepared by casting from polymer solutions or by mixing well with carbon paste, but one of the more robust and rapidly responsive (and hence analytically useful) preparations was developed by Shaw and Creasy.²⁴ A mixture of carbon and zeolite powders is bound by a radical-initiated copolymerization of styrene and divinylbenzene; the result is a "hard" composite with a surface which can be polished. Comparing the voltammetric responses for MV^{2+} and $\text{Ru}(\text{NH}_3)_6^{3+}$ at the "hard" composites with those previously obtained with zeolite/carbon-paste composites¹¹ showed that the "hard" composites were more sensitive to these cations in solution, gave more reproducible currents and shorter response times, and were more convenient to use.

A different approach to a conductive zeolite-containing composite employs encapsulation within a conducting polymer. The possible advantage of this approach is to extend the electrochemically reactive zone beyond the boundary defined by the electrode surface and the first layer of zeolite particles, so that all the zeolite particles are available for electronic communication. In a modification of our co-electrodeposition procedure,^{8,18} a zeolite-polypyrrole composite was formed on rotated platinum or

glassy-carbon disk surfaces by oxidizing pyrrole in a slurry containing zeolite powder. Surprisingly, more uniform zeolite-polypyrrole coatings could be formed in an "upside-down" configuration which maximized incorporation of zeolite in the forming polymer. In this latter procedure, a drop of the pyrrole/zeolite/electrolyte slurry is placed on the face of a disk electrode mounted face-up, and two platinum wires (as auxiliary and reference electrodes) are positioned at the edge of the drop; as the assembled "cell" is not protected against vibration, enough vibration is transmitted through the electrode mount to prevent settling of the particles. The zeolite is gravitationally encapsulated as the pyrrole is oxidized and polypyrrole is electrodeposited. This procedure also works for other particulates; good composite coatings could be formed with ion-exchange resin beads encapsulated in polypyrrole.

The voltammetric behavior of such composites (in our work) in electrolyte solutions in acetonitrile has the broad capacitive background usually observed for electrodeposited polypyrrole films. Polypyrrole encapsulation of NaA provides yet another example of the tenacious adsorption of oxygen by zeolite A and its dominance of the amperometric response of overlayers containing zeolite. This is demonstrated in Fig. 3 for the response (in aqueous solution) of a polypyrrole/NaA composite coated on platinum (Fig. 3b) in comparison with that of a polypyrrole coating prepared similarly on glassy carbon (Fig. 3a). For both aqueous and acetonitrile electrolyte solutions, the qualitative character of the voltammetric response of polypyrrole and polypyrrole/NaA composite coatings in a blank solution becomes similar after sufficient deoxygenation of the zeolite-containing coating [compare Fig. 3a

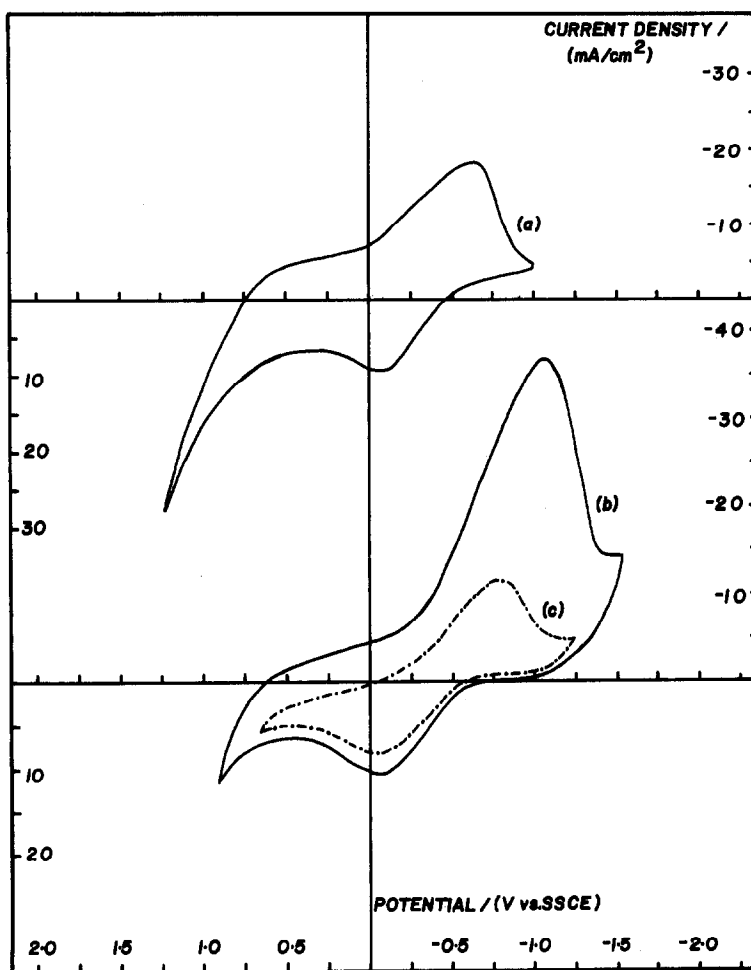

Fig. 3. Voltammetric response at 100 mV/sec in 10mM NaOH/0.1M Na₂SO₄ electrolyte for (a) polypyrrole electrodeposited (from CH₃CN) onto glassy carbon; (b) and (c) polypyrrole-NaA composite electrodeposited (from CH₃CN) onto Pt [(b) second scan; (c) sixth scan].

with the voltamperogram obtained with the polypyrrole/NaA composite after exhaustion of the zeolite-entrained oxygen (Fig. 3c)].

The obverse approach to making zeolite-conducting polymer composites, *i.e.*, encapsulating the conducting polymer within the zeolite, has also been explored. Synthesizing conducting polymer chains inside a zeolite offers two unique materials-science opportunities: (i) if growth is constrained so that bulk conducting polymer cannot form, the properties of oriented small-dimension conducting polymers can be studied; (ii) wiring the interior of a zeolite with an electronic conductor allows molecular electronic designs and constrained electron-transfer chemistry to be explored. The ability of zeolites modified with transition metals to polymerize adsorbed acetylene^{25,26} and pyrrole²⁷ has demonstrated the feasibility of this approach; recent work by Bein and Enzel (on polyaniline,^{28,29} polythiophene³⁰ and polypyrrole³¹) has expanded the chemistry and the characterization of such systems to bring the possibilities above closer to realization. Successful preparation of such molecular wiring inside zeolites will certainly create electroanalytical possibilities.

Cation-selective electrodes—potentiometric detection

The most obvious analytical application of the aluminosilicate zeolites is as ion-selective membranes for the potentiometric determination of cations. This is such a natural application that the use of zeolites in ion-selective electrodes dates back to 1939.³² In subsequent work Barrer and James demonstrated the importance of the size of the cations in competitive adsorption by zeolites, by their observation of complete selectivity of NaA membranes for Na^+ relative to Et_4N^+ ;³³ these membranes were formed by pressing zeolite microcrystals with polymer powders (such as polystyrene, the polymer of choice for casting zeolite-polymer suspensions on electrode surfaces^{2,3}) or casting with thermosetting resins.^{33,34}

Johansson *et al.* studied mordenite-type zeolite embedded in low-viscosity resin as a Cs^+ -selective membrane³⁵ and found near-Nernstian responses for Cs^+ and selectivity relative to the other alkali-metal ions and Ba^{2+} , Ca^{2+} and Cu^{2+} . Work by Demertzis and Evmiridis with Fe(III)- and Cu(II)-exchanged zeolites A and X, also in epoxy-embedded membranes, emphasized the necessity of good zeolite/epoxy ad-

hesion to achieve ideal Nernstian behavior from zeolite membranes.³⁶ Likewise, Barrer and James also found their zeolite membranes had improved selectivities after impregnation with silicone oil to seal cracks in the membrane and minimize alternative solution paths for ion transport.^{33,34}

Our study of the potentiometric response of NaA-polymer films to Cd^{2+} also highlighted the nature of the binder on the stability of the measurement. Near-Nernstian response to Cd^{2+} (33 mV/decade) was achieved for NaA-polysulfone films cast on glassy carbon, in contrast to the flat background response of polysulfone-coated glassy carbon to 10^{-5} – $10^{-2} M$ Cd^{2+} . Erratic results were obtained for both polymer and NaA-polymer coatings in Cd^{2+} solutions when the polymer was polystyrene or polycaprolactone. Sub-Nernstian (11 mV/decade), but linear, response was obtained for an NaA-polysulfone coating exposed to 10^{-5} – $10^{-1} M$ Al^{3+} .

Kinetic possibilities and electroanalysis with zeolite overlayers

Because the size of the zeolite particles placed in overlayers on electrodes can be varied, the compactness or porosity of the coating can be varied. When the residence time of an analyte in the zeolite layer needs to be considered, possibly to increase its interactive or reaction time with the zeolite, prior to its detection at an imposed potential at the electrode, the porosity of the coating can be exploited as one of the variables of the method.

We observed this for our co-electrodeposited coatings of NaA and 1,4-dinitrobenzene, in which the zeolite particle size could be varied from that of the pure powder, $<10 \mu\text{m}$ (as determined by scanning electron microscopy¹⁸), to larger size ranges obtained by sieving ground Linde 4A pellets. As would be expected, coatings formed from larger particles, though visibly compact, were more open to electroactive solute in solution than those formed with the pure NaA powder. This can be seen in Fig. 4, where the limiting current obtained at a zeolite-coated platinum electrode for an electroactive species in solution is contrasted with that at an uncoated platinum electrode of equivalent area. Compact coatings formed from pure NaA powder typically blocked 70–80% of the electrode surface (compare Fig. 4d with Fig. 4c), while compact coatings formed from 4A sieve ground to 88–125 μm typically blocked only 30–40% of the surface (compare Figs. 4a and 4b).

Fig. 4. Limiting current density as a function of potential for rotated Pt disk electrodes [(a), (c)] and Pt disk electrodes compactly coated with a co-electrodeposited layer of NaA/1,4-dinitrobenzene [(b), (d), (e)], for (a) and (b) 1mM ferrocene in 0.1M $\text{Et}_4\text{NClO}_4/\text{CH}_3\text{CN}$, $\omega = 1600$ rpm, sweep rate = 50 mV/sec; (c–e) 0.2mM 1,4-benzoquinone in 0.1M $\text{Et}_4\text{NClO}_4/\text{CH}_3\text{CN}$, $\omega = 900$ rpm; (c) and (e) sweep rate = 50 mV/sec; (d) sweep rate = 5 mV/sec; (b) 4A sieve ground to 88–125 μm ; (d) and (e) NaA powder, <10 μm particle size.

The pure NaA powder coatings were so compact that loss of hydrodynamic control of mass transport occurred if the electrode potential was swept too rapidly—as seen in Fig. 4e, a voltamperogram indicative of surface-confined mass transport results. Though ferrocene and 1,4-benzoquinone (the electroactive solutes used in obtaining Fig. 4) are not analytes that would necessarily benefit from manipulation of the duration of their interaction with the zeolite, they demonstrated that the porosity of the zeolite overlay can be readily changed without

altering the nature of the chemical and physical characteristics of the zeolite.

CONCLUSION

Our characterization of zeolite A coatings electrodeposited on rotated disk electrodes (and understanding of the variables controlling the electrodeposition¹⁸) has given us an appreciation of the subtle and overwhelming influences zeolites can have on an electrochemical interphase. As described in this paper, especially through the results of other workers, the analytical implications of these zeolitic influences can be discerned. The electroanalytical promise of the size/shape selectivity and cation-exchange capacity of the aluminosilicate zeolites as described here is great, but also two-edged in that unexpected consequences (e.g., entrainment of apparently “spectator” species, such as oxygen or water; potential ion-association reactions between charge-compensating zeolite cations and the analyte, the mobility of cations in and out of the zeolite) can affect what seemed to be a straightforward analysis. As with analytical chemistry in general, the characteristics of the analyte, the medium, other components of the solution, and the sensor, must be known before successful analyses can be obtained.

IMMOBILIZATION OF LACTATE OXIDASE IN A POLY(VINYL ALCOHOL) MATRIX ON PLATINIZED GRAPHITE ELECTRODES BY CHEMICAL CROSS-LINKING WITH ISOCYANATE

KIAMARS HAJIZADEH, H. BRIAN HALSALL and WILLIAM R. HEINEMAN*

Edison Sensor Technology Center and Department of Chemistry, University of Cincinnati, Cincinnati, OH 45221-0172, U.S.A.

(Received 15 November 1989. Accepted 27 March 1990)

Summary—A new method for development of an electrochemical sensor based on lactate oxidase is described. Platinized spectroscopic-grade graphite electrodes were modified by chemically cross-linking L-lactate oxidase from *Pediococcus species* into a poly(vinyl alcohol) network through reaction with a tri-isocyanate. The immobilized enzyme exhibits high activity and long-term stability. The sensor provides a linear response to L-lactate over a concentration range of 2×10^{-5} – $4 \times 10^{-3} M$ and a sensitivity of $1.71 \mu A.l. mmole^{-1}$. The response time of the sensor is 10–45 sec and the detection limit is $10 \mu M$. Stable response to the substrate was obtained over a period of 3 months. The new sensor was also used for the analysis of some dairy products without any special pretreatment.

The last decade has seen unprecedented interest in the development of probes for the qualitative and quantitative monitoring of biological samples of analytical interest.^{1,2} Many of these are based on enzymes and a number of different procedures are available for enzyme immobilization.³ Whereas much enzyme-sensor development is devoted to glucose oxidase, because of its recognized importance in glucose assay as a diagnostic monitor for diabetes,⁴⁻⁶ there is also a growing interest in the development and application of other sensors.

One of the enzymes that has attracted a considerable degree of attention is lactate oxidase (LOD). Blood lactate concentration is indicative of certain pathological states such as shock, respiratory insufficiencies and heart disease.⁷ The lactate concentration in blood rises rapidly as a result of anaerobic glucose metabolism when delivery of oxygen to body tissues is insufficient (Fig. 1). The fact that the hydrogen ions produced from dissociation of lactic acid are effectively buffered by bicarbonate makes pH measurements less useful than direct lactate determination. Also, though transcutaneous oxygen measurements and the arterial-venous pO_2 difference (measured with oxygen sensors) may have some utility as indicators of blood flow, lactate measurement is more convenient and useful.⁸ This becomes especially important

when the tissue oxygen is adequate but aerobic metabolism is inhibited.

In sports medicine, the lactate concentration is a very useful indicator for assessing the general physical condition of an athlete or racing animal.⁸ Highly trained individuals produce less lactate than unconditioned ones for a given exercise.

The involvement of lactate in the metabolism of glucose poses more demand on the use of a lactate sensor in conjunction with a glucose sensor for diabetic patients;⁹ the applicability of such a combination has been demonstrated in the evaluation of an endocrine artificial pancreas.

In the food industry, measurement of lactate in dairy products and for the control of additives (in wines *etc.*) is also of considerable importance. The lactic acid content of food products influences their flavor, stability and keeping quality.¹⁰

Several different methods are available for the electrochemical determination of lactic acid by use of immobilized lactate oxidase, but the three below have been most widely used.

Lactate oxidase from *Mycobacterium smegmatis*, which acquires flavin adenine mononucleotide as a co-factor in the consumption of oxygen, converts lactate into acetate and carbon dioxide. The measurement of oxygen depletion is used as an indirect means of estimating the lactate level.^{11,12}

*Author for correspondence.

Fig. 1. Anaerobic glucose metabolism.

Lactate oxidase from *Pediococcus species*, an enzyme dependent on flavin adenine dinucleotide (FAD), catalyses the conversion of lactate into pyruvate and hydrogen peroxide by consumption of oxygen.^{12,13} In this case, the production of hydrogen peroxide can be measured as an indicator of the lactate concentration.^{14,15}

In the third approach, the catalytic activities of LOD and lactate dehydrogenase (LDH) are coupled, the LOD being enzymatically regenerated by the LDH. This enzymatic cycling reaction greatly amplifies the response.¹⁶⁻¹⁸ Although this system is conceptually attractive and yields low detection limits, it suffers from slow response time (4-9 min). Also, the preparation of the enzyme support involves some complicated steps and takes several days.

Isocyanates have been used extensively as cross-linking agents¹⁹ in polyurethane technology. Their reactions generally involve chain extension and network formation through interaction of nucleophilic groups (*e.g.*, hydroxyl, amino) with the isocyanate electrophilic carbon atoms. Some isocyanates have also been used as cross-linking agents for enzymes such as ribonuclease and chymotrypsin.²⁰

The ability to prepare well-defined model networks of the polyurethane type by end-linking hydroxyl-terminated chains by means of aromatic tri-isocyanates (TIC)²¹ has made their use attractive in the preparation of enzyme-based biosensors.²² Poly(vinyl alcohol) is a neutral partially water-soluble²³ and biocompatible polymer²⁴ and is, therefore, an appropriate matrix for consideration in sensor preparation.

Fig. 2. Chemical structure of TIC.

In the present work we report incorporation of FAD-dependent LOD into a poly(vinyl alcohol) (PVAL) network prepared by cross-linking the available reactive nucleophilic groups (hydroxyl, amino *etc.*) with TIC (Fig. 2). Hydrogen peroxide, a product of the enzymatic reaction, was detected amperometrically at an electro-platinized spectrographic graphite electrode, which has been shown to lower the oxidation overpotential of hydrogen peroxide considerably.^{5,25}

EXPERIMENTAL

Reagents

PVAL [hydrolysed from poly(vinyl acetate)] of average molecular weight 8.6×10^4 , and Nafion solution (5% solution in a mixture of aliphatic alcohols and 10% water) were obtained from the Aldrich Chemical Company, Inc.

Lactate oxidase (L-lactate: oxygen oxidoreductase E.C. No. 1.1.3.2), from *Pediococcus species*, was purchased from Boehringer Mannheim Biochemicals.

L(+)-Lactic acid (lithium salt) was obtained from the Sigma Chemical Company. The high-reject polymer was provided by Yellow Springs Instruments (YSI).

TIC (triphenylmethane isocyanate) was generously provided by Dr. D. H. Chadwick of Mobay Chemical Company, New Martinsville, WV.

Dimethylsulfoxide (DMSO; Fisher Scientific) and other chemicals were of reagent grade and used without further purification unless otherwise stated.

Demineralized organic-free water was used for the preparation of all solutions.

Apparatus

Amperometric experiments were performed with a Bioanalytical Systems CV-27 voltammograph and recorded with a Houston Instruments series 5000 $x-t$ recorder.

A thermostatically controlled circulating-water bath (Lauda Model S-1) was used for controlled-temperature experiments.

Scanning electron micrographs (SEMs) were obtained with a Cambridge Stereo Scan 600 scanner at the Materials Science Department, University of Cincinnati.

Sensor preparation

The cylindrical surfaces of the rod-shaped spectrographic graphite electrodes (Poco

Graphite, Inc., grade AXF-SQBL-1, lot 430, Cat. No. 366-BD) were sprayed with "Krylon" as a protective coating and the flat ends were fine-polished on 600-grit emery paper. After sonication in an ultrasonic bath (Branson Ultrasonics Corp.) in "nano-pure" water to remove any loosely attached material, they were dried at room temperature in a dust-free atmosphere. Chronocoulometric measurements in 1mM potassium ferricyanide/0.5M potassium chloride/0.02M phosphate at pH 7 were used to calculate the surface area of the electrode before coating.²⁶ The average electrode area was 0.17 cm².

Electro-deposition of platinum onto the polished surface of the graphite electrodes was done from a 10mM hexachloroplatinic acid solution by holding the potential at -200 mV vs. Ag/AgCl for 10 min.

Different approaches were used for enzyme immobilization on the platinized area of the electrode.

PVAL-LOD. This electrode was made in layered form, with 5 μ l of PVAL solution (3.0% in water), 11 activity units of LOD, and 10 μ l of the PVAL solution added successively, with drying between additions. The electrode was used without any cross-linking treatment.

LOD-ISO. This electrode was simply made by covering the platinized graphite electrode with 11 activity units of LOD, letting it dry, and then treating it with 1.1 μ l of the isocyanate solution (0.045 g in 0.25 ml of DMSO).

PVAL-LOD-ISO-1. This approach is based on that developed for alkaline phosphatase.²² First, the equivalent of 11 activity units of LOD (in 5 μ l of solution) was placed at the middle of the active surface of the electrode and spin-dried, and 2.5 μ l of PVAL solution (3.0% w/w in DMSO) were placed on this layer. Finally, 1.1 μ l of TIC solution (0.045 g in 0.25 ml of DMSO) was applied and mixed in by spinning the electrode. A gel was formed in a few seconds, indicating cross-linking of the PVAL-LOD system. The electrode was then immersed in stirred water for 5 min to remove unreacted material. The cross-linked polymer and/or polymer-enzyme shrinks to the middle part of the electrode surface, looking like a small disk (\approx 0.2 mm in diameter).

PVAL-LOD-ISO-2. In this approach the cross-linking was performed with the polymer and enzyme both in the dry state; 5 μ l of the PVAL solution were applied on the electrode and spin-dried, then 5 μ l of LOD solution (11

units of activity) were added and dried similarly. The electrode was finally covered with 10 μ l of PVAL solution, dried by spinning, and left in a dust-free atmosphere for 3 hr. Finally, the dried film was treated with 1.1 μ l of TIC solution for 45-60 sec. During this period the color of the electrode surface changed to white, indicative that the cross-linking process had taken place. The electrode tip was then immersed in DMSO for 5-10 sec and agitated to ensure removal of the unreacted ingredients. Finally, it was rinsed in stirred, demineralized organic-free water for 5 min and kept in phosphate buffer at pH 7 until use.

PVAL-LOD-ISO-3. This electrode was prepared identically to PVAL-LOD-ISO-2 except that a total of 25 μ l of PVAL solution was used.

PVAL-LOD-ISO-4. In this procedure, cross-linking was performed with all the reacting components mixed together in solution on the electrode surface.

The electrodes' responses were determined by hydrodynamic amperometry. This was done by immersing the sensors in stirred phosphate buffer and applying the required oxidative potential. When the background current had stabilized, an appropriate amount of concentrated lactate solution was introduced to give a preselected concentration. The faradaic current increased as a function of time and eventually reached a limiting value. The difference between the limiting and the background current was taken as the sensor response to any particular lactate concentration.

In accordance with previous reports,^{5,25} electrochemical deposition of platinum on the graphite lowered the oxidation potential of H₂O₂ to +0.300 V vs. Ag/AgCl, compared with 1.2 V on an unplatinized graphite electrode, which is advantageous in that the sensor response is then less susceptible to electrochemical interferences. The platinized graphite surface retained its catalytic properties for over five months when stored in phosphate buffer at room temperature or 4° or in the dry state at room temperature.

RESULTS AND DISCUSSION

Assessment of the cross-linking procedure

An important aspect of sensor development is finding reaction conditions that effectively immobilize a sufficient concentration of the enzyme in an active, accessible and stable form to provide adequate sensor performance. For

this purpose five different procedures for the immobilization of LOD were evaluated with respect to lactate response. Sensor performance for each of these electrode types is summarized in Table 1 and the important features of each are discussed below. Performance was evaluated with respect to the amperometric response to an aliquot of lactate injected into a stirred solution. A representative response is shown in Fig. 3.

PVAL-LOD. Electrodes coated with successive layers of PVAL, LOD and PVAL exhibited a high initial sensitivity to lactate. The active enzyme is immobilized for a short time in the slightly soluble polymer film. However, slow dissolution of PVAL over the course of several hours of immersion in aqueous samples releases LOD and the sensitivity decreases dramatically. Similar behavior has been observed for glucose oxidase in PVAL.²² Whereas this arrangement gave the highest response to lactate, the short lifetime renders it impractical for preparation of a stable sensor. However, the strong initial response was used as a standard (100% in Table 1) against which the performance of electrodes prepared by other procedures was compared. The loss of enzyme activity in this case can also be attributed to the generally accepted fact that non-cross-linked proteins are less stable than their corresponding cross-linked forms.^{20,27}

LOD-ISO. Enzyme cross-linked with TIC directly on the electrode surface without PVAL gave a response to lactate. A thin, white and somewhat swollen film with a lustrous appearance was formed. Microscopic examination revealed a web-like network of cross-linked enzyme. This electrode lost most of its activity within several hours and the response remained at only 3% of that of the standard electrode. Addition of TIC solution to a solution of LOD

Fig. 3. Typical hydrodynamic amperogram of a chemically cross-linked PVAL-LOD-ISO-2 electrode in 2mM lactate solution in phosphate buffer (pH 7.0). Applied potential 300 mV vs. Ag/AgCl.

Table 1. Properties of lactate sensors made by different methods

Electrode	Relative response,* %	Response time, sec	R.S.D.,† %
PVAL-LOD	100	>45	6.4
LOD-ISO	28	~30	—
PVAL-LOD-ISO-1	14	6	5.2
PVAL-LOD-ISO-2	72	10-45	1.3
PVAL-LOD-ISO-3	79	60	3.2
PVAL-LOD-ISO-4	56	>20	6.0

*Relative to the LOD-PVAL electrode in 2mM lactate at pH 7 (0.1M phosphate buffer).

†Five measurements.

in DMSO results in the formation of an insoluble clump which is believed to be inactivated cross-linked enzyme.

PVAL-LOD-ISO-1. This electrode gave the poorest sensitivity to lactate. The cross-linked film was condensed as a clump on the middle of the electrode surface. The faster response of this sensor can be attributed to the fact that the area surrounding the clump, although appearing to be bare, is actually covered by a very thin layer of enzyme, which will make the electrode surface more readily accessible to the products of enzymatic reaction.

The considerable loss of enzyme activity in PVAL-LOD-ISO-1 is presumably due to extensive intra- and inter-molecular cross-linking of LOD molecules. The results are consistent with the work of other investigators on other enzyme systems with various cross-linking procedures, including isocyanate reactions.^{20,28,29}

PVAL-LOD-ISO-2. The procedure in which the enzyme and polymer were in the dry state on the electrode surface before cross-linking with TIC gave a sensor with good sensitivity, reasonably fast response and the best precision for lactate. This sensor was very smooth and homogeneous in appearance.

The lower response of PVAL-LOD-ISO-2 compared to the PVAL-LOD standard sensor is believed to be a result of the cross-linking process rather than of denaturation caused by the presence of DMSO. As a test, TIC-free DMSO was applied to the active surface of a PVAL-LOD electrode. After 1-4 min of contact with DMSO, which is longer than the cross-linking period of less than 1 min, no loss of enzyme activity was observed.

PVAL-LOD-ISO-3. This electrode differs from the previous one only in the amount of PVAL used, which was almost doubled. The resulting increase in polymer-film thickness

caused an increase in response time, which is most likely due to the greater distance through which the substrate/product must diffuse in the polymer film.

PVAL-LOD-ISO-4. Although this electrode provided a relatively good sensitivity to lactate, it had an irregular clumpy appearance with some loose particles, which led to a relatively poor precision compared with the *PVAL-LOD-ISO-2* electrode.

The *PVAL-LOD-ISO-2* electrode was adopted for the rest of this work, because of its better properties and performance overall.

Microscopic observations

The scanning electron micrograph (SEM) of the end of a spectroscopic graphite rod (Fig. 4A) reveals a very porous surface. The SEM of an electro-platinized graphite electrode (Fig. 4B) shows that the surface retained the roughness and porosity, but was essentially coated with platinum. Energy-dispersive X-ray analysis spectra obtained during the SEM study of the platinized surface clearly showed the presence of platinum.

The porosity of the electrode material is advantageous in that some polymer soaks in and anchors the film.³⁰ The adhesion and mechanical strength of the cross-linked film on the electrode were found to be excellent.

Although the platinized graphite electrode that was coated with polymer and lactate oxidase (*PVAL-LOD-ISO-2*) had a smooth and continuous visual appearance, SEM showed a web-like network with aggregates in the middle part of the electrode where the enzyme was originally placed (Fig. 4C). The film thickness was about 50–80 μm in the dry state. This was estimated from an SEM of the side of an electrode coated with PVAL film.

The aggregates were fairly uniform in size and roughly spherical, with an average diameter of about 0.5 μm . These aggregates were not observed in a chemically cross-linked PVAL film in the absence of LOD (Fig. 4D). The surface of the latter coating appears to be smooth. Since we have already observed some indications of enzyme cross-linking and do not see a similar network in the absence of the lactate oxidase, we can ascribe these aggregates to cross-linked LOD and/or cross-linked

Fig. 4. Scanning electron micrographs of A, polished graphite electrode (2000 \times), B, platinized graphite electrode (2000 \times), C, platinized graphite *PVAL-LOD-ISO-2* electrode (10000 \times) and D, platinized *PVAL* graphite electrode cross-linked with TIC (1000 \times).

PVAL-LOD. Similar observations have been made when gamma-irradiation was used for enzyme immobilization.^{5,31}

Effect of DMSO on enzyme activity

Since DMSO is one of the constituents used in the cross-linking process, its effect on enzyme activity was evaluated. Hydrodynamic amperometry was used for direct measurement of the hydrogen peroxide produced by the free enzyme in solution. The initial rate of hydrogen peroxide formation was taken as a good estimate of the enzyme activity.

The response for free LOD in aqueous solution or 50% v/v water-DMSO was 1.6 $\mu\text{A}/\text{min}$, whereas that of the enzyme incubated in 100% DMSO was zero.

These results are consistent with our previous results showing the need for the presence of water to maintain greater enzyme activity for glucose oxidase.²² This effect becomes important when the enzyme is immobilized by cross-linking in the presence of DMSO.

Effect of pH and solution matrix

The effect of pH on the activity of the lactate sensor was also studied. Table 2 shows the sensor response to lactate solution in phosphate buffer in the pH range 6.0–11.1. Phosphate buffer of pH 7.0 was chosen as optimal for the rest of this work. The reported optimum pH range for the free enzyme is 6–7,³² which is comparable to that found for the immobilized LOD. The free enzyme is known to be stable in the pH range 6–9, but the cross-linked LOD was found to be stable from pH 6 to 11.1. The background current increased significantly at pH values above 8. When the lactate sensor was then returned to pH 7 it gave 95% of its original response under the same conditions. The orig-

11.2	2.2

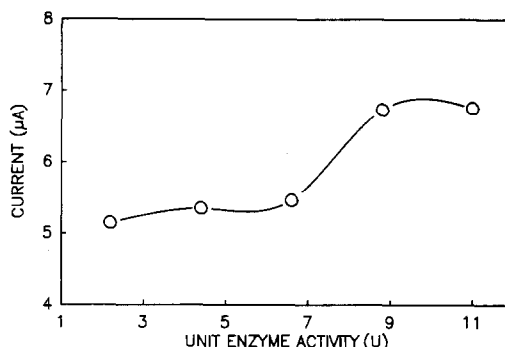

Fig. 5. Effect of the amount of immobilized LOD, on the sensor response.

inal loss of response at high pH values can be attributed, in part, to partial unfolding of the enzyme, which refolds when it is brought into contact with the solution of pH 7. Thus the sensor is reversibly inactivated by high pH. The optimum pH value reported for lactate oxidase immobilized by a different method is 7–7.5.¹³

The presence of 4.6mM azide in 0.1M phosphate buffer (pH 7), used initially as a bacteriostat, attenuated the electrode response by about 60%. Azide was therefore omitted from the buffer solution for lactate measurements. In contrast to an earlier report,¹³ the presence of potassium chloride, magnesium chloride and FAD had no significant effect on the sensitivity of the sensor, except for a higher background current and increased stabilization time.

Effect of the amount of immobilized LOD

LOD (from 2.2 to 11 activity units) was immobilized by the cross-linking process on five electrodes. As the amount of LOD increased, a larger response to the addition of substrate was obtained (Fig. 5); a loading of 5.5 activity units (260 μg) of LOD was chosen for economy.

Response to lactate

To construct a calibration curve, various amounts of L-lactate solution were added while the sensor was immersed in the stirred buffer, and hydrodynamic amperograms were recorded.

Figure 6 represents the calibration curve for lactate, obtained from the average responses of five electrodes. The sensors' responses increased with the concentration of lactate up to 14mM. The linear range was 0.02–4mM, the equation being $Y (\mu\text{A}) = 1.71X (\text{mM}) + 0.097$, with a correlation coefficient of 0.9994. The average relative standard deviation over the linear range

Fig. 6. Calibration curve for different concentrations of L-lactate on chemically cross-linked PVAL-LOD-ISO-2 sensors.

was 3.6%. The average detection limit of the sensors was $10\mu M$.

The loss of linearity at higher concentrations is attributed to oxygen limitation. Oxygen is a co-substrate in enzymatic degradation by oxidases and its limiting effect on the rate of reaction has already received considerable theoretical treatment.^{33,34} It has been shown that regeneration of oxygen at the electrode where the oxidase is located significantly increases the sensitivity of the electrode to the substrate. We have also observed that passing oxygen into a $5mM$ lactate solution in the presence of the LOD electrode leads to a sharp rise of $\sim 15\%$ in the stabilized current, which falls to a stable increase of $\sim 7\%$ after the oxygen flow is turned off. We have shown³⁵ that a lactate sensor prepared by gamma-irradiation immobilization of LOD in PVAL has an upper linear response limit of $8mM$ lactate when used under continuous oxygen flow.

The upper limits for these sensors are comparable to or better than those for many other amperometric lactate sensors: $3mM$ for LOD entrapped in a cellulose-based dialysis membrane in the presence of polyurethane on a

Fig. 7. Effect of temperature on the activity of the LOD electrode.

Pd/Au-sputtered carbon electrode,³⁶ $0.2mM$ for LOD from *Mycobacterium smegatis* cross-linked on chemically treated nylon nets by glutaraldehyde,⁷ and $0.5\mu M$ by enzymatic cycling procedures designed for the detection of very low lactate concentrations.¹⁵

By incorporation of a membrane of low permeability on top of a high-reject lactate membrane (Yellow Springs Instrument Co.) the diffusion of the analyte to the underlying enzyme layer was restricted and, as a result, the upper limit of the linear range extended to $10mM$.³⁷

The Michaelis-Menten constant, K_m (apparent), for the immobilized LOD was $9.75mM$, as measured by Cornish-Bowden plots.³⁸ The K_m value for the free enzyme was $0.7mM$.³² This change in K_m is likely to be due to a combination of the effect of diffusion of the substrate(s) to the active sites being modified by the microenvironment of the enzyme,³⁹⁻⁴¹ and of the effect of structural changes in the enzyme as a result of the chemistry of cross-linking. It has been demonstrated that, for a two-substrate enzyme reaction in which the relative affinities of the substrates are significantly different, the Michaelis-Menten constant increases as the diffusion is more efficiently restricted.³⁹

Temperature effects

The temperature dependence of the sensor response was measured between 10 and 75° in $1mM$ lactate solution (Fig. 7). The sensor was held at each temperature for 15 min, including the rise-time. The probe response gradually increased to a maximum at 60° and then fell more sharply. The background current and the noise increased with increasing temperature. On cooling to 35° , the electrode gave the same response as before heating. Since the optimum temperature for the free enzyme is 35° , with activity retained up to 45° ,³¹ it appears that the enzyme has been stabilized by the cross-linking.

Electrochemical interferences

Since hydrogen peroxide can be detected very efficiently at 0.3 V vs. Ag/AgCl on a platinized graphite electrode, the number of potential electrochemical interferences will be minimal. Uric acid and acetaminophen, two commonly encountered interferents in biological samples, do not interfere significantly with the detection of hydrogen peroxide at a platinized electrode.⁴² Ascorbic acid, however, may interfere because it can be oxidized at potentials lower than

300 mV. To minimize the effect of ascorbate, an additional layer of Nafion or YSI high-reject polymer was incorporated in the sensor preparation. The electrodes were prepared identically. First Nafion or the high-reject polymer was coated onto the bare electrode and then the PVAL enzyme and PVAL layers were applied in turn, following the method of preparation used for the PVAL-LOD-ISO-2 sensor. After each layer had been applied, the response of the electrode to ascorbic acid was recorded. Figure 8 shows the normalized responses of the modified sensors to ascorbic acid compared with that of the bare platinized graphite electrode. An electrode (B) covered with only a layer of chemically cross-linked PVAL gives an ascorbate signal 87% lower than that of the bare platinized electrode (A). Incorporation of LOD into the cross-linked PVAL (by sandwiching it between two PVAL layers and then cross-linking) attenuates the relative ascorbate response even more, by 90.5% (C). Therefore, the normal preparation of cross-linked PVAL-LOD-ISO-2 in the absence of a Nafion or high-reject polymer layer attenuates the ascorbate response considerably. The addition of a Nafion layer (D) reduces the interfering response by 98.4%, and the high-reject polymer (E) provides 96.2% attenuation. Although this seems to be only a small change relative to the attenuation by the cross-linked PVAL-LOD-ISO-2 electrode (90%), because in both cases the response is compared with that of the bare platinized electrode, the actual current produced by ascorbate at the high-reject polymer or Nafion PVAL-LOD-ISO-2 electrode is less

Fig. 8. Attenuation of ascorbate interference by incorporation of Nafion or high-reject polymer films. Electrodes: A, platinized graphite, B, platinized graphite/cross-linked PVAL, C, platinized graphite/cross-linked PVAL-LOD-ISO-2, D, platinized graphite/Nafion/cross-linked PVAL-LOD-ISO-2 and E, platinized graphite/high-reject polymer/cross-linked PVAL-LOD-ISO-2. Ascorbic acid concentration 200 μ M.

Fig. 9. Relative responses of PVAL-LOD-ISO-2 electrodes in 2mM lactate. A, Uncoated; B, coated with 500 μ g of Nafion, C, coated with high-reject polymer.

than half of that produced at the PVAL-LOD-ISO-2 electrode.

Although Nafion or high-reject polymer reduces the ascorbate response, it also lowers the response to lactate (Fig. 9). The electrodes with Nafion or high-reject polymer coated with cross-linked PVAL-LOD had a sensitivity to lactate that was only \sim 45% of that of the cross-linked PVAL-LOD electrode, probably because of the restricted diffusion of hydrogen peroxide in the thicker films.

To investigate this effect in more detail, a series of systematic studies was conducted. The amperometric responses of three sets of platinized graphite electrodes to 4.6mM hydrogen peroxide were recorded before (A) and after coating with Nafion (B) high-reject polymer (C) and cross-linked PVAL (D). The results are summarized in Fig. 10.

Electrodes B and C gave relative signals of only 4.3 and 5.7%, respectively. The response of these two modified electrodes was instantaneous. Electrode D, on the other hand, produced a response of 8.6%, with a response time of 9.6 sec. This clearly shows that the Nafion and high-reject layers restrict the diffusion of

Fig. 10. Hydrogen peroxide response on platinized graphite electrodes coated with A, no film; B, Nafion; C, high-reject polymer; D, cross-linked PVAL. H_2O_2 concentration 4.6mM.

hydrogen peroxide to a great extent, and the sensitivity of the sensor can be substantially impaired.

If the Nafion film thickness could be optimized so that ascorbate is excluded but the hydrogen peroxide flux through the film is increased, the sensitivity of the Nafion cross-linked PVAL-LOD-ISO-2 electrode could be enhanced.

Table 3 shows the response to hydrogen peroxide of two sets of platinized graphite electrodes before and after coverage with (A) 167 and (B) 83 μ g of Nafion. For electrode A, the response to different hydrogen peroxide concentrations varies from 5.1 to 7.0% relative to that of the uncovered electrode. On the other hand, sensor B, which is covered with half as much Nafion, provides a 31–44% relative response for the same range of hydrogen peroxide concentration.

Table 4 gives the responses of electrodes A and B to different ascorbate concentrations. As expected, electrode A has a lower response than electrode B to ascorbate, but this is outweighed by the greater sensitivity of the electrode B to hydrogen peroxide.

This result could be used to advantage in the preparation of an LOD-based sensor, featuring both the desired sensitivity to peroxide and the lower interference by ascorbic acid. On this basis, an LOD-based electrode was prepared with 83 μ g of Nafion coating. This sensor shows essentially no loss of sensitivity to lactate, compared with the LOD sensor without Nafion, but

the response to ascorbic acid (Table 5) is only 5% of that of the bare electrode. The response time of this Nafion PVAL-LOD-ISO-2 electrode was 40–60 sec.

Lifetime

Figure 11 shows the effect of storage of the electrodes under various conditions. The buffer was renewed before each measurement. The electrodes show good stability over a period of two months. The PVAL-LOD-ISO-3 electrode stored dry in phosphate salt continued to give a stable response to lactate for another 100 days, with 2.3% R.S.D. and a total lifetime in excess of 5 months.

Analysis of dairy products

The concentrations of L-lactate in different kinds of dairy products (sour cream, plain yoghurt and milk) were determined. Table 6 summarizes the results and the pooled relative standard deviation obtained for six readings on each of four LOD-based electrodes. The dairy products were diluted by a factor of 150–500 for amperometric analysis, with no other pre-treatment. The lactate concentration in plain

yoghurt B, which was a commercially available product, matches very well with the values reported in the literature (83.7 and 80.6mM) and obtained by using a different immobilization method for preparing the electrode.¹³ To assess the accuracy of the results obtained by these sensors, a standard-addition method was used with two lactate sensors. For yoghurt of two different dilutions (195 and 390), and six readings, the recovery was $95.6 \pm 2.7\%$ and for sour cream $93.1 \pm 3.6\%$. These results show good accuracy and the reliable measurement of lactate in more complex matrices.

CONCLUSIONS

Chemical cross-linking based on isocyanate chemistry is a feasible method for the immobilization of lactate oxidase and has several important and advantageous characteristics. The immobilization method is very simple, making it especially useful for the manufacture of an LOD-based sensor. The sensors can be fabricated in 1–3 hr if all the reagents are prepared beforehand.

The present results compare very well with those reported by others. The response of the chemically cross-linked sensors to lactate is fast (less than 1 min), whereas for the tedious enzyme-cycling methods, which usually need several days for preparation of the sensor,¹⁴ it ranges from 4 to 9 min. The electrodes prepared here have longer lifetimes than those made by other workers. The modified films are relatively rugged; no cracks were observed when the electrodes were stored in the dry state. The linear range of the sensors includes the physiological concentrations (1–2.7mM),³⁶ which may be useful for diagnostic purposes. Extension of the upper limit of the linear range to even higher values is currently under investigation. Owing to the relatively high sensitivity of the sensor, samples may be diluted by several orders of magnitude and it is possible to use very small sample volumes (100–250 μ l).

AMPEROMETRIC ENZYME ELECTRODES FOR THE DETERMINATION OF L-GLUTAMATE

RHODORA L. VILLARTA,^{1,2} DAVID D. CUNNINGHAM^{2,*} and GEORGE G. GUILBAULT^{1,2,†}

¹Department of Chemistry, University of New Orleans, New Orleans, LA 70148 and

²Universal Sensors Inc., P.O. Box 736, New Orleans, LA 70148, U.S.A.

(Received 19 February 1990. Accepted 30 April 1990)

Summary—Electrodes for amperometric measurement of L-glutamate were prepared by immobilization of L-glutamate oxidase on an Immobilon-AV Affinity membrane and attachment to an oxygen/hydrogen peroxide sensor. The response of the hydrogen peroxide sensor was linear over the concentration range 5.0×10^{-8} – $5.0 \times 10^{-4} M$ L-glutamate, with a limit of detection of 35 nM. Attachment of a size-exclusion membrane (cut-off for molecular weight > 100) or of a hydrophobic oxygen membrane eliminated electro-oxidizable interferences, but the response was attenuated by a factor of 2–3. The response may be amplified 10-fold by co-immobilizing L-glutamate dehydrogenase with the L-glutamate oxidase. The electrode initially lost 25% of its activity but was then stable for more than 320 days and at least 200 assays. The electrode was successfully used to assay glutamate in a protein tablet and in several food products. A flow-injection system was assembled for the continuous assay of L-glutamate.

There is considerable interest in the rapid determination of glutamate, which is found in many kinds of foods and biological materials. Glutamate is a potent neuroexcitatory amino-acid¹ associated with the neurological pathways involved in a variety of behavior patterns. For example, the modulation of pupil diameter,^{2,3} morphine-induced muscular rigidity,⁴ retrograde amnesia⁵ and visual-task learning⁶ have all been shown to be glutamate-dependent. Monosodium glutamate (MSG) is a popular flavor enhancer linked to the Chinese-restaurant syndrome.⁷ In addition, the determination of L-glutamic acid is important in monitoring the transamination reaction, assay of protein hydrolysate, and detection of disease states associated with abnormalities of L-glutamic acid levels.⁸

Glutamate has been determined by chromatographic methods,^{9–12} potentiometric titrations^{13,14} and other indirect methods.¹⁵ However these methods are time-consuming and tedious. Enzyme-based methods are more selective, and several electrodes for potentiometric glutamate assay have been prepared from glutamate decarboxylase and glutamate dehydrogenase,^{16–23} but these systems proved to be unstable.

L-Glutamate oxidase, from *Streptomyces sp.* X119-6 has been found to react exclusively with L-glutamate, with few inhibitors.²⁴ The enzyme reacts with glutamate according to the equation

An electrode for amperometric determination of glutamate was prepared by immobilizing L-glutamate oxidase on a cellophane membrane sandwiched between Teflon and dialysis membranes.²⁵ The electrode response was linear over the concentration range 0.01–1.0 mM and suffered from interference by L-glutamine, L-aspartate, and L-asparagine.

In this paper, we report amperometric enzyme electrodes based on the immobilization of L-glutamate oxidase on pre-activated Immobilon-AV Affinity membranes. Oxygen or hydrogen peroxide may be monitored amperometrically, and the resulting change in steady-state current or its derivative with respect to time is directly proportional to the glutamate concentration. The base membrane material is a hydrophilized fluorocarbon polymer with the entire surface chemically treated for covalent immobilization of protein through the ϵ -amino groups of lysine.²⁶ The membranes are easy to handle, require very small

†Author for correspondence.

quantities of the expensive enzymes and allow fast and simple enzyme immobilization. To eliminate interferences from electro-oxidizable substances, a hydrophobic oxygen membrane or a size-exclusion membrane (cut-off for molecular weight > 100; "100 m.w. cut-off membrane") was inserted between the electrode and the enzyme membrane. The response was further amplified by co-immobilizing L-glutamate dehydrogenase [EC 1.4.1.4] with the L-glutamate oxidase. The reaction catalysed by glutamate dehydrogenase is

The two-enzyme system causes cycling of L-glutamate, α -ketoglutarate, and NH_4^+ between the two enzymatic reactions, in the presence of NADPH, resulting in an increase in the rate of oxygen consumption. The electrode thus prepared was included in a flow-injection system for the continuous assay of glutamate.

The electrode is more selective, sensitive and stable than any previously reported.

EXPERIMENTAL

Instrumentation and materials

Steady-state currents were measured with a Bioanalytical Systems (BAS) LC-4B Amperometric Detector (BioAnalytical Systems, Inc., W. Lafayette, IN). Rate measurements were made with a Gould Differentiator Amplifier Model 13-4615-71 and Gould Medium Gain Preamplifier Model 13-4615-10 (Gould Inc., Cleveland, OH). All measurements were recorded by a Houston Microscribe Strip Chart Recorder, Model 4521 (The Recorder Co., San Marcos, TX).

Immobilon-AV Affinity Membranes, 0.65 μm pore size, (Millipore Corporation, Bedford, MA), Pall Immunodyne ImmunoAffinity Membranes (Pall Biosupport Division, East Hills, NY), Nuclepore Polycarbonate Membranes, 0.03 μm pore size, (Nuclepore Corporation, Pleasanton, CA) and UltraBind Affinity Membranes, 0.45 μm pore size, (Gelman Sciences, Inc., Ann Arbor, MI) were purchased. The 100-m.w. cut-off membrane was cast from a solution of cellulose acetate in cyclohexanone, and propan-2-ol according to the procedure of Taylor *et al.*,²⁷ The hydrophobic polyethylene

oxygen membrane, amperometric oxygen electrode and internal-filling solution were from Universal Sensors, Inc., Metairie, LA.

Figure 1 shows a schematic diagram of the flow-injection system utilized for the continuous assay of L-glutamate. The flow-injection system included a Rainin Rabbit Peristaltic Pump and a Rheodyne 4-way sample injection valve. The flow-through cell was constructed in our laboratory from a plastic cuvette machined to fit the electrode tip exactly.

Reagents

L-Glutamate oxidase from *Streptomyces sp.* X119-6 was a gift from Yamasa Shoyu Co., Japan. L-Glutamic dehydrogenase [EC 1.4.1.4] from *Proteus sp.* was purchased from Toyobo Co., Ltd., Japan. L-Glutamic acid (monosodium salt, Sigma No. G-1626, 99–100%), bovine serum albumin (98–99%) and glutaraldehyde (Grade II, 25% aqueous solution) were from Sigma Chemical Co., St. Louis, MO. All reagents not listed were of analytical grade.

Regular and spicy "Season All", seasoned and unseasoned meat-tenderizer, (McCormick and Co., Inc., Baltimore, MD), "Your Life" multi amino-acid tablets (P. Leiner Nutritional Products, Inc., Torrance, CA), "Mrs. Dash" extra-spicy seasoning (Alberto-Culver Co., Melrose Park, IL), and "Accent" (Pet Inc., St. Louis, MO) were purchased from a local grocery store.

Measurements were made on samples in Dulbecco's buffer, which was prepared with demineralized water and stored at 5°. Dulbecco's buffer, pH 7.4, contains the following salt concentrations: 137mM NaCl, 2.7mM KCl, 8.0mM Na_2HPO_4 , and 1.5mM KH_2PO_4 .

Solutions of L-glutamate were prepared in Dulbecco's buffer, pH 7.4, containing 5mM sodium azide.

Fig. 1. Block diagram of flow system: (A) carrier solution reservoir [carrier solution: Dulbecco's buffer], (B) peristaltic pump, (C) sample injector, (D) L-glutamate oxidase electrode, (E) amperometric detector, (F) recorder, (G) amplifier, (H) differentiator.

Electrode preparation

The pre-activated membrane was attached to an inverted electrode jacket, (0.78 cm² tip area) with a rubber O-ring. 10 μ l of 72 units/ml L-glutamate oxidase solution were pipetted onto the membrane for the single-enzyme system and 5 μ l of 72 units/ml glutamate oxidase and 5 μ l of 400 units/ml glutamate dehydrogenase for the two-enzyme membrane. The membranes were allowed to dry at room temperature for 1–2 hr and were kept immersed in Dulbecco's buffer at 4° when not in use.

Procedure

The electrode jacket was filled with an internal filling solution, after which the electrode body was carefully inserted. A constant potential of +650 mV *vs.* Ag/AgCl was applied to the Pt working electrode. Electrode responses were then measured after addition of various amounts of standard L-glutamate solution to 10.00 ml of stirred Dulbecco's buffer. For the oxygen-based sensor, a hydrophobic oxygen membrane was inserted between the electrode tip and enzyme membrane. A constant potential of –650 mV *vs.* Ag/AgCl was applied to the Pt working electrode. The steady-state current change was read directly from the detector. The maximum rate of response was determined either from the peak height of the first derivative of current change with respect to time, or calculated from the slope of the line drawn through the maximum rate of current change with time, on the chart recording.

The electrode was included in a flow-injection system for the continuous assay of L-glutamate. Dulbecco's buffer, which served as the carrier solution, was pumped at a flow-rate of 0.80 ml/min. Injections of 100 μ l of standard solutions of L-glutamate were made after the electrode had attained a constant baseline potential.

To measure the glutamate content of a solid, the sample was weighed and then ground and homogenized by use of mortar and pestle. The samples were all dissolved and diluted with Dulbecco's buffer and the solutions were aerated for 5 min before testing.

The extent of enzyme retention on the membranes was determined by colorimetric assay of the storage buffer solutions for glutamate oxidase.²⁸ Two ml of 0.0025M dye solution, 0.50 ml of 16 units/ml peroxidase, 0.50 ml of 15% L-glutamate solution and 0.30 ml of dilute L-glutamate oxidase solution were pipetted into a

cuvette and mixed for a few seconds by use of a vortex mixer. The increase in absorbance at 510 nm was monitored for 3–4 min and the rate of absorbance change was calculated from the linear portion of the plot.

RESULTS AND DISCUSSION

Electrode response

The steady-state current of the electrodes was determined by the reduction of oxygen or oxidation of hydrogen peroxide at the Pt working electrode. Before the addition of glutamate, the electrodes exhibited steady-state currents of 160–220 and 0.1–0.3 nA when polarized at –650 and +650 mV respectively. The background noise at +650 mV was about 7 pA. Figure 2 shows the calibration of the hydrogen peroxide sensor, as a logarithmic plot. The response is linear from $5 \times 10^{-8}M$ up to about $5 \times 10^{-4}M$ L-glutamate. The response of the electrodes levelled off at glutamate concentrations above 1mM, owing to the nearly complete consumption of oxygen at the electrode tip. With substrate recycling, the response levelled off at a much lower concentration, $1.0 \times 10^{-4}M$. The detection limit of the hydrogen peroxide sensor is 30nM for steady-state measurements and 90nM for rate measurements (Fig. 3). The detection limit is defined as the substrate concentration which gives a signal $Y_{DL} = Y_{blank} + 3s$, where s is the standard deviation of y_{blank} .²⁹ Generally, steady-state measurements are more sensitive than rate measurements. However, rate measurements have a larger linear range and the maximum rate occurs at about 14 sec after sample injection, in comparison to 2 min for steady-state measurements.

Fig. 2. Calibration of hydrogen peroxide sensor (logarithmic plot). Response is shown as the log of steady-state current change *vs.* -log (L-glutamate concentration).

Fig. 3. Calibration plots for ● initial rate and △ steady-state measurements for low concentrations of L-glutamate. Left-hand scale is change in steady-state current. Right-hand scale is the time derivative of current. X_s = DL for steady-state measurements. X_r = DL for initial rate measurements.

Figure 4 shows the correlation of rate of current change, peak current and assay time with flow-rate. A relative response of 100 corresponds to 350 nA/min and 150 nA for maximum rate and peak height, respectively. The rate response is optimum at 0.80 ml/min, and the peak current and assay time decrease non-linearly with flow-rate. Thus, 0.80 ml/min was chosen as giving the best compromise with regard to response and assay time and was used for subsequent studies. Between 50 and 60 100- μ l samples may be assayed per hour under these conditions.

Figure 5 shows a comparison of the responses of the hydrogen peroxide sensors with and without the 100-m.w. cut-off membrane and of the oxygen sensors with and without substrate recycling. Without a second membrane, the

Fig. 5. Correlation of ○ initial rate, ▲ peak current, and □ assay time, with flow rate at 25°. Right-hand scale is the relative response for initial rate and peak current. A relative response of 100 corresponds to 350 nA/min and 150 nA for initial rate and peak current respectively. Left-hand scale is the assay time for one measurement, which includes response time and time for baseline recovery. Carrier solution—Dulbecco's buffer, substrate—0.439mM L-glutamate; base sensor—oxygen electrode.

steady-state current slope is 0.36 nA/ μ M (correlation coefficient 0.995). Addition of the 100-m.w. cut-off membrane reduced the sensitivity by about 50%, owing to the slower diffusion of hydrogen peroxide through the less porous membrane. With the addition of a hydrophobic oxygen membrane, and with the electrode polarized at -650 mV, the current slope is reduced by about 60%, with a detection limit of approximately $4 \times 10^{-6}M$. The linearity range of the oxygen sensor is regulated by the solubility of oxygen in the sample matrix and by the diffusion of oxygen across the membranes. A much higher detection limit is expected since the signal is measured against a high background current.

Amplification of response current was attained by substrate recycling. In the absence of NADPH and excess of ammonium ions, the responses of the single-enzyme and two-enzyme electrodes to L-glutamate are similar, indicating that the co-immobilization of the two enzymes does not cause any major drawbacks. In the presence of 5mM ammonium chloride and 1mM NADPH, the response of the two-enzyme system was amplified 10-fold (Fig. 4). Since oxygen is not produced in the reaction, substrate recycling leads to a shift of the linear range of the sensor to lower glutamate concentrations.

Optimization of parameters

The performance was evaluated for the electrodes made with Immobilon-AV Affinity

membranes, Pall Immunodyne ImmunoAffinity membranes, UltraBind Affinity membranes, and Nuclepore membranes. The immobilization on Pall and UltraBind membranes was similar to that on Immobilon, as described earlier. The best electrode constructed with the two other pre-activated membranes was only half as sensitive as the electrode prepared with Immobilon, and the membrane lost 50% of its activity after 20 days when stored in buffer at 4°. The enzyme was also immobilized on a Nuclepore polycarbonate membrane with the inert protein bovine serum albumin (BSA) and cross-linked with glutaraldehyde in aqueous medium. The much larger amount of 3.6 units of glutamate oxidase, with an immobilization matrix of 1 μ l of 2.5% glutaraldehyde solution and 10 μ l of 10% BSA solution, was needed to construct an electrode with the same performance as that of an electrode with 0.36 units of enzyme immobilized on Immobilon. When stored in Dulbecco's buffer at room temperature, the electrode was totally inactive after 100 days. The loss of activity is probably due to microbial degradation of the protein in the matrix.

The effects of varying the amount of enzyme load and the immobilization time, on the performance of the electrode constructed from Immobilon, were evaluated. The response increased with enzyme load up to 0.30 units of L-glutamate oxidase per 0.78 cm² of membrane and up to 60 min immobilization time, then started to level off. It was also found that the response varies linearly with the square of percentage of immobilization between 36 and 72%, with a correlation coefficient of 0.990.

Analytical characteristics of the electrode

The effect of pH on the electrode response was studied for four buffer systems with pH ranging from 3.70 to 11.0. The results are shown in Fig. 6. The response does not vary much with the type of buffer used. The response of the immobilized enzyme is optimum at pH 6–8, which is similar to the optimum for the free enzyme, reported to be pH 7–8 at 5°.¹⁹

D-Glutamic acid, various L-amino-acids (aspartic acid, tyrosine, alanine, arginine, glycine, isoleucine, valine, serine, tryptophan, histidine, leucine, proline, methionine, glutamine, cysteine, lysine, asparagine, threonine, and phenylalanine), various compounds containing glutamate (gly-glu, glu-glu and glutamic acid diethyl ester), and several species found in the brain extra-cellular fluid (ascorbic acid, gluta-

thione, dopamine, norepinephrine, 3,4-dihydroxyphenylacetic acid, homovanillic acid and 5-hydroxyindoleacetic acid) were tested as possible interferents. At -650 mV, with the hydrophobic oxygen membrane, no interference from 10mM solutions of these compounds was observed. The oxygen-based sensor is totally specific for L-glutamate, except for samples which contain volatile electroactive compounds (e.g., volatile amines from hydrolysed protein). These compounds diffuse across the hydrophobic membrane to give a positive interference. At +650 mV, a number of amino-acids such as cysteine, tyrosine, dihydroxyphenylalanine, and tryptophan and the neurotransmitters and their metabolites are electro-oxidizable. The incorporation of the 100-m.w. cut-off membrane effectively removes or at least reduces the interference from these compounds to at most 2% when they are present in amounts equal to the glutamate concentration. In addition, the second, less porous, membrane is needed to protect the electrode from fouling by deposition of macromolecules from the sample matrix. In certain applications such as *in vivo* determinations, the monitoring of hydrogen peroxide has advantages. The initial oxygen content of tissues can vary, and this would make electrode calibration difficult and the net current change low. The sensitivities of the oxygen sensor or of the hydrogen peroxide sensor with a 100-m.w. cut-off membrane are enough for most of the intended applications of the device. For example, the calculated *in vivo* concentrations of glutamate in rat brain, determined by microdialysis and voltammetry, range from 1.9 to 22 μ M.³⁰ Substrate recycling increases the

Table 1. Stability of membrane in various conditions at room temperature

sensitivity of the sensor but α -ketoglutarate and NADPH must be added to the sample matrix. This procedure is not strongly recommended, because NADPH is a cofactor for many enzymatic reactions, and might introduce unpredictable interferences.

The stability of the enzyme membrane in different solutions at room temperature is shown in Table 1. The electrode response was considerably inhibited by 5mM hydrogen peroxide and 5mM thimerosal. When stored in Dulbecco's buffer at 4°, the membrane lost 25% of its activity after 7 days, but was then stable at that level for 320 days and at least 200 assays. The stability of the electrode under operating conditions depends on the sample matrix.

Matrices which contain reducing agents or heavy metals such as mercury will rapidly deactivate the enzyme membrane. In buffered solutions of glutamate and other amino-acids, the enzyme membrane remains usable for a long time, depending on the operating temperature, required sensitivity and exposure time of the membrane to the test solution.

Table 2 shows the experimentally determined L-glutamate content of a protein tablet and some food seasonings. The values obtained are in close agreement with the manufacturer's specification within an acceptable range of error.

The immobilization of enzymes on pre-activated membranes has many advantages over the conventional methods of polymerization of the protein by use of a cross-linking agent, and attachment onto a porous membrane. The former procedure is a one-step process and should be more reproducible. Ready-to-use probes utilizing very small amounts of enzymes could be prepared routinely in 1 hr. This is especially important for industrial applications. In the L-glutamate electrode prepared, immobilization of the enzyme on an Immobilon-AV Affinity membrane gave an electrode with better sensitivity and stability than those prepared in the conventional way.

ENZYME ELECTRODE STUDIES OF GLUCOSE OXIDASE MODIFIED WITH A REDOX MEDIATOR

P. N. BARTLETT*, V. Q. BRADFORD and R. G. WHITAKER†

Department of Chemistry, University of Warwick, Coventry CV4 7AL, U.K.

(Received 30 October 1989. Revised 12 December 1989. Accepted 18 December 1989)

Summary—Glucose oxidase modified by the covalent attachment of ferrocenecarboxylic acid or ferroceneacetic acid groups undergoes direct oxidation at metal electrodes. Studies of the comparative stability of the two modified enzymes on storage and on electrochemical cycling show that the material modified with ferroceneacetic acid is the more stable. Amperometric studies of enzyme electrodes based on these modified forms of glucose oxidase show that their application in practical biosensors is severely limited by the poor stability of the oxidized form of the covalently attached ferrocene mediator. A comparison of the results obtained with the native enzyme and with that modified with ferroceneacetic acid, for the oxidation of glucose, D-mannose, 2-deoxy-D-glucose, D-xylose and D-galactose, suggests that the modification procedure has little effect on the selectivity of the enzyme.

The amperometric use of enzyme electrodes has been extensively studied over the past decade. The combination of the selectivity offered by enzyme catalysis with the simplicity and low cost of an amperometric detector is an attractive approach to the production of chemical sensors for a range of biomedical and biotechnological applications.

The coupling of the electron-transfer reactions of the biological component with electron transfer at the electrode poses a major problem. For example, glucose oxidase (GOD) catalyses the oxidation of glucose by molecular oxygen in a two-step process:

In the first step the flavin group (FAD) in the enzyme is reduced by reaction with glucose to give the reduced form of the enzyme, GOD(FADH₂). In the second step molecular oxygen reoxidizes the flavin to regenerate the oxidized form of the enzyme, GOD(FAD). To make use of this in an enzyme electrode for glucose we must detect either hydrogen peroxide production or oxygen consumption, or we must

replace the reoxidation with oxygen by anodic reoxidation of the enzyme.

Very similar considerations apply to the development of biosensors based on other flavoproteins, including D-amino-acid oxidase, L-amino acid oxidase, xanthine oxidase and choline oxidase.

A number of approaches to this general problem have been investigated.¹⁻³ Monitoring the production of hydrogen peroxide or consumption of oxygen,^{9,10} although quite successful, can suffer from oxygen limitation, particularly when used *in vivo*. An alternative is to replace the reaction with oxygen in the second step, by reaction with an artificial mediator:

The reduced form of the mediator, M, can then be reoxidized at the electrode. This approach has been used very successfully, with a ferrocene derivative as the mediator, in a range of applications¹¹⁻¹⁵ and is the basis of a commercial glucose monitor.¹⁶ Another approach is to use a conducting organic salt, such as TTF.TCNQ, as the working electrode in the amperometric sensor,¹⁷ the reduced form of the enzyme being oxidized at the conducting salt electrode. The mechanism of this reaction is not well understood.¹⁸⁻²⁰ Conducting polymers have also been

used to entrap glucose oxidase at electrode surfaces²¹⁻²³ and it has recently been suggested that direct oxidation of glucose oxidase is possible in polypyrrole films²⁴ or in films of *N*-alkylferrocene derivatives of pyrrole.²⁵

Studies by Hill,²⁶ Degani and Heller^{27,28} and ourselves²⁹ have shown that direct oxidation of the flavin centre of glucose oxidase at unmodified electrodes can be achieved if the enzyme is first modified by the covalent attachment of ferrocene groups to amino-acid residues within the protein. This observation has been rationalized²⁷ by the suggestion that the covalently bound ferrocenes act as "stepping stones" allowing electrons to tunnel between the electrode and the active site in a number of consecutive steps.

Hill²⁶ describes the coupling of an average of 8 ferrocenecarboxylic acid groups to glucose oxidase by use of isobutyl chloroformate. In their initial work Degani and Heller²⁷ also describe the modification of glucose oxidase with ferrocenecarboxylic acid, although they employed a different coupling procedure. In a subsequent paper the same authors²⁰ extended this work to include the modification of D-amino-acid oxidase and the use of ferroceneacetic acid and ruthenium pentamine complexes as alternative mediators. In preliminary studies they found that the stability of the modified enzymes varied, depending on the oxidation state of the ruthenium, with the Ru(III) form being more stable than the Ru(II) of the bound mediator. For enzymes modified with ferrocenecarboxylic acid and ferroceneacetic acid they reported a 10% loss of current, determined by cyclic voltammetry, after incubation of the enzyme for 2 hr with 0.03M glucose. In our previous work²⁹ we studied glucose oxidase modified with ferrocenecarboxylic, ferroceneacetic, and ferrocenebutanoic acids. We found differences in the stability of the different modified enzymes on storage (at 4° and pH 7.0, in 0.085M phosphate buffer); the enzyme modified with ferroceneacetic acid was the most stable and that modified with ferrocenebutanoic acid the least.

The covalent attachment of mediators to redox enzymes is interesting for a number of reasons. First, it offers the prospect of reagentless biosensors. Secondly, such modified enzymes might be well suited to *in vivo* applications (because the mediator is covalently bound, the enzymes should not be dependent on oxygen). Thirdly, modified enzymes of this type

may prove useful in the development of bio-electronic devices based on the localization of enzymes on microelectronic substrates. Finally they are of interest in the study of the interactions between enzymes and electrodes and in the study of electron transfer to biomolecules.

In this paper a study of glucose oxidase modified with ferrocenecarboxylic acid (FCA) and ferroceneacetic acid (FAA) is presented. Their behaviour is compared with that of the native enzyme and results for membrane electrode studies with glucose and several other substrates are also given.

EXPERIMENTAL

Ferrocenecarboxylic acid and ferroceneacetic acid were obtained from Aldrich. All other chemicals were AnalaR grade from B.D.H. Glucose oxidase (E.C. 1.1.3.4) from *Aspergillus niger* was purchased from Sigma (type VII, activity 1.769×10^5 U/g). The enzyme was modified by the method of Degani and Heller^{27,28} and the products were purified by gel filtration chromatography on Sephadex G-15. The concentration of modified enzyme in each fraction was estimated from the absorbance at 450 nm and a molar absorptivity³⁰ of 14.1×10^3 l.mole⁻¹.cm⁻¹. The enzyme activity was estimated by a dye-linked spectrophotometric assay based on an earlier procedure.^{31,32} The iron contents of the modified enzymes were determined by atomic-absorption spectrophotometry. Measurements were made in duplicate at two or more concentrations, the buffers used were found to be essentially iron-free. The number of iron atoms per enzyme molecule was found to be 2 for the native enzyme, 13 for the enzyme modified with ferrocenecarboxylic acid and 22 for the one modified with ferroceneacetic acid.

All electrochemical experiments were carried out in 0.15M phosphate buffer (pH 7.0), containing 0.20M sodium chloride. Buffer solutions were freshly prepared with water from a Whatman WR50 water-purification system. Sugar solutions were allowed to equilibrate at room temperature for 24 hr before use. An Oxford Electrodes potentiostat and a Gould Bryans 60,000 series XY/t recorder were used. All potentials are reported with respect to the saturated calomel electrode (SCE).

Membrane electrodes were constructed from glassy-carbon rod (David Feckenham, diameter 0.4 cm) press-fitted into a Teflon mantle and then polished to a mirror finish with alumina

slurry. Solutions of the native or modified enzyme were applied to the glassy-carbon electrode with a micropipette (typical volumes 10–30 μl). The droplets of solution were allowed to evaporate at room temperature (ca. 2 hr) before the membrane was applied. The membranes were made from Medicell dialysis tubing pretreated according to the manufacturer's instructions and held in place by silicone rubber 'O'-rings. The assembled electrodes were kept in buffer solution for at least 30 min and then transferred to the electrochemical cell (kept at $25 \pm 0.1^\circ$) and held at a potential of 0.50 V vs. SCE (this is in the limiting-current region for the oxidation of the ferrocenecarboxylic and ferroceneacetic acids). The background current was allowed to become stable (typically in 20 min) before portions of stock glucose solution were added. On addition of glucose, and after mixing, the enzyme membrane electrode responses became steady in less than 20 sec. All solutions were deoxygenated by passage of oxygen-free nitrogen through them for at least 15 min.

RESULTS

Native enzyme

The initial membrane electrode studies were done with the native enzyme, with 1mM ferrocenecarboxylic acid in the bulk solution. Figure 1 shows typical results for the variation of the current at a membrane electrode of this type with increasing glucose concentration.

These results can be analysed in terms of our model for amperometric membrane enzyme electrodes, and assuming no product inhibition.^{20,33,34} In this model the electrode response is characterized by two parameters, the effective electrochemical rate constant for the enzyme

and

$$K_{\text{ME}} = [K_{\text{M}}/Lk_{\text{cat}} + e_{\text{z}}/k'_{\text{s}}]/[1/Lk_{\text{cat}} + 1/k'] \quad (6)$$

In these equations K_{M} and k_{cat} are the normal Michaelis–Menten terms describing the reaction of glucose with GOD, e_{z} is the concentration of enzyme behind the membrane, L is the thickness of the enzyme layer, k'_{s} is the mass-transport rate constant for the diffusion of glucose through the membrane, and k' is the heterogeneous rate constant (cm/sec) describing the rate of electrochemical reoxidation of the enzyme. When free mediator is present in solution, k' is given by $Lk_{\text{a}}m$, where k_{a} is the rate constant for the reaction between the mediator and the enzyme and m is the mediator concentration. A full discussion of the model can be found in the review by Albery and Craston.²⁰

In Fig. 1, the solid line represents the best fit of the data to this model. From this analysis we find that, at low glucose concentrations, the response is determined by diffusion of glucose through the dialysis membrane. From this and similar data we obtain a mean value for k'_{s} , the mass-transport rate constant for diffusion of glucose through the membrane, of 4.75×10^{-5} cm/sec, in excellent agreement with values in the literature.²⁰ At high glucose concentrations the response reaches a plateau limited either by the rate of the reaction between enzyme and mediator or by the enzyme kinetics. Figure 2 shows the effect of increasing the concentration of ferrocenecarboxylic acid in the bulk solution at a

constant (and enzyme-saturating) glucose concentration. At low ferrocenecarboxylic acid concentrations ($<0.5\text{mM}$) the current depends upon the mediator concentration and hence reaction of the mediator with the enzyme is the limiting factor. At high ferrocenecarboxylic acid concentrations the current is limited by the saturated-enzyme kinetics.

Stability of ferrocene-modified enzymes

The stability of glucose oxidase modified with ferrocenecarboxylic acid or ferroceneacetic acid on storage in deoxygenated aqueous buffer at 4° was monitored by a spectrophotometric assay of the activity in glucose oxidation by molecular oxygen. Figure 3 shows results for the two types of modification. The enzyme modified with ferroceneacetic acid is the more stable, retaining 88% of its activity after storage for 6 days.

To find the cause of the loss of activity, the possibility of loss of FAD from the modified enzyme during storage was first investigated. Gel permeation chromatography of "aged" samples of the enzymes gave no evidence of free FAD in solution and also the absorption spectra of freshly prepared and "aged" modified enzymes were identical. Finally, the addition of free FAD at $1\mu\text{M}$ concentration was found to have no effect on the glucose oxidation activity. We therefore concluded that the loss of activity did not arise from loss of FAD from the active site.

The effect of storage on the number of ferrocene units attached to the enzyme was also investigated. "Aged" samples were purified by gel permeation chromatography after cold storage for 13 days and then assayed for iron content by atomic-absorption spectrometry. The results showed that for the enzyme modified with ferroceneacetic acid the iron content had

Fig. 3. Comparison of the storage stability at 4° in oxygen-free phosphate buffer (pH 7.0) of GOD modified with (a) ferroceneacetic acid and (b) ferrocenecarboxylic acid. The activity of the enzyme for glucose oxidation by molecular oxygen was assayed spectrophotometrically.

Fig. 4. Comparison of the stability of GOD modified with (a) ferroceneacetic acid and (b) ferrocenecarboxylic acid, determined electrochemically by continuous potential cycling at a glassy-carbon electrode at 20° in a 2-ml cell.

fallen from an initial value of 22 ± 2 to a final value of 6.5 ± 1 iron atoms per enzyme molecule.

In use, the ferrocene groups attached to the enzyme will cycle between the ferrocene and ferricinium oxidation states. To investigate the effect of this, the stability of the enzymes towards continuous potential cycling at a glassy-carbon electrode was also monitored in a small-volume (2 ml) electrochemical cell containing 80mM glucose. The electrode was polished before each current measurement, to eliminate any problems caused by fouling of the electrode. The results are shown in Fig. 4. In this experiment there is little difference in the stability of the two modified enzymes.

Thus there appear to be two aspects to the problem of stability: (i) cold storage produces a loss of enzyme activity for glucose oxidation, accompanied by some loss of iron from the modified enzyme and (ii) there is a much more rapid loss of activity during cycling in the electrochemical assay. We believe that the latter is associated with the loss of iron from the ferrocene groups attached to the modified enzyme, and that this process occurs much more rapidly for the ferricinium form of the mediator, which is generated during the electrochemical measurement.

Membrane electrode studies of modified GOD

To assess the suitability of the modified enzymes for use in sensors we investigated their use in membrane enzyme electrodes. The reproducibility of response of electrodes made with glucose oxidase modified with the ferrocenecarboxylic acid was poor. Curves (a) and (b) in Fig. 5 show results for two membrane electrodes prepared from different batches of the modified enzyme at nominally identical loadings. In both

Fig. 5. Plots of the corrected current vs. glucose concentration for two membrane enzyme electrodes based on GOD modified with ferrocenecarboxylic acid: (a) 0.04 mg (7.08 U) of enzyme, (b) 0.041 mg of enzyme and (c) response in fresh solution, recorded directly after (a).

cases the steady-state responses reached saturation at very low glucose concentrations. We have analysed the results of a number of membrane electrode experiments, using our model,³³ and the results for three different batches of modified enzyme are presented in Table 1. For these electrodes k'_{ME} is smaller than the diffusion-limited value for glucose through the membrane, k'_S , as already determined with the native enzyme. Hence, the response at low glucose concentrations is determined by the enzyme kinetics. From equation (5), by using the values of k'_{ME} and K_{ME} in Table 1, the enzyme loading and the value of k'_S , we can estimate k_{cat} for the modified enzyme to be in the range 10^{-3} – 10^{-2} sec^{-1} . These values are unrealistically small when compared with the values of 5 sec^{-1} measured in homogeneous solutions.²⁹ We be-

lieve that this is because we have grossly overestimated the active enzyme loading and that much of the modified enzyme becomes inactive during preparation of the electrode for use. The poor reproducibility observed can then be attributed to the poor stability of the modified enzyme once it is placed behind the membrane (whether the enzyme is from the same batch or different batches).

If the electrode is removed from the glucose solution and placed in fresh buffer and the calibration is then repeated, we find an almost total loss (> 90%) of response [Fig. 5, curve (c)]. This was the case for all the ferrocenecarboxylic-acid type modified membrane electrodes used, and is not due to a loss of enzyme activity towards glucose oxidation, because when free mediator (1mM ferrocenecarboxylic acid) is added to the bulk solution, a large response to glucose is obtained, consistent with our results for the native enzyme (Table 1). Thus the loss of response from the glucose oxidase modified with ferrocenecarboxylic acid is due to the decomposition of covalently bound mediator rather than loss of enzyme activity for glucose oxidation.

The response of the modified glucose oxidase membrane electrode during continuous operation in 0.10M glucose (Fig. 6) declines almost exponentially over a period of approximately 1 hr.

The electrodes made with the enzyme modified with ferroceneacetic acid give much larger responses and appear to be better behaved and more reproducible. Figure 7 shows results for three different enzyme loadings. The results of the analysis of data from these and related experiments are presented in Table 2. In this case the k'_{ME} values are much closer to the value for k'_S and consequently the response is determined both by diffusion of glucose through the membrane and by the enzyme kinetics. The

Fig. 7. Plots of the corrected current *vs.* glucose concentration for three different membrane enzyme electrodes based on GOD modified with ferroceneacetic acid. Enzyme loadings: E1 0.138 mg (24.5 U), E2 0.208 mg (36.8 U), E3 0.277 mg (49.0 U).

stability of these electrodes is also much better than that of those made with ferrocenecarboxylic acid as the enzyme modifier. After 20 hr at room temperature in glucose-free buffer the electrode still showed some response towards glucose (the response decreased by approximately 90% over this period). The analysis of these results is also given in Table 2. After 20 hr the k'_{ME} values were smaller by a factor of approximately 10, so the enzyme kinetics became rate-limiting. This was presumably the result of a loss in electrochemical activity of the enzyme over this period.

Selectivity

To investigate the effects of redox modification of the enzyme on selectivity, four other substrates (2-deoxy-D-glucose, D-mannose, D-

Fig. 8. Plots of the corrected current *vs.* substrate concentration for the homogeneous reaction with native GOD (0.976 mg/ml) mediated by 1mM ferrocenecarboxylic acid, for five different substrates.

galactose and D-xylose) were studied. The selectivity of the native enzyme was investigated in homogeneous solution, with ferrocenecarboxylic acid as the mediator. Figure 8 shows that the responses for the five sugars are consistent with rate data given in the literature:³⁵ glucose > 2-deoxy-D-glucose > D-mannose > D-xylose = D-galactose.

Figure 9 shows a set of results for the corresponding ferroceneacetic-acid type modified enzyme electrode and the same sugars. The results are similar to those for the native enzyme.

CONCLUSIONS

Our studies show that, although glucose oxidases modified with ferrocenecarboxylic acid and ferroceneacetic acid undergo direct unmediated oxidation at metal electrodes, they are not suitable for sensor applications because of their poor stability, which is due to the loss of the covalently bound ferrocene mediator from the

enzyme. This occurs more rapidly for the oxidized form and is a more severe problem for the enzyme modified with ferrocenecarboxylic acid. Szentrimay *et al.*³⁶ studied the stability of ferricinium ions in buffered aqueous solution (pH 7.0, phosphate) and found half-lives of 0.50 and 4.3 hr for the ferricinium forms of the carboxylic acid and acetic acid derivatives respectively. They suggested that the oxidized ferrocenes undergo a hydrolysis reaction involving disproportionation to give hydrous ferric oxide.

The results of Szentrimay *et al.* are consistent with our own observations. In the case of the membrane enzyme electrodes, where there is a small quantity of modified enzyme held at the electrode surface, with the ferrocenes in the oxidized form, the stability is very poor. This is especially true of the enzyme modified with ferrocenecarboxylic acid, where much of the bound mediator is presumably lost during the stabilization period, before the measurements of glucose response start. Similar problems may be expected if these modified enzymes are immobilized within a membrane at, or covalently attached to, an electrode surface. To overcome this problem it is necessary to replace the ferrocenecarboxylic acid or acetic acid derivatives used in this study, by more stable mediators.

DETERMINATION OF TOCOPHEROLS BY REVERSE-PHASE LIQUID CHROMATOGRAPHY AND ELECTROCHEMICAL DETECTION AT A SURFACE-OXIDE MODIFIED PLATINUM MICROELECTRODE, WITHOUT ADDED ELECTROLYTE

DARRYL L. LUSCOMBE and ALAN M. BOND*

Department of Chemical and Analytical Sciences, Deakin University, Geelong, Victoria 3217, Australia

(Received 30 May 1989. Revised 11 September 1989. Accepted 18 September 1989)

Summary—The reverse-phase separation and electrochemical detection of α -, γ -, and δ -tocopherol at a potential of +0.90 V vs. a gold pseudo-reference electrode is possible down to $10^{-7}M$ concentrations, with surface-modified platinum microdisc electrodes in a methanol/water (95:5) solvent mixture. The use of microelectrodes with radii of 10–70 μm , rather than electrodes of conventional size, minimizes problems associated with iR drop and obviates the need for deliberately added electrolyte. These features simplify the analytical procedure. The background response of an untreated platinum microelectrode in the methanol/water (95:5) system at positive potentials is characterized by processes arising from adsorption/oxidation of methanol and formation of surface oxides. Amperometric detection is of little use under these conditions. However, preoxidation of the electrode surface in 2M nitric acid inhibits the methanol adsorption/oxidation reaction but not the tocopherol response and therefore allows highly sensitive amperometric detection.

When electrochemical detection (ECD) is employed in conjunction with separation by liquid chromatography, it is generally considered necessary to have a sufficiently high concentration of an inert supporting electrolyte in the mobile phase, to ensure that this is electrically conducting and to reduce the cell/solution resistance, *i.e.*, reduce the so-called iR (voltage) drop across the cell. It is also considered necessary, although less importantly for flow systems, to add electrolyte to overcome the effects of the migration current of charged electroactive species in the solution. A useful rule is that to eliminate the effects of migration, the concentration of the supporting electrolyte should be 100 times that of the analyte,¹ *e.g.* with $10^{-6}M$ analyte being present, a $10^{-4}M$ electrolyte concentration is required. However, such a concentration of supporting electrolyte would not usually be regarded as high enough to reduce the cell resistance to a functional level in conventional ECD, and much higher concentrations of the electrolyte are usually added.

The need to add electrolyte is a distinct disadvantage, adding to the risk of contamination and increasing the cost of experiments. Methods for eliminating this need are therefore

desirable. It has been demonstrated that when microelectrodes are used instead of conventional electrodes, addition of a supporting electrolyte may not be necessary.³ Dissociation of the solvent (or impurities) will provide the necessary background conductivity in such experiments. The ability to combine liquid chromatography or flow-injection analysis with electrochemical detection at microelectrodes, without addition of large quantities of supporting electrolyte, makes electrochemical detectors more economical.³ If a buffer is added to the solvent system to aid either the chromatography or the electrochemical detection of a particular species, it also serves as the background electrolyte.

Electrochemical detection at positive potentials is usually done with solid electrodes constructed from platinum, gold, or various forms of carbon.⁴ The background response of noble metal electrodes, particularly of platinum in aqueous media, is characterized by surface oxide formation and hydrogen sorption/desorption.⁵ The nature of the surface oxide layer on platinum electrodes has been a subject of considerable debate over the last thirty years. Particular interest has centred on both the catalytic properties of the oxide layer with respect to electrochemical oxidation of the compounds of

*Author for correspondence.

interest, and conversely, the ability of the oxide layer to inhibit the oxidation of organic compounds.⁶⁻⁸ It is now generally agreed that the surface oxide layer initially consists of a reversibly chemisorbed hydroxo species, probably in the form of PtOH. This species may be stabilized by exchange reactions with the platinum surface, and converted into the irreversibly bound PtO.⁹ Though the exact nature of the surface oxide phases is not yet settled, it should be noted that the PtOH phase has been implicated in the catalytic oxidation of a number of species [e.g., As(III), carbohydrates, alcohols, amino-acids],¹⁰ whereas the PtO phase appears to inhibit many oxidation reactions.⁶ Thus while some of the surface properties induced at positive potentials by oxide film formation restrict the analytical usefulness of platinum electrodes, others can advantageously passivate the surface towards interfering species.¹¹

In the present work the analytical utility of the selectivity produced by a surface oxide phase at a platinum microelectrode is demonstrated by the electrochemical detection of tocopherols in a reverse-phase HPLC separation with a methanol/water mobile phase containing no electrolyte. Preoxidizing the electrode surface to form a PtO surface layer inhibits the methanol adsorption/oxidation process which overlaps the tocopherol electrode process. If this modified platinum electrode is used as a microelectrode, α -, γ - and δ -tocopherol (Fig. 1) can be oxidatively detected in a methanol/water (95:5 v/v) mobile phase without deliberate addition of a supporting electrolyte.

Ikenoya *et al.*,¹² using a conventional glassy-carbon electrode for electrochemical detection in the chromatographic separation of tocopherols with methanol as eluent, were obliged to add a supporting electrolyte and chose sodium perchlorate for the purpose. They found that the detector signal initially rose very rapidly with increase in sodium perchlorate concentration, reached a maximum at about 0.05M perchlorate

and then decreased at higher concentrations of the supporting electrolyte. It was found that the retention time and capacity factor were constant for use of eluents containing up to 0.05M perchlorate, but band-broadening and increased retention times were observed when higher concentrations were used. Thus it is desirable to minimize the perchlorate concentration, which is readily done by the use of microelectrodes.

EXPERIMENTAL

Reagents

The three tocopherol isomers (α , γ , δ) were obtained from Kodak, and used as received. Methanol and water were both of chromatographic solvent grade, and supplied by Waters Associates. Tetraethylammonium perchlorate (Southwestern Chemicals) was recrystallized from ethanol/water, then dried in a vacuum desiccator over phosphorus pentoxide.

Chromatographic system

The chromatographic system was assembled from the following components: an ICI LC1500 HPLC pump (ICI Scientific Instruments, Australia), a Rheodyne 7125 sample injector fitted with a 20 μ l loop (Rheodyne Corp.), a Spherisorb ODS2 15 cm \times 4.6 mm column, an ICI TC1900 temperature controller, a Metrohm 656 electrochemical detector (Metrohm, Herisau, Switzerland), a Keithley 614 digital electrometer (Keithley Instruments), an ICI SD2100 photometric detector, and an ICI DP600 dual-pen chart-recorder.

Electrochemical detection measurements were made with a two-electrode system, with a platinum disc microelectrode as the working electrode and either an Ag/AgCl (3M KCl) reference electrode, or a gold disc (radius 1.5 mm) acting as pseudo-reference electrode. Ultraviolet detection was performed at 296 nm, and all chromatographic determinations were done at $30 \pm 0.5^\circ$.

Microelectrodes

The microelectrodes were fabricated according to previously published methods,¹³ and their radii were calculated from the steady-state (slow scan-rate) voltamperograms obtained with a conventional cell, for oxidation of ferrocene ($1.05 \times 10^{-3}M$) in acetonitrile (containing 0.10M Et₄NClO₄), and use of the relationship.¹⁴

$$i_d = 4nFDcR \quad (1)$$

α - tocopherol	5,7,8 trimethyl
β - tocopherol	5,8 dimethyl

where i_d = diffusion-controlled limiting current, n = number of electrons transferred (1 for ferrocene), F = the Faraday constant, C = bulk concentration, D = diffusion coefficient (2.3×10^{-5} cm²/sec),¹⁵ and r = radius of the microelectrode.

Electrode pretreatment

The platinum disc microelectrodes were given the following oxidative pretreatment before use

in the detector cell. Each electrode was placed in a beaker containing 2M nitric acid, and a potential of +1.80 V vs. Ag/AgCl was applied for the requisite time. Oxygen was evolved at the electrode surface during the pretreatment. After the oxidation, the electrode was rinsed several times in distilled water, then several times in methanol/water (95:5) solution before being placed in the electrochemical detector cell. No attempt was made to polish or dry the electrode.

Fig. 2. Cyclic voltamperograms obtained at positive potentials (V vs. Ag/AgCl) applied in methanol/water (95:5) containing no added electrolyte, with a 12.5 μ m radius platinum microdisc electrode: (a) initial scan, (b) response observed with repeated cycling of the potential, (c) equilibrium response obtained after approximately 30 scans. Scan rate 100 mV/sec, temperature 22°.

RESULTS AND DISCUSSION

Stationary cell voltammetry

The ability of voltammetric microelectrodes to provide useful information with a minimum of distortion when used in high-resistance solvents has been demonstrated.² This feature has been used to study the mechanism of adsorption processes, in the absence of deliberately added electrolyte.¹⁶

Cyclic voltamperograms obtained with a platinum microelectrode (radius 12.5 μm) in methanol/water (95:5) without added supporting electrolyte are shown in Fig. 2. On repeated scanning there is growth of the wave at 0.75 V *vs.* Ag/AgCl on the forward (increasingly positive potential) scan, and of a wave at 0.45 V *vs.* Ag/AgCl on the reverse scan. Both waves have the same current sign despite the different scan direction. This anomalous behaviour has been reported for the oxidation of methanol in acidic solution at conventional-size electrodes,^{17,18} but not for reactions at microelectrodes, or without electrolyte being present.

The forward scan can be divided into a number of distinct potential regions (E *vs.* Ag/AgCl). On the basis of the work by Hamp-

son *et al.*,¹⁹ the following assignments can be made:

- (a) $0.0 < E < 0.2$ V double-layer region,
- (b) $E > 0.2$ V region where oxygen and methanol are adsorbed at the electrode surface, and an oxidation wave is observed,
- (c) $E > 0.75$ V region where a peak is formed owing to displacement of methanol by the more strongly bound oxide film,
- (d) $E > 0.90$ V region where the current increases because of oxide formation and possible methanol oxidation on the oxide film.

It should be noted that the initial scan [Fig. 2(a)], when PtOH is absent from the electrode surface, shows almost no oxidation taking place. The oxidation response grows as the surface coverage of oxide increases [Fig. 2(b)] up to an equilibrium value [Fig. 2(c)].

The behaviour displayed in the reverse scan has also been described for conventional-size

Fig. 3. Cyclic voltamperogram obtained at positive potentials (V *vs.* Ag/AgCl) applied in methanol/water (95:5) containing no added electrolyte, with a 12.5 μm radius platinum microdisc electrode preoxidized for 60 sec in 2M nitric acid at a potential of 1.80 V *vs.* Ag/AgCl: (a) blank, (b) $1.33 \times 10^{-3}M$ α -tocopherol. Scan rate 100 mV/sec, temperature 22°.

electrodes in acidic methanol solutions, the most fully substantiated explanation being that presented by Giner.¹⁷ In the reverse scan some of the oxide film formed at positive potentials is reduced, which leads to an increasing number of sites free from inhibiting oxide and adsorbed methanol. This in turn leads to an increased rate of oxidation of methanol, shown by the increased oxidative current observed in the reverse scan.

It therefore appears that at a platinum microelectrode, even in the absence of electrolyte, the oxide layer inhibits the oxidation of methanol at potentials >0.75 V *vs.* Ag/AgCl. However, since no oxidation of methanol is observed at a clean electrode [Fig. 2(a)], the formation of an oxide layer can also be said to catalyse the response over a limited potential range. At a

potential <1.2 V *vs.* Ag/AgCl the most likely oxidized phase giving rise to the catalysis is PtOH.⁹ Scanning to very positive potentials, which is likely to lead to the formation of PtO, also appears to inhibit the response for oxidation of methanol.

Since the application of very positive potentials appeared to inhibit the potentially interfering background process, the response of an electrode which had previously been oxidized at 1.80 V *vs.* Ag/AgCl in 2M nitric acid was examined. The results obtained in methanol/water (95:5) after the electrode had been held at this potential in 2M nitric acid for 60 sec and then transferred to the methanol/water solvent mixture are shown in Fig. 3(a). Repeated cycling over the potential-range of interest had little effect on the response, indicating

Fig. 4. Cyclic voltamperograms obtained with a $12.5 \mu\text{m}$ radius platinum microdisc electrode, for the oxidation of $2.66 \times 10^{-4} M$ α -tocopherol in methanol/water (95:5) containing (a) $10^{-3} M$ tetraethylammonium perchlorate, (b) no added electrolyte. Other conditions as for Fig. 3.

that the coating is strongly bound to the surface, and effectively inhibits the response for methanol adsorption/oxidation. The most likely composition of the surface film formed at very positive potentials would be PtO_2 ,⁹ which, unlike the PtOH film, is deposited irreversibly.

Although the background response is reduced to an acceptable level by the preoxidation at 1.8 V *vs.* Ag/AgCl, this is of little use if the response of the species to be detected at the platinum microelectrode is also inhibited. A cyclic voltamperogram for $1.33 \times 10^{-3} M$ α -tocopherol in methanol/water (95:5) at a surface-modified platinum microelectrode is shown in Fig. 3(b). The sigmoidal response expected for a faradaic process at a microelectrode is observed, showing that the tocopherol oxidation process is not inhibited. However, the response for tocopherol at the mM concentration level is slightly distorted by iR -drop effects in the absence of electrolyte. Hysteresis effects commonly occur with this type of coated electrode.²⁰ The extent to which iR -drop was the cause of this hysteresis in the absence of electrolyte was determined by experiments in $10^{-3} M$ tetraethylammonium perchlorate methanol/water (95:5). Figure 4 shows that with electrolyte present there is no hysteresis in the response of the tocopherol oxidation, which shows that iR -drop is the most likely cause of the hysteresis.

These results demonstrate that the pretreatment of the platinum surface effectively favours the tocopherol response over the methanol adsorption/oxidation reaction. The utility of

Fig. 5. Hydrodynamic voltamperograms for the oxidation of approximately $10^{-3} M$ α -, γ -, and δ -tocopherol solutions in methanol/water (95:5) (no added electrolyte), at a pre-oxidized $65.7 \mu\text{m}$ radius platinum microdisc electrode, in a wall-jet flow-cell with data recorded under HPLC conditions. Flow-rate 2 ml/min, temperature 30.0° , sample volume $20 \mu\text{l}$. Electrode stabilized for 30 min prior to determination.

this preoxidized microelectrode was then examined in a high-performance liquid chromatographic separation of a number of tocopherols with a methanol/water mobile phase without added electrolyte.

Other conditions as for Fig. 5.

water in a flow cell, obtained with a microelectrode which had been preoxidized for 30 sec in nitric acid are shown in Fig. 5. Although the oxidation waves are somewhat drawn out, over a 600-mV range, they are well defined sigmoids. The half-wave potential for oxidation of α -tocopherol (0.63 V *vs.* Au) in the absence of electrolyte was found to be 70 mV less positive than that for γ -tocopherol (0.70 V *vs.* Au), which agrees with data reported for a glassy-carbon electrode in methanol.¹² The half-wave potential for oxidation of δ -tocopherol is almost the same as that of α -tocopherol. Apart from slight differences in oxidation potentials, in contrast to previously published data, the tocopherols show essentially the same voltammetric behaviour.^{12,21,22}

On the basis of data obtained from the hydrodynamic voltamperograms, the reversed-phase chromatographic separation and electrochemical detection of α -, γ - and δ -tocopherol was examined in detail. Amperometric detection without added electrolyte was used, at an applied potential of 0.90 V *vs.* Au, and the mobile phase consisted of methanol/water (95:5). The electrode was a platinum microdisc (radius 65.7 μ m). Figure 6(a) shows that the response for the tocopherol oxidation at a freshly polished platinum electrode is masked by the methanol adsorption/oxidation background reaction. In contrast, Fig. 6(b) shows that an electrode which has been preoxidized for 60 sec as described in the experimental section gives an excellent response for all three tocopherol compounds. Pre-oxidation of the electrode surface reduces the background current observed in the methanol/water mobile phase from 5.2 nA with the polished electrode, to 600 pA with the pre-treated electrode.

Pretreatment of microelectrodes at a very positive applied potential (*e.g.*, +1.80 V *vs.* Ag/AgCl) in the methanol/water (95:5) mobile phase proved a much less efficient method of preparation than pretreating the electrodes in 2M nitric acid at an applied potential of +1.80 V *vs.* Ag/AgCl. Part of the reason for this may be that the *iR*-drop in the methanol/water mixture reduces the effective applied voltage. Pretreatment in 2M nitric acid at an applied potential less than that for oxygen evolution was found to give higher background currents and a lower response for tocopherol, indicating a thinner coating of PtO. Pretreatment in acid solution (for up to 2 hr) without an applied

Fig. 7. Initial variation of the chromatographic peak height observed in electrochemical detection of α -tocopherol with a 65.7 μ m radius platinum microdisc electrode preoxidized for 30, 60 and 120 sec. Other operating conditions as for Figs. 5 and 6.

voltage had little effect on the response obtained at a freshly polished electrode.

The stability of the preoxidized platinum microelectrode, maintained at a potential of 0.90 V *vs.* Au, was monitored by means of the response to repeated chromatographic injections of α -tocopherol. The response of a freshly prepared electrode was found to increase over a period of about 30 min (Fig. 7) until a constant peak height was obtained. This behaviour may be attributed to the influence (on the oxide film) of the lower applied potential used in the amperometric detection (+0.90 V *vs.* Au) compared with the pretreatment potential (+1.80 V *vs.* Ag/AgCl), a mixture of PtOH and PtO probably being produced.

The long-term stability was good, the responses varying by less than 8% over 10 hr (Fig. 8). Thus reproducible measurements may be obtained over extended periods from a single electrode without the need for further treatment. However, the electrochemical response for α -tocopherol was found to decrease significantly if the electrode was left in the cell at open circuit for extended periods of time. This implies that the applied potential of +0.90 V *vs.* Au stabilizes the oxide coating in the methanol/water system.

The response at platinum microelectrodes was also found to be critically dependent on the duration of the pretreatment. An optimum pretreatment time of 60 sec was established from the data shown in Fig. 9. A plausible explanation of these data is that a certain thickness of this PtO layer is required to inhibit the methanol adsorption/oxidation reaction, and

Fig. 8. Long-term stability of chromatographic peak height observed in electrochemical detection of α -, γ -, and δ -tocopherol with a 65.7 μm radius platinum microdisc electrode preoxidized for 60 sec. Other operating conditions as for Figs. 5 and 6.

that after an oxidation time of 60 sec the surface layer is so thick that it begins to inhibit the oxidation of the tocopherols.

Linear plots of peak-height vs. concentration were obtained from about 2×10^{-7} to $2 \times 10^{-5}M$. The limit of detection for the three tocopherols was calculated to be $1 \times 10^{-7}M$, or 2 pmole on the column for a 20 μl injection, based on a signal to noise ratio of 2:1 for the 67.5 μm platinum microdisc electrode with a pretreatment time of 60 sec. Detection limits (2:1 signal to noise ratio) with ultraviolet detection were found to be $2 \times 10^{-7}M$. This slightly greater sensitivity of electrochemical detection of tocopherols has been noted previously.¹² The relative standard deviation for ten 20- μl injections of $5 \times 10^{-6}M$ α -tocopherol, with the same electrode used for detection, was found to

Fig. 9. Variation of the chromatographic peak current for α -tocopherol with duration of preoxidation of the micro-disc electrode. The electrode was stabilized in the flow-cell for 30 min prior to the determination. Other operating conditions as for Figs. 5 and 6.

be 5%. A similar reproducibility was obtained with ultraviolet detection, implying that the variation is due to the chromatographic system, not the detector response. The variation in the peak height for $5 \times 10^{-6}M$ α -tocopherol from electrode to electrode, or pretreatment to pretreatment, was always better than 10%. Application of electrochemical detection has been reported at glassy carbon electrodes.^{12,23,24} The present method appears to be equally sensitive.

AMPEROMETRIC DETECTION AT A CARBON-FIBRE ARRAY RING/GLASSY-CARBON DISK ELECTRODE IN A WALL-JET CELL

HUAMIN JI and ERKANG WANG*

Laboratory of Electroanalytical Chemistry, Changchun Institute of Applied Chemistry,

(Received 27 June 1989. Accepted 25 October 1989)

Summary—A wall-jet cell incorporating a carbon fibre array ring/glassy-carbon disk electrode has been constructed, and characterized by the cyclic voltammetry and flow-injection techniques. The ring (composed of several microdisks) and glassy-carbon disk electrode, can be used separately for different purposes, e.g., detection in solution without a supporting electrolyte, collection/shielding detection with dual-electrode and voltammetric/amperometric detection with series dual-electrode. The electrode shows better collection and shielding effects than the usual ring-disk electrode in quiescent solution and the series dual-electrode in a thin-layer flow-through cell. The detection limit at the ring electrode is comparable with that at a conventional-size electrode, and has been used in the mobile phase without a supporting electrolyte, proving to be a promising detector for normal-phase liquid chromatography.

Electrochemical (EC) detection has been of continuing interest^{1,2} since the pioneer work by Kissinger *et al.*³ Amperometric and voltammetric detectors with conventional-size electrodes of mm or greater dimensions are frequently used as detectors in liquid chromatography (LC) and flow-injection analysis (FIA) because of their high sensitivity, low dead volume, simplicity and reasonable selectivity towards electroactive compounds. There have been many reports on the improvement in selectivity, stability, signal to noise (S/N) ratios and other detection properties obtained by using multiple working electrodes,^{4–8} modified electrodes,^{9–12} scanning of the potential at the electrode,^{13–15} and microelectrodes.^{16–37} There are some aspects of EC detection that can be improved by using a microelectrode detector, e.g., flow-rate effects, iR drop, S/N ratio and time-constant.

Microelectrodes have attracted great interest in the fundamental investigation of mass transport, kinetics and analytical applications since the initial interest in detection of catecholamines *in vivo*,^{16–18} and recently they have been incorporated into flow-through cells. These electrodes fall into two categories: (a) single microelectrodes (microdisk,²⁸ microring^{31,34} and microcylinder^{20–37}) and (b) multiple active units (bundles of carbon fibres,¹⁹ ordered array elec-

trodes^{29–31,35,36} and random-array electrodes^{32,33}). The first group have the advantage of easy construction and convenient use, and can be combined with columns of very small dimensions, such as open-tube capillary columns,²⁰ microcolumns²⁴ or capillary-zone electrophoresis columns.²⁶ However, femtoampere currents must then be measured at low analyte concentration, which is difficult unless one electrode dimension is large.³⁴ The bundle or array type of electrode has the advantage of simple instrumentation, and can be used with a modified or commercially available potentiostat.¹⁹

Although most reports still describe the use of amperometric detectors with only a single working electrode, dual-electrode amperometric detectors are becoming more popular and have been used in a variety of configurations such as series, parallel-adjacent and parallel-opposed, to achieve different modes of operation.¹ The main advantages of all the dual-electrode techniques are better selectivity and lower detection limit. Recently, Lunte *et al.*^{38–40} reported a different mode of operation for series dual-electrodes, called voltammetric/amperometric detection, in which the potential is scanned at the upstream electrode and the electrode product reaction is monitored amperometrically at the downstream electrode. Two detection modes, called collection and shielding, were described. In the former, the downstream

*Author for correspondence.

electrode is kept at a potential which reverses the reaction which has taken place at the upstream electrode, and in the latter it is kept at the same potential as the upstream electrode (and thus detects any of the analyte that has *not* reacted at the upstream electrode. The technique is similar to voltammetry at the ring-disk electrode⁴¹ except that the current/voltage/time relationship in the flowing stream is continuously monitored.⁴⁰ There are two problems with such a configuration, however. One is the low efficiency of collection and shielding, which depends on the cell configuration, the areas of the two electrodes and the gap between. It can be improved by reducing the gap and increasing the area of the downstream electrode, but this may be difficult to implement and may increase the dead volume. The other is the serious cross-talk effect due to the large solution resistance in the thin-layer flow-through cell, which limits the potential scan-rate at the upstream electrode. For these reasons, we now report a wall-jet cell which has been proved to have superior current sensitivity⁴² and minimum solution-resistance,⁴³ in which the solutions impinge on the reaction electrode (upstream), and flow through the collection or shielding electrode (downstream), which is a carbon-fibre array ring placed very close to the upstream electrode.

Although there have been reports about the use of a ring-disk electrode for EC detection,^{44,45} we describe one which is simple and easily constructed. The carbon-fibre array ring (CFAR) and glassy-carbon disk (GCD) electrodes have also been used for different purposes, *e.g.*, detection in a solution without supporting electrolyte, amperometric detection with a series dual-electrode, and voltammetric/amperometric detection.

EXPERIMENTAL

Construction of the electrode

The CFAR electrode was similar to that used by Khoo *et al.*³¹ except that the inner support material was a glassy-carbon rod instead of a glass tube. A 5.0-cm length of glassy-carbon rod (Beijing Institute of Artificial Crystal Material, China), 6.0 mm diameter, was first insulated with a very thin layer of epoxy resin. Sixteen carbon fibres, 33 μm in diameter, were stretched lengthwise and parallel on the rod, about 1 mm apart to ensure that the current responses of the individual fibres were independent of each other, and then fixed in position with a layer of

epoxy resin. To make electrical contact the carbon fibres at one end of the rod were embedded in silver cement, to which a copper wire was sealed. The electrode was then heated at 70° for 2 hr to cure the epoxy resin and silver cement. To expose the ends of the microfibrils, the other end of the electrode was polished on abrasive papers, and then with 1.0, 0.3, 0.03 μm α -alumina on a polishing cloth, and finally ultrasonicated in water for 5 min. The electrode was fitted into the wall-jet cell by a screw as shown in Fig. 1.

Apparatus

The LCP-350 injection pump (JASCO, Japan) was used with a home-made six-port valve with changeable sample loops (10 μl –1 ml) for FIA. Chromatographic experiments were done with a Nucleosil C18 (7 μm) column (200 \times 5 mm) (Dalian Institute of Chemical Physics, China). A home-made cyclic voltammetric analyser with triangular wave output into the bipotentiostat for simultaneously recording voltamperograms for the ring and disk electrodes, was used with a conventional three-electrode cell for cyclic voltammetry in quiescent solution. A laboratory-built bipotentiostat was used for FIA with voltammetry at the CFAR-GCD electrode, to measure pA–mA

Fig. 1. Schematic illustration of the wall-jet cell with the CFAR-GCD electrode. (A) Side view of the cell; (B) top view of the electrode. 1, Solution inlet; 2, reference electrode; 3, glassy-carbon disk (GCD); 4, carbon fibre array ring (CFAR); 5, outlet, auxiliary electrode; 6, cell body (Plexiglas).

currents by changing the feedback resistance in a current-to-voltage converter. A Pine Instrument RDE 4 bipotentiostat was used with the Pt-ring/GC-disk electrode for the ring-disk experiment. An Ag/AgCl (satd. potassium chloride) reference electrode was used for cyclic voltammetry in quiescent solution, and a saturated calomel electrode (SCE) for FIA.

Reagents

All reagents were as reported previously.⁹ All solutions were prepared with doubly-distilled water, and all experiments were done at ambient temperature ($20 \pm 2^\circ$).

RESULTS AND DISCUSSION

Cyclic voltammetry at the CFAR-GCD electrode

Voltammetry in quiescent solution is an effective way to characterize microelectrodes and assess the quality of their fabrication.^{16,46} The cyclic voltamperogram for the oxidation of ferrocyanide (1 mM in 2M potassium chloride) at the CFAR electrode is shown in Fig. 2A. A sigmoidal voltamperogram was obtained, with a limiting current of 64.5 nA at a scan-rate of 10 mV/sec. This is a typical steady-diffusion voltamperogram for microdisk electrodes.¹⁶ A value of 58 mV was obtained for $E_{3/4} - E_{1/4}$, in good agreement with the theoretical value of 56.4 mV for a one-electron transfer. According to the equation²⁹

$$i = 4nFDCr$$

where r is the radius of the electrode, C the bulk concentration of the analyte, D the diffusion

coefficient and the other symbols have the usual meaning, the sum of the limiting currents at the individual microfibre disk electrodes was 64.1 nA for the 16 microdisks, in good agreement with the experimental measurement. This indicates that none of the fibres was broken during construction of the electrode, that all are active, and also that the fibres and the disk are well insulated, and that diffusion takes place independently at individual microfibre disks.

Figure 2B shows the collection effect at the CFAR-GCD electrode, when the potential was scanned from 0 to 0.7 V vs. Ag/AgCl at the GCD electrode to oxidize the ferrocyanide and the CFAR electrode was kept at 0 V to reduce the oxidized product from the GCD electrode. The product reached the CFAR electrode only by diffusion, without the convection that occurs with the conventional ring-disk electrode. The voltamperogram shows that even in quiescent solution the CFAR electrode is an effective collector, whereas the conventional ring-disk electrode is not (Fig. 2C). The remaining experiments were done in flowing solution.

Amperometric detection at the CFAR-GCD electrode

The improvement of detectors based on use of conventional-size electrodes, by such means as modification of the electrode surface to increase the EC activity^{10,12} or enhance the selectivity or stability,^{9,11} and incorporation of microelectrodes into the detector, is an active area in EC detection. So far, however, no reports have been published on the use of combinations of these

Fig. 2. Cyclic voltamperograms for ferrocyanide at the CFAR-GCD electrode and ring-disk electrode in quiescent solutions. Scan-rate, 10 mV/sec; (A) 1mM $K_4Fe(CN)_6 + 2M$ KCl at the CFAR electrode; (B) 50 μ M $K_4Fe(CN)_6 + 2M$ KCl at the CFAR-GCD electrode with $E_{CFAR} = 0$ V; (C) 1mM $K_4Fe(CN)_6 + 0.1M$ KH_2PO_4 at Pine's ring-disk electrode with $E_{ring} = 0$ V.

electrodes. In earlier papers^{27,47} we reported the use of a flow-through carbon-fibre electrode in a poly(vinyl chloride) tube, combined with an LC column, which was used successfully for the determination of vitamin B₆. The experiments with dilute supporting electrolyte showed that the flow-through cell had a large solution-resistance arising in the connecting tube between the working electrode and the reference electrode. We have therefore changed the cell to one of wall-jet type, and attempted to combine microelectrodes with a conventional-size sensor, into one electrode.

An advantage of the CFAR-GCD electrode in the wall-jet cell is that the ring and the disk can be used independently for different purposes. It was found that the hydrodynamic voltamperograms (HDVs) obtained at the two electrodes were the same as those for the conventional thin-layer cell in FIA, and that the new electrode (Fig. 1) was easier to recondition and more convenient to operate than the thin-layer cell. The coefficient of variation of FIA peak currents at the CFAR electrode for replicate injections of 5 ppm hydroquinone (HQ) over a period of 12 hr was 1.5%, indicating that the electrode was very stable and suitable for analytical application. Good linearity between FIA peak current (nA) and HQ concentration was obtained over the range 0.1–20 ppm, the regression equation being $i = -0.10 + 0.774C$, $r = 0.9998$. The baseline noise was found to be about 0.8 pA, so the detection limit was estimated to be 2.6 ng/ml (26 pg) at $S/N = 3$. Although experiments at such low concentrations were not done, owing to the FIA injection peak, we may still conclude that the CFAR is a sensitive electrode.

In the wall-jet cell, the distance between the nozzle and the electrode has a remarkable influence on the sensitivity and the dead volume of the detector, owing to mass transport at the electrode,⁴³ especially the CFAR-GCD electrode. In a wall-jet cell the current is not uniformly generated over the electrode, especially when the wall-jet ring-disk electrode is used.⁴⁴ Figure 3 shows the influence of the distance between the nozzle and electrode on the FIA peak current and peak width. The peak current decreases greatly and the peak width increases slightly at the GCD electrode and more so at the CFAR electrode, with increasing distance. These observations differ from those of Gunasingham,⁴⁵ who reported a slight increase of the LC peak width obtained by detection at the ring

Fig. 3. Influence of the distance of the jet-electrode separation on the FIA peak current (a,b) and half-peak width (sec) (c,d) at the GCD (a,d) and CFAR (b,c) electrodes: 10 μ l of 5 ppm HQ injected every time; potential 0.7 V; mobile phase 0.1M KH_2PO_4 + 50 μM EDTA; flow-rate 0.8 ml/min.

electrode over that for detection at the disk electrode, and of Alberly *et al.*⁴⁴ who reported that the current increased with separation distance. This difference may be due to either the very small jet and electrode separation in our cell, or the different configuration. Therefore, in subsequent experiments we kept the jet and electrode as close as possible, but the distance had to be optimized for each analyte system.

The detection limits are very dependent on flow-rate. In microelectrode detectors, however, this dependence is considerably reduced by the enhanced radial diffusion due to the large edge-to-area ratios. We have reported that practically no dependence was found on flow-rate for the flow-through carbon fibre detector.²⁷ As expected, a lower dependence on flow-rate was found for the new electrode when used in FIA; the peak current at the CFAR electrode changed only from 0.567 to 0.570 nA with change in flow-rate from 0.2 to 0.5 ml/min, but from 1.96 to 2.80 μA at the GCD electrode over the same flow-rate range. Higher flow-rates were not examined, owing to the time-constant limitations of the potentiostat and recorder. However, a different dependence was found for the limiting currents in the voltamperograms. With injection of 1 ml of 1 mM HQ and recording of the voltamperogram during retention of the

analyte on the electrode, the slopes of log-log plots of limiting current *vs.* flow-rate (from 0.2 to 1.2 ml/min) were found to be 0.133 at the CFAR electrode and 0.353 at the GCD electrode. A similar dependence for peak currents and equilibrium currents at ultra-thin ring and band microelectrodes was obtained by Bixler *et al.*³⁴ In the present case we are concerned only with the peak currents.

Collection/shielding effects at the CFAR-GCD electrode

The collection and shielding efficiencies at the CFAR-GCD electrode detector were determined in a way slightly different from that used by Roston and Kissinger.⁴ In the dual-electrode detector, the upstream and downstream electrodes had almost the same area, and the collection efficiency was defined as the ratio of the current at the indicator (downstream) electrode to that at the generator (upstream) electrode, and a similar ratio for the shielding efficiency. The maximum collection efficiency found was 0.37 for hydroquinone as test compound.⁴ (Below this value it was termed the effective collection efficiency, which is related to the reaction mechanism). Even when the distance between the electrodes was varied from *ca.* 10 to 100 μm , the collection efficiency did not exceed 0.38. Various expressions have been derived for describing the collection efficiency,⁴⁸⁻⁵⁰ and although they have not been completely experimentally validated, they do indicate which detector dimensions are critical factors. The expressions contain two parameters based on cell dimensions: the ratio of the distance between the two electrodes to the length of the upstream electrode along the flow axis, and the ratio of the lengths of the two electrodes along the flow axis. Roosensaal and Poppe⁵⁰ derived a diffusion-limited current expression for the dual-electrode which could be applied at different potentials, in which the reconverted fractions (collection efficiency) and shielding factors were described. The two effects are maximal when the distance between the electrodes is zero. With a relatively long upstream electrode and a very short downstream electrode, a shielding factor of over 0.80 is observed when the gap is less than the length of the downstream electrode.⁵⁰ No attempts were made to improve the collection and shielding efficiencies experimentally.

The shielding mode of detection was not paid much attention until Lunte *et al.*³⁹ reported its

utility as a general method for electrochemical detection of compounds giving electrochemically reversible or irreversible reactions. The shielding efficiency is an important factor affecting the detection limit.

Since the ring electrode (CFAR) is much smaller than the disk electrode, we cannot use the Roston and Kissinger method to determine the collection efficiency. For the CFAR-GCD detector, the collection efficiency N_c is defined as

$$N_c = \frac{i(\text{ring})}{i'(\text{ring})} \quad (1)$$

where $i(\text{ring})$ and $i'(\text{ring})$ are the currents at the CFAR electrode with and without potential applied at the GCD electrode. The shielding efficiency is defined as

$$N_s = 1 - \frac{i(\text{ring})}{i'(\text{ring})} \quad (2)$$

In both cases, the potentials at the two electrodes are sufficiently positive or negative for the currents to be limited solely by mass transport.

Figure 4 shows the hydrodynamic voltamperogram for the CFAR electrode over the applied potential range from -0.2 to 0.8 V when the upstream (GCD) electrode is kept at 0.7 V to generate oxidized products for detection at the CFAR electrode. Figure 5 shows that when the CFAR electrode was kept at limiting-current potential (-0.15 V) and the potential of

Fig. 4. Hydrodynamic voltamperogram of HQ at the CFAR electrode with the GCD electrode at 0.7 V. Experimental conditions as for Fig. 3.

Fig. 5. Hydrodynamic voltamperograms of HQ at the CFAR electrode (a) and the GCD electrode (b) when the CFAR electrode is kept at -0.15 V and the potential at the GCD electrode is changed. Experimental conditions as for Fig. 3.

the GCD electrode was scanned from 0.1 to 0.8 V, the hydrodynamic voltamperograms for the two electrodes had the same general pattern. Figure 6 shows the electrode currents for the different applied-potential modes in FIA with the CFAR–GCD electrode detector. For the collection mode, the GCD was kept at 0.7 V and the CFAR at -0.15 V, which are both in the limiting-current potential range. In the shielding mode, both electrodes were kept at 0.7 V. From Fig. 6 the collection efficiency was measured as 0.869 and the shielding efficiency as 0.75, by use of equations (1) and (2). These values are larger than those reported for the thin-layer dual-electrode.^{4,39} The high collection efficiency at the CFAR–GCD electrode has the advantages that

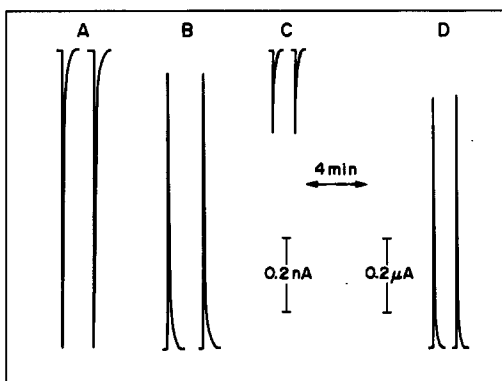

Fig. 6. FIA peaks at the CFAR (A, B, C) electrode and GCD (D) electrode with different applied-potential modes. Potentials: CFAR electrode: A, B -0.17 V; C, 0.7 V; GCD electrode: A, 0.7 V; B, 0 V; C, 0 V; D, 0.7 V. Other conditions as for Fig. 3.

the downstream electrode is a sensitive indicator electrode, and the selectivity is greatly improved because compounds giving electrochemically irreversible reactions are not detected at the downstream electrode.

The influence of the cell dimensions (*e.g.*, distance between jet and electrode) on the collection and shielding efficiencies are more complex than in the thin-layer flow-through cell. Additionally, the flow-rate, which has no influence in the thin-layer cell, affects the two efficiencies because of its different effects at the two electrodes, as described above. It was found that the collection efficiencies decreased with increasing flow-rate, but the shielding efficiencies were unchanged.

Detection in a mobile phase containing no supporting electrolyte

EC detection with conventional-size electrodes has not been generally extended to normal-phase LC, although it could be achieved by adding electrolyte pre- or post-column.^{51,52} When a low-polarity solvent (*e.g.*, *n*-hexane) is used as the mobile phase in normal-phase LC, it is difficult to find an electrolyte that is sufficiently soluble in it, and the presence of the electrolyte may affect the retention times of the analytes.

An EC detector which could be operated without the presence of a background electrolyte would be desirable. The very small currents measurable with microelectrodes make it possible for an EC detector made with them to be used in normal-phase LC.

In the previous report,²⁷ we examined the detection behaviour of the flow-through carbon-fibre detector in dilute supporting electrolyte, and found that the *S/N* values decreased with dilution of the electrolyte, owing to the large solution-resistance. Bixler and co-workers^{28,34} have described the use of microdisk and microring electrodes as detectors for use with a low electrolyte concentration in an acetonitrile mobile phase. Here we describe applications of our CFAR electrode in reversed-phase LC without supporting electrolyte, but have not yet tested its use in normal-phase LC.

A mixture of hydroquinone and catechol was chosen as a test model for reversed-phase LC separation with a mixture of water and methanol as mobile phase without supporting electrolyte. Figure 7 shows the hydrodynamic voltamperograms of HQ at the CFAR and GCD electrodes, measured independently, with

Fig. 7. Hydrodynamic voltamperograms at the CFAR electrode (a) and GCD electrode (b), with 30% v/v methanol in water as mobile phase without supporting electrolyte; 10 μ l of 5 ppm HQ injected.

30:70 v/v methanol–water mixture as mobile phase. It can be seen that the voltamperogram at the CFAR electrode is the same as that obtained with supporting electrolyte present (Fig. 5), but the one at the TCD electrode is flatter. As shown in Fig. 8, good linearity was found between LC peak current and HQ concentration with the CFAR electrode but not with the GCD electrode.

Thus the CFAR electrode would be the detector of choice for use with a wide concentration range of analyte in normal-phase LC with a mobile phase containing no background electrolyte, but the GCD electrode would be more useful at very low μ l concentrations.

Fig. 8. Calibration curves for peak current at the CFAR electrode (a) and GCD electrode (b) vs. concentration of HQ, without the addition of supporting electrolyte to the mobile phase. Injection volume 10 μ l; potential 0.7 V; mobile phase: 30% v/v methanol in water.

Fig. 9. FIA peaks at the CFAR electrode (a) and GCD electrode (b) for collection-mode (A) and shielding-mode (B) detection, with water as mobile phase without supporting electrolyte. (A) $E_{CFAR} = 0$ V, $E_{GCD} = 0.7$ V; (B) $E_{CFAR} = 0.8$ V, $E_{GCD} = 0.7$ V; 10 μ l of 5 ppm HQ injected.

Moreover, the CFAR–GCD electrode system has lower solution-resistance than any of the microelectrode cells reported,^{19,20,24,28–30,34} because of the narrow electrode gap possible with the wall-jet configuration.

Another interesting phenomenon was found when the dual-electrode was operated with the CFAR–GCD electrode in a mobile phase without added electrolyte (Fig. 9). Figure 9A shows that at the CFAR electrode used in the collection mode an irregular cathodic current and a small anodic current were observed. Similar peaks were obtained in the shielding mode but with a more rapid increase of cathodic current (Fig. 9B). A regular peak was observed at the GCD electrode in both cases. This can be explained as due to the large change in potential distribution in the flow, because of the high solution-resistance in pure water–methanol solution. When a large peak current is produced at the GCD electrode, then the large iR drop between the reference electrode and the CFAR and GCD electrodes may act as a potential step making the potential of the CFAR electrode more negative, so that a large cathodic current is produced at the CFAR electrode. When the current at the GCD electrode returns to the baseline, a corresponding potential step is applied to the CFAR electrode, making its potential more positive, and producing a rapid fall of cathodic current and appearance of a small anodic current at the CFAR electrode; this anodic current then returns slowly to the

baseline. This is similar to the cross-talk effect in dual-electrode detection.³⁹ Care must therefore be taken to avoid such effects in the dual-electrode detection.

CONCLUSION

Microelectrodes and conventional-size electrodes can be successfully combined for EC detection and also used independently. When they are combined as a ring-disk electrode in a wall-jet cell, some special advantages are obtained, such as high collection and shielding efficiencies. This electrode is promising for voltammetric/amperometric detection, but the electrode gap must be optimized for each application.

ELECTROANALYSIS AT MODIFIED CARBON-PASTE ELECTRODES CONTAINING NATURAL IONIC POLYSACCHARIDES

JOSEPH WANG*, ZIAD TAHA and NAJIB NASER

Department of Chemistry, New Mexico State University, Las Cruces, NM 88003, U.S.A.

(Received 28 April 1989; Accepted 21 July 1989)

Summary—The strong affinity of natural ionic polysaccharides for certain metal ions is exploited in the design of a new class of voltammetric sensing devices. In particular, carbon-paste electrodes containing pectic and alginic acids are used for the nonelectrolytic collection and subsequent voltammetric determination of copper and lead, respectively. Cyclic and differential pulse voltammetry are used to quantify the accumulated ions. The response is characterized with respect to modifier loading, preconcentration period, metal concentration, reproducibility, possible interferences and other variables. Titrimetric experiments illustrate the potential of polysaccharide electrodes for speciation work. Preliminary data are also given for analogous measurements of copper at heparin-modified electrodes. Detection limits are 1 $\mu\text{g/ml}$ and the relative standard deviation is 4.8%.

Chemically modified electrodes (CMEs) hold great promise for use as electrochemical sensors. The electrode surfaces can be tailored to meet the needs of many sensing problems. One promising direction is to use surfaces capable of preferentially preconcentrating target analytes from solutions.¹⁻³ In this approach, a non-electrochemical preconcentration step is employed, followed by voltammetric quantification of the surface-bound analyte. Most popular schemes used to collect analytes are based on coordination reactions^{4,5} and electrostatic attraction^{6,7} at surfaces carrying an appropriate ligand or ion-exchanger. Bioaccumulation at electrodes based on micro-organisms can also be used.⁸ The preconcentrating agent is commonly incorporated into the surface by mixing it with carbon-paste matrices or by forming derivatives of polymeric films. The reactivity obtained by proper choice of the surface modifier can greatly enhance the selectivity and sensitivity of voltammetric devices (compared to those of conventional bare surfaces that utilize electrolytic preconcentration).

This paper describes a new class of modifying species, natural ionic polysaccharides, for use in making CMEs for preconcentrations. The strong interaction of ionic polysaccharides with various bivalent ions has been the subject of several investigations.⁹⁻¹² Electrochemical techniques such as polarography⁹ or potentiometry¹²

have been used, along with other methods, for exploring the binding of copper and lead to ionic polysaccharides. Such binding occurs by electrostatic interaction with carboxylate groups as well as other specific interactions. Important applications (based on this), ranging from removal and recovery of metal ions from polluted water¹³ to protection of people and animals against toxic metals¹⁴ have been reported. Preconcentrating CMEs based on the strong affinity of biopolyelectrolytes for certain metal ions have not been reported. The characteristics, advantages and analytical performance of carbon-paste electrodes containing pectic and alginic acids are described in this paper.

EXPERIMENTAL

Apparatus

Polysaccharide-modified carbon-paste electrodes were prepared by thoroughly hand-mixing the polysaccharide with graphite powder (Acheson 28) and mineral oil (40% w/w). Electrodes containing 21% pectic acid or 20% alginic acid (w/w) were used in most experiments. A portion of the paste was packed into the end of a glass tube (3 mm i.d.), and its inner end was connected to a copper wire.

Three 10-ml cells were used for the preconcentration, measurement and "cleaning" (renewal) steps; these contained the metal test solution, the supporting electrolyte solution and the acid "cleaning" solution, respectively.

*Author for correspondence.

An Ag/AgCl reference electrode (Model RE-1, Bioanalytical Systems) and a platinum wire auxiliary electrode completed the three-electrode system in the measurement cell. A Princeton Applied Research Corp. (PARC) Model 264A voltammetric analyzer, in conjunction with a PARC Model 0073X-Y recorder, was used to obtain the voltamperograms.

Reagents

Doubly distilled water was used to prepare all solutions. Pectic acid (75% purity, Kodak), alginic acid (Fluka) and heparin (Sigma) were used as surface modifiers. Sodium acetate (Mallinckrodt) and sodium perchlorate (Fisher) were used for preparing the supporting electrolyte solutions. Copper and lead solutions were prepared from their analytical grade nitrates. Atomic-absorption standard solutions of other metals (1000 ppm), used in the interference studies, were from Aldrich.

Procedure

All experiments were performed by using the preconcentration/medium-exchange/voltammetry/regeneration scheme. For the preconcentration step, the modified electrode was immersed in the stirred sample solution for a given period of time; the preconcentration proceeded at open circuit. The electrode was then removed from the preconcentration cell, briefly rinsed with doubly distilled water, and placed in the electrochemical cell containing a deaerated sodium perchlorate solution. The initial potential (-0.9 and -0.6 V for lead and copper, respectively) was then applied and after

15 sec a positive-going scan was initiated. After the scan the electrode was transferred to the cleaning (acid) cell for regenerating a "metal-free" surface (as indicated by a subsequent voltammetric run). Several such collection/measurement/cleaning cycles were required to precondition virgin surfaces. Specific details of the experimental procedure are summarized in Table 1.

RESULTS AND DISCUSSION

Three model substances, pectic and alginic acids and heparin, were used as surface modifiers to illustrate the potential of natural polysaccharides for analytical sensing.

Electrodes modified with pectic acid

Pectic acid (polygalacturonic acid) is a natural polyacid obtained from pectins. Its incorporation into the carbon-paste matrix results in effective accumulation and subsequent quantification of copper ions. Figure 1 compares cyclic voltamperograms obtained with the plain (A) and pectic acid (B) carbon-paste electrodes for 25 ppm copper, following 1-min stirring (open-circuit conditions) and transfer of the electrode to a blank/electrolyte solution. The scans were run by initially holding the electrode at -0.6 V to reduce the complexed copper to the metal. Voltammetric peaks are not observed when the unmodified electrode is used, as expected in the absence of copper collection. In contrast, the first scan (designated as 1) at the modified electrode exhibits a distinct current response ($E_{p,a} = +0.05$ V). The peak clearly corresponds to the oxidation of the copper

Table 1. Summary of experimental conditions

Analyte	copper	lead
CME	pectic acid (21%) in carbon paste	alginic acid (20%) in carbon paste
Preconditioning	five preconcentration/voltammetry/regeneration cycles with 25 ppm copper solution	two scans, between -0.9 and -0.2 V in blank solution, followed by two preconcentration/voltammetry/regeneration cycles with 10 ppm lead solution
Preconcentration solution	stirred $0.10M$ acetate buffer, pH 5.4	stirred $0.05M$ $NaClO_4$, pH 5.0
Voltammetric measurement	deaerated $0.05M$ $NaClO_4$ solution; potential range from -0.6 to $+0.2$ V; differential pulse waveform, 25 mV amplitude and 10 mV/sec scan rate	deaerated $0.05M$ $NaClO_4$ solution; potential range from -0.9 to -0.2 V; differential pulse waveform, 25 mV amplitude and 10 mV/sec scan rate
Surface regeneration	immersion in HNO_3 (pH 1.8) for 60 sec	immersion in HCl (pH 1.5) for a time equal to the preconcentration period

Fig. 1. Cyclic voltamperograms for unmodified (A) and pectic acid modified (B) carbon-paste electrodes after immersion for 1 min in a stirred 25 ppm copper solution and transfer to the blank/electrolyte solution. Open circuit during accumulation. Scan rate, 50 mV/sec; solutions as in Table 1.

metal arising from reduction of the copper(II) taken up electrostatically by the pectic acid. Subsequent voltamperograms, recorded by continued scanning, yield smaller and smaller peaks. With a 50 ppm copper solution, full surface coverage was attained by stirring for 120 sec. The steady-state (saturation) response corresponded to a charge of $66.1 \mu\text{C}$ and surface coverage of 1.75×10^{-9} mole/cm². The cyclic voltammetric peak current at saturation increased nonlinearly (from 21 to 52 nA) on increase in scan rate from 10 to 200 mV/sec. The peak potential shifted from 0.00 to 0.06 V on increase in scan rate, yielding a linear plot of peak potential *vs.* log (scan rate).

Figure 2 shows the dependence of the peak current on the accumulation time for (a) 9 and

(b) 18 ppm copper. As the accumulation time increases, the response rises rapidly at first and then more slowly. Apparently, the binding reaches equilibrium in accumulation for 3 min. The uptake of metal ions by the pectic acid electrode is strongly dependent on the pH. The effect of pH on the copper response is shown in Fig. 3(a). The peak increases rapidly with increase of pH between 2 and 5, and then starts to level off. Such a profile reflects the proton competition for the carboxylate binding sites. Accordingly, reversal of the metal ion binding, *i.e.*, surface regeneration after the voltammetric scan, can easily be accomplished by exposure to an acidic medium. The effect of the paste composition is shown in Fig. 3(b). The copper response increases as the pectic-acid loading is

Fig. 2. Response of the pectic acid modified electrode as a function of accumulation time for (a) 9 and (b) 18 ppm copper. The electrode was immersed for different periods in the stirred copper solution, washed, and placed in the blank/electrolyte solution. Conditions as in Table 1.

increased between 0 and 21% (w/w), as expected from the increased binding capacity of the electrode. Increased electrode resistance accounts for the marked decrease in response at higher modifier loadings.

Virgin polysaccharide-modified electrodes were found to be less efficient for the collection of metal ions, compared to "old" surfaces (that had already undergone several measurement cycles). A preconditioning step, involving several such cycles was thus required (see

Fig. 3. Effect of (a) pH and (b) pectic acid content on the differential-pulse copper response. Solution of 18 ppm copper stirred for 60 sec. Other conditions as in Table 1.

Fig. 4. Carry-over (A) and precision (B) experiments. Copper concentrations: (A) a, c, 9; b, d, 27 ppm; (B), a-e, 25 ppm. Accumulation for 30 sec; other conditions as in Fig. 2. Initial potential positions displaced for clarity.

Table 1 for details). A similar process was reported earlier for carbon-paste electrodes modified with various ligands,^{4,15} and was attributed to a certain degree of ordering of the surface ligand molecules after the metal binding.

The sensing potential of pectic-acid modified electrodes is indicated by Fig. 4, which shows voltamperograms obtained by sequential exposure to copper solutions differing in concentration (A) and for repetitive measurements at a given concentration (B). Well defined differential-pulse peaks are observed ($E_p = 0.05$ V), after short (30 sec) accumulation times. The electrode responds rapidly to the switching between the 9 and 27 ppm copper solutions. Modified electrodes conditioned and renewed as described in the experimental sections could be employed for numerous accumulation/reduction/cleaning cycles. For example, the voltamperograms shown in Fig. 4B are from a series of ten repetitions with a 25 ppm copper solution. This series yielded a mean peak current of $80.3 \mu\text{A}$, a range of $76\text{--}85 \mu\text{A}$ and a relative standard deviation of 4.8%. Such precision compares favorably with that reported for various preconcentrating CMEs.² The precision might be improved by use of flow-injection preconcentration schemes.¹⁶ The same electrode surface was used throughout each day, with no noticeable loss in activity.

Figure 5 shows calibration plots for copper, over the 1×10^{-4} – 8×10^{-4} M (6–48 ppm) range, after (a) 30 and (b) 60 sec preconcentration. In both cases the response is linear up to 4×10^{-4} M, with curvature at higher

Fig. 5. Voltammetric response of the pectic acid modified electrode as a function of copper concentration for (a) 30 and (b) 60 sec accumulation times. Other conditions as in Fig. 2.

concentrations (as saturation of binding sites is approached). Least-squares treatment of the initial linear portions yielded slopes of $0.19 \mu\text{A} \cdot \text{l} \cdot \mu\text{mole}^{-1}$ (deposition for 30 sec) and $0.22 \mu\text{A} \cdot \text{l} \cdot \mu\text{mole}^{-1}$ (deposition for 60 sec), with correlation coefficients of 0.998 and 0.997, respectively. A detection limit of about 1 ppm copper was estimated from the signal-to-noise characteristics ($S/N = 3$) of the response following 5 min accumulation (not shown). Clearly, the detectability is not as low as that of conventional stripping measurements at mercury surfaces.

The advantages of the preconcentrating-CME approach lie in the selectivity of the accumulation process (which is derived from the reactivity patterns of the surface modifier), the use of "mercury-free", low-cost, surfaces, and suitability for speciation work. Surfaces containing natural polysaccharides exhibit reactivity different from that provided by modified electrodes based on common ligands or ion-exchangers. The following metal ions were tested at the 50 ppm level and found not to interfere in the determination of 25 ppm copper: Cd(II), Co(II), Ni(II), Zn(II), Cr(III) and Ca(II) (60 sec accumulation; other conditions as in Fig. 2). Minor changes in the 25 ppm copper response were observed in the presence of 50 ppm Mn(II), Pb(II), Ag(I), Bi(III) and Sn(IV) (8, 9 and 20% increases, 6 and 20% decreases, respectively). Such interference is expected to

increase at higher concentrations of these ions. The transfer of the electrode, with the collected analyte, to a blank electrolyte solution precludes interference from solution-phase species.

Preconcentrating CMEs based on natural ionic polyelectrolytes provide an interesting opportunity to explore the binding of metal ions with these materials and can serve as useful tools for metal speciation studies. Preliminary experiments indicated the potential of the pectic acid CME for speciation work. For example, a gradual decrease of the peak for $4 \times 10^{-4} M$ copper was observed when the concentration of EDTA or NTA was increased from 0.5×10^{-4} to $4 \times 10^{-4} M$ (accumulation for 30 sec). Complete disappearance of the copper response was observed for $4 \times 10^{-4} M$ EDTA, in agreement with the 1:1 stoichiometry of the Cu-EDTA complex. Work is in progress to obtain better understanding of the speciation data obtained with this and other preconcentrating electrodes, and particularly to identify the metal species measured.

Electrodes modified with alginate acid or heparin

Alginate acid is a copolymer of α -L-glucuronic acid and β -D-mannuronic acid. It has a very high binding capacity ($50 \mu\text{g}/\text{ml}$) for lead.¹⁴ The ability of alginate acid modified carbon-paste electrodes to take up lead ions from solutions prior to voltammetric analysis is illustrated below. Figure 6 compares cyclic voltammograms of (A) unmodified and (B) alginate acid modified electrodes following a 60-sec immersion in a 30 ppm lead solution, rinsing with water and placement in the blank (sodium perchlorate) solution. No distinct redox processes are observed at the plain carbon surface. In contrast, a sharp anodic peak, corresponding to the oxidation of the surface-bound lead, is observed when the modified electrode is used ($E_p = -0.46 \text{ V}$). Continuing to scan the CME in the blank solution causes the peak to decrease gradually. The oxidation peak (in Fig. 6B) reflects a full surface coverage, and corresponds to a charge of $61.7 \mu\text{C}$ and coverage of $1.63 \times 10^{-9} \text{ mole}/\text{cm}^2$.

The binding of lead by the surface-bound alginate acid can be utilized for effective preconcentration prior to voltammetric analysis. Figure 7 shows current *vs.* accumulation-time plots for (a) 5 and (b) 15 ppm lead. At both levels the peak rises rapidly at first and then more slowly. The effects of the solution pH and modifier loading were examined with a 10 ppm

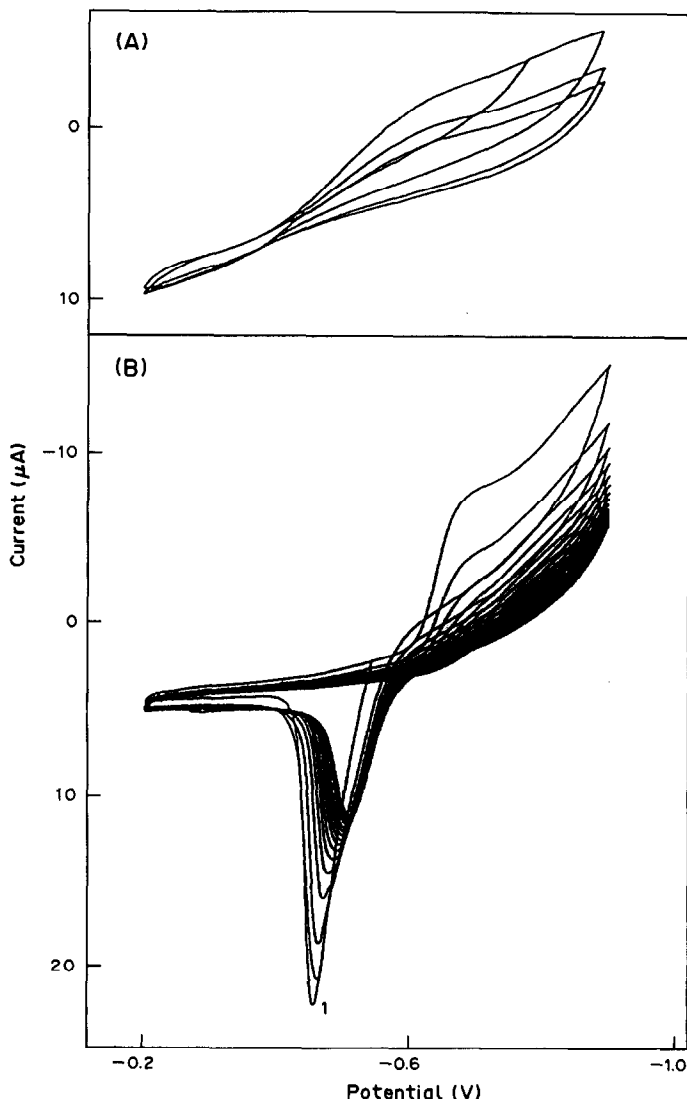

Fig. 6. Cyclic voltamperograms for unmodified (A) and alginic-acid modified (B) carbon-paste electrodes after immersion for 1 min in a stirred 30 ppm lead solution and transfer to the blank/electrolyte solution. Open circuit during accumulation. Scan rate, 50 mV/sec; solutions as in Table 1.

lead solution and stirring for 30 sec. The profiles obtained are similar to the trends shown for pectic acid (in Fig. 3), with a gradual increase in the response between pH 1 and 5, and maximal response at 20% alginic acid loading (not shown). Acid treatment was found effective for stripping the lead at the end of each cycle.

The alginic acid CME exhibits a well defined concentration dependence and reproducible response. Figure 8 shows voltamperograms for solutions with lead concentration increasing from 5 to 20 ppm, after accumulation for 20 sec and transfer to a blank solution. Well-defined peaks are observed ($E_p = -0.48$ V, $b_{1,2} = 90$ mV). A detection limit of 1 ppm can be

estimated from the 5 ppm response. Calibration plots obtained with accumulation for 20 and 60 sec were linear up to 30 and 25 ppm, respectively (slopes, 3.4 and 5.5 $\mu\text{A}\cdot\text{ml}\cdot\mu\text{g}^{-1}$, respectively; correlation coefficients, 0.998). The reproducibility was estimated from twelve successive measurements of stirred 10 ppm lead solution (30 sec accumulation). The mean peak current was 51.9 μA , range 48.4–55.2 μA , relative standard deviation 4.8%.

Interference studies were performed with 10 ppm lead in the presence of 20 ppm of different metals. The lead response was not affected by the presence of Cd(II), Ni(II), Mn(II), Ag(I) or Ca(II). In contrast, competition for surface binding sites was indicated by the 20, 26, 29 and

Fig. 7. Response of the alginic acid modified electrode as a function of accumulation time for (a) 5 and (b) 15 ppm lead. The electrode was immersed for different periods in the stirred lead solution, washed and placed in the blank/ electrolyte solution. Conditions as in Table 1.

33% decrease of the peak height in the presence of Zn(II), Cr(III), Fe(III) and Cu(II), respectively. The standard additions method or the use

Fig. 8. Voltamperograms for solutions containing increasing levels of lead, 5–20 ppm (a–d). Accumulation for 20 sec; other conditions as in Table 1. Initial current positions displaced for clarity.

Fig. 9. Cyclic voltamperograms for unmodified (A) and heparin-modified (B) carbon-paste electrodes after immersion for 5 sec in a 25 ppm copper solution. Scan rate 50 mV/sec; electrolyte 0.1M acetate buffer (pH 6.8). Electrode composition: 30% heparin/38% graphite powder/ 32% high-vacuum silicone grease.

of selective masking agents should overcome these interferences.

In addition to electrodes modified with pectic and alginic acids, carbon-paste electrodes modified with the mucopolysaccharide heparin were used for some preliminary experiments. Physicochemical studies have demonstrated the binding of copper ions to this anticoagulant.¹⁷ Figure 9 compares cyclic voltamperograms recorded for a 25 ppm copper solution, after 5 sec immersion of the unmodified (A) and 30% heparin (B) carbon-paste electrodes. The collection of copper at the modified electrode is evident from the 25-fold enhancement of the copper oxidation peak and 50 mV negative shift in the peak potential.

In conclusion, the binding of metal ions by the negatively-charged sugar units of the polysaccharide chain was exploited for designing novel polysaccharide-modified electrodes for preconcentration/voltammetry. Because they give biological collection of metals, such surface modifiers offer unique reactivity patterns. New insights into the interaction of polysaccharides with metal ions can also be obtained. The carbon paste is shown to be a

useful matrix for the incorporation of these modifiers in a stable, responsive and reproducible form. While the work presented here is within the context of natural polysaccharides, other biological materials (*e.g.*, selected fungi and bacteria¹⁸) offer considerable promise for use as surface modifiers in connection with bioaccumulation/voltammetric sensing. These CMEs, however, cannot compete with the sensitivity of the mercury electrodes used in stripping voltammetry.

Summary—Electrodes modified with Chromotrope 2B incorporated by ion-exchange into a polycationic film of electropolymerized $[Ru(v-bpy)_3]^{2+}$ ($v-bpy = 4\text{-vinyl-4'-methyl-2,2'-bipyridyl}$) have been employed in the amperometric determination of copper in solution and exhibit very high sensitivity as well as linear calibration curves in the concentration range 7×10^{-8} – $1 \times 10^{-4}M$. The effects of competing ligands, including chloride, bromide, oxalate, ammonia, acetate, citrate, borate, humic and fulvic acids, or the presence of competing metal ions such as cobalt or nickel on the uptake of copper by the modified electrodes have also been studied. The presence of competing ligands or metal ions decreases the analytical signal due to copper incorporation. The magnitude of this effect is dependent on the relative strength of coordination of the competing ligands for copper ions or of Chromotrope 2B for the competing metals, and also on the concentration of the interferents. The relevance of this work to speciation studies is discussed.

Chemically modified electrodes¹⁻⁸ are of great use in the development of analytical strategies and sensors, owing to the high specificity that can be achieved by appropriate choice of modifier, and the high sensitivity that can be achieved by preconcentration of the analyte at the surface-modified electrode. In addition, the methodologies and instrumentation involved are relatively simple. A large number of analytical applications of chemically modified electrodes have been reported.⁹⁻²⁶

In our work, we have sought to exploit the advantages of polymer-modified electrodes for the determination of transition metal ions¹⁸⁻²³ and organic functional groups.²³⁻²⁶ The methods have been based on preconcentration of the analyte (metal ion or organic species) at an electrode surface modified with polymers carrying reagents for the selective and sensitive determination of the species of interest.

For the determination of transition metal ions we employ bifunctional or multifunctional polymer films containing electroactive centers and coordinating groups. The internal redox center is used to induce precipitation of the polymer on the electrode surface and thus allows precise control of the coverage and also serves in the determination of the number of immobilized

ligand sites, which is important as it allows *a priori* determination of the saturation response. A coordinating group is chosen that will bind strongly and selectively to the metal ion of interest. In addition, we have also employed carbon-paste electrodes, in which the polymer containing the ligand is mixed with the pasting material. This approach allows rapid renewal of the electrode surface.

The analysis is based on the electrochemical determination of the amount of immobilized metal/ligand complex and can employ either a metal or ligand redox process to provide the analytical signal which is related to the concentration of the analyte in solution. We have demonstrated the applicability of this approach to the determination of iron, copper, cobalt, nickel and calcium.¹⁸⁻²³

We are also interested in assessing the utility of chemically modified electrodes in speciation studies, which are of great importance in analysis of environmental samples since the toxicity of metal ions is often strongly dependent on the form in which they are present. Speciation studies are difficult because the concentration levels are low, the given ion may be present in numerous forms, and the method of analysis must not only be sufficiently sensitive, but also not perturb the species distribution.

Fundamentally, speciation involves analysis of the competitive equilibria between the metal

*Author for correspondence.

ion of interest and the ligands present in solution. We have therefore initially investigated the response of electrodes modified with Chromotrope 2B (for structure see Fig. 1) for the determination of copper ions in solution in the presence of competing ligands or metal ions.

EXPERIMENTAL

Reagents

Chromotrope 2B (C2B) (Aldrich) was purified by three recrystallizations from an ethanol/water mixture. The water was purified by a Hydro water purification train or a Millipore Milli-Q system. Buffer solutions and standard copper solutions were prepared from reagent grade materials. Acetonitrile (Burdick and Jackson distilled in glass) and dried over molecular sieves (4 Å). Tetra-*n*-butylammonium perchlorate (TBAP) (G. F. Smith) was recrystallized three times from ethyl acetate and dried under vacuum at 75° for 72 hr. $[\text{Ru}(\text{v-bpy})_3]^{2+}(\text{PF}_6)_2^*$ was prepared as previously described.²⁷ All other reagents were of at least reagent grade quality and were used without further purification.

Instrumentation

Prior to use, platinum or glassy-carbon disk electrodes sealed in glass or teflon, respectively, were polished with 1 μm diamond paste (Buehler), rinsed with water, placed in an ultrasonic bath (in water) for 1 min and rinsed with acetone.

Electrochemical cells of conventional design with three compartments separated by medium porosity sintered-glass disks were used throughout.

Electrochemical experiments were performed with either an IBM Instruments EC 225 Voltammetric Analyzer or a BAS 100 Electrochemical Analyzer. Data were recorded on a Soltec X-Y recorder. Differential pulse voltammetric experiments were done with a 50 mV pulse amplitude and a sweep rate of 10 mV/sec. All potentials are referred to the sodium chloride saturated calomel electrode (SSCE) without regard to the liquid-junction potential.

Procedures

Electrodes were modified with a polymeric film of $[\text{Ru}(\text{v-bpy})_3]^{2+}$ by reductively initiated

polymerization from acetonitrile/0.1M TBAP solution as previously described.²⁷ The exact coverage was determined from the charge under the voltammetric wave for the Ru(III/II) process at about +120 V. Typical coverages were 2–3 equivalent monolayers. The modified electrodes were immersed in a stirred 10mM aqueous solution of Chromotrope 2B for 15 min. After rinsing with water, the electrodes were placed in contact (for 15 min, with stirring) with aqueous solutions of Cu(I) [obtained by the addition of a fivefold excess of hydroxylamine hydrochloride to Cu(II) chloride solutions] at various concentrations and in the presence (or absence) of other metal cations or ligands, also at various concentrations. Afterwards, the electrodes were rinsed with water.

Determinations (by differential pulse voltammetry) were performed in either aqueous trifluoroacetate buffer (pH 5.25) or in acetonitrile/0.1M TBAP. The currents were normalized with respect to the surface coverage, which was determined as described above. At least five replicate determinations were performed.

RESULTS AND DISCUSSION

Preliminary voltammetric characterization

In the absence of copper, C2B did not exhibit any redox response in trifluoroacetate buffer at a glassy carbon electrode in the potential range between -0.5 and +1.0 V. Upon addition of copper ions, a well defined wave was observed, which had a conditional potential of -0.05 V and that we ascribe to formation of a stable C2B/Cu complex.

The electrochemical behavior of electrodes modified with poly- $[\text{Ru}(\text{v-bpy})_3]^{2+}$ and loaded with C2B was also investigated before and after its exposure to an aqueous copper solution. Prior to exposure (Fig. 1,A), the only electrochemical response observed between -0.50 and +1.40 V was that of the poly- $[\text{Ru}(\text{v-bpy})_3]^{2+}$ at about +1.20 V. After exposure, however, an additional redox response with a formal potential of -0.05 V was observed (Fig. 1,B); consistent with the results in solution.

When the electrochemical response of modified electrodes (again prior to and after exposure to copper-containing solution) was measured in acetonitrile medium, analogous results were obtained except that the wave for the C2B/Cu complex was at a formal potential of +0.45 V.

*v-bpy = 4-vinyl-4'-methyl-2,2'-bipyridyl.

Fig. 1. Differential pulse voltamperograms for a glassy-carbon electrode modified with poly- $[\text{Ru}(\text{v-bpy})_3]^{2+}$ loaded with C2B prior to (A) and after (B) exposure to a $50\mu\text{M}$ solution of copper. Inset: structure of C2B.

Copper determination studies

Electrodes modified with C2B were exposed to aqueous copper solutions (pH 5.25) at various concentrations, as described in the experimental section. Subsequently, the electrochemical response of the surface-immobilized C2B/Cu complex in either aqueous pH 5.25 buffer or acetonitrile/ $0.1M$ TBAP was obtained, with the waves at formal potentials of -0.05 and $+0.45$ V respectively, as the analytical signal.

Figure 2 shows a plot of the logarithm of the normalized current (for the determination in acetonitrile medium) *vs.* the logarithm of the copper concentration in solution. A fairly good correlation ($r = 0.98$) was obtained over the concentration range 7.2×10^{-8} – $1.1 \times 10^{-4}M$. This illustrates the sensitivity of the method and its wide dynamic range. A saturation response is obtained as shown by the levelling of the curve at the higher concentrations,

Fig. 2. Calibration curve for the determination of copper with electrodes modified with poly- $[\text{Ru}(\text{v-bpy})_3]^{2+}$ loaded with C2B.

because of coordination of all the available surface sites. This was corroborated by the fact that the current for the immobilized C2B/Cu complex did not increase with further increase in the solution concentration of copper. In addition, the observed currents correlated very well with our estimates for a completely metalated film, calculated from the experimentally determined surface coverage of the polymer on the electrode surface assuming complete neutralization of the charge due to the pendant $[\text{Ru}(\text{v-bpy})_3]^{2+}$ groups, by the sulphonate side-chains in C2B. This is based on the fact that we could precisely determine the amount of surface-immobilized $[\text{Ru}(\text{v-bpy})_3]^{2+}$ (from its voltammetric response) and from this, determine the maximum amount of C2B that could be incorporated by ion-exchange. Since the Cu/C2B stoichiometry is known, the measurement of the redox response due to the immobilized metal/ligand complex for an ostensibly metal-saturated film yields the amount of C2B incorporated. The experimental and calculated values were always in good agreement. We have also previously shown¹⁸ that for similar ligands there is virtually no loss of ligand or complex from the electrode surface upon potential cycling or in the presence of high ($1.0M$) electrolyte concentrations for extended time periods.

At the low-concentration end, the response appears to level off at a copper concentration of about $5.4 \times 10^{-8}M$. This, however, appears to be due not to the limit of detection of the technique, but to background levels of copper in the reagents employed.

Competitive binding studies

We have studied the effects of competitive binding of copper ions by other ligands or of other metals by the surface-immobilized ligand (C2B). These studies will be helpful in trying to apply the approaches described here to speciation studies since speciation fundamentally involves competitive equilibria.

Competitive binding of copper by other ligands.

In the investigation of the effects of competing ligands on the determination of copper, the modified electrode was exposed to solutions of copper at a fixed concentration of $1 \times 10^{-5} M$, which also contained a competing ligand at various concentrations. In this manner, we studied the effects of chloride, bromide, oxalate, ammonia, acetate, citrate, borate, humic and fulvic acids as competing ligands. Figure 3 shows representative results obtained when the competing ligands were chloride, bromide, oxalate and humic acid. In all cases there was a diminution in the response for the surface-immobilized C2B/Cu complex and the magnitude of this effect was proportional to the solution concentration of the competing ligand. The linearity of the $\log(i/\Gamma)$ vs. $\log[\text{competitive ligand}]$ plots strongly suggests that indeed the observed effects are due to competitive binding between the surface-immobilized C2B and the

ligand in solution. In addition, for the cases where there are reliable values for the conditional stability constants (β') of the copper complexes with the competitive ligands, we find that a plot of $\log(i/\Gamma)$ vs. $\log \beta'$ is also linear. In other words, the response depends on the conditional formation constants for the copper complexes under the specific conditions used.²⁸ This supports our assertion that competitive binding effects are responsible for the observed diminution in the analytical signal, and more importantly, establishes that the relative strengths of coordination of the various ligands are maintained under the experimental conditions employed. This implies that the coordination properties of an interface (a modified electrode in this case) can be systematically and deliberately controlled by choice of the immobilized ligand as well as by the presence of other competitive ligands in solution. This should have significant implications for speciation studies, which we are currently exploring.

Competitive binding of other metals by surface-immobilized Chromotrope 2B. We have also performed some preliminary studies on the effects of other metal cations on the determination of copper by electrodes modified with C2B. The electrodes were exposed to solutions containing copper at a concentration of $50 \mu M$

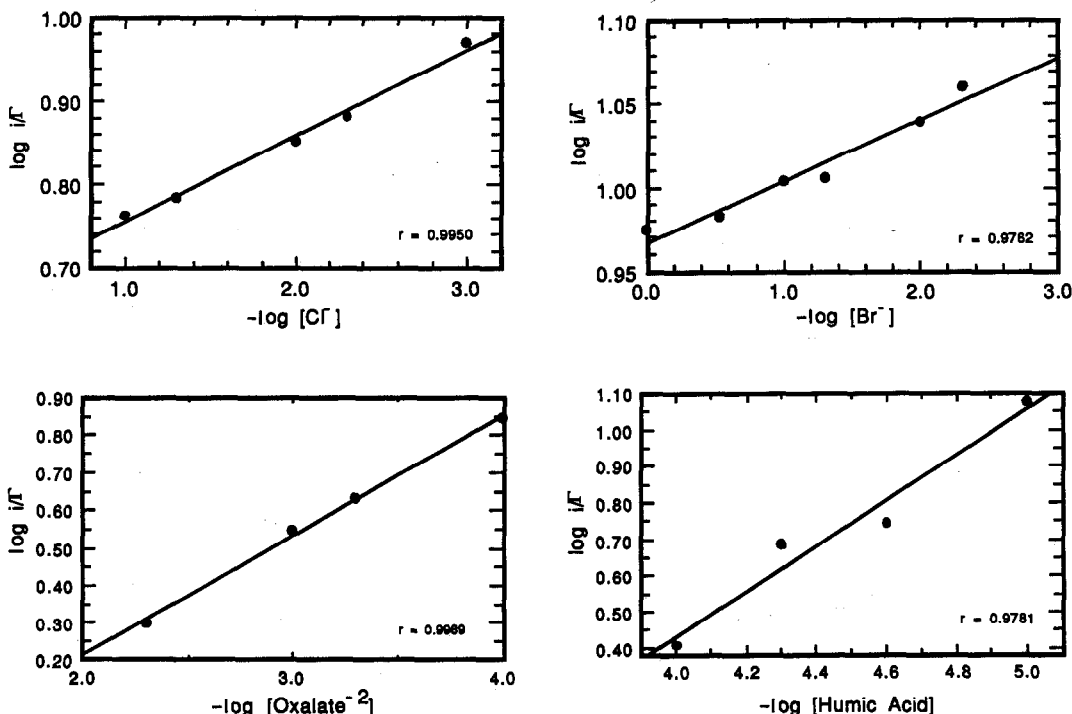

Fig. 3. Effects of competing ligands at various concentrations on the determination of copper at a solution concentration of $1 \times 10^{-5} M$ at electrodes modified with poly-[Ru(v-bpy)₃]²⁺ loaded with C2B.

	[M]/[Cu]*	i_p , arbitrary units
M' = cobalt	0.0	5.55
	1.0	4.00
	5.0	3.90
M' = nickel	0.0	5.55
	0.2	2.73
	1.0	1.05

*[Cu] held constant at 50 μ M.

as well as either Co(II) or Ni(II) at various concentrations. The signal due to the immobilized C2B/Cu complex was then obtained. The results (Table 1) show that Ni(II) had a more dramatic effect on the signal than Co(II) did, which is consistent with the higher formation constant for the nickel complex. (The formation constants obtained in the literature were for Chromotrope 2R²⁹ and we have assumed that the trends in coordination strength are the same for the closely related C2B.) The lack of additional data on formation constants precludes any further analysis, but the trends are consistent with differences in the strength of coordination.

The presence of nickel gave rise to an additional redox response at -0.29 V. Thus, electrodes modified with C2B could be employed in the determination of nickel in solution.

CONCLUSIONS

We have demonstrated that electrodes modified with C2B can be employed in the determination of copper in solution at concentrations down to $7 \times 10^{-8}M$, with a wide dynamic range. The presence of competing ligands or other metal ions affects the analytical signal in proportion to the strength of coordination of the other ligands with copper ions or of other ions with the surface-immobilized C2B. The presence of competitive equilibria suggests that this analytical approach might be applicable to speciation studies, and this is currently under investigation.

ANION-EXCLUDING POLYPYRROLE FILMS

M. FREUND, L. BODALBHAI and A. BRAJTER-TOTH*

Department of Chemistry, University of Florida, Gainesville, FL 32611, U.S.A.

(Received 27 July 1989. Accepted 12 September 1989)

Summary—A new method for modifying polypyrrole films is described. It involves complete oxidation of the film. The film produced is electronically non-conductive but ionically conductive, and has ion-selective properties based on the exclusion of anionic species. The effective pH within the film can be controlled by the choice of supporting electrolyte used during the oxidative treatment, without loss of selectivity. Cyclic voltammetry is used to demonstrate the effect of film pH on the rate of dopamine oxidation in a neutral supporting electrolyte.

Since the discovery of electrochemical polymerization of pyrrole at electrode surfaces,^{1,2} there has been considerable interest in the manipulation of polypyrrole (PPY) films to produce selective and catalytic surfaces for use as sensors. Because PPY films can be produced easily and with widely varying electrochemical characteristics, they have been the focus of several papers.³⁻⁸ Such films have been produced by electropolymerization of suitable *N*-substituted pyrroles,⁹⁻¹² by physically trapping catalysts,^{5,9} and by choosing counter-ions with desired characteristics.^{6,7}

In this study we report a new method for treating PPY to produce analytically useful films. It involves irreversibly oxidizing the films, which changes their characteristics, according to the supporting electrolyte used in the treatment. It has been reported that oxidation of PPY films at potentials $> +1.0$ V *vs.* SCE results in loss of the electrical conductivity of the film.^{13,14} This irreversible oxidation is attributed to nucleophilic attack by anions and/or water on the cationic pyrrole nuclei in the polymer, resulting in loss of conjugation and hence conductivity.¹³ Redox reactions at the underlying electrode still occur in spite of the loss of conductivity, contrary to what has been reported.¹⁴ This indicates that the film is porous enough to allow diffusion of analyte and electrolyte to the underlying electrode surface. The response of the films depends on the charge of the redox couple. The cyclic voltammetry responses of anionic redox couples are suppressed, whereas those of neutral and cationic redox couples are not.

The pH of the supporting electrolyte used during preparation of the film determines the effective pH within the film, as well as the peak shifts in oxidation of pH-sensitive biological molecules. For example, the use of basic electrolytes produces films that give greater reversibility in the oxidation of dopamine in pH 7 phosphate buffer.

This new treatment can produce ion-selective PPY films, the effect of which on pH-sensitive responses of biological molecules can be controlled by the method of preparation of the film. Development of such surfaces is currently of considerable interest.¹⁵⁻¹⁷ In this paper, we discuss the effects of the treatment on the responses of ferricyanide and small biological molecules involved in 2-electron 2-proton oxidations, and show how the reversibility of these redox couples can be manipulated by choice of the supporting electrolyte used in preparation of the film.

EXPERIMENTAL

Reagents and methods

All chemicals were reagent grade, and used as received. Pyrrole, acetonitrile (MeCN), and tetrabutylammonium perchlorate (TBAP) were from Kodak. Potassium ferricyanide, ascorbic acid, and disodium hydrogen phosphate and trisodium phosphate were from Mallinckrodt. Potassium chloride, sodium dihydrogen phosphate and sodium hydroxide were from Fisher, and dopamine was from Sigma.

All electrochemical experiments were performed with a Bioanalytical Systems Analyzer

*Author for correspondence.

(BAS-100) at $25 \pm 2^\circ$. A saturated calomel electrode (SCE) was used as a reference, a 1-cm² platinum foil as an auxiliary electrode, and glassy carbon was used to make the working electrode, either alone or coated with PPY films. Glassy-carbon electrodes (GCE) freshly polished with grade B γ -alumina (Fisher) on an Alpha A cloth (Mark V Laboratory) followed by ultrasonication for 5 min were used for each electrochemical measurement, and for the production of each PPY film. The GCE electrode areas were determined by chronocoulometry. The potential was stepped from +0.400 to +0.100 V *vs.* SCE in 1mM potassium ferricyanide (1M KCl, $D_{ox} = 7.63 \times 10^{-6}$ cm²/sec), with a pulse width of 500 msec. Typical electrode areas were *ca.* 0.068 cm². All solutions were deoxygenated by bubbling nitrogen through them for 5 min.

Preparation of polypyrrole films

Polypyrrole electrodes were made by electropolymerizing pyrrole on polished glassy carbon-electrodes at +0.950 V *vs.* Ag.³ The solution used for polymerization was 50mM pyrrole and 0.1M TBAP in MeCN. The film thickness was controlled by measuring the charge passed during the electropolymerization. Film thicknesses of 0.1 μ m were deposited by passage of 24 mC per cm² of electrode area.³ The amount of charge passed was always within 2% of the required amount calculated from the electrode area. The electrodes were then washed with distilled water and allowed to dry.

The PPY films were then cycled ten times, in aqueous solution, between +0.900 and -0.300 V *vs.* SCE. The supporting electrolytes used were all 0.5M and the scan rate was 20 mV/sec. The electrodes were finally washed with distilled water.

RESULTS AND DISCUSSION

When 0.1- μ m thick perchlorate-doped PPY films were oxidized in the presence of 0.5M sodium perchlorate by cycling as described above, the background signals obtained in 0.5M phosphate buffer (pH 7) were much smaller than those obtained with untreated polypyrrole (see Fig. 1). During oxidation of the PPY film, it is likely that the ratio of pyrrole units to perchlorate decreases, which may convert the PPY film from an electronic/ionic conductor¹⁸ into a non-electronic but purely ionic conductor. The decreased back-

Fig. 1. Cyclic voltammograms (20 mV/sec) of (a) an untreated PY and (b) a sodium perchlorate treated PPY film in 0.5M phosphate buffer, pH 7. Areas of the GC substrate are (a) 0.0696 ± 0.0009 and (b) 0.0612 ± 0.0016 cm².

ground, which is comparable to that obtained with a glassy-carbon electrode, supports this conclusion.

The response of ferricyanide on the new film formed by oxidative treatment is suppressed relative to that on glassy carbon or on untreated PPY. Figure 2 shows voltammograms of 1mM ferricyanide in 0.5M phosphate buffer (pH 7) obtained with a GCE and the treated PPY film; in both cases the geometric electrode areas were approximately the same. The response of ascorbic acid in pH 7 phosphate buffer is also suppressed at the treated PPY electrode, in accord with the ferricyanide response, since the ascorbic acid ($pK_a = 4.2$)¹⁹ will be present as ascorbate at pH 7. The oxidation of dopamine, which is positively charged at pH 7,⁸ results in a

Fig. 2. Cyclic voltammograms (20 mV/sec) of 1mM ferricyanide in 0.5M phosphate buffer, pH 7, on (a) a GCE electrode and (b) a sodium perchlorate treated (pH 5.8) PPY film. Geometric areas of the GC substrate are (a) 0.0794 ± 0.0004 and (b) 0.0612 ± 0.0016 cm².

Fig. 3. Cyclic voltammograms (20 mV/sec) of 1mM ascorbic acid (solid line) and 1mM dopamine (dashed line) in 0.5M phosphate buffer (pH 7) obtained with a sodium perchlorate treated (pH 5.8) PPY film. Geometric area of the GC substrate is $0.0612 \pm 0.0016 \text{ cm}^2$.

significantly higher faradaic response than that of the two negatively-charged species. Figure 3 shows the responses of 1mM ascorbic acid and 1mM dopamine in 0.5M phosphate buffer (pH 7) on the same electrode, and illustrates the effect of the charge of the redox couple.

To determine whether this effect depended on the anion present in the supporting electrolyte during film preparation, PPY electrodes were treated in several different supporting electrolytes, as described in the experimental section, because the electrical conductivity of PPY films is known to be dependent on the anion present during the electropolymerization.^{20,21} The electrolytes used included 0.5M sodium hydroxide (pH 13.3), sodium phosphate (pH 12.7), sodium chloride (pH 6.5), sodium perchlorate (pH 5.8), and sodium dihydrogen phosphate (pH 4.4) (Table 1). In every case the anion-response was suppressed, irrespective of the supporting electrolyte used. This suggests that a PPY film with increased electronegative

character may be produced, resulting in reduction of the faradaic current produced by anionic redox species.

The response of positively charged analytes on treated PPY films is lower than that observed on GC and depends on the electrolyte anion used in the treatment (Table 1). This difference in response suggests that the effective electrode area is decreased by the presence of the film. As mentioned above, this could result from the formation of ionically conductive but electronically non-conductive films of fairly low porosity.

The reversibility of the oxidation of dopamine depends on the pH of the supporting electrolyte used in the oxidation of the film. Films treated in basic supporting electrolytes have surfaces which increase the reversibility of dopamine oxidation. Several electrodes were made by treating PPY films in the presence of 0.5M sodium hydroxide (pH 13.3), trisodium phosphate (pH 12.7), sodium chloride (pH 6.5), sodium perchlorate (pH 5.8), or sodium dihydrogen phosphate (pH 4.4). Figure 4 shows the shift in anodic peak potential for the oxidation of 1mM dopamine in 0.5M phosphate buffer (pH 7) on films prepared in the different supporting electrolytes. At low pH, the pH-dependence of the anodic peak potential of dopamine is linear and has a slope of 64 mV/pH, in fair agreement with that expected from the Nernst equation for a reaction involving a $2e^- - 2H^+$ transfer. The pK_a of dopamine is 8.92,²² and the oxidation of dopamine

Fig. 4. Plot of anodic peak potential for the oxidation of 1mM dopamine in 0.5M phosphate buffer (pH 7) as a function of pH of the electrolyte used during treatment of the PPY film. Each point represents a different supporting electrolyte used during treatment (see text). Scan rate 20 mV/sec.

Table 1. Effect of supporting electrolyte on response for 1mM dopamine in 0.5M phosphate buffer (pH 7); scan rate 20 mV/sec

Electrolyte	pH	$\mu A.l.cm^{-2}.mmole^{-1}$
NaH ₂ PO ₄	4.4	36.75
NaClO ₄	5.8	17.01

NaOH	13.3	141.7
GCE	—	169.1

becomes pH-independent as the pH of the film increases, as shown in Fig. 4.

The response observed for dopamine is determined by the type of film used and suggests that the internal pH of the film is controlled by the pH of the electrolyte used during oxidation, and controls the response, irrespective of the bulk solution pH. Typical responses for dopamine in 0.5M phosphate buffer (pH 7) at two electrodes of different effective pH are shown in Fig. 5.

Change in the internal pH of the film can lead to an improvement in sensitivity, which is not simply a result of improved electrochemical kinetics of the analyte. Table 1 shows peak currents, normalized for concentration and electrode area, for the oxidation of 1mM dopamine in 0.5M phosphate buffer (pH 7). Films oxidized in 0.5M sodium hydroxide (pH 13.3) yielded the largest and most reversible responses, which were close to those obtained with unmodified GC, indicating that diffusion of dopamine through the film must be fast under these conditions. No peaks were observed for ferricyanide or ascorbate, as expected from the difference in response to cations and anions, already mentioned. After some use (10 complete scans), the magnitude of the response decreased by 23% but a well defined current-potential curve was maintained, with no shifts in peak potentials. This was contrary to the observed poisoning of untreated GC by dopamine oxidation products, which resulted in anodic peak shifts and a decrease in oxidation current. This poisoning effect of catecholamines is common with solid electrodes.²³ Therefore, this reduction

Fig. 5. Cyclic voltammograms (20 mV/sec) of 1mM dopamine in 0.5M phosphate buffer (pH 7) on a PPY electrode treated in 0.5M NaH_2PO_4 (solid line) and in 0.5M Na_3PO_4 (dashed line). Geometric areas of the GC substrate are 0.0676 ± 0.0006 and 0.0618 ± 0.0008 cm^2 respectively.

in response could be a result of changes in film structure, and in turn porosity, over long periods of use.

A plot of $\log i_{p,a}$ vs. $\log v$ (scan rate) was made for the oxidation of 1mM dopamine in 0.5M phosphate buffer (pH 7) at a film oxidized in the presence of 0.5M sodium hydroxide, to determine whether the responses were diffusion-controlled. The plot had a slope of 0.499 ± 0.004 with a correlation coefficient (R^2) of 0.9998. For oxidation at an untreated GCE the slope was 0.460 ± 0.054 ($R^2 = 0.9867$). The GCE was resurfaced and ultrasonicated between each measurement. A slope of 0.5 indicates that the redox process is diffusion-controlled.²⁴

The results thus far obtained indicate that the anions present in the supporting electrolyte during oxidation of the film may in fact control the structure and chemical properties of the resulting PPY film. More experiments are necessary to elucidate the film structure. Further experiments are currently under way to quantify the responses of several redox couples on these surfaces. Other applications of these films are also being explored.

(Received 9 August 1990. Accepted 7 September 1990)

Summary—A chemically modified electrode (CME) containing 1-(2-pyridylazo)-2-naphthol is evaluated for its ability to preconcentrate bismuth(III) prior to quantification by voltammetry. The CME approach is shown to be sufficiently sensitive for sub-nanomolar concentrations to be determinable after chemical deposition for 60 sec. Further, when the bismuth is deposited from iodide-containing sulphuric acid media, the discrimination against interference by copper(II) is significantly better than that obtained with conventional stripping analysis. The results obtained for Bi(III) in an NBS reference solution agree well with the recommended value.

Stripping voltammetry is a sensitive approach to the determination of traces of Bi(III) in aqueous media.^{1,2} Nanomolar concentrations, for example, can be determined after just a few minutes of electrolytic deposition at a mercury film electrode.³ However, the advantage of the highly sensitive stripping technique is often overshadowed by difficulties encountered in practical applications. One problem is that the diffusion-controlled electro-reduction of Bi(III) takes place at a potential which is considerably more negative than the stripping potential. This implies that Cu(II), which behaves more reversibly, and is electroactive at near the Bi(III) reduction potential, is likely to interfere. In addition, since amalgamated Bi(III) is stripped at near the mercury oxidation potential, a significant current due to oxidation of the electrode material is typically superimposed on the Bi(III) stripping signal. In this work we survey a different technique for determination of traces of Bi(III). Like conventional stripping methods, the technique includes a deposition step and a voltammetric measurement step. The difference is that the analyte is accumulated by non-electrochemical attachment to a chemically modified electrode (CME).⁴⁻⁶ The CME is based

on carbon paste and a reagent with chemical affinity for Bi(III). In most respects, the analytical approach is analogous to that for nickel(II),^{7,8} and Cu(I),⁹ which were determined with carbon-paste CMEs containing highly selective modifiers (dimethylglyoxime and 2,9-dimethyl-1,10-phenanthroline, respectively). However, no selective reagent for Bi(III) is available. Instead, the CMEs are constructed from graphite paste containing 1-(2-pyridylazo)-2-naphthol (PAN). PAN is a commercially available reagent for solvent extraction of metal chelates, and is used in many extractive procedures for a wide variety of metal species.¹⁰ PAN is non-selective, but its preference for extraction of the individual metals can be controlled through the pH of the metal solution, and the concentration of a competing water-soluble reagent, such as iodide. A study of this has revealed that chemical deposition and voltammetric determination of Bi(III) is feasible. Furthermore, subnanomolar concentrations can be determined following chemical deposition for 60 sec from dilute sulphuric acid media. Equally important, when excess of iodide is added to the deposition medium, the selectivity for Bi(III) is such that the signal for 53nM Bi(III) is not affected by the presence of 0.53mM of Cu(II). Moreover, the CME results for Bi(III) in a well defined reference solution, containing twenty different metal species, agree well with the recommended concentration.

EXPERIMENTAL

Reagents

Mineral acids of suprapur (Merck) grade and triply distilled water were used throughout the study. Standard solutions of metal ions were prepared by dissolving analytical grade AgNO_3 , $\text{Bi}(\text{NO}_3)_3 \cdot 5\text{H}_2\text{O}$, $\text{CoCl}_2 \cdot 6\text{H}_2\text{O}$, $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$, Fe_2O_3 , $\text{Pb}(\text{NO}_3)_2$, $\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$, $\text{ZnSO}_4 \cdot 7\text{H}_2\text{O}$ and $\text{SnCl}_2 \cdot 2\text{H}_2\text{O}$ in dilute H_2SO_4 medium (pH 0.75). Graphite pastes were prepared with PAN (Merck 7531), graphite powder (*purum*), silicone oil (Merck 9762, type 550), and anhydrous ethyl alcohol. The reference sample Trace Elements in Water (NBS 1643b) was obtained from National Bureau of Standards, Washington, D.C. All solutions were kept in polyethylene bottles.

Graphite-paste electrodes

PAN/graphite mixtures (29, 38, 44, 46, and 50% PAN w/w) were prepared in the following fashion. About 3 g of PAN was accurately weighed, and warm ($\sim 45^\circ$) anhydrous ethyl alcohol was added slowly, until complete dissolution was achieved. The warm solution was placed on a hot-plate ($\sim 50^\circ$), the appropriate weight of graphite powder was added, and the resulting slurry stirred until a dry PAN-coated graphite powder was obtained. Plain (unmodified) and modified carbon pastes were prepared by hand-mixing 5 g of graphite or graphite/PAN mixture with 2 ml of silicone oil. Plain carbon paste electrodes (PCPE) and modified carbon paste electrodes were prepared from the pastes by a technique which has been described elsewhere.⁷

(g) -25 mV potential step
(h) current computed as the difference of (f) and (c)

Apparatus

Voltammetric measurements were made by using a computerized analyser.¹¹ The cells used for chemical deposition and for voltammetric measurements were 50-ml lidded polyethylene beakers, in which solutions were stirred from below by means of magnetic stirrer bars. In addition to the beaker and the carbon-paste working electrode, the voltammetric assembly included a saturated calomel reference electrode (Radiometer K401) and a counter-electrode (a platinum wire, 1 cm long and 0.5 cm thick). Prior to use, all bottles and beakers were soaked in 2M nitric acid for 7 days, washed three times with triply distilled water, and finally kept in 1M sulphuric acid. The solutions used for chemical deposition and for voltammetric measurements were freed from dissolved oxygen by passage of argon for at least 60 sec.

Procedure

First, the Bi(III) was chemically deposited on a CME (or PCPE), simply by immersing the electrode for a specified period of time in 20 ml of the deposition solution. Next, the electrode was transferred to the electrochemical cell and connected to the working electrode terminal of the potentiostat and the current *vs.* potential curve was recorded. Finally the electrode surface was regenerated.

Several variations of the basic procedure were tested. The chemical deposition was performed from solutions of Bi(III) (and potentially interfering metals) in 1M potassium sulphate, 0.1M hydrochloric acid, dilute sulphuric acid (pH 1.50, 1.32, 0.85, 0.75 and 0.62) and 5mM potassium iodide in dilute sulphuric acid (pH 0.75). The voltammetric measurement was made with dilute sulphuric acid (pH 0.75) in the electrochemical cell. The voltammetric waveforms are specified in Table 1.

Three different methods of regeneration of the CME surface were tested: polarization of the CME at +700 mV for 120 sec, exposure of the disconnected CME for 120 sec to $10^{-2}M$ EDTA in borax medium (pH 9.0), and scraping off the exposed CME surface and polishing the new surface on paper until it was shiny.

RESULTS AND DISCUSSION

The cyclic voltamperograms obtained after exposure of the unmodified electrodes for 60 sec

Fig. 1. Linear sweep cyclic voltamperograms recorded after 10-sec CME exposures to the blank sulphuric acid medium (1) and to this medium spiked with 2×10^{-7} (2) and $10^{-6}M$ (3) Bi(III).

to $1 \mu M$ Bi(III) in neutral to acidic media ($1M$ K_2SO_4 , $0.1M$ HCl , and $0.1M$ H_2SO_4) were featureless. Thus there were no signs of attachment of Bi(III) to the plain carbon paste. All the modified pastes, on the other hand, accumulated Bi(III), but their suitability as electrode materials depended on the modifier loading. The highest sensitivity was observed with CMEs based on the 38% (w/w) PAN/graphite mixture. Therefore such CMEs were used in all subsequent work. The experiments showed that Bi(III) could be deposited both from $1M$ potassium sulphate and from $0.1M$ hydrochloric acid. However, the highest sensitivity was observed for deposition from dilute sulphuric acid media. Figure 1 shows the cyclic voltamperograms recorded after a 10-sec exposure of the CME to a blank sulphuric acid medium (pH 0.75) (1), and to this medium spiked with $2 \times 10^{-7}M$ (2) and $10^{-6}M$ (3) Bi(III). Clearly, electroactivity was observed both for the unspiked and the spiked sulphuric acid medium. Furthermore, the oxidative voltammetric signal obtained for the blank medium overlapped the signals recorded after spiking with Bi(III). This blank response was attributed to metal impurities in the sulphuric acid medium. Such impurities—especially Co(II), Cu(II), Fe(III), Ni(II), and Sn(II)—can be extracted by PAN from acidic media,¹⁰ and CME experiments revealed

that all five species could be accumulated and exhibit electroactivity at potentials ranging from 300 to 500 mV vs. SCE. The CME-sensitivity for Ni(II) was almost as high as that for Bi(III), but the sensitivities for Cu(II), Co(II), Fe(III), and Sn(II) were about 25, 48, 28, and 16%, respectively, of that for Bi(III). Thus all five metal species presented a potential source of interference in the determination of traces of Bi(III). However, when iodide was added to the sulphuric acid medium, the blank signal decreased drastically, and the selectivity for Bi(III) was considerably improved. The sensitivity and selectivity for Bi(III) depended somewhat on pH and the concentration of potassium iodide. However, at pH 0.75 and $5mM$ iodide in the sulphuric acid medium the sensitivities for Co(II), Cu(II), Fe(III), Ni(II), and Sn(II) were all below 1% of the sensitivity for Bi(III). The most efficient CME regeneration was achieved by squeezing out a 2-mm column of the carbon paste, scraping off the excess, and polishing the electrode surface on paper. This procedure left no evidence of previous CME-exposure to Bi(III). Both the electrochemical (positive polarization), and the chemical (exposure to EDTA) treatment of the CME-surface removed part of the analyte deposit, but neither was satisfactory for repeated determinations of Bi(III) at sub-micromolar concentration levels. Table 2 summarizes the recommended experimental conditions.

These experimental conditions allowed the determination of ultratrace concentrations of Bi(III), e.g., in the unspiked deposition medium. In fact, a well defined programmed pulse voltammetric Bi(III) signal of 150 nA was observed after exposure of the CME to the blank medium for 60 sec. Furthermore, when the blank deposition medium was spiked with $10^{-10}M$ Bi(III), the mean and standard deviation of the signals recorded in 11 consecutive deposition/voltage scanning experiments were 450 and 55 nA, respectively. Thus the reagent blank concentration was lower than $10^{-10}M$, and the limit of detection for a 60-sec chemical deposition was of the order of $10^{-10}M$. The sensitivity of the CME procedure increased with the duration of chemical deposition. For instance, with $10^{-7}M$ Bi(III) in the deposition solution, the analytical signal increased linearly (correlation coefficient >0.99) with deposition time from 4 to 120 sec. The signal vs. concentration behaviour was studied with four CMEs and chemical deposition for 60 sec. In all four

cases the blank deposition medium could be spiked with more than 10^{-8}M Bi(III) before the signal *vs.* concentration plot became non-linear (correlation coefficient < 0.99). Linear behaviour was also observed from 10^{-9} to 10^{-7}M , with chemical deposition for 4 sec. Thus standard addition afforded a viable means of quantification.

Compared with the conventional stripping procedure, which is based on electrolytic deposition, the CME procedure discriminated well against interference from Cu(II). This aspect was demonstrated by experiments in which the influence of Cu(II) additions on the Bi(III) signal was studied by the conventional stripping procedure and the CME procedure. The solution investigated was the NBS 1643 b reference solution Trace Elements in Water. According to NBS, this solution contains 53nM Bi, 345nM Cu(II), and 18 other known metal species. In addition, the solution contains 0.5M nitric acid. For the present purpose a 20-ml volume of the solution was spiked with 5mM potassium iodide, and further acidified (to pH 0.75) by addition of a few drops of concentrated sulphuric acid.

The conventional stripping analyses revealed that the deposition of Bi(III) required a potential which was equal to or more negative than that used in the CME procedure for reduction of the Bi-PAN deposit (-100 mV *vs.* SCE).

After electrolysis at this potential Cu(II) did not produce a distinct stripping peak. However, the experiments showed that Cu(II) was in fact deposited, and that its subsequent stripping gave rise to currents at the Bi(III) stripping peak potential. This effect is demonstrated in Fig. 2A,

which shows the stripping voltamperograms obtained following 60-sec electrolytic deposition from the NBS water (a) and from the NBS water spiked with $25 \mu\text{M}$ Cu(II) (b).

In contrast, the analytical CME response was insensitive to addition of Cu(II). As shown in Fig. 2B, the Bi response obtained from the unspiked sample (a) was not significantly different from that obtained after addition of $600 \mu\text{M}$ Cu(II) (b).

In order to study the CME-performance in a practical analytical situation, the CME-procedure was used to determine traces of Bi(III) in tap water and in NBS-SRM 1643 b solution. In the latter determination, quantitative results were obtained first by a standard-additions approach, then from a calibration graph obtained by CME-analysis of standard Bi(III) solutions. The results are shown in Table 3. Clearly, despite manual regeneration of the CME the results obtained were mutually consistent. Furthermore, the results for the NBS water agreed well with the NBS recommended value. The use of calibration plots requires a selective sensing device. Thus the agreement of the calibration and standard-addition results gave additional evidence of a selective analytical approach.

We conclude that the CME approach is sufficiently sensitive for nanomolar concentrations of Bi(III) to be determined after chemical deposition for 60 sec.

The recommended regeneration method requires manual skill on the part of the experimenter. However, this disadvantage is overshadowed by the discrimination against Cu(II), which is considerably higher than that obtained by using electrolytic analyte deposition.

AMPEROMETRIC BIOSENSORS FOR GLUCOSE BASED ON CARBON PASTE MODIFIED ELECTRODES

A. AMINE, J.-M. KAUFFMANN and G. J. PATRIARCHE*

Université Libre de Bruxelles, Institut de Pharmacie, Campus Plaine, CP 205/6,
Bd. du Triomphe, 1050 Bruxelles, Belgium

(Received 26 October 1989. Accepted 6 February 1990)

Summary—The modification of carbon-paste electrodes by incorporation of the enzyme glucose oxidase (GOD) is described. The resulting probes can be operated as amperometric glucose sensors in the presence or absence of a mediator (1,1'-dimethylferrocene) mixed into the paste. Extended linear calibration ranges have been obtained up to 90 and 50mM glucose respectively. The electrode responses were rapid, reaching steady-state values within 30–40 sec. Advantages of using a GOD–paste formulation are suggested. Plasma glucose assays were correlated with spectrophotometric determinations based on glucose oxidase ($y = 1.07x - 0.16$, $r = 0.973$, $n = 17$).

The characteristics and performances of enzyme-based electrochemical sensors for glucose measurements have been extensively studied and reviewed.¹⁻³ Selectivity, extended linearity and short response times are generally regarded as the main criteria for the applicability of glucose probes in "real sample" analysis. Amperometric detection systems employing glucose oxidase (GOD) as a natural catalyst have mainly been developed.

Non-mediated and redox-mediated systems can be considered for construction of glucose sensors. The former monitor either oxygen consumption or hydrogen peroxide production, or the electrochemical behavior of the two FADH₂ redox centers of the enzyme.⁴ The mediated biosensors generally couple small electron-carriers with redox proteins to facilitate electron transfer between the enzyme and the electrode material. Sensors based on the ferrocene/ferricinium couple have been shown to be quite useful in this respect.

The ferricinium ion [Fe(cp)⁺] competes favorably with the natural mediator oxygen to oxidize the reduced GOD. The reoxidation of the

reduced ferricinium [Fe(cp)] is monitored at the electrode at low potential (+160 mV vs. SCE) to minimize interferences. These devices require close proximity of the mediator to the electrode surface and the enzyme redox centers or its rapid diffusion between them. Several recent strategies, which combine GOD and mediator immobilization on or in the electrode material have been reported.^{5,6} The enzyme GOD may be entrapped in a thin ferrocene-containing polymer film electropolymerized onto the electrode⁵ or it can be incorporated into a carbon-paste matrix (graphite particles in liquid paraffin) in the presence of a ferrocene–polysiloxane backbone.⁶ There has been a growing interest in incorporating enzymes⁷⁻⁹ or mediators⁹⁻¹³ into carbon-paste electrodes (CPE) to enhance mechanical and electrochemical properties. In the present work both the mediated and non-mediated systems have been investigated and the resulting probes tested for glucose assays.

EXPERIMENTAL

Apparatus

Cyclic voltammetry measurements were performed with a BAS CV 27 voltamperograph connected to a Hewlett-Packard 7090 A X-Y recorder. A BAS three-electrode cell was used with the carbon-paste working electrode, saturated calomel reference electrode (SCE) and a platinum wire auxiliary electrode.

Amperometric measurements were made with a Bruker E 100 polarograph connected to a

*Author for correspondence.

Servogor X–Y recorder. The 50-ml electrochemical cell used to test the enzyme electrodes was operated in a three-electrode configuration. The temperature of the cell was controlled at $24.0 \pm 0.2^\circ$ by a Haake F thermostatic bath. The pH of the solution was measured with a Tacussel Mini 80 pH-meter.

Reagents

All reagents were of analytical grade and supplied by Sigma or Merck. The solutions were prepared with demineralized water. The supporting electrolyte was 0.1M phosphate buffer (pH 7.0). Glucose oxidase, type X–S, activity 150,000 U/g was from Sigma. Standard solutions of glucose (1M) were prepared one day before use by dissolution in 0.1M phosphate buffer and stored at 4° for no longer than one week. Liquid paraffin was from Sigma (spectroscopic grade). Colloidal graphite powder was from Marly and purified by lixiviation with chloroform. The carbon paste was from Metrohm (EA 207C).

Electrode preparation

The enzyme electrode was made by pressing the active paste into the well of the body of the BAS electrode (3 mm in diameter, 2 mm deep). The paste surface was manually smoothed on clean paper. Paste I was prepared by careful mixing of 100 mg of carbon paste (Metrohm) and 6 mg of GOD in a mortar. Paste II was prepared by mixing graphite and 1,1'-dimethylferrocene [DMFe(cp)] in a mortar with a minimum amount of chloroform, evaporating the solvent, adding GOD and paraffin oil, and blending the mixture into a paste. The best mechanical and electrochemical stability and signal to noise ratio (amperometric background current 300 nA) were obtained with 125 mg of graphite, 11 mg of DMFe(cp), 18 mg of GOD and 66 mg of oil. The pastes were stored at room temperature.

Procedures

Enzyme electrodes made with paste I were conditioned for 2 hr in quiescent phosphate buffer (pH 7.0) containing 10mM glucose, with the electrode at +1.1 V *vs.* SCE. After conditioning, the electrodes gave more stable responses and extended linear ranges. Between experiments the electrode was stored in 1mM glucose solution in pH 7.0 phosphate buffer at room temperature and at open circuit. Enzyme electrodes made of paste II were conditioned for

12 hr in similar conditions but with the electrode at +0.16 V *vs.* SCE. Between experiments the probe was kept in the buffer, at +0.16 V *vs.* SCE and at room temperature.

Assay of plasma glucose. Plasma samples, stored in fluoride/oxalate-treated tubes, were obtained from a routine clinical laboratory. The electrode was covered by a Nuclepore 0.22- μ m membrane prior to plasma assays. Measurements were made on 2.5 ml of phosphate buffer plus 0.5 ml of plasma. After the potential was applied the background current was allowed to decay to a constant value before plasma samples were added to the stirred solution.

RESULTS AND DISCUSSION

The incorporation of GOD alone or GOD and ferrocene-linked polymers into graphite pastes has already been described.^{6,7} The pastes used were home-made and contained relatively small amounts of oil, approximately 8 and 13% w/w respectively. Since mechanical instability along with large background currents may be encountered with such pastes,^{14,15} it was of interest to prepare carbon pastes with higher amounts of binder.

Paste I modified electrode (GOD–CPE)

The amperometric response to glucose was investigated in the concentration range 1–30mM and at three different applied potentials (+0.16, +0.90 and +1.1 V *vs.* SCE). At +1.1 V, evolution of oxygen started to occur. More positive potentials were therefore avoided, as high background currents and unstable signals were observed. No electrochemical response was detected at +0.16 V *vs.* SCE but currents linearly related to glucose concentration were obtained at the two other potentials; the slope of the response at +1.1 V was four times that at +0.90 V *vs.* SCE. By studying the amperometric oxidation of hydrogen peroxide solutions at the carbon paste electrode (CPE), it was possible to detect its electroactivity at potentials higher than +0.60 V *vs.* SCE. At +1.1 V *vs.* SCE and in the presence of 1mM H₂O₂ the signal obtained at the CPE was approximately 10 times that obtained under identical conditions with 1mM glucose at the GOD–CPE. Further experiments at +1.1 V *vs.* SCE indicated that the linear range of response at the GOD–CPE was extended up to 50mM glucose ($r = 0.9992$) with 90% response times of 20–30 sec. Figure 1 shows a typical calibration plot for

Fig. 1. Calibration curve for glucose enzyme electrode (GOD-CPE). Steady-state current measured at +1.1 V vs. SCE, pH 7.0, 24°.

Fig. 3. Calibration curve for mediated glucose enzyme electrode [GOD-DMFe(cp)-CPE]. Steady-state current measured at +0.16 V vs. SCE, pH 7.0, 24°.

the GOD-CPE. The electrode responded up to 300mM glucose with an analytically useful range up to ~130mM. The apparent Michaelis constant was 75mM. Such an extended range of electrode response may be attributed to the slight evolution of oxygen at +1.1 V vs. SCE and the presence of a relatively high amount of liquid paraffin in the paste formulation (~30% w/w).¹⁶ The oily phase containing GOD and surrounding the graphite particles may act as a barrier restricting substrate diffusion at the electrode-solution interface. Such effects of the CP binder have already been pointed out in connection with investigation of organic substrates at carbon paste electrodes.^{13,14}

Paste II modified electrode [DMFe(cp)-GOD-CPE]

Ferrocene mixed into carbon paste electrodes has been shown by cyclic voltammetry to be-

Fig. 2. Cyclic voltamperograms taken with the GOD-DMFe(cp) modified carbon paste electrode in 0.1M phosphate buffer, pH 7.0, scan rate 10 mV/sec: (a) no glucose present; (b) with 100mM glucose, (c) with 200mM glucose.

have reversibly.¹⁰ Figure 2 shows a typical cyclic voltamperogram of DMFe(cp) mixed into the Metrohm CPE. By addition of glucose to the solution, the quasi-reversible behavior of the DMFe(cp)-DMFe(cp)⁺ couple was altered. The presence of glucose induced an increase in the DMFe(cp) oxidation current and concomitant lowering of the DMFe(cp)⁺ reduction current. This behavior is indicative that the regeneration of DMFe(cp) is catalyzed by the incorporated GOD.¹⁷ Amperometric measurements were made with the electrode at +0.16 V vs. SCE in order to minimize interferences from easily oxidized compounds. A typical calibration graph of the steady-state current vs. glucose concentration (Fig. 3) was linear over the range 20-90mM ($r = 0.9982$) then non-linear up to concentrations as high as 300mM. The apparent Michaelis constant was again 75mM. Variation of the stirring speed had no significant effect on the DMFe(cp)-GOD-CPE signal. The response times of freshly prepared electrodes (90% of total current) were 10 sec during the first 2 days of use and 30 sec for older probes. The electrode stability was checked daily by obtaining calibration plots over the concentration range 0.5-10mM glucose. Linear plots were obtained in all cases, with 10, 70 and 90% decrease in response on days 2, 4 and 8 respectively. The limited electrode lifetime may be related to progressive leaching out of the ferricinium ion from the electrode, which is permanently kept at +0.16 V vs. SCE. The extended linearity obtained may again be attributed to diffusion-limited conditions through and within the oily electrode interface. Leaching of ferricinium from the electrode was detected by recording cyclic voltamperograms in the absence of glucose and with and without stirring

Fig. 4. Correlation between results for plasma glucose by the mediated enzyme electrode [GOD-DMFe(cp)-CPE] method and routine spectrophotometric assay.¹⁸

of the solution. The oxidation peak was not affected by stirring, whereas the reverse peak was completely removed.

Assay of plasma glucose

Correlation of the results (y) of glucose assays of plasma samples with probes based on paste II with the results (x) from a routine spectrophotometric method¹⁸ based on glucose oxidase gave a linear regression of $y = 1.07x - 0.16$ ($r = 0.973$, $n = 17$) (Fig. 4).

CONCLUSION

The incorporation of the enzyme GOD and redox mediators into a paste formulation may offer significant advantages for construction of glucose biosensors. The ease of paste preparation, handling and storage, along with possible miniaturization of the probes¹⁹⁻²¹ is highly advantageous, allowing various probe compositions and configurations. Further developments, which would additionally mix appropriate phospholipids into the enzyme-modified carbon paste,^{22,23} can be considered.

AN ELECTROCHEMICAL MICROSENSOR FOR CHLORIDE

SHAOJUN DONG* and GUANGLI CHE

Laboratory of Electroanalytical Chemistry, Changchun Institute of Applied Chemistry, Chinese Academy of Sciences, Changchun, Jilin 130022, People's Republic of China

(Received 6 November 1989. Revised 12 March 1990. Accepted 28 March 1990)

Summary—The potential-response of a microdisk electrode made with a chloride-doped polypyrrole (PPY) film on a carbon fibre (CF) has been examined. The effect of the polymerization conditions on the response characteristics is discussed. The optimum conditions for preparing the electrode are: cycling potential from +0.8 to +1.0 V in 0.1–0.2M pyrrole (Py) containing 0.1M LiCl, electropolymerization time 15–20 min. The electrode gives a Nernstian response of 56–58 mV/pCl and a detection limit of 3.6×10^{-5} M chloride. It has the advantages of low resistance, short conditioning time and fast response. It has been used satisfactorily for detection of chloride in serum.

The development and application of potentiometric chloride sensors remains an active area of investigation, particularly in clinical analysis. Hansen *et al.*, and Dahms and co-workers^{2,3} have used an Ag/AgCl electrode to detect chloride in sweat and serum. Coetzee and Freiser^{4,5} have developed another kind of chloride-sensitive electrode. In recent years, several groups have attempted to attach active species directly to a polymer to prepare ion-selective electrodes. Oka *et al.*⁶ prepared a chloride ion-selective electrode by grafting quaternary ammonium groups onto a polymer, and Sun and Zhang⁷ used a polymer doped with an alkylpyridine. Dong *et al.*⁸ studied a conventional electrode prepared with a chloride-doped conducting polymer. So far, a chloride-selective microsensor has not been reported. This paper describes such a sensor, prepared by electrochemical polymerization of pyrrole (Py) on a carbon fibre (CF) microdisk electrode in a chloride solution. This microsensor has been used to detect chloride in serum. It has some advantages over conventional electrodes, such as fast response, short conditioning time and lower detection limits. It is expected to be able to detect chloride *in vivo*.

EXPERIMENTAL

Reagents

Pyrrole (Fluka) was purified by distillation from calcium hydride and was stored under a nitrogen atmosphere at low temperature, and

protected from light. Lithium chloride, sodium sulphate, acetonitrile and other reagents used were of analytical reagent grade. Serum was taken from fresh blood. Doubly distilled water was used throughout.

Apparatus

All electrochemical experiments were done with a PAR model 370 Electrochemistry System, and potentials were measured with a PHS-400 pH-meter. Glass capillaries were prepared with a laboratory-made capillary puller.

Carbon fibre (CF) microdisk electrode. Carbon fibres, 30 μ m in diameter, were washed with acetone, dried and cut into pieces 1.5 cm long. One such piece was fixed on a copper wire (0.3 mm diameter) with solder, and the wire was inserted into a dry glass capillary, which was then drawn to a tip (diameter 35–50 μ m) with the capillary puller. The other end was dipped into epoxy resin, and then cured in an oven at 70° for 2 hr. The tip where the carbon fibre was exposed was cut off and the exposed wire and fibre surface was polished with alumina powder and cleaned.⁹ From the microdisk electrodes thus prepared, one with low resistance (< 1 k Ω) was chosen, and its characteristics were examined by cyclic voltammetry in acetonitrile solution containing 5×10^{-3} M ferrocene and 0.1M lithium perchlorate.

Chloride-doped polypyrrole (PPy) film CF microdisk electrode. The PPy film was prepared on the CF microdisk electrode surface by constant-potential electrolysis of an aqueous solution containing 0.1–0.2M pyrrole (Py)

monomer and 0.1M lithium chloride. The film thickness was controlled by the electropolymerization time. solution), and the CF microdisk electrode as working electrode was employed for the electrochemical polymerization. The potential of the PPy film CF microdisk electrode was measured with the PHS-400 pH-meter.

RESULTS AND DISCUSSION

Electrochemical behaviour of the CF microdisk electrodes and their surface characterization

Figure 1 shows cyclic voltamperograms obtained with a CF microdisk electrode. At slow scan rates (<100 mV/sec), the voltamperograms exhibit the sigmoidal shape expected for steady-state behaviour, with little change of current. The limiting current depends only on the number of electrons transferred (n), the analyte concentration (C) and diffusion coefficient (D), and the electrode radius (r), and not on time. The results obtained are consistent with the equation⁹ $i = 4nFDCr$. Figure 2 shows scanning electron micrographs of a CF microdisk with and without a PPy film on the surface. Many holes are observed on the surface of the CF microdisk electrode (Fig. 2a), whereas the CF microdisk electrode modified with a PPy film has a smooth surface (Fig. 2b). It has been verified that a good response to chloride is obtainable only when the holes are completely covered with the PPy film.

Chloride-response of the CF microdisk electrodes

The chloride-doped PPy-coated CF microdisk electrode gives a stable response to chloride after conditioning for a sufficient period of time. As with conventional electrodes, the response of a newly made electrode drops rapidly with time,⁸ but becomes stable after conditioning for 24 hr, in contrast to the 2–3 days needed for a conventional electrode.⁸ Figure 3 shows the response curves after different conditioning times. The response is also more rapid (<30 sec) than that of a conventional electrode,⁸ owing to

Fig. 4. Potential response of Cl^- -doped PPy film CF microdisk electrodes prepared with a cycling potential of +1.0 V, in 0.2M Py in 0.1M LiCl, and electrochemical polymerization for 20 min. Conditioning time: (1) 24, (2) 48, (3) 96 hr (three electrodes).

the low resistance. Figure 4 shows that the response of the chloride-doped PPy-coated CF microdisk electrode conditioned for >24 hr is Nernstian.

Effect of preparation conditions on response

Effect of the applied potential. The cycling potential has a direct influence on the structure of the PPy film.^{8,10-12} The film electrode prepared at 0.5–1.1 V shows a stable Nernstian response to Cl^- , but films prepared at lower (<0.5 V) or higher (>1.0 V) cycling potential give unstable responses, and electrodes prepared at the higher cycling potentials show high resistance. Non-Nernstian response occurs with electrodes made at lower cycling potential if the conditioning time is long. The optimum cycling potential is 0.8–1.0 V.

Effect of pyrrole concentration. When the Py concentration used is low (<0.1M), the PPy film formed is thin and the response is not a linear function of pCl^- . When the conditioning time is too long, the film can be lost from the surface of the PPy-coated CF microdisk electrode, resulting in no response at all to Cl^- . A Py concentration in the range 0.1–0.2M is found suitable.

Effect of doping chloride concentration. The concentration of the doping ion used in the electrochemical polymerization is important. At 1.0 V the polymerization takes 20 min. When the chloride concentration used is less than 0.1M, the response of the electrode is unstable and the slope decreases with time. The chloride-doped PPy-coated CF microdisk electrode ex-

hibits good Nernstian response with a low detection limit when prepared in 0.1M lithium chloride.

Effect of electrochemical polymerization time. Provided that the PPy film covers the surface of the electrode completely, a good response to chloride is obtained. As the PPy film thickness is mainly controlled by the polymerization time, this needs to be long enough. It is found that the PPy electrode response is unstable and non-Nernstian if the polymerization time is too short, and if it is too long (>40 min) the electrode shows slow response owing to its high resistance, and linear response to chloride can be obtained only with a longer conditioning time (>24 hr). Normally, the electrochemical polymerization time is 15–20 min.

The conditions recommended for preparing the chloride-doped PPy-coated CF microdisk electrode are therefore cycling potential 0.8–1.0 V, polymerization time 15–20 min, Py concentration 0.1–0.2M, and supporting electrolyte 0.1M lithium chloride.

The PPy-coated electrode thus prepared gives a stable Nernstian response to 10^{-4} –0.1M chloride, with a slope of 56–58 mV/pCl and a detection limit of 3.6×10^{-5} M chloride. It also has faster response and shorter conditioning time than a conventional electrode. It may be used to detect chloride *in vivo* and in organic solvents.

Figure 5 shows that the response to 10^{-3} M chloride is almost constant over the pH range 3–5–7.0.

Table 1 gives the selectivity coefficients for various anions. The electrode is not particularly selective for chloride, and several ions cause considerable interference.

*Values obtained with a C-200AP Chlor Meter by the hospital.

Human body fluids contain chloride, generally at about 96–106mM level in healthy cases. Therefore, the determination of chloride is important in clinical medicine, and the utility of the chloride-doped PPy-coated CF microdisk electrode for determination of chloride in serum has been examined.

Table 2 shows the results obtained by diluting 0.5 ml of serum 100-fold with doubly distilled water, and determining the chloride content by the standard-addition method. The relative standard deviation was 5.6%.

Analysis of five patients' serum gave the results shown in Table 3, together with the results obtained by an independent method, and the recoveries for a 100mM chloride spike added to the serum.

CALIBRATION OF A SOLID-STATE COPPER ION-SELECTIVE ELECTRODE IN CUPRIC ION BUFFERS CONTAINING CHLORIDE

BOY HOVER

Department of Chemistry, Aarhus University, Langelandsgade 140, DK-8000 Aarhus C, Denmark

(Received 5 February 1990. Accepted 15 March 1990)

Summary—It is shown that near-Nernstian calibration slopes can be obtained with a $\text{Cu}_{1,8}\text{Se}$ electrode in a range of cupric ion buffers in spite of a high chloride content. Best results are obtained with the ligands ethylenediamine, glycine and histidine. The onset of cupric ion toxicity towards marine organisms falls within the pCu calibration range obtained with glycine, and the $\text{Cu}_{1,8}\text{Se}$ electrode could, therefore, be useful for monitoring cupric ion activity in bioassays in sea-water media.

Cupric ion is of great environmental concern in natural waters, owing to its high toxicity towards aquatic organisms. Bioassays based on a range of growth-rate parameters and aquatic organisms (especially algae) have shown that the toxicity is a function of the activity of the cupric ion.¹⁻⁴ Thus, the overall toxicity of copper(II) is generally lowered by complexation, but lipid-soluble copper complexes are an important exception.⁵

Potentiometry with a cupric ion-selective electrode (Cu-ISE) is the only technique that allows selective determination of the cupric ion activity without disturbing equilibria in the sample. Therefore, a Cu-ISE seems to be the obvious choice for monitoring cupric ion activity in toxicity studies and environmental control. In practice, however, the utility of a Cu-ISE is limited by several factors. In media containing no bound copper(II), the lower limit of Nernstian response towards cupric ion is 10^{-7} – $10^{-6}M$,⁶ which is too high for studies of natural waters. However, with cupric ion buffers the electrode can be calibrated⁷ down to cupric ion activities as low as $10^{-19}M$, provided that the total concentration of copper(II) species is above $10^{-6}M$. Therefore, a Cu-ISE may still be useful in toxicity studies performed with cupric ion buffers.² The other major limitation to the utility of a Cu-ISE is the chloride interference,⁶ which researchers hitherto have regarded as an *a priori* obstacle to its use in sea-water studies. Although the chloride interference can be suppressed in media containing high concentrations of free cupric ion by polymer coating of the electrode,⁸ no attempts have been made to calibrate Cu-

ISEs in sea-water media containing cupric ion buffers.

This paper demonstrates that it is possible to obtain near-Nernstian calibration slopes for a Cu-ISE in a range of cupric ion buffers with high chloride content. The experiments were done in a manner which could easily be adapted to bioassays and the media employed closely resembled sea-water. Moreover, the range of cupric ion activities within which the onset of toxic effects of this ion towards aquatic microorganisms occurs¹⁻⁴ is included in the Nernstian calibration ranges obtained.

EXPERIMENTAL

Apparatus

The Cu-ISE was a Radiometer F1112Cu Selectrode, which employs a single crystal of $\text{Cu}_{1,8}\text{Se}$ as the sensing element. The reference electrode was a Radiometer K701 double-junction saturated calomel electrode with $2M$ potassium nitrate as the bridging solution. Potential readings were taken with a Radiometer PHM64 pH-meter (0.1 mV resolution). The cell was kept at $28 \pm 2^\circ$ with a water-jacket. Solutions were stirred with a Teflon-coated magnetic bar during measurement.

Reagents

Analytical grade chemicals and triply distilled water were used throughout. All calibration experiments were performed at pH 8.4 ($10^{-2}M$ boric acid/ $2.5 \times 10^{-3}M$ sodium hydroxide buffer). The complexing agent solutions (mostly standardized by complexometric

titration with cupric ion, monitored with the Cu-ISE) were ethylenediamine (en), diethylenetriamine (dien), tris(2-aminoethyl)amine (tren) and nitrolotriactic acid (NTA) at pH 8.4 and EDTA at pH 4.7 in 0.1M acetate buffer. Iminodiacetic acid (IDA), histidine and glycine were standardized by acid-base titration. The purities of en, dien and tren were checked by gas chromatography and found to be adequate.

Procedure

Prior to each calibration run, the Cu-ISE was polished with Radiometer D709 abrasive agent and 0.25 μm diamond paste, followed by rinsing with ethanol. Between experiments, the electrode was stored in distilled water.

Calibrations were performed by adding cupric ion from $[\text{Cu}^{2+}]_{\text{total}} = 2 \times 10^{-6} \text{M}$ up to the stoichiometric equivalent of the ligand concentration. Concentration increments were chosen so that approximately evenly spaced values of $\log[\text{Cu}^{2+}]_{\text{total}}$ were obtained. Calibrations were performed with 10^{-4} and 10^{-3}M ligand present, with and without addition of 0.5M sodium chloride to the medium. Potential readings were taken when electrode drift was below 0.2 mV/min, which occurred after a waiting period of at most 5 min [at low Cu(II) concentrations]; usually, a waiting period of 1 min sufficed.

After introduction of sample solution, the measurement cell was closed with plastic film and oxygen was removed by continuous passage of argon. In the calibration experiments, measurements were made in order of increasing copper concentration. The cell and the electrodes were carefully rinsed twice with 0.02M nitric acid and once with water before a solution

with a lower copper content than the previous one was introduced into the cell.

The theoretical equilibrium values of $[\text{Cu}^{2+}]$ were calculated by use of the program MINEQL⁹ with equilibrium constants from Smith and Martell.¹⁰

RESULTS

Figure 1 shows a typical calibration curve for the Cu-ISE in the presence of a Cu(II)-binding ligand. Clearly, a highly significant linear relationship between pCu and the electrode potential holds in most of the pCu range covered. The theoretical (Nernstian) slope of the calibration line is $(RT/nF) \ln 10 = (29.9 \pm 0.2) \text{ mV/pCu}$ at $(28 \pm 2)^\circ$. At high pCu values, the calibration curve levelled off in most cases, indicating that the total concentration of Cu(II) was insufficient to give a Nernstian electrode response. This part of the curve was always discarded in the calculation of the linear regression data. In the calibration experiments with NTA and EDTA, the electrode potential was almost independent of the Cu(II) concentration and no regression data for the calibration curve could be obtained. Table 1 summarizes the regression data for the calibration experiments.

It has previously been shown that coating the Cu-ISE with the perfluorosulphonate polymer Nafion greatly suppresses chloride interference in media containing high concentrations of free copper(II).⁸ However, this approach did not prove to be feasible for the copper(II)-binding media in this study, because the response times were too long.

DISCUSSION

From Table 1 it can be seen that addition of chloride to the media containing Cu(II)-binding ligands did not have any large or unequivocal effect on the calibration data for the Cu-ISE. Moreover, chloride addition did not significantly change the absolute values of the electrode potential. In the tren system, the slope of the calibration line was increased by addition of chloride, whereas the opposite effect was observed for dien. For the other ligands, the slope was not significantly affected by addition of chloride. The sub-Nernstian calibration data for IDA and the unsuitability of the NTA and EDTA media for electrode calibration is in agreement with previous results.^{11,12} The explanation of the distinctly super-Nernstian slopes

obtained in the 10⁻³ M tren medium with and without chloride and in the 10⁻³ M dien medium without chloride is not known.

For the ligands en, glycine and histidine, near-Nernstian calibration slopes were obtained in media having approximately the same chloride content as sea-water. This result could be of great utility in studies on the toxic effect of Cu(II) towards marine organisms. In particular, the onset of toxic effects of Cu(II) towards micro-organisms occurs in the pCu range 9–11,¹⁻⁴ which lies within the Nernstian calibration range for glycine, making this ligand the most suitable for such studies.

Non-stoichiometric copper selenide sensors are far more sensitive towards copper(I) than copper(II), and the sensitivity towards copper(II) is attributed to the exchange reaction^{6,13}

The equilibrium constant for this reaction is

$$K_{\text{ex}} = \frac{a_{\text{Cu}^+}^2}{a_{\text{Cu}^{2+}}} \quad (2)$$

and the electrode potential is given by

$$E = E^0 + \frac{RT}{F} (a_{\text{Cu}^+} + K_{\text{Cu}^+, \text{Cu}^{2+}}^{\text{pot}} a_{\text{Cu}^{2+}}^{1/2}) \quad (3)$$

where $K_{\text{Cu}^+, \text{Cu}^{2+}}^{\text{pot}} = K_{\text{ex}}^{1/2}$. Thus, the contribution of copper(II) to the electrode potential will be governed solely by the surface concentration of copper(I) generated by reaction (1), if this reaction is fast enough to establish the equilibrium at the electrode surface. However, several complicating factors may contribute to the overall response of the Cu-ISE,^{6,14} such as reaction (1) not reaching equilibrium, the rates of transport of copper(II) and copper(I) species to and from the electrode surface, dissolution of the Cu_{1.8}Se, causing an intrinsic contribution to the copper(I) concentration at the electrode surface, the rates of the complexation and dissociation reactions of copper(I) and copper(II) species in the vicinity of the electrode surface, all of which can produce kinetic effects on the response. Although it is beyond the scope of this paper to investigate these effects in detail, it is interesting to note that addition of chloride to the copper(II)-binding media did not shift the absolute values of the electrode potential significantly. For those ligands for which the stability constants of their copper(I) complexes could be found (en, glycine and histidine), equilibrium calculations showed that the activity of copper(I) was dramatically reduced by addition of chloride (assuming a large excess of ligand). In all cases, the

complexes formed between copper(II) and the added ligands are so strong that addition of chloride has no effect on the activity of copper(II). On a kinetic basis, it would be expected that chloride, because of its smaller size, will react much faster with copper(I) than the copper(II)-binding ligands do. In view of the mechanisms listed it seems likely that transport of copper(I) from the electrode surface governs the electrode potential in the en, glycine and histidine media.

(Received 3 January 1990. Revised 19 April 1990. Accepted 30 May 1990)

Summary—Most FIA applications involve simple unidirectional continuous-flow regimes. This paper continues the development of the flow-reversal (frFIA) approach and its applications. Flow-reversal flow programming achieves flexibility in operation without requiring manifolds to be refitted. The sensitivity of FIA titrations can be increased by use of frFIA.

Flow-injection analysis (FIA) has demonstrated its utility in the automation of serial assays^{1,2} and sample pretreatment³ and as a method for achieving higher orders of analytical information.⁴⁻⁶ A common characteristic of these three classes of application is their use of flow programming, *i.e.*, the use of pumps and valves to propel, manipulate and chemically treat the sample according to a preset scheme. Flow-programming techniques range from simple single-line, uninterrupted flow systems to much more complicated arrangements. For instance, by stopping the flow at an appropriate time it is possible to measure the rate constants of enzymatic reactions,⁷ enzymatic activity,^{8,9} or the substrate concentration.¹⁰ Flow programming can also be used for steps such as dilution,^{11,12} extraction¹³ and preconcentration.¹⁴

Another technique using flow programming is flow-reversal FIA (frFIA), which employs repetitive reversals of flow to achieve various tasks.¹⁵⁻¹⁹ For example, frFIA can allow a variable amount of mixing between the sample and carrier,^{15,16,18} increase the efficiency of solvent extraction,¹⁷ lead to multiple detection capabilities¹⁸ and allow sampling and preconcentration of gaseous analytes.¹⁹

Two variables are often used separately to describe the extent of mixing or equilibration of the sample with the carrier/reagent. The dispersion coefficient, D , is the ratio of the concen-

tration of analyte detected to the concentration injected, and is therefore indicative of the amount of mixing between the sample and carrier in the element of fluid on which the measurement is made.

The overall equilibration of sample with carrier is often treated by the classical theory of mixing,^{20,21} which relates the degree of mixing to the number, N , of mixing stages in the FIA system. The length of such a mixing state is a fundamental parameter of the type and geometry of the FIA reactor and flow system (in formal analogy to plate-height theory in chromatography). Thus for a particular conventional FIA manifold with a reactor of length, L , N is fixed since the equivalent theoretical plate height, H , is also fixed. Adjustment of the reactor length is the technique most often used to adjust the amount of mixing in the FIA apparatus.¹¹⁻¹³ Thus, varying L in a flow-reversal experiment provides an additional means of varying the number of mixing stages.

An application that benefits from the use of frFIA to vary the number of mixing stages is FIA titration. The FIA titration theory was developed by using the one-tank model.^{22,23} It follows, from the equation for FIA titration,²⁴ that adjusting the number of mixing stages allows versatile control of the sensitivity of the determination. This paper is concerned primarily with developing a capillary-based FIA titration system which allows easy adjustment of the mixing conditions by avoiding the need for physical reconfiguration of the flow manifold.

EXPERIMENTAL

Apparatus

A home-made FIA analyzer based in part on the FIALab system (Alitea U.S.A.) was used. The design of the components and software is discussed elsewhere.²⁵

Hardware. A single-line manifold was used (Fig. 1). The reaction-coil length, a , was varied, typically being 50, 93 or 250 cm, the reactor tubing (0.5 mm bore) being coiled round a metal framework. FIALab Teflon spacers served as connectors. A Rheodyne pneumatically actuated injection valve was used, with an injection volume of 25 μl (0.8 mm bore tubing).

Alitea C-6V peristaltic pumps were used to propel the carrier, reagent and sample streams. A Z-shaped flow-cell with a volume of 10 μl was used. Optical fibers were used to guide light from a tungsten lamp into the flow-cell and hence to the detector.

A Milton Roy Spectronic Mini 20 Spectrophotometer served as the monochromator and detector. The analog signal was amplified from 50 mV to 10 V full scale by a home-made linear-gain amplifier, which employed an Analog Devices AD625 programmable-gain amplifier. The signal from the amplifier was filtered with a 4-pole filter, which removed any periodic noise with a frequency above 2 Hz, and was then directed to an IBM Data Acquisition and Control Adapter (DACA). The amplifier-filter and DACA configuration is described elsewhere.²⁵

In addition, a Radiometer REA 112 chart recorder was connected in parallel with the amplifier to provide real-time signal output. The signal was split before entering the amplifier, being converted into absorbance by a logarithmic converter before being recorded.

Fig. 1. Flow-reversal single-line flow-injection manifold for the titration of strong acids (HCl , H_2SO_4 , H_3PO_4): a and b are coils of Microline tubing. D is the flow cell. An IBM-compatible AT computer was used for experimental control and data acquisition.

Automated operation. A computer program was used to control operation of the pumps and injection valve to acquire data.²⁵ Before the beginning of an experiment, the appropriate pump sequence was entered into the program. The experiment was started by loading the valve and injecting the sample. The program, upon receiving an interrupt generated from the DACA board, read the 12-bit analog-to-digital converter and stored the data in memory. Each time the interrupt pulse was received by the program, a counter was incremented. This counter was used as a timer for control of the pumps, with an accuracy of 30 msec for a 60-sec FIA experiment.

Reagents

A 0.01M solution of borax (sodium tetraborate decahydrate) was used as the carrier for part of the study. A Bromothymol Blue (BTB) solution was prepared by adding 0.4 g of BTB to 25 ml of 96% ethanol and diluting to 100 ml with the borax solution; a 100 $\mu\text{g/ml}$ solution prepared by further dilution with borax solution was used as the test sample in the dye tracer experiments. The titrations were done with 0.001M sodium hydroxide as carrier, containing 100 $\mu\text{g/ml}$ BTB.

Procedure

The reactor length was held constant (see Apparatus). The flow-rates were measured by collecting the carrier for 3 min in a graduated cylinder. After injection, the sample was allowed to travel part-way in the coiled reactor. At the appropriate time the direction of pump rotation was instantaneously reversed. After an appropriate period of reversed flow the pump was again reversed and the sample propelled in the forward direction. The number of flow-reversal periods was preset according to the extent of mixing desired. After the final flow-reversal period, the sample was propelled to the flow-cell. Absorbance measurement was made at 620 nm, at which the base form of the indicator is monitored.

The parameters of the flow program were the flow-time up to the first reversal, the duration of the reversed-flow cycle, and the number of flow-reversal cycles. In general, two types of experiments were performed. In one, the effect of flow-reversals on the peak shape for a tracer dye was examined. In the other, the effect of flow-reversals on FIA titrations was studied.

RESULTS AND DISCUSSION

Some investigators^{15,16,18} allow the sample bolus to pass through the flow-cell before the flow is reversed, so that the sample passes through the detector twice. This approach has several obvious advantages, *e.g.*, the opportunity to repeat measurement of the analyte several times in one run, by repeated reversals. If the reaction kinetics is suitable, the rate of formation of the reaction product may be calculated. However, most flow-cells have flow paths greater in diameter than the bore (0.5 mm) of the tubing commonly used in FIA systems, so passage through the detector on each flow-reversal cycle may then cause band broadening. In such a case, the flow-cell acts like a gradient device. In this study, the effects of changing the length of sample travel, L , on FIA titrations and on bolus shape were examined by not using flow reversal after the sample had passed through the flow-cell (and, as far as possible, while it was still partly in the injection loop).

Effect of flow reversal on tracer dyes

An experiment was performed to determine the effect of carrier-flow reversal on the peak shape. The bolus was retained in the reaction and injection loop. A series of flow reversals, each lasting 4.5 sec in each direction, was used. Since the flow-rate was set at 3.36 ml/min, the volume moved in each pulse was 252 μ l. The injection volume was 25 μ l and the reactor was 215 cm long, corresponding to a volume of 430 μ l. Other flow-rates were examined, although not systematically, because the primary interest was in the effects of flow-reversal. Other factors which may contribute to the degree of mixing, including flow-rate, injection volume and reactor length, were held constant. The dispersion during each flow-reversal period in each direction would be expected to vary with the flow-rate, as in conventional flow-injection analysis.¹

The total volume (excluding the flow-cell volume and neglecting the connector dead volume) was 455 μ l, so the bolus was retained primarily in the reactor and to a lesser extent in the injection loop. The responses for 0–4 flow-reversal periods are shown in Fig. 2. The time axis refers to the duration of the signal measurement: the recorder was started immediately before the calculated appearance of the peak, *i.e.*, the separate peaks are not related to the flow-reversal periods. It is clear that the peak undergoes a transition from a skewed to a more

Fig. 2. Effect of flow-reversal on peak shape: 0–4 flow-reversal periods are used in the five runs.

symmetrical and almost Gaussian form, as reported by Betteridge *et al.*¹⁵ As would be expected, the peak heights are reduced by increasing the number of flow-reversals, as a result of the increased length of travel of the bolus. Other experiments (data not shown) demonstrated that the residence time of the peak after one or several flow-reversal cycles is the sum of the residence time in the absence of flow-reversal, plus the sum of the times of each complete flow-reversal cycle.

The absorbance values at the maxima of the peaks are plotted in Fig. 3 as a function of the residence time of the peaks. The residence time was used since it is one of the contributing factors in the dispersion of the analyte bolus. It is important to remember that the same reactor was used, and the number of flow reversals was increased. The peak height decreased as the residence time increased. Rule 3 of Růžička and Hansen¹ states that “the dispersion of the sample zone increases with the square root of the distance travelled through the tubular conduit.” Therefore, D is proportional to the square root of the residence time, τ , since $L = \tau U_{ave}$, where U_{ave} is the linear flow velocity. The dispersion coefficient was plotted as a function of the square root of the residence time and the linearity was confirmed by a regression coefficient, R^2 , of 0.996.

Effect of flow-reversal on titrations

The effect of the flow-reversal on peak shape and dispersion is clear. The sample bolus undergoes dispersion proportional to the square root of the length of travel. Another feature is the transition from the skewed peak, which is characteristic of a system with a single mixing

Fig. 3. Absorbance at peak maximum as a function of the total residence time for 0-5 flow-reversal periods of 4.5-sec duration.

stage, to a curve which is more symmetrical, because of more complete axial mixing. The question is whether data generated by using frFIA will be as useful as data generated by traditional techniques.

Number of flow-reversal periods. A simple, unidirectional FIA titration of hydrochloric acid with sodium hydroxide solution gives peaks

Fig. 4. Effect of 0-4 flow reversals on the titration of 0.1M HCl with 0.001M NaOH.

which increase in width with increasing acid concentration.²⁶ With the single-line manifold shown in Fig. 1, the effect of flow-reversal on the titration of 0.1M hydrochloric acid with 0.001M sodium hydroxide was examined; the results are shown in Fig. 4. The peak width was measured at a constant absorbance (half the steady-state absorbance).²² As expected, increasing the number of flow-reversal periods increased the time corresponding to equivalence (peak width, Δt).

Five concentrations of hydrochloric acid ranging from 0.01 to 0.1M were titrated, with 0-4 flow-reversal periods. The results are plotted in Fig. 5 and the regression data are given in Table 1. The salient features of the graph are the increasing slope and the increased intercept at $\log[\text{HCl}] = 0$, with increasing number of reversals. It is also seen that increasing the number of flow-reversal periods increases the peak width for a given acid concentration, and hence the sensitivity.

Other experiments, in which the length of the flow-reversal cycle was varied, confirmed that the increase in sensitivity was due to the increase in total residence time. The flow-reversal time of 4.5 sec was the longest which allowed the sample

Fig. 5. Plots of peak width, Δt , vs. $\log[\text{HCl}]$ for different numbers of flow-reversal periods: (○) 0; (+) 1; (◆) 2; (▲) 3; (■) 4.

Table 1. Regression data for peak width as a function of $\log[\text{HCl}]$ for different numbers of flow-reversals

Number of reversals	Intercept	Slope	R^2
0	9.3	2.70	0.998
1	10.4	2.96	0.999
2	11.3	3.28	0.997
3	12.4	3.68	0.996
4	16.5	4.08	0.996

bolus to remain within the reactor used, thereby yielding the largest enhancement of sensitivity (while excluding mixing effects from the detector and injector) and was therefore used in the remainder of the experiments.

Concentration dependence. Intuitively, the frFIA titration of a strong acid would be expected to behave similarly to the "normal", unidirectional FIA titration. Figure 7 shows the titration curves for several concentrations of hydrochloric acid, ranging from 0.01 to 0.1M. They are very similar to those for unidirectional titrations.²⁶ Figure 6 shows that the peak widths in Fig. 7 are linearly proportional to the logarithm of the acid concentration.

Dependence on neutralization stoichiometry. Polyprotic acids are often titrated by use of FIA titration devices. The effect of neutralization stoichiometries on the titration curve was examined. Strong acids of equal concentration but different proticity would intuitively be expected to give identical FIA titration curves for a given degree of neutralization. In a potentiometric FIA titration, the steps for the titration of the first two protons of phosphoric acid can be differentiated. In a dye-based FIA system, however, where the dye changes color at a fixed pH, the two steps cannot be distinguished. If the dye

Fig. 6. FIA traces for the titration of 0.01–0.1M HCl with one flow-reversal period.

Fig. 7. Plots of the peak width, Δt , vs. $\log[\text{H}_2\text{SO}_4]$ for the titration of H_2SO_4 with different numbers of flow-reversals (key as for Fig. 5).

has a sufficiently low $\text{p}K_a$ only the first step will be observed, and if it has a high enough $\text{p}K_a$ the sum of the two steps will be obtained. The latter is the case with sulfuric acid titrations. Figure 7 shows excellent linearity for the relation of peak width to the logarithm of the acid concentration. The plots also exhibit the expected increase in slope for increasing number of flow-reversal periods. Titrations of phosphoric acid showed similar behavior.

Empirical equation. The equation²⁴ for the titration of an analyte was derived by using the single mixing-tank model. It has been shown here that both the slope and intercept of the calibration line increase with increasing number of flow-reversal periods (Table 1). Thus an appropriate empirical equation might be:

$$\begin{aligned} \Delta t &= 2.303k_1(V_m/Q) \log(C_S^0/C_R^0n) \\ &\quad + 2.303k_2(V_m/Q) \log(S_V/V_m) \\ &= 2.303k_1(V_m/Q) \log C_S^0 + 2.303(V_m/Q) \\ &\quad \times [k_2 \log(S_V/V_m) - k_1 \log(C_R^0n)] \end{aligned} \quad (1)$$

where V_m is the volume of the mixer/reactor, Q is the volumetric flow-rate, C_S^0 is the concentration of the analyte, C_R^0 is the concentration of the titrant and S_v is the sample volume. The different slopes and intercepts for different numbers of flow-reversal cycles are reflected by change in k_1 and in both k_2 and k_1 , respectively. Since these variables are an integral part of the calibration curve, the calibration is accomplished by plotting the peak width against the logarithm of the analyte concentration.

CONCLUSIONS

The primary advantage cited by Betteridge *et al.*¹⁵ for the use of frFIA was the increased travel length of the sample, which in turn increases the sample dispersion. Increasing the dispersion beyond that attainable by unidirectional flow allows alteration of the reaction conditions without reconfiguration of the entire system. In this work, it is demonstrated that the use of flow-reversal enhances FIA titrations by allowing the analyst to control the amount of mixing. In flow-reversal FIA, the dispersion and extent of axial mixing are increased, leading to greater sensitivity of FIA titrations.

Both the capillary and gradient-chamber approaches have benefits and difficulties. The capillary-based system has the advantage of speed, but lacks the dispersive power for dealing with highly concentrated solutions, whereas gradient-chamber devices permit the necessary expansion of concentration range, but often provide too large a dilution, causing the analyte concentration to be indeterminate.¹⁰ By its nature, the gradient chamber also has a long wash-out time, which lowers the sampling frequency.¹⁵ Neither approach is particularly easily adjustable to allow optimization of the technique.

Flow-programming is a fairly novel FIA technique. So far only six papers^{11,15-19} utilizing flow-reversal FIA have come to the attention of the authors. The reasons for this scarcity are as follows.

(1) Many FIA practitioners have used chromatographic intuition in their design of FIA manifolds and techniques and, except for column back-flushing,²⁷ chromatographic techniques do not utilize flow reversal.

(2) The technique requires the use of pumps designed for instantaneous flow reversal, and of computer programs or sophisticated timers to

control them. Until recently, these tools were not readily available.

The motivation for employing flow-reversal is that, as with chromatographic flow programming,²⁸ it provides another adjustable experimental parameter. Control of the analyte bolus and its dispersion is critical in FIA and this technique supplies another means of manipulating the sample zone.

(Received 21 December 1989. Revised 5 July 1990. Accepted 10 July 1990)

Summary—A new, very useful application of open-closed configurations to kinetic studies is reported. The multipeak recordings provided by the manifold used, which features a single conventional photometric detector, were used to calculate the rate constants and reaction orders of a chemical system, namely the ligand displacement reaction between the cobalt(II)-EGTA complex and PAR.

Since its inception, flow-injection analysis (FIA) has gained increasing popularity, both for routine analyses and for research purposes. Among the latter, the determination of different physicochemical constants (*e.g.*, viscosity,¹ diffusion coefficients,² kinetic parameters³) makes the technique a very useful tool for scientific research.

Flow-injection analysis combines the advantages of continuous-flow mixing methods and stopped-flow methods^{4,5} and overcomes their disadvantages, *e.g.*, it allows faster reactions to be investigated and ensures continuous flushing of the measuring cell (it resembles the continuous-flow mixing methods in this respect), and a single experiment provides information on the reaction kinetics through the recorded concentration/time curve. The main disadvantages of the traditional open manifold are the high reagent consumption and the limited amount of information that can be obtained from development of the reaction in a single injection. These drawbacks could be efficiently eliminated by using an open-closed system.⁶⁻⁸ In this way, multipeak detection could be accomplished without the need to install a series of detectors along the manifold, which could prove rather expensive. An additional advantage of open-closed systems is the possibility of reaching reaction equilibrium, which is not always feasible with open systems. Because of the intensive mixing in open-closed flow systems when

the system volume considerably exceeds the injected volume, static reaction conditions (*i.e.*, constant concentration of one of the reactants), which otherwise require sophisticated equipment,⁴ can be readily accomplished.

Open-closed systems have already been applied for determination of partial reaction orders and rate constants of different reactions widely used in chemical analysis.⁶⁻⁸ The results are most likely to be affected by the hydrodynamic regime of the flow system and cannot be considered "pure" chemical kinetic parameters. One approach to the determination of true reaction orders and rate constants irrespective of the flow pattern in the manifold involves finding a relation between the signals obtained under the same hydrodynamic conditions in the absence and presence of the chemical reaction investigated.

This paper reports on the theoretical development of such an approach and its application to the study of the ligand-displacement reaction between the cobalt(II)-EGTA complex and PAR.

THEORETICAL FOUNDATION

The dispersion of the analyte in traditional open FIA systems can be described on the basis of an axially-dispersed plug flow model,⁹ which is represented mathematically by the equation:

$$dC/dt = D_L d^2C/dx^2 - u dC/dx \quad (1)$$

where t is time, x the axial distance, C the concentration, u the mean linear flow-rate and D_L the axial dispersion coefficient. This last

*Permanent address: Department of Analytical Chemistry, Faculty of Sciences, University of Sofia, 1126 Sofia, Bulgaria.

parameter depends on the extent of convective mixing and on the molecular diffusion, and can be calculated theoretically when this type of mixing is prevalent.¹⁰

When the analyte is involved in a first or pseudo-first order reaction, equation (1) becomes:

$$dC/dt = D_L d^2 C/dx^2 - u dC/dx - kC \quad (2)$$

However, it can be shown that substitution of $C^0 \exp(-kt)$ into equation (2) yields equation (1), with a new dependent variable, C^0 replacing C . Obviously, C^0 is the analyte concentration which would be detected in the absence of chemical reaction. On the basis of the reasoning above, if the injected analyte is involved in a first (or pseudo-first) order reaction, the actual rate constant can be determined by processing the data obtained by injecting the analyte into the carrier without $[C^0(t)]$ and with reactant $[C(t)]$ according to the equation:

$$C(t) = C^0(t) \exp(-kt) \quad (3).$$

If the reaction product rather than the analyte itself is monitored, then we may write:

$$dC_p/dt = D_{Lp} d^2 C_p/dx^2 - u dC_p/dx + kC \quad (4)$$

where C_p is the concentration of the product and D_{Lp} its axial dispersion coefficient.

If, in addition, we assume the axial dispersion coefficients of the analyte (D_L) and the product (D_{Lp}) to be similar, then the following relationship will hold:

$$C_p + C = C_p^0 = C^0 \quad (5)$$

where C_p^0 is the concentration of product that would arise if all the analyte reacted immediately after injection.

By using the equations

$$C = (C_p^0 - C_p) = C_p^0 \exp(-kt) \quad (6)$$

and

$$C_p = C_p^0 [1 - \exp(-kt)] \quad (7)$$

equation (4) can be transformed into a form of equation (1) in which the variable C_p^0 replaces C . Further, if the product is monitored, the rate constant can be calculated from equation (6) provided the shape of the concentration/time curve obtained by injection of the product or the analyte in the absence of chemical reaction is known in advance. The assumption that the axial dispersion coefficients of the analyte and the product are very similar imposes no substantial limitations as long as the dispersion pro-

cesses in the flow system are governed by convective mass-transfer, since any difference between the diffusion constants of the analyte and the product would result in no substantial differences between the corresponding axial dispersion coefficients. In fact, the flow pattern of an open-closed flow system is convectively controlled because of the intensive mixing resulting from the use of the peristaltic pump.

According to these considerations, the concentration of the monitored chemical species (*i.e.*, the analyte or the product) at the detection point in the absence of a chemical reaction can be taken as the initial or final (steady-state) value under batch conditions, while the concentrations monitored in the event of a chemical reaction can be regarded as the transient concentrations corresponding to these initial or final concentrations.

It may be assumed that, if the condition involving the equality of the axial dispersion coefficients of all the chemical species taking part in the reaction is valid, this reasoning could also be applied to reactions other than those of first or pseudo-first order. In this respect, the following reaction stoichiometry and kinetic equation are a representative example:

$$dC_p/dt = kC_1 C_2 \quad (9)$$

where C_1 and C_2 are the concentrations of reactants R_1 and R_2 , respectively. If the concentration/time curves for at least two of the chemical species involved in the reaction in the absence of chemical interaction (*e.g.*, C_1^0 and C_2^0) are known, then, taking into account that $C_1 = C_1^0 - C_p$ and $C_2 = C_2^0 - C_p$, the corresponding solution of equation (9) allows the rate constant to be calculated. Assuming the product is the chemical species monitored:

$$\frac{1}{(C_2^0 - C_1^0)} \ln \left[\frac{C_1^0(C_2^0 - C_p)}{C_2^0(C_1^0 - C_p)} \right] = kt \quad (10)$$

If only the stoichiometry is known and both the rate constant and the reaction orders are to be determined, then the following approach could be applied: (i) the time-dependence of C_1^0 , C_2^0 and C_p should be obtained; (ii) among the kinetic equations with solutions similar to equation (10), *i.e.*, $f(C_1^0, C_2^0, C_p) = kt$, that yielding the same k value for all time points should be selected as the most likely kinetic equation; (iii) such an equation should be

Fig. 1. Scheme of the open-closed FIA manifold. R_1 , R_2 , reagents; P, peristaltic pump; V_1 , selecting valves for channels (1) and (2); V_2 , injection valve.

checked at different initial concentrations (*i.e.*, C_1^0 and C_2^0 should be varied).

EXPERIMENTAL

Reagents

Aqueous solutions of ethyleneglycol bis-(β -aminoethyl ether)- N,N,N',N' -tetra-acetic acid (EGTA), 4-(2-pyridylazo)resorcinol monosodium salt monohydrate (PAR), cobalt(II) nitrate (guaranteed reagent grade) and boric acid/sodium hydroxide buffer¹¹ (pH = 8.8) were used.

Apparatus

A Hewlett-Packard 8452A diode-array spectrophotometer furnished with a Hellma 178.12QS flow-cell (18 μ l) and interfaced to a Hewlett-Packard Vectra ES/12 personal computer was used. A Gilson Minipuls-2 peristaltic pump, Tecator L 100-1 and Rheodyne 5041 injection valves, and a Tecator TM-III chemifold were also used.

Manifold

The manifold used is depicted in Fig. 1. Valve V_1 is an ordinary valve that can be switched between channels 1 and 2, while the other channels lead to waste. The sample containing both reagents, mixed at a confluence point upstream of the injection valve V_2 , is introduced into the flow system previously closed by valve V_1 . The reagent concentration in the carrier stream, and the pH, are the same as in the injected sample. Pump P ensures the flow circulation in the closed system. The lengths of the two reactors are 75 and 360 cm, respectively. Teflon tubes of 0.5 mm bore are used. The flow-rate in the closed system is measured from its total volume (2.08 ml) and

the mean residence time is taken as the time difference between two adjacent peaks. The volume of sample injected is 77 μ l. All volumes are determined from the weight of doubly distilled water required to occupy them. The volume of the sample loop is also checked on the basis of the injected analyte concentration, the volume of the closed system and the equilibrium analyte concentration in the absence of chemical reaction.

Chemical reactions and spectral data

Under the experimental conditions, *viz.* pH = 8.8, the predominant species of PAR is the singly charged species, HR^- ,¹² and the complex of cobalt(II) with EGTA occurs in the forms CoY^{2-} , $CoHY^-$, and CoH_2Y , the stability constants of which are $10^{12.3}$, $10^{4.9}$ and $10^{3.3}$, respectively.¹³ Cobalt(II) forms a red complex with PAR with a metal-ligand ratio of 1:2 in slightly alkaline media.¹⁴ The stability constants of the complexes $CoHR^+$ and $Co(HR)_2^+$ are $10^{10.0}$ and $10^{7.1}$,¹⁵ respectively. It should be noted that magnetic susceptibility measurements have revealed that cobalt occurs as cobalt(III) in its complexes with PAR and PAN.¹⁶ According to Funahashi and Tanaka,¹³ the oxidation of cobalt(II) occurs immediately after the incorporation of the second PAR molecule.

The ligand-substitution reaction can be represented schematically in two stages:

where Y' denotes all forms of EGTA, irrespective of their extent of protonation.

The overall reaction can be obtained by adding equations (11) and (12):

The electrical charges of all chemical species in equations (11)–(13) have been omitted for clarity and simplicity. The proton mass-balance has not been taken into account, because all the chemical reactions take place in a buffered medium.

The kinetics of reaction (11) on the one hand, and of reactions (12) and (13) on the other, can be elucidated if CoY' is in excess in the first case, and PAR in the other two. Calculations based on the stability constants of $CoHR$ and

Fig. 2. Spectra of $2.50 \times 10^{-5} M$ solutions of: (1) PAR; (2) CoY'; (3) CoHR; (4) EGTA (coinciding with the spectrum of CoY'); (5) Co(HR)₂. The spectrum of Co(HR)₂ was recorded with excess of PAR present.

Co(HR)₂ showed that if equal volumes of equimolar solutions of cobalt(II) and PAR are mixed, the 1:1 complex obtained is predominant (>99.9%), whereas if the concentration of PAR is twice that of cobalt(II) the Co(PAR)₂ complex should predominate. On the basis of this, solutions of CoHR and Co(HR)₂ were prepared. By mixing equal volumes of equimolar solutions of cobalt(II) and EGTA, the corresponding complex (CoY') was obtained.

The spectra of CoY', PAR, CoHR, Co(HR)₂, and EGTA are shown in Fig. 2. All solutions were prepared in boric acid/sodium hydroxide buffer (pH 8.8).

The ligand-displacement reaction was investigated by monitoring the absorbance of the flowing solution at 410 nm (λ_{\max} for PAR), 448 nm (isosbestic point for PAR and CoHR), 505 nm (maximum for CoHR) and 515 nm, where the absorbance was due almost exclusively to CoHR. Concentration *vs.* absorbance plots obtained at these wavelengths over the concentration range $0-5.00 \times 10^{-5} M$ for PAR, CoHR, and Co(HR)₂ were all linear.

Procedure

During the experiments, the following injections were made:

(i) $5.00 \times 10^{-4} M$ solutions of PAR and CoHR into a carrier containing only buffer.

(ii) $5.00 \times 10^{-4} M$ solution of CoHR into a carrier containing $2.50 \times 10^{-4} M$ PAR or 1.25×10^{-5} , 2.50×10^{-5} , 5.00×10^{-5} , 1.25×10^{-4} or $2.50 \times 10^{-4} M$ CoY'.

(iii) $5.00 \times 10^{-4} M$ solution of CoY' into a carrier containing 1.25×10^{-4} or $2.50 \times 10^{-4} M$ PAR.

In all cases, the corresponding confluent solutions of CoY' and PAR were twice as concentrated as the carrier. This resulted in a

reagent concentration in the sample loop of valve V₂ (Fig. 1) equal to that in the carrier.

The experiments were repeated for three different carrier flow-rates (1.7, 2.5 and 3.1 ml/min).

RESULTS AND DISCUSSION

In the first series of experiments the ligand-displacement reaction was investigated under pseudo-first-order kinetic conditions. For that purpose, solutions of CoHR (Fig. 3B) and CoY' (Fig. 3C) were injected into carrier solutions in which PAR was in large excess. The axial dispersion coefficients of all reagents and products of the reactions studied were assumed to be equal, and the absorbances for individual species were assumed to be additive. The dispersion of CoHR was calculated from the recordings shown in Fig. 3A. The recordings in Fig. 3B allowed calculation of the extent of the reaction $\text{CoHR} + \text{HR} \rightleftharpoons \text{Co(HR)}_2$, by solution of the simultaneous equations for the total absorbances at 510 and 550 nm, and the corresponding molar absorptivities of CoHR and Co(HR)₂. The extent of the displacement reaction was similarly calculated from Fig. 3C.

Under the experimental conditions above, only reaction (12), the interaction of CoHR with excess of PAR, and reaction (13), the overall ligand-displacement reaction, again in excess of PAR, were investigated. In both cases, the rate law could be expressed by means of first-order kinetic equations.

$$dC_{\text{CoHR}}/dt = -k_2 C_{\text{CoHR}} \quad (14)$$

$$dC_{\text{CoY'}}/dt = -k_{1,2} C_{\text{CoY'}} \quad (15)$$

This was supported by the good linearity of the corresponding first-order plots (Fig. 4). The k_2 and $k_{1,2}$ values, determined by the least-

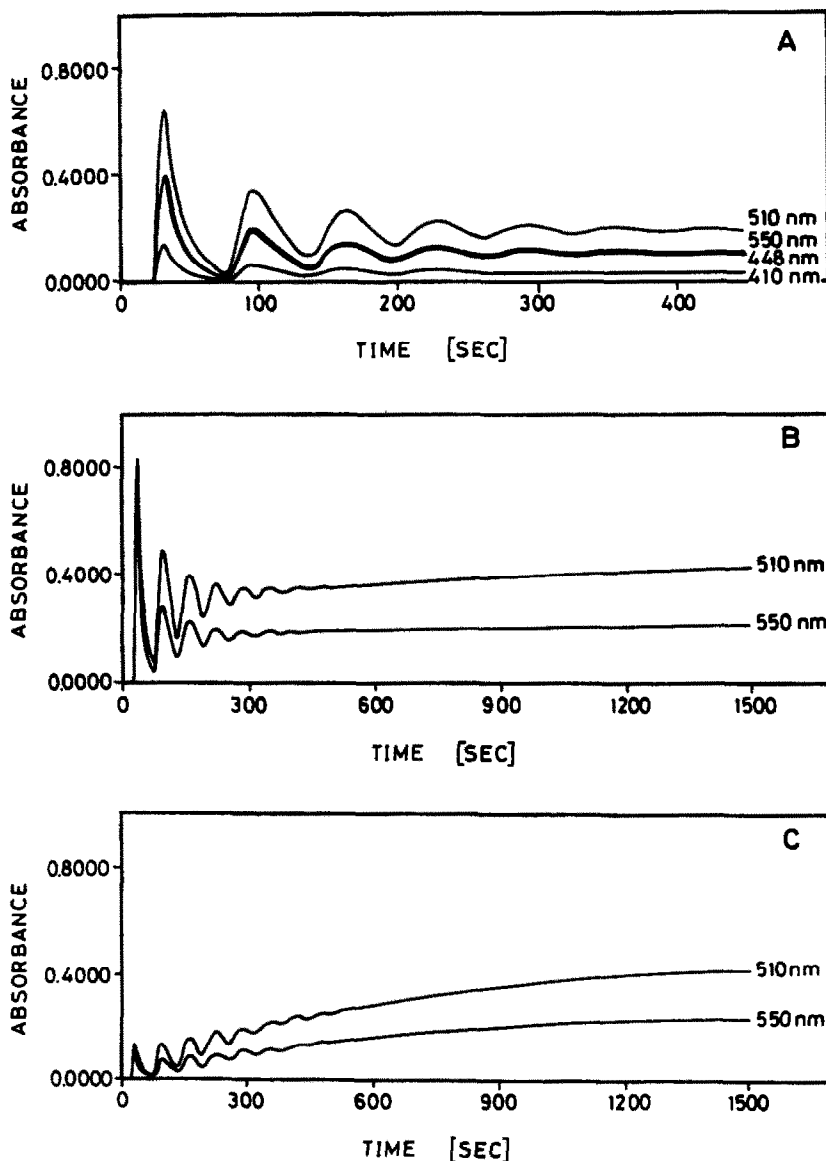

Fig. 3. Recordings obtained upon injection of CoHR into a carrier containing buffer only (A) or $2.50 \times 10^{-4}M$ PAR (B), and of CoY' into a carrier containing $2.50 \times 10^{-4}M$ PAR (C). The flow-rate was 1.7 ml/min in all cases.

squares method, were 8.85×10^{-3} and $2.41 \times 10^{-3} \text{ sec}^{-1}$, respectively.

A PAR solution ($5.00 \times 10^{-4}M$) was injected into a carrier containing only buffer or CoY' at various concentrations (1.25×10^{-5} – $2.50 \times 10^{-4}M$) for investigation of reaction (11). The concentration/time curve obtained by injecting PAR into a carrier containing buffer only was almost identical to that obtained on injection of CoHR into the same carrier. This shows that the assumption involving the equality of the axial dispersion coefficients of the reagents, on which the proposed method relies, is valid for the CoHR/PAR/CoY'/EGTA system. Con-

centrations of CoY' in the carrier above $2.50 \times 10^{-5}M$ ensured completion of the ligand-displacement reaction in a few seconds, and the recordings showed only the dispersion of the already obtained CoHR complex (Fig. 3A). The absorbance/time recordings obtained for 2.50×10^{-5} and $1.25 \times 10^{-5}M$ CoY' in the carrier solution are shown in Fig. 5A and B, respectively. In both cases, the concentrations of CoHR, CoY, and PAR were of the same order of magnitude, so the pseudo-first order simplification may not be applied. The concentrations of PAR and CoHR at each peak maximum were determined from the molar absorptivities of

Fig. 4. First-order plots corresponding to equation (14) (○) and equation (15) (●), where $A = \ln(C_{\text{CoHR}}^0/C_{\text{CoHR}})$ and $B = \ln(C_{\text{CoY}}^0/C_{\text{CoY}})$.

PAR and CoHR (Table 1) at the wavelengths monitored and the absorbance values at the same wavelengths. Only the first five peaks were processed. As only the data for 2 wavelengths were required, 410 and 448 nm were chosen. Good agreement with the data found at 510 and 550 nm was observed. The data obtained were processed by using the kinetic equations listed in Table 2. First, an initial CoY' concentration of $1.25 \times 10^{-5} M$ in the carrier was used, as it allowed the first four peaks to be processed. The

reaction was completed before the appearance of the fifth peak. At an initial CoY' concentration of $2.50 \times 10^{-5} M$, the reaction was completed by the time the third peak was recorded, so only the first two peaks could be used. For all calculations, the initial concentration of PAR at each peak maximum was determined by injection into a carrier containing buffer only, while the initial concentration of CoY' was assumed to be that in the carrier prior to introduction of the PAR sample.

The results obtained are plotted in Fig. 6. Parameter R is the term on the left-hand side in the solution of a given kinetic equation (Table 2), divided by its maximum value (*i.e.*, that corresponding to the last peak used in the calculations). Parameter T is the time, divided by that of the appearance of the last peak maximum used. According to this normalization, the co-ordinates of the last peak used in the calculations will be $T = 1$; $R = 1$, irrespective of the kinetic equation used. The following kinetic equation provided the best fit to the experimental data at a CoY' concentration in the carrier of $1.25 \times 10^{-5} M$:

$$dC_p/dt = k \sqrt{C_1 C_2} \quad (16)$$

Fig. 5. Recordings obtained for injection of $5.00 \times 10^{-6} M$ PAR into a carrier containing CoY' at a concentration of $2.50 \times 10^{-5} M$ (A) and $1.25 \times 10^{-5} M$ (B). The flow-rate was 3.1 ml/min.

Table 1. Molar absorptivities ($l. mole^{-1}. cm^{-1}$) of PAR, CoHR and $Co(HR)_2$

Compound	Wavelength, nm			
	410	448	510	550
PAR	3.23×10^4	1.54×10^4	1.26×10^3	650
CoHR	6.31×10^3	1.59×10^4	2.84×10^4	1.67×10^4
$Co(HR)_2^*$			5.57×10^4	2.36×10^4

*The spectral features of $Co(HR)_2$ were investigated with excess of PAR present. Under such conditions, the molar absorptivities of $Co(HR)_2$ could not be determined at 410 and 448 nm because of the very high absorbance of the PAR.

Table 2. Kinetic equations used for the calculations

No.	Equation	Solution
(1)	$dC_p/dt = kC_1 C_2$	$\frac{1}{C_2^0 - C_1^0} \ln \frac{C_1^0(C_2^0 - C_p)}{C_2^0(C_1^0 - C_p)} = kt$
(2)	$dC_p/dt = kC_1 C_2^2$	$\frac{1}{C_1^0 - C_2^0} \left[\frac{C_p}{C_2^0(C_2^0 - C_p)} - \frac{1}{C_2^0 - C_1^0} \ln \frac{C_1^0(C_2^0 - C_p)}{C_2^0(C_1^0 - C_p)} \right] = kt$
(3)	$dC_p/dt = kC_1 C_2^{1/2}$	for $A > 0$: $\frac{1}{\sqrt{A}} \left[\ln \frac{(\sqrt{A+X} - \sqrt{A})(\sqrt{C_2^0} + \sqrt{A})}{(\sqrt{A+X} + \sqrt{A})(\sqrt{C_2^0} - \sqrt{A})} \right] = -kt$ for $A < 0$: $\frac{2}{\sqrt{-A}} \left[\arctan \sqrt{\frac{A+X}{-A}} - \arctan \sqrt{\frac{C_2^0}{-A}} \right] = -kt$
	$A = C_2^0 - C_1^0$ $X = C_1^0 - C_p$	
(4)	$dC_p/dt = kC_1^{1/2} C_2$	the same as the solution for equation (3) but C_2^0 replaced everywhere by C_1^0
	$A = C_1^0 - C_2^0$ $X = C_2^0 - C_p$	
(5)	$dC_p/dt = kC_1^{1/2} C_2^2$	for $A > 0$: $\frac{1}{A} \left\{ \frac{\sqrt{A+X}}{X} - \frac{\sqrt{C_1^0}}{C_2^0} + \frac{1}{2\sqrt{A}} \ln \left[\frac{(\sqrt{A+X} - \sqrt{A})(\sqrt{C_1^0} + \sqrt{A})}{(\sqrt{A+X} + \sqrt{A})(\sqrt{C_1^0} - \sqrt{A})} \right] \right\} = -kt$ for $A < 0$: $\frac{1}{A} \left\{ \frac{\sqrt{A+X}}{X} - \frac{\sqrt{C_1^0}}{C_2^0} + \frac{1}{\sqrt{-A}} \left[\arctan \sqrt{\frac{A+X}{-A}} - \arctan \sqrt{\frac{C_1^0}{-A}} \right] \right\} = -kt$
	$A = C_1^0 - C_2^0$ $X = C_2^0 - C_p$	

Subscripts 1 and 2 refer to PAR and CoEGTA, respectively.

where C_1 and C_2 are the concentrations of PAR and CoY' respectively.

However, the equation

$$dC_p/dt = k \sqrt{C_1} C_2^2 \quad (17)$$

cannot be completely discarded as a possible approximation to the true kinetic equation for the ligand-displacement reaction studied. The values of both rate constants obtained by a least-squares method were $6.53 l^{0.5}. mole^{-0.5}. sec^{-1}$ for equation (16) and $1.15 \times 10^6 l^{1.5}. mole^{-1.5}. sec^{-1}$ for equation (17).

Processing the results obtained with a CoY' concentration of $2.50 \times 10^{-5} M$ in the carrier solution yielded the following values for the two rate constants above: $5.11 l^{0.5}. mole^{-0.5}. sec^{-1}$ for equation (16) and $2.55 \times 10^5 l^{1.5}. mole^{-1.5}. sec^{-1}$ for equation (17). These results allow us to conclude that the most likely kinetic equation for reaction (11) is equation (16). Accordingly, the reaction must

be much faster in the presence of excess of CoY' than excess of PAR. This was experimentally confirmed, which is an additional proof for the validity of equation (16).

CONCLUSIONS

The proposed method for the determination of kinetic constants and reaction orders of chemical reactions can be successfully applied to kinetic studies, and can be implemented most efficiently in open-closed flow-injection systems where several peak maxima can be obtained from a single injection, and where the course of the chemical reaction from the beginning to equilibrium can be monitored with a single detector. These two major advantages make open-closed systems superior to traditional open flow-injection systems for this purpose.

AUTOMATED DETERMINATION OF TOTAL PHOSPHORUS IN AQUEOUS SAMPLES

SHEN DONG and PURNENDU K. DASGUPTA*

Department of Chemistry and Biochemistry, Texas Tech University, Lubbock, TX 79409-1061, U.S.A.

(Received 30 July 1990. Accepted 13 August 1990)

Summary—The determination of total phosphorus in an automated microbatch analyzer system is described. The procedure combines persulfate digestion of the sample and colorimetric detection of orthophosphate by the ascorbic acid reduction of phosphomolybdate in a single processing chamber. Approximately 9 min are required per sample; ~1.7 ml of sample and 0.17 ml of total reagent are consumed. The limit of detection is $\leq 10 \mu\text{g/l}$. phosphorus. The method is tolerant of variations in salinity of the sample. Good agreements with ASTM procedures are shown for a variety of test compounds, lake water, wastewater and urine samples.

The microdetermination of phosphorus is of major importance in clinical and environmental contexts. Two publications on this topic^{1,2} are among the ten most cited papers in the analytical literature.³

Conversion of phosphorus into inorganic orthophosphate enables its straightforward determination. The first option listed in the current American Society for Testing and Materials (ASTM) standards⁴ is the ascorbic acid reduction of phosphomolybdate to molybdenum blue, originally due to Chen *et al.*¹ It is, however, the conversion of other forms of phosphorus into orthophosphate that is the tedious and time-consuming step. Acid-hydrolyzable phosphorus is operationally defined by ASTM as that which can be completely converted into orthophosphate by boiling for 30 min in dilute sulfuric acid; The acid-hydrolyzable phosphorus compounds are most notably inorganic meta-, pyro- and polyphosphates. Total phosphorus also includes the organically bound element; its conversion into orthophosphate is accomplished by including persulfate in the sulfuric acid digestion medium.

Determination of total P rather than orthophosphate or acid-hydrolyzable phosphorus is the parameter usually required by regulatory agencies. The persulfate digestion method for total phosphorus in sea-water was introduced by Menzel and Corwin⁵ and subsequently developed for general application by Gales *et al.*⁶ In lieu of boiling on a hot-plate, autoclaving the

digestion mixture (30–60 min at 120°) is frequently advocated,^{7–9} but is not easily automated. Attempts to automate continuous flow systems have been made with a UV-aided in-line flow digester (85°) in an air-segmented system¹⁰ or with a 10-m long PTFE capillary digester (at 160°, with an inserted platinum wire of equal length serving as a catalyst) in a flow-injection system.¹¹ Although both of these methods have advantages and their applicability to the determination of total phosphorus in natural waters has been demonstrated, complete conversion of certain degradation-resistant compounds, *e.g.*, thiophosphorus insecticides, into orthophosphate has not been established, and this can often only be achieved by conventional block- or autoclave-digestion methods as required by the ASTM.

We have recently introduced the automated microbatch analyzer (AMBA) and demonstrated its utility for a number of different applications.^{12–15} The present work describes a unique application of the AMBA system—the determination of total phosphorus by adaptation of the ASTM procedure. Digestion at elevated temperature and pressure is followed by colorimetric measurement in the same cavity, requiring less than 9 min per sample.

EXPERIMENTAL

Apparatus

The AMBA system was similar to that in previous descriptions^{14,15} except as detailed below. The cavity was machined from 1½ in. diameter poly(vinylidene fluoride) (Kynar®,

*Author for correspondence.

Pennwalt Corp.) and has a rounded bottom, 9.2-mm inner diameter and a 34.6-mm deep well. The heater element is contained within a 1.2-mm diameter, 16-mm long ceramic sleeve and is capable of generating 25 W at 30 V (Watlow Inc., St. Louis, MO). This is inserted within a thin-walled pyrex tube (*ca.* 1.8-mm outer diameter) sealed at one end, and packed with magnesium oxide as heat-transfer agent. The heater is inserted through a hole in the cavity lid, offset from the center, to such a depth that its bottom tip is several mm above the stirrer bar when the cavity is sealed with the lid and its attendant O-ring, and the top of the heating element is several mm below the sample level. The glass tube encasing the heater is sealed into the lid with a compression fitting. The light source is a high radiant-intensity infrared light-emitting diode (LED) (CN-305, 8 mW at 880 nm and 50 mA, Stanley Electric, Tokyo, Japan) coupled to a silica fiber as shown in the inset of Fig. 1. The LED is inserted within a $\frac{1}{4}$ -28 to 10-32 compression-fitting union commonly used in liquid chromatography (an all-plastic black version is available from Dionex Corp., Sunnyvale, CA). A small infrared photodiode, R, is placed immediately behind the LED, L. The leads are suitably insulated from each other with sleeves and the assembly is fixed in place with a $\frac{1}{4}$ -28 fitting (not shown). The silica fiber

F (1-mm core, Ensign-Bickford Optics, Avon, CT) butts against L (the connecting passage between the two sides of the fitting is enlarged by drilling) and is held in place by a plastic compression fitting. L is powered by a constant-current source at 50 mA and the photodiode R receives enough light reflected off the front surface of L to make the arrangement practical and avoid the need for a bifurcated fiber optic. The receiving and transmitting optical fibers are both sealed into the cavity with compression fittings, diametrically opposite to each other, and both protrude slightly into the cavity, resulting in an optical path-length of ~ 6 mm. The receiving fiber optic is coupled to an infrared photodiode and the output of this and the reference detector R are in turn processed by a log ratio amplifier (AD757N, Analog Devices, Norwood, MA) to provide an output of 1 V for an absorbance of 1.0.

The fluid system is also schematically shown in Fig. 1. All liquid reservoirs are pressurized by the same nitrogen supply at 15 psig. The different flow-rates of the individual liquids are achieved by use of appropriate lengths and diameters of the standard wall thickness (SW) PTFE tubing (Zeus Industrial Products, Raritan, NJ) connecting the liquid reservoirs to the cavity. The sample and pressure/vent lines enter the cavity through 23 gauge tubes, and the

acid/persulfate, color reagent and wash lines have ~30 cm of 30 gauge, ~15 cm of 30 gauge and ~40 cm of 20 gauge tubing, respectively, as primary restrictions. Only the color development reagent enters through the side of the cavity (below the digested liquid level), and all the other connections, except for the waste line, are made through the cavity lid as shown. The sample loop was made from 18 gauge tubing and the volume delivered was found gravimetrically to be 1.66 ± 0.09 ml.

Reagents

Except as mentioned below, all chemicals were obtained from Aldrich. Adenosine-5'-monophosphate and α -D-glucose-1-phosphate were obtained from Sigma, sodium metaphosphate from Fisher Scientific, analytical-reagent grade potassium dihydrogen phosphate from Mallinckrodt, disodium phenyl phosphate dihydrate from Fluka and *O,O*-diethyl-*O*-(3,5,6-trichloro-2-pyridyl)phosphorodithioate (Chlorpyrifos®) was obtained as an analytical standard from the Dow Chemical Company. The pesticide Dursban® (Gro-Tec Inc.) was purchased locally.

The acid/persulfate reagent contained 2.5 g of ammonium persulfate dissolved in 10 ml of 2.75M sulfuric acid. The mixed reagent, as used here, is unstable and should be prepared daily. A 66.0- μ l volume of this reagent is dispensed under our operational conditions. If the acid and the oxidant are kept separate, the usable lifetime can be greatly improved. The color development reagent was prepared by dissolving 390 mg of potassium antimonyl tartrate (J. T. Baker), 16.8 g of ammonium heptamolybdate tetrahydrate (Fisher) and 106 ml of concentrated sulfuric acid in water and diluting to 1000 ml, and then dissolving 1.50 g of ascorbic acid (Merck) in 100 ml of this solution. A 100- μ l aliquot of the reagent is dispensed. The formulations of the acid/persulfate and the color development reagents are adaptations of the ASTM recipes to provide the same acidity and reducing power in the present method. Note that if the sample contains very substantial amounts of acid or base, this recipe will need adjustment.

Aqueous solutions of all compounds were directly used except for the Dursban®, for which an aqueous extract was used. Recovery of total phosphorus from the test compounds was investigated in the concentration range 100–1000

μ g/l., with 2–8 replicates per sample for the test compounds as well as for the urine and environmental samples.

Operational procedure

The timing and functional sequence of the analyzer are shown in Table 1. The operational status is described by an 8-bit number (1 = ON, 0 = OFF), the first (most significant) through to the seventh bit representing valves V1–V7 [2-way valves allow fluid flow when on; for 3-way valves, the common port (solid line) is connected to the dashed-line port when the valve is on], and the last bit representing the heater status. A major time-consuming step is the cool-down period; this is necessary to avoid the loss of ebullient liquid that would occur if the cavity were vented at temperatures $> 100^\circ$. Conceivably, this period can be reduced by using a thinner-walled cavity that will allow faster cooling.

RESULTS AND DISCUSSION

The system gives linear response in the range 0–1 μ g/ml phosphorus, and may be described by the equation $A = (0.187 \pm 0.002) C + (0.002_1 \pm 0.001_1)$, $r^2 = 0.9991$, where A is the absorbance and C the phosphorus concentration in μ g/ml. The standard error of estimate for A is 0.002₂. Because the color reagent is added when the solution is still very hot, color development is very rapid. As may be evident from the system output shown for blanks and samples containing 0.025 μ g/ml P (Fig. 2), the analytical signal is best taken as the sharp absorbance change that occurs immediately upon addition of the color reagent when

phosphorus is present. The detector signal drifts for thermal reasons. When the heater is turned off, the temperature decreases continuously and the associated change in refractive index causes the signal drift, especially with the more sensitive detector settings. The drift rate is increased further upon addition of the relatively cool reagent. However, as may be obvious from Fig. 2, the drift is slow relative to the sample-induced signal and no significant problems are encountered in interpreting the results.

City of Wofforth	4.00 \pm 0.06	4.13 \pm 0.00 ₄

Interestingly, this procedure obviates the need for using calibrants that are exactly matrix-matched with the sample, e.g., sea-water, to prevent the refractive index effects common to flow-through detectors. The limit of detection in our system may be estimated from Fig. 2 to be $\leq 10 \mu\text{g/l}$. phosphorus.

Recovery of phosphorus from a number of disparate test compounds is shown in Table 2, relative to the value obtained by the ASTM method (assumed to be 100%). With the exception of Chlorpyrifos[®] (this is also the active ingredient in Dursban[®]), the recovery is $\geq 95\%$, adequate for most purposes. If the digestion time is increased from 5 to 9 min, the recovery for the more difficult samples increases considerably, that for metaphosphate, for example, to $98.3 \pm 1.0\%$. The presence of sodium chloride at salinities typical of ocean water has no marked effect on the result, nor is there any major interference from organic compounds or surface-active agents, which have been reported to cause problems.¹¹ The results for a number of environmental samples appear in Table 3 and those for urine samples in Table 4; in all cases good agreement with the ASTM method is observed.

Table 4. Results for urinary phosphorus*

SIMULTANEOUS DETERMINATION OF CALCIUM AND MAGNESIUM BY USING A FLOW-INJECTION SYSTEM WITH SIMULTANEOUS INJECTION OF TWO SAMPLE PLUGS AND A MASKING AGENT PLUG

TAKESHI YAMANE* and EIICHI GOTO

Department of Chemistry, Faculty of Education, Yamanashi University, Takeda-4, Kofu 400, Japan

(Received 24 May 1990. Revised 6 July 1990. Accepted 13 July 1990)

Summary—A flow-injection system is described for the simultaneous determination of calcium and magnesium with simultaneous injection of two sample plugs and a masking agent plug and with a single detector. The system utilizes the simultaneous injection of an ethylene glycol-bis(2-aminoethylether)-*N,N,N',N'*-tetra-acetic acid plug and two small sample plugs into the same carrier stream and which are merged downstream with 3,3'-bis[*N,N*-bis(carboxymethyl)aminomethyl]-*o*-cresolphthalein solution for spectrophotometric determination of calcium and magnesium. The results for the analysis of natural waters by the proposed method correspond well with those obtained by the conventional titration method with ethylenediaminetetra-acetic acid, and showed good reproducibility. The rate of analysis is about 15 samples/hr.

Calcium and magnesium are often determined for environmental and biological monitoring. Titrimetry, spectrophotometry and atomic-absorption spectrometry are the most frequently used techniques for such determinations.

Flow-injection analysis (FIA) has proved to be a suitable tool for rapid, simple and reproducible analysis with rather inexpensive apparatus. FIA has also been found useful for simultaneous determination of two or more components in a sample. Reviews of such determinations and speciation measurements with FIA have appeared in the literature.^{1,2} We previously reported an approach to a simple FIA system which allows the simultaneous determination of two components with a single detector.³

This paper extends this FIA system to the simultaneous determination of calcium and magnesium in natural waters. Several FIA methods with spectrophotometric detection have been proposed for calcium⁴⁻⁷ or magnesium^{8,9} with various chromogenic reagents. These are, however, focused on single component determination, with the exception of the total hardness determination. FIA spectrophotometric methods with one detector, with Chlorophosphonazo III¹⁰ or murexide and Eriochrome Black T (EBT),¹¹ so far described

for the simultaneous determination of calcium and magnesium, should be better described as sequential,¹ because two consecutive injections are required along with switching of the reagent solution for the determination of the two components. Such methods also require a switching valve and therefore would lead to a complicated and troublesome system. A sequential FIA determination of calcium and magnesium with EBT as reagent has also been reported.¹² The FIA system described here exploits a simple configuration which does not need switching or splitting of the flow stream, and allows a simple and rapid simultaneous determination. Natural waters such as river water, ground water and sea-water were satisfactorily analysed by the proposed method.

EXPERIMENTAL

Manifold and procedure

A Jasco UVIVDEC-320 spectrophotometer equipped with a flow cell, a Hitachi 655A-13 pump, and a Hitachi K-1600 16-port valve were used. All pieces of tubing, including a 4-m long separation coil (SC), a 15-cm masking agent loop (R, 31 μ l) and two 15-cm sample loops (S1, S2, 31 μ l) which were connected to a 16-port valve, were made of Teflon (0.5 mm i.d.). The flow-injection manifold used is shown in Fig. 1. Two small sample plugs and a masking agent

*Author for correspondence.

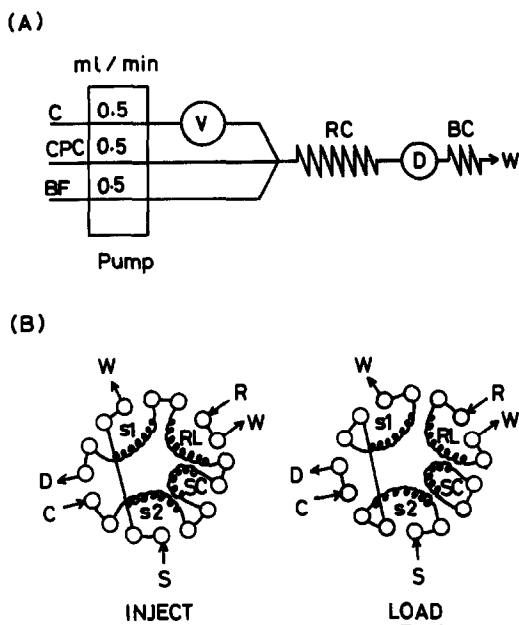

Fig. 1. (A)—Schematic diagram of FIA system for simultaneous determination of calcium and magnesium; (B)—16-port valve and loop configuration. For further details see text. C, Carrier (water); CPC, 0.050% CPC solution; BF, ammonia buffer solution (pH 10.1); V, 16-port valve with two sample loops, separation coil and a masking reagent loop; s1, s2, sample loop (15 cm long, 31 μ l); SC, separation coil (4 m); RC reaction coil (1-m long); RL, masking reagent loop (15 cm long, 31 μ l); R, $3.0 \times 10^{-3}M$ EDTA solution; S, sample loading; D, spectrophotometric detection (575 nm); BC, back-pressure coil (0.25 mm i.d., 2.5 m); W, waste.

plug are simultaneously injected into the same carrier stream by making effective use of the 16-port valve. In one of the sample plugs (s1), calcium is complexed with ethylene glycol-bis(2-aminoethylether)-*N,N,N',N'*-tetra-acetic and (EGTA) by penetration of the s1 and R plugs during transport to the reaction coil (RC). Calcium and in the other sample plug (s2), are kept as they were in the original sample. The mixing of these sample plugs with the 3,3'-bis[*N,N*-bis(carboxymethyl)]-*o*-cresolphthalein (CPC) solution causes two peaks to be observed in the spectrophotometric measurement at 575 nm, as shown in Fig. 2(b). The first peak corresponds to magnesium and the second to the sum of calcium and magnesium. The concentration of calcium can be calculated by difference. The peaks in Fig. 2(b) were recorded for a single injection of a mixture of calcium and magnesium. Calibration graphs, two for magnesium (one for the first peak, the other for the second, which is more dispersed) and one for calcium, were prepared separately.

Reagents

Unless otherwise noted, all reagents were of analytical grade and were used as received. The standard solutions of calcium and magnesium were prepared from 100- μ g/ml stock solutions (Wako Pure Chemical Industries, Osaka, Japan). The CPC solution (0.05%) was prepared by dissolving the reagent (Dojindo Laboratories, Kumamoto, Japan) in water, adding 50 ml of ammonia buffer solution (pH 10.1) and diluting to 100 ml with water. The EGTA solution ($1.0 \times 10^{-2}M$) was prepared by dissolving the reagent (Dojindo Laboratories) in a dilute solution of ammonia and then diluting to volume with water. More dilute solutions were prepared by dilution of this stock solution with water. The ammonia buffer solution was prepared by mixing 2.0M ammonia solution (50 ml) and 1.0M ammonium chloride solution (25 ml), adding one of the components to adjust the pH to 10.1 and finally diluting to 100 ml with water.

RESULTS AND DISCUSSION

FIA manifold for simultaneous determination

In the present approach, a long coil (separation coil) filled with carrier solution between two sample plugs was used. This configuration prevents any overlap of the two zones. The effect of the length of the separation coil on the efficiency of peak separation was investigated by injecting a 20- μ g/ml magnesium solution, with use of the manifold in Fig. 1. Good separation of the two peaks was observed with separation coils longer than 2 m. Longer coils resulted in better separation but caused a decrease in peak height and an increase in the width of the second peak. The height of the first peak was independent of the separation coil length, as expected. A 4-m coil was used in this study to avoid any penetration of the reagent R into sample plug s2. With a 4-m coil the height of the second peak for calcium and/or magnesium did not change when the $3.0 \times 10^{-3}M$ EGTA solution in R was replaced by water. This indicated that EGTA did not affect the complex formation of calcium and magnesium with CPC in plug s2. The length of the reaction coil is important for controlling the dispersion of the sample zone (s1) and the masking reagent zone (R), because there must be effective penetration of these zones. A 1-m reaction coil was found to be suitable both for the masking of calcium and for obtaining good separation of the two peaks as

Fig. 2. Typical recordings for calcium and magnesium with injection of the solutions containing (a) 10 $\mu\text{g/ml}$ calcium alone and (b) 10 $\mu\text{g/ml}$ calcium and 20 $\mu\text{g/ml}$ magnesium in a mixture.

shown in Fig. 2. It is of interest to note that increasing the sample coil length (*s1*) from 15 cm to 30 cm improved the peak height about twofold, but the masking capacity of $3.0 \times 10^{-3}M$ EGTA was limited to 20 $\mu\text{g/ml}$ calcium in the *s1* plug.

Detection of calcium and magnesium with CPC

CPC reacts with both calcium and magnesium in alkaline medium to form red complexes which have similar absorption spectra, with broad maxima at about 570 nm for magnesium and 575 nm for calcium. Thus, a wavelength of 575 nm was chosen so that both analytes could be detected with a single detector. For this simultaneous determination, it was desirable for the signal for one component to be obtained separately, in addition to the signal for the sum of the two components. It was decided to mask one component (calcium) in the sample with EGTA, because there is a considerable difference between the log *K* values for the EGTA complexes of calcium and magnesium.¹³ Experiments at pH 10.1 with ammonia buffer solution indicated that calcium (up to 30 $\mu\text{g/ml}$) could be masked by addition of $3.0 \times 10^{-3}M$ EGTA since only one peak was found when the solution containing only calcium was injected [Fig. 2(a)]. A smaller concentration ($1.0 \times 10^{-3}M$) of EGTA resulted in incomplete masking. Thus, a $3.0 \times 10^{-3}M$ solution was adopted.

The effect of the CPC concentration on the peak height was studied by injecting a 10- $\mu\text{g/ml}$ calcium solution and 0.010, 0.025, 0.050 and 0.075% CPC solutions. The peak height was found to be almost independent of the CPC

concentration in the range 0.025–0.075%, but it slightly decreased at 0.010%. The baseline absorbance increased almost linearly with increase in CPC concentration. The 0.050% solution was chosen for this study.

The pH dependence of the complex formation of calcium and magnesium with CPC was studied. The pH was adjusted with ammonia–ammonium chloride buffer solutions. The peak height for calcium increased gradually from pH 9.5 to 10.7, whereas a maximum peak height was observed for magnesium at about pH 10.4 (Fig. 3). This effect may be due to the hydrolysis and precipitation of magnesium in more alkaline media. Experiments with higher concentrations of buffer solutions at constant pH or with more alkaline solutions buffered with ammonia or borate–sodium hydroxide caused too much baseline disturbance. As a result, a pH of 10.1 for complex formation and a buffer solution of 1.0M ammonia–0.25M ammonium chloride were employed in this FIA system. Only small changes in the baseline caused by changes in refractive index still appeared in the first peak region under these conditions (Fig. 2). This, however, is not a serious drawback in measuring the peak height, because of the low noise and good stability in the baseline.

Calibration

Under the conditions described, calibration graphs were linear up to at least 30 $\mu\text{g/ml}$ for each analyte as shown in Fig. 4. Slopes obtained by least squares for two series of solutions with successively increasing magnesium concentrations (5.0, 10, 20, and 30 $\mu\text{g/ml}$) and fixed 10 $\mu\text{g/ml}$ calcium concentration and solutions

Fig. 3. Effect of pH on the second peak for 10 $\mu\text{g/ml}$ of calcium and magnesium.

Fig. 4. Calibration graphs for calcium and magnesium. Mg1 and Mg2 indicate the heights of the first and second peaks, respectively, for magnesium.

containing successively increasing calcium (5.0, 10, 20, and 30 $\mu\text{g/ml}$) and fixed 10 $\mu\text{g/ml}$ magnesium were in good agreement with those of the corresponding calibration graphs for the individual elements. This indicates good recoveries of calcium and magnesium in synthetic mixtures even at differing ratios. The relative standard deviations for 10 $\mu\text{g/ml}$ of both calcium and magnesium in a synthetic mixture were 0.4 and 0.8%, respectively. The limit of detection (signal three times the standard deviation of the average blank signal) was 0.2 and 0.3 $\mu\text{g/ml}$ for calcium and magnesium, respectively.

At a flow-rate of 0.5 ml/min for each channel in Fig. 1, an injection rate of 15 samples/hr could be achieved.

Interferences

The interference study involved focusing on some metals that may be found occasionally at

levels up to several $\mu\text{g/ml}$ in natural waters, and some anions that might cause precipitation of calcium and magnesium. Solutions were prepared which contained 10 $\mu\text{g/ml}$ of both calcium and magnesium, together with the other ions to be examined. These were injected exactly as in the experiments described above. In order to investigate interferences in the calcium determination in more detail, solutions from which magnesium was omitted were injected. No significant interference was observed for the following ions ($\mu\text{g/ml}$); Fe(III) (5), Al(III) (5), Cu(II) (5), Zn(II) (1), Ni(II) (1), Mn(II) (1), Co(II) (1), PO_4^{3-} (20), SO_4^{2-} (500), tartrate (500), citrate (20), oxalate (20). Significant interference was defined as causing a deviation of more than 3%. Phosphate, citrate and oxalate at levels of several hundred $\mu\text{g/ml}$ affected the determination of both analytes, especially that of calcium (negative interference). This interference is probably caused by the formation of complexes or low solubility species. The concentrations of these ions in most natural waters is usually low enough for no interference in the present method to be expected. It is important to note that the sample solution to be injected must be nearly neutral, or at least have a $\text{pH} > 4$, because the colour development for detection with CPC is sensitive to pH variation.

Analysis of natural waters

The proposed FIA method was applied to the analysis of natural waters such as river water, ground water and sea-water. The ground water and sea-water were diluted until the concentrations would fit into the linear range of the calibration graphs. As shown in Table 1, the results obtained by the FIA method compare well with those found by the conventional EDTA titration method. Differences in most

Table 1. Analysis of natural waters by the proposed FIA method

Sample	Dilution	Metal ion found, $\mu\text{g/ml}$			
		FIA method		Titration method	
		Ca	Mg	Ca	Mg
Ground water					
Tohkohji	2/5	29.6 (0.5)*	9.8 (1.3)*	31.3	10.1
Kunado	1/5	57.3 (1.0)	9.6 (2.5)	61.0	9.6
River water					
Fuefuki river		7.8 (0.6)	1.4 (2.0)	—	—
Kamanashi river		13.3 (0.5)	2.1 (7.0)	14.6	2.2
Sea-water					
Numazu coast	1/100	435 (0.5)	11.6×10^2 (1.0)	436	12.0×10^2

*Values in parentheses are the relative standard deviations of 3–5 determinations.

results for calcium are less than 6%, and better agreement is observed in the magnesium determination. The concentrations of calcium and magnesium obtained by the FIA method for the sea-water sample are comparable with the average concentrations published in the literature. The reproducibilities of this method are satisfactory for both calcium and magnesium, with relative standard deviations of less than 3% for most water samples, except for a value of 7% in the determination of magnesium in river water. These results indicate that the proposed FIA approach can provide a simple and rapid procedure for simultaneous determination of calcium and magnesium, with good precision and accuracy. Although the sensitivity of the proposed method is lower than for flame atomic-absorption spectrometry (but much higher than that for conventional titrimetry), it should be applicable to the analysis of most common natural waters.

IMPROVEMENTS IN THE *N,N*-DIETHYL-*p*-PHENYLENEDIAMINE METHOD FOR THE DETERMINATION OF FREE AND COMBINED RESIDUAL CHLORINE THROUGH THE USE OF FIA

G. GORDON, D. L. SWEETIN, K. SMITH and G. E. PACEY
Miami University, Oxford, OH 45056, U.S.A.

(Received 27 April 1990. Revised 13 June 1990. Accepted 21 June 1990)

Summary—In the determination of free and combined chlorine, the reaction of permanganate standards with *N,N*-diethyl-*p*-phenylenediamine (DPD) exhibits nonlinearity presumably because both the colored semiquinoid product and the colorless quinoid product are both formed. The titrimetric DPD method titrates both of the products while the colorimetric method monitors only the colored semiquinoid products. This results in a nonlinear response for the colorimetric method above 1.0 mg/l. as Cl₂. Under FIA conditions, the nonlinearity of the DPD colorimetric method is eliminated in the 0.1–5.0 mg/l. (as Cl₂) range and the linear range is expanded to 0.1–8.0 mg/l. as Cl₂. Also, relative standard deviations are improved by 0.5–11% relative to the colorimetric method and 1.5–4.0% relative to the titrimetric method. The FIA method was developed further to sequentially determine both free and combined chlorine, since chloramine was found to have a negligible interference in the free chlorine determination.

Although the 1986 Safe Drinking Water Amendments will reduce the use of chlorine for disinfection of water and wastewater, an accurate spectrophotometric method for the determination of free chlorine (Cl₂, HOCl, OCl⁻) and combined chlorine (chloramines) is needed, especially as the use of monochloramine (NH₂Cl) as a disinfectant residual may increase. Because free and combined chlorine have different germicidal capabilities and health effects, it is important to differentiate these species in order to assess contact time (CT) values properly.¹⁻³

The most widely accepted methods for measuring free chlorine (Cl₂, HOCl, OCl⁻) and combined chlorine (NH₂Cl, NHCl₂) are based on use of *N,N*-diethyl-*p*-phenylenediamine (DPD).^{4,5} DPD can be used as an indicator for both acid-base and oxidation reactions.⁶⁻⁸ The initial oxidation products formed are highly colored semiquinoid free radicals which are relatively stable owing to resonance stabilization,⁷ but are susceptible to further oxidation to less stable colorless quinoid products.⁷ This oxidation of the semiquinoid product is responsible for the apparent "fading" in the DPD colorimetric reaction.

DPD undergoes oxidation by both free chlorine and monochloramine to form the colored

semiquinoid free radical. The semiquinoid radical may be reduced to the colorless diamine by titration with ferrous ammonium sulfate (FAS) or its absorbance may be measured.

Because monochloramine also reacts with DPD, it is considered to be a major interferent in the free chlorine measurement.⁶ However, whereas free chlorine species react almost instantaneously with DPD, chloramines react much more slowly. At pH 6.3, the monochloramine reaction has a rate constant of about 10 l.mole⁻¹.sec⁻¹.⁸ However, if potassium iodide is added in a catalytic amount, monochloramine will react with it to produce iodine, which in turn reacts with DPD to produce the colored semiquinoid product almost instantaneously.⁴ The kinetic difference between the reactions of free chlorine and monochloramine with DPD can be exploited by flow-injection analysis (FIA).

The highly reproducible mixing and timing in FIA allow analytical measurements to be made before equilibrium is reached, and the free chlorine species can react with DPD and be measured before the monochloramine has had time to react.⁹

This paper describes a method for the determination of free chlorine and total chlorine, and hence also the amount of combined chlorine.

EXPERIMENTAL

Reagents

Reagent grade chemicals and triply distilled water (resistivity 18.6 M Ω /cm) were used throughout. The DPD titrimetric method and colorimetric method were followed as described in the literature⁴ except where otherwise stated.

A standard permanganate stock solution was prepared, and standardized with dried sodium oxalate.¹⁰ Anhydrous DPD sulfate (Sigma) was used to make DPD solutions of various concentrations. A 137 mg/l. ammonium chloride solution was prepared and used to make the chloramine solutions. A 50 mg/ml solution of sodium hypochlorite was used as a free-chlorine stock solution.

Apparatus

An HP 8450A spectrophotometer was used to measure absorbances at 510 nm, with 1-cm fused-silica cells. Metrohm Herisau Dosimat E535 and Multi-Dosimat E415 autoburets were used for all titrations and to make the standard permanganate solutions. The flow-injection system was made up of a Tecator 5020 FIA unit with an internal dual injector, and two Tecator 5023 detectors with 1-cm flow cells and 520 nm filters. Teflon tubing with 0.5 mm bore was used throughout.

FIA manifold and experimental conditions

A CHEMIFOLDTM type II manifold was used throughout. For the free chlorine determination, the DPD stream (1.2 ml/min) was merged with pH 6.3 buffer (1.2 ml/min) in a 60° T-piece. The mixture was pumped through a 10-cm coil and merged with the water carrier stream (2.2 ml/min) and sample in a second 60° T-piece. The sample (200 μ l) was injected into a water carrier stream to minimize reagent depletion. The reaction mixture then went

through a 30-cm mixing coil to detector D1. The portion of Fig. 1 enclosed in a dashed line shows the FIA system used for the free chlorine determination.

For the determination of total chlorine, the flow from detector D1 was merged with potassium iodide solution (1.2 ml/min) in a 90° T-piece before going on to detector D2 (Fig. 1).

RESULTS AND DISCUSSION

Permanganate standards were made that were equivalent to a concentration range of 0.100–4.000 mg/l. Cl_2 and analysed by the DPD titrimetric and colorimetric methods. For the titrimetric method a plot of concentration of permanganate found *vs.* the known concentration was linear with a slope of 1.005, a *y*-intercept of -6×10^{-4} mg/l., and a correlation coefficient of 0.99998.

For the colorimetric method the concentration of permanganate found by titration was plotted *vs.* absorbance. The plot was nonlinear at concentrations equivalent to >1 mg/l. Cl_2 (with a DPD concentration of $4.29 \times 10^{-3} M$.) A typical plot is shown in Fig. 2. Table 1 lists the linear regression data for different concentration ranges of permanganate standards. The DPD colorimetric method is reported⁴ to be applicable up to 5 mg/l. Cl_2 , but true linearity, without a significant *y*-intercept, is observed only up to 1 mg/l. Cl_2 .

Table 1. Linear regression data for different concentration ranges of permanganate standards

Concentration range, mg/l. Cl_2	Slope, l./mg	<i>y</i> -Intercept	Correlation coefficient
0.10–4.00	0.1891	0.032 ₂	0.9948
0.10–3.00	0.2070	0.018 ₀	0.9977
0.10–2.00	0.2212	0.009 ₇	0.9987
0.10–1.00	0.2431	0.001 ₃	0.9993

Table 2. Linear regression data for increasing DPD concentration (colorimetric method)

[DPD], M	Slope, l./mg	y-Intercept	Correlation coefficient	Linear range, mg/l.Cl ₂
4.22×10^{-3}	0.1817	0.034 ₅	0.9936	0.10-1.50
4.52×10^{-2}	0.2287	0.031 ₀	0.9950	0.10-2.50
4.51×10^{-1}	0.2417	0.003 ₇	0.9999 ₅	0.10-4.00

To find the reason for the deviation from linearity, an additional study was made with DPD solutions of different initial concentrations. In the colorimetric method, as the DPD concentration was increased, the response became linear with a smaller y -intercept (Table 2). Figure 3 shows that in the FIA system, as the concentration of the DPD solution increased, the linearity range of the response curve also increased.

The results indicate that in the standardization procedure, permanganate reacts with DPD to form both the semiquinoid product and the quinoid product. The formation of the quinoid product occurs if the semiquinoid is further oxidized, and the formation of this quinoid product explains the decolorization. In the titrimetric procedure with ferrous ammonium sulfate, both the semiquinoid and quinoid forms are titrated. As a result, an accurate determination of oxidant concentration can be made in the titration method. In the colorimetric method only the absorbance of the semiquinoid is measured, but if any of the quinoid product is present owing to further oxidation by the oxidizing species as described above, the calibration plot will not be linear.

However, if the FIA method is used, even with concentrations of DPD ($4.29 \times 10^{-3}M$) that cause error in the manual procedure, the curvature is eliminated because in the FIA system the DPD to sample ratio is much higher, so the oxidant is less likely to react with the

colored radical to form the unwanted quinoid product, and the calibration is linear. This problem with nonlinearity in the colorimetric batch standardization procedure with permanganate should be considered as a potential source of error in the determination of free and combined chlorine at higher concentrations.

Measurement of free chlorine

The FIA system for the free chlorine measurements is shown in the dashed portion of Fig. 1. A linear response, with a slope of 3.28×10^{-3} l./mg, a y -intercept of 0.042 mg/l. and a correlation coefficient of 0.9999, was obtained in the FIA method for the permanganate concentration range equivalent to 0.1-8.0 mg/l. Cl₂. Solutions of varying concentrations of NaOCl were used to compare the standard titration method⁴ with the FIA method. As expected, the FIA method was more precise and the results agreed well with those from the titrations (Table 3). A plot of titration data against FIA data was linear with a slope of 1.007, a y -intercept of -0.037 mg/l., and a correlation coefficient of 0.9997.

In additional experiments, chloramine was introduced into the FIA system in order to determine the extent of chloramine interference in the free chlorine reading. By varying the starting ratio of the 137 mg/l. ammonium ion solution to the OCl⁻ solution, different proportions of free chlorine to chloramine were obtained. These solutions were also titrated to determine the concentrations of free chlorine and chloramine. Once the concentrations of each were known, appropriate dilutions were made to achieve the desired concentrations of each species. A series of solutions was made with a constant free chlorine concentration (1.83

Fig. 3. Effect of increasing concentration of DPD with KMnO₄ standards: □ $4.29 \times 10^{-3}M$ DPD; ◆ $4.29 \times 10^{-4}M$ DPD; ■ $4.29 \times 10^{-5}M$ DPD.

Table 4. Data (mg/l. Cl₂) from sequential detection (*n* = 10); "actual" values are from triplicate titrations⁴

Free chlorine		Combined chlorine	
Measured	Actual	Measured	Actual
5.63 ± 0.02	5.65 ± 0.07	3.88 ± 0.04	3.89 ± 0.02
4.36 ± 0.02	4.37 ± 0.03	1.55 ± 0.03	1.53 ± 0.04
1.98 ± 0.01	1.89 ± 0.03	1.32 ± 0.02	1.35 ± 0.02
1.02 ± 0.01	0.95 ± 0.03	1.05 ± 0.03	1.04 ± 0.02
0.31 ± 0.00	0.36 ± 0.02	0.09 ± 0.03	0.10 ± 0.01

mg/l. as Cl₂) and a steadily increasing concentration of monochloramine (0–1.86 mg/l. as Cl₂). The absorbance values, when measured with the FIA system, were constant (0.383 ± 0.001). Thus, no significant monochloramine interference was observed.

Measurements of free and total chlorine

The FIA system for free and total chlorine determination is also shown in Fig. 1. Chloramines react with iodide to produce iodine, which is reactive with DPD.⁴ A potassium iodide stream was added to the system to allow determination of total chlorine concentration. After measurement of the amount of free chlorine and total chlorine, the amount of chloramine in the solution could be calculated. In the context of our experiments, introduction of the iodide stream to catalyze the chloramine reaction with DPD produced correspondingly more of the colored semiquinoid radical but also diluted the sample as it came from the free chlorine determination. Therefore, the absorbance reading at the second detector was not simply the sum of the free chlorine absorbance reading and the chloramine absorbance reading. The absorbance reading at the second detector required correction by a dilution factor dependent on the volume of iodide solution added to the reaction stream from the first detector.

Absorption measurements were made for permanganate standards at both the first and second detectors in order to determine the degree of dilution in the system. The response curves that correspond to the absorbances at each detector can be used to calculate the dilution factor from the ratio of the slopes. Once the dilution factor is known, it can be applied for correcting the second absorbance measurement. The absorbance (*y*) measurements at the first detector gave a line with the equation $y = -0.0059 + 0.0667x$; $r = 0.998$, where *x* is the equivalent Cl₂ concentration (mg/l.). The ratio of the slopes is 0.0667/0.0420, which gives a dilution factor of 1.59. Results for free chlor-

Table 5. Comparison of detection limits and rsd for DPD methods⁶

Method	Detection limit,	
	mg/l. Cl ₂	rsd, %
Titration	0.05	2–7
Colorimetric	0.05	1–14
FIA	0.07	0.5–3

ine and calculated chloramine concentrations from sequential detection are given in Table 4. The detection limits and relative standard deviations⁶ are shown in Table 5.

CONCLUSIONS

The ferrous ammonium sulfate titrimetric method reduces all the oxidation products. Therefore, both the quinoid and semiquinoid are titrated, giving an accurate measure of oxidant. However, in the colorimetric method, any colorless quinoid present is not detectable but causes the absorbance to be lower than that corresponding to the amount of oxidant than is actually present. When using the DPD colorimetric method to measure the amounts of free chlorine and monochloramine in solution, it must be recognized that if the concentrations of these species are high (*i.e.*, ≥ 1 mg/l. as Cl₂) or if the initial mixing is poor, there may be formation of the unwanted quinoid product, resulting in nonlinearity of the response curve, and low results.

The use of FIA, with a thorough understanding of the chemistry involved, has been shown to improve the DPD chlorine method by minimizing the formation of the colorless quinoid species and by minimizing the interference of monochloramine in the free chlorine reading, by kinetic discrimination. The FIA method has a much higher throughput than either the titration or colorimetric method because there are no sample-transfer steps and all mixing is done during flow through the FIA system. This ability to analyze more samples in a short time period and hence run more replicates in a given time allows for greater statistical confidence in the results. The FIA system also exhibits a greater linear range than either of the other methods (0.1–8.0 mg/l.).

THE SPECIATION OF ARSENIC(V) AND ARSENIC(III), BY ION-EXCLUSION CHROMATOGRAPHY, IN SOLUTIONS CONTAINING IRON AND SULPHURIC ACID

M. J. HEMMINGS* and E. A. JONES

Analytical Science Division, Mintek, Private Bag X3015, Randburg 2125, Republic of South Africa

(Received 30 May 1990. Revised 26 June 1990. Accepted 6 July 1990)

Summary—Arsenic(V) and arsenic(III) can be separated, by ion-exclusion chromatography, in solutions containing iron and sulphuric acid. Iron is removed by ion-exchange before the speciation of arsenic, with phosphoric acid as the eluent. The separated arsenic(V) and arsenic(III) are measured spectrophotometrically in the ultraviolet region at a wavelength of 195 nm. Arsenic(V) and arsenic(III) can be determined at concentrations ≥ 3 mg/l. The relative standard deviations are 1.3% for arsenic(V) and 0.9% for arsenic(III), at the 10 mg/l. level. The time required for the separation of the inorganic arsenic species is 11 min.

The measurement of inorganic arsenic species in metallurgical solutions allows the easy monitoring of their oxidation levels in various processes. In several commercial processes, such as the Giammarco-Vetrocoke and Thylox processes,¹ arsenate is used to oxidize hydrogen sulphide to elemental sulphur and as an intermediate oxygen-transfer reagent.

The behaviour of arsenic species during the leaching of sulpharsenide materials such as tennantite ($\text{Cu}_{12}\text{As}_4\text{S}_{13}$) and arsenopyrite (FeAsS) is relevant from both the processing and environmental points of view. The presence of arsenite in solutions that result from the bio-leaching of arsenopyrite samples slows down the autocatalytic reaction caused by *Thiobacillus ferrooxydans*, which is the most common ore-leaching bacterium.

There is a great variation in the toxicological activity of the various arsenic species present in foodstuffs and therefore a knowledge of the actual forms present is required in order to assess the dietary risk. Of the two arsenic species, arsenite is considered to be a potentially far greater hazard than arsenate.²

The determination of these species by ion chromatography in simple matrices is already well established³ but a different approach is required for more complicated matrices. Analytical methods using ion chromatography (IC) with conductivity detection have been reported previously for the determination of arsenic

species.^{4,5} In solutions containing large amounts of iron and sulphuric acid,⁴ a pre-separation of cations is performed; the arsenic species are then separated on an ion-exchanger, and arsenic(V) is detected by conductivity detection. A second portion of the sample is oxidized with *aqua regia* so that the arsenic(III) can be determined by difference. A similar system is described for the separation of arsenic species in the presence of iron and hydrochloric acid.⁵ The same authors describe the simultaneous detection of both arsenic species by the combination of electrochemical and conductivity detection.⁶

The use of ion-exclusion chromatography (IEC) for the separation of weak-acid anions from strong-acid anions is an old technique that has been attracting renewed attention. As a result of Donnan exclusion, strong inorganic mineral acids are not retained by the stationary phase, and are eluted as a single peak within the dead-volume time. Weakly dissociated species can penetrate through the solid resin network into the resin bead; this retards their passage through the column, and allows separation to take place. Ion-exclusion work has been extensively documented elsewhere.⁷⁻⁹ Butler¹⁰ determined arsenic(III) species in bottled mineral water by use of ion-exclusion chromatography coupled with amperometric detection. Total arsenic was determined as arsenic(III) after arsenic(V) had been reduced by sulphur dioxide.

The main disadvantages were that arsenic(V) and arsenic(III) cannot be determined simultaneously and the detection system is complex,

*Author for correspondence.

i.e., two detectors in series are required. In addition, Tan and Dutrizac⁴ established that the pH value of the solutions containing ferric sulphate and sulphuric acid affects the conductivity measurements. The presence of large amounts of chloride and sulphate in solutions to be analysed could result in overloading of the column, and an exact knowledge of the concentration of the matrix is therefore required before the analysis.

The suitability of ultraviolet detection for inorganic ions, even for those without suitable chromophores, has been demonstrated repeatedly.^{8,11-13} Williams¹³ describes the application of variable-wavelength detection in series with a conductivity detector. He highlights various advantages, such as the ability to detect anions that cannot normally be detected by conductivity (sulphide and arsenite), the elimination of problems associated with the carbonate "dip", the identification of unknown peaks, and the resolution of overlapping peaks.

The present investigation describes the separation and determination of arsenic(V) and arsenic(III) in solutions containing iron and sulphuric acid at levels as high as 30 g of iron and 100 g of total sulphate per litre. The iron was removed by a cation-exchange procedure before the separation of the arsenic species. After the separation, the species were monitored by means of an ultraviolet detector.

EXPERIMENTAL

Apparatus

Chromatographic separations were obtained by use of a Dionex model 2010i ion chromatograph fitted with a 50 μ l sample loop and an HPICE-AS1 ion-exclusion column. The photometric detector (Linear UVIS 200 detector) was set at 195 nm, and the absorbance output data were recorded with a Spectra-Physics SP4200 computing integrator.

Reagents

All the solutions were prepared from analytical-grade reagents, and distilled water was used. A standard stock solution of 1 g/l. arsenic(III) was prepared by dissolving 0.1320 g of arsenious oxide (As_2O_3) in 10 ml of 10% sodium hydroxide solution. The solution was acidified with dilute sulphuric acid and diluted to 100 ml. A stock solution of 1 g/l. arsenic(V) was prepared by dissolving 0.4160 g of sodium arsenate heptahydrate in water and diluting the solution

to 100 ml. These solutions were standardized by standard atomic-absorption spectrophotometric measurements. The eluent was 0.01M phosphoric acid.

Sample preparation

On dilution, to avoid the precipitation of matrix cations and hence co-precipitation of arsenic, which would produce low results, the acidity had to be maintained at 0.05M sulphuric acid. A sample clean up procedure is recommended to prevent the poisoning of the separation column by cations.

A series of Monoject 20-ml plastic syringes (20 mm \times 85 mm), the ends of which were sealed with a borosilicate disc, were filled to the 10-ml mark with a slurry of Bio-Rad AG 50W-X8 H⁺ form (50-100 mesh) resin, and assembled in clamps in a rack. The resin beds were equilibrated with 0.05M sulphuric acid, and each syringe was placed above a suitable standard flask. The required volume of sample was transferred to the resin bed in the syringe (care being taken not to disturb the surface of the resin), and iron and other cations were sorbed. The arsenic species and other anions were eluted by washing the resin with three 10-ml portions of 0.05M sulphuric acid.

Between samples the resin was regenerated by passing three 10-ml portions of 1M sulphuric acid through the syringe, followed by equilibration with 0.05M sulphuric acid.

Chromatographic procedure

A flow-rate of 0.7 ml/min was selected for the eluent, and the Dionex ion-exclusion column was equilibrated with 0.01M phosphoric acid until a stable baseline was obtained. The chart speed was set at 2.5 mm/min, and a suitable attenuation was selected. The sample was then injected, and the arsenic species were separated. The eluted species were monitored at 195 nm. A set of calibration standards was run, ranging from 10 to 30 mg/l. for arsenic(V) and from 5 to 10 mg/l. for arsenic(III). Calibration graphs were constructed. Arsenic(V) and arsenic(III) were identified by their retention times, and their concentrations were determined by measuring their peak heights, and comparing these with those in the calibration graphs.

RESULTS AND DISCUSSION

The separation of the arsenic species was initially attempted by means of a Dionex AS-4A

anion-separator column, which was coupled to a conductivity detector and an electrochemical detector in series. After separation, arsenic(V) was determined conductometrically, and the weakly dissociated arsenic(III) was determined amperometrically. Owing to the complex matrix of the samples that had to be analysed, this approach presented a number of problems, most notably the overlap of the arsenic(V) peak by that of the large amounts of sulphate present. Arsenious acid is a very weak acid and, as a result of its low dissociation constant, cannot be detected at low levels by conductivity measurements. When electrochemical detection was used, the electrode surface used for the detection of arsenic(III) showed a dark coating, indicating that the electrode was susceptible to poisoning. This was accompanied by a reduction in peak size when consecutive injections of the same sample were made.

Instead, it was decided to use ion-exclusion chromatography with photometric detection for the determination of arsenic species. Ion-exclusion columns for use in the separation of weak-acid anions contain totally sulphonated

cation-exchange resins consisting of beads of polystyrene cross-linked with divinylbenzene. The proportion of divinylbenzene cross-linkage determines, to some extent, the rate of diffusion into the resin beads.⁷ Arsenic species, as well as weak-acid anions such as sulphide and sulphite, enter the resin phase, whereas strong-acid anions such as sulphate, nitrate and chloride are excluded, passing through the column and being eluted with the solvent front.

At a wavelength of 195 nm most anions—including chloride and nitrate—absorb light. Since phosphate does not absorb at the wavelength used, phosphoric acid was chosen as the eluent.

A chromatogram of the separation of arsenic(V) and arsenic(III) is shown in Fig. 1. The two species are clearly separated, with arsenic(V) and arsenic(III) eluted with an adjusted retention time of 1.2 and 4.8 min, respectively. Interfering anions such as chloride and nitrate are elute with the solvent front in 5 min. Use of ultraviolet detection showed that arsenic(III) was more sensitive than arsenic(V).

Fig. 1. Separation of arsenic(V) and arsenic(III) with a DIONEX AS-1 ion exclusion column. Elution with 0.01M H_3PO_4 at 0.7 ml/min. Detection at 195 nm.

Table 1. Retention times for arsenic(V), arsenic(III) and various sulphur species

Species	Adjusted retention time, <i>min</i> ($t_0 = 5.3$ min)
As(V)	1.2
SO ₃ ²⁻	2.5
As(III)	4.8
S ²⁻	13.3
SO ₄ ²⁻	Not detected
SCN ⁻	} Eluted with the solvent front
S ₂ O ₃ ²⁻	
S ₄ O ₆ ²⁻	

The presence of sulphate in quantities equal to or less than 120 g/l. did not pose a problem when an ion-exclusion column was used.

Sulphate is eluted with the solvent front and does not absorb light at the wavelength used for speciation of arsenic. Therefore, it will not interfere with the detection of the arsenic species. Sulphur species known to have absorption characteristics at 195 nm, such as thiocyanate, thiosulphate, and tetrathionate, do not affect the speciation of arsenic since they are eluted with the solvent front. Both sulphide and sulphite absorb at the same wavelength, but have retention times different from those of the arsenic species (Table 1).

Several common anions were tested. Nitrate was eluted with the solvent front. Under the conditions chosen, cyanide was not detected, and chloride was detected but with very low sensitivity.

The pre-separation of iron(II) and iron(III), and other cations, such as cobalt(II), nickel(II) and copper(II), that are present in the sample, is required to avoid the co-precipitation of arsenic during dilution, which would cause low arsenic results. The removal of hydrolysable cations also prevents the deterioration of the column. Iron was removed by means of a cation-exchanger in the hydrogen form.

In order to establish the validity of the proposed method, samples containing arsenic species in a high-sulphate matrix were analysed by ion-exclusion chromatography, and total arsenic was determined by atomic-absorption spectrophotometry. Table 2 gives a summary of the results obtained for samples with a matrix consisting of approximately 30 g/l. iron, 10 g/l. sulphuric acid, and a total sulphate concentration ranging from 50 to 100 g/l. The agreement between both sets of results is good at both the mg/l. and the g/l. levels.

The arsenic species can be determined in the concentration range 10–30 mg/l. for arsenic(V) and 5–20 mg/l. for arsenic(III). Linear calibration graphs were obtained over these ranges.

The relative standard deviation for the method, which was calculated from 13 replicate analyses of a synthetic sample containing 10 mg/l. arsenic(V) and arsenic(III), was found to be 1.3% for arsenic(V) and 0.9% for arsenic(III).

RECOMMENDATIONS

The coupling of the chromatographic separation of inorganic anions with instrumental techniques other than conductimetric, amperometric, or UV/VIS detection is not a new concept.^{2,3} Because of the lack of sensitivity of the ultraviolet detector for the determination of arsenic species at trace levels, atomic-absorption spectrophotometry (AAS) could be considered for their low-level detection. Since AAS does not suffer interference from common anions, the separation of the arsenic species can be achieved on a less efficient, but much faster, column (250 mm in length and 5 mm in diameter), packed with conventional cation-exchange particles. At an eluent concentration of 0.005M phosphoric acid and a flow-rate of 0.4 ml/min, the separation time for the arsenic species could

be reduced to less than 4 min (Fig. 2). Because of its speed, such an arrangement can be easily coupled to an AAS instrument, and both arsenic species can be conveniently, and much more sensitively, determined in the hydride form.

ARRHENIUS PLOTS FOR ACTIVATION ENERGY OF ATOMIZATION IN GRAPHITE-FURNACE ATOMIC- ABSORPTION SPECTROMETRY

C. L. CHAKRABARTI* and S. J. CATHUM

Centre for Analytical and Environmental Chemistry, Chemistry Department, Carleton University,

(Received 20 November 1989. Revised 13 July 1990. Accepted 25 July 1990)

Summary—Activation energy plots drawn by use of various Arrhenius-type equations for atomization reactions in graphite-furnace atomic-absorption spectrometry (GFAAS) do not give reliable kinetic information about the atomization mechanism of the analyte element beyond a few data-points located near the very beginning of the absorbance signal profile. These plots are non-linear if they are drawn with data points near the maximum of the absorbance signal profile. This paper presents two Arrhenius-type equations which give linear plots over a long range of data-points, and hence reliable values for the activation energy. Also, a simple method is proposed for calculating the activation energy from the data-points anywhere from the initial appearance of the absorbance signal to its maximum. Activation energy values given by these two equations and by the method of calculation are compared with each other and with those given by the commonly used methods. The calculated activation energy values obtained can be used to verify those obtained experimentally. The three proposed methods also provide reliable kinetic information on atom-formation reactions in GFAAS. A mechanism for the atomization of copper, based on the experimentally determined activation energy and reaction order is proposed.

Arrhenius plots constructed from absorbance data from electrothermal atomization have been widely used since their introduction by Tessari and co-workers,¹⁻³ and the more extensive study by Sturgeon *et al.*,⁴ and later by Smets.⁵ Frech *et al.*,⁶ and Chung⁷ compared several methods for extracting kinetic parameters. Recently, Yan Xiuping *et al.*⁸ have reported an improvement of the Smets method. Holcombe⁹ and Bass and Holcombe¹⁰ have reported that the use of Arrhenius-type plots, which are often non-linear, to obtain energies characterizing the atom formation reaction in graphite-furnace atomic-absorption spectrometry (GFAAS) is likely to be erroneous and have attributed the non-linearity in Arrhenius plots obtained at 1 atm pressure to the finite residence time of analyte atoms.

Most commercially available electrothermal atomizers have a common feature in that the atom formation in the analysis volume and the atom removal from it are temperature-dependent. It may therefore be possible to determine rates of atom formation from the effect of temperature on the atom release in these atomizers. According to the Arrhenius law, the rate

constant, k , for atom formation can be expressed as

$$k = k_{\infty} \exp(-E_a/RT) \quad (1)$$

where k_{∞} is the pre-exponential factor, E_a is the activation energy, R is the gas constant and T is the absolute temperature. The activation energy is determined by plotting $\ln k$ vs. $1/T$; the slope ($-E_a/R$), yields the activation energy, E_a .

The methods reported in the literature^{5,7,11} for obtaining the Arrhenius plots do not satisfactorily account for the noticeable curvature in these plots when data points are taken near the absorbance maximum. The problem of large uncertainties in the determination of activation energy,^{6,9,10} and the possibility that atomization reactions do not necessarily follow first-order kinetics¹² have hindered progress in the application of activation energy for elucidating atomization mechanisms. Most studies on atomization mechanisms have been done by using data points near the very beginning of the absorbance signal profile, and have ignored the later part of the absorbance signal profile, which also contains useful information on atomization mechanisms. Also, the widely used Smets method⁵ does not provide reliable kinetic information on atomization reactions except near

*Author for correspondence.

the appearance of the absorbance signal profile.^{5,10}

The objectives of this work were to provide a method for activation energy calculation that is valid for any order of reaction; to develop Arrhenius-type equations that are useful for extracting kinetic parameters such as the activation energy, and to increase the range of data points usable for Arrhenius plots, utilizing data from the appearance of an absorbance signal to the absorbance maximum.

THEORY

Arrhenius-type equations

The following simplifying assumptions are made: (a) all unatomized analyte atoms are at the same temperature at the time of atomization; (b) the rate of atom removal in the gas flow mode of atomization is faster than the rate of atom supply; (c) there is no activation energy for the analyte atom diffusion through the gas phase; (d) the rate constant for atom formation is approximated by the Arrhenius law at a constant heating rate and (e) atomization of the sample occurs at a constant, low heating rate.

With these assumptions, the time-dependence of the analyte atom population in a graphite furnace can be described by consecutive reactions as follows:¹³

where n is the order of reaction (assumed constant), N_w is the number of analyte entities left unatomized at time t , N_g is the number of analyte entities that are in the gas phase at time t (not to be confused with the number of analyte atoms in the analysis volume), N_{lost} is the number of analyte atoms lost from the atomizer at time t , and k_1 and k_2 are the temperature-dependent rate constants for the supply and removal functions, respectively. The time-dependent variation of N_g is expressed as a convolution:¹⁴

$$[N_g] = \int_0^t S(t')R(t-t') dt' \quad (3)$$

where $S(t)$ is the supply function defining the supply rate of analyte atoms, $R(t)$ is the mass transport or removal function for analyte atoms and t' is a variable of integration. The square brackets in equation (3) and subsequent equations have been used simply to enclose certain terms in the equations, and do not stand

for molar concentrations of the enclosed terms. If the removal rate is very rapid compared to the supply rate,¹⁴ then

$$[N_g] = S(t) \int_0^\infty R(t) dt = S(t) \tau, \quad (4)$$

where τ , is the overall time constant of the removal function. Thus the shape of a plot of N_g or absorbance A vs. time will reflect the time-dependence of the supply function. Conversely, if the removal rate is very slow compared to the supply rate the shape of the absorbance signal profile is determined by $R(t)$.¹⁴

From reaction scheme (2), we may write the following for the release of analyte atoms N_g :

$$d[N_g]/dt = nk_1[N_w]^n - k_2[N_g] \quad (5)$$

Equation (5) has been reported earlier for $n = 1$.¹⁵ With forced convection at low heating rates and no activation energy for the removal of analyte atoms, the loss by diffusion and convection is fast and therefore cannot be the rate-determining step. We will discuss this in greater detail in the Results and Discussion section. Under these conditions, the supply function is approximated by:

$$\begin{aligned} A &= \beta Q d[N_g]/dt = -\beta Q d[N_w]/dt \\ &= \beta Q nk_1 [N_w]^n = \beta Q S(t) \end{aligned} \quad (6)$$

where Q is a proportionality constant which relates the absorbance, A , to the number of analyte atoms present in the analysis volume at time t , and β is the atomization efficiency, defined by Smets⁵ as the fraction of analyte atoms which are atomized.

The next step in developing the new method is to find a mathematical relationship between the rate constant for atom formation and the absorbance. This can be done by integrating both sides of equation (6) to find an expression for $[N_w]$, which is then substituted back into equation (6) subject to the boundary condition that the number of unatomized analyte atoms is $[N_w^0]$ at $t = 0$ and $[N_w]$ at time t :

$$-\int_{N_w^0}^{N_w} [N_w]^{-n} d[N_w] = \int_0^t nk_1 dt$$

which can be solved for $n \neq 0$ and $n \neq 1$ to yield¹⁶

$$\begin{aligned} [N_w]^n &= [N_w^0]^n \\ &\times \left(1 + (n-1)[N_w^0]^{n-1} \int_0^t nk_1 dt \right)^{n/(1-n)} \end{aligned} \quad (7)$$

and, for $n = 1$ to yield

$$[N_w] = [N_w^0] \exp\left(-\int_0^t k_1 dt\right) \quad (8)$$

Substituting equation (7) into equation (6) and arranging terms yields

$$A = \beta Q n k_1 [N_w^0]^n \times \left(1 + (n-1)[N_w^0]^{n-1} \int_0^t n k_1 dt\right)^{n(1-n)} \quad (9)$$

Substituting equation (8) into equation (6) gives

$$A = \beta Q k_1 [N_w^0] \exp\left(-\int_0^t k_1 dt\right) \quad (10)$$

At the very beginning of the absorbance signal profile $\int_0^t k_1 dt \rightarrow 0$. Hence, applying the Arrhenius law to k_1 in equations (9) and (10) and taking natural logarithms of both sides of the resulting two equations we obtain the following expression (for $n \neq 0$):

$$\ln A = -E_a/RT + Z \quad (11)$$

where $Z = \ln(\beta Q [N_w^0] k_\infty)$ and is a constant, R is the gas constant, and T is the absolute temperature. By use of the transition-state theory Sturgeon *et al.*⁴ have derived equation (11) from a general relationship between k_1 and $T^a \exp(-\Delta G^{0*}/RT)$, where ΔG^{0*} is the standard free energy change of activation and $a = 1$. Equation (11) is valid for any order of reaction for atom release except for $n = 0$, whereas the other methods are valid only when atom formation follows a first-order reaction.

L'vov¹⁷ has reported that with the Massmann-type graphite furnace integrated absorbance has a much greater potential than peak-height absorbance for giving absolute measurement of absorbance. Use of integrated absorbance in an Arrhenius-type equation will increase the temperature range usable for collecting absorbance data for Arrhenius plots. For this, equation (6) is used to obtain integrated absorbance. Rearranging and integrating this equation, subject to the boundary condition that $[N_w] = 0$ at $t = \infty$ and $[N_w]$ at time t , gives

$$[N_w] = (1/\beta Q) \int_t^\infty A dt \quad (12)$$

Similarly, equation (6) can be integrated, subject to the boundary condition that $[N_w] = [N_w^0]$ at $t = 0$ and $[N_w]$ at time t , to yield

$$[N_g] = (1/\beta Q) \int_0^t A dt \quad (13)$$

Equations (13) and (14) were also derived by Smets⁵ and used by Bass and Holcombe.¹⁰ Substituting equation (13) into equation (6) gives:

$$k_1 = cA \left(\int_t^\infty A dt\right)^{-n} \quad (14)$$

where

$$c = n^{-1}(\beta Q)^{n-1}$$

It is of interest to note that β will appear in equation (14) only for $n \neq 1$. We will describe later in this paper how equation (14) can be used to determine E_a from the absorbance signal profile by a method (named the method of calculation) without recourse to Arrhenius plots, provided that the value of n is known. The value of n can be determined at the absorbance maximum by the method reported in another publication from this laboratory.¹⁶ For $n = 1$, equation (14) reduces to:

$$k_1 = A \left(\int_t^\infty A dt\right)^{-1} \quad (15)$$

which is another form of the Smets equation.⁵ Other forms of equation (15) have been developed by Frech *et al.*,⁶ Bass and Holcombe,¹⁰ L'vov *et al.*,¹⁸ and Guerrieri *et al.*¹⁹ Application of the Arrhenius law equation (1) to k_1 in equation (15) allows E_a to be determined from a plot of $\ln(A/\int_t^\infty A dt)$ vs. $1/T$; the slope equals $-E_a/R$, yielding the value of E_a .

Absorbance profile obtained with a constant heating rate of the atomizer. Mathematical treatment of atomization under non-isothermal conditions is simplified if the atom release process follows first-order kinetics and the temperature is increased at a constant heating rate, α , from an initial temperature, T_i (kelvin) to the final temperature T (kelvin):

$$T = \alpha(t_0 + t'') = \alpha t \quad (16)$$

where t_0 is the time when the temperature of the tube wall is T_i , t'' is the time required for the temperature to increase from T_i to T , and t is the time that would elapse if the heating were started at absolute zero.

Substituting equation (16) into equation (1) (the Arrhenius law) gives

$$k_1 = k_\infty \exp(-\epsilon/t) \quad (17)$$

where

$$\epsilon = E_a/\alpha R \quad (18)$$

In the integrated form equation (17) becomes

$$\int_0^t k_1 dt = \int_0^t k_\infty \exp(-\epsilon/t) dt \quad (19)$$

If high heating rates are excluded, the integral $\int_0^t k_\infty \exp(-\epsilon/t) dt$ in (19) can be approximated by the expression (see Appendix A):

$$\int_0^t k_1 dt = t^2 \epsilon^{-1} k_\infty \exp(-\epsilon/t) \quad (20)$$

Substituting (15) into (20) and taking into account equations (16) and (18) yields

$$-\ln \left(\frac{\int_t^\infty A dt}{\int_0^\infty A dt} \right) = T^2 (\alpha^2 \epsilon)^{-1} k_\infty \exp(-E_a/RT) \quad (21)$$

which can be rearranged to give

$$y = v \exp(-E_a/RT) \quad (22)$$

where

$$y = -\ln \left(\frac{\int_t^\infty A dt}{\int_0^\infty A dt} \right) / T^2 \quad (23)$$

and $v = k_\infty (\alpha^2 \epsilon)^{-1}$, which is a constant.

The terms on the right-hand side of (23) are experimentally measurable. Taking natural logarithms of both sides of (22) gives

$$\ln y = -E_a/RT + \ln v \quad (24)$$

A plot of $\ln y$ vs. $1/T$ should be linear with a slope $-E_a/R$ and an intercept $\ln v$.

Determination of activation energy. As a by-product of the mathematical formulation above, the activation energy, E_a , can be determined directly with any data points from the initial appearance of the absorbance signal to its maximum, by using equation (21), provided that atom formation follows first-order kinetics. This method allows a cross-check of the activation energy values that are obtained graphically from Arrhenius plots. From equation (21) for a constant heating rate of the atomizer, the activation energy, E_a , can be expressed by (see Appendix B):

$$E_a = -(ART^2)(\gamma \ln \Psi)^{-1} \quad (25)$$

where

$$\gamma = \alpha \int_t^\infty A dt$$

and

$$\Psi = \int_t^\infty A dt / \int_0^\infty A dt$$

A , T and the other terms (except R , which is the gas constant) on the right-hand side of equation (25) are experimentally measurable.

An Arrhenius-type equation developed by taking atom redeposition into account

The following approximations are used to simplify the mathematical treatment: (a) all unatomized analyte atoms are at the same temperature at the time of atomization; (b) atom formation and redeposition of gaseous atoms on the graphite surface follow first-order kinetics; (c) the rate of release and the redeposition of analyte atoms in the gas flow interrupt mode of operation are equal;¹⁹ (d) rate constants of both atom formation and redeposition are approximated by the Arrhenius law; (e) the atomization occurs at a constant low heating rate.

With these assumptions the following reaction scheme is proposed:

where N_w is the number of analyte entities on the graphite surface at time t , and N_g is the number of gaseous analyte atoms, k_1 and k_2 are first-order rate constants for atom release from and redeposition of atoms on the graphite surface, respectively, N_{lost} is the number of analyte atoms lost from the analysis volume at time t , and k_3 is the first-order rate constant for analyte atom loss. In the gas flow interrupt mode of operation we assume that the transformation of N_g into N_{lost} is much slower than the rate of formation of N_g and the rate of the reverse reaction (back to N_w). Hence, as a first approximation, k_3 may be ignored in the rate equation for N_g :

$$d[N_g]/dt = k_1[N_w] - k_2[N_g] \quad (27)$$

Using assumption (c), at equilibrium we can rewrite (27) as

$$0 = k_1[N_w] - k_2[N_g]$$

or,

$$k_1/k_2 = [N_g]/[N_w] \quad (28)$$

For the gas flow interrupt mode of operation, $[N_g]$ and $[N_w]$ can be expressed by the following two equations:

$$[N_g] = (1/\beta Q) \langle k_2 \rangle \int_0^t A dt \quad (29)$$

and

$$[N_w] = (1/\beta Q) \langle k_2 \rangle \int_t^\infty A dt \quad (30)$$

where $\langle k_1 \rangle$ and $\langle k_2 \rangle$ are the mean values of k_1 and k_2 over the indicated time interval. Substituting (29) and (30) into (28) and rearranging terms gives

$$k_1/k_2 = \int_0^t A dt / \int_t^\infty A dt \quad (31)$$

Here it is assumed that $\langle k_1 \rangle = \langle k_2 \rangle$ as done by Smets.⁵ Applying the Arrhenius law [equation (1)] to k_1 and k_2 in (31), and taking natural logarithms of both sides of the resulting equation, yields

$$\ln \varphi = -\Delta E_a/RT + X \quad (32)$$

where

$$\varphi = \left(\int_0^t A dt / \int_t^\infty A dt \right)$$

and

$$X = \ln(k_{1\infty}/k_{2\infty})$$

and ΔE_a is the difference between the energy of activation for release of analyte atoms from the graphite surface and the energy of activation for redeposition of analyte atoms on the graphite surface, and $k_{1\infty}$ and $k_{2\infty}$ are pre-exponential factors in the Arrhenius law corresponding to rate constants k_1 and k_2 , respectively. A plot of $\ln \varphi$ vs. $1/T$ should be linear with a slope of $-\Delta E_a/R$ and intercept X .

EXPERIMENTAL

Apparatus

A Perkin-Elmer model 503 atomic-absorption spectrophotometer, equipped with a deuterium-arc background corrector and a model 76B heated graphite atomizer (HGA) was used. The atomic-absorption spectrophotometer was modified in our laboratory to allow signals to be registered with a time constant of 20 msec. The graphite furnace was heated with a laboratory-made power supply capable of supplying variable heating rates up to 7 K/msec. Pyrolytically-coated graphite tubes (Perkin-Elmer part No. BOO91-504) were used. The signals were measured with a programmable model 4094 digital oscilloscope (Nicolet Instrument Corporation, Madison, WI, USA). The integrated absorbance was measured by use of a software package provided by Nicolet Instrument Corporation. A copper hollow-cathode lamp (Perkin-Elmer) was used and operated at a lamp current of 10 mA. The experimental parameters are given in Table 1.

Table 1. Experimental and instrumental parameters for atomization of copper from a pyrolytically-coated graphite-tube surface

Wavelength	324.8 nm
Charring temperature	800 K
Atomization temperature	2300 K
Heating rate	477 K/sec
Mass of copper (interrupt mode)	5 ng
Mass of copper (flow mode)	200 ng
Volume of test solution	10 μ l

Standard solutions

A stock 1000 μ g/ml copper solution was prepared by dissolving 0.5005 g of copper foil of 99.90% purity in 10 ml of Baker "Ultrex" nitric acid (1 + 1); the solution was boiled, cooled and diluted accurately to 500 ml with ultrapure water. Ultrapure water of resistivity 18.3 M Ω .cm was obtained direct from a Milli-Q2 water purification system (Millipore Corporation). Test solutions containing 5.00 ng/ml copper were prepared by serial dilution of the stock solution just before use. In all cases, 10 μ l of the test solution were injected into the graphite furnace with an Eppendorf micropipet fitted with a disposable plastic tip.

Gas

Argon (99.995% pure) was used as sheath gas and purge gas for the graphite furnace.

RESULTS AND DISCUSSION

Figure 1 shows a plot of the absorbance signals, both the peak-height and the integrated absorbance, given by 200 ng of copper as a function of the flow-rate argon (purge gas) through the graphite furnace. The signals fall

Fig. 1. Absorbance signals of 200 ng of copper (as the nitrate) at a constant heating rate as a function of the flow-rate of argon: (A) peak-height absorbance; (B) integrated absorbance.

Fig. 2. Arrhenius-type plots from this work compared with those of Sturgeon *et al.*⁴ and Smets.⁵ The ordinate, $\ln \Omega$, stands for: (A) $\ln \phi$ vs. $1/T$, equation (32); (B) $\ln y$ vs. $1/T$, equation (24); (C) $\ln(A/\int_0^\infty A dt)$ vs. $1/T$, equation (15); (D) $\ln A$ vs. $1/T$, equation (11).

rapidly before levelling off at high flow-rates, which can be explained as follows. At low flow-rates of argon, the supply function is much larger than the removal function; at high flow-rates of argon, the removal function is much larger than the supply function. Therefore, at the high argon flow-rate of 625 ml/min (*i.e.*, under the increased forced convection) the supply of atoms is much slower than their removal, and hence is the rate-determining step.

Figure 2 shows curves of two Arrhenius-type plots (curves A and B) from this work compared with those of Sturgeon *et al.*,⁴ curve C, and Smets,⁵ curve D. The plots from the four equations [(11), (15), (24) and (32)] were drawn by normalizing all data points to equation (15). Figure 2 shows that curves A and B obtained from equations (24) and (32) are closer to linearity over a greater range of data points (from the beginning to the maximum of the absorbance signal profile) than curves C and D obtained from equations (11) and (15). However, the data points (near extreme right of Fig. 2) taken at the beginning of the absorbance signal profile give practically linear curves for all four equations.

In Fig. 2, the plot of $\ln A$ vs. $1/T$, curve D, was drawn by using data points from the very beginning of the absorbance signal profile to its maximum. In order to test the reproducibility, three replicate determinations of the activation energy were made from Fig. 2, by use of the first few data points taken from the very beginning of the absorbance signal profile. The choice of these data points was based on the assumption that this plot ($\ln A$ vs. $1/T$, curve D) was valid only for these data points, as explained in the theory section (equation (11)). Table 2 (first horizontal row) summarizes the E_a values from these three replicate determinations.

The activation energy determined from the plot of $\ln(A/\int_0^\infty A dt)$ vs. $1/T$, (Fig. 2) curve C, with the data points taken from the very beginning of the absorbance signal profile are also shown in Table 2 (second horizontal row) for three replicate determinations. It should be noted here that in Fig. 2, both methods *i.e.*, $\ln A$ vs. $1/T$ and $\ln(A/\int_0^\infty A dt)$ vs. $1/T$ plots, curves D and C, respectively, have been developed with the same mathematical treatment except for the order of reaction. In spite of the different assumptions for the order of reaction, good agreement between the two plots is observed, in Fig. 2, at the onset of the Arrhenius-type plot. The activation energy values obtained by the two methods above lead to the following conclusion about the order of reaction for the atomization of copper. Since both plots give closely agreeing values for E_a , and the order of reaction for one plot is assumed to be unity, the order of reaction for the other plot must also be unity. Thus, it may be concluded that the order of reaction has no effect on the determination of activation energy for atomization of copper by these two equations under these experimental conditions provided that the data are taken from the very beginning of the absorbance signal profile. It should be noted that one of the

*Calculated by using data from the initial segment, *i.e.*, near the appearance temperature of the absorbance signal.

†Calculated by using data from the top segment of the absorbance signal, *i.e.*, long after the appearance temperature of the absorbance signal.

serious limitations of using the $\ln A$ vs. $1/T$ plots, curve D (Fig. 2) to obtain activation energy is that the condition that the integral $\int_0^t k_1 dt \rightarrow 0$ in equations (9) and (10) is fulfilled only by the data points near the very beginning of the absorbance signal profile, where the value of the integral is extremely small and can be taken as equal to zero. Activation energy plots drawn with data points corresponding to longer times do not fulfill this condition, and hence such plots bend towards the abscissa soon after the initial data points (*i.e.*, after the very beginning) of the absorbance signal profile. However, the method based on the $\ln A$ vs. $1/T$ plot can be used to obtain activation energy for an atomization reaction of any order provided that the data are taken near the very beginning of the absorbance signal profile. The method is also useful when the order of reaction for the atomization reaction is not known.

The activation energy values obtained from the three replicate determinations by using a plot of $\ln y$ vs. $1/T$, curve B (Fig. 2) are also given in Table 2 (third horizontal row). The increase in the range of data points for linear plots for obtaining the activation energy by using $\ln y$ vs. $1/T$, curve B, results from using integrated absorbance in developing the method. The reliability of the activation energy values obtained from curve B can be tested by using the proposed method of calculation by equation (25). The activation energy values from the two methods [equations (24) and (25)] should be comparable. Table 3 shows the repro-

ducibility [of activation energy values obtained from equation (25)] of three replicate determinations; these values may be compared with those obtained graphically (Table 2). The following conclusions can be drawn from Tables 2 and 3: the data taken from the very beginning of the absorbance signal profile to the absorbance maximum and used in the Arrhenius plots give activation energy values in agreement with those obtained graphically; the results marked with a superscript dagger (and obtained from the data points from the high-temperature parts of the Arrhenius plots) agree among themselves. These results show the usefulness of equation (25) for obtaining the activation energy by using any data points from the beginning of the absorbance signal profile to its absorbance maximum.

The plot of $\ln \phi$ vs. $1/T$, curve A, Fig. 2, shows a longer linear range of data points than that of the other Arrhenius plots. This improvement is probably the result of taking atom redeposition into account. Analyte atoms initially generated from the sample are redeposited onto the graphite surface, and are subsequently released at higher temperatures, as reported by Black *et al.*²⁰ This may cause a curvature in the Arrhenius plot if the atom redeposition is not taken into account. For the data points taken from the beginning of the absorbance signal profile, this plot agrees very well with the other Arrhenius plots (Fig. 2). This agreement may be attributed to insignificant redeposition of copper, and hence, insignificant

Fig. 3. A plot of $\ln[A/(A_m - A)]$ vs. $1/T$ used by Chung.⁷

desorption of copper atoms near the appearance temperature. Table 2, first horizontal row (curve A, Fig. 2) shows that closely agreeing values of the activation energy are obtained from the data points taken at longer times *i.e.*, some time after the appearance of the absorbance signal.

For comparison, a plot of $\ln[A/(A_m - A)]$ vs. $1/T$ is shown in Fig. 3. This kind of Arrhenius plot was used by Chung⁷ for elucidating atomization mechanisms in GFAAS. Figure 3 shows that the slope increases asymptotically for the data points taken after the initial few data points of the absorbance signal profile, making kinetic information on the absorbance signal profile after the initial few data points questionable. Several research workers^{4,5,10,19} have reported that the Arrhenius plots bend towards the abscissa as they approach the data for the absorbance maxima. However, the activation energy values obtained by using the data near the very beginning of the absorbance signal profile (Table 3) are satisfactory and can be used to elucidate atomization mechanisms which are valid for atomization reactions occurring near the beginning of an absorbance signal profile.

MECHANISMS OF ATOMIZATION

From published reports^{4,5,7,10,20,21} on activation energy for copper in GFAAS, it is clear that the reported activation energy values are widely divergent and the reason for this divergence still remains unclear. The difference in the reported values of E_a for copper atomization is in many cases due to curvatures in the Arrhenius plots used by the workers to obtain the activation energy values. Arthur and Cho²¹ obtained an E_a value of 265 kJ/mole under vacuum conditions; Smets⁵ reported 310

kJ/mole; Sturgeon *et al.*,⁴ 322 and 184 kJ/mole (for two different atomization mechanisms) and Chung⁷ 338 and 202 kJ/mole (for two different atomization mechanisms) under normal operating conditions. Using the Monte Carlo simulation technique, Black *et al.*²⁰ obtained 126 kJ/mole for a first-order release process for copper from a sub-monolayer coverage on the graphite tube surface.

The E_a values above range from the low value of 126 kJ/mole obtained from the Monte Carlo simulation technique, through 202 kJ/mole obtained from a higher-temperature region, to a still higher value, 338 kJ/mole, obtained from a lower-temperature region of the Arrhenius plots. This highest value correlates with the heat of sublimation of copper, $\Delta H_s = 338$ kJ/mole,²² whereas the lower values of E_a have been accounted for differently by different workers.^{4,5,7,20,21}

In this work, by deriving Arrhenius-type equations that are capable of giving data points covering a wider range of temperatures for linear activation energy plots, we have attempted to eliminate some of factors that cause curvatures in Arrhenius-type plots. Also, we have given a method which enables the E_a value to be determined by using any data points from the beginning of the absorbance signal profile to its absorbance maximum; this also allows a cross-check of the E_a value obtained graphically.

The E_a values in Tables 2 and 3 obtained by using data points corresponding to the appearance time of the absorbance signal and some later times can be used to elucidate the mechanism of copper atomization reaction as follows. Copper nitrate (taken as an aqueous solution) is reduced to free copper metal atoms on being heated in the graphite furnace.^{4,7,20,21} The energy required to release copper atoms from the graphite tube surface is not known for certain. Some authors⁴ have assumed that this energy is the heat of vaporization of the pure copper metal, which can be equated with the energy of desorption of copper from the graphite tube surface. However, the energy of desorption of an analyte metal from rough surfaces, such as graphite surfaces, may have different values because the analyte atoms may be trapped inside the surface at different depths and inside tortuous channels, resulting in a multitude of different energies being required to release them. Even though the pyrolytically-coated graphite tube possesses a smooth surface on a macroscopic scale, the surface is rough on a

Table 4. Correlation of ΔH_{273}^0 for sublimation of copper, carbon reduction of copper oxide, and dissociation of copper oxide, with the experimental activation energy

338	46	389	402	343	338

microscopic scale, and it is reasonable to conclude that the energies required to release copper atoms from such a rough surface will have different values, depending on the barrier encountered by the copper atoms in diffusing to the surface and being released from it. If the surface is molecularly flat and there is no significant interaction between the copper atoms and the surface, the activation energy for release of copper atoms from that surface should have a single value.

Interpretation of activation energy values

Tables 2 and 3 show that the E_a values obtained in this work can be subdivided into two classes, depending on the time (*i.e.*, the temperature) on the absorbance signal profile at which the data for calculating the E_a values were taken. Regardless of the method for determining the activation energy, the E_a values corresponding to data points at or immediately after the appearance temperature of copper, *i.e.*, at low temperatures, are consistently high, and those corresponding to data points at longer times after the appearance temperature, *i.e.*, at high temperatures, are consistently low (Tables 2 and 3). There is also a set of E_a values in Table 3 that are shown as corresponding to data points which are in between the "low" and the "high" temperature region (the so-called "transition region").

As can be seen from Table 4, the low-temperature value of the experimental activation energy (the median value is 338 kJ/mole, Table 3) correlates very well with the sublimation enthalpy of pure copper metal and also with the dissociation energy of $\text{CuO}_{(g)}$ (343 kJ/mole), whereas the high-temperature E_a values are quite different from any values in Table 4. In order to consider the possibility of the reaction, $\text{CuO}_{(g)} \rightarrow \text{Cu}_{(g)} + \text{O}$, as a pathway for $\text{Cu}_{(g)}$ it is necessary to know the energy required to sublime $\text{CuO}_{(s)}$ and the thermal stability of $\text{CuO}_{(g)}$ at elevated temperatures. The high-temperature decrease in the experimental activation energy values may be attributed to the desorption of copper from a graphite tube

surface which was initially clean. Copper has been reported^{5,12} to undergo short-range adsorption-desorption with increasing time (temperature) of atomization, which is particularly important in the long (28 mm), pyrolytically-coated graphite tubes used in this work. It should be noted that the low-temperature E_a values have been obtained by using data points near the appearance time (*i.e.*, appearance temperature) of copper, at which the loss of $\text{Cu}_{(g)}$ is assumed to be almost nil, whereas the high-temperature E_a values have been obtained by using the data points corresponding to much longer times, at which the loss of $\text{Cu}_{(g)}$ by condensation onto the graphite tube surface is substantial. The E_a values shown in Table 3, which have been obtained by using the data points from the "transition region" reflect the increasing contribution of the adsorbed Cu atoms to the $\text{Cu}_{(g)}$ as the atomization time (temperature) increases. As rightly pointed out by Holcombe⁹ and Bass and Holcombe¹⁰ there should be no single value for the activation energy except within strictly defined limits.

APPENDIX A

Solving the integral $\int_0^t k_\infty \exp(-\epsilon/t) dt$ in equation (19)

Let

$$x = \epsilon/t \quad (1A)$$

then

$$dx = -\epsilon/t^2 dt \quad (2A)$$

Substitute equation (1A) in equation (2A) for t

$$dt = -\epsilon/x^2 dx \quad (3A)$$

Taking into account (1A) and (3A) gives

$$\int_0^t k_\infty \exp(-\epsilon/t) dt = \epsilon k_\infty \int_x^\infty x^2 e^{-x} dx \quad (4A)$$

From mathematical tables,

$$\int_x^\infty x^{\nu-1} e^{-\mu x} dx = \mu^{-\nu} \Gamma(\nu, \mu x) \quad (5A)$$

Therefore,

$$\begin{aligned} \int_0^t k_\infty \exp(-\epsilon/t) dt \\ = \epsilon k_\infty \int_x^\infty x^{-2} e^{-x} dx = \epsilon k_\infty \Gamma(-1, x) \end{aligned} \quad (6A)$$

Again, from mathematical tables,

$$\Gamma(-n, x) =$$

$$(-1)^n/n! \left(E_1(x) - e^{-x} \sum_{n=0}^{n-1} [(-1)^n n! / x^{n+1}] \right) \quad (7A)$$

where

$$E_1(x) = \Gamma(0, x) \quad (8A)$$

For $n = 1$, (7A) becomes

$$\Gamma(-1, x) = E_1(x) - x^{-1} e^{-x} \quad (9A)$$

The solution for $E_1(x)$ can be obtained from mathematical tables as follows:

$$E_1(x) = x^{-1} e^{-x} \sum_{j=0}^{\infty} ((-1)^j j! / x^j) \quad (10A)$$

Substituting (10A) into (9A) gives

$$\Gamma(-1, x) = x^{-1} e^{-x} \sum_{j=0}^{\infty} ((-1)^j j! / x^j) - x^{-1} e^{-x} \quad (11A)$$

If $x \gg 1$

$$\Gamma(-1, x) = x^{-2} e^{-x} \quad (12A)$$

Substituting (12A) into (6A) and considering (1A) gives

$$\int_0^t k_\infty \exp(-\epsilon/t) dt = (t^2/\epsilon) k_\infty \exp(-\epsilon/t) \quad (13A)$$

A similar treatment has been published in the literature.²³

APPENDIX B

Starting with equation (21) in the theory section:

$$\begin{aligned} \ln \left(\int_t^\infty A dt / \int_0^\infty A dt \right) \\ = T^2 (\alpha^2 \epsilon)^{-1} k_\infty \exp(-E_a/RT) \end{aligned} \quad (1B)$$

The Arrhenius law is

$$k_1 = k_\infty \exp(-E_a/RT) \quad (2B)$$

All the terms above have been defined previously. Substituting (2B) into (1B) for $k_\infty \exp(-E_a/RT)$ yields

$$-\ln \left(\int_t^\infty A dt / \int_0^\infty A dt \right) = T^2 (\alpha^2 \epsilon)^{-1} k_1 \quad (3B)$$

k_1 can be expressed by the following equation [see equation (15) in the theory section]:

$$k_1 = A \left(\int_t^\infty A dt \right)^{-1} \quad (4B)$$

Substituting (4B) into (3B) for k_1 gives

$$\ln \left(\int_t^\infty A dt / \int_0^\infty A dt \right) = T^2 (\alpha^2 \epsilon)^{-1} A \left(\int_t^\infty A dt \right)^{-n} \quad (5B)$$

Taking into account (18) (theory) and rearranging terms in (5B) gives the following expression for the activation energy, E_a :

$$E_a = -(ART^2) \left(\alpha \int_t^\infty A dt \ln \left[\int_t^\infty A dt / \int_0^\infty A dt \right] \right)^{-1} \quad (6B)$$

$$= -(ART^2) (\gamma \ln \Psi)^{-1} \quad (7B)$$

where

$$\gamma = \alpha \int_t^\infty A dt$$

and

$$\Psi = \int_t^\infty A dt / \int_0^\infty A dt$$

ON-LINE PHOTO-OXIDATION FOR THE DETERMINATION OF ORGANOARSENIC COMPOUNDS BY ATOMIC-ABSORPTION SPECTROMETRY WITH CONTINUOUS ARSINE GENERATION

RAJA H. ATALLAH and DAVID A. KALMAN*

Department of Environmental Health, SC-34, University of Washington, Seattle, WA 98195, U.S.A.

(Received 10 May 1990. Revised 19 June 1990. Accepted 21 June 1990)

Summary—A method has been developed for on-line conversion of organoarsenicals into arsenate, which is readily detected by atomic-absorption spectrometry with continuous arsine generation. The photo-reactor consists of a mercury lamp wrapped with 5 m of PTFE tubing (0.5 mm i.d.). The photo-oxidation conditions were optimized, with a flow-injection analysis procedure, for arsenobetaine, monomethylarsonic acid, dimethylarsinic acid, *o*-arsanilic acid, and phenylarsonic acid, all organoarsenicals of biological and environmental importance. Solutions were continuously pumped at a flow-rate of 2.0 ml/min and combined with a stream of potassium persulfate (flow-rate 0.6 ml/min) before entering the photo-reactor. With reactor dwell times of 36 sec, conversion efficiencies for these compounds were above 95% under these conditions. Interfacing of this flow-through conversion and detection system with a chromatographic inlet permits real-time analysis of mixtures of these organoarsenic compounds, in a manner suitable for environmental or biomedical samples.

Arsine-generation atomic-absorption spectrometry (AG/AAS) offers a highly sensitive, selective and simple technique for the determination of arsenic in solutions, at the nanogram level.¹ The technique can be used to differentiate between arsenic species that form volatile arsenic compounds,^{2,3} and can be easily combined with continuous flow systems.⁴⁻⁶

In speciation methods where a chromatographic separation scheme precedes the arsenic determination, detection by atomic-absorption spectrometry or inductively-coupled plasma atomic-emission spectrometry (ICP/AES) based on continuous flow is preferable to batch methods. Graphite-furnace atomic-absorption spectrometry (GFAAS), although permitting sensitive determination of all forms of arsenic, is not convenient as a detector for use with chromatographic eluents, owing to the large number of GFAAS measurements that are needed for each chromatogram, and the inability to monitor the separations in real time.⁷

Currently, ICP/AES is the most widely used method of detection in liquid chromatography arsenic speciation studies,⁸⁻¹⁰ though this technique lacks the high sensitivity of AG/AAS. In

recent studies, liquid chromatography coupled with ICP/AES and mass spectrometry (LC-ICP-MS) has been used to achieve higher sensitivities for arsenic,¹¹⁻¹³ but because of the high cost of ICP-MS equipment the technique is still beyond the reach of most laboratories.

The determination of organoarsenicals in environmental and biological samples has been of interest to various research groups.¹⁴⁻¹⁶ The major naturally occurring arsenic compounds that can be found in these sample types are the two inorganic forms of arsenic, As(III) and As(V), plus organic forms such as monomethylarsonic acid (MMA), dimethylarsinic acid (DMA), and other organoarsenicals such as arsenobetaine (AsB).¹⁷ The toxicity of these compounds decreases in the order As(III) > As(V) > MMA > DMA. Several studies have revealed that arsenobetaine is the major arsenic compound found in many sea-foods,¹⁷ and is non-toxic.¹⁸ Since many of these forms of organic arsenic, including arsenobetaine, would not be detected in an assay based on arsine, such as AG/AAS, the presence of these arsenic species in foodstuffs or tissues must be inferred by comparing the amount of total arsenic with that of arsine-forming species when such methods are used. The significance of the question of arsenic species in foodstuffs is illustrated

*Author for correspondence.

by the U.S. Environmental Protection Agency 1984 assessment of arsenic exposure in the U.S. population, which considered the bulk of dietary arsenic intake as being comprised of organoarsenic species that are not thought to have any toxic properties,¹⁴ without citing any detailed evidence for this assumption. An arsenic speciation assay having the sensitivity and specificity of arsine methods and the ability to detect all of the major arsenic species found in food and human biological samples is therefore of interest.

In order to utilize the AG/AAS technique for the determination of all soluble arsenic species, conversion of organoarsenicals into hydride-reactive arsenic is required. This might be achieved by acid or base batch digestion procedures, in which all arsenic species are converted into inorganic arsenic,¹ but these procedures are laborious, slow, and impractical when large numbers of samples are to be analyzed. In addition, batch digestion is not compatible with speciation assay, and is subject to contamination from digestion reagents. Andreae has reported¹⁶ that some organoarsenicals such as arsenobetaine are unusually resistant to acid digestion and require heating with magnesium oxide in a muffle furnace for complete decomposition. Organoarsenicals have been reported to be completely decomposed by wet oxidation with a nitric-sulphuric-perchloric acid mixture.¹⁹

Previous studies have shown that organoarsenicals can be made to undergo photo-oxidation in the presence of different mineral acids²⁰ or a combination of nitric acid and hydrogen peroxide.²¹ Cullen and Dodd reported the batch photo-oxidation of organoarsenic compounds to arsenate,²⁰ by ultraviolet irradiation in fused-silica tubes for 1 hr with a medium-pressure mercury lamp. The samples were analyzed by batch hydride generation and graphite-furnace AAS.

On-line ultraviolet irradiation procedures have been employed to improve the selectivity and sensitivity of detection of many organic compounds. The first commercially available flow-through photo-reactor was recently introduced.²² All of these systems have been used for post-column derivatization of HPLC effluents to enhance the detection of a variety of organic compounds with fluorometric,^{23,24} and electrochemical detectors.^{24,25}

The use of continuous flow methods in hydride generation makes it possible to interface a liquid chromatography effluent stream with AAS⁶ or ICP/AES⁸ detectors. These systems allow continuous and direct transfer of the generated volatile arsine products to the detector. In previous studies of arsenic species distribution, we found that organic arsenic species exhibit different responses from those of inorganic arsenic in batch or continuous flow AG/AAS detection. This is due to differences in reaction kinetics, volatilities, and efficiency of flame conversion of the corresponding arsines into elemental arsenic. Such differences affect the sensitivity of detection for each species and may introduce bias for some species. These considerations led us to develop a procedure that would allow the on-line formation of volatile arsine species from organoarsenicals that are resistant to hydride formation.

In this paper we report the successful on-line photo-oxidation of organoarsenicals to inorganic arsenic. The reaction is used within a flow-injection analysis (FIA) system. The arsenate generated by oxidation of organoarsenicals is reduced to arsine and continuously detected by AAS.

EXPERIMENTAL

Apparatus

A schematic diagram of the on-line photo-oxidation hydride generation/atomic-absorption detection system is shown in Fig. 1.

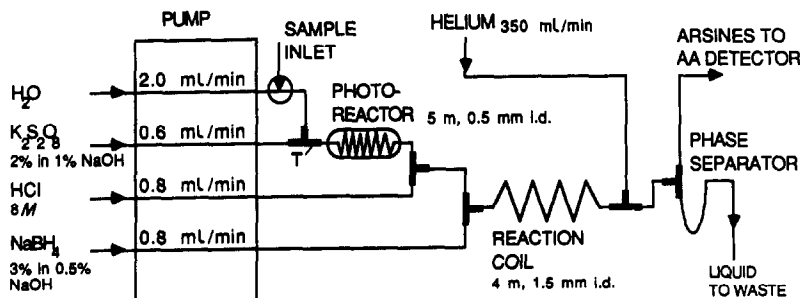

Fig. 1. On-line photo-oxidation/hydride generation/atomic-absorption system.

The components are a flow-injection hydride generation manifold, photo-reactor, gas-liquid phase-separator, and arsenic detector.

The FIA manifold is made with PTFE tubing and Kel-F T-fittings. Tubing lengths and diameters are shown in Fig. 1. A six-port Rheodyne type 50 low-pressure sample injection valve with a sample loop volume of 100 μ l is used to inject samples. Two Ismatec peristaltic pumps (Cole-Parmer) are used to pump the sample and reagent streams. The glass phase-separator used in the continuous arsine generation is similar to that described by Vijan and Wood.⁵

The photo-reactor unit is made from the mercury lamp of a portable ultraviolet light-source used for viewing samples of TLC plates (o.d. 1.5 cm, length 20 cm, Alltech). The lamp is wrapped with 5 m of 0.56-mm i.d. PTFE tubing. The source emits short wavelength light with $\lambda_{\text{max}} = 254$ nm. The unit is enclosed in aluminum foil to increase the light intensity reaching the coil and to prevent eye exposure to ultraviolet radiation.

The detector is a Perkin-Elmer atomic-absorption spectrometer Model 305 B, equipped with an arsenic electrodeless discharge lamp, monitored at 193.7 nm, and a hydrogen-flame combustion detection cell.² Absorption signals are recorded with a Hewlett-Packard model HP 3396A integrator. Peak heights and areas are obtained.

Batch photo-oxidation is performed with a photo-oxidation unit (Ace Glass, Vineland, NJ) which contains a high-pressure mercury lamp, 1200 W (o.d. 2.5 cm, length 45 cm, Hanovia), and an air fan to cool the unit and the sample tubes. Samples are placed in 150-ml fused-silica tubes and positioned around the lamp at a distance of 10 cm from it.

Reagents

The oxidizing solution, 20 mg/ml potassium persulfate (Fisher, purity 99.9%) in 10 mg/ml sodium hydroxide solution was freshly prepared before use. The reducing solution, prepared daily, was 30 mg/ml sodium tetrahydroborate (Alfa) in 5 mg/ml sodium hydroxide solution, and filtered before use.

Calibration standard stock solutions were prepared from sodium arsenate (Matheson, Coleman & Bell, OH, U.S.A.); sodium monomethylarsonate (MMA; Battelle NW, Sequim, WA); dimethylarsinic acid, (DMA; Sigma); phenylarsonic acid, (PAsA; Alfa); and *o*-arsanilic acid (*o*AsA; Aldrich). Arsenobetaine

was synthesized according to the method of Edmonds *et al.*²⁶ Diluted solutions were standardized against an inorganic arsenic(III) standard (NIST, SRM 3103) by graphite-furnace atomic-absorption spectrometry. All calibration and method development test solutions were prepared in 0.1M hydrochloric acid made with distilled demineralized water.

Method development

Photo-oxidation conditions were optimized by batch reactor tests. In each test, 10 ml of 2.5 ppm arsenobetaine solution containing the appropriate concentrations of oxidizing reagents were placed in fused-silica tubes and irradiated with the 1200 W source for 15 min. The initial selection of reagents was based on the mineral acids and oxidizing agents (such as hydrogen peroxide and persulfate) used earlier in lengthier batch photo-oxidation procedures.^{20,21} In later experiments, neutral and basic solutions were tested in the presence and absence of oxidizing agents. Photo-oxidation products were identified as inorganic arsenic, MMA, DMA, and trimethylarsine (TMA) by a previously described arsenic speciation scheme based on batch arsenic reduction and sparging, cryogenic trapping, thermal desorption and AAS detection.³

Conditions for the continuous flow generation of volatile arsines after the photo-oxidation were optimized with an arsenate solution and held constant throughout the photo-reactor optimization experiments. The stream leaving the photo-reactor (carrier flow 2.0 ml/min and oxidant flow 0.6 ml/min) was acidified by merging with a 0.8 ml/min flow of 8M hydrochloric acid before merging with a 0.8 ml/min flow of sodium borohydride solution. The concentration of sodium borohydride was kept high (30 or 40 mg/ml) as it was necessary to reduce excess of persulfate as well as the arsenate. The reduction reaction occurred in the reaction coil (4 m) and the arsine vapor generated was stripped with a 350 ml/min flow of helium before it reached the gas-liquid phase-separator. The separated gas was combined with hydrogen and air just before entering the combustion cell of the AAS detector. The resulting transient signals were recorded and integrated. In all the following experiments, the values obtained were the average peak areas of at least three sample injections of each test solution.

The photo-reactor system parameters were optimized with a 1 ppm AsB solution. The effect

of potassium persulfate concentration, photo-reactor coil length, and flow-rate of the carrier stream on the response signal were evaluated independently. The flow-rates of potassium persulfate solution, hydrochloric acid, and sodium borohydride solution were kept constant at 0.6, 0.8 and 0.8 ml/min, respectively.

The concentrations of persulfate solutions tested were 1, 5, 10, 20, and 45 mg/ml in 10 mg/ml sodium hydroxide solution. A 45 mg/ml solution was also prepared in distilled water. A saturated potassium persulfate solution contains approximately 50 mg/ml. The carrier stream flow-rate was kept at 2.0 ml/min; the reactor coil length was 5 m.

The effect of photo-reactor coil length was studied by wrapping 0.4, 0.75, 1.5, 2, 3.2, and 5 m of the PTFE tubing around the mercury lamp. The experiment was repeated at overall flow-rates of 1.0, 2.2, and 3.2 ml/min, with 20 mg/ml potassium persulfate. Standard As(V) solution was injected for comparison with AsB solution to correct for small variations in detection system response occurring with changes in the photo-reactor parameters.

The system response for several arsenic species under the optimum conditions found for the AsB solution was determined by using injections of 1 ppm solutions with the following conditions: (a) ultraviolet source off, without persulfate; (b) source on, with persulfate solution; (c) source off, with persulfate.

On-line detection of separated arsenic species was demonstrated by merging an ion-chromatograph effluent with the persulfate stream at point T in Fig. 1. AsB, MMA, DMA and As(V) were separated on a strong base anion-exchange column (Macherey-Nagel, Nucleosil 10 SB column, 250 mm × 4.6 mm i.d.) with 0.05M sodium phosphate buffer (pH = 7.4) at a flow-

rate of 1.5 ml/min. The sample volume injected was 200 μ l.

RESULTS AND DISCUSSION

The results of batch photo-oxidation reaction experiments are shown in Table 1. The arsenobetaine photo-oxidation products were identified as inorganic arsenic, monomethylarsonate, dimethylarsenate, and trimethylarsine. Little or no photo-conversion occurred in the presence of nitric acid and/or hydrogen peroxide. The best photo-oxidation was obtained in neutral or basic solutions with potassium persulfate present. Persulfate in basic medium converted AsB completely into inorganic arsenic, a specie that can easily be reduced to arsine and quantitatively measured. Results from batch photo-oxidation of 2.5 ppm solutions of MMA, DMA, PAsA and oAsA in 20 mg/ml persulfate solution in 50 mg/ml sodium hydroxide solution indicated complete decomposition of these compounds to give arsenate.

Basic sodium persulfate solution, which gave a single product in the batch procedure, was selected as the photo-oxidation medium of choice. On-line conversion was observed for injected AsB solutions mixed with basic persulfate solution when the photo-reactor was switched on. No signal was observed for AsB when the ultraviolet source was switched off and the response was reduced by 90% when the persulfate solution was prepared in distilled water instead of a basic solution.

The efficiency of photo-oxidation under the given experimental conditions was found to increase with increasing persulfate concentration, reaching a constant response of $97 \pm 2\%$ of that of As(V) at persulfate concentrations above 10 mg/ml. The efficiency of the

photoconversion reaction decreased when old persulfate solutions were used. Throughout this work, freshly prepared 10 or 20 mg/ml oxidant solutions were found necessary to maintain constant and optimal photo-conversion. The persulfate solution decomposed with time and was stable for only one day.

The effect of coil length or carrier flow on photoconversion efficiency showed a similar threshold effect, as shown in Fig. 2. Varying the residence time in the photo-reactor had the same effect, whether the variation was due to changes in reactor coil length or in pumping speed.

As an example, the 36 sec residence time for the 2 ml/min flow-rate was achieved by using a coil length of 5 m. For the experimental conditions studied, the optimal photo-reactor residence time was found to be 20–25 sec with coil lengths of 2 m or more, and pumping speeds of 1 ml/min.

The flow-through photo-reactor conversion efficiency for five arsenic species is shown in Table 2. Some of these species, such as MMA, DMA, and PAsA, are capable of direct detection by the arsine generation system, with responses different from that for arsenate. Without the presence of oxidant or the ultraviolet light source, the largest response was for As(III) and the lowest for oAsA. Because the continuous flow hydride system is optimized for rapid conversion of arsenate, arsine-forming species that react more slowly with borohydride, such as DMA, are detected with reduced response. For this reason, detection of DMA is only 23% as efficient as that of an equivalent amount of arsenate. oAsA response increased by 45% when persulfate was added, even without the ultraviolet light on. The decomposition of this compound to arsenate in the presence of persulfate was reported by Ricci *et al.*⁶ As(III) gave a higher response than As(V), owing to the ease of its reduction to arsine. The responses of the same solutions with ultraviolet irradiation indicated that As(III), MMA, oAsA and PAsA were completely converted into arsenate, and the DMA response increased from 23% to 92% of that for arsenate. Arsenobetaine, a species that could not be detected by conventional arsine assay, was found to give a response $\geq 97\%$ of that for arsenate.

The observed differences in the responses of the different arsenic species led us to assay the photo-reaction products of the different species formed by use of photo-reactor coil lengths of 3 and 5 m and 40 mg/ml persulfate solution. This was done by assaying the collected arsenic solutions pumped through the photo-reactor, for arsenic species. Speciation was achieved by means of an ion-chromatographic separation, as illustrated in Fig. 3. The results shown in Table 3 confirm that As(III), PAsA, and oAsA

Fig. 4. Calibration curves for As(V), AsB and DMA.

are completely converted into arsenate; MMA and DMA shows incomplete conversion into arsenate, which increases with increase in the coil length. Photo-oxidation of AsB produces arsenate, DMA and MMA. The different response of these intermediate photo-oxidation products during arsine generation can therefore account for the differences in detection efficiency presented in the last column of Table 2.

By use of a series of diluted calibration solutions and the flow-through detection system, response curves were obtained for standard As(V), AsB, and DMA solutions over the concentration range 0.1–2.5 ppm, as shown in Fig. 4. The linearity of response and the good precision at each calibration level demonstrate the suitability of this technique for quantitative multi-component analysis. As would be expected from the conversion efficiencies observed (Tables 2 and 3), the AsB plot overlapped the As(V) line, but the slope for DMA was lower.

Persulfate solution absorbs strongly in the ultraviolet region (maximum absorbance at

235 nm). It has been reported that persulfate solution under ultraviolet irradiation undergoes a photo-decomposition reaction giving highly reactive hydroxyl radicals which can result in the conversion of organic compounds into carbon dioxide.²⁷ We suggest here that photo-induced persulfate oxidation of organoarsenicals, giving arsenate, water, and carbon dioxide, is similarly mediated by hydroxyl radicals. A decrease in photoconversion was observed when ammonium persulfate was used instead of potassium persulfate. Interference from ammonium ions was examined for AsB solution prepared in ammonium phosphate solution. Other solutions were prepared in methanol and urea solution. Decreases of 67, 57, and 42% in signal response were observed for 1 ppm AsB solutions prepared in 0.05M ammonium phosphate, 95% v/v methanol and 10 mg/ml urea solutions, respectively. These results indicate that the photo-decomposition reaction is hindered by the presence of certain species. Therefore, to apply the photoconversion reaction to biological and environmental samples, evaluation of the

sample matrix for possible interferences is essential and sample pretreatment to remove these interferences may be needed.

CONCLUSIONS

Application of the arsine generation technique is limited to aqueous solutions of those arsenic species that undergo reduction with sodium borohydride to form volatile arsenic hydrides. Thus, many naturally occurring arsenic compound found in biological and environmental samples cannot be detected by this method. This study has demonstrated the feasibility of determination of selected organoarsenicals in solution by using on-line photo-conversion followed by a continuous flow arsine-generation/atomic-absorption system. A photo-oxidation conversion efficiency of above 95% was achieved for all arsenic species tested. Efficiencies can be further improved by increasing the reaction coil length, and using lower reagent flow-rates or (possibly) a higher intensity ultraviolet source.

The continuous flow photo-oxidation system has the advantage of being simple, fast, and free from cross-contamination. When used with liquid chromatography and AAS or ICP/AES detection, continuous flow photo-oxidation will increase the sensitivities for assay of organoarsenicals. The system might be adapted to other organohydride-forming elements, such as tin, selenium, and antimony, and organomercury compounds of environmental and biological importance. The photo-conversion of methylmercury into inorganic mercury has been demonstrated in our laboratory and will be the subject of a future paper.

A SOLVENT EXTRACTION-ATOMIC ABSORPTION TECHNIQUE FOR THE SIMULTANEOUS DETERMINATION OF LOW CONCENTRATIONS OF IRON, NICKEL, CHROMIUM AND MANGANESE IN DRINKING WATER

D. RAMESH BABU and P. R. NAIDU*

Department of Chemistry, Sri Venkateswara University, Tirupati 517502, India

(Received 9 May 1989. Revised 12 February 1990. Accepted 21 July 1990)

Summary—A simple and rapid method has been developed for the extraction of Fe, Ni, Cr and Mn in drinking water samples with a new reagent, pentamethylene dithiocarbamate, into methyl isobutyl ketone (MIBK) and their subsequent determination by atomic-absorption spectrometry. The extraction has been carried out at a high aqueous:organic phase ratio to achieve a 35-fold preconcentration factor. Extraction parameters and interference factors are discussed. The precision based on replicate analyses is between 3 and 10% for a concentration range of 2–250 $\mu\text{g/l}$. of the four metals. The detection limits (3σ) for Fe, Ni, Cr and Mn are 0.30, 0.36, 0.40 and 0.22 $\mu\text{g/l}$., respectively, corresponding to a metal concentration of 0.50 $\mu\text{g/l}$.

The determination of trace elements, particularly the heavy metals, has received increasing attention in pollution studies. The development of atomic-absorption spectrometry (AAS) by Walsh,^{1,2} however, provided a technique which has been particularly useful in the determination of trace metals because of its reduced susceptibility to interference. A number of techniques, including co-precipitation and co-crystallization,³ chelation-solvent extraction,⁴⁻⁹ chelating ion-exchange resins¹⁰⁻¹³ and electrolysis¹⁴⁻¹⁶ have been used for the preconcentration of metals. Solvent extraction of trace metals from water samples is a powerful technique for accomplishing preconcentration of trace metals to levels well above the normal instrumental detection limit and enhancement factors as high as 100 can easily be achieved. In addition, this technique is simple, fast, easy to manipulate, eliminates matrix effects and provides matrix normalization (*i.e.*, making the matrix of samples the same as that of the standard).

Most separation methods in use, however, are based on the formation of metal-dithiocarbamate complexes and their subsequent extraction into an organic solvent. The chelating agents, ammonium pyroolidinedithiocarbamate (APDC) and sodium diethyldithiocarbamate (NaDDC) are the two reagents most generally used for the complexation. Of these, APDC has

been found to be more suitable than NaDDC especially at low pH values.^{17,18} However, the use of APDC has certain disadvantages. Many workers have reported that the Mn-complex of APDC in MIBK (methyl isobutyl ketone) is extremely unstable and recovery is very poor.^{9,18-21} According to Sturgeon *et al.*⁹ determination of chromium is most imprecise at low concentration when APDC is used as a complexing reagent, owing to its poor extraction characteristics. Hence, we have attempted to overcome these difficulties by choosing pentamethylene dithiocarbamate (PMDTC), also known as piperidine dithiocarbamate (pipDTC), as a complexing reagent for the extraction of four trace elements (Fe, Ni, Cr, Mn) in natural drinking water supplies.

EXPERIMENTAL

Apparatus

Atomic-absorption measurements were recorded on a model 2380 Perkin-Elmer atomic-absorption spectrometer equipped with a standard burner for use with an air-acetylene flame. Standard hollow-cathode lamps were used as a line source for all elements.

An Elico Model LI-120 pH meter with combined glass electrode was used for pH measurements. Polyethylene 1-litre screw-cap bottles were used as the containers for water samples. All extraction studies were done in 500-ml borosilicate glass separatory funnels fitted with

*Author for correspondence.

Teflon stopcocks and polyethylene stoppers. Organic extracts were collected in 15-ml glass-stoppered borosilicate glass centrifuge tubes. MIBK was added with a 10-ml pipette. Other reagents were added with adjustable micro-pipettes with polypropylene tips. All the glass-ware was cleaned by the method described by Danielsson *et al.*⁷

Reagents and solutions

High-purity water was obtained by double distillation of demineralized water in a quartz still. This was used for cleaning and for preparation of standard solutions used for calibration.

Stock metal solutions which contained 1 mg/ml of each metal, were prepared with the pure metal for Fe and Ni. BDH AnalaR potassium dichromate and manganese sulphate were used for preparing Cr(VI) and Mn(II) solutions.

Mixed standards were prepared from stock solutions by progressive dilution and the concentrations were similar to those in the water samples.

Preparation of the sodium salt of pipDTC. Carbon disulphide (80 g) was slowly added to a solution of piperidine (85 g) in 25 ml of water at 5°, with constant stirring, followed by 40 g of sodium hydroxide dissolved in 20 ml of water.

The reagent solution was prepared by dissolving 1 g of the reagent in 100 ml of water, and contaminants, if any, were removed by shaking with 50 ml of MIBK.

A 0.5M ammonium acetate buffer was prepared and purified by addition of 5 ml of a 1% solution of purified pipDTC and extraction with 25 ml of MIBK. This was repeated until the aqueous layer was free from trace metal impurities and it was then stored in a clean 1-litre polyethylene bottle.

Redistilled commercial grade methyl isobutyl ketone and analytical reagent grade nitric acid were used.

Preservation and pretreatment of the samples were done as described in the literature.²²

Procedure

Water samples (350 ml) were transferred to 500-ml separatory funnels. Acetate buffer (2 ml) was added and the pH was adjusted to 4.0 ± 0.5 , followed by the addition of 5.0 ml of 1% pipDTC solution. The funnel was shaken well, 17 ml of MIBK were added and the mixture was shaken for 3 min. At equilibrium 7 ml of the solvent entered the aqueous phase owing to its

solubility, resulting in a 357:10 phase ratio. The organic phase was separated and analysed by AAS.

Standardization

Standard solutions were prepared with extracted water samples, to match the matrix of the standards to that of the samples. These samples were extracted two or three times with 10 ml of MIBK to ensure that the water was as free as possible from the trace metals under investigation. They were then combined and 350 ml portions were transferred to each of four separating funnels. The pH was adjusted and increasing amounts of the four metal solutions were added to give concentrations of 0, 2, 5 and 10 $\mu\text{g/l}$. The standards were then extracted by the recommended procedure with 10 ml of MIBK. The resulting extracts were used for calibration.

RESULTS AND DISCUSSION

Procedure optimization

The effect of pH on extraction efficiency was evaluated by performing extractions on 350 ml of water at different pH values ranging from 1 to 8 and containing 15 μg of Fe, Ni or Cr, or 50 μg of Mn the results are shown in Fig. 1.

The absorbance remains constant over the pH ranges 3.0–4.5 for Fe, 3.0–7.0 for Ni, 3.0–5.0 for Cr and 3.5–6.0 for Mn. Hence, extractions have been carried out over these pH ranges for the maximum recovery of the metals. A pH of 4.0 ± 0.5 was chosen for the simultaneous extraction of the four metals.

The solubility of MIBK in the aqueous phase was determined from the solubility data used for construction of a solubility curve, of the type described by Brooks *et al.*⁵ It was observed that 2.0 ml of MIBK dissolved in 100 ml of the aqueous phase on equilibration.

The stability of the complexes was measured by preparing a pipDTC extract in MIBK and comparing the absorbance of the "aged" samples to freshly extracted samples. The minimum times for which no appreciable loss of absorbance was noted are shown in Table 1.

Precision and recovery

The precision (expressed as the RSD) of the method was established by individually preparing ten solutions each containing the same amount of each of the four metals. The results are shown in Table 2 for a sample spiked

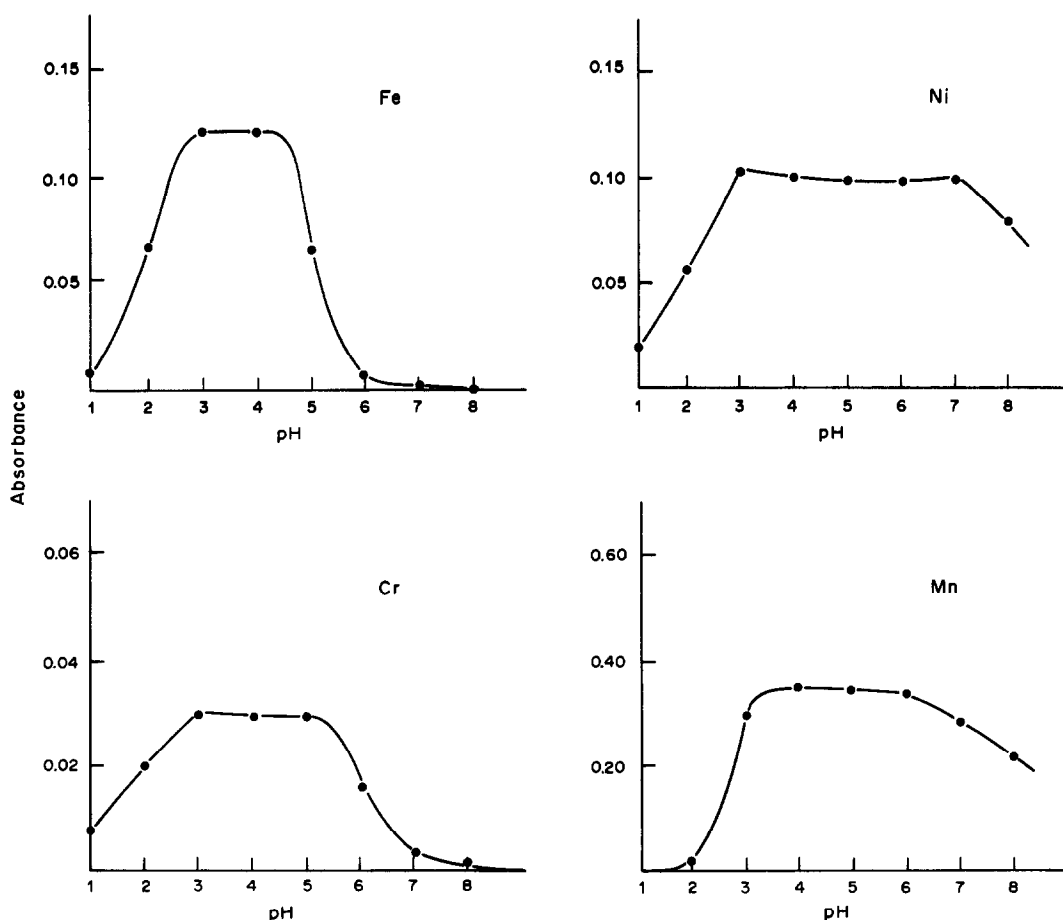

Fig. 1. Dependence of absorbance on pH of extraction.

with 2, 5, 25 and 250 $\mu\text{g/l.}$ of the metals and indicate that the precision ranges from 3 to 10%. This is comparable to that reported in the literature.⁴⁻¹¹

The recovery was computed by the method of Sturgeon *et al.*⁹ The results (Table 3) show that the extraction efficiency decreases considerably at concentrations of 250 $\mu\text{g/l.}$ for all four metals. Because a single extraction gives only partial recovery, it is essential to apply the complete procedure in preparing the calibration graph.

Table 1. Analytical parameters

Parameter	Fe	Ni	Cr	Mn
Minimum time for which complex is stable, <i>hr</i>	5	9	12	3
Limits of detection, $\mu\text{g/l.}$	0.30	0.36	0.40	0.22
Sensitivity, $\mu\text{g/l.}$	1.20	1.60	2.80	0.80
Linear working range, $\mu\text{g/l.}$	1-300	1.0-250	1.5-300	0.5-250

Sensitivity, detection limit and range of linearity

The sensitivity is expressed as the concentration which produces 1% absorption. The linear working range was determined by preparing a series of standards (0, 2, 5, 10, 25, 100, 250, 500 and 5000 $\mu\text{g/l.}$ of the metal) and after extraction their absorbance values were measured. The results are shown in Table 1.

The detection limits (based on 3 times the standard deviation of the blank) for Fe, Ni, Cr and Mn were evaluated for a concentration of 0.50 $\mu\text{g/l.}$ with a scale expansion of $A \times 10$ and an instrumental noise suppression of 4. The values are given in Table 1.

Table 2. Precision of the method for a spiked water sample

Concentration of spike, $\mu\text{g/l.}$	<i>n</i> *	RSD, %			
		Fe	Ni	Cr	Mn
2.0	10	8	9	10	6
5.0	10	6	7	9	4
25.0	10	5	6	7	3
250.0	10	3	6	3	6

*Number of observations.

Table 3. Recovery from a spiked water sample

Concentration of spike, $\mu\text{g/l.}$	Recovery*, %			
	Fe	Ni	Cr	Mn
2.0	92.0	92.7	92.0	92.5
5.0	93.0	91.0	92.0	94.0
25.0	91.0	90.8	91.0	94.7
250.0	90.4	90.5	90.7	93.4
500.0	82.7	74.3	78.5	73.7

*Calculated from $R = 100A_1/(A_1 + A_2 + A_3)$, where, A_1 , A_2 and A_3 are the signals from three successive extractions of an aliquot.

Table 4. Trace elements in drinking water

Water sample	Concentration, $\mu\text{g/l.}$			
	Fe	Ni	Cr	Mn
1	6.0	1.2	4.0	0.5
2	4.6	0.8	1.5	—
3	12.5	—	0.8	0.8
4	19.0	1.0	1.5	3.0
5	11.0	—	1.0	—
6	8.0	0.5	1.6	1.2

Effect of foreign ions

Interferences were studied for samples containing 10 and 25 $\mu\text{g/l.}$ of each of the metals.

No interference is observed from SO_4^{2-} , HCO_3^- , PO_4^{3-} , NO_3^- , F^- , Cl^- , Br^- and I^- up to 250 mg/l. ; from CN^- , EDTA up to 40 mg/l. ; and from Ca^{2+} , Mg^{2+} , Na^+ , K^+ up to 300 mg/l.

Interference from heavy metals, *viz.* Pb, Cd, Zn, Co and Cu was studied. Up to 3 mg/l. concentrations of these do not interfere to any

significant extent in the determination of Fe and Ni. However, in the extraction of Cr and Mn, these metals interfere at 2.5 mg/l. level.

Application of the method

Six untreated water samples collected at different places have been analysed for trace metals by the recommended procedure (Table 4). An alternative analysis for chromium and manganese by the method of Brooks *et al.*⁵ was also performed and the results are compared in Table 5.

Table 6 gives some of the physicochemical characteristics of the six water samples.

CONCLUSION

The results of the present investigation show that the reagent pipDTC could be successfully used for the quantitative extraction of manganese into an organic solvent (MIBK) in which the chelate is sufficiently stable (3 hr) for a routine determination. The determination of chromium is more precise with the pipDTC method than the APDC method, for all six samples. This is an added advantage of the method described here.

Considering the range of precision (3–20%) and recoveries (>90%), this method could be successfully applied to any water sample in the concentration range 2.0–250 $\mu\text{g/l.}$ of the metals being determined in a single extraction, if applied under the conditions used here.

ANALYSIS OF POLYNUCLEAR AROMATIC HYDROCARBON MIXTURES IN VARIOUS ENVIRONMENTS BY TIME-RESOLVED FLUORESCENCE SPECTROSCOPY

KI-MIN BARK* and R. KEN FORCÉ†

Department of Chemistry, University of Rhode Island, Kingston, RI 02881, U.S.A.

(Received 30 May 1990. Revised 3 July 1990. Accepted 10 July 1990)

Summary—Time-resolved molecular fluorescence spectroscopy is presented as a sensitive and selective method for the characterization of mixtures of polynuclear aromatic hydrocarbons in the collision-free vapor phase at elevated temperature, in the condensed phase at room temperature, and at 77 K in a Shpol'skii matrix. This technique is applicable for all three conditions and the quantitative analysis for each component in mixtures has a fairly small error. Also the advantages and disadvantages are discussed for these different environments. Anthracene, pyrene and fluoranthene are used as model compounds.

Polynuclear aromatic hydrocarbons (PAH) are multi-aromatic ring systems produced at high temperatures by the incomplete combustion of fossil fuel or as the result of synthesis by some plants and formation during natural forest and prairie fires.^{1,2} A high correlation between the photodynamic action of certain PAH and their ability to induce carcinogenic responses has been found,³⁻⁵ and recently it was shown that PAH can be transformed into reactive cytotoxic and mutagenic intermediates by exposure to sunlight and other sources of radiation.⁶ A comparison of the mutagenicity of several PAH following exposure to sunlight or an artificial source of ultraviolet light has been made.⁷

Laser-induced molecular fluorescence (LIMF) spectroscopy has been shown to be one of the more sensitive techniques for quantifying PAH^{8,9} and also allows their dynamic measurement while they are in the vapor phase.⁹ Because many PAH compounds exhibit substantially different fluorescence emission spectra, spectral interference from other PAH present can be minimized through careful selection of emission wavelengths. This selectivity can be greatly improved by fluorescence line-narrowing techniques such as Shpol'skii spectroscopy.¹⁰⁻¹²

The measurement of fluorescence emission is inherently a multiparametric technique because

even the simplest such measurements involve the exploitation of more than one parameter. Obviously the introduction of additional parameters has advantages, increased selectivity being cited as the most important benefit. The multiparametric approach has been used most often in systems where the fluorescence intensity is observed as a function of excitation and emission.¹³⁻¹⁹ Time-resolved fluorescence measurements can also be incorporated into a multidimensional analysis technique. Because fluorescent molecules possess a characteristic fluorescence lifetime (the time for the decay to reach $1/e$ times its initial value), in many cases spectral interferences can be substantially minimized in this way, allowing an individual component in a mixture of PAH to be determined.

In this paper, we present results for the use of time-resolved LIMF (TRLIMF) spectroscopy as a sensitive and selective method for the determination of PAH in the collision-free vapor phase at elevated temperature, in the condensed phase at room temperature, and at 77 K in a Shpol'skii matrix. The advantages and disadvantages are also discussed for these three different environments. Pyrene, anthracene and fluoranthene are used as model compounds.

EXPERIMENTAL

The fluorescence emission spectra and the lifetime of PAH in a collision-free vapor state, a condensed phase at room temperature, and at

*Present address: Department of Chemical Education, Kyungsang University, GaJwa-dong, Jin Ju, South Korea.

†Author for correspondence.

77 K have been obtained with a system described previously.^{9,20} The excitation source used was a laboratory-built pulsed nitrogen laser having output at 337.1 nm ($29,665\text{ cm}^{-1}$) with a nominal pulse width of 12 nsec (FWHM), an average power of 4 mW and a pulse rate of 10 pulse/sec. A Schott WG360 or GG375 cut-off filter was placed in front of the monochromator to absorb the scattered light from the excitation source. To remove the laser plasma lines, an interference filter, with a transmission maximum at 337 nm and 10 nm band width (FWHM), was positioned in front of the laser output.

The vapor phase fluorescence cell was operated as a dual chamber oven to prevent the condensation of PAH on the windows. The temperature of the cell's main body, including the windows, was higher than that of the sample chamber. The fluorescence cell was connected to a vacuum pump (Model 25, Precision Scientific Co.) so that a constant back pressure of 0.005 torr could be maintained within the cell. The temperature of the cell was regulated by a tube furnace and was measured to $\pm 2^\circ$ with an iron-constantan thermocouple. The vapor phase cell has an optical path length of 1.90 cm and has been described in detail elsewhere.⁹

Low concentrations ($\sim 10^{-5}M$) were used to avoid any solute-solute interaction and self-absorption in the condensed phase experiments. The samples were held in 6 mm o.d. (4 mm i.d.) glass tubes for room temperature and 1.2 mm o.d. glass capillary tubes for low temperature (77 K) fluorescence measurements. Since Pyrex is transparent down to about 320 nm, a shorter wavelength than that of the nitrogen laser line (337.1 nm), it was not necessary to use fused silica vessels. Sample solutions were degassed by the freeze-pump thaw method at 0.005 torr a minimum of three times. A laboratory built Dewar flask with a transparent window was used in measurement of the low temperature fluorescence signal.

The fluorescence was focused into an ISA Model H-20 monochromator with 2 nm slits and detected by an RCA-1P28 photomultiplier tube (PMT). The signal from the PMT was processed by a PAR model 162/164/165 boxcar integrator with a 5 nsec window, in the model 165 module, and displayed on a X-Y recorder or strip chart recorder. A small portion (about 10%) of the laser output was split off with a microscope slide and routed to a fast photodiode to provide a triggering pulse for the

boxcar integrator. Data were passed to an IBM-XT compatible computer (10 MHz MEGA-XT) for analysis. Data and graphical analysis and three dimensional plotting were carried out with ASYSTANT[®] software. The time-dependent spectra shown in Figs. 1-3 were generated by acquiring spectra at different delay times and laminating them by using matrix manipulation routines available in ASYSTANT[®]. The concentrations of the PAH in the mixtures were calculated by the internal standard method. Since pyrene had the longest fluorescence lifetime, it was used the most frequently as the internal standard. For the determination of pyrene, fluoranthene, which differs from pyrene in emission profile, was used as the internal standard.

Reagent-grade anthracene (MC&B) and fluoranthene (Aldrich) were used without further purification. These compounds were analyzed for impurities by high performance liquid chromatography and were found to contain no impurities that would significantly interfere with either the spectral emission or decay profiles. Reagent-grade pyrene (Aldrich) was purified twice by recrystallization from reagent-grade toluene (Aldrich). The recrystallized solid was then washed with HPLC grade methanol (Fisher Scientific). HPLC grade n-hexane (Fisher Scientific) was used as the solvent in condensed phase experiments.

The fluorescence lifetimes of the different PAH were obtained by the deconvolution technique known as least-squares iterative reconvolution.¹⁹ All measurements were made at least three times.

RESULTS AND DISCUSSION

The fluorescence emission spectra of pyrene, anthracene and fluoranthene at room temperature, at 77 K, and in the vapor phase at elevated temperature are shown in Fig. 4. The large Stokes loss and broad emission band of fluoranthene have been discussed previously.²⁰ For all three compounds, no significant shift in the emission bands is caused by changing the environmental conditions, as is expected since the fluorophores and solvents are nonpolar. For anthracene there was a small red shift (~ 10 nm) in the room-temperature solution spectrum relative to the vapor phase spectrum, but for pyrene, a slight blue shift (~ 5 nm) was observed. The latter is an unusual property and needs further investigation, since a red shift, due

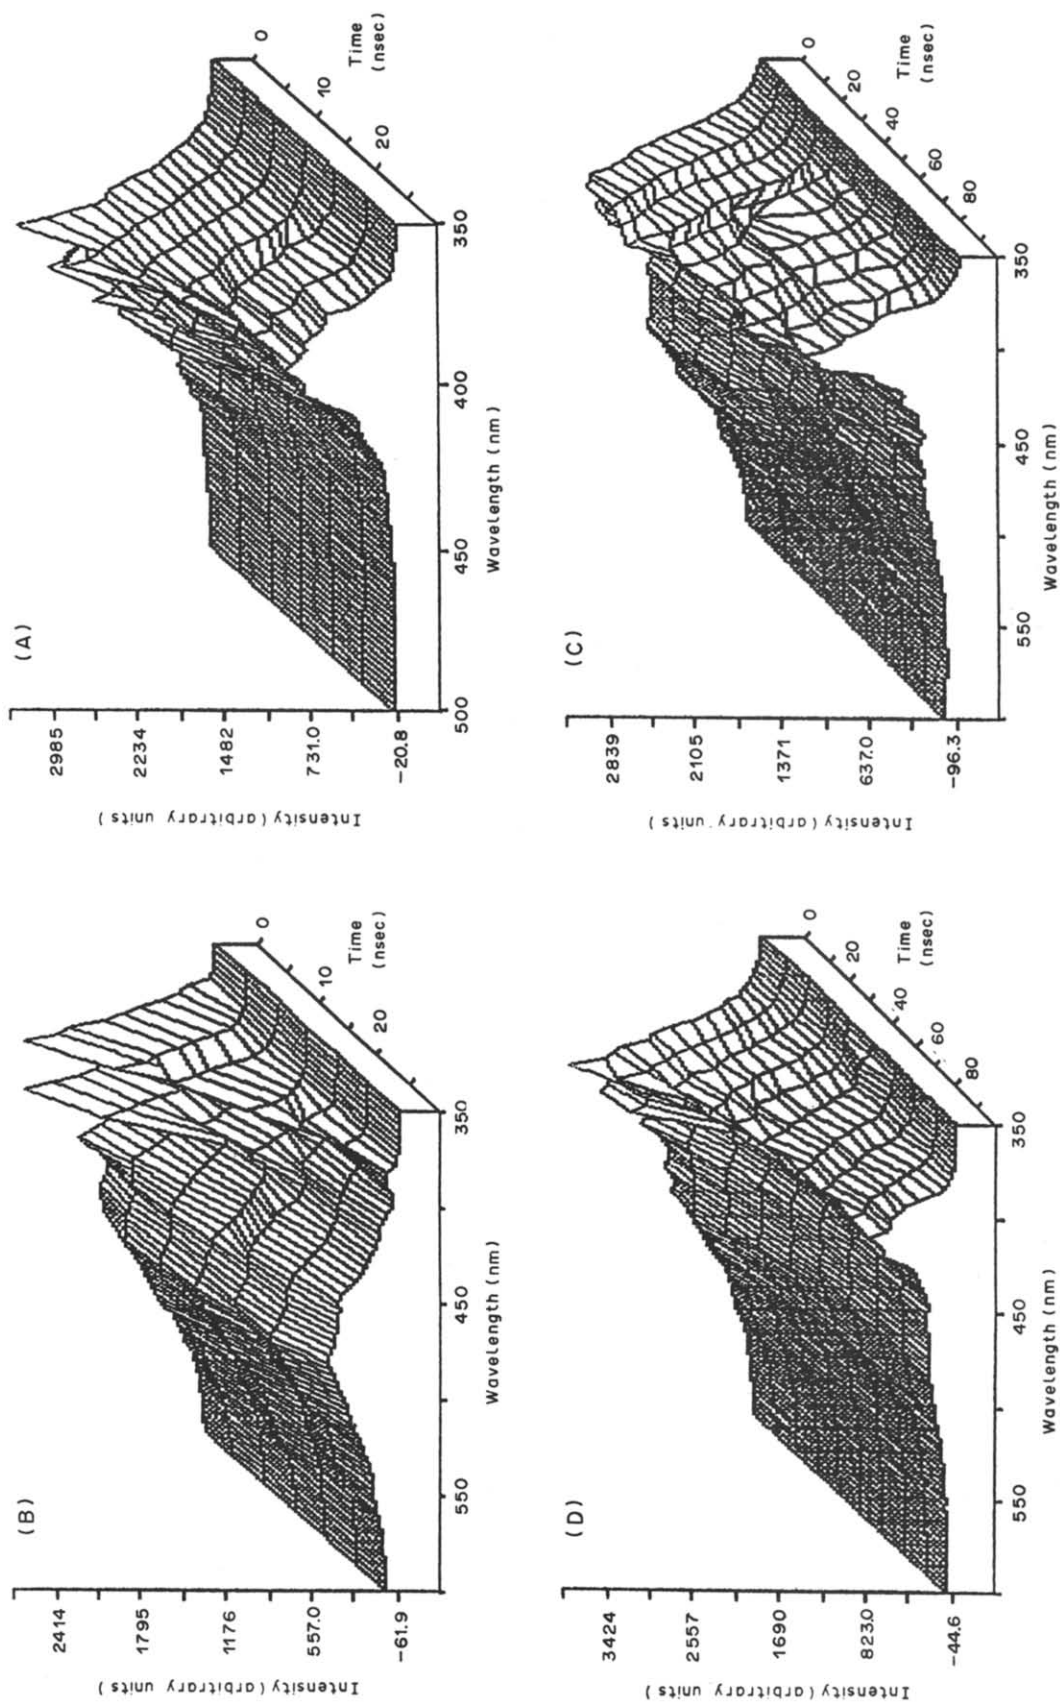

Fig. 1. Time-resolved fluorescence emission spectra (TRFES) in hexane at room temperature. The mixtures are (A) anthracene ($1 \times 10^{-6} M$) and pyrene ($1 \times 10^{-5} M$), (B) anthracene ($1 \times 10^{-6} M$) and fluoranthene ($1 \times 10^{-5} M$), (C) pyrene ($1 \times 10^{-5} M$) and fluoranthene ($1 \times 10^{-6} M$), (D) anthracene ($1 \times 10^{-6} M$) and fluoranthene ($1 \times 10^{-5} M$).

to solvent effects, would be expected. For fluoranthene, a small red shift is also expected but the band change observed did not exceed the experimental error. At 77 K, pyrene exhibits significant vibrational structure due to the Shpol'skii effect^{11,12} but anthracene does not show any significant line-narrowing. Although the Shpol'skii effect is due to a reduction in the inhomogeneity of the environment for molecules trapped in low-temperature *n*-alkane crystals, whether or not highly resolved spectra are obtained for a particular combination of guest molecule and *n*-alkane depends on a number of experimental parameters. This effect is not clearly understood, even though the physical interpretation has invariably been based on some dimensional and geometrical correlations between the solute and host molecules. The composition and the mode of preparation of the sample appear to be important in this respect.²¹

Hexane and heptane are the best solvents for pyrene and anthracene, respectively.²¹ Some vibrational structure was also observed for fluoranthene at 77 K.

In the fluoranthene spectrum at 77 K (Fig. 4) the emission between 350 and 400 nm has been the subject of much controversy.²⁰⁻²⁴ These signals were not observed in mixtures of the PAH at 77 K. Further investigation is required to identify the origin of these bands.

The emission maximum of fluoranthene occurs at a different wavelength than the emission maxima of pyrene and anthracene. In the mixtures of these three compounds, the signals are not well resolved, especially for the pyrene and anthracene mixture, and each compound cannot be identified with any certainty without a pre-separation step. A new parameter, lifetime, was introduced to analyze these mixtures directly. The fluorescence lifetimes of anthracene, pyrene and fluoranthene are shown in Table 1. Figure 1 shows the time-resolved spectrum of various PAH mixtures at room temperature. The sensitivity for anthracene is about 10 times that for pyrene and fluoranthene, mainly due to the larger molar absorptivity at 337.1 nm, the laser line. Time zero was taken as corresponding to the emission maximum in the fluorescence decay curve at the principal band wavelength. As shown in Fig. 1A, at time zero, the two components of the mixture cannot be distinguished. When the signal acquisition is delayed, the anthracene signal decays very quickly owing to the short lifetime. As a result, these two compounds become more clearly resolved in this time-resolved spectrum. The fluoranthene band is separated from that of anthracene or pyrene relatively well at time zero because of the different emission band positions. In the time-resolved spectra as shown in Fig. 1B and 1C, the separation becomes much clearer. In Fig. 1D, the time-resolved spectra of the three-compound mixture is shown. At time zero, the anthracene and pyrene bands are completely mixed and the presence of fluoranthene is also

Table 1. Fluorescence lifetimes (nsec) of PAH; the solvent in the condensed phase is *n*-hexane

PAH	Room temperature	77 K	Vapor phase
Pyrene	430	860	420 (160°)
Anthracene	8	14	7 (150°)
Fluoranthene	77	82	*32 (150°)

*Refer to reference 20 for more details on this unusually small value.

not clear because a large part of its band is buried by the strong combined bands of anthracene and pyrene. As the time is delayed, the anthracene signal disappears, and the pyrene and fluoranthene become well resolved.

The same experiment was repeated at 77 K. At this temperature the fluoranthene signal is very weak compared to the anthracene and pyrene signals, owing to its small molar absorptivity at 337.1 nm. To observe the fluoranthene signal, it is necessary to increase its concentration by at least a factor of ten relative to that of anthracene and pyrene. As shown in Fig. 2, the resolution of each component is much clearer than in the room temperature spectra. This is due to the increased fine structure from the Shpol'skii effect. Therefore, it should be possible to analyze complex samples, owing to the improved selectivity at low temperature.

In the vapor phase, as shown in Fig. 3, the benefit of time-resolved spectra can be seen even though the emission bands for each component have very little fine structure. With 337.1 nm excitation, pyrene gives very weak emission and its presence in the mixture is not very evident. However, the pyrene signal can be identified with careful observation. This phenomenon is mainly due to the small molar absorptivity of pyrene at 337.1 nm in the vapor phase, since the vapor pressures for the three compounds are similar at elevated temperature.

By utilizing the time-resolved signal, the spectrum of each component can be reconstructed from the spectra of mixtures and used to calculate the concentration of each component. A representative example is shown in Fig. 5. The solid line in Fig. 5A is the spectrum of an anthracene and pyrene mixture in hexane at zero delay time and room temperature. The broken line in Fig. 5A is the spectrum of the same mixture at 30 nsec delay, multiplied by the decay factor for pyrene at 30 nsec, and is actually the pyrene spectrum at zero delay time because all of the anthracene signal is gone after 30 nsec delay. The decay factor (the ratio of the relative pyrene fluorescence intensity at the two delay times) is derived from the fluorescence decay curve for pure pyrene. The spectrum in Fig. 5B is obtained as the difference between the spectra in Fig. 5A and is the reconstructed anthracene spectrum. The intensity ratio of the anthracene and pyrene spectra at their principal emission wavelengths was used to calculate the anthracene concentration in the spectrum of the three-component PAH mixture, with the known

Fig. 5. Fluorescence emission spectra at room temperature. (A) (—): pyrene and anthracene mixture in hexane at zero delay time (---): pyrene and anthracene mixture in hexane at 30 nsec delay. (B) Reconstructed spectrum obtained by subtraction of broken line from solid line in (A).

concentration of pyrene as the reference. The concentrations of other components in the PAH mixture were calculated by the same procedure, with an appropriate known reference, preferably a long lifetime component. This technique can be applied for all three conditions. The results of these calculations are shown in Table 2. The uncertainty of this method is

Table 2. Concentrations of PAH in mixtures, calculated by the internal standard method

PAH	Known concentration	Calculated concentration	Relative error, %
Room temperature in hexane solution			
Anthracene	$1.0 \times 10^{-6}M$	$9.7 \times 10^{-7}M$	-3
Pyrene	$1.0 \times 10^{-5}M$	$8.9 \times 10^{-6}M$	-11
Fluoranthene	$1.0 \times 10^{-5}M$	$1.1 \times 10^{-5}M$	+10
Low temperature (77 K) in hexane solution			
Anthracene	$5.0 \times 10^{-6}M$	$4.1 \times 10^{-6}M$	-18
Pyrene	$3.5 \times 10^{-6}M$	$2.9 \times 10^{-6}M$	-17
Fluoranthene	$5.0 \times 10^{-5}M$	$5.9 \times 10^{-5}M$	+18
Vapor phase at 138°			
Anthracene	$6.3 \times 10^{-6}M$	$6.0 \times 10^{-6}M$	-5
Pyrene	$4.4 \times 10^{-6}M$	$4.0 \times 10^{-6}M$	-9
Fluoranthene	$4.3 \times 10^{-6}M$	$4.7 \times 10^{-6}M$	+9

*The % error is the percentage difference between the known concentration and the calculated concentration, determined from the time resolved spectra, divided by the known concentration.

fairly good considering that there was a 5–10% error in the pulse-to-pulse laser intensity. The increased error in the low temperature experiments is due, in large part, to non-reproducibility of positioning in the Dewar flask which results in a decreased reproducibility of the spectra low temperature spectra.

Time-resolved fluorescence measurements can be applied to analyze PAH mixtures in all three different environments. At room temperature in hexane, the mixtures can be well resolved even though this is relatively unsuitable for the analysis of complex mixtures, owing to the rather broad emission signals. The experimental procedures are the simplest and the calculated concentrations in the mixture have relatively small error. This room temperature technique would be effective for the analysis of relatively simple mixtures.

Time-resolved fluorescence spectroscopy in a low temperature Shpol'skii matrix would be excellent for the analysis of more complex mixtures. Vibrational structure and time-resolved spectra can provide highly detailed information for the analysis of complex samples, but this technique requires more specialized apparatus and effort. Also the quantitative analysis has a higher uncertainty. If this technique is combined with some simple preliminary fractionation, PAH in environmental samples should be clearly identifiable.

Time-resolved fluorescence in the vapor phase is also more complicated but this method allows dynamic measurement of the PAH directly while they are in the vapor phase. If this technique is combined with use of a temperature programmed furnace or any other precise vaporization device, rapid characterization of many types of samples could be done directly, especially samples often difficult to analyze by gas chromatographic methods, such as heavy oils, tar residues and resinous materials. It also holds considerable promise as a technique that can be applied to the study of combustion dynamics.

In summary, time-resolved fluorescence spectroscopy is a good technique for mixture

analysis with applicability to the condensed phase at room temperature, a solid phase at 77 K, and the vapor phase.

PRECAPACITIVE PROCESSES IN SINGLE POTENTIAL-STEP CHRONOAMPEROMETRY

XIANG YUAN and RAY VON WANDRUSZKA*

Department of Chemistry, University of Idaho, Moscow, ID 83843, U.S.A.

(Received 28 February 1990. Revised 26 June 1990. Accepted 5 July 1990)

Summary—Extremely short-lived anodic currents were observed in the early parts of the transient response following the application of a cathodic potential step to a mercury working electrode. It is proposed that this phenomenon is due to the existence of a brief precapacitive period, which precedes full development of the double-layer charging current, and which allows momentary reaction (reduction) of species present at the electrode surface. The observed anodic currents are explained in terms of a re-oxidation of such “resident” species that were reduced during this precapacitive period. The subsequent capacitive surge produced by the charging of the electrical double layer leads to an anodic shift of the electrode potential that can be sufficient for the re-oxidation of the precapacitive amalgam. The anodic peak is linearly related to depolarizer concentration and varies with supporting electrolyte concentration, ion mobility and potential step size. Cathodic preconcentration of the depolarizer enhances the effect.

The behaviour of transient faradaic currents produced by a single potential step has been described theoretically by Miaw and Perone,¹ and Miaw.² They used the classical treatment of Feldberg³ to develop algorithms that allowed them to generate digitally simulated chronoamperometric curves. In subsequent work in this laboratory, high-speed instrumentation was used to produce experimental transient currents in simple reversible electrochemical systems.⁴ It was shown that the faradaic peak current varied with depolarizer concentration, yielding a calibration curve with two distinct linear regions. The temperature effect was found to be significant, giving a concentration-dependent “switch temperature”.

The application of a potential step to an electrode in an electrolyte solution gives rise to a relatively high initial current, due to the charging of the electrical double layer at the electrode–electrolyte interface. This capacitive current is given by

$$i = \frac{\Delta E}{R_u} \exp\left(\frac{-t}{R_u C_{dl}}\right) \quad (1)$$

where ΔE is the size of the potential step, R_u the uncompensated cell resistance, t the time, and C_{dl} the double-layer capacitance.

During the charging of the double layer, as the capacitive current decays the potential of

the working electrode “scans” toward its final value, as indicated by equation (1).¹

Faradaic processes can only occur when the potential reaches the decomposition potential of the active species in the course of this “pseudo-scan”. Double-layer charging currents are normally regarded as interferences in electroanalytical work and various steps are taken to minimize them. In the present investigation, their property of effectively generating a fast scan of the electrode potential is utilized as such. We have shown in previous work^{4,5} that the similarity of this process to ultra-fast linear-sweep voltammetry gives it the potential for interesting analytical applications. However, the fundamental phenomena are not well understood and further research is needed before a feasible technique can be developed.

Algorithms developed by Miaw² show that a chronoamperometric plot of the faradaic current component flowing during the first 10 time constants of the cell is peak-shaped (Fig. 1), not unlike a conventional linear-sweep voltamperogram. Laitinen and Kolthoff⁶ have described the transient faradaic response represented by the area beyond the peak, which decays with time, t , as a function of $t^{-1/2}$. In this region, the current is under diffusion control and is described by the well-known Cottrell equation:

$$i = nFA(D/\pi t)^{1/2}C \quad (2)$$

where the symbols have their usual electrochemical significance. During the period

Fig. 1. Theoretical shape of a transient faradaic chronoamperogram produced by a single potential step.

preceding the faradaic peak, the rising current is caused by the potential pseudo-scan; to explain the peak shape of the chronoamperometric curve, it is useful to invoke depolarizer depletion effects, commonly discussed with reference to linear-sweep voltammetry.^{4,7}

The previous theoretical treatment¹ indicates that linearity of the current-concentration curve should not be expected for relatively high-level and wide-ranging analyte concentrations. This leaves the relationships at lower concentrations and within narrower concentration ranges to be investigated. Digital simulation also predicts that current-concentration behaviour will vary significantly at different measurement times during the existence of the transient. In our previous investigation,⁴ we chose to obtain our measurements at the peak of the faradaic transient, which occurs after about one cell time constant. This point is easily identifiable and does not vary significantly among solutions giving similar time constants.

In the present work, unexpected faradaic behaviour manifested itself at the very beginning of the cathodic potential step, at times less than approximately 0.3 times the cell time constant. A reproducible "dip" appeared in the faradaic current curve, indicating an oxidative process that briefly precedes the reductive one. The magnitude of this reverse current was found to be proportional to the depolarizer concentration in low concentration ranges and to increase with supporting electrolyte concentration. An explanation for the phenomenon is proposed.

EXPERIMENTAL

Electrodes and control/data system

A three-electrode cell was used, with a hanging mercury drop working electrode (Metrohm Herisau AG CH-9100), a calomel reference electrode, and a platinum counter-electrode.

The control/data system has been discussed in detail elsewhere⁸ and will be described only briefly here. It consists of three interactive parts: a potential-step generator and a high-speed data-acquisition module, both linked to an Apple IIe microcomputer. The instrument is capable of taking current readings (12-bit resolution) at a rate of 500 kHz after application of the potential step. A block diagram is shown in Fig. 2.

The digital portion of the potential-step generator is built around a 12-bit digital-to-analogue converter (DAC) and data are provided by the computer through a custom-built interface.⁸

The data-acquisition circuit comprises a high-speed 12-bit analogue-to-digital converter (Datel ADC-817) with a maximum conversion time of 2 μ sec. The digital data generated by the ADC are stored in 768 on-board memory locations. After application of the potential step, the data-acquisition system cycles at maximum speed, the ADC restarting itself after each conversion. When 768 current readings have been gathered in this way, the system shuts itself off and control is returned to the computer for data reduction and storage.

Chemicals

Distilled, demineralized water treated with a Millipore purification system to give 10^{18}

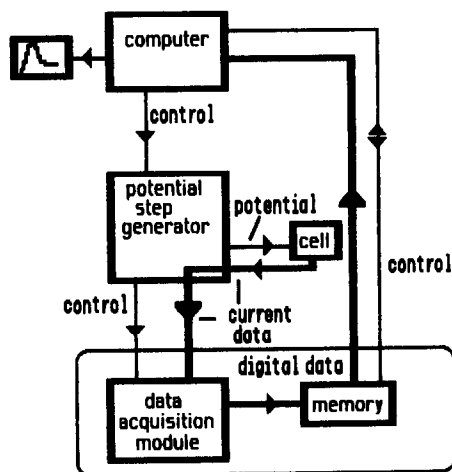

Fig. 2. Diagram of instrumentation used for measurement of faradaic transients.

M Ω .cm resistivity was used for all solutions. All electrolytes were of analytical grade from EM Science and were used without further purification. The mercury used in the working electrode was high quality electronic grade (Aldrich). Triton X-405 was obtained from Sigma as a 70% aqueous solution.

Procedure

All solutions were deaerated by passage of nitrogen for at least 10 min. A single cathodic potential step, from 0.0 to -1.0 V *vs.* SCE, was applied to the working electrode. The length of time the electrode was held at the starting potential generally varied from 5 to 10 sec. The total current readings (capacitive + faradaic) for a sample were first recorded in the data module memory, then transferred to the computer memory and committed to disk. The reported data are averages of triplicate determinations and a fresh mercury drop electrode was used for each experiment. The same procedure was followed for a blank solution, containing only supporting electrolyte. The latter data, consisting of capacitive current readings only, were digitally subtracted from the sample readings, yielding the faradaic current produced by the depolarizer. Induced charging-current effects may be operative during the period of changing faradaic current, but the focus of this investigation is on the precapacitive section of the transient, which precedes the flow of substantive charging current of any type.

Fig. 3. Actual shape of a faradaic chronoamperogram produced by a single potential step from 0.0 to -1.0 V on a mercury electrode in $0.5M$ KCl with $2.0 \times 10^{-6}M$ Cd $^{2+}$. Inset: total component currents for; a, blank and b, sample.

Fig. 4. Variation of anodic peak current with Cd $^{2+}$ concentration ($0.5M$ KCl supporting electrolyte).

RESULTS AND DISCUSSION

In the present study it was noted that at the very beginning of the pseudo-scan resulting from the cathodic potential step, at times less than 0.3 times the cell time constants, the current-time curve showed a brief negative excursion (Fig. 3). In practical terms, this means that the blank (capacitive only) cathodic current during that period was greater than the sample (capacitive + faradaic) current. This suggests that this initial faradaic portion of the current was anodic in nature, leading to a smaller total current, which was otherwise entirely cathodic.

The magnitude of the anodic faradaic peak was found to be linearly related to depolarizer concentration over a limited concentration range (Fig. 4). Moreover, the current depended on the concentration of the supporting electrolyte, increasing in a non-linear fashion (Fig. 5).

The data in Table 1 show that the size of the anodic peak for Cd $^{2+}$ in different supporting electrolytes varied almost linearly with cation mobility. While the data were mostly obtained with chlorides, additional work has shown that potassium nitrate as electrolyte gave similar results. The size and position of the cathodic potential step significantly influenced the anodic peak: it decreased in magnitude with decreasing step size. This was the case when the initial potential was kept constant and the final potential was changed in the anodic direction and also when the initial potential was shifted cathodically and the final potential was left at -1.0 V (Fig. 6).

The addition of 0.0035% Triton X-405 detergent obliterated the entire transient effect,

Fig. 5. Variation of anodic peak current of $5.0 \times 10^{-6} M$ Cd^{2+} with KCl concentration.

both anodic and cathodic, in the chronoamperogram. Only at high concentrations of Cd^{2+} ($1.0 \times 10^{-3} M$ and above) were both peaks discernible again.

As pointed out in the procedure section, the electrode was normally left at the initial potential of 0.0 V for 5–10 sec before the potential step was applied. The length of this period was found to have no significant effect—the final chronoamperogram showed no changes even when the initial potential was applied for several minutes.

To find further evidence for the origins of the anodic peak, the influence of cathodic preconcentration was investigated. A potential of -1.0 V vs. SCE was applied to the working electrode for a duration of 100 sec in Cd^{2+} solutions ranging from 5.0×10^{-7} to $1.0 \times 10^{-5} M$. This was followed by the customary 0.0 to -1.0 V potential step. In all cases it was found that the size of the anodic peak increased about fourfold relative to the corresponding situation without preconcentration.

The propagation delay and current settling time of the potentiostatic control circuit were less than 300 nsec, while the relevant electrochemical responses typically extended to approximately 100 msec. This precludes electronic artifacts as the causes of the observed effects and indicates the presence of electrochemical transients, even in the earliest measurements. The most plausible explanation of the phenomenon involves the time-average *resident* (not necessarily adsorbed) depolarizer species at the electrode surface.⁴ It should be noted that existing theory does not specifically address the early

part of the faradaic transient and does not recognize the possibility that the conditions created by the double-layer charging current require a finite time to develop fully. We propose that the slowness of movement of hydrated ions in aqueous solution, relative to the movement of electrons in a metallic conductor, results in a brief “precapacitive” period immediately following the application of the potential step. During this time, the electrode potential is close (or even equal) to the applied potential, since the potential drop due to the charging current has not yet developed. This allows for the momentary reaction of the electroactive species resident at the electrode surface at that instant, provided that the charge transfer is sufficiently fast. This contention is supported by our observation that the capacitive (blank) current initially rises to a maximum, before it decays according to equation (1). The rise typically lasts 6–8 μ sec in our system with 0.5M potassium chloride solution and is resolved into 3 or 4 data points. The faradaic processes that occur during the precapacitive period, *i.e.*, before the capacitive current has risen sufficiently to cause an electrode potential drop below the decomposition potential, are resolved into 1 or 2 data points. The bulk of the precapacitive reduction probably takes place during the first 1–2 μ sec following the potential step and therefore falls outside the time resolution capability of our instrument.

The fast reduction and concurrent amalgamation of cadmium and lead ions renders them amenable to the precapacitive surface reduction described above. The beginning of

Fig. 6. Variation of the anodic peak current of $10 \times 10^{-5} M$ Cd^{2+} in 0.5M KCl with range of potential step sizes; A, from 0.0 V to final potential and B, from initial potential to -1.0 V.

the capacitive process therefore sees a quantity of amalgam, formed under the influence of the precapacitive full applied potential, in the very surface layer of the mercury drop. The subsequent flow of double-layer charging current shifts the electrode potential in an anodic direction and causes the re-oxidation of this amalgam. The resulting anodic current is effectively subtracted from the capacitive current, which is overwhelmingly "cathodic" in direction. The initially measured cathodic current in a solution containing a reversible depolarizer is, therefore, smaller than the corresponding current in a solution with supporting electrolyte only. The various currents involved in the precapacitive and early capacitive processes are shown in Fig. 7.

The explanation offered here accounts for the observed dependence of the anodic peak on depolarizer concentration. The time-average presence of depolarizer at the electrode surface is essentially a bulk effect and the amount of precapacitive amalgam formed therefore depends directly on the depolarizer concentration. The loss of linearity observed at higher concentrations (Fig. 4) results from surface saturation of the electrode by resident species. The number density of depolarizer ions sufficiently close to the surface to be available for precapacitive reduction has an upper limit dictated by the hydrated radius of the ion. Further increases in concentration beyond this saturation point cannot produce more amalgam for subsequent re-oxidation and the anodic peak current therefore reaches a maximum.

Fig. 7. Magnified view of earliest measurable portions of transient currents. A, double-layer charging current; B, faradaic current. First data point approx. 2 μ sec after potential step.

The enhancement of the anodic peak by an increase in supporting electrolyte concentration and by greater ion mobility provides further evidence for the proposed mechanism. Both result in increased capacitive surges upon double-layer formation and hence lead to increased anodic shifts during the process. This, in turn, gives rise to a higher re-oxidation current.

As mentioned above, a smaller potential step produces a smaller anodic peak, whether the initial potential is more cathodic or the final potential is more anodic. This is also in agreement with the precapacitive mechanism; the smaller step decreases the capacitive surge and hence the anodic potential drop, leading to decreased re-oxidation current. If the size of the potential step is reduced by shifting the final potential anodically, an additional effect is operative: the precapacitive electrode potential is now less cathodic, so the extent of initial amalgamation is decreased. This leads to a yet smaller re-oxidation current.

The observation that the addition of detergent to the solution eliminates both anodic and cathodic transient peaks is expected in view of electrode surface coverage by the detergent and disturbances in the extent and speed of double-layer formation.

Strong evidence for the proposed mechanism is provided by the cathodic preconcentration experiment, especially in contrast with the case where non-electrolytic initial potentials are used. A separate and prolonged reductive accumulation of cadmium and lead in the electrode leads to a greatly enhanced anodic transient, which is no longer dependent on the presence of resident species at the electrode surface. Since the reduction in this case is not limited to the brief precapacitive period and the accumulation is therefore significantly greater, the amount of amalgam available for re-oxidation is increased. The anodic potential drop during the capacitive surge, however, is still effective, and the anodic peak increases in accordance with the amount of preconcentrated depolarizer. For all bulk concentrations considered at the chosen preconcentration time, the anodic peak increased linearly, suggesting that the mechanism can be likened to an ultra-fast anodic stripping procedure. It is worth noting that depolarizer adsorption on the electrode does not appear to play a major role under the conditions of this study, since leaving the electrode at the starting potential (0.0 V vs. SCE)

for relatively long periods did not change the eventual anodic peak current.

CONCLUSIONS

The proposed process, involving a precapacitive period during which species resident at the electrode surface are reduced and re-oxidized during the capacitive surge, accounts for the observed anodic component in an otherwise entirely cathodic process. The mechanism is suggested as a plausible explanation of the experimental findings. The present investigation has dealt with a mercury-drop electrode and amalgam-forming depolarizers and further studies are needed to determine whether similar processes are operative with non-amalgamating depolarizers and at noble metal and carbon electrodes. Interesting possibilities exist for analytical applications of such fast anodic stripping of preconcentrated analytes, with speed of analysis as the prime benefit.

ON-LINE MONITORING OF CHLORAMINE REACTIONS BY MEMBRANE INTRODUCTION MASS SPECTROMETRY

TAPIO KOTIAHO*, ANITA K. LISTER, MARK J. HAYWARD and R. GRAHAM COOKS†
Department of Chemistry, Purdue University, West Lafayette, IN 47907, U.S.A.

(Received 14 June 1990. Revised 16 July 1990. Accepted 25 July 1990)

Summary—Membrane introduction mass spectrometry has been applied to on-line monitoring of the reaction of monochloramine with hydrogen chloride. The detection limit for monochloramine introduced by a sheet-membrane direct-insertion probe and measured by electron impact ionization and selected ion detection was found to be 0.7 mg/l. Formation of dichloramine, trichloramine and molecular chlorine in response to the addition of hydrogen chloride to the monochloramine solution was measured on-line. The flow-through membrane introduction mass spectrometry method for detection of chloramines and characterization of their chemistry has minimal memory effects, high molecular specificity, high speed of analysis owing to fast response times, and low detection limits.

Monochloramine, dichloramine and trichloramine are toxic compounds formed during chlorination of potable and waste water. Monochloramine (typical levels 1 mg/l.) is sometimes used as a disinfectant in drinking water.¹⁻⁶ The standard methods used for measuring these compounds are colorimetric, spectrophotometric and titrimetric,^{1-5,7} and sometimes high-performance liquid chromatography is also used.^{4,8,9} All the methods above are susceptible to interferences, and differentiation between chloramines can be difficult. Savikas *et al.*¹⁰ indicated that membrane introduction mass spectrometry (MIMS) might provide a solution to these problems.

Membrane introduction mass spectrometry is a well-established analytical technique, which has undergone several stages of development¹¹⁻¹⁶ since its introduction by Hoch and Kok in 1963.¹¹ An important recent advance was the introduction of the flow-through concept¹⁴⁻¹⁵ which has since been used by various groups.¹⁶⁻¹⁸ In the flow-through method the sample flows through or across the membrane surface, which is located in the ion source of the mass spectrometer. This procedure minimizes the problems due to analyte dilution, memory effects and slow response times associated with interfaces where the membrane is remote from the ion

source. Membrane introduction mass spectrometry has already proven to have important applications in the analysis of trace organic compounds in aqueous solutions,^{12,13,17} environmental analysis¹⁹⁻²² and the monitoring of biochemical processes.^{23,24}

In the present work, procedures are developed to detect and quantify monochloramine, dichloramine and trichloramine by on-line membrane introduction mass spectrometry. The detection limit for monochloramine has been measured and the chemistry of chloramine interconversion monitored.

EXPERIMENTAL

An instrumental configuration which allows on-line reaction monitoring experiments to be performed with a mass spectrometer interfaced to a membrane introduction system has already been described.¹⁴ The present work employed a modified form of this interface with a sheet direct insertion membrane probe, S-DIMP,¹⁶ instead of a capillary tube interface (Fig. 1). As in previous work, the membrane was a dimethylvinyl silicone polymer (ASTM: VMQ Dow Corning) with a thickness of 0.13 or 0.25 mm. The temperature of the membrane probe, which was controlled independently of that of the ion source, was 70°. The main advantages of the S-DIMP interface are that memory effects sometimes encountered with the capillary tube interface were almost entirely eliminated and response times were decreased

Fig. 1. Instrumentation for on-line monitoring of the reactions of monochloramine with HCl, employing the sheet direct insertion membrane probe and a triple quadrupole mass spectrometer.

through optimization of the membrane temperature. Detection limit data were obtained with the flow-injection analysis apparatus described elsewhere²⁴ with sample sizes of 250 μ l. A water stream was continuously supplied to the probe by an Ismatec multichannel peristaltic pump (Model 7618-30) and aliquots of reaction mixture or standard solution were injected into this stream as needed. A Finnigan 4500 triple quadrupole mass spectrometer equipped with an Incos data system and operated under electron impact (70 eV) ionization conditions was employed. Full mass spectra and selected ion monitoring experiments were performed. When data were recorded as a function of reaction time, the results were manipulated with the data handling system normally used to record chromatography experiments. The identities of the reaction products were confirmed by measuring the spectra of the daughter ions obtained with a collision energy of 20 eV and collision gas (argon) pressure of 1 mtorr, which corresponds to multiple collision conditions.

The monochloramine solutions (540 and 140 ppm) were supplied by the United States Environmental Protection Agency, Cincinnati. Solutions for the detection limit studies were prepared by serial dilution of the stock solutions with distilled water. The on-line reaction monitoring experiments were done either by adding known volumes of 0.1M hydrochloric acid or concentrated hydrochloric acid to a 540 ppm monochloramine solution (15 ml) or by adding calcium hypochlorite (6 ml of 1 mg/ml solution) to an aqueous ammonia solution (50 ml, 0.015M) and then acidifying the mixture by stepwise addition of 0.1M hydrochloric acid or concentrated hydrochloric acid. In the latter procedure, the pH of the reaction mixture was measured with a Corning 130 pH meter and continuously recorded with a chart recorder. The resulting solution was sampled continuously with the apparatus shown in Fig. 1.

RESULTS AND DISCUSSION

Table 1 lists the ions observed in the EI mass spectrum of an aqueous solution (540 ppm) of monochloramine. The mass spectrum of this compound has not previously been reported. The molecular ion, NH_2Cl^+ , constitutes the base peak and is remarkably stable in contrast to the high reactivity and instability of its neutral counterpart.¹ The daughter ion mass spectrum recorded for both isotopic forms of the molecular ion of monochloramine confirms its stability (Table 2). The agreement between these two daughter spectra confirms the assignments made in Table 1. The detection limit ($S/N = 3$) for monochloramine by membrane introduction mass spectrometry is 0.7 mg/l. (Fig. 2). The detection limit was measured by using flow-injection analysis apparatus (250 μ l sample volume), EI and selected ion detection (ions monitored at m/z 51, 53, 55). The detection limits for dichloramine and trichloramine are about the same, as indicated by similar responses in the corresponding experiments. Under steady state conditions still lower detection limits can be reached.

The reactions of monochloramine with hydrogen chloride were studied on-line and they clearly show formation of dichloramine and trichloramine (Fig. 3) as Margerum *et al.*^{2,3} demonstrated earlier by using spectrophotometry. Data presented in Fig. 3 were collected by scanning full EI mass spectra (mass range 33-300) in real time as the reaction, induced by addition of portions of hydrochloric acid, proceeded. The initial rise of the monochloramine signal represents the time during which water was replaced by 540 ppm monochloramine solution. After the first addition of hydrochloric acid (5 ml of 0.1M solution, added after 3.1 min) formation of dichloramine was

observed and a short time later small amounts of trichloramine were also detected. The full EI mass spectrum (Fig. 4A) at this point (4.4 min) shows ions characteristic of dichloramine and traces of ions characteristic of trichloramine. The mass spectra of the daughter ions from parents with *m/z* 85 and 87 confirm the production of dichloramine (Table 2). Note that almost all monochloramine has been removed, as demonstrated by the negligible abundance of *m/z* 53, which is the heavy isotopic form of the molecular ion, *m/z* 51, of monochloramine. The peak for *m/z* 51 is due to both the molecular ion of monochloramine, NH₂³⁵Cl⁺⁺, and a fragment ion, N³⁷Cl⁺⁺, of dichloramine and trichloramine. The latter ion is formed by dehydrochlorination of the molecular ion (isotopic form *m/z* 87) of dichloramine or by chlorine loss from the molecular ion (isotopic forms *m/z* 121 and 123) of trichloramine. This is demonstrated by

the measured daughter ion mass spectra (Table 2). For this reason the NH₂³⁷Cl⁺⁺ ion, *m/z* 53, is the appropriate ion for monitoring monochloramine.

The production of trichloramine occurred in good yield after the second addition of hydrochloric acid (1 ml of concentrated acid) at 9.1 min (Fig. 3). It shows up clearly in the mass spectrum taken at this time (Fig. 4B) and is confirmed by its daughter spectra (Table 2). The daughter spectra of the molecular ions of dichloramine and trichloramine both show preferential formation of the ionized bivalent species NHCl⁺ and NCl₂⁺. Note that Fig. 4B demonstrates the generation of molecular chlorine (ions *m/z* 70, ³⁵Cl₂⁺; *m/z* 72, ³⁵Cl³⁷Cl⁺ and *m/z* 74, ³⁷Cl₂⁺) simultaneously with the trichloramine. As shown in Fig. 3, the chlorine produced by the second addition of hydrochloric acid disappears quite rapidly, whereas that produced by

Fig. 2. Two consecutive injections (250 μ l each) of 0.7 mg/l. monochloramine solution, illustrating the detection limit obtained by MIMS. Data were collected by use of EI and the selected ion detection mode. Ions measured were m/z 51 ($\text{NH}_2^{35}\text{Cl}^{+\bullet}$), m/z 53 ($\text{NH}_2^{37}\text{Cl}^{+\bullet}$) and m/z 55 (background ion).

further additions of the acid disappears only slowly.

The reaction sequence above was also carried out with a monochloramine solution which was

generated *in situ* from ammonia and calcium hypochlorite solutions at a pH of 11.7. In the case of this reaction mixture, formation of dichloramine was observed after the pH of the

Fig. 3. On-line monitoring of the reactions of monochloramine with HCl. Mass chromatograms presented are m/z 51 ($\text{NH}_2^{35}\text{Cl}^{+\bullet}$) and m/z 53 ($\text{NH}_2^{37}\text{Cl}^{+\bullet}$) for $\text{NH}_2^{35}\text{Cl}$, m/z 70 ($^{35}\text{Cl}_2^{+\bullet}$) and m/z 72 ($^{35}\text{Cl}^{37}\text{Cl}^{+\bullet}$) for chlorine, m/z 85 ($\text{NH}^{35}\text{Cl}_2^{+\bullet}$) and m/z 87 ($\text{NH}^{35}\text{Cl}^{37}\text{Cl}^{+\bullet}$) for NHCl_2 , and m/z 119 ($\text{N}^{35}\text{Cl}_3^{+\bullet}$) and m/z 121 ($\text{N}^{35}\text{Cl}_2^{37}\text{Cl}^{+\bullet}$) for NCl_3 . Additions of HCl were made at the times indicated by the arrows. Data were collected by scanning the full EI mass spectra (m/z 33–300). Note that the ion m/z 51 is due to $\text{NH}_2^{35}\text{Cl}^{+\bullet}$ and $\text{N}^{37}\text{Cl}^{+\bullet}$, in the proportion 4:1.

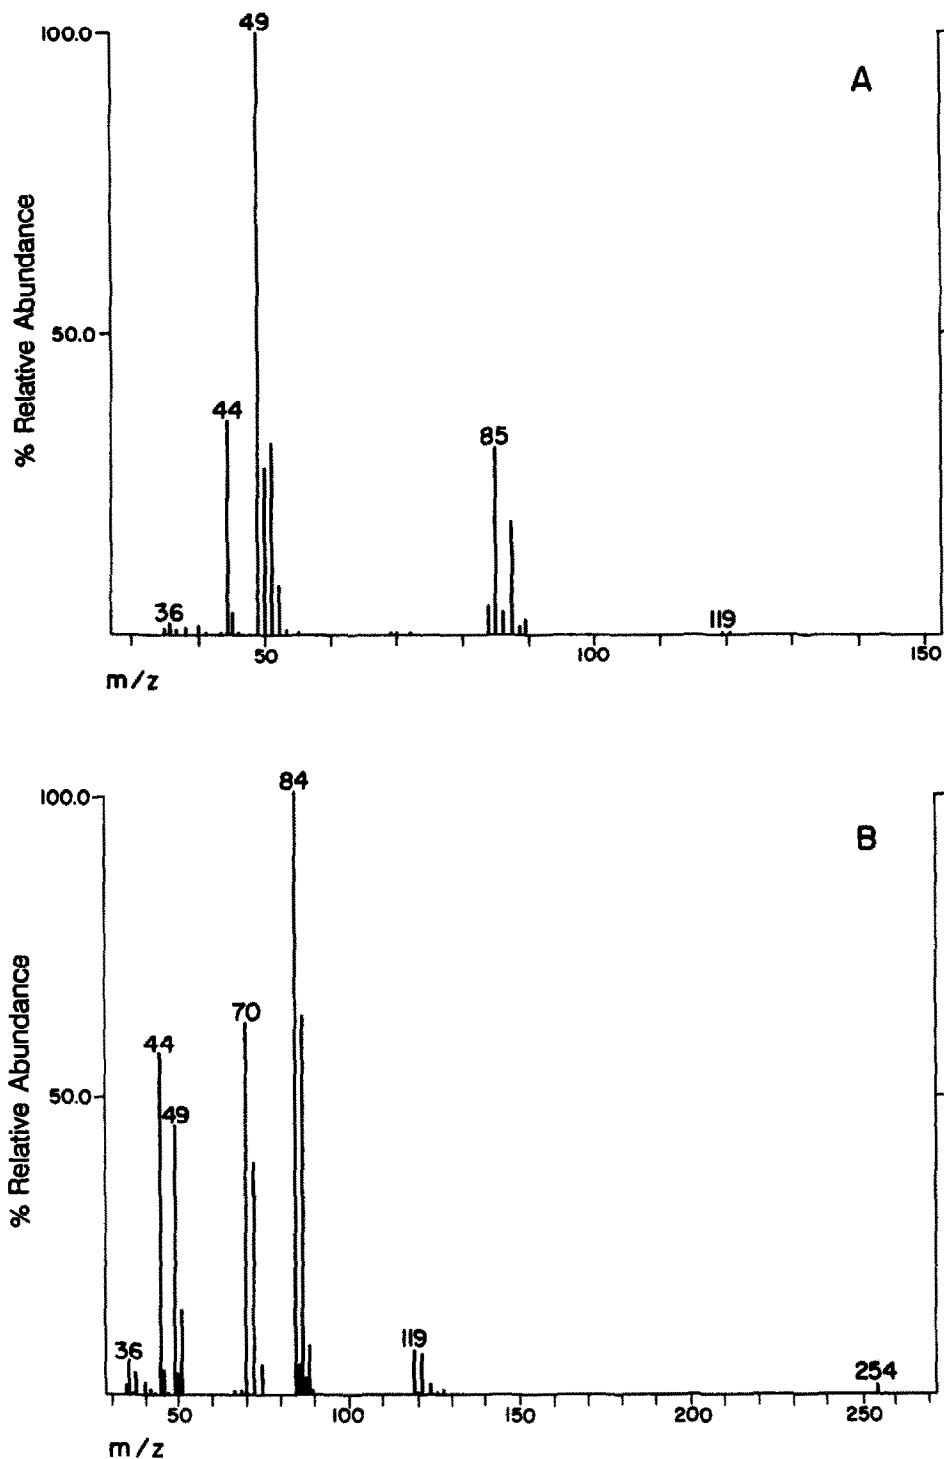

Fig. 4. Representative EI mass spectra for the on-line monitoring experiment (see Fig. 3). A, shows the mass spectrum acquired during scans 266 to 270 (4.4 min) and B, shows the mass spectrum acquired during scans 580 to 585 (9.1 min).

mixture was lowered to 3.3 by addition of hydrochloric acid. Formation of trichloramine required that the pH of the reaction mixture be further lowered to 0.4 by further addition of acid. These results are consistent with the sug-

gestion² that monochloramine, dichloramine, and trichloramine are formed according to the following reactions:

At pH above 9.5 only the formation of monochloramine is observed, and this is in agreement with the suggestion that the only reaction channel available is reaction (1).² When the pH of the reaction mixture is lowered, formation of dichloramine is observed first [reaction (2)] and with further additions of hydrochloric acid conversion of dichloramine into trichloramine is observed [reaction (3)]. The formation of large amounts of chlorine at the same time occurs because, at a pH of 3 or below, the amount of molecular chlorine in equilibrium with hypochlorous acid [HOCl, reaction (4)] is substantial.¹ Chlorine formation could also proceed partly by reaction (5), proposed by Corbett *et al.*,²⁵ since soon after the second hydrochloric acid addition the signal due to trichloramine disappears (Fig. 3). Owing to its high volatility¹ trichloramine may also be partly lost by evaporation.

Other ions of interest observed during the reaction occur at m/z 36, 38, 44, 127 and 254. Ions with m/z 36 and 38 are due to hydrochloric acid, and the ion with m/z 254 is most probably due to molecular iodine, which is liberated from iodide impurities under the strong oxidizing conditions, and m/z 127 is the I^+ fragment. The signal at m/z 44 increases significantly when the solution is acidified and is due to carbon dioxide which is driven out of the solution with decreasing pH, in accordance with the well known bicarbonate (HCO_3^-) and carbonate (CO_3^{2-}) equilibria. The identity of the ion with m/z 44 was confirmed by recording its daughter spectrum (m/z 28, 40%). The signal at m/z 44 decreases slowly after its initial rise and is detected until the end of the experiment (about 30 min).

This study clearly demonstrates the advantages of membrane introduction mass spectrometry for on-line monitoring of the reactions of chloramines and for the determination of chloramines in water down to low ppm levels. The main advantages of MIMS are high specificity for chloramines, high speed of analysis, low detection limits and the ability to automate the sampling process.

Acknowledgements—The authors thank William L. Budde of the US Environmental Protection Agency (Cincinnati, Ohio) for valuable suggestions and H. Paul Ringhand of the

same agency for providing the monochloramine samples. The support of the US Environmental Protection Agency (EPA CR-815749-01-0) is acknowledged. The support provided for T.K. by the Emil Aaltonen Foundation and Suomen Kulttuurirahasto is greatly appreciated.

THE RESPONSE OF SOME ORGANIC MICROSENSOR COATINGS TO A VARIETY OF VAPORS

ALAN R. KATRITZKY*, G. PAUL SAVAGE and MARIA PILARSKA

Department of Chemistry, University of Florida, Gainesville, FL 32611, U.S.A.

(Received 12 April 1990. Revised 25 May 1990. Accepted 12 June 1990)

Summary—Six organic compounds were spray-coated onto surface acoustic wave devices which were then exposed to vapors of acetone, diethyl ether, dichloromethane, chlorobenzene, benzene, and acetonitrile. Changes in the resonant frequency of the device or in the resistance of the coating were collected by computer-controlled data acquisition. Different patterns of response to the six vapors were observed for each of the coatings.

We have previously reported the utility of a number of coatings for chemiresistor and surface acoustic wave (SAW) microsensor devices.¹⁻⁴ Chemiresistor devices⁵ record the change in the resistance between the interdigitated electrodes on the surface of the device upon exposure of a thin film of semiconducting coating to a vapor. SAW microsensors^{6,7} record changes in the resonant frequency of the device upon exposure to vapors. The mode of operation of SAW devices has been described in detail elsewhere.^{4,7}

There are two basic aspects in the development of chemical microsensors. One involves the interface or surface problems associated with the effective and reproducible application of the coating materials to small electronic devices, to take maximum advantage of the chemical properties of the coating. The other is the planning, synthesis, and characterization of new coating materials that satisfy requirements such as sensitivity, selectivity, and chemical stability for the expected operational lifetime of the chemical sensor. Although microsensor technology shows great promise, the lack of adequate coating materials currently impedes their successful development and use.

We have already prepared and tested novel organic compounds as coatings for the sensitive and selective detection of chloroethyl ethyl sulfide (CEES) vapor (a mustard gas simulant) and dimethyl methylphosphonate (DMMP) vapor (a nerve agent simulant). Each coating was also tested against water vapor as this would be the main interferent (in the form of ambient

humidity). This investigation has important application for industrial pesticide monitoring and military defense.⁴ We now turn our attention to coatings that may be suitable for the detection of various other vapors of industrial (acetonitrile, acetone, diethyl ether) and environmental (chlorinated hydrocarbons, benzene) importance. In addition, the detection of diethyl ether vapor has an important application in the monitoring of illicit drug manufacture, as it is a common solvent used in the preparation of cocaine.

The compounds we have selected (1-6, Fig. 1) to test against these vapors have previously been tested against CEES, DMMP and, most importantly, water.^{2,8,9} In each case a minimal response to water vapor was observed.

EXPERIMENTAL

The following compounds have been prepared previously by our group, checked for purity and used without further purification: (1) 2'-*tert*-butyl-5,6-dihydro-4-phenylbenzo[*h*]chromenylium tetrafluoroborate, m.p.¹⁰ 212-214°; (2) 4-*tert*-butylphenylmethylphosphoric acid, m.p.¹¹ 193-194°; (3) diethyl 4-cyanophenylphosphonate, m.p.^{12,13} 31-33°; (4) 4-carboxyphenylphosphonic acid, m.p.^{12,14} > 300°; (5) 2,5-bis(octylthio)-1,3,4-thiadiazole, m.p.⁹ 32°; (6) *N,N*-dimethyl-*N*-octyl-*N*-(2-dodecylthio-1,3,4-thiadiazole-5-thioethyl)ammonium bromide, m.p.¹⁵ 96-98°. The structures are shown in Fig. 1.

Simultaneous chemiresistor and SAW measurements were performed while exposing the device (in turn) to acetone, diethyl ether,

*Author for correspondence.

Fig. 1. Structures of compounds investigated.

dichloromethane, chlorobenzene, benzene, and acetonitrile vapors. The dual 52-MHz surface acoustic wave apparatus used (Microsensor Systems, Inc.), has been described in detail previously.^{1,4}

The SAW resonant frequency was monitored with a digital frequency counter, Phillips Model PM 6674 universal frequency counter (550 MHz). Conductivity measurements were made by application of a I-V bias to one of the two remaining electrodes, and measurement of the current. The precision current-to-voltage converter used consisted of an operational amplifier and a switch-selectable feedback resistor.

The coatings were dissolved in a volatile organic solvent, typically spectroscopic grade dichloromethane, and the device was spray-coated with an air brush, with dry nitrogen as the propellant. The coating thickness was monitored by means of the frequency counter, until a frequency shift of *ca.* 50 kHz was obtained. The frequency shifts caused by the coating were recorded as an indication of coating thickness. Test vapors were generated by passing a regulated flow of nitrogen through the pure liquid at 0°, in a vapor bubbler equipped with a gas dispersion tube. The flow-rate over the detector device was controlled with a flowmeter and was found to be 7.5 ml/min by means of a bubble meter. The vapor concentrations were calculated¹ and were as follows: acetone 190 mg/l., dichloromethane 820 mg/l., benzene 126

mg/l., diethyl ether 840 mg/l., chlorobenzene 15 mg/l., and acetonitrile 60 mg/l. The conditions used were kept the same for successive runs.

Initially the system was purged with nitrogen for 5 min to establish a baseline. The device was then exposed to the vapor for 40 min and this was followed by a nitrogen purge for 50–60 min. If a response was irreversible, the SAW device was cleaned and recoated before exposure to the next vapor. The SAW devices used were rinsed with acetone between runs and this was followed by ultrasonic cleaning for 10 min in spectroscopic grade 2-propanol.

RESULTS AND DISCUSSION

The responses obtained are recorded in Table 1. The frequency shifts were calculated by subtracting the lowest frequency recorded during vapor exposure from the initial (baseline) frequency. Resistance changes were calculated by dividing the initial (baseline) resistance by the lowest resistance recorded during exposure to the vapor. Thus, for the resistance factors, a value close to unity essentially denotes no change. Values marked with an asterisk indicate responses that were irreversible. Results were reproducible within $\pm 5\%$.

As can be seen from Table 1, the compounds were generally of little value as chemiresistor coatings. Because of the noise inherent in

Table 1. Response of compounds 1-6† to various vapors

Vapor	Change in frequency, kHz						Change in resistance (factor)					
	1	2	3	4	5	6	1	2	3	4	5	6
Acetone	5.0	1.6	6.3	2.4	0.0	1.0	2.6	1.3	5.8	1.0	1.0	1.0
Diethyl ether	0.0	2.4	1.7	4.5	6.4	2.2	2.2*	1.6	1.3	1.0	1.0	1.0
CH ₂ Cl ₂	14.9	3.6	9.8	5.3	0.0	3.4	2.6	4.8	17.9	1.5	1.0	1.0
Chlorobenzene	1.0	1.5	2.3	4.4	4.7	1.9	1.0	0.6*	2.6	1.0	1.0	1.0
Benzene	0.0	0.0	1.9	4.0	0.0	1.4	2.6	1.0	2.8*	2.0	1.0	1.0
CH ₃ CN	6.1	0.0	3.3	0.0	0.0	0.4	6.8	1.0	9.0	1.0	1.0	10.0*

*Irreversible response.

†Each coating was applied to a thickness that caused a shift of 53 ± 2 kHz in the frequency.

chemiresistor devices, a signal-to-noise ratio of at least 3 is required and a change in resistance of at least 100-fold is desirable. The largest chemiresistor response recorded with these coatings was 17.9-fold (compound 3 with dichloromethane).

In contrast, several of the compounds showed good responses as SAW coatings. SAW devices usually have better signal-to-noise ratios than chemiresistor devices and so even a frequency shift of a few kHz can be easily distinguished as a signal.

Figure 2 shows the SAW adsorption/desorption curves for the six vapors with compound 1 as the coating. With the vapors that caused a response, it can be seen that the response is quite rapid (*ca.* 5 min) and that the return to baseline frequency also occurs reasonably rapidly when exposure to the vapor is stopped (*ca.* 45 min). This adsorption/desorption profile is typical of each of the coatings.

It is immediately apparent from Table 1 that none of the coatings is completely selective. In

Fig. 2. Plot of change in SAW frequency vs. time for different vapors, with 1 as coating: a, acetone; b, acetonitrile; c, benzene; d, dichloromethane; e, chlorobenzene; f, diethyl ether.

each case a response was observed for at least two different vapors. However, the six coatings gave such different patterns of responses (Fig. 3) that an array of these coatings, coupled with a microprocessor and a pattern-recognition technique,¹⁶⁻²⁰ could easily distinguish between the vapors. Indeed, even the three coatings 1, 2 and 5 together in an array could adequately distinguish between the six vapors.

A clear rationale for the occurrence of these differing responses is not immediately evident. However, compound 1 gave its best responses to the more polar vapors and no response to the less polar vapors (benzene and diethyl ether). This can easily be rationalized in terms of the solubility of the analyte in the coating, and the

Fig. 3. Patterns of responses of coatings 1-6 to various vapors. The coating is indicated in the top left of each graph.

hydrogen-bond acceptor/donor natures of the analyte and coating. Such interactions in the adsorption of organic compounds have previously been discussed in terms of linear solvation energy relationships.^{21,22}

SOLUBILITY OF IRON(II) CARBONATE AT TEMPERATURES BETWEEN 30 AND 80°

ROBERT D. BRAUN

Department of Chemistry, University of Southwestern Louisiana, Lafayette, LA 70504-4370, U.S.A.

(Received 19 March 1990. Revised 18 May 1990. Accepted 22 May 1990)

Summary—Measurements were made of the forward rate-constant (k_f) for the dissolution of FeCO_3 at 10° temperature intervals between 30 and 80° and in buffered solutions at pH 4, 5, 6 and 7. The solubility product (K_{sp}) of FeCO_3 was measured at the same six temperatures. The forward rate-constant is related to temperature (T , $^\circ\text{C}$) and pH by $\text{p}k_f = \text{pH} - 0.0350T + 0.695$. The solubility product of FeCO_3 is related to temperature by $\text{p}K_{sp} = 0.0314T + 10.20$. Kinetic data indicate that, under the conditions of the study, the rate-determining step of the dissolution reaction is $\text{FeCO}_3(\text{s}) + \text{H}^+ \rightarrow \text{Fe}^{2+} + \text{HCO}_3^-$.

In carbon dioxide environments, iron(II) carbonate scale often forms in iron and steel pipes. In some cases the scale is protective and retards or prevents corrosion.¹ Carbonate and iron(II) carbonate have been suggested^{2,3} to be important factors in the mechanisms of corrosion of iron. For that reason, it is important to have reliable values of the solubility product and rate of dissolution of iron(II) carbonate, and these can be used to help estimate corrosion rates. In this study measurements have been made between pH 4 and 7, and at 10° temperature intervals between 30 and 80° .

Measurements of the iron(II) carbonate solubility product are complicated by carbonate/bicarbonate equilibria in aqueous solutions, and accurate determinations require accurate values of the equilibrium constants for the several chemical equilibria involved. Furthermore, heterogeneous chemical equilibria between solid minerals such as siderite (FeCO_3) and its ions in solution are often established slowly. It is probably for these reasons that relatively few successful studies of the solubility parameters of iron(II) carbonate have been completed.

Smith⁴ measured the solubility product of iron(II) carbonate in a carbon dioxide environment and found its value to be 3.453×10^{-11} at 25° . Singer and Stumm⁵ later obtained values of 7.6×10^{-11} , 6.1×10^{-11} , 5.8×10^{-11} and 5.6×10^{-11} at temperatures of 17, 22.5, 25 and 30° respectively. Bardy and Pere⁶ reported a value of 4.0×10^{-11} at 20° . Helgeson⁷ used a value of 2.0×10^{-11} at 25° for thermodynamic calculation of values at higher temperatures.

The calculated values are 9.1×10^{-12} , 6.2×10^{-12} , 1.1×10^{-12} , 1.4×10^{-13} , 8.9×10^{-15} , 4.8×10^{-16} and 2.1×10^{-17} at 50, 60, 100, 150, 200, 250 and 300° respectively. In a related study, Reiterer *et al.*⁸ found the equilibrium constant at 50° for the reaction

to be 4.07×10^7 . Apparently no experimental values of K_{sp} for FeCO_3 at temperatures above 30° are available.

EXPERIMENTAL

Iron(II) was measured spectrophotometrically at 508 nm as its 1,10-phenanthroline complex.⁹ Standard and analyte solutions were prepared by adding sufficient 1,10-phenanthroline solution (Aldrich Chemical Co., Gold Label, 2.50 g/l.) to occupy a tenth of the volume (10–500 ml) of the chosen standard flask. A portion (1–5 ml) of the analyte solution was pipetted into the standard flask and the solution was diluted to the mark with demineralized water. After at least 15 min, a portion of the well-mixed solution was placed in a 1-cm cuvet and its absorbance measured at 508 nm. A calibration curve was prepared, covering the range from 5×10^{-6} to $2 \times 10^{-4} M$. Analyte solutions were diluted so that their concentrations were within this range.

Owing to the large number of calculations performed in the study, the calibration graph was stored in either a Commodore 64 or a Heath H89 computer by use of the appropriate

BASIC program, which was also used to calculate analyte concentrations from the readings taken with a Beckman model B spectrophotometer. Programs were also written in BASIC to perform the remainder of the calculations described in the paper. Listings of the programs can be obtained from the author.

Each of the studies was performed at least three times. The buffer solutions used were prepared as described elsewhere.¹⁰ The pH 4 and 7 buffers had accurately known pH values throughout the temperature range used. The pH 4 buffer was 0.0500*M* potassium hydrogen phthalate. The pH 5 buffer was prepared by adding 430.0 ml of 0.1052*M* sodium hydroxide to 1000 ml of 0.1000*M* potassium hydrogen phthalate. The pH 6 solution was prepared by adding 114.0 ml of 0.1052*M* sodium hydroxide to 1000 ml of 0.1000*M* potassium dihydrogen phosphate. The pH 7 buffer was 0.025*M* potassium dihydrogen phosphate/0.025*M* disodium hydrogen phosphate. The pH 4 and 7 buffers were used for adjustment of the pH-meter to the corresponding known pH¹⁰ at each temperature. The pH values of the thermally equilibrated pH 5 and 6 buffers were measured at each temperature with the adjusted pH-meter and a glass indicator electrode. The values are listed in Table 1. The pH of each test solution was measured at the appropriate temperature after each study. The buffer solutions were used to adjust the pH-meter prior to each measurement.

Studies were performed with the reaction systems in constant-temperature baths at 30, 40, 50, 60, 70 and 80°, controlled to ±0.1° for water baths and to ±1° for oil-baths (70 and 80° only).

Test solutions were prepared by adding 100 ml of buffer solution to 2 g of FeCO₃ (Strem Chemicals, Inc., Newbury, MA) in a 250-ml glass reagent bottle; the bottle was immediately placed in the appropriate bath, the time recorded, and the solution deaerated by rapid passage of high-purity nitrogen through it. The

bottle was then tightly sealed with a rubber stopper, and allowed to come to thermal equilibrium.

An appropriate portion (1–5 ml) of the supernatant liquid was removed from the bottle by pipet (under an atmosphere of nitrogen) once a day for the first 5 days of each study, and thereafter about once a week until equilibrium was established. The sample was collected at the bath temperature. No correction was applied for volume expansion when taking samples at various temperatures. After removal of each portion, the solution was simultaneously stirred and deaerated by rapid passage of nitrogen through it for about 1 min, and the bottle was then immediately tightly stoppered again. Because the iron carbonate was a finely divided powder, it formed a suspension that typically required a day to settle. Tyndall scattering from suspended particles would interfere with the spectrophotometry so sampling was limited to once each day. Each bottle remained in the constant-temperature bath throughout the entire procedure. The starting time and sampling times were recorded to the nearest minute. Each sample was assayed for iron(II) as described above.

THEORY

The solubility of the iron(II) carbonate in each of the buffers at all six temperatures was measured by monitoring the concentration of iron(II) as a function of time until equilibrium was established, as shown by a constant absorbance for several consecutive samplings. After each final iron(II) determination the pH of the sample mixture was measured.

Forward rate-constant

The dissolution of iron(II) carbonate is shown in equation (1), where k_f is the forward rate-constant and k_b is the reverse (backward) rate-constant:

The carbonate released during the dissolution will be in equilibrium with bicarbonate or carbonic acid:

These two reactions have an effect on the dissolution, shifting the equilibrium in equation (1)

Table 1. The pH values of the buffer solutions at the temperatures of the studies

Temp., °C	Buffer solution			
	4	5	6	7
30	4.02	5.09	6.08	6.85
40	4.04	5.07	6.01	6.84
50	4.06	5.10	6.01	6.83
60	4.09	5.13	6.00	6.84
70	4.13	5.20	6.02	6.85
80	4.16	5.24	6.02	6.86

to the right. More dissolution should occur as the pH is decreased. The rate of dissolution is given by equation (4), where the brackets represent molar concentrations, and t is time:

$$\text{Rate} = d[\text{Fe}^{2+}]/dt = k_f - k_b[\text{Fe}^{2+}][\text{CO}_3^{2-}] \quad (4)$$

Early during the dissolution process, little Fe^{2+} and CO_3^{2-} exist in the solution. The concentration of Fe^{2+} is always greater than that of CO_3^{2-} because of the effect of the reactions shown in equations (2) and (3). If the concentrations of Fe^{2+} and CO_3^{2-} are sufficiently small, then $k_b[\text{Fe}^{2+}][\text{CO}_3^{2-}]$ in equation (4) is negligible relative to k_f , and the equation simplifies to:

$$\text{Rate} = d[\text{Fe}^{2+}]/dt = k_f \quad (5)$$

Integration of equation (5) yields

$$[\text{Fe}^{2+}] = k_f t \quad (6)$$

From this equation it is apparent that in the early course of dissolution a plot of $[\text{Fe}^{2+}]$ vs. t should be linear with a slope of k_f . Plots obtained for dissolution in the pH 4 and 5 buffers are linear for the first five days of study, with regression coefficients >0.92 , and these data were used to calculate k_f .

Typical plots are shown in Fig. 1. At $\text{pH} > 5$, k_f was smaller than at pH 4 or 5. Equilibrium was established more rapidly at higher pH because the equilibrium concentrations were lower. Consequently, the forward rate-constant could be calculated from data obtained during a shorter period (typically one or two days).

Fig. 1. Typical plots of iron(II) concentration as a function of time for the first 5 days of studies in pH 4 buffered solutions.

Equilibrium calculations

To estimate K_{sp} (the solubility product) for FeCO_3 , a knowledge of the equilibrium constants for reactions (2) and (3) at the temperatures of the studies is required:

$$K_1 = [\text{H}^+][\text{HCO}_3^-]/[\text{H}_2\text{CO}_3] \quad (7)$$

$$K_2 = [\text{H}^+][\text{CO}_3^{2-}]/[\text{HCO}_3^-] \quad (8)$$

K_1 and K_2 are temperature-dependent. It is possible to use the enthalpy changes and equilibrium constants for these reactions at 25° along with the van't Hoff equation to estimate K_1 and K_2 at other temperatures, but this approach assumes that the enthalpies are temperature-independent. A better approach uses the work of Oddo and Tomson,¹¹ who fitted equations to observed values of conditional equilibrium constants at different temperatures and ionic strengths. Those equations were used in this study.

For measurement of the K_{sp} values for FeCO_3 in the various buffers it is necessary for chemical equilibrium to be established. In the pH 4 buffer this required between $3\frac{1}{2}$ and 7 months, whereas in the pH 7 buffer equilibrium was usually established within several days. Intermediate periods were required to establish equilibrium in the pH 5 and 6 systems. Equilibrium was established more rapidly at higher pH, primarily because less FeCO_3 dissolved. During the lengthy equilibrium periods a significant amount of FeCO_3 dissolves (equivalent to $0.01M$ Fe^{2+} or more in the pH 4 buffer). As FeCO_3 dissolves, both the ionic strength and the pH of the test solution are altered. The volume of the test solution also significantly decreases during the lengthier experiments owing to the many samples removed for assay, and some carbon dioxide may escape from the solution at lower pH. Because of the complications associated with these and other experimental problems, the data obtained with the pH 7 buffer were exclusively used to calculate the K_{sp} of FeCO_3 . In the pH 7 solutions, equilibrium was established relatively rapidly, the pH did not change during the study, and escape of CO_2 should have been negligible.

Because FeCO_3 is sparingly soluble at pH 7, the ionic strength (I) of the solution will be governed by the buffer components, and for the pH 7 buffer is $0.100M$. According to Oddo and Tomson,¹¹ the equilibrium constants K_1 and K_2 [equations (7) and (8)] vary with temperature

(τ , °F) as shown in equations (9) and (10), where the superscript indicates a corrected variable:

$$pK_1^T = 6.4093 - 1.5936 \times 10^{-3}\tau + 8.517 \times 10^{-6}\tau^2 \quad (9)$$

$$pK_2^T = 10.6059 - 4.9700 \times 10^{-3}\tau + 13.3080 \times 10^{-6}\tau^2 \quad (10)$$

These equilibrium constants also vary with ionic strength, the combined effect being expressed by

$$pK_1^{I,T} = pK_1^T - 0.4772I^2 + 0.1180I \quad (11)$$

$$pK_2^{I,T} = pK_2^T - 1.1660I^2 + 0.3466I \quad (12)$$

The values used in the present study were obtained by using equations (9)–(12). First pK_1^T and pK_2^T were calculated for each temperature used (after conversion of the temperature units), and then substituted into equations (11) and (12) along with the ionic strength to give $pK_1^{I,T}$ and $pK_2^{I,T}$.

The corresponding values of $K_1^{I,T}$ and $K_2^{I,T}$ were used to calculate K_{sp} of FeCO_3 . The various values for the pH 7 buffer systems are listed in Table 2.

Because the only source of carbonate in each test solution was the FeCO_3 dissolved, the mass-balance equation for carbonate is

$$[\text{Fe}^{2+}] = [\text{H}_2\text{CO}_3] + [\text{HCO}_3^-] + [\text{CO}_3^{2-}] \quad (13)$$

In this and the other equations, $[\text{H}_2\text{CO}_3]$ should be understood to mean the sum of $[\text{H}_2\text{CO}_3(\text{aq})]$ and $[\text{CO}_2(\text{aq})]$. From the values of $K_2^{I,T}$ listed in Table 2, it is apparent that in these studies $[\text{CO}_3^{2-}]$ is negligible compared to $[\text{HCO}_3^-]$, so the mass-balance simplifies to

$$[\text{Fe}^{2+}] = [\text{H}_2\text{CO}_3] + [\text{HCO}_3^-] \quad (14)$$

The values of $K_1^{I,T}$ in Table 2 can be used to obtain an expression for $[\text{H}_2\text{CO}_3]$ in terms of $[\text{HCO}_3^-]$ at each temperature used. Substitution of that expression and the measured equilibrium concentration of iron(II) into equation (14) allows calculation of $[\text{HCO}_3^-]$. The calculated value of $[\text{HCO}_3^-]$ is then used with the

expression for $K_2^{I,T}$ at the appropriate temperature and the equilibrium hydrogen-ion concentration to calculate $[\text{CO}_3^{2-}]$, and hence the solubility product of FeCO_3 at that temperature:

$$K_{sp} = [\text{Fe}^{2+}][\text{CO}_3^{2-}] \quad (15)$$

RESULTS AND DISCUSSION

Forward rate-constant

The forward rate-constant varies as a function of both the temperature and the pH of the solution. The measured values are listed in Table 3. The pK_f values at a particular temperature varied with pH according to

$$pK_f = a\text{pH} + b \quad (16)$$

where a and b are constants at that temperature. The constants and regression coefficients obtained by least-squares fits of the data points are listed in Table 4. An example of a plot of pK_f as a function of pH is shown in Fig. 2.

The slopes (a) were essentially constant, irrespective of temperature, the mean slope for the six plots being 1.02 ± 0.04 (standard deviation). The slope corresponds to the reaction order with respect to H^+ . Hence the dissolution reaction is first order in H^+ throughout the temperature and pH range used, so the rate-determining step in the dissolution is

The intercepts (b) on the pK_f axis varied linearly ($r = 0.993$) with temperature (T , °C):

$$b = -0.0350T + 0.695 \quad (18)$$

A single equation relating pK_f to temperature and pH can be obtained by taking a as unity and substituting b into equation (16):

$$pK_f = \text{pH} - 0.0350T + 0.695 \quad (19)$$

which can be used to estimate the rate constant for the dissolution of FeCO_3 at any pH between 4 and 7, and at any temperature between 30 and 80°.

Several other experimental factors could affect the dissolution rate, such as particle size and stirring rate. The iron(II) carbonate particle size was too small to be measured with the equipment available but was sufficiently small to result in a suspension which took about a day to settle, so it is unlikely that the dissolution rate would have been significantly increased by further decrease in particle size. The stirring rate

†The anomalous reading at pH 5 was ignored when calculating the values at 60°.

could be important because it could determine the total iron carbonate surface area exposed to the solvent, and because without stirring the dissolution rate is governed by the diffusion coefficients of the ions concerned. In this study the mixture was stirred once each day immediately after removal of the test sample. Although stirring was not extensive, it was sufficient to cause some of the iron carbonate to become suspended. Continuous stirring was not practicable, since the suspension did not completely settle until just before acquisition of the next sample. In any case, it cannot be assumed that the rate constants measured in this study would apply to iron(II) carbonate dissolution when the particle size or mixing rate varied from that used for these measurements.

It was also possible that phosphate or phthalate from the buffer solutions could form complexes with iron(II), thereby increasing the rate of dissolution. Very few studies of iron(II) complexation with phosphate or phthalate have been performed. Lahiri and Aditya¹² proposed

Fig. 3. Variation of the intercepts b (of plots of pK_f as a function of pH) with temperature.

Fig. 4. A plot of pK_{sp} for $FeCO_3$ as a function of temperature.

the existence of an $FeHPO_4$ complex. Their conclusions were based upon potentiometric measurements of solutions containing mixtures of iron(III) and iron(II), but their results are incompatible with the much lower values reported later by Nriagu.¹³ However, the $FeHPO_4$ complex is certainly weak.

Koh and Ryan¹⁴ performed fluorimetric studies of iron dissolved in phthalic acid solutions at pH 4–5. The presence of an iron(II)–phthalate complex was not considered and it is unlikely that such a complex exists. Therefore, the conclusions from the studies performed in the solutions at pH 4 and 5 should not be affected by the use of phthalate buffer solutions.

The presence of an $FeHPO_4$ complex could affect the dissolution kinetics in the pH 6 and pH 7 buffer solutions. The presence of the complex would not have been detectable in the present study. Because 1,10-phenanthroline forms a strong complex with iron(II) ($\log K = 21.3$),¹⁵ the HPO_4^{2-} in any $FeHPO_4$ complex formed would have been displaced by 1,10-phenanthroline during the assay, and this would have caused an erroneously high value for the concentration of dissolved Fe^{2+} , resulting in an erroneously large rate constant for the dissolution.

Solubility product

The solubility product of $FeCO_3$ at each temperature was calculated from the measured values of $[Fe^{2+}]$ at equilibrium in the pH 7 buffer and the conditional equilibrium constants for carbonic acid, as described above. The results are listed in Table 5. The value of K_{sp} decreased with increasing temperature, as observed for a

Table 5. Measured mean solubility products of $FeCO_3$; SD is the standard deviation of the results

Temp., °C	Mean K_{sp}	SD	Trials	pK_{sp}
30	7.85E-12	1.21E-12	3	11.105
40	5.35E-12	1.16E-12	3	11.272

smaller temperature range by Singer and Stumm,⁵ and as calculated by Helgeson.⁷ The pK_{sp} values varied linearly with temperature, and the equation for the best straight line ($r = 0.947$) was found to be

$$pK_{sp} = 0.0314T + 10.20 \quad (20)$$

for the centigrade temperature range 30–80°.

Extrapolation of this equation yields $K_{sp} = 1.0 \times 10^{-11}$ at 25°, which compares favorably (within the probable accumulated experimental error) with the value of 2.0×10^{-11} used by Helgeson for his calculations. The value obtained at 60° by using equation (21), however, is 8.2×10^{-13} , compared to Helgeson's calculated value of 6.2×10^{-12} at the same temperature. In light of these studies, perhaps some of the results from calculations based upon Helgeson's calculated K_{sp} values should be reconsidered. Comparisons are made with Helgeson's values because those values are widely used in corrosion studies.

A comparison of the literature values of K_{sp} reported in the introduction to this paper, with values calculated by equation (21), is shown in Table 6. In each case the value obtained from equation (21) is less than the literature value. If significant formation of an $FeHPO_4$ complex had occurred, the calculated K_{sp} values should have been erroneously large. Since the actual values are less than the corresponding values obtained by other workers who did not use phosphate buffers, it is unlikely that the use of a phosphate buffer significantly altered the results.

Table 6. A comparison of K_{sp} values of $FeCO_3$ obtained by using equation (21) with literature values

DETERMINATION OF LEAD(II) BY ARGENTIMETRY

O. E. S. GODINHO, J. J. R. ROHWEDDER, M. N. EBERLIN,
L. M. ALEIXO and G. DE OLIVEIRA NETO

Instituto de Química, Universidade Estadual de Campinas, C.P. 6154, 130891 Campinas, SP, Brazil

(Received 10 August 1989. Revised 11 July 1990. Accepted 25 July 1990)

Summary—A titrimetric method for determination of lead(II), based on the reaction between plumbite and silver ions, is described. Sodium hydroxide solution is added to the sample until the precipitate of lead hydroxide has redissolved. The solution is then made 0.025M in sodium chloride and titrated with silver nitrate. The titration is monitored with a silver electrode. An error smaller than 0.5% has been obtained for 0.05M lead (II).

The yellow precipitate formed by the reaction between plumbite and silver ions was first described by Wöhler,¹ who gave it the formula $\text{Ag}_2\text{O} \cdot 2\text{PbO}$. Compounds such as $\text{Ag}_2\text{O} \cdot \text{PbO}$, $2\text{Ag}_2\text{O} \cdot \text{PbO}$, $2\text{Ag}_2\text{O} \cdot 3\text{PbO}$ and $2\text{Ag}_2\text{O} \cdot 7\text{PbO}$ have been described by Aston.² Ag_2PbO_2 was first synthesized in the crystalline form by Bullheimer.³ Later Byström and Evers⁴ studied the crystal structure of this compound and found that the other compounds obtained by Aston are actually mixtures of Ag_2PbO_2 and Ag_2O or PbO . Recently Godinho and Eberlin⁵ drew attention to the fact that although known for a long time, this compound is no longer employed for analytical purposes but could be employed, for example, for the identification of lead or silver ions. The present work describes a method for determination of lead(II) by titration of plumbite with silver nitrate, monitored by use of a silver electrode.

EXPERIMENTAL

Reagents

All reagents were of analytical grade. Silver nitrate solutions were standardized by potentiometric titration of sodium chloride in the usual way.⁶ Lead nitrate solutions were standardized by EDTA titration, with Eriochrome Black T as indicator.⁷

Apparatus

A Micronal B375 pH-meter, a silver electrode made in the laboratory, and a Metrohm EA 404 calomel electrode with a salt bridge made with saturated sodium nitrate solution were employed in potentiometric measurements. The silver electrode consisted of a 1-cm length of

1-mm diameter silver wire, but any commercially available silver electrodes may be employed.

Procedure

Pipette 25 ml of 0.05M lead(II) solution into a 100-ml beaker, slowly add 3.0–3.5 ml of 4M sodium hydroxide or alternatively enough sodium hydroxide to dissolve the precipitate. Add 3 ml of 0.25M sodium chloride, immerse the electrodes in the solution and titrate with 0.1M silver nitrate. Read the potential difference after the addition of each aliquot of titrant. By using the titrant volume–potential data-points near the equivalence point, analytically evaluate the end-point by the second derivative method.⁸

During the addition of sodium hydroxide the solution needs to be stirred to avoid the formation of the alkali-insoluble yellow lead(II) oxide. The silver electrode should be conditioned in 0.5M sodium hydroxide solution for about 30 min before beginning the titration.

RESULTS AND DISCUSSIONS

Some examples of titration curves corresponding to the titration of lead(II) in the presence of 0.5M sodium hydroxide with silver nitrate are shown in Fig. 1, which shows a decrease in potential after the inflection corresponding to the equivalence point in the titration performed in the absence of chloride. At this point the precipitate flocculates and acquires a green tone due to the adsorption of silver oxide at the surface of the precipitate. The drop in potential may be explained by considering the formation of a supersaturated solution

Fig. 1. Titration curves corresponding to the titration of 20.01 ml of solution, 0.0499M in $\text{Pb}(\text{NO}_3)_2$ and 0.5M in NaOH with 0.1005M AgNO_3 : (a) in absence of chloride; (b) in presence of $1.0 \times 10^{-3} \text{M Cl}^-$; (c) $2.5 \times 10^{-2} \text{M Cl}^-$; (d) $5.0 \times 10^{-2} \text{M Cl}^-$. Equivalence volume = 19.88 ml

of silver ions before the adsorption of silver oxide. After this point, following the addition of titrant, the formation of a black precipitate of silver oxide in the supernatant solution is observed. However, in the presence of chloride, there is precipitation of silver chloride after the equivalence point and the fall of potential is retarded.

The results of the study of the influence of concentration of sodium hydroxide on the titration of 0.05M lead(II) in the form of plumbite with silver nitrate are shown in Fig. 2. The most adequate working range of sodium hydroxide concentration is between 0.4 and 1.0M. It was observed for 0.05M lead(II) solutions that if sodium hydroxide solution is added until dissolution of the lead(II) hydroxide, the resulting alkali concentration lies in this favourable range although even in this range a positive systematic error, tends to be observed. This error, which is of the order of +1% for lead(II) concentrations equal to or above 0.05M, tends to increase with decrease in the concentration of lead(II).

Fortunately, for 0.05M lead(II) solutions, this error may be reduced if the titration is performed in the presence of chloride. As may be seen in Table 1, good accuracy was obtained when the titrations were performed in 0.5M

Fig. 2. Influence of the concentration of NaOH on the results of titration of 20.00 ml of 0.0502M $\text{Pb}(\text{NO}_3)_2$ with 0.1000M AgNO_3 , in the absence of chloride.

sodium hydroxide and in the chloride concentration range 0.01–0.05M. Above 0.05M chloride there is a decrease in potential jump at the equivalence point. Thus the presence of 0.025M sodium chloride was included in the procedure.

The range of concentration of lead(II) adequate for the application of the method is between 0.05 and 0.07M. For concentrations of lead(II) above 0.07M the formation of yellow lead(II) oxide, which is difficult to dissolve in excess of alkali, was observed. In the recommended lead(II) concentration range addition of the volume of sodium hydroxide solution just necessary to allow dissolution of the precipitate is adequate for the application of the method.

The results of the study of the effect of some foreign ions on the precision and accuracy of the method are presented in Table 2. The non-interference of carbonate shows that it is not necessary to avoid the influence of carbon dioxide during the titration.

Sulphate, if present at the level of concentration of lead(II), does not interfere, irrespective of the order of addition of sulphate and sodium hydroxide. If sulphate is added first, a precipitate of lead(II) sulphate occurs with subsequent dissolution in sodium hydroxide if this is added immediately. At first, this fact indicates the possibility of previous separation of lead(II) from interfering ions in the form of its sulphate,

Table 1. Determination of lead(II) in the presence and absence of chloride

Concentration of lead(II) taken, M	Chloride present, M	Concentration of lead(II) found,*M	r.s.d., %	Error %
0.0503	—	0.0508	0.2	+1.0
0.0503	0.0100	0.0502	0.4	-0.2
0.0503	0.0250	0.0505	0.4	+0.4
0.0503	0.0425	0.0502	0.4	-0.2

*Average of 6 determinations.

Table 2. Study of the influence of foreign ions: the concentration of all interfering ions is 0.05M and all solutions are also 0.025M in chloride

Ion present	Concentration of lead(II) taken, M	Concentration of lead(II) found, M	Error, %
CO ₃ ²⁻	0.0503	0.0504	+ 0.2
SO ₄ ²⁻	0.0503	0.0505	+ 0.4
Zn(II)	0.0503	0.0500	- 0.6
Cu(II)	0.0503	0.0501	- 0.4
NH ₃	0.0496	0.0513	+ 3.4

with subsequent dissolution of the precipitate with sodium hydroxide followed by titration with silver nitrate. However, it was observed that when the suspension of lead(II) sulphate is submitted to the treatment required⁷ for adequate filtration of the precipitate its quantitative dissolution does not occur.

Zinc(II) and copper(II) ions do not interfere at the concentration level studied, which may be of interest in the application of the method to the determination of lead(II) in some alloys. In the first case, the titration is performed in the presence of tetrahydroxozincate and in the second the titration can be performed even in the presence of the precipitate of copper(II) hydroxide.

However, tin(IV) is not completely dissolved and adequate titration curves are not obtained

in its presence. Therefore, it is necessary to separate tin before the titration of lead. Similarly, the large error observed in the case of ammonia is due to difficulty of location of the end-point of titration in virtue of the formation of the silver diammine complex.

The method is simple and requires only readily available reagents. Its accuracy is comparable to that of some classical titrimetric methods. The method may be employed instead of gravimetric or other titrimetric methods where great accuracy is required.

(Received 9 February 1990. Revised 1 June 1990. Accepted 12 June 1990)

Summary—A simple potentiometric method for the determination of organoisothiocyanates is described. The isothiocyanate is treated in acetonitrile medium with an excess of primary amine to convert it into a substituted thiourea and the surplus amine is converted into a dithiocarbamate by addition of carbon disulphide. The solution is then titrated with a copper(II) solution in acetonitrile. The three-step titration curve enables the results to be calculated on the basis of the dithiocarbamate and/or thiourea formed. The method has been successfully applied to the analysis of a commercial insecticide formulation based on isothiocyanate and important mixtures containing isothiocyanates.

The wide commercial use of organoisothiocyanates necessitates convenient and reliable procedures for their determination. The method described here is based on the following reactions. In acetonitrile medium an excess of primary amine smoothly and quantitatively converts isothiocyanates into the corresponding substituted thioureas:

The residual amine can be converted into a dithiocarbamate by treatment with carbon disulphide:

Copper(II) perchlorate in acetonitrile medium oxidizes the thiourea to the corresponding substituted formamidine disulphide¹

and the dithiocarbamate to the corresponding thiuram disulphide² in two well-defined steps:

*Author for correspondence.

The first of these steps results in simultaneous formation of thiuram disulphide and copper(I) dithiocarbamate, the organic moiety of which is then also oxidized to thiuram disulphide.

Potentiometric titration of this system gives a curve with three distinct inflection points. The dithiocarbamate is completely titrated before the potential rises enough to begin the oxidation of the substituted thiourea. This has been confirmed by titration of various mixtures of dithiocarbamates and thioureas.

The method gives the option of calculating the results on the basis of the first and/or second inflection points (corresponding to the amount of dithiocarbamate) or the third inflection point (corresponding to the amount of thiourea formed). The method has been used for analysis of a commercial insecticide formulation (based on methyl isothiocyanate) and analysis of isothiocyanate–isocyanate and isothiocyanate–thiourea mixtures.

Isothiocyanates and isocyanates are similar both in structure and their reactions with ammonia and amines to form substituted thioureas and ureas respectively. Treatment of a mixture (containing one of each species) with an excess of amine and then with carbon disulphide in acetonitrile followed by potentiometric titration with copper(II) could be used to determine both components. The first two steps in the titration curve correspond to the amount of dithiocarbamate (and consequently indirectly to the amount of isothiocyanate and isocyanate present in the mixture) and the third corresponds to the amount of thiourea produced and hence the isothiocyanate content of the mixture. The amount of isocyanate can be found by difference.

The analysis of isothiocyanate–thiourea mixtures is also of importance since isothiocyanates serve as the starting materials for the preparation of thioureas and the method can again be used.

EXPERIMENTAL

Reagents

Acetonitrile (Merck). Distilled twice from phosphorus pentoxide (5 g/l.).

Copper(II) perchlorate standard solution in acetonitrile. Prepared and standardized as described earlier.³

Organoisothiocyanates. Allyl, methyl and phenyl isothiocyanates (Fluka) were distilled

before use. Other alkyl isothiocyanates were prepared by a known method.⁴

Organoisocyanates. *n*-Butyl and α -naphthyl isocyanates (Fluka) were distilled before use. Phenyl isocyanate was prepared by the method of Allen and Bell.⁵

Thioureas. Thiourea (Sarabhai M. Chemicals) was recrystallized before use. Alkyl thioureas were prepared from their corresponding isothiocyanates.⁴

Apparatus

Potentiometric titrations were performed with a bright platinum wire as indicator electrode, a modified calomel electrode (filled with saturated methanolic potassium chloride solution) as reference, and a Toshniwal (India) CL06A type potentiometer.

Potentiometric determination of isothiocyanates with copper(II) perchlorate

Aliquots of isothiocyanate solution in acetonitrile were added with stirring to known volumes of standard (0.02M) *n*-butylamine in acetonitrile, in glass-stoppered vessels and the volumes made up to 20–25 ml with acetonitrile. The vessels were stoppered, swirled to mix the reactants and set aside for 5 min to complete the reaction. Each solution was mixed with 1 or 2 drops of carbon disulphide and titrated at room temperature ($\sim 23^\circ$) with standard (0.2M) copper(II) perchlorate potentiometrically. Figure 1 shows the profile of a typical three-step potentiometric titration. The results calculated on the basis of the first (residual amine) and third (thiourea formed) breaks are given in Table 1.

Analysis of formulations

The experimental details are the same as described above for organoisothiocyanates, the only difference being that aliquots of an acetonitrile solution of the liquid formulation (instead of the isothiocyanate) were added to known volumes of standard *n*-butylamine solution. The profiles of the potentiometric titrations are similar to those obtained for isothiocyanates. The results (Table 2) are compared with those obtained by an independent method.⁶

Analysis of isothiocyanate–isocyanate mixtures

Aliquots of acetonitrile solutions of isothiocyanate and isocyanate in various proportions were analysed by the procedure already given

Fig. 1

for isothiocyanates. The results for a mixture of phenyl isothiocyanate and phenyl isocyanate are given in Table 3.

Analysis of isothiocyanate-thiourea mixtures

Aliquots of acetonitrile solutions of isothiocyanates and thioureas in various proportions were also analysed in the same way as isothiocyanate solutions. The results for analysis of a mixture of *n*-butyl isothiocyanate and *n*-butyl thiourea are given in Table 4.

RESULTS AND DISCUSSION

Organoisothiocyanates are quite resistant to oxidation and reduction. However, they react

Table 2. Recovery of methyl isothiocyanate from technical formulation containing 23.5% active ingredient (mean \pm standard deviation of 5 determinations)

Active ingredient taken, mg	Present method		Comparison method ⁶	
	Found, mg	Recovery, %	Found, mg	Recovery, %
2.82	2.78	98.6 \pm 0.36	2.77	98.4 \pm 0.42

8.46	8.39	99.2 \pm 0.52	8.32	98.3 \pm 0.60
11.28	11.09	98.3 \pm 0.48	11.11	98.5 \pm 0.50

with primary amines to form substituted thioureas, which can be easily oxidized. Hence, this reaction could serve as an important tool for the determination of isothiocyanates. Because isothiocyanates are insoluble in water but react with it⁷ and substituted thioureas are sparingly soluble in water, a non-aqueous solvent is required for the transformation of isothiocyanates into thioureas and oxidimetric determination of the latter. Acetonitrile has been chosen as the solvent for the following reasons.

(i) It is a versatile solvent for non-aqueous redox titrations because of its high dielectric constant, resistance to oxidation reduction, convenient liquid range, ready availability, wide electrochemical range and low toxicity.^{8,9}

(ii) A solution of copper(II) perchlorate in acetonitrile is very stable and is a powerful oxidizing agent.^{8,9}

(iii) In this solvent, carbon disulphide converts amines quantitatively into dithiocarbamates, so isothiocyanates can also be determined through measurement of the residual amine from the derivatization reaction.

Taken, mg	Found, mg	Taken, mg	Found, mg	
4.00	4.04 \pm 0.032	4.00	4.04 \pm 0.028	1:1
4.00	4.03 \pm 0.036	8.00	7.96 \pm 0.024	1:2
4.00	3.96 \pm 0.032	12.00	12.06 \pm 0.048	1:3
4.00	4.00 \pm 0.018	16.00	15.92 \pm 0.072	1:4
8.00	7.94 \pm 0.072	4.00	4.05 \pm 0.036	2:1
12.00	11.93 \pm 0.056	4.00	4.04 \pm 0.032	3:1
16.00	16.12 \pm 0.067	4.00	3.97 \pm 0.032	4:1

Copper(II) oxidizes both a dithiocarbamate and a thiourea in a mixture of the two, giving a three-step titration curve (Fig. 1). The redox potentials of thioureas and dithiocarbamates are sufficiently different to permit selective titration [E° for diethyldithiocarbamate-tetraethyl thiuram disulphide is -0.58 V (*vs.* SCE);¹⁰ E° for thiourea-formamidine disulphide is $+0.42$ V (*vs.* SCE)¹¹]. The results in Table 1 show that the overall standard deviations calculated from the pooled data of all the titrations performed with 2.5 and 5 mg of each isothiocyanate are 0.022 and 0.043 mg, respectively (on the basis of the first potential break, for residual amine) and 0.024 and 0.050 mg, respectively (on the basis of the third potential break, for thiourea formed). The recoveries of methyl isothiocyanate in the analysis of the formulation were in the range 98.3–99.2% with standard deviations in the range 0.4–0.7% (Table 2).

The proposed methods for the analysis of isothiocyanate-isocyanate and isothiocyanate-thiourea mixtures, besides being simple, accurate and reliable, have the added advantage that the complete analysis can be conducted with the same sample solution, resulting in a saving of time and effort. A single potentiometric titration with copper(II) perchlorate enables each mixture to be analysed for both

components. The synthetic mixtures of phenyl isothiocyanate and phenyl isocyanate with ratios in the range 1:4–4:1 were analysed with an average standard deviation of 0.7% for phenyl isothiocyanate and 0.6% for phenyl isocyanate (Table 3). The method has been extended to other mixtures such as ethyl isothiocyanate/ethyl isocyanate; n-propyl isothiocyanate/n-propyl isocyanate; isopropyl isothiocyanate/isopropyl isocyanate; n-butyl isothiocyanate/n-butyl isocyanate, with similar performance to that for the model mixture. The method has also been applied to the analysis of mixtures of isothiocyanates and thioureas. The results recorded in Table 4 for the analysis of synthetic mixtures of n-butyl isothiocyanate and n-butylthiourea with ratios in the range 1:4–4:1 have an average standard deviation of 0.6% for both components. The method has been extended to other mixtures such as methyl isothiocyanate/methyl thiourea; ethyl isothiocyanate/ethyl thiourea; n-propyl isothiocyanate n-propyl thiourea; isobutyl isothiocyanate/isobutyl thiourea; pentyl isothiocyanate/pentyl thiourea, with performance similar to that for the model mixtures.

EXTRACTION AND SEPARATION OF URANIUM AND LEAD WITH LIQUID ANION-EXCHANGERS

N. M. SUNDARAMURTHI and V. M. SHINDE

Analytical Laboratory, Institute of Science, 15 Madam Cama Road, Bombay 400032, India

(Received 24 May 1989. Revised 29 January 1990. Accepted 16 July 1990)

Summary—A method is proposed for the extraction and separation of microgram amounts of uranium(VI) and lead(II) from sodium salicylate solution with high molecular-weight amines such as Aliquat 336, TOA, TIOA, Amberlite LA-1 or Amberlite LA-2 dissolved in xylene. From a critical study of pH, salicylate concentration, amine concentration, diluent and period of equilibration, the optimum conditions were identified. The method permits separation of uranium and lead from binary mixtures with metal ions commonly associated with them, the determination of uranium, and of lead in air samples.

Lead, a toxic and harmful element, is an important constituent of some copper alloys and tin-based white metals. Uranium, an essential element for nuclear energy programmes, is found in association with metals such as copper, iron, cerium, titanium, vanadium, chromium and thorium in ores such as carnotite, torbernite, davidite and brannerite. Estimation of lead at ppm level in environmental samples is also required. There are comparatively few methods for extraction and spectrophotometric determination of uranium(VI) and lead(II). High molecular-weight amines such as trioctylamine (TOA),¹⁻⁵ Aliquat 336,^{6,7} n-dodecylamine,² tri-laurylamine,⁷ Amberlite LA-1,⁷⁻¹¹ Amberlite LA-2,^{12,13} Primene JMT⁷ and tri-iso-octylamine¹⁴ have been used for the extraction of uranium and lead from various aqueous solutions. However, the existing methods suffer from limitations such as the need for strict temperature control,¹⁻⁴ long extraction time^{2,8,12} and emulsification problems.^{2,7} In a few methods^{4,6,10,13,14} the extractions are incomplete. Spectrophotometric determinations at trace level often require pre-concentration of the analyte by extraction, but there has been no systematic study for both uranium and lead, so an attempt has been made to develop a simple method for extraction, separation and spectrophotometric determination of uranium and lead. The method is free from the limitations mentioned above.

EXPERIMENTAL

Apparatus

A Unicam SP 500 spectrophotometer with 1-cm fused-silica cells, a Control Dynamics

digital pH-meter with a combined glass electrode, wrist-action flask shakers and a Varian Techtron AA6 atomic-absorption spectrometer were used.

Reagents

All chemicals used were of analytical grade unless indicated otherwise.

Stock solutions of uranium and lead were prepared by dissolving 1.0 g of uranyl nitrate in 2 ml of concentrated nitric acid, and 0.4 g of lead nitrate in 1 ml of concentrated nitric acid and accurately diluting to 250 ml with distilled water. The solutions were standardized by known methods¹⁵ and diluted as required.

Aliquat 336 (tricaprylylmethylammonium chloride), TOA (trioctylamine), TIOA (tri-iso-octylamine), Amberlite LA-1 (*N*-dodecyltrialkylmethylamine) and Amberlite LA-2 (*N*-lauryltrialkylmethylamine) were used without purification. Solutions of Aliquat 336 (10 mg/ml), TOA, TIOA, Amberlite LA-1 and Amberlite LA-2 (50 mg/ml) in xylene were equilibrated with an equal volume of 1M sodium salicylate before use.

A 1 mg/ml aqueous solution of 4-(2-pyridyl-azo)resorcinol (PAR) was used for spectrophotometric determination of uranium and lead, at 530 and 520 nm respectively.

Sample solution preparation

Add 5 ml of concentrated nitric acid to 0.1 g of leaded copper-base alloys such as gunmetal, brass or bronze and evaporate the solution to dryness. Take up the residue with 4M nitric acid and filter off any metastannic acid, washing it

with 5 ml of hot dilute nitric acid and finally with 10 ml of hot water. Dilute the filtrate to 25 ml with water. Dissolve 0.1 g of tin-base white metal in 5 ml of 47% hydrobromic acid, evaporate the solution to dryness, cool, add 3 ml of 25% v/v sulphuric acid and evaporate the mixture nearly to dryness. Finally dissolve the white mass in 4 ml of concentrated hydrochloric acid and dilute to 25 ml with distilled water.

Heat a suitable weight of calcined bone ash or milk powder with 10 ml of *aqua regia* for 5 min, cool, dilute to about 15 ml, filter, and dilute accurately to 25 ml with water.

For analysis of air-borne particulates, bring the sample into solution by digesting it with a few ml of 25% v/v nitric acid, filter the solution and dilute it accurately to 10 ml.

Extraction of uranium(VI) and lead(II)

To an aliquot of solution containing 1–80 μg of uranium or lead add enough sodium salicylate to give the desired concentration in a final volume of 25 ml. Adjust the pH with dilute hydrochloric acid and sodium hydroxide sodium, transfer the sample into a 125-ml separating-funnel and extract with 5 ml of the selected extraction reagent. Separate the two layers and strip the metal ion from the organic phase with the appropriate stripping agent (see Table 1). Wash the strippings with 5 ml of xylene to remove any dissolved amine and then analyse for the metal ion, either spectrophotometrically or by atomic-absorption spectrometry.

RESULTS AND DISCUSSION

Extraction conditions

Uranium(VI) and lead(II) were extracted over the pH range 3.0–10.0 from sodium salicylate

Fig. 1. Extraction behaviour of uranium(VI) as a function of pH. Extraction of uranium from 0.05M sodium salicylate solution with (A) 1% Aliquat 336; (B) 5% Amberlite LA-1; (C) 5% Amberlite LA-2; (D) 5% TOA and (E) 5% TIOA as an extractant.

solutions in the range 0.0025–0.125M, with various concentrations (0.125–5%) of the high molecular-weight amines. The optimum extraction conditions are reported in Table 1 and Figs. 1 and 2. Microgram amounts of lead were determined by atomic-absorption spectrometry and the results compared with those obtained spectrophotometrically. Both methods were sufficiently sensitive. Since Aliquat 336 extracts metal ions over a wider range of pH than the other ions it was used for further studies.

Effects of solvents

The effect of various solvents such as xylene, toluene, benzene, chloroform, carbon tetrachloride, hexane and cyclohexane on the extraction of uranium and lead with Aliquat 336 was studied and it was found that the extraction of uranium was quantitative with xylene, toluene

Table 1. Optimum extraction conditions for uranium(VI) and lead(II)

Metal ion amount	Salicylate concentration, M	Extractant	pH	Extraction period, sec	Stripping agent	Determination procedure
Uranium(VI) 60 μg	0.05	1% Aliquat 336	3.0–7.5	30	0.5M NaOH (2 \times 4 ml)	Spectrophotometry with 0.5 ml of 0.1% 4-(2-pyridylazo)-resorcinol ⁷
		5% TOA	3.0–4.0	60		
		5% Amberlite LA-1	3.0–3.5	60		
		5% Amberlite LA-2	3.0–3.2	60

Fig. 2. Extraction behaviour of lead(II) as a function of pH. Extraction of lead from 0.025M sodium salicylate solution with (A) 1% Aliquat 336; (B) 5% Amberlite LA-2; (C) 5% Amberlite LA-1; (D) 5% TOA and (E) 5% TIOA as an extractant.

and benzene whereas extraction of lead is feasible only with xylene and toluene. Aliquat 336 solutions (10 mg/ml) in other solvents such as chloroform, carbon tetrachloride, hexane and cyclohexane gave only 74–96% extraction of lead and uranium.

Shaking time

The shaking time for extraction was varied from 10 to 120 sec. The minimum shaking time required is shown in Table 1; longer shaking has no adverse effect.

Choice of stripping agent

Mineral acids in the concentration range 0.8–1.0M and sodium hydroxide solution (0.5–3.0M) were found to be suitable for stripping uranium, but water does not strip it. The results are shown in Fig. 3. Distilled water

Fig. 3. Effect of different stripping solutions for uranium. (A) Hydrochloric acid; (B) nitric acid; (C) sodium hydroxide, (D) perchloric acid and (E) sulphuric acid.

quantitatively strips lead from the organic phase.

Nature of the extracted species

A log–log plot of distribution ratio *vs.* Aliquat 336 concentration at fixed pH and salicylate concentration or of distribution ratio *vs.* salicylate concentration at fixed pH and Aliquat 336 concentration, showed the molar ratio of both extractant and salicylate to metal ion to be 2:1, for both uranium and lead. Hence the species extracted were thought to be ion-association complexes of probable composition $2R_4N^+ \cdot UO_2Sal_2^-$ and $2R_4N^+ \cdot PbSal_2^-$.

Effect of foreign ions

The effect of various amounts of foreign ions on the extraction and determination of uranium and lead (with Aliquot 336 as extractant) was tested. The tolerance limit was set at the amount of foreign ion required to cause $\pm 2\%$ error in

Table 2. Tolerance limit for added ions

Metal ion	Foreign ion tolerated*
Uranium(VI) (60 μg)	Ca (3000); Ba (3000); Hg (2400); Cr (2400); As (1800); W (1800); Au (1200); Al (1200); Mg (1800); Mo (1200); Zn (1200); Cd (1200); Co (600); Ca (600); Ni (600); Mn (600); Hf (600); Pb (600); Ru (600); Ce (300); Os (300); Bi (300); Ti (300); Zr (180); Fe (180); V (150); thiourea (4800); nitrate (4800); fluoride (4800); iodide (3600); bromide (3600); EDTA (3000); citrate (3000); cyanide (2400); oxalate (2400); thiosulphate (2400); tartrate (2400); phosphate (2400); chloride (1800); sulphate (1200); thiocyanate (600).

*Values in parentheses are in μg .

the recovery of uranium and lead. The results are reported in Table 2. A 180- μg amount of both zirconium(IV) and iron(III) is up to 50% co-extracted but does not interfere in the subsequent spectrophotometric determination of uranium with PAR. However, 150 μg of interface vanadium interferes.

In the extraction of lead, ions such as zirconium(IV), iron(III) and zinc(II) are co-extracted but the interference by zinc can be eliminated by selective masking with thiocyanate. Zirconium and iron, however, do not interfere in the determination of lead with PAR. Copper is co-extracted with uranium and lead, and thus interferes in their determination. However, copper can be separated by the selective stripping technique described in the separation of binary mixtures.

Separation from binary mixtures

The separation of uranium(VI) from binary mixtures containing thorium(IV), titanium(IV), zirconium(IV), hafnium(IV) or cerium(IV) was done by selective stripping of uranium with 8 ml of 0.5M sodium hydroxide. Thorium, titanium, zirconium, hafnium and cerium remained in the organic phase and were subsequently stripped with 0.8M hydrochloric acid, 2M sulphuric acid, 2M hydrochloric acid, 1M perchloric acid and 2M hydrochloric acid, respectively. Separation of uranium from copper(II) and calcium(II) was done by first stripping copper and

calcium with water and then stripping uranium with 0.5M sodium hydroxide. Vanadium(V) and chromium(VI) are not extracted into Aliquat 336, so their separation from uranium is possible. Unextracted vanadium and chromium were determined in the aqueous phase whereas the uranium, in the organic phase, was stripped and determined by the recommended procedure. Separation of uranium and iron was done by stripping iron(III) with 1M hydroxylamine hydrochloride and uranium with 0.5M sodium hydroxide.

Similarly, the binary separation of lead from nickel, copper, cobalt and manganese was attempted by selective stripping of nickel and cobalt with 1M ammonia solution, copper with 0.5M ammonia solution and manganese with hydrogen peroxide in ammonia solution. Lead was not separated with any of these solutions, but was finally removed with distilled water and determined by the recommended procedure. Separation of lead from uranium, iron and titanium was done by stripping lead with water, and uranium, iron and titanium with 0.5M sodium hydroxide, 1M hydrochloric acid and 2M sulphuric acid, respectively. Chromium and vanadium are not extracted and hence their separation from lead was possible. The results of the separations are given in Table 3. The recoveries of uranium(VI), lead(II) and the added ions were $\geq 98.8\%$.

Analysis of lead and uranium in 'real' samples

The proposed method was applied to the separation and determination of lead in lead-based alloys such as gunmetal, brass, bronze and tin-base white metal. The results are in good agreement with the certified value (Table 4). The air-borne particles collected from 5 different sites in Bombay by Municipal Corporation Air Quality Monitoring were brought into solution and were extracted as described in the extraction procedure. Results are given in Table 5. Levels of uranium in spiked samples such as calcined animal bone and powdered milk are given in Table 4. The detection limit of lead and uranium was 1–80 $\mu\text{g}/25\text{ ml}$. In environmental samples the detection limit of lead was 0.38 $\mu\text{g}/\text{m}^3$.

Acknowledgement—The authors thank the University Grants Commission, New Delhi for financing the project and the award of a fellowship to N.M.S. Thanks are also due to Mrs. Deshpande, Scientist-in-charge, Municipal Corporation Air Quality Monitoring Bombay for providing air-borne particles.

SPECTROPHOTOMETRIC DETERMINATION OF NICKEL IN VEGETABLE OIL WITH AMMONIUM 2-AMINO-1-CYCLOHEXENE-1-DITHIOCARBOATE

A. SAFAVI, A. A. ENSAFI and A. MASSOUMI

Department of Chemistry, Faculty of Sciences, Shiraz University, Shiraz, Iran

(Received 4 January 1990. Revised 8 August 1990. Accepted 24 August 1990)

Summary—The reaction between nickel and ammonium 2-amino-1-cyclohexene-1-dithiocarboate in aqueous acetone medium at pH 3.0–8.0 results in a stable dark red complex. The ratio of reagent to nickel in the complex is 2:1 and the formation constant is $7.38 \pm 0.12 \times 10^{10}$. Beer's law is obeyed up to $4 \mu\text{g/ml}$ nickel at the absorption maximum at 535 nm. The apparent molar absorptivity is $2.8 \times 10^4 \text{ l. mole}^{-1} \cdot \text{cm}^{-1}$, and the detection limit is 10 ng/ml nickel. The method is applied to the determination of nickel in vegetable oil.

Ammonium 2-amino-1-cyclohexene-1-dithiocarboate (AACD) was first synthesized by Takeshima *et al.*¹ To the best of our knowledge, no work on the chelation properties and analytical use of this compound has been reported. An intense dark red complex is formed between AACD and nickel(II). It is soluble in most organic solvents and in an acetone–water mixture. The colour of the complex ($\lambda_{\text{max}} = 535 \text{ nm}$) contrasts well with the yellow reagent solution ($\lambda_{\text{max}} = 388 \text{ nm}$), permitting the visual detection of very small amounts of nickel. 2-Amino-1-cyclopentene-1-dithiocarboic acid, an analogue of AACD, was introduced earlier as an analytical reagent for nickel.²

A review of the existing analytical methods for the determination of nickel in oils and fats shows that there are some drawbacks associated with each of them.^{3–5}

The spectrophotometric procedure described here is a simple and highly sensitive means of determining trace concentrations of nickel. The method is applied to the determination of nickel in different synthetic samples and in vegetable oil.

EXPERIMENTAL

Reagents

A nickel stock solution (1 mg/ml) was prepared in distilled demineralized water from nickel nitrate and diluted further as required. Stock solutions of other elements (10 mg/ml) were prepared by dissolving suitable salts in water or dilute sulphuric or hydrochloric acid.

AACD was prepared and purified according to Takeshima *et al.*¹ and used as an aqueous $1.0 \times 10^{-3} M$ solution.

Apparatus

The spectra were recorded on a Beckman DK-2A spectrophotometer. Absorbances at a fixed wavelength were measured with a Spectronic 70 spectrophotometer.

General procedure

Transfer 2 ml of a nearly neutral solution containing not more than $40 \mu\text{g}$ of nickel into a 10-ml standard flask, add 1 ml of AACD solution ($3 \times 10^{-3} M$) and dilute to the mark with acetone. Measure the absorbance at 535 nm against a reagent blank, in 1-cm path-length cells.

Determination of nickel in vegetable oil

The standard-addition technique is used. For this purpose, transfer 40.0 g of oil into a 100-ml standard flask and dilute to the mark with acetone. Transfer 5-ml aliquots of this solution into 10-ml standard flasks and add appropriate volumes of standard nickel solution containing 0–20 μg of nickel. Then add 1.0 ml of $3.0 \times 10^{-3} M$ AACD in acetone to each flask and dilute the solution to the mark with acetone. Measure the absorbances at 535 nm against the appropriate blank. Plot absorbance *vs.* amount of nickel added and read the intercept on the *x*-axis in the usual way.

RESULTS AND DISCUSSION

In an aqueous solution, nickel and AACD form a sparingly soluble reddish complex. In water-acetone mixtures the complex is formed almost instantaneously and is soluble if the acetone content of the mixture is $\geq 50\%$ v/v. The absorption maximum of the complex is at 535 nm and that of the ligand is at 388 nm. As neither nickel nor the ligand shows any absorption at 535 nm, this wavelength is used for analytical purposes.

The absorption spectrum of the complex in 50% v/v aqueous acetone was examined at various apparent pH values. Formation of the complex was found to be maximal at apparent pH values in the range 3-8.

The complex is quite stable and the calibration graph is linear. Beer's law is obeyed for nickel concentrations up to 4 $\mu\text{g/ml}$. The molar absorptivity is $2.8 \times 10^4 \text{ l. mole}^{-1} \text{ cm}^{-1}$ at 535 nm and the detection limit is 10 ng/ml nickel.

The continuous-variations⁶ and molar-ratio⁷ methods both show that a 2:1 ligand:metal complex is formed.

Because the nickel complex of AACD is only sparingly soluble in water, an organic solvent must be added. Methanol, ethanol, acetone, acetonitrile and dioxan were tried in different proportions. Aqueous acetone and dioxan were found to be the best solvents. The maximum sensitivity was reached when the organic solvent content was 50% v/v or more.

Varying the ionic strength between 1.17×10^{-4} and 2.00 (with sodium perchlorate) did not affect the absorbance.

The formation constant of the complex, calculated by the method of Likussar and Boltz,⁸ is $(7.38 \pm 0.12) \times 10^{10}$.

Interferences

The criterion for interference was taken as a change of $\pm 2\%$ in the absorbance for 10 μg of

Table 1. The tolerance limit for cations in the determination of 1.0 $\mu\text{g/ml}$ nickel

	Concentration, $\mu\text{g/ml}$
Zn(II), Al(III), Hg(I), Zr(IV), Mg(II), Na(I), K(I), Pt(IV), Pd(II), Mo(VI), La(III), Ce(III), Ti(IV), Hf(IV), Sn(II), Sn(IV), Te(IV), Ca(II)	1000*
Fe(II), Mn(II), Co(II)†	200

nickel, in the presence of a tenfold molar ratio of AACD. No interference results from the presence of 1000-fold weight ratio of chloride, bromide, iodide, sulphate, nitrate, oxalate, citrate, acetate, tartrate, periodate and phthalate. However, carbonate and phosphate interfere when present at 50-fold weight ratio to nickel. These ions can be removed by the addition of barium nitrate to the test solution and filtration of the precipitate prior to the addition of AACD. EDTA is obviously a serious interferent and must be absent.

The tolerance limits for various cations in the determination of 1.0 $\mu\text{g/ml}$ nickel are given in Table 1. Al(III), Zr(IV), Zn(II), Hg(I), La(III), Pd(II), Pt(IV), Ca(II), Mg(II), Hf(IV), Na(I), K(I), Mo(VI), Ce(III), Ti(IV), Te(IV), Sn(II), Sn(IV) at 1 mg/ml concentration did not interfere. Cu(II), Co(III), Fe(II), Fe(III), Mn(II), Bi(III), Ag(I) reacted with the reagent and thus interfered. The effect of these interferents was easily removed by the addition of saturated ammonium thiocyanate to the test solution and separation of any precipitate [Bi(III)] or extraction of the complexes into methyl isobutyl ketone. Under the recommended conditions, thiocyanate does not react with nickel. Pb(II) and Hg(II) can be removed by the addition of sulphate and iodate, respectively, to the test solutions prior to addition of AACD.

Table 2. Analysis of samples by the proposed method

†Vegetable oils were of soya bean origin.

‡Ni content obtained by atomic-absorption spectrometry = $2.85 \pm 0.06 \mu\text{g/g}$.

§Ni content obtained by atomic-absorption spectrometry = $0.401 \pm 0.010 \mu\text{g/g}$.

Applications

The recommended procedure is highly sensitive for the determination of nickel and sufficiently selective for analysis of some natural samples as well as a variety of nickel-containing alloys. The method is simple and rapid. Its utility is shown by the satisfactory analysis of various synthetic samples and by the determination of nickel in vegetable oil (Table 2).

ANALYTICAL DATA

X-RAY POWDER DIFFRACTION DATA FOR NINE ANALGESICS

J. E. KOUNTOURELLIS* and C. K. MARKOPOULOU

School of Pharmacy, 106, Aristotle University, Thessaloniki, 54006, Greece

F. A. UNDERWOOD and B. CHAPMAN

School of Physics, University of Bath, Bath BA2 7AY, England

(Received 22 November 1989. Revised 18 March 1990. Accepted 6 July 1990)

Summary—X-Ray powder diffraction data for nine analgesics have been obtained by using a powder diffractometer. The results obtained by using the McCreery and Byström-Asklund methods of sample loading were averaged and tabulated in terms of the lattice spacings and the relative line intensities. Data from powder camera films were compared with the diffractometer data, and certain discrepancies in the intensities are discussed.

The early work by Hanawalt *et al.*¹ introduced the powder diffraction technique as an instrumental analytical method for the identification of polycrystalline materials. This technique is used here to characterize nine analgesics in terms of interplanar *d* spacings and line intensities relative to the intensity of the strongest line. As the pharmaceutical compounds² examined have not been studied previously by X-ray diffraction and these data are not included in the 1987 Powder Diffraction File,³ the new information may be useful for their identification.

EXPERIMENTAL

Samples

The samples of buprenorphine ($C_{12}H_{17}NO_3$), diclofenac sodium ($C_{14}H_{10}Cl_2NNaO_2$), flufenamic acid ($C_{14}H_{10}F_3NO_2$), mefenamic acid ($C_{15}H_{15}NO_2$), nefopam hydrochloride ($C_{17}H_{19}NO.HCl$) and niflumic acid ($C_{13}H_9F_3N_2O_2$) were purchased from Sigma. Fentiazac acid ($C_{17}H_{12}ClNO_2S$), dipyrone ($C_{13}H_{16}N_3NaO_4S$), (Ercifar S.A. Pharmaceuticals, Athens) and tolmetin ($C_{14}H_{10}F_3NO_2$), (Farmalex S.A. Pharmaceutique, Athens) were kindly donated by the manufacturers.

The samples were at least 99.6% pure and most of them were dried overnight in an oven at 60°. Some samples were suitable as supplied, but

when necessary the particle size was reduced to less than 5 μm by grinding in an agate mortar. The grinding was performed under an infrared lamp to avoid adsorption of atmospheric moisture. Microscopy was used, with the aid of a graticule, to measure the particle size, and the well defined lines on the X-ray diffraction photographs were a strong indication that all the particles were of approximately the same size.

Apparatus and sample preparation

The Debye-Scherrer X-ray photographs were obtained with a Philips 11.4 cm diameter camera (PW 1034/10) with iron-filtered cobalt radiation ($Co K_{\alpha}$ 1.790 Å)

The Philips diffractometer goniometer (PW 1050/25) was used in conjunction with a Xenon proportional counter (PW 1965/30) and a Philips ratemeter/single channel analyser (PW 4620) with output to a chart recorder (PM 8000). Nickel-filtered copper radiation ($Cu K_{\alpha}$ 1.542 Å) was produced by a normal focus tube operated at 40 kV and 20 mA. Samples were scanned at 20° over the 2θ range 5–45° at 1°/min.

In applying this technique, three fundamental methods of packing the sample are possible: (i) loading the powder from the front, (ii) the McCreery method of loading the powder from the back, and (iii) the Byström-Asklund method of loading the powder from the edge.⁴⁻⁷

*sh = shoulder on strong line; b = broad line; the three most intense lines are underlined.

The front-packing method is the least successful way of preparing samples because preferred orientation is not reduced to a minimum. In this case the relative intensities of lines at low angles are distorted and the data may be misleading. Loading methods (ii) and (iii) were therefore employed, and the data in Table 1 are averages of results from the two methods. The diffractometer patterns were recorded by mounting ~2 g of sample in a window in an aluminium specimen holder and then exposing it to the X-ray beam for ~40 min. The calibration of the goniometer was checked with silicon as a standard.

RESULTS AND DISCUSSION

Table 1 shows the data obtained for the nine analgesics in terms of the lattice spacings and the relative line intensities.

The best results, in terms of resolution and separation, were obtained by the powder diffractometer technique. In general the powder camera patterns agreed well with the diffractometer traces, but there were discrepancies in the case of mefenamic acid. Generally, most of the characteristic lines in the diffraction patterns were prominent and sharp, so measurement of the angles and hence of d -values was accurate.

In the diffraction data for the tolmetin the lines occurring at $2\theta > 20^\circ$, although of reasonable intensity, were broad compared to the other lines. In this case the values for the d spacings should be treated with caution.

When the Debye-Scherrer photographic technique was employed for the investigation of mefenamic acid, it was observed that the first two or three lines at low Bragg angles were very intense. The corresponding lines in the patterns obtained by the powder diffractometer, where preferred orientation was reduced to a minimum, were of low or moderate intensity. If these lines at low Bragg angles are ignored, the three most intense lines indicated in Table 1 were the same for both the diffractometer and camera techniques.

Flufenamic acid exhibited the least reproducible diffraction pattern intensities. Some lines in the patterns or in the microdensitometer traces were very intense and prominent in one diffraction pattern or very weak in another under identical conditions of sample loading

and diffractometer operation. Specifically, the lines at 4.69, 4.53, 3.18 and 2.903 Å were sometimes observed to be very intense and at other times rather weak while the lines at 4.98, 4.53 and 3.65 Å were of variable intensity and were either very often split into two lines or had a characteristic shoulder.

In the case of dipyrone, the first line at 8.27 Å is included as one of the three strongest lines because its intensity was not reduced even when the specified alternative methods of packing the sample were used. In some diffraction patterns, the line at 5.61 Å was split into two peaks (5.64, 5.57 Å), and the lines at 4.67 and 3.52 Å had shoulders.

For the remaining compounds, the values of the interatomic d spacings and relative intensities are in agreement for both techniques and both methods of preparing the samples.

CONCLUSION

X-Ray powder diffraction patterns provide a means of identification of crystalline pharmacologically active compounds, but attention to sample preparation is essential. In this study the data presented were obtained by the diffractometer technique, with use of two methods of packing by which random alignment of crystals in the sample is achieved. No fundamental discrepancies in the d spacings were found when comparisons were made with the powder camera results. Some variation between the intensities of the strongest lines in the diffraction patterns obtained by two techniques are explained in terms of preferred orientation in the specimens.

CHARACTERIZATION OF RETENTIVITY OF REVERSED PHASE LIQUID CHROMATOGRAPHY COLUMNS

(Received 17 August 1990. Revised 9 October 1990. Accepted 3 November 1990)

Summary—There are dozens of commercially available reversed phase columns, most marketed as C-8 or C-18 materials, but with no useful way of classifying their retentivity. A useful way of ranking these columns in terms of column “strength” or retentivity is presented. The method utilizes a value for $\ln k'_w$, the estimated retention of a solute from a mobile phase of 100% water, and the slope of the plot of $\ln k'$ vs $E_T(30)$, the solvent polarity. The method is validated with 26 solutes varying in $\ln k'_w$ from about 2 to over 20, on 14 different reversed phase columns. In agreement with previous work, it is found that the phase volume ratio of the column is the most important parameter in determining retentivity. It is strongly suggested that manufacturers adopt a uniform method of calculating this value and that it be made available in advertising, rather than the uninterpretable “% carbon”.

The molecular mechanism of retention for small molecules in reversed phase liquid chromatography is becoming well understood.¹ Dill and co-workers have developed mean-field statistical mechanical theory to account for the interactions of the solute in the mobile phase and in the stationary phase, and have accounted for the variation in chain interactions as a function of the bonding density of alkyl chains on the silica surface.^{2,3} We have been experimentally investigating these theories, and in general, have found excellent agreement.

Theory predicts that two driving forces dominate retention: (i) the free-energy change due to contact interactions of the solute with surrounding molecular neighbors in the stationary and mobile phases, as measured by binary interaction constants, and (ii) the partial ordering of the grafted stationary-phase chains which, at sufficiently high bonding density, leads to an entropic expulsion of solute from the stationary phase relative to that which would be expected in a simpler amorphous oil-phase/water partitioning process. We have tested (i) against an extensive data base of almost 350 sets of experiments and in agreement with theory have found that the mobile-phase contribution to retention

can be described by the binary interaction constants of solutes with solvents.⁴ We have also tested (ii) by synthesizing reversed phase stationary phases over an octadecyl bonding-density range of 1.6–4.1 $\mu\text{mole}/\text{m}^2$, and have found a maximum in the partition coefficient at approximately 3.0 $\mu\text{mole}/\text{m}^2$.⁵ At bonding densities in excess of this value actual partitioning decreases, as the energy required to create a cavity in the stationary phase becomes the dominant force. At low bonding densities retention is driven by enthalpic processes, and at high bonding densities ($> 3.0 \mu\text{mole}/\text{m}^2$), retention is driven by entropic processes. The bonding density of virtually all commercially available reversed phase columns is in the range 2.3–3.0 $\mu\text{mole}/\text{m}^2$.

Whereas partitioning goes through a maximum as a function of bonding density, retention, as measured by the capacity factor, reaches an approximate plateau at a chain-density value of 3.0 $\mu\text{mole}/\text{m}^2$. This apparent anomaly is easily explained. The capacity factor is the product of the partition coefficient and the phase-volume ratio (stationary/mobile) and at high chain densities, while the partition coefficient is decreasing, the volume of the stationary phase is increasing, and the two effects virtually offset each other. This “leveling off” behavior has been reported by others.⁶⁻⁸

†Author for correspondence

While theory has adequately described the partitioning process, there is still a need for a convenient empirical description of retentivity, or column strength. Reversed phase columns are made with a wide variety of functional groups, including C-18, C-8, C-1, phenyl, cyano, and others. Recent studies have compared the retentivity and selectivity of many of these columns, and have shown that even for ostensibly equivalent columns, such as C-18 materials, there are great differences in their properties.⁹⁻¹¹

This variability is due to many factors, including properties of the initial silica such as surface area, pore diameter and volume, and impurities, and also to differences in the bonding reaction used to synthesize the reversed phase material. These variabilities have caused many difficulties for the practicing chromatographer. Choosing the "best" column for a given separation is most often a trial and error process, and methods developed in one laboratory are difficult to use in another unless the brand and manufacturer of the column are the same.

There have been many attempts to classify columns according to their retentivity or selectivity for a particular class of compounds. They include chemometric approaches,¹²⁻¹⁴ the use of compounds from Snyder's solvent selectivity triangle,¹⁵ and others.^{16,17} Smith and Burr have advocated a retention index system based on a series of alkyl aryl ketones to define the retention properties of different columns; a different set of constants for each column is obtained for every different mobile phase composition used, requiring new calibration every time either the mobile phase or stationary phase is changed.^{18,19} Sander and Wise have proposed a series of three polyaromatic hydrocarbons as a probe of the shape-selectivity characteristics of reversed phase materials, and these compounds are now available as a National Institute of Standards and Technology Standard Reference Material (SRM 869).²⁰ Antle and Snyder used gradient elution theory to characterize columns according to their solvophobic retention.^{21,22} They examined columns produced from the same base silica but having different bonded functional groups, such as C-18, C-8, phenyl, C-1 and cyano groups. One unique aspect of their studies was the use of 22 solutes of widely differing chemical properties in the hope that their results would be more widely applicable to everyday separation problems. They combined the phase-volume ratio and the polarity of the stationary phase into an effective "strength"

parameter and ordered the columns in terms of retentivity as C-18 > C-8 > phenyl > C-1 > cyano. They further concluded that the contribution of the polarity of the column to retentivity is small compared to the contribution of the phase-volume ratio. Though their results are useful for other workers, the methodology does not lend itself to characterization of new columns, because of the complexity of the data collection, and the necessity to use both a reference and a standard column.

Here we present a simple method to characterize the retentivity of commercial reversed phase columns, by use of binary mobile phases of water and an organic solvent under isocratic conditions. No reference or standard column is necessary, and solutes of widely varying chemical properties are used to ensure the results will be broadly applicable to everyday separation problems.

EXPERIMENTAL

All retention measurements were obtained either with a Spectra-Physics SP8700 ternary proportioning LC system (Spectra-Physics, San Jose, CA, USA) or with two Spectroflow 400 pumps (ABI Analytical, Kratos Division, Ramsey, NJ, USA). A Valco C6W injection valve (Valco Instrument Company, Houston, TX, USA) and a 20 μ l sample loop were used to inject the solutes. The detection system was either a Spectroflow 783 absorbance detector/gradient controller or a Spectroflow 757 absorbance detector (ABI Analytical) operated at 254 nm. When the two Spectroflow 400 pumps were used, a Rainin Dynamax dual chamber mixer (Rainin Instrument Company, Inc., Woburn, MA, USA) was placed before the injector valve for better mixing of the binary solvents. A Fisher Recordall Series 5000 (Fisher Scientific, Pittsburgh, PA, USA) strip chart recorder was used to record the chromatographic peaks. The solvents used were HPLC grade from Fisher Scientific and the water was treated with a Barnstead Nanopure II system (Barnstead Company, Dubuque, IA, USA) before use.

Chromatographic columns

All DuPont Zorbax columns were purchased from Fisher Scientific; the B&J columns were from Burdick & Jackson Laboratories, Inc. (Baxter Healthcare Corp., Burdick & Jackson Division, Muskegon, MI, USA), and the

Ultrasphere column from Beckman (Beckman Instruments, Inc., Fullerton, CA, USA). The high-density column was synthesized and packed in our laboratories.²³ Some of the properties of these columns, as supplied by the manufacturers, are listed in Table 1.

Chromatographic parameters

The columns were maintained at 30° by a water jacket and a Haake D1 circulator (Fisher Scientific). The 26 solutes used are listed in Table 2. They were from various suppliers and were used without further purification. The solutes were initially injected individually and then, to prevent peak overlap, were grouped into mixtures containing no more than five solutes. Peak assignments were made by comparing both peak area and elution order. The void volume of each column was determined by the injection of water at a mobile phase composition of 75% water and 25% organic modifier. The flow-rate was maintained at 1 ml/min, except for the Burdick & Jackson C-18 column which was used with a flow-rate of 1.5 ml/min. All the retention data were obtained by averaging at least two measurements of a solute. The $E_T(30)$ polarity values for the different mobile phase compositions were calculated from the quadratic relationship between percentage of organic modifier and the $E_T(30)$ values reported by Dorsey and Johnson.²⁴

Regression calculations

The regression calculations were performed with the StatWorks (Heydon and Son Inc., Philadelphia, PA, USA) program on a Macintosh SE (Apple Computer, Inc., Cupertino, CA, USA) microcomputer.

RESULTS AND DISCUSSION

For any given column, the retention is adjusted by changing the strength of the mobile

Table 1 Properties of the RPLC columns as supplied by the manufacturers

phase. Then it is necessary to have an accurate description of mobile-phase strength effects on retention before column retentivity can be explored. It is commonly assumed that a plot of the logarithm of the capacity factor ($\ln k'$) vs. volume fraction of organic modifier will show linear behavior. In fact, it has been known for many years that this is not strictly true. It has been shown both theoretically² and experimentally²⁵ that there is a quadratic dependence of retention on the volume fraction of organic modifier. We have previously shown that the strength of the mobile phase can be conveniently expressed by its $E_T(30)$ solvatochromic solvent polarity.²⁶ With a data set of 332 different retention/volume fraction dependencies, we showed that there is a linear relationship between $\ln k'$ and $E_T(30)$ solvent polarity.²⁶ This relationship can be expressed as

$$\ln k' = mE_T(30) + C \quad (1)$$

where $E_T(30)$ is the polarity value (kcal/mole) of the mobile phase, and m and C are the slope and y -intercept of the linear regression. The slope is then a valid measure of mobile phase strength. Moreover, the slope has also been shown to be directly proportional to the size of the solutes and to the binary interaction constant of water and the organic modifier.⁴ We feel the slope from equation (1) is then a valid descriptor for the mobile-phase contribution to solute retention.

Molecular descriptor approach

The first approach we took was to search for a molecular descriptor of the test solutes that would show the retention effects of the stationary phase and that would be a convenient measure to plot against the slope of equation

Table 3 Regression data for slopes from equation (1) plotted vs van der Waals volume, V_w , of the test solutes

Column	Modifier	Slope $\times 10^3$	y-intercept	r^2
Zorbax ODS	ACN*	4.08	0.845	0.533

Zorbax phenyl	ACN	4.27	0.593	0.484
Zorbax TMS	ACN	9.25	0.336	0.861
Zorbax cyano	ACN	6.98	0.310	0.472

*Acetonitrile

(1). The slope of this plot should show the retentivity of the column being tested. As cavity creation in the stationary phase is a major contribution to solute retention,¹⁻³ we felt a linear relationship should exist between the slope from equation (1) and a molecular size descriptor. It has previously been reported that a linear dependence exists between $\ln k'$ for some solutes and the van der Waals volume, V_w ,²⁷⁻²⁹ or the molecular connectivity index, χ .^{30,31} Slopes from equation (1) were plotted against both of these descriptors, and the regression results for five Zorbax columns are given in Tables 3 and 4. The V_w and χ values were calculated by the methods given in the papers cited, and Figs. 1 and 2 show the data from the Zorbax TMS column, which gave the "best" results with these descriptors. It is curious that this column gave the best results with these descriptors, as the retention mechanism of a TMS column is probably dominated by "adsorption" effects, meaning that the chain length is too short for penetration of the solute into the bonded stationary phase.

The coefficients of determination, r^2 , of these regressions are all well below 0.9, indicating that there is no significant correlation between the slopes from equation (1) and the two molecular size descriptors chosen. There are several possible reasons for this poor correlation. Both the van der Waals volume and the molecular connectivity index are *estimations* of a solute size; furthermore, they cannot account for other interactions that may occur between the solute and the stationary phase.

Table 4 Regression data for plots of slopes from equation (1) vs molecular connectivity index of the test solutes

Column	Modifier	Slope $\times 10^2$	y-intercept	r^2
Zorbax ODS	ACN*	6.21	0.992	0.401
Zorbax C-8	ACN	6.54	1.14	0.417
Zorbax phenyl	ACN	7.14	0.723	0.379

*Acetonitrile.

Fig. 1 Slope from equation (1) vs. van der Waals volume for the 26 test solutes, on the Zorbax TMS column.

Approach using $\ln k'_w$

The second approach we took was to seek a parameter which would accurately include all the interactions between the solute and the stationary phase. An *experimental* measure would be best, as no approximations would be necessary. It had been previously shown that the logarithm of the capacity factor of a solute with a mobile phase composition of 100% water, $\ln k'_w$, is highly correlated to the logarithm of the partition coefficient between octanol and water for that solute.³²⁻³⁵ The $\ln k'_w$ value should be ideal for the purposes of assessing stationary phase retentivity, as it is a measure of partitioning between the stationary phase in question and *pure water*, which effectively deconvolutes any contributions from the mobile phase.

One problem with this descriptor is that it is extremely difficult to measure experimentally. Excessively long retention times and poor peak shapes arising from slow mass transfer effectively eliminate experimental determination of this value, and $\ln k'_w$ is most often estimated by extrapolation (to 100% water) of a linear

Fig. 2 Slope from equation (1) vs molecular connectivity index for the 26 test solutes, on the Zorbax TMS column

Fig. 3 Slope from equation (1) vs $\ln k'_w$, the capacity factor in 100% water, for the 26 test solutes, on the Zorbax TMS column

regression of $\ln k'$ vs. volume per cent organic modifier.^{32,33,36-38}

$$\ln k'_w = S(\% \text{ organic}) + C'$$

We have recently shown that this extrapolation leads to *different* values for the same solute and column with methanol/water and acetonitrile/water mobile phases.³⁹ However, an extrapolation of $\ln k'$ vs. $E_T(30)$ solvent polarity leads to a common intersection for methanol/water, ethanol/water and acetonitrile/water mobile phases for a given solute/column combination, giving much greater confidence that the extrapolated value is meaningful.^{39,40}

Since the slopes from equation (1) and $\ln k'_w$ of the solute summarize the retention effects due to the mobile phase and any specific solute interactions with the stationary phase, respectively, the slope of a plot of these two parameters for a column should be independent of the two effects and should unveil the retentivity of the column, see Fig. 3. The regression parameters of these

plots for all the columns studied are presented in Table 5. The 95% confidence intervals of the slopes of these regressions have been calculated and are listed in the last column of Table 5. The confidence intervals show that almost all the slopes of the regressions are statistically different from one another. Good linearity between the two parameters is also shown, with $r^2 > 0.9$ for all the columns tested, except for the Zorbax ODS and C-8 columns with acetonitrile as the organic modifier. The high r^2 confirms that the slopes from equation (1) are highly correlated with $\ln k'_w$ for the test solutes.

This type of slope vs. $\ln k'_w$ plot is not new. Hammers *et al.* have shown that plots of the slope S and $\ln k'_w$ from equation (2) are linear.⁴¹ They found that the slopes and y -intercepts of these plots formed two empirical parameters that can be used to classify solutes into different groups, and these solute groups can be used to recommend the use of $\ln k'_w$ for the estimation of $\log P_{o/w}$. Schoenmakers *et al.* found good linearity for equation (2) when methanol is used as the mobile-phase modifier but not with acetonitrile or THF.²⁵ They have shown that when linearity is observed, the slopes of these plots can be used to specify the shape of the gradient program to be employed. Moreover, these slopes can be employed to predict isocratic capacity factors from a simple gradient analysis.²⁵ Baty and Sharp observed good correlation between S and $\ln k'_w$ methanol, acetonitrile and THF, with structurally similar solutes.³⁶ They tried to use the slopes and y -intercepts of these plots to predict the capacity factors of the solutes but found that the slopes and y -intercepts vary with the nature of the organic modifiers and columns. Therefore, the chro-

Fig 4 Slope from equation (1) vs $\ln k'_w$ for the 26 test solutes on five Zorbax columns

matographic system and the solute group have to be defined before the capacity factors can be predicted.

For a given organic modifier the general retentivity of the columns in this study is found to be inversely proportional to the slope of a plot of the slopes from equation (1) vs $\ln k'_w$. The usefulness of this relative retentivity scale can be seen by plotting the linear regressions for the five Zorbax columns with acetonitrile as modifier, on one graph, Fig. 4. The slopes from equation (1) are found to be proportional to the size of the cavity created by the solutes;⁴ therefore, at a given solute cavity size, the linear regression having the smallest slope will correspond to the largest $\ln k'_w$ and hence the largest retentivity. From the data shown in Fig. 4, the Zorbax cyano column has the largest slope, followed by the TMS column, phenyl column, ODS column and C-8 column; the retentivity of these columns is in the order C-8 > ODS > phenyl > TMS > cyano. The Zorbax C-8 column seems to have a higher retentivity than the Zorbax ODS column when acetonitrile is used as modifier. However, a careful examination of the confidence interval of these two slopes demonstrates that they actually have no statistical difference. These rankings for the Zorbax columns agree with those found by Walczak *et al.*¹⁴ and Antle *et al.*²² and lend confidence that our approach is valid. The apparently stronger retentivity of the Zorbax cyano column compared to the TMS column with methanol as modifier can be attributed to the hydrogen bonding between the surface silanol groups and the methanol. Cyano columns have been shown to have silanol groups that are more accessible than those of other columns.^{15,42} Since methanol can form hydrogen bonds with these silanol groups,

the surface of cyano columns is significantly modified by the methanol and hence its apparent retentivity is stronger than that of the TMS column. When acetonitrile is used as modifier, its lack of hydrogen-bonding ability results in the retentivity of the TMS column being greater than that of the cyano column. Other commercial columns can be tested by the same procedures and their retentivity compared with that of the Zorbax columns. With methanol as modifier, the B&J C-18 column is found to have greater retentivity than any of the Zorbax columns. The B&J C-8 column is found to have approximately the same retentivity as the Zorbax TMS column, and the Ultrasphere C-8 column is shown to have retentivity between that of the Zorbax ODS and the C-8 columns.

One interesting point raised by many researchers is the importance of the phase ratio of the column on the total retentivity of the column. The significance of the phase ratio for retentivity was also investigated in this study. There is some ambiguity in the calculation of this value. Many methods have been recommended for the measurement of the mobile phase volume.⁴³⁻⁴⁶ Here we use the *maximum* volume of mobile phase as measured by the gravimetric method.⁵ Though this volume includes any organic modifier in the solvation structure of the stationary phase, this still seems the most relevant volume, as there is no energy barrier for diffusion of a solute associated with that organic modifier in the solvation layer, back into the moving mobile phase. The stationary-phase volume was calculated by the method of Sentell and Dorsey and is the volume occupied by the bonded alkyl chains.⁴⁷ The phase ratios of the columns studied were calculated and are listed in Table 6. These values should be viewed with some caution, however, as we used the nominal values for % carbon as supplied by the manufacturer. These values had only one or two significant figures and were probably

Table 6 Phase-volume ratio of the columns in this study

Column	Phase ratio
Zorbax ODS	0.367

Zorbax phenyl	unknown
Zorbax TMS	0.172
Zorbax cyano	unknown
B&J C-8	0.0619
B&J C-18	0.110
Ultrasphere C-8	0.380
High density	0.465

averages from several production runs. In the case of the phenyl and cyano columns, the density of the ligands was not available and the stationary-phase volume and phase ratio of these columns could not be calculated. With the exception of the two B&J columns, the phase ratio of the columns displays the same order as the relative retentivity of the columns. The high-density column, which has the largest phase ratio, is found to be close to having the highest retentivity. This result points out that the phase ratio of a column indeed makes a vital contribution to the overall retentivity of the column.

CONCLUSIONS

This work demonstrates a simple method for the classification of the retentivity or "strength" of reversed phase columns. In agreement with previous work, we have found that the phase-volume ratio is the dominant parameter in determining retentivity. Carbon content, which is the most often used figure of merit in the advertising of commercial columns, is only useful for predicting retentivity if presented along with surface area of the bare silica, or with the bonding density of the ligands. The two most useful values for the practicing chromatographer are bonding density and phase-volume ratio, and the adoption of these numbers is strongly encouraged.

DETERMINATION OF AMINOSACCHARIDES BY HIGH-PERFORMANCE ANION-EXCHANGE CHROMATOGRAPHY WITH PULSED AMPEROMETRIC DETECTION

DEAN A. MARTENS and WILLIAM T. FRANKENBERGER, JR

Department of Soil and Environmental Sciences, University of California, Riverside, CA 92521, U S A

(Received 6 June 1990 Revised 14 August 1990 Accepted 18 August 1990)

Summary—High-performance anion-exchange chromatography (HPAC) was used for the determination of aminosaccharides in microbial polymers, chitin, animal waste, sewage sludge, plant residues and soil. The aminosaccharides, galactosamine, mannosamine and glucosamine were separated on a strong anion-exchange column with 10mM sodium hydroxide as the eluent and determined by pulsed amperometric detection (PAD). The HPAC-PAD methodology was compared with high-performance liquid chromatography (HPLC) with refractive index detection (RI) in terms of selectivity and sensitivity for aminosaccharides. The results indicate that HPAC-PAD required less sample preparation, and was more precise and nearly two orders of magnitude more sensitive than HPLC-RI. HPAC-PAD was not subject to matrix interferences and was highly selective for aminosaccharides. More than 3% of the total nitrogen in alfalfa, and 20% of that in straw, was found to be present as aminosaccharides.

Aminosaccharides are widely distributed in nature and have been reported to occur in plants,¹ micro-organisms,² and crustaceans,³ and have recently been found to be an important constituent of the soil nitrogen pool.⁴ They not only serve as a nitrogen source for plant growth, but may also have an important role in the promotion of good soil structure.⁵

It is believed that 5–10% of the total nitrogen in surface soils is present as aminosaccharides.⁴ Chitin is a polymer of *N*-acetylglucosamine frequently found in soil, and is present in the cell walls, structural membranes and skeletal components of insects and fungal mycelia.⁵ Conditions which favor microbial growth and proliferation in soils tend to increase the hexosamine content of soils. Aminosaccharides are somehow protected from decomposition in soils by being incorporated into the humic acid fraction.^{6,7}

Aminosaccharides in soils are normally extracted by hydrolysis with hydrochloric acid and the resulting ammonium ion is determined by the standard colorimetric method of Elson and Morgan⁸ or by alkaline distillation. The Elson and Morgan method is based on the chromogen formed when the aminosaccharide is heated with an alkaline solution of acetylacetone and then an acidic ethanolic solution of *p*-dimethylaminobenzaldehyde. However, many sub-

stances in soils, including iron and amino acids, produce colors which interfere with this determination of aminosaccharides. The alkaline distillation method involves deamination of aminosaccharides by heating with an alkali. The ammonia released through deamination is then determined by steam distillation, collection in boric acid solution,⁹ and titration.

Aminosaccharides have been isolated from soil hydrolysates by both paper chromatography and ion-exchange chromatography. Previous studies have indicated that most of the aminosaccharides occur as D-glucosamine and D-galactosamine, with the former occurring in the greatest amounts.⁵ *N*-Acetylglucosamine has also been found in soils.¹⁰

High-performance liquid chromatography (HPLC) analysis with refractive index (RI) detection is the most common method for quantification of saccharides but has lagged behind in the determination of aminosaccharides because of poor selectivity of the existing stationary phases and insensitivity of the RI detector. The use of high-performance anion-exchange chromatography (HPAC) with pulsed amperometric detection (PAD) has several advantages over RI detection. PAD with a gold electrode is selective only for compounds containing oxidizable functional groups, including hydroxyl, amine and sulfide. Aminosaccharides

are weak acids with pK_a values in the range 9–11 and thus can be separated as anions by control of the pH of the mobile phase.

The objective of this study was to optimize the chromatography in the determination of aminosaccharides in biological materials and to compare HPAC–PAD with HPLC–RI for quantification of aminosaccharides. Chromatographic parameters such as selectivity, resolution and precision were determined for various aminosaccharides to optimize separation and detection.

EXPERIMENTAL

Reagents

All saccharide standards were obtained from Supelco (Bellefonte, PA). Chitin was obtained from Sigma (St. Louis, MO).

Chromatographic instrumentation

HPAC–PAD detection. The HPAC–PAD analysis was performed with a Dionex (Sunnyvale, CA) LC gradient pump module and Model PAD2 detector. Sample injection was by a Dionex autosampler equipped with a 200- μ l sample loop. Aminosaccharides were separated with a CarboPac PA1 pellicular anion-exchange resin (250 \times 4 mm) and a CarboPac PA guard column (25 \times 3 mm) at a flow-rate of 0.8 ml/min at ambient temperature with a 5–200mM sodium hydroxide gradient system. The aminosaccharides were eluted isocratically with 5mM sodium hydroxide for 15 min, then the eluent concentration was ramped to 200mM in 5 min, and then maintained at this level for a further 5 min. With the instrumentation used, this was achieved with three solutions: A was 18-M Ω water filtered through a 0.22- μ m membrane, B was 100mM sodium hydroxide and C 200mM sodium hydroxide. These were combined in the following proportions.

	0–15 min	15–20 min	20–25 min
A, %	95	95 \rightarrow 0	0
B, %	5	5 \rightarrow 0	0
C, %	0	0 \rightarrow 100	100

The 200mM sodium hydroxide was used to elute interfering species that may act as displacing ions and shorten the retention times in subsequent runs. The mobile phase was degassed to prevent sorption of carbon dioxide and subsequent production of carbonate which would act as a displacing ion and shorten retention times. Sodium hydroxide (300mM) was used as

a post-column addition to reduce baseline shifts that occur with the 5–200mM sodium hydroxide gradient and also to increase the PAD sensitivity. Detection was by triple-pulsed amperometry with a gold working electrode.¹¹ The following working pulse potentials and durations were used for detection of aminosaccharides: $E_1 = 0.05$ V ($t_1 = 720$ msec); $E_2 = 0.60$ V ($t_2 = 120$ msec); $E_3 = -0.60$ V ($t_3 = 120$ msec). The CHOH groups are oxidized at E_1 , E_2 removes the reaction products and E_3 cleans the electrode. Cyclic voltammetry was used in selection of the three potentials. The response time of the PAD was set to 1 sec. Chromatographic data were collected and plotted with the Dionex AutoIon 300 software.

HPLC–RI. The HPLC–RI analysis was performed with a Beckman (Fullerton, CA) System Gold™ liquid chromatograph equipped with a Beckman 110B solvent pump and a Rheodyne Model 7000 sample injector (Berkeley, CA) fitted with a 20- μ l stainless-steel injection loop. The system was composed of the following: a Vydac (Separations Group, Hesperia, CA), 1630 anion-exchange column (250 \times 4.1 mm i.d.), a Bio-rad (Richmond, CA) carbohydrate microguard column (30 \times 4.6 mm), a Beckman μ -Spherogel 300 \times 7.5 mm carbohydrate column (300 \times 7.5 mm i.d.), an Eldex Model III (Menlo Park, CA) thermostatic column heater, an Altex (Fullerton, CA) 156 refractive index detector, and a Hewlett–Packard Model 3390A printer–plotter integrator with variable input voltage. The mobile phase was HPLC-grade water (heated to 85°) at a flow-rate of 0.5 ml/min.

Gas chromatography

Samples were reduced and the acetylated derivatives analyzed by gas chromatography¹ with a Hewlett–Packard 5890A gas chromatograph with a flame-ionization detector. The column used was a 0.2-mm i.d. Chrom Q fused silica capillary column (Alltech, Deerfield, IL). The operating conditions with helium as a carrier gas were injection temperature, 250°; detector temperature, 250° and column temperature, 210°; gas flow, 20.0 ml/min.

Soil treatment

Field plots (2 m \times 2 m) were established by incorporating 25 metric tons per hectare levels of straw (*Hordeum vulgare*) [carbon/nitrogen ratio (C/N), 48.0], poultry manure (C/N, 5.0), sewage sludge (C/N, 5.0) (Riverside, CA), and

alfalfa (*Medicago sativa*) (C/N, 7.0) into an Arlington soil (coarse-loamy Haplic Durixeralf) (pH 7.9; C/N, 12.0) at the Citrus Field Station of the University of California, Riverside. The additives were mixed into the upper 15 cm of soil and irrigated (12 cm water/day) once a week for three months. Field-moist soil samples were sieved through a 1-mm mesh sieve to remove large organic debris. The carbon content was determined by a modified Mebius method¹² and the nitrogen content by a micro-Kjeldahl method.¹³

Isolation of bacterial polymers

The bacterial polymers were isolated as described by Anderson *et al.*¹⁴ and Martin and Richards.¹⁵

Aminosaccharide extraction

Samples (1 g) of air-dried soil, 0.5-g samples of sewage sludge and poultry manure, 0.3-g samples of straw and alfalfa, 0.1 g of chitin, and 1 mg of bacterial polymer carbon [*Chromobacterium violaceum*, American Type Culture Collection (ATCC) 9544 and *Hansenula holstii*, ATCC 2448] were treated with 1.25 ml of 12*N* sulfuric acid for 2 hr at room temperature, then after addition of 1.25 ml of water (to give 6*N* sulfuric acid) were heated at 90° under a reflux condenser for 16 hr.⁴ The mixtures were cooled, then treated with 4–5 ml of water and 1 ml of 0.1*M* EDTA, titrated to pH 4 with 5*M* potassium hydroxide, and centrifuged at 10⁴ rpm. The supernatant solution was diluted to 12 ml.

Purification of acidic extracts

A 1-ml aliquot of acid extract of organic additive, microbial polymer or soil was diluted to 5 ml with water and passed through a Supelco™ strong-acid cation-exchanger (3-propylsulfonic acid, H⁺ form) 3-ml solid-phase extraction column (SCX) (Bellefonte, PA). The SCX column was then rinsed with 3 ml of water to elute all non-retained compounds. The aminosaccharides were eluted with 5 ml of 0.3*M* hydrochloric acid. Quantification by HPLC–RI required further purification of the extracts. An aliquot to be analyzed by HPLC–RI and containing 10–25 mg of aminosaccharides was applied to a column of Bio-Gel™ P-2 (100–200 mesh, 12 × 2.8 cm; Bio-Rad, Richmond, CA). The aminosaccharides were eluted with water.

All samples were filtered through GS 0.22- μ m filters (Millipore, Bedford, MA) before analysis.

RESULTS AND DISCUSSION

Extraction

Numerous reports have shown that aminosaccharides can be extracted from biological materials by treatment with hot mineral acids,^{1,4,16} but the use of these acids at 6*N* concentration results in a high salt concentration in the extracts. The high levels of salts and other possible interference present in the 6*N* acid extracts cause few difficulties for the HPAC–PAD analysis, because of the high level of sodium hydroxide (300*mM*) used as a post column treatment. On the other hand, the HPLC–RI method is subject to many interferences in the analysis of plant and soil extracts. The non-saccharide impurities were selectively removed from the extracts. EDTA (disodium salt) was added before neutralization to prevent co-precipitation of the bi- and trivalent cations with the saccharides extracted. Strong-acid cation-exchange columns were used to retain the aminosaccharides, and elution with water removed most of the impurities. Tests conducted with the SCX resins and the aminosaccharide standards galactosamine, mannosamine, glucosamine, acetyl-D-galactosamine, acetyl-D-glucosamine and acetyl-D-mannosamine showed 98–100% recovery. Acid extracts analyzed by HPLC–RI required an additional pretreatment with the Bio-Rad P-2 gel for removal of salts and other neutral low molecular-weight compounds. Tests conducted with the same aminosaccharide standards showed 100% recovery with the gel. HPAC–PAD required only the treatment with SCX resin before the analysis. Neutral (non-ionic) and basic compounds were eluted in the void volume during the HPAC–PAD analysis.

Liquid chromatographic analyses

The chromatographic characteristics, including t_R , k' and number of theoretical plates are listed in Table 1. The retention times of selected aminosaccharides detected by HPLC–RI indicate co-elution problems with galactosamine, mannosamine and glucosamine (6.30–6.50 min) and *N,N'*-diacetylchitobiose, acetylgalactosamine, acetylmannosamine and acetylglucosamine (10.60–10.72 min). Chromatograms of a mixture of 7 aminosaccharides analyzed by HPLC–RI and HPAC–PAD are shown in Figs. 1 and 2, respectively. All 7 aminosaccharides were detected by HPAC–PAD, but only 3 peaks were evident with HPLC–RI. 2-Deoxy-

Table 1 Chromatographic characteristics in detection of aminosaccharides by HPAC-PAD and HPLC-RI*

Aminosaccharide	HPAC-PAD			HPLC-RI		
	t_R , min	k' †	N ‡	t_R , min	k' †	N ‡
D-Galactosamine	11.24	4.50	3300	6.45	1.1	1160

Acetyl-D-glucosamine	19.90	7.05	6600	10.63	2.6	2970

*HPAC-PAD; CarboPac PA1 (250 × 4.6 mm); eluent, 5mM NaOH for 15 min then ramped to 200mM NaOH in 5 min

HPLC-RI column, Beckman μ -Spherogel (300 × 7.5 mm), eluent, HPLC grade H₂O (85°).

† $k' = (t_R - t_M)/t_M$, where t_R = retention time of solute and t_M = retention time of solvent front

‡ N , number of theoretical plates = $16[t_R/W]^2$ where t_R is the retention time and W the peak width

ribose was used as an internal standard for both analyses. The time of analysis for detection of all 7 solutes by HPAC-PAD was < 20 min.

Column efficiency, expressed as number of theoretical plates (N), ranged from 2800 (D-mannosamine) to 6600 (acetyl-D-glucosamine) for the HPAC-PAD analysis and 1160 (D-galactosamine) to 2978 (*N,N'*-diacetylchitobiose) for the HPLC-RI analysis (Table 1). When the N values were pooled and averaged for all the solutes, the mean N was 4757 for HPAC-PAD and 2550 for HPLC-RI, indicating that the HPAC-PAD analysis was almost twice as efficient for separation of the aminosaccharides.

The precisions and limits of detection (LODs) for HPAC-PAD and HPLC-RI quantification of the selected saccharides are given in Table 2. Precision was determined from the results of ten

200- μ l (HPAC-PAD) or 20- μ l (HPLC-RI) injections of combined standards at 1 mg/l. level for HPAC-PAD and 20 mg/l. for HPLC-RI. The relative standard deviations for detection of various saccharides ranged from 0.1 to 0.25% (HPAC-PAD) and from 0.5 to 0.9% (HPLC-RI). The LODs were examined by spiking extracts with a known amount of the saccharide to be determined. The results show that the LODs for the saccharides tested ranged from 0.15 to 0.35 mg/l. with HPAC-PAD (200- μ l injection), and 30 to 50 mg/l. with HPLC-RI (20- μ l injection), based on a 3-fold signal-to-noise ratio for the baseline ($S/N = 3$). The HPAC-PAD response was linear from the LOD to 5 mg/l. Samples were diluted when necessary. HPAC-PAD gave detection limits nearly two orders of magnitude lower than those given by HPLC-RI. Increasing the injection size beyond 20 μ l in the HPLC-RI analysis

resulted in decreased resolution, owing to increased peak distortion and overlap.

Table 3 shows the resolution (R_s) of selected aminosaccharides detected by HPAC-PAD and HPLC-RI. Overall, HPAC-PAD provided much better separation, with R_s values ranging from 1.05 to 6.10, indicating >96% resolution of Gaussian peaks.¹⁷

Detection of aminosaccharides in chitin, plants and soil

Acetyl-D-glucosamine is a major constituent in the hard shells of crustaceans. Crab shell chitin was used to evaluate the hydrolysis procedure, preliminary purification, and detection of aminosaccharides by HPAC-PAD. Figure 3 is a chromatogram showing the detection of D-glucosamine and acetylglucosamine in a 6N sulfuric acid extract of crab shell chitin. Approximately 65% of the chitin sample solubilized by 6N sulfuric acid was recovered as glucosamine and acetylglucosamine.

Figure 4 shows the HPAC-PAD chromatograms of sulfuric acid extracts of alfalfa,

Fig 3 HPAC-PAD chromatogram of an acidic extract of chitin. Chromatographic conditions as described in Table 1 [1 = 2-deoxyribose (internal standard), 2 = glucosamine; 3 = acetylglucosamine]

soil amended with alfalfa (after three months of decomposition), and an unamended soil. In the alfalfa and alfalfa-amended soil, higher levels of galactosamine, mannosamine, glucosamine, *N,N'*-diacetylchitobiose, acetylglucosamine and acetylmannosamine were detected than in the unamended soil. Gas chromatographic analysis confirmed the

*ND, not detected

detection of glucosamine, galactosamine and mannosamine. The concentration of glucosamine detected in the organic-amended soils was comparable with the values obtained in GC analysis of soils by Benzing-Purdie,¹ although the GC analyses did not detect acetyl-aminosaccharides present in the samples. The concentration of the total aminosaccharides directly extracted from the animal wastes and plant residues ranged from 0.46 g/kg (poultry manure) through 0.64 g/kg (sewage sludge) and 13.5 g/kg (alfalfa), to 17.2 g/kg for straw (Table 4). Glucosamine was the predominant aminosaccharide in the plant materials. Previous work suggested that aminosaccharides in soil were of microbial origin and not from plant additions.^{1,18} However, this study indicates that animal and plant residues may make an important contribution to the aminosaccharide pool in soil. The results also indicate that about 3.7% of the total nitrogen in alfalfa and about 20% of that in straw was present as aminosaccharides. The *Chromobacterium violaceum* polymer contained about 8% aminosaccharides, mainly galactosamine, acetylmannosamine, *N,N'*-diacetylchitobiose and acetylglucosamine whereas, the *Hansenula holstii* polymer contained only a low amount of *N,N'*-diacetylchitobiose (Table 4). Upon decomposition of plant residues in soil, aminosugars released may provide energy for the soil organisms or be complexed in the organic matter fraction.^{7,19}

CONCLUSIONS

The HPAC-PAD work described for quantification of aminosaccharides allows separation and analysis of a complex mixture of aminosaccharides in plant materials, chitin and soil. This study shows that minimal sample preparation is needed for HPAC-PAD. The

combination of an anion-exchange column with triple-pulse amperometric detection and SCX purification results in high selectivity for aminosaccharides. HPAC-PAD is much more rapid, precise, sensitive and selective than HPLC-RI for the determination of aminosaccharides.

DETERMINATION OF METAL IONS BY LIQUID CHROMATOGRAPHIC SEPARATION OF THEIR 2-ACETILPYRIDINE-4-ETHYL-3-THIOSEMICARBAZONE CHELATES

MARK V. MAIN and JAMES S. FRITZ*

Ames Laboratory and Department of Chemistry, Iowa State University, Ames, IA 50011, U S A

(Received 15 June 1990 Revised 27 July 1990 Accepted 1 August 1990)

Summary—A new thiosemicarbazone was prepared, characterized, and used as a complexing reagent for the chromatographic separation and determination of metal complexes by reverse-phase HPLC. The reagent was sufficiently soluble in methanol-water solutions for metal ions to be complexed in this aqueous organic phase, without need for extraction. Many variables affected the retention times of the metal complexes. Several metals were determined selectively by complexation with the reagent and chromatographic separation of the complexes. Interference effects from other metal ions were also investigated.

Determination of several metal ions in the same test sample is often made possible by adding a complexing agent to the sample and then separating the various metal complexes by liquid chromatography. Several review articles have appeared on this approach.¹⁻⁶ It is most convenient to use reagents that form complexes which are water-soluble but are easily separated from each other by liquid chromatography, such as β -diketones,⁷ methylhydroxamic acids,⁸ and bis-hydrazones of 2,6-diacetylpyridine.^{9,10}

In the present work, 2-acetylpyridine-4-ethyl-3-thiosemicarbazone (abbreviated to Hapet) is used for the determination of metal ions through chromatographic separation of their metal complexes.

Hapet

Thiosemicarbazones derived from 2-formyl- and 2-acetylpyridine have proved useful for chelation of various metal ions both for medicinal use¹¹⁻¹⁶ and analytical application.¹⁷⁻²² However, no chromatographic separation of

metal complexes of this type has yet been proposed for the determination of metal ions.

EXPERIMENTAL

Synthesis and characterization of Hapet

To a 100-ml round-bottomed flask were added 0.027 mole of 2-acetylpyridine (Aldrich) and 0.027 mole of 4-ethyl-3-semicarbazide (Aldrich) in approximately 45 ml of absolute ethanol. The mixture was refluxed for 3 hr and after the reaction mixture had cooled, 25 ml of water were added and approximately 45 ml of the ethanol/water solvent was removed under vacuum, with the temperature kept below 35° at all times. The product, 2-acetylpyridine-4-ethyl-3-thiosemicarbazone, was then collected and washed with 10 ml of a 1:1 v/v mixture of methanol and water. The product, which had a very detectable odor, probably due to the presence of excess of 2-acetylpyridine, was recrystallized from 3:2 v/v methanol-water mixture, yielding white needle-shaped crystals.

The following procedures were used to characterize the product. The infrared spectrum was taken with an IBM IR/98 instrument (KBr pellet). The NMR spectrum was obtained on a Nicolet NT-300 with CDCl₃ as the solvent and TMS as the chemical shift standard. The mass spectrum of the sample was obtained with a Kratos MS-50. Elemental analysis of the crystals gave 54.0% C, 6.4% H, 25.2% N, and 14.7% S; C₁₀H₁₄N₄S requires 54.03% C, 6.35% H, 25.20% N, and 14.42% S.

*Author for correspondence

Liquid chromatography studies

The chromatographic system consisted of an LKB 2156 solvent conditioner, an LKB 2249 HPLC gradient pump (mixing chamber volume 0.5 ml), a Rheodyne 7125 injector (20- μ l injection loop) and a Kratos Spectroflow 783 UV-VIS detector. Critical parts of the pump and injector were made of titanium. The column was a PLRP-S 100-Å, 5- μ m polystyrene-divinylbenzene (15 cm \times 4.6 mm) column from Polymer Laboratories.

Eluents were prepared daily by dissolving the components in mixtures of specified volumes of Fisher HPLC grade acetonitrile and tetrahydrofuran and water purified with a Barnstead Nanopure II system. No corrections were made for non-additivity of volume. Acids, bases and ion-pairing salts were all reagent grade or better. All eluents were prepared with aqueous buffers. Possible changes in apparent pH were ignored, except in the study of the effect of eluent pH on retention times of the metal complexes. Most eluents contained $5 \times 10^{-4}M$ Hapet, 25 mM sodium perchlorate, and 21 mM ammonium acetate (pH = 7), unless stated otherwise. Eluent components were mixed and then filtered with 0.2- μ m Nylon 66 (Rainin) filters before use. The flow-rate was 1.0 ml/min

Preparation of solutions

Stock solutions of the metals were prepared from appropriate salts (chloride, sulfate, nitrate and perchlorate). The gallium solution was a commercial standard purchased from Aldrich.

The UV-VIS spectra of Hapet and its gallium complex in 20 mM formate buffer (pH 4.0) were taken, with the buffer as reference. The Hapet

concentration was 40 μ M, and that of the gallium complex was 10 μ M.

Chromatographic samples were prepared by taking an aliquot of stock metal solution and adding enough Hapet to give a final concentration of 1–3 mM. Metal complexes were formed by adding excess of reagent to a somewhat acidic sample and then adjusting the pH. All sample solutions were buffered at the pH of the eluent, and all adjustments in pH were made with sodium hydroxide solution. The samples for the interference studies were prepared in the same way except that the final Hapet concentration was held constant at 3mM. Analyte and interferent metals were both present before addition of the reagent. Analytes were held constant at $1 \times 10^{-4}M$ concentration throughout the interference study (except for gallium, which was $5 \times 10^{-2}M$). The interference study was conducted with an eluent composed of 60% CH₃CN, 40% H₂O, 25 mM NaClO₄, 0.5 mM Hapet, and 12 mM formate (pH = 4.0).

Hapet is moderately soluble in methanol at room temperature. It is possible to prepare a 5 mM stock solution of the reagent in methanol and dilute it with water to 1 mM Hapet, without precipitation of the reagent. The physical characteristics of Hapet are given in Table 1.

RESULTS AND DISCUSSION

Hapet is similar in chemical structure to the bis-hydrazones of 2,6-diacetylpyridine previously used for chromatographic separation of metal ions.^{9,10} However, replacement of the carbonyl groups in the latter reagent by the thiocarbonyl group in Hapet would be expected to

result in increased complexation of metal ions having an affinity for sulfur, and decreased complexation of metal ions that prefer oxygen. A preliminary survey based on spectral evidence indicated that many metal ions form complexes with Hapet, including (a) Hg^{2+} , Pb^{2+} , Cu^{2+} , Bi^{3+} and several platinum-group metal ions, and (b) Co^{2+} , Ni^{2+} , Zn^{2+} , Cd^{2+} , Fe^{3+} , Ga^{3+} and In^{3+} . Good chromatographic separations were obtained for the group (b) Hapet complexes, but the group (a) complexes produced either chromatographic peaks that were too broad to be useful, or none at all.

Both Hapet and its metal ion complexes are soluble in water containing some methanol or acetonitrile. The metal complexes can be separated on polymeric LC columns and detected spectrophotometrically

Conditions for detection

Hapet and its metal complexes absorb in the ultraviolet region. Most of the complexes also absorb in the visible region and are yellow. The spectra of Hapet and the gallium(III) complex at pH 4 are shown in Fig. 1. Most of the other metal complexes gave spectra similar to the spectrum of the gallium(III) chelate. A bathochromic shift is observed on changing from pH 7 to pH 3.3 or 4.0. Detection wavelengths of 380 and 405 nm for chromatographic separations performed at pH 7 and 4, respectively, were chosen so as to maximize the absorbance of the metal complexes relative to that of the free reagent.

The molar absorptivities of most of the metal complexes at 380 nm were about 10^4

Fig 1 Absorbance spectra of Hapet (—) and gallium complex (---) at pH 4

Fig 2 Separation of Co(II), Fe(III), In(III), Zn(II) and Cd(II) Hapet complexes on a PLRP-S column. Eluent conditions: 60% CH_3CN , 40% H_2O , 25 mM NaClO_4 , 0.5 mM Hapet, 21 mM ammonium acetate (pH 7).

$\text{l.mole}^{-1}.\text{cm}^{-1}$ at pH 7, and slightly lower at 405 nm and pH 4, with the exception of the cadmium and zinc complexes, for which they were only 600 and 400 $\text{l.mole}^{-1}.\text{cm}^{-1}$, respectively. The absorbance of free Hapet in the eluent was subtracted electronically.

Eluent

It was necessary to add Hapet to the eluent to prevent partial decomposition of the metal complexes during their chromatographic separation. The retention times of the complexes were not affected by change in the Hapet concentration used, but the chromatographic peaks were considerably broader at very low Hapet concentrations. A concentration of 0.5 mM Hapet gave good peaks (Fig. 2) for 0.1 mM concentrations of the complexed metal ions. The peak at around 2 min appears to be associated with iron in the sample.

Figure 3 shows that as the percentage of acetonitrile in the eluent was increased, the retention times of the complexes were reduced. The slopes of the plots are not parallel, indicating that the elution order can be affected by the percentage of acetonitrile in the eluent.

As the concentration of the ion-pairing reagent (ClO_4^-) in the eluent was increased, the retention time of the Co(II), Fe(III) and In(III) complexes increased, indicating these complexes are positively charged. In contrast, the retention time of the Cd(II) and Zn(II) complexes did not increase with increase in perchlorate concentration in the pH 7 eluent, indicating that the Cd(II) and Zn(II) complexes are neutral. The Zn(II) and Cd(II) complexes were also much more insoluble than the other metal complexes,

Fig. 3. Dependence of adjusted retention time on the percentage of acetonitrile in the eluent

which would also indicate that they were neutral.

Table 2 shows that the adjusted retention times of the Ga, Co, Fe and In complexes were unaffected by the eluent pH, whereas those of the Zn, Ni and Cd complexes varied greatly. Formation of neutral complexes of these metal ions with Hapet would require the removal of protons, so dependence of their retention time on pH is not surprising. Either the thiol or thione form of the semicarbazone could be involved in chelation of the metal ions, but the exact structure of the metal complexes in solution was not determined.

Chromatographic separation of metal-Hapet complexes

Many of the metal complexes could be separated successfully under both neutral (pH = 7) and acidic (pH = 4) conditions. The Ni(II), Co(II), Fe(III), In(III) and Ga(III) complexes all produced nice chromatographic peaks under both conditions. Figures 4 and 5 show chromatographic separations of the Ni(II), Co(II), Fe(III) and In(III) complexes and the Ga(III) and In(III) complexes,

respectively, under acidic conditions. Almost identical results were obtained under neutral conditions.

Although an excellent separation of complexed gallium(III) and indium(III) was obtained (Fig. 5), the iron(III)-Hapet complex was co-eluted with the gallium complex. It was hoped that reduction of iron from (III) to (II) and complexation with 1,10-phenanthroline would permit the chromatographic determination of gallium without interference from iron, but though this treatment did remove the chromatographic peak due to iron, the gallium peak was also missing from the chromatogram. Attempts were also made to resolve the iron and gallium peaks by replacing some of the acetonitrile in the eluent with tetrahydrofuran, but this only decreased the already poor resolution of the two metal complexes.

Calibration and determination

Calibration graphs were prepared for In(III), Co(II), Zn(II), Ni(II), Ga(III), Fe(III) and Cd(II) under isocratic elution conditions. The elution conditions, linear calibration range, and limits of detection are shown in Table 3. All the

Fig. 5 Separation of the Ga(III), and In(III) Hapet complexes on a PLRP-S column. Eluent conditions: 60% CH₃CN, 40% H₂O, 25 mM NaClO₄, 0.5 mM Hapet, 12 mM formate (pH 4)

metal complexes were eluted at between 3 and 8 min under the conditions used.

Good linear calibration plots were obtained for all the metals over at least 2 orders of magnitude, except for zinc. The lower end of the range for some metal complexes was limited because of co-elution of excess of reagent. The upper end of the range for Zn(II) and Cd(II) at

pH 7 was limited by the solubility of the metal complexes. Although most of the calibration work was performed for neutral pH conditions, it should be noted that In(III) also gave a linear calibration curve from 7×10^{-7} to $1 \times 10^{-3} M$ at pH 4.3. For determination of Ni(II), Co(II), Ga(III), Fe(III) and In(III) a pH of 4 appears to work quite nicely. If Zn(II) or Cd(II) are also

present, however, the pH should be raised to increase their retention times and remove their potential interference.

Interferences

These were tested for by adding various metal ions to sample solutions containing Ni(II), Co(II), Fe(III), Ga(III) and In(III). A foreign ion was considered to interfere if the peak height of the metal complex was changed by more than $\pm 5\%$. A 1000-fold molar ratio (to analyte) of Na^+ and Ca^{2+} , 100-fold molar ratio of Al^{3+} and 10-fold molar ratio of Mn^{2+} , Pb^{2+} , Ce^{3+} and Bi^{3+} gave no interference in the analyses. Hg^{2+} , Cu^{2+} , Zn^{2+} and Cd^{2+} could be tolerated only at equimolar concentrations. It should be noted that although the Zn(II) and Cd(II) complexes interfere in determination of many of the metal complexes at pH 4, this interference can be removed by raising the pH of the eluent.

(Received 5 June 1990 Accepted 27 July 1990)

Summary—Effective methods are described for the chemical separation of rhenium, osmium and molybdenum. The methods are based on distillation and anion-exchange chromatography, and have been the basis for rhenium–osmium isotope studies of ore deposits and meteorites. Successful anion-exchange separation of osmium requires both recognition and careful control of the osmium species in solution; thus, distillation of osmium tetroxide from a mixture of sulfuric acid and hydrogen peroxide is preferred to anion-exchange. Distribution coefficients measured for perhenate in sulfuric acid media are sufficiently high ($K_d > 500$) for rhenium to be directly loaded onto an ion-exchange column from a distillation residue and subsequently eluted with nitric acid. Polymerization of molybdenum species during elution is prevented by use of a solution that is 1M in hydrochloric acid and 1M in sodium chloride.

The rhenium-187–osmium-187 decay scheme provides the basis for a powerful geochemical and geochronological tool that has been known for more than 30 years.^{1,2} The widespread application of this isotopic system, however, has been hampered by the lack of suitable mass-spectrometric techniques and appropriate chemical separations. Renewed interest in rhenium–osmium isotopes has been created by the recent demonstration of the ability of secondary ionization mass spectrometry (SIMS) to measure precisely and sensitively isotopes of these two elements.^{3,4} At least four other techniques now may become competitive with SIMS by virtue of sensitivity, speed of measurement, and precision; these techniques are laser microprobe mass analysis, inductively coupled plasma mass spectrometry (ICP-MS), tandem accelerator mass spectrometry, and resonance ionization mass spectrometry (RIMS). Each of these techniques has been applied to measurements of osmium isotopes.⁵⁻⁸

Previous analytical methods reported for the rhenium–osmium isotopic system have generally depended on the acid dissolution of a metal,

sulfide or silicate, followed by distillation of osmium tetroxide from a sulfuric acid medium containing Cr(VI)^{2,3,9} or Ce(IV).⁸ In another approach, fusion with sodium peroxide was used to dissolve Cretaceous–Tertiary boundary material before distillation of osmium tetroxide from perchloric acid.⁶ In a related area, the quantitative distillation of osmium tetroxide from a mixture of sulfuric acid and hydrogen peroxide, after an alkaline fusion,¹⁰ has been used successfully in the carrier-free separation of osmium from platinum metal ore for neutron-activation analysis.¹¹ After osmium separation, rhenium may be recovered by distillation at a higher temperature from a dichromate–sulfuric acid solution^{2,9} or from perchloric acid.¹² In most recent studies, solvent extraction of rhenium has been preferred. Aliquat-336‡ and other quaternary amines are widely favored,^{13,14} but the ease of back-extraction into alkaline or ammoniacal media has made tertiary amines¹⁵ particularly attractive.^{3,8}

Approaches to the separation of rhenium, osmium and molybdenum reported here have formed the basis for the development of effective rapid methods for numerous studies of rhenium–osmium isotope geochemistry and geochronology.¹⁶⁻¹⁹ Materials analyzed contain from less than 1 ng/g to more than 10 µg/g rhenium and osmium and vary widely in place of origin, geological age and bulk composition. Samples include iron meteorites, carbonaceous

and enstatite chondrites, chromitites, gold-rich ores and many types of sulfides. Chemically, the sulfides ranged from molybdenite (molybdenum disulfide) to ores containing up to 19% copper and up to 49% nickel. The separations described in detail in this account of research provide data on anion-exchange and chemical species that are applicable to many chemical investigations of rhenium and osmium in rocks, minerals and meteorites.

EXPERIMENTAL

Apparatus

The elution of osmium, rhenium and molybdenum from ion-exchange columns was monitored by inductively coupled plasma atomic emission spectrometry (ICP-AES). Aerosols produced from eluent solutions by a fixed cross-flow nebulizer were injected into an argon plasma sustained by 1.1 kW of forward power from a 27.12-MHz generator. Flows of argon through each of the plasma-torch channels were: injector, 0.64; intermediate, 0; and outer, 17 l./min. A constant flow (0.8 l./min) of each eluent solution to the nebulizer was provided by a peristaltic pump (Gilson Minipuls 2). Background-corrected relative intensities of the Mo(II) 202.030 nm, Os(II) 228.226 nm, and Re(I) 197.313 nm lines were measured at 16-mm observation height with a direct-reading polychromator (Jarrell-Ash model 1160) having a focal length of 0.75 m and a bandpass of 0.036 nm. The polychromator was equipped with a separate 0.5-m Ebert monochromator (bandpass 0.04 nm) that functioned as a tunable channel.²⁰ Measurements for osmium and rhenium were made with the 0.5-m Ebert monochromator, which, unlike the polychromator, has no motor-driven quartz refractor plate at the entrance slit to enable automatic correction of the spectral background. Thus, the signal generated by a blank solution was subtracted from the gross line signal to provide the background correction, which always constituted less than 5% of the gross signal. Concentrations of osmium, rhenium and molybdenum in the eluent solutions were kept well above the detection limits²¹ (by a factor of at least 50) to enable relative standard deviations of less than 1% for four replicate measurements.

Reagents

Osmium Much of the fascination, and most of the exasperation, related to osmium chemistry

lies in the multiplicity of oxidation states and complex species that can exist, and often co-exist, in solution. Thus, preparation of a recognizable single species is an important first step because both the ion-exchange behavior and the response of the ICP-AES are affected by the chemical form of osmium.^{22,23} Three 250-ml stock solutions [Os-1, Os-2 and Os-3] were prepared from 0.25 g each of osmium tetroxide (Fisher purified osmic acid) contained in sealed glass ampules. Each solution was treated so that it contained a species of osmium different from that in the others. Three dilutions of each stock solution were made, and each dilute solution was treated to form or maintain a distinct osmium species. A fourth solution was prepared from ammonium hexachloro-osmate(IV). Details concerning the preparation of these solutions are given below.

Os-1. The osmium tetroxide dissolved rapidly in a solution of 10.5 g of sodium hydroxide in 100 ml of water to give a brown solution of $\text{Na}_2[\text{OsO}_4(\text{OH})_2]$. Ethanol (5 ml) was added, and the solution turned very dark brown. The solution was warmed for 20 min, during which the brown color changed to purple. Another 5 ml of ethanol were then added, and the solution was gently heated to complete the color transformation to purple. This solution was diluted to 250 ml with 1M sodium hydroxide to provide a final concentration of 624 $\mu\text{g/ml}$ Os as $\text{Na}_2[\text{OsO}_2(\text{OH})_4]$. Portions of 30 ml each were treated as follows and diluted to give 100 ml of solution containing 187 $\mu\text{g/ml}$ osmium.

Os-1A. Addition of 2.8 g of sodium hydroxide to a portion of Os-1 solution and subsequent dilution gave a purple solution of $\text{Na}_2[\text{OsO}_2(\text{OH})_4]$ in 1M sodium hydroxide.

Os-1B. Addition of 32.5 ml of 4M nitric acid to a portion of Os-1 solution caused the solution to become opaque black and to appear on the point of precipitating hydrated OsO_2 . The solution became colorless after stirring for 20 min. After dilution, this solution contained OsO_4 in 1M nitric acid.

Os-1C Addition of 11 ml of 12M hydrochloric acid to an Os-1 solution gave, after dilution, a pale brownish-yellow solution (unlike solution Os-2, described later) of $\text{Na}_2(\text{OsO}_2\text{Cl}_4)$ in 1M hydrochloric acid.

Os-2. Osmium tetroxide was dissolved in sodium hydroxide solution and diluted to a final volume of 250 ml to give a solution containing 603 $\mu\text{g/ml}$ osmium as $\text{Na}_2[\text{OsO}_4(\text{OH})_2]$ in 1M sodium hydroxide. Portions of 30 ml were

diluted to 100 ml after the following treatments, to give solutions containing 181 $\mu\text{g/ml}$ osmium.

Os-2A. Addition of 2.8 g of sodium hydroxide to a portion of Os-2 solution gave the same light brown solution as Os-2, which contained $\text{Na}_2[\text{OsO}_4(\text{OH})_2]$ in 1M sodium hydroxide.

Os-2B. Addition of 32.5 ml of 4M nitric acid to a portion of Os-2 solution immediately produced a colorless solution without the intermediate blackening observed previously for Os-1B.

Os-2C. Addition of 11 ml of 12M hydrochloric acid to a portion of Os-2 solution and subsequent dilution immediately gave a colorless solution that contained OsO_4 in 1M hydrochloric acid. The solution gradually became colored, and after one week it was light yellow, presumably because of the presence of $\text{H}_2(\text{OsO}_2\text{Cl}_4)$.

Os-3. Osmium tetroxide was dissolved in 100 ml of 2M nitric acid but went into solution very slowly. The solution was diluted to 200 ml to contain 720 $\mu\text{g/ml}$ osmium as OsO_4 in 1M nitric acid. Portions of 25 ml were treated as described below and diluted to 100 ml each to contain 180 $\mu\text{g/ml}$ osmium.

Os-3A. Addition of 18.8 ml of 4M nitric acid to a portion of Os-3 solution and subsequent dilution gave a colorless solution that contained OsO_4 in 1M nitric acid.

Os-3B. Addition of 5.2 g of sodium hydroxide to a portion of Os-3 solution and subsequent dilution gave the same light-brown solution obtained as Os-2; the resulting solution contained $\text{Na}_2[\text{OsO}_4(\text{OH})_2]$ in 1M sodium hydroxide.

Os-3C. Sodium hydroxide (5.2 g) and 1 ml of ethanol were added to a portion of Os-3 solution. As this mixture was warmed, the dark brown color that developed on addition of ethanol changed to purple, as with Os-1. After dilution with water, the solution contained $\text{Na}_2[\text{OsO}_2(\text{OH})_4]$ in 1M sodium hydroxide.

Os-4. Ammonium hexachloro-osmate $[(\text{NH}_4)_2\text{OsCl}_6]$ was heated to constant weight at 150° and then dissolved in 250 ml of 4M hydrochloric acid to give a reddish-yellow solution containing 320 $\mu\text{g/ml}$ osmium. A 25-ml portion of the resulting solution was diluted to 200 ml in 3M hydrochloric acid to give a solution that contained 40.0 $\mu\text{g/ml}$ osmium.

Rhenium. High-purity rhenium ribbon (H. B. Cross, 0.03-mm thick, 7.6-mm wide) weighing 0.1034 g was dissolved in 10 ml of concentrated nitric acid (J. T. Baker, Ultrex), and the result-

ing colorless solution was diluted to 250 ml to give a solution containing 414 $\mu\text{g/ml}$ rhenium as HReO_4 in 1.4M nitric acid. This solution was used for the elution experiments. In the batch equilibration experiments to determine distribution coefficients in sulfuric acid medium, evaporation of this solution to remove nitric acid gave erratic results, apparently because of incomplete dissolution of the dried residue. A second stock solution was prepared by dissolving KReO_4 in the appropriate concentration of sulfuric acid (0.25–2.5M) to give solutions containing between 194 and 207 $\mu\text{g/ml}$ rhenium.

Molybdenum. Two stock solutions were prepared, one from ammonium heptamolybdate tetrahydrate, $(\text{NH}_4)_6\text{Mo}_7\text{O}_{24}\cdot 4\text{H}_2\text{O}$ and one from sodium molybdate. A 23-g quantity of the heptamolybdate was dissolved in a mixture of 150 ml of water and 20 ml of concentrated ammonia solution, and then diluted to 250 ml to give a solution containing 50 mg/ml molybdenum in 1M ammonia solution. A quantity of 2.52 g of $\text{Na}_2\text{MoO}_4\cdot 2\text{H}_2\text{O}$ was dissolved in H_2O together with 8 g NaOH to give 200 ml a solution containing 5.0 mg/ml molybdenum in 1M sodium hydroxide.

Anion-exchange columns. Anion-exchange resin was supported between plugs of glass wool in Pyrex glass columns that were 1 cm in diameter and 15 cm long. Each column had a 200-ml spherical glass reservoir at the top and a Teflon stopcock at the bottom. The columns were packed with 5.5 g wet weight (equivalent to 3.5 g of dry weight) of BioRad AG 1 \times 8 resin, 200–400 mesh, chloride form, that had been slurried with water, to yield a column 12–13.5 cm long. The columns were washed with 100 ml of water to remove a pink impurity from the resin, and then conditioned with the appropriate acid.

RESULTS AND DISCUSSION

Rhenium

The anion-exchange of ReO_4^- in chloride and nitrate systems is well known^{24–26} and, in principle, provides a ready means to separate rhenium from molybdenum and other contaminants.^{22,27,28} Most osmium distillation procedures leave a residual solution that is 2–4M in sulfuric acid. Rhenium may be recovered from this solution by solvent extraction with a tertiary amine dissolved in chloroform,³ but this procedure can be messy and rhenium recoveries may be inexplicably low. An ion-exchange

procedure that could be applied directly to the residual sulfuric acid solution appeared attractive. Although the strong sorption of rhenium by anion-exchange resin from sulfuric acid medium seems well known,²⁹ this element was not included in the extensive study by Strelow and Bothma³⁰ and apparently has not been systematically studied in a quantitative way elsewhere.

Distribution coefficients (K_d) were determined by taking 1-g (dry weight) batches of resin that had been converted into the sulfate form and then pre-equilibrated for 4 hr with the appropriate concentration of sulfuric acid. The resin was then equilibrated for 4 hr with 25-ml aliquots of sulfuric acid varying in concentration from 0.25 to 2.5M and each containing 200 $\mu\text{g/ml}$ rhenium. Equilibrations at each concentration were conducted in triplicate. The concentration of Re remaining in the solution was determined by ICP-AES; because the K_d values are large (>500), estimation of the amount of rhenium on the resin by difference introduced insignificant error. Results are summarized in Table 1. Over the concentration range studied, rhenium is strongly sorbed by the anionic resin. The variation of $\log K_d$ with \log molality or molarity of sulfuric acid is remarkably linear, particularly above 0.5M (Fig 1). The underlying physicochemical reasons for this linearity are not clear, as it is not observed with hydrochloric, hydrobromic, or nitric acids²⁵ (Fig 2). For a wide range of acid concentration, Re occurs almost entirely as the strong monobasic acid HReO_4 ,³¹ and sorption by the resin depends largely upon competition with the major anionic species. In the resin, the sulfuric acid is present predominantly as HSO_4^- .³² The K_d values for rhenium in the various acids might be expected to follow inversely the trends determined by acid strength [$\text{ClO}_4^- > \text{NO}_3^- > \text{Br}^- > \text{Cl}^- > \text{HSO}_4^-$], so that

Table 1 Distribution coefficients* (K_d) for rhenium in sulfuric acid solution

K_d values for the sulfuric acid systems would be larger than those for hydrochloric acid systems, as is the case for solvent extraction with tertiary amines.¹⁵ In fact, the reverse, is true, as can be seen from Figs. 1 and 2, the K_d values for sulfuric acid solutions are uniformly lower than those for hydrochloric acid solutions.

Osmium

Osmium can be reversibly sorbed by anion-exchange resins from dilute hydrochloric acid, apparently as $\text{OsO}_2\text{Cl}_4^{2-}$.^{22,33} This observation was confirmed for 3 ml of solution Os-1, containing 624 $\mu\text{g/ml}$ osmium as the purple $\text{Na}_2[\text{OsO}_2(\text{OH})_4]$. The solution was acidified, diluted to a final volume of 10 ml in 1M hydrochloric acid, and allowed to stand at room temperature for 10 min before it was loaded onto the column, predominantly as $\text{Na}_2(\text{OsO}_2\text{Cl}_4)$. Elution with 0.8M nitric acid appeared to remove osmium from the column, although, for reasons discussed later, the experiment was not quantitative. In a second experiment, the same procedure was followed, except

Fig 2 $\log K_d$ rhenium vs \log (molality of hydrochloric, hydrobromic and nitric acids) BioRad AG 1 × 8 resin, 200–400 mesh

Fig 3 Elution of osmium with 1M hydrochloric acid and 0.8M nitric acid from BioRad AG 1 × 8 resin, 200–400 mesh, chloride form, in a column 10 mm in diameter and 125 mm long

that the solution in 1M hydrochloric acid was gently warmed for 10 min before being cooled quickly in ice and loaded onto the column. This experiment also could not be shown to be quantitative, and the recovery was lower, possibly because of the formation of some Na_2OsCl_6 , which is strongly retained by the resin (Fig. 3). The elution experiments were not continued because the easy sorption of rhenium from the residual liquid from the osmium distillation offered an attractive alternative means of separation. In addition, Wee³³ has confirmed that osmium and rhenium can be separated cleanly and in good yield by elution with nitric acid.

The elution experiments for osmium were not quantitative because of a peculiarity in the determination of this element by ICP–AES. Very large differences in response were observed for the various chemical forms of osmium (Table 2). The results confirm the marked increase of sensitivity for osmium when present as OsO_4 in non-alkaline solution.^{23,34} The signal observed for OsO_4 in hydrochloric acid and

nitric acid solution is approximately 20 times that of corresponding solutions containing Os(VIII) or Os(VI) in sodium hydroxide or Os(VI) and Os(IV) in hydrochloric acid. Mallet *et al.*³⁴ found the sensitivity for Os(VIII) as OsO_4 to be 10 times that for Os(VI) as hexachloro-osmate. Summerhays *et al.*²³ reported an enhancement of a factor of 50 for OsO_4 in water relative to “ OsCl_3 ” in 10% v/v hydrochloric acid, and a 15-fold increase in sensitivity if the “ OsCl_3 ” were oxidized in 9M nitric acid for 4 hr. Given these large variations and the uncertainty concerning the chemical form of osmium (originally present as $\text{OsO}_2\text{Cl}_4^{2-}$) that is eluted with 0.8M nitric acid, accurate standardization was not possible. For osmium, radioactive tracer experiments would clearly be a better choice for quantitative elution studies.

Molybdenum

The anion-exchange behavior of molybdenum has been studied for nitric acid, hydrochloric acid,^{26,35} sulfuric acid³⁰ and sodium hydroxide solutions,³⁶ and also for hydrochloric acid–hydrofluoric acid and hydrochloric acid–ammonium thiocyanate mixtures.^{35,37} The marked minimum in K_d for molybdenum in approximately 1M hydrochloric acid²⁷ should afford an easy separation from rhenium, which has a K_d of 1000,²⁸ or more,²⁵ at this acidity. Most previous studies were made at very low concentrations of molybdenum, however, and many investigators used radioactive tracers. The chemistry of molybdenum is complicated by a tendency towards condensation polymerization reactions that are strongly dependent on molybdenum concentration.³⁸ In an initial experiment, a solution made from ammonium heptamolybdate containing 150 mg of molybdenum in 25 ml of 2.5M hydrochloric acid formed a green band on the resin. The band separated into several components that were difficult to elute cleanly. Suspecting that the problem arose from the

Table 2 Relative sensitivities of ICP–AES for osmium species

Solution	Oxidation state	Species	Medium	Color	Relative sensitivity*
4	IV	OsCl_6^{2-}	3M HCl	Reddish-yellow	110
1A	VI	$\text{OsO}_2(\text{OH})_2^{2-}$	1M NaOH	Purple	110
3C	VI	$\text{OsO}_2(\text{OH})_2^{2-}$	1M NaOH	Purple	90
1C	VI	$\text{OsO}_2\text{Cl}_4^{2-}$	1M HCl	Yellow	120

1B	VIII	OsO_4	1M HNO ₃	None	1800
2C	VIII	OsO_4	1M HCl	None	2700

*Relative sensitivity for Os is measured for the Os (II) 228 226 nm line, in counts $\text{sec}^{-1} \mu\text{g}^{-1}$

original heptamolybdate form, we fused the salt with sodium hydroxide at 625 K for 1 hr; this fusion produced no significant improvement. The starting material was changed to sodium molybdate, and the elution experiments were repeated at much lower concentration (1.5 mg of Mo in 10 ml of 1M hydrochloric acid loaded onto the column). There was no sign of polymerization, and tailing was insignificant. At higher concentrations, polymerization became more apparent, even with sodium molybdate. Tailing was significant when 15 mg of molybdenum in 10 ml of 1M hydrochloric acid was loaded onto the column; at higher concentrations, polymerization was indicated by the fractionation of colored bands on the resin, and multiple elution peaks. These problems were easily circumvented, however, by replacing the 1M hydrochloric acid medium with a 1M hydrochloric acid–1M sodium chloride mixture. Tailing was reduced to very low levels to give almost symmetrical elution peaks (Fig. 4), and even with a solution containing 150 mg of molybdenum in 50 ml, no polymerization was visible. These results provide a simple means for the study of rhenium and osmium in molybdenite. In this mineral, osmium is entirely radiogenic [^{187}Os formed from the decay of ^{187}Re ($t_{1/2} = 4.23 \times 10^{10}$ years)³⁹]. Even for the oldest molybdenites, the sample size needed is governed by the sensitivity for osmium, because rhenium is present in large excess. For sample sizes up to 500 mg, after sodium hydroxide–sodium peroxide fusion, an aliquot (5 or 10% of total volume) could be taken for the rhenium analysis, and a solution suitable for ICP–MS

or RIMS obtained in a single anion-exchange step. Alternatively, sample sizes of up to 250 mg of molybdenite (containing 150 mg of molybdenum) could be processed by two anion-exchange steps.

CONCLUSIONS

Anion-exchange studies of rhenium, molybdenum and osmium suggest that these elements may be separated from each other. Rhenium is readily held on the column from sulfuric acid of concentration up to 2.5M or hydrochloric acid up to at least 5M, and from dilute (< 1M) nitric acid. Elution by higher nitric acid concentrations (> 3M) is essentially quantitative. The strong sorption from sulfuric acid solution is particularly useful if osmium is first distilled from sulfuric acid–hydrogen peroxide because the residue can then be passed directly through an anion-exchange column for recovery of rhenium. Separation of rhenium from substantial amounts of molybdenum (important because molybdenite is the major rhenium-rich mineral) is possible in one or two steps when polymerization of molybdenum is curtailed by using hydrochloric acid–sodium chloride solution. Osmium can be reversibly sorbed as $\text{OsO}_2\text{Cl}_4^-$ by an anion-exchange resin from dilute hydrochloric acid and eluted with nitric acid, but distillation may be preferable. The sensitivity of determination of osmium by ICP–AES is very dependent on the presence of osmium tetroxide, and for quantitative elution experiments, use of radioactive tracers may be a more useful technique for this element.

(Received 9 January 1990 Revised 27 July 1990 Accepted 22 August 1990)

Summary—A study has been made of the sorption of Ir(IV), Rh(III), Pt(IV), Ru(IV), Os(VIII), Pd(II) and Au(III) from aqueous solutions by silica chemically modified with nitrogen-containing organic ligands, as a function of hydrochloric acid concentration, time of contact, concentration of the element and the ionic strength. Sorption of noble-metal ions at $\text{pH} > 1$ on a sorbent containing monoamine groups seems to be due to a complexation mechanism, and to an anion-exchange mechanism at $\text{pH} < 1$. With aminopropyl-silica 1000-fold concentration of Ir(IV) and Rh(III) from their 10^{-8} – $10^{-7}M$ solutions was achieved and these metals were subsequently determined on the sorbent surface by X-ray fluorescence. Detection limits were 10–20 ng/ml. There was no interference from 1000-fold quantities of non-ferrous metal ions and Fe(III). With the sorbent containing bonded diethylenetriamine groups, 1000-fold concentration of Au(III) was achieved, and it was then determined on the sorbent surface by an atomic-emission method. Conditions for desorption of Au(III) with pyridine and potassium thiocyanate were developed.

Elucidation of the mechanism of sorption of noble-metal ions and optimization of the sorption conditions are difficult. Despite the great variety of papers devoted to this problem the methods developed for sorption concentration and separation of noble metals do not meet all analytical requirements.

Many different sorbents have been used to extract noble metals from solution, the greatest attention now being paid to complex-forming sorbents. These sorbents are characterized by the higher selectivity and efficiency of sorption of noble metals in the presence of accompanying metals (especially Cu, Fe, Ni, Co, Al and Ca, which are the main components of most natural and industrial samples) that can be attained with ion-exchangers. The functional groups of these polymeric sorbents often contain sulphur¹ and, more frequently, nitrogen atoms; in particular, diethylamine,² ethylenediamine,³ iminodiacetate⁴ and heterocyclic nitrogenous ligands⁵ may be mentioned.

A distinctive feature of platinum metals is their very low rate of ligand exchange, which results in their sorption on complex-forming sorbents taking place only on prolonged heating. This fact, together with the very complex

range of ionic states of platinum metals in aqueous solutions, presents difficulties when sorption procedures are developed.

In recent years, polymeric organic sorbents have been developed, including polymeric tertiary amines of general formula $[(\text{CH}_2)_3\text{N}]_n$,⁶ which are characterized by a rather high rate of sorption of platinum metals at room temperature. Sorption on these sorbents is a two-stage process. First an anion-exchange reaction takes place, with the formation of ion-associates, then, with increasing sorption time and temperature, co-ordinately solvated compounds are formed with the sorbent functional groups.

We are mainly interested in the sorbents based on silica with organic ligands chemically bonded to the surface. These sorbents can be successfully used for concentration and separation of various transition metals,⁷ mainly because of the rapidity of the reactions. However, there have been practically no publications on their use for sorption of platinum metals, probably because of the low rate of sorption as the result of the kinetic inertness of these metals. This means that one of the main merits of the chemically modified silicas is lost, so the change from an organic polymer matrix to a mineral matrix for the sorption is not justified. This view is in general confirmed by the published data for

*Author for correspondence

sorption of platinum metals by silicas chemically modified with cyclopentenedithiocarbonyl groups,⁸ pyrrole-, furan- and thiophenecarbonamides,⁹ formazans,¹⁰ thioaniline¹¹ and 5-methylene-2-(2'-thiazolylazo)anisole.¹² In our view, however, this choice of ligands⁸⁻¹² does not allow the advantages of chemically modified silicas to be utilized. We have used silica bonded with aliphatic amines and polyamines, since the analogous polymeric organic sorbents give the highest rates of interaction with noble metal ions. Preliminary investigations were encouraging, equilibrium for sorption of Pt(IV), Pd(II) and Ir(III) on aminopropyl-silica being attained in 2 min.¹³

The present paper discusses the results of a systematic investigation of the sorption of platinum metal ions and gold(III) on chemically modified silicas. Examples of applications to concentration, separation and determination of these elements are given.

EXPERIMENTAL

Apparatus

Absorbance was measured with an SF-16 spectrophotometer. X-Ray fluorescence determinations of elements in the sorbent matrix were performed with an EGG-ORTEC TEFA-III X-ray fluorescence energy-dispersive analyser equipped with an X-ray tube having a double Mo/W anode. Radiation from ²⁴¹Am (59 keV, activity 2.2×10^{12} dpm, irradiation for 600 sec) was used as an excitation source for samples containing rhodium, ruthenium and palladium. The intensities of the K_{α} -lines for rhodium, ruthenium and palladium and the L_{α} -lines for iridium, osmium and platinum were used as analytical parameters.

An alternating current arc (8 A) was used for atomic-emission analyses. The 267.6-nm line was used for gold. Samples of the sorbent were placed in the carbon electrode channels (2.5 mm depth and 4.5 mm inner diameter). The activity of the solutions was measured with a PPV-8 unit and an MST-17 counter, at constant geometry.

Reagents

Standard solutions of platinum metal salts (concentrations 0.7–5 mg/ml) were prepared by dissolving precise quantities of $K_4[Ru_2OCl_{10}]$, K_2IrCl_6 , $RhCl_3 \cdot 4H_2O$, $PdCl_2$ and $HAuCl_4$ in 2M hydrochloric acid, $H_2PtCl_6 \cdot 6H_2O$ in 1M hydrochloric acid, and $H_2[OsO_4(OH)_2]$ in 0.4M sodium hydroxide, and were standardized

gravimetrically. Less concentrated solutions were obtained by dilution of the initial solutions before use. All reagents used were of analytical reagent grade. Demineralized distilled water was used for dilution.

Sorbents

The sorbents were synthesized with Silochrome S-120 silica (specific surface area 120 m²/g, mean pore diameter 45 nm, particle size 0.1–0.2 mm) as substrate Aminopropyl-silica (sorbent I) was obtained by reaction with γ -aminopropyltriethoxysilane in toluene at 100° (10 hr); sorbents II–V were obtained by modification of the silica with 3-bromopropyltrichlorosilane followed by ethylenediamine (II), diethylenetriamine (III) or tetraethylenepentamine (IV) in ethanol or by reaction with trimethylamine (V) in nitromethane. The surface concentration of the bonded ligands was determined by combustion analysis. For sorbents I–IV potentiometric titration with an acid was also used.

Sorption by the batch method

The required amount of solution containing the metal ions to be studied and a calculated amount of hydrochloric acid or sodium hydroxide solution (to create the necessary acidity) were diluted with water to a fixed volume in a vessel fitted with a glass stopper. For pH > 1, the acidity was measured before and after the sorption. Then 0.1–0.2 g of the sorbent was added and the vessel was shaken on a mechanical vibrator until equilibrium was attained. The sorbent was filtered off and the equilibrium concentrations of metal ions in the aqueous phase were determined by spectrophotometry: Ru with 1,10-phenanthroline, Os with sodium thiocyanate, Pd with 4-(2-pyridylazo)resorcinol, Pt with stannous chloride, Rh with 1-(2-pyridylazo)-2-naphthol, Au with Chrompyrazole I (and radiometrically with ¹⁹⁸Au), and Ir by the luminescence method with 2,2'-bipyridyl. The equilibrium concentration in the sorbent phase was determined as the difference between initial concentration and the equilibrium concentration in the aqueous phase. At pH < 1 the metal content in the sorbent phase was determined by X-ray fluorescence analysis.

To plot the calibration graphs, the required amounts of standard platinum metal solution were added to 0.2-g portions of sorbent and ground with silica in an agate mortar, the total weight being 1.5 g (for Ir, Os, Pt) or 2.0 g (for

Rh, Ru, Pd). The sample for X-ray fluorescence analysis was prepared by pressing the powder thus obtained into tablets (32 mm diameter, pressure 2.5×10^3 kg/cm²). The background radiation was approximated by a cubic polynomial (by the least-squares method) and the maximum background noise was used.¹⁴ The calibration curve of analytical signal *vs.* metal concentration, $I = f(c)$, was obtained by the method of Savitchev and Fogelson.¹⁵ The detection limit for Rh, Ru and Pd is 6 μ g/g, while for Ir, Os and Pt it is 4 μ g/g.

Sorption under dynamic conditions

A 0.2–0.4 g portion of sorbent was packed into a 5-mm bore chromatographic column and washed with hydrochloric acid of the same concentration as that in the test solution. The test solution was then passed through the column at the preselected rate and the column was washed with 5–10 ml of the hydrochloric acid. In the case of the platinum metals, the sorbent was taken out of the column, dried and analysed by X-ray fluorescence. In the case of Au(III), the analyte was desorbed and then determined by spectrophotometry, or was determined directly on the sorbent by atomic-emission analysis.

RESULTS AND DISCUSSION

The commonest oxidation states of the noble metals—Ru(IV), Rh(III), Pd(II), Os(VIII), Ir(IV), Pt(IV) and Au(III)—were examined. Hydrochloric acid medium was used because the metals are generally separated and identified in the form of chloride complexes, and their standard solutions are generally prepared from the chloride complexes.

Silicas chemically modified with (1) aliphatic mono- and polyamines that can act as weak anion-exchangers and complex-formers, and (2) tetra-alkylammonium salts, which are strong anion-exchangers, were used as sorbents (Table 1). They are easily obtained, especially

Table 1 Sorbents investigated

Sorbent	Grafted group	Surface of concentration grafted groups, mmole/g
I	$-(\text{CH}_2)_3\text{NH}_2$	0.36
II	$-(\text{CH}_2)_3\text{NHCH}_2\text{CH}_2\text{NH}_2$	0.40
III	$-(\text{CH}_2)_3\text{NH}(\text{CH}_2\text{CH}_2\text{NH})_2\text{H}$	0.20
IV	$-(\text{CH}_2)_3\text{NH}(\text{CH}_2\text{CH}_2\text{NH})_4\text{H}$	0.30
V	$-(\text{CH}_2)_3\text{N}(\text{CH}_3)_3^+\text{Cl}^-$	0.20

aminopropyl-silica, and can be widely used in the analytical chemistry of noble metals.

The concentration of the grafted ligands is fairly high, and equal to 1–2 molecules per nm² of surface. At the same time, there are still many residual silanol groups on the surface, and in some cases these groups can participate in sorption.¹⁶ To find whether this was the case, an additional study was made of noble metal sorption on the unmodified silica Silochrome S-120.

The main factors influencing the sorption (duration of phase contact, acidity and ionic strength of the solution, metal ion concentration) were studied. All investigations were made at room temperature.

Duration of phase contact

One of the most surprising facts found was the high rate of equilibration, which was similar to that for non-ferrous metals. Under batch conditions a constant degree of sorption was reached for Rh(III), Pd(II), Ir(IV), Pt(IV), Au(III) in 1–5 min, and for Ru(IV) and Os(VIII) in 10 min. Under dynamic conditions the sorption of platinum metals attained a maximum at a flow-rate of 10–20 ml.min⁻¹.cm⁻², and gold was quantitatively extracted at a flow-rate of 60–70 ml.min⁻¹.cm⁻². The sorption rates of Rh(III) and Ir(IV) were almost the same in both strongly acidic and weakly acidic media.

Solution acidity

Figures 1–3 show the effect of solution acidity on the sorption of microquantities of platinum metal ions on sorbent I and silica, and of Au(III) on all the sorbents studied. In the first place it can be concluded that the contribution of the silanol groups to the sorption is negligible

Fig 1 Effect of pH on sorption of Ru(IV) (■), Rh(III) (●), Pd(II) (▲), Os(VIII) (□), Ir(IV) (○) and Pt(IV) (△) on aminopropyl-silica I. $C_{\text{Me}} = 5 \times 10^{-5} \text{M}$, sorbent 0.1 g, solution volume 10 ml, duration of phase contact 30 min.

Fig 2 Effect of pH on sorption of Ru(IV) (■), Rh(III) (●), Pd(II) (▲), Os(VIII) (□), Ir(IV) (○) and Pt(IV) (△) on silica. Conditions as for Fig 1

and that the metal ions are bound solely by their interaction with the grafted ligands.

The multiple maxima and minima on the curves for sorption of Au(III) on all sorbents except strong anion-exchanger V were of great interest. The curves obtained were reproduced many times and their form was independent of the sorption mode (batch or dynamic) and the method of analysis (radioactive tracer method or spectrophotometry). The fact that similar maxima and minima are obtained with different sorbents strongly suggests that they arise from changes in the forms of gold in the solution, owing to aquation and hydrolysis,¹⁷ and differences in the strength of binding of the grafted ligands with various Au(III) complexes. Interaction of Au(III) with polyamines in hydrochloric acid solutions also leads to different complexes, depending on the acidity of the

Fig 3 Effect of pH on sorption of Au(III) on sorbents I (1), II (2), IV (3) and V (4). $C_{Au} = 6 \times 10^{-5} M$, $I = 1$ (NaCl), other conditions as for Fig. 1

solution.^{18,19} Similar effects are also found for the platinum metal ions but, as can be seen from Figs. 1 and 2, to a much lesser extent.

In our opinion, the form of the curves for sorption of Ru(IV), Ir(IV) and Rh(III) on aminopropyl-silica is due to changes in the sorption mechanism. We propose that in strongly acidic medium (1–6M hydrochloric acid) these ions are sorbed on the protonated amino groups by an anion-exchange mechanism. Under these conditions, Rh(III) will exist at least partly as the $[RhCl_6]^{3-}$ complex, and the charge of this, being higher than that of the other platinum-metal chloro-complexes, is presumably responsible for the better sorption of Rh(III). With decreasing solution acidity the contribution of complex formation to bonding of the metal ions increases.

Sorption mechanism

There are no direct proofs of insertion of the grafted ligands into the inner co-ordination spheres of the noble metal ions. However, in our opinion the results given below strongly support this hypothesis. As can be seen from Fig. 3, there is a fundamental difference between the sorption of Au(III) on the complex-forming sorbents I–IV and on the strong anion-exchanger V. The decrease in sorption of Au(III) on sorbent V with increasing acidity can be attributed to the aquation reaction, which is very specific for Au(III):

This reaction takes place in strong acid medium and leads to the formation of uncharged species.¹⁷ The sorption on the complex-forming sorbents in strong acid media is significantly higher than that on sorbent V. The decrease in the degree of extraction with increasing acidity is probably due to protonation of the grafted ligands and thus a decrease in the surface concentration of the free complexing ligands. The increase in the denticity of the grafted ligands, in the sorbent sequence $I < II < III < IV$, should enhance the stability of the complexes. This is confirmed by the shift of the sorption curves with increase in acidity (Fig. 3). With increasing concentration of background electrolytes ($NaClO_4$, Li_2SO_4 and $NaCl$) the degree of Au(III) sorption decreases (Fig. 4). The effect of these electrolytes on the sorption is in the order $LiCl > Li_2SO_4 > NaClO_4$. If sorption had taken place by an anion-exchange mechanism, Li_2SO_4 should have had the greatest effect. The fact

Fig 4 Effect of ionic strength (I) on sorption of Au(III) on sorbent I 1—NaClO₄, 2—Li₂SO₄, 3—NaCl

that lithium chloride has the greatest suppressive effect indicates the existence of two competitive reactions: formation of a complex with the grafted ligand and formation of chloride complexes.

Pt(IV), Ir(IV) and Pd(II) ions have a greater tendency than Ru(IV), Rh(III) and Os(VIII) to form complexes with aliphatic amines. As can be seen from Fig. 1, at pH 0–6 (where the complex-formation reaction is dominant) the sequence of sorption of metal ions on sorbent I, in general, coincides with the stability sequence of the amine complexes. Formation of different complexes during sorption of Ru(IV), Ir(IV) and Rh(III) and correspondingly change in the sorption mechanism with the solution acidity (Fig. 1), is confirmed by mathematical simulation of the equilibria in the system Pd(II)–(HCl, H₂O)–aminopropyl-silica. It has been shown that the predominant forms in the sorbent phase are the complex PdCl₃R (pH 4–1M HCl) and the ion-associate PdCl₃⁻RH⁺ (>1M HCl), where R is the sorbent functional group. Different molecular and ionic forms were taken into consideration: PdCl_x, PdCl_xR_n, PdCl_x(RH), RH (charges are omitted for simplicity).

Effect of metal concentration

As seen from Fig. 5, the sorption capacity of the sorbents for noble metals does not exceed 0.15 mmole/g, much lower than for similar sorbents based on organic polymers. When the metal concentration and degree of surface coverage with metal ions are low, the isotherms are linear. Under optimal sorption conditions, the distribution coefficients are 10⁴ ml/g for Ru(IV), Rh(III), Ir(IV), Pd(II) and Pt(IV), 10³ ml/g for Os(VIII) and 10⁵ ml/g for Au(III).

The modified silicas studied can be recommended for noble metal extraction from dilute solution. In this case the low sorption capacity is not important, but the high distribution coefficients and sorption rates are.

Fig 5 Effect of metal ion concentration on sorption of Rh(III) (1) and Ir(IV) (2) C_{HCl}, 1—3.0M, 2—2.0M; sorbent 0.05 g, solution volume 10 ml, duration of phase contact 1 hr

Desorption

Desorption of Au(III) was studied in detail. Two acids were selected for desorption: hydrochloric because chloride is a complexant for Au(III), and perchloric because it contains a large anion. In addition, different compounds forming stable complexes with Au(III) were used, among them ammonium salts, thiocyanate, thiourea and pyridine. The degree of desorption under the following conditions was used to estimate the elution power of these species: 50 μg of Au sorbed on 0.2 g of sorbent; 5 ml of eluent at a flow-rate of 20 ml·min⁻¹·cm⁻². The degree of desorption was monitored by a radioactive tracer method.

Typical dependences of the desorption on eluent concentration are shown in Fig. 6. Mineral acids are ineffective for eluting Au from sorbents I–IV, but the elution power of hydrochloric acid is higher than that of perchloric acid. Desorption by mineral acids is quantitative only for the strong anion-exchanger V. This difference in the behaviour of sorbents I–IV and V is additional evidence for the formation of

Fig. 6 Desorption of Au(III) with different eluents. 1–3—NH₄SCN; 4—pyridine, 5,6—HCl, 7—HClO₄, Sorbents: II—2,6, III—1,4, IV—3,7, V—5

Au(III) complexes with the amino-groups of sorbents I-IV.

Desorption of Au(III) by an ammonium nitrate solution is also inefficient. Gold is quantitatively desorbed from all sorbents with 0.1M thiourea in 0.1M hydrochloric acid, but this eluent cannot be used for analytical purposes because it causes difficulties in the determination of Au in the eluates. However, it is convenient to use for regeneration of the sorbents. Among the eluents studied, 1-2M potassium thiocyanate²⁰ and 3M pyridine are the best and give quantitative desorption of Au(III) from all the sorbents.

The platinum metals are eluted by acids only under conditions so severe that the sorbent is destroyed. An alternative is the application of strong complexants [as in the case of Au(III)], but the subsequent determination of metals is rather difficult.

Analytical application

There are two trends in application of sorbents in analytical chemistry: (a) ion sorption with subsequent desorption and determination by routine techniques; (b) sorption and direct determination of the sorbed ions in the sorbent phase, by any physical method applicable to solid samples (hybrid methods of analysis²¹). In general, the analyte is both separated from accompanying elements and concentrated at the sorption stage. During elution, the concentration factor decreases because the mass of eluent is larger than that of the sorbent. The detection limits obtained by the hybrid method are then of particular advantage.

Two methods were used to determine the ions in the sorbent phase: X-ray fluorescence for the platinum metals and atomic emission for Au.

The noble metals were first concentrated from the initial solution. Sorbent I was used for Rh(III) and Ir(IV), and sorbent III for Au(III).

The acidity was adjusted to give maximum extraction of the ion and at the same time separation from accompanying transition metal ions or other noble metals. Rh(III) and Ir(IV) were concentrated from 3M hydrochloric acid, and at pH 0.6. The results obtained are presented in Table 2. A systematic negative error (75% extraction) was found for Rh and Ir. This is probably due to a fraction of these metals being in a form with lower reactivity (as a result of competitive equilibria, polymerization, *etc*) which are not sorbed under dynamic conditions. The error can be compensated for by means of a correction factor or applying the whole procedure to the calibration standards.

The detection limit obtained by X-ray fluorescence is 0.01-0.02 $\mu\text{g/ml}$, for concentration from 1 litre of solution with 0.3 g of sorbent. Atomic-emission spectrometry is more sensitive and permits the detection of 0.1 μg of Au(III) on 0.02 g of sorbent, so the detection limit for concentration from 1 litre of solution with 0.1 g of sorbent is 0.5 ng/ml in the initial solution.

Under similar conditions, the noble metals can be separated from large amounts of transition metal ions—Cu, Co, Ni, Mn, Zn, Fe(III), *etc.* (Table 3). These metals are concomitant with noble metals in many natural and technological materials.

Separation of the platinum metals is also of great interest. X-Ray fluorescence permits the detection of pairs of these metals, one from each of the triads (Ru-Rh-Pd and Os-Ir-Pt) in a ratio of 1:10³. For metals in the same triad, however, the analytical lines are so close that determination is difficult. Table 4 shows that sorption of Ir(IV) from 3M hydrochloric acid (dynamic conditions) allows its separation from a 50-fold quantity of Pt(IV) and 1000-fold quantity of Os(VIII). The separation of Ir and Pt can be improved by using lower concentrations of these ions in the test solution. Under the same

conditions Rh(III) can be separated from a 50-fold quantity of Pd(II), but quantitative separation of Rh and Ru is not successful even at 1:1 Rh:Ru ratio.

CONCLUSION

Silicas with chemically grafted aliphatic mono- and polyamines have a high rate of sorption for noble metals. This is attributed to the combined mechanisms of ion-exchange and complex formation. The high strength of binding of the noble metal ions permits their concentration from dilute solutions, with concentration factors of ~10³, as well as their quantitative separation from 10⁴-fold quantities of accompanying metals. Desorption of the noble metal ions from the surface of the modified silicas is complicated, so it is best to determine them directly in the sorbent phase by X-ray fluorescence and atomic emission

(Received 2 July 1990 Revised 25 July 1990 Accepted 31 July 1990)

Summary—A flow-injection system is described that incorporates a small column reactor containing two co-immobilized, synergistically operating oxidoreductases, allowing determination of minute amounts of substrates by means of enzyme amplification and subsequent chemiluminescence detection of the hydrogen peroxide generated in the repeated redox cycling. With lactate oxidase and lactate dehydrogenase, and taking advantage of the fact that the enzymatic degradation step and the ensuing detection step can be individually optimized, the FIA-system has been optimized by factorial experiments to yield an amplification factor of over 140 for each of the two substrates lactate and pyruvate. With a linear calibration range of 0–6 μ M, the limits of detection for the two species were 48 and 103 nM, respectively, and the sampling rate was 50–60/hr. The optimized system has also been employed for assay of glucose by utilizing a column reactor with immobilized glucose oxidase and glucose dehydrogenase, but yielded amplification factors of only 3–4. The large discrepancy in the performance of the two enzyme systems is discussed.

In a previous communication,¹ we reported the determination of minute amounts of substrates by means of enzyme amplification, with two synergistically operating oxidoreductase enzymes co-immobilized on small glass beads in a small column-reactor which was incorporated into a flow-injection analysis (FIA) system.² Because the repeated recyclings consume oxygen and NADH and generate NAD⁺ and hydrogen peroxide (Fig. 1), it was found preferable to base the ultimate detection on a chemiluminescence reaction of the hydrogen peroxide formed. To make the analytical system practical, a preset condition was that the entire analytical cycle could be accomplished within 1–1.5 min, thus facilitating a sampling frequency of at least 40/hr. Preliminary investigations with a model system comprised of lactate oxidase (LOD) and lactate dehydrogenase (LDH) demonstrated that the approach worked satisfactorily, but as the amplification factor was only 38 it was assumed that the system could be further optimized. This paper reports an optimization procedure which has resulted in amplification factors of more than 140. In addition, the optimized FIA system has been used in an attempt to assay glucose with a column-reactor containing

immobilized glucose oxidase and glucose dehydrogenase.

Because the enzymatic step and the detection step in the FIA approach are entirely separate, in contrast to the case for enzyme electrodes, it is feasible to optimize them individually. In concordance with the previously reported work, this optimization was focused on (a) the influence of the relative flow-rates and concentration levels of the reagents used in the chemiluminescence detection of the hydrogen peroxide generated and of the sequence of mixing the reagent and analyte streams (*i.e.*, the detection step) and (b) the molar ratio of the two co-immobilized enzymes and their absolute quantities (*i.e.*, the enzymatic degradation step).

Inherently, the optimized FIA system should be applicable for assay of a variety of substrates provided that suitable oxidoreductase combinations can be found. One such combination is glucose oxidase (GOD) and glucose dehydrogenase (GDH). As seen in Fig. 1, the LOD/LDH and GOD/GDH enzyme systems operate very similarly, but in the glucose system there is a possible side-reaction, *i.e.*, the glucono- δ -lactone formed as an intermediate in the degradation of glucose might be hydrolysed to gluconic acid; if this happens, the cycle will be

Fig 1 Amplification reactions for (a) pyruvate and lactate by means of lactate oxidase (LOD) and lactate dehydrogenase (LDH) and (b) glucose by means of glucose oxidase (GOD) and glucose dehydrogenase (GDH). In the latter the side-reaction leading to formation of gluconic acid will remove the substrate for the GDH and hence terminate the cycle

terminated. This side-reaction is very fast, and indeed Schubert *et al.*,³ who attempted to use this enzyme combination in a membrane electrode, only managed to obtain amplification factors of 3–8. In a column reactor in a FIA system, where the radial mass transfer is much more intense than in diffusion-controlled membrane, it might be expected that this side-reaction could be minimized, thereby allowing determination of glucose in the sub-micromolar range.

EXPERIMENTAL

Reagents

Distilled demineralized water was used throughout. L-Lactate dehydrogenase [LDH] (EC 1.1.1.27, lyophilized, salt-free powder, 940 U/mg), lactate oxidase [LOD] (EC 1.1.3.2, crystalline, 30 U/mg), L(+) -lactic acid (Li salt) and pyruvic acid were purchased from Sigma. A batch of lactate oxidase (lyophilized, 20 U/mg) was also obtained from Boehringer Mannheim Biochemicals. Glucose dehydrogenase [GDH] (EC 1.1.1.47, lyophilized, 220 U/mg) and D(+) -glucose were from Merck. Glucose oxidase [GOD] (EC 1.1.3.4, lyophilized, 240 U/mg) and NADH were supplied by Serva. Other chemicals used were of analytical reagent quality.

As support for the immobilized enzymes CPG 10 glass beads (diameter 0.75–0.125 mm, pore size 70 nm, Serva) silanized with 3-aminopropyltriethoxysilane in sodium-dried toluene,^{1–4} were used. Approximately 4–5 mg of enzyme mixture was dissolved in 1 ml of phosphate buffer (pH 7.0). For the LOD/LDH pair, the best results were obtained with a

molar enzyme ratio of *ca.* 1:1 (see Results and Discussion).

The enzymes were co-immobilized on 100 mg (250 μ l) of the support by the glutardialdehyde method as detailed previously.^{1,4} For use, the treated glass beads were packed into a column consisting of a piece of polyethylene tubing (i.d. 1.18 mm) furnished with small nylon nets at the ends to retain the glass beads within the reactor during operation. When not in use, the packed column reactors were stored in 0.1M citrate buffer (pH 6.0) in a refrigerator at 4° to minimize microbiological degeneration.

Aqueous lactate, pyruvate, glucose and hydrogen peroxide standards in the range 1–100 μ M were made by sequential dilution of 1.0mM L(+) -lactic acid, pyruvic acid, glucose and hydrogen peroxide stock solutions with distilled water. All solutions were freshly prepared every day. The liquid streams propelled in the FIA system shown in Fig. 2 (which depicts the finally optimized FIA manifold for the LOD/LDH system) were: carrier stream of distilled water; buffer stream of 0.015M phosphate buffer (pH 6.8) containing 1.5mM NADH; 1.5mM luminol (5-amino-2,3-dihydro-1,4-phthalazinedione) in 0.1M potassium carbonate (pH 11.5), and 30mM aqueous potassium hexacyanoferrate(III). For the manifold containing the GOD/GDH enzyme reactor the parameters were the same, except that pH 6.0 phosphate buffer was used.

Apparatus

The FIA manifold (Fig. 2) comprised two peristaltic pumps: P1 (Ventur, variable flow, Alitea, Sweden) for the aqueous carrier stream [into which the sample solution (50 μ l) was injected] and the buffer/NADH stream, and P2 (Mini-S-840, Ismatec, Switzerland) for the

Fig 2 Optimized FIA manifold for the determination of lactate or pyruvate by enzyme amplification with ensuing detection by chemiluminescence (Lum). S, sample injection (50 μ l), LOD/LDH, column reactor (140 μ l) containing the two co-immobilized enzymes (LOD/LDH), C, mixing coil (40 cm) and W, waste. Solutions were propelled by two peristaltic pumps (that for the carrier and buffer/NADH streams allowing variable pumping rates)

reagent streams [luminol and hexacyanoferrate(III)] needed for the chemiluminescence determination of the hydrogen peroxide generated by the enzymatic conversion processes in the packed reactor. The detector consisted of a home-made luminometer with two photodiodes (BPW 34), details of which have been given elsewhere.⁴ All connecting lines in the FIA manifold consisted of 0.5 mm i.d. Microline tubing.

All experiments were executed at room temperature (*ca.* 20°) and to make the apparatus as simple and practical as possible, no attempt was made to operate the FIA manifold at controlled or elevated temperature.

RESULTS AND DISCUSSION

Optimization of the detection system

The optimization was based on that of the previously used FIA manifold,¹ which was rather similar in design to that in Fig. 2, except that the luminol and hexacyanoferrate(III) streams were mixed before joining the combined carrier/buffer stream. The reason for this approach, which has been used extensively in this laboratory, is that a composite solution of these two reagents is not stable, so they have to be mixed immediately before use, which can best be done in the manifold. However, it was found that the signal to noise ratio and the signal amplitudes could be considerably improved with the sequence of addition shown in Fig. 2, which was therefore adopted. This improvement is probably due to more efficient mixing of the strongly alkaline luminol stream and the combined carrier/buffer stream, which has a certain buffering capacity.

The FIA system was first optimized for assaying hydrogen peroxide, in order to obtain as low a detection limit as possible, *i.e.*, the LOD/LDH reactor was not used in these tests. In addition to the preselected condition as to sampling frequency (*i.e.*, a minimum of 40 samples/hr), the following restrictions were imposed.

(a) The injection volume should be maintained at 50 μ l (to allow for situations where sample material might be limited).

(b) The flow velocities of the buffer stream and the carrier stream should be about the same and the combined flow velocity should not exceed 1.0 ml/min (so that in the complete system there would be sufficient residence time for the sample in the enzyme reactor and any risk that tight packing of the column material

might lead to increased back-pressure would be minimized).

(c) The concentration of phosphate in the combined carrier/buffer stream solution should be 0.005M and the pH should be fixed at 7.0. This should secure sufficient buffering capacity to maintain this pH within the enzyme reactor.

(d) The concentration of potassium carbonate in the luminol solution should be maintained at 0.1M, which had previously been found reasonable.⁵

(e) The length of the mixing coil should be 40 cm, which is a judicious compromise between efficient mixing and acceptable dispersion (and hence dilution) of the injected sample solution.

(f) The distance between the last merging point and the chemiluminescence detector should be minimized so that the chemiluminescence (CL) signal (which appears as a rapid pulse) actually recorded would be as large as possible. In this case the distance was 2 cm, the minimum physically allowable length in the detection device used.¹

With these restrictions imposed, six parameters were to be optimized. These were first screened in a fractional factorial experiment, where each parameter was tested at two levels as follows (the values in brackets denote the high and low levels used). (1) The flow velocity of the combined carrier/buffer stream (0.5 and 1.0 ml/min); (2) the flow velocity (1.5 and 2.5 ml/min) and (3) the concentration (10 and 20mM) of the hexacyanoferrate(III) stream; (4) the flow velocity (1.5 and 2.5 ml/min) and (5) the concentration (0.2 and 1.0mM) of the luminol stream; (6) the pH of the luminol solution (10.5 and 11.5) The response function chosen was the peak height from injection of a 30 μ M hydrogen peroxide standard solution, and the screening experiment showed that the parameters should all be used at the high level. Therefore two series of complete 2² factorial experiments were executed to find the interdependence between the two reagent flows, and their combined influence on the response. One series used the flow velocities of the luminol and hexacyanoferrate(III) solutions as parameters, and the other the concentrations of the two reagent solutions as parameters. Because the aim was to minimize the limit of detection, yet maintain high sensitivity and a low blank value, the response function (*RF*) was chosen as $RF = 100 [0.50 PH_5 + 0.25\alpha + 0.25(1 - \beta)]$ where PH_5 is the peak height obtained for injection of a 5 μ M hydrogen peroxide standard

Fig 3 Calibration runs for lactate and pyruvate with the system in Fig 2 (a) Hydrogen peroxide standards in the concentration range 67–200 μM and (b) lactate standards in the same concentration range, with a buffer stream not containing NADH (*i.e.*, non-amplified signals), the peaks indicate that 100% conversion of lactate was obtained under the prevailing conditions (c) Lactate standards and (d) pyruvate standards in the concentration range 0.25–6.00 μM with a carrier/buffer stream containing NADH (*i.e.*, amplified signals), revealing an amplification factor of 100 for both species (*cf.* Fig 4) Note that the residence time for the sample is less than 1 min, allowing a sampling frequency exceeding 60/hr

solution, α the slope of the calibration graph and $(1 - \beta)$ the intercept on the ordinate. Obviously, the three values were weighted 50, 25 and 25%, respectively. All values were normalized, *e.g.*, $PH_5 = (PH_5^{\text{obs}} - PH_5^{\text{min}})/(PH_5^{\text{max}} - PH_5^{\text{min}})$, where the superscript *obs* refers to the observed values in an individual experiment and *min* and *max* to the minimum and maximum values in a series.

This fine-tuning showed that the optimal combinations of flow velocity and concentration for the luminol and hexacyanoferrate(III) solutions were 2.5 ml/min and 1.5 mM and 2.3 ml/min and 30 mM, respectively. Combined with the results of the screening experiment, this resulted in the manifold design depicted in Fig. 2 (except that the LOD/LDH reactor was absent and the carrier and buffer streams were pumped at equal rates, *i.e.*, 0.5 ml/min). The system was calibrated by injection of standards of aqueous hydrogen peroxide, and the detection limit was found to be 0.19 μM . This is *ca.* 10 times lower than that with the non-optimized system¹

Optimization of the FIA enzyme amplification system

The FIA system was next optimized with the LOD/LDH enzyme reactor installed. In these experiments a reactor with 1:1 molar ratio of the two immobilized enzymes (corresponding to

a weight ratio of 2:3) was employed, because the earlier reported experiments indicated that this would be preferable (for further discussion, see below). The manifold was further slightly modified in that the ratio of the carrier to buffer flow-velocity was altered to 2:1 to limit the dispersion and hence dilution of the injected sample, thereby ultimately securing a lower limit of detection. For the same reason, the phosphate concentration in the buffer stream was increased to 0.015 M to give a final concentration of 0.005 M in the combined carrier/buffer stream.

For optimization of the total FIA system, one of the parameters would be the flow-rate of the combined carrier/buffer stream, because this affects the residence time of the sample in the enzyme reactor and thus the amplification. In this context it is important to keep in mind that the detection system was optimized to yield maximum CL response at a fixed flow-rate of the combined carrier/buffer stream (*viz.* 1 ml/min). Because the CL signal is dynamic in nature and appears as a rapidly fading pulse, any change in the flow-rate of the carrier/buffer stream, and hence the flow velocity through the detector, will cause a shift in the portion of response that is actually recorded by the detector. If the conversion of analyte is proportional to the residence time, a lower flow-rate through a given reactor volume should increase the conversion, but would result in a lower CL signal, whereas a higher flow-rate (*i.e.*, close to 1 ml/min), despite the shorter residence time would give a higher signal. With these considerations in mind, the following experiments were executed.

With a packed enzyme column reactor having a volume of 75 μl , the system was subjected to a complete 2³ factorial experiment, where the following parameters were tested (the values in brackets denote the high and low levels used and refer to the conditions immediately prior to, and *in*, the reactor): (1) the pH (7.0 and 7.5); (2) the NADH concentration (0.33 and 0.50 mM), (3) the flow-velocity (0.64 and 0.88 ml/min) of the combined carrier/buffer stream. In all cases, lactate standards in the concentration range 0–6 μM were injected. The response function was selected as $RF = 100[(AF^{\text{obs}} - AF^{\text{min}})/(AF^{\text{max}} - AF^{\text{min}})]$, where *AF* is the amplification factor and the superscripts have the same meanings as above. This response function obviously requires that the efficiency of conversion of lactate by LOD (*i.e.*, without NADH present in

Fig 4 Calibration plots for hydrogen peroxide and lactate (unamplified) together with pyruvate (●) and lactate (○) (both amplified) in the concentration range 0–6 μM (cf Fig 3) For concentrations exceeding *ca* 5–6 μM , the calibration signals for both species start to level off, indicating depletion of reagent (*i.e.*, NADH)

the carrier stream) is 100% and this was found to be the case (Fig. 3). In addition to the amplification experiments, a calibration for hydrogen peroxide was run for each combination of experimental parameters, because it can alter with a change in the pertinent parameters. In particular, the total flow velocity will influence the CL response. The sampling rate was omitted from the factorial design, because all the preliminary tests showed that a rate of 50/hr was possible, which satisfied the requirement of a minimum rate of 40/hr.

The results of this analysis showed that the influence of NADH concentration within the range tested was negligible. However, with the other parameters constant it was found preferable to operate the system at the low flow velocity and low pH levels which yielded an amplification factor of 56. From the literature it is known that the two enzymes in soluble form have maximum activity at pH 6.5 (LOD) and 7.5 (LDH), respectively^{6,7} Although these pH maxima might change when the enzymes are immobilized, they will very likely remain at the same order of magnitude.⁸ A pH of *ca.* 7.0 should therefore be more favourable for the combined system, as corroborated by these experiments. The lower flow velocity implies a longer residence time of the sample within the enzyme reactor (allowing a greater number of redox cycles, leading to increased amplification), but leads to a lower sampling frequency. The lack of influence of the concentration of NADH can be explained by the fact that the LDH is already saturated with the coenzyme when this is present at the lower level.

The length of the reactor might influence the amplification and hence the signal recorded, because a longer reactor should allow more redox cycles (provided that the reagents, oxygen and NADH, are in excess). For that reason, an experiment was conducted with a longer column reactor, of 110- μl volume, and the same enzyme preparation as before (with a flow-rate of 0.64 ml/min for the combined carrier/buffer stream, containing 0.5mM NADH). This system yielded an amplification factor of 82. Further optimization of the pH of the carrier/buffer stream showed that the optimal pH was 6.8, resulting in an amplification factor of 99.5. Hence, this pH was used in all further experiments. The concentration of the phosphate buffer was not altered, because the buffering capacity at this slightly lower pH value is only marginally affected and was sufficiently large.

As stated above, the original detection system was optimized with a combined carrier/buffer flow-rate of 1.0 ml/min, which for the given parameters of the detection system itself yielded the maximum CL response. Hence, with the pumping rate at the high level (0.88 ml/min, which was the closest possible to 1.0 ml/min with the available pump tubes when operating at the carrier:buffer ratio 2:1), it is necessary to use a longer enzyme reactor in order to reach an amplification factor of say, 100. In this case a 140- μl column was required. The FIA manifold of this system is that shown in Fig. 2, and its performance is reproduced in Fig. 3. When the signals for the unamplified lactate and hydrogen peroxide standards are compared, it is seen that the conversion for lactate was 100% and from the unamplified and amplified lactate signals it is seen that the amplification factor was indeed 100. Pyruvate also gave 100% conversion and the amplified pyruvate and lactate signals were virtually identical for similar concentrations. The calibration plots in the recorded range were linear, as shown in Fig. 4, and almost congruent. Therefore, a single calibration graph could be used, but for the highest precision it is preferable to calibrate for the two species individually. At higher concentrations (6 μM and above) the calibration signals start to level off, indicating shortage of reagents. This is not a limitation, however, because at higher concentrations the species can be assayed directly without the need for amplification reactions. The detection limit for this system was found to be 48nM for lactate and 103nM for pyruvate, as calculated from the regression bands (95%

confidence interval) of the calibration plot.⁹ The precision for lactate, determined from estimated response variances for the eight calibration standards ($n = 16$), was 1.9%; for pyruvate it was slightly higher. It was also calculated that for a response equal to the average response of the standards in the range 0–4 μM inclusive, the 95% confidence limits for the corresponding lactate concentration would be $1.20 \pm 0.05 \mu\text{M}$ (expected value 1.25 μM). The sampling frequency was 50–60/hr.

The incorporation of even larger enzyme columns in the FIA system yielded higher amplification factors, but the increase was not proportional to the reactor volume. There was also an increased back-pressure, resulting in variations in performance of the system and impaired precision, and for that reason it was decided not to use columns with a volume larger than *ca.* 140 μl , which already gave amplification factors (of *ca.* 100) which were considered to be very satisfactory. Furthermore, increased amplification would lead to a still narrower calibration range because of depletion of the reagents, particularly NADH. Although the concentration of this species can potentially be increased, it was previously found that this was not advisable because higher concentrations appeared to induce side-reactions with the hydrogen peroxide generated.¹ Furthermore, it has been reported that impurities in high concentrations of NADH can inhibit enzymes.¹⁰ As far as the interplay between the pumping rate of the combined carrier/buffer stream and the length of the enzyme reactor column is concerned, it appears that for given dimensions of the detection system and a required sampling frequency, it is necessary to optimize each system individually.

The results compare very favourably with those of a recent work where the detection limit for lactate was reported to be 119 nM.¹¹ However, in that work an enzyme reactor of 350 μl and a sample volume of 200 μl were used and detection was based on use of a specially constructed flow-cell for amperometric determination of the consumption of oxygen. The largest amplification factor was 70.

Optimization of the packed enzyme column reactor

Previously published results indicated that the molar ratio of the two enzymes should be close to unity.¹ This is intuitively to be expected, because it would mean (provided that the

enzymes are randomly immobilized on the support) there would be a higher probability of contiguous site-fixation of the two enzymes, which should favour the repeated redox cycling of the analyte. To corroborate this, a series of enzyme columns was prepared with molar ratios of LOD/LDH ranging from 1:3 to 4:1. With the same column size (140 μl) and the optimized conditions stated in Fig. 2, the amplification factors varied between 100 and 142 (in the latter case the detection limit for lactate was lowered to 34 nM). These variations were not statistically significant, in view of the inherent lack of absolute control of the immobilization procedure. It was therefore concluded that the molar ratio, contrary to expectation, does not play an important role provided that it approximates to unity. Both crystalline and lyophilized enzyme preparations were tested, but owing to lack of sufficient materials it was not possible to draw any firm conclusion as to the preference for either. These findings are in good agreement with those reported by Asouzu *et al.*,¹¹ although these authors did not elaborate on this theme. The enzyme reactor columns did not reveal any significant decrease in activity over a period of two months.

It is concluded that the increase in amplification, over that in the previously reported procedure, is to be ascribed mainly to the optimized detection system. It is possible that glass beads of pore size other than that used in this investigation and enzymes of improved quality and higher specific activity could influence the amplification, but probably only marginally. However, although higher amplification would give a lower limit of detection, it would be at the expense of a shorter linear calibration range.

Determination of glucose

The optimized FIA system in Fig. 2 was subsequently adapted for assay of glucose by incorporating a 150- μl enzyme column reactor with GOD/GDH mixed in *ca.* 1:1 weight ratio (prepared from one Merck vial of GDH, *i.e.*, *ca.* 250 U, and 2 mg of GOD, corresponding to *ca.* 440 U). With the same NADH carrier/phosphate buffer stream as for lactate (0.005 M NADH, pH 6.8) and glucose standards in the range 10–100 μM , the amplification factor was found to be only 3.5 (for 50 μM glucose). Lowering the pH of the combined carrier/buffer stream enhanced the amplification factor slightly. Thus for a pH of 6.0 it was increased to 4.1, but further decrease in pH lowered it

again (to 3.7 at pH 5.5). Citrate buffers were also tested, but produced no significant change in amplification. Although very disappointing, these results are similar to those of Schubert *et al.*,³ who found an amplification of 3 for 0.1–1.0mM glucose with 1mM NADH, which was increased to 8 by using 0.1M NADH but at the expense of very long response times (several minutes). Scheller *et al.*¹² employed a large column reactor (0.8 ml) of co-immobilized GOD, GDH and catalase, and enthalpimetric quantification, but even with this very sensitive system they only managed to obtain an amplification of 8 for 100 μ M glucose. Thus, although it was hoped that the combination of convection and diffusion in the column reactor of the FIA system would result in much better amplification, it appears that the poor results compared with those of the LOD/LDH-system are due to some fundamental differences, for which there are several possible explanations.

First, the Michaelis–Menten constants (K_M) for the GOD/GDH enzyme systems are almost two orders of magnitude larger than for the LOD/LDH enzymes. The K_M -values for the enzymes are as follows: LOD (lactate) 0.7mM;¹² LDH (pyruvate) 0.14mM;¹² GOD (glucose) 33mM;^{13,14} GDH (glucose) 47mM.¹⁵ Thus although the substrate concentrations in all experiments were well below the K_M -values, ensuring pseudo first-order reaction conditions, the reaction rate of the GOD/GDH system would be considerably lower than that of the LOD/LDH system. This is all the more unfavourable because of the inherent risk of the side-reaction of spontaneous hydrolysis of the primarily formed glucono- δ -lactone. This irreversible reaction, whereby the lactone is removed from the reaction sequence and the cycle terminated, is very fast. Generally, the rate of hydrolysis of lactones decreases at lower pH values. Hence, the slightly enhanced amplification factor at pH 6.0 might be ascribed to this phenomenon, although this pH is not likely to be the optimum for the enzyme pair (pH_{opt} is ca. 8 for GDH,¹⁵ and 5.5 for GOD^{13,16}). It has also been reported that the hydrolysis *per se* is fairly slow, but is catalysed by the enzyme gluconolactonase present as an impurity in the commercial preparations of glucose oxidase.^{17,18} Thus, Hanazato *et al.*¹⁷ found that at pH lower than 6, the spontaneous hydrolysis of glucono- δ -lactone hardly occurred, but its rate increased exponentially with pH at pH > 6, and was greatly accelerated when gluconolactonase was

present. Interestingly, they also found that the activity of gluconolactonase was strongly inhibited by phosphate, and was minimal at pH 5.5. Therefore the use of a phosphate buffer at this pH should ostensibly be preferable to other buffer solutions for the enzyme amplification applications. The results reported here do not appear to support this, however.

A second complication is the potential presence of catalase in the enzyme preparations, because this would result in degradation of the generated hydrogen peroxide and thus exclude it from detection by the luminescence procedure. Catalase is probably the enzyme with the highest known specific activity (4×10^4 U/mg), and therefore even minute amounts of this constituent would have serious effects on the method. Both enzyme preparations were therefore examined for the possible presence of catalase, by making separate column reactors in which approximately similar number of units of the two enzymes were immobilized either individually or together, then injecting hydrogen peroxide standards into the FIA system with and without the enzyme column installed, and comparing the areas under the peaks. For the GOD, which according to the manufacturer's specification contains less than 5 U of catalase per mg (the GOD/catalase ratio being guaranteed to be at least 60), no significant differences in the recorded areas were found, indicating that catalase was not a problem. Furthermore, injection of equimolar standards of hydrogen peroxide and glucose (50 μ M) showed that the peaks were identical, indicating 100% conversion. For the GDH columns, however, injection of hydrogen peroxide standards gave considerably smaller signal areas than those for the "empty" system, irrespective of whether NADH was present. The commercially available GDH enzyme from Merck is reported to have been prepared by chromatography and no mention is made as to the presence of catalase. When NADH is present in the carrier/buffer stream, the decrease in signal could be explained by the previously mentioned side-reaction between hydrogen peroxide and NADH (as catalysed by the enzyme), but the decrease without NADH present is truly surprising. Whether the decrease in signal is due to the presence of catalase remains to be determined, but the observed phenomenon does partly account for the fact that such poor amplification is recorded. In this context it is interesting to note that Schubert *et al.*³ measured the disappearance of oxygen as

the basis for quantification of the amplification. If the initially generated hydrogen peroxide is partly split into oxygen and water, it would explain why these authors found amplification factors of the same order of magnitude as reported here, although their detection method relied only on diffusion (in the electrode assemblies), whereas the present work employed a combination of diffusion and convection in the FIA column-reactor

CONCLUSIONS

Application of the FIA approach for assaying substrate concentrations in the nM – μM range by means of enzyme amplifications, based on the use of co-immobilized enzymes contained within a small column reactor incorporated into an FIA manifold, appears to be very attractive, because it allows the enzymatic degradation step and the ensuing detection of a suitable reaction product to be individually investigated and optimized. The conditions optimized by factorial experiments with co-immobilized LOD and LDH in a molar ratio of 1:1 and chemiluminescence for detection of the hydrogen peroxide formed by the repeated redox cycling yielded an amplification factor of more than 140 in assays of lactate or pyruvate. Since the entire analytical cycle could be accomplished in less than 1 min, thus allowing sampling rates of *ca.* 60/hr, the FIA approach seems to have interesting potential. Inherently, the optimized FIA system should be applicable for assays of a variety of substrates, provided that suitable oxidoreductase combinations can be found. One such combination, glucose oxidase (GOD) and glucose dehydrogenase (GDH), has been tested, but the amplification factor was found to be only about 4. Possible explanations for this low amplification might be the presence of gluconolactonase in the GOD and catalase in the GDH. Gluconolactonase would increase the rate of hydrolysis

of the initially formed glucono- δ -lactone, thereby terminating the cycling procedure, and the presence of catalase would lead to degradation of the concurrently formed hydrogen peroxide and thereby prevent monitoring of the amplification sequence. It is therefore possible that purer enzyme preparations could lead to considerably improved amplification

(Received 16 June 1990 Revised 27 August 1990 Accepted 4 September 1990)

Summary—A general assay procedure for a wide variety of thiols is described. The technique has three steps: (1) formation of *S*-nitrosothiols with nitrous acid, (2) destruction of the excess of nitrous acid, (3) hydrolysis of the *S*-nitrosothiols with mercuric ions and subsequent formation of an azo-dye by means of the nitrous acid liberated. Both manual and flow-injection analysis (FIA) versions of the assay are described. Since the final step of the assay does not depend on the thiol assayed but only on the reaction of nitrous acid to form azo-dyes, the calibration graphs should be identical for all thiols. The manual system is about four times as sensitive as the FIA system, but the latter permits a high sample throughput and shows significantly lower sensitivity to interference by tryptophan. Though this general technique cannot be used for the assay of many sterically hindered thiols, it can be used for the assay of some protein thiol groups.

The assay of thiols is of interest in a broad range of disciplines, including biochemistry, synthetic organic chemistry and environmental monitoring. Accordingly there are many reports of analytical methods for the assay of thiols, based on a variety of techniques, including titrimetry, chromatography, atomic-absorption spectrometry and colorimetry. There have been several recent reviews on the assay of thiols.¹⁻⁶ Though other techniques obviously have their strengths, colorimetric and fluorometric assays are attractive because of their simplicity and ease of automation. The disadvantages of such assays are that some lack specificity, some respond to other functional groups, and many have differential responses to different thiols.¹⁻¹¹ We have been interested in developing methods which retain the simplicity of the colorimetric and fluorometric assays but have greater selectivity than most of them. We have chosen to examine multi-step methods based on the reaction of thiols with nitrous acid to form their stable *S*-nitroso derivatives, destruction of the excess of nitrous acid, metal-catalyzed hydrolysis of

the *S*-nitroso derivatives, and formation of azo-dyes with the nitrous acid released.

Specific methods for the detection and determination of thiols by means of their reaction with nitrous acid have been reviewed by Ashworth.¹² The thiols are mixed with sodium nitrite and ethanol, and then acidified. Primary and secondary thiols yield a red product, whereas tertiary and aromatic thiols produce a short-lived green product which then turns red. These products are the comparatively stable *S*-nitrosothiols, which absorb light strongly in the range 330–344 nm. The reactions are normally quantitative. Examples of this type of assay include the assay of 2-mercaptoethanol in thiodyglycol,¹³ thioglycollic acid in hair-waving solution,^{13,14} glutathione reductase in rat liver,¹⁵ and tertiary thiols.¹⁶ The addition of some metal ions, *e.g.*, magnesium¹⁸ or cobalt,¹⁹ produces a hyperchromic effect. The titration of thiols with sodium nitrite in acid medium has been reported.²⁰

The *S*-nitrosothiols are resistant to hydrolysis,²¹ and normally unaffected by large amounts of various compounds (*e.g.*, ammonium sulfate) which are known to react rapidly with nitrous acid. However, the hydrolysis of

*Author for correspondence

the nitrosothiols is catalyzed by mercury(II), silver(I), and copper(II) salts. The nitrous acid liberated can be detected by reaction with sulfanilamide followed by coupling the resulting diazonium compound with *N*-(1-naphthyl)ethylenediamine to give an azo-dye. The azo-dye can then be determined spectrophotometrically. The sulfhydryl groups of cysteine as the free amino-acid^{22,33} and in proteins^{24,25} have been determined in this manner.

The potential usefulness of the coupling of *S*-nitrosation¹⁷ and azo-dye formation²¹ prompted us to investigate its utility as a general method for assay of thiols. We report the utilization of this method as a batch technique as well as its utilization in FIA systems for the assay of thiols in complex mixtures. The three steps are shown below.

 $+ \text{N}-(1\text{-naphthyl})\text{ethylenediamine} \rightarrow \text{azo-dye}$

EXPERIMENTAL

Reagents

All reagents used were of analytical grade. The stock solutions were 2 mg/ml sodium nitrite in water, 20 mg/ml ammonium sulfamate in water and 0.1M hydrochloric acid. Reagent A was prepared by stirring 2 g of sulfanilamide with 1.5 ml of concentrated hydrochloric acid, diluting the mixture with about 100 ml of water, adding 1 g of mercuric chloride and (after complete dissolution of the solid) diluting the mixture to a final volume of 200 ml. Reagent B was made by dissolving 0.1 g of *N*-(1-naphthyl)ethylenediamine dihydrochloride in 50 ml of water, adding 1 ml of concentrated hydrochloric acid and diluting to a final volume of 100 ml.

Samples

All thiol samples were high-purity chemicals. Solutions of toluene- α -thiol, 4-toluenethiol and benzenethiol were prepared in acetonitrile and standardized by iodimetry.²⁶ An accurately weighed amount of a fresh sample of penicil-

lamine (Sigma) was treated with 1 ml of 0.1M hydrochloric acid, dissolved in water and diluted to a known volume. Solutions of other thiols were made in water and standardized by titration with 2-iodosobenzoate for cysteine hydrochloride, homocysteine and glutathione,²⁷ by reaction with hexacyanoferrate(III) for mercaptosuccinic acid and 3-mercaptopropionic acid,²⁸ by reaction with mercury(II) for 2-mercaptopropionic acid and thioglycolic acid,²⁹ and by iodimetry for 2-mercaptoethanol, 2-diethylaminoethanethiol hydrochloride and 2-mercaptoethylammonium chloride.²⁶ Stock solutions were standardized immediately before use and sequentially diluted to the desired concentration.

Apparatus

A Pye Unicam SP8-100 spectrophotometer (1-cm fused-silica cells) was used for the batch method absorbance measurements.

A schematic of the flow-injection manifold used is shown in Fig. 1. A Rainin model Rabbit miniplus II peristaltic pump (with 1.0 mm bore Tygon pump tubings) was employed to deliver both the reagents and carrier solution. Samples were introduced into the carrier stream through a Valco C14W 6-way injection valve with a 50- μ l loop made of 0.5 mm bore tubing. Teflon tubing (0.5 mm bore) joined with Omnifit high-pressure connectors and Chemnert Milton Roy Tees (Kel-F, 0.79 mm bore) was used for the flow lines. The absorbance of the azo-dye formed was measured at 544 nm in a Gilford 260 spectrophotometer provided with a Hellma 1-cm path-length 8- μ l flow-through cell. An OmniScribe chart recorder operated at 100 mV full scale was used to record the FIA peaks. The peak maximum appeared 11 sec after sample injection.

Fig. 1 Schematic of FIA manifold used for thiol determination ($L_1 = 50$ cm, $L_2 = 100$ cm). (a) Hydrochloric acid carrier; (b) reagent A (mercuric chloride and sulfanilamide); (c) reagent B [*N*-(1-naphthyl)ethylenediamine dihydrochloride]. General features: P, peristaltic pump (flow-rate in each channel, 1 ml/min); S, sample injected (50 μ l); D, detector, 1-cm path-length, 8 μ l volume; R, recorder; W, waste, all tubes in contact with the sample were 0.5 mm bore.

Procedures

Batch method. In step (1) known volumes of standard thiol solution (to give 1–35 μM final thiol concentrations) were separately added to 25-ml standard flasks and mixed with 0.5 ml of 2-mg/ml sodium nitrite solution and 1 ml of 1% v/v hydrochloric acid. In step (2) the reaction mixture was allowed to stand for 1 min then the residual nitrous acid was destroyed by the addition of 1 ml of 20-mg/ml ammonium sulfamate solution, shaking the mixture, then letting it stand for 2 min. In step (3) 5 ml each of reagents A and B were added to the reaction mixture, with swirling, and the solution was diluted to the mark with demineralized water. The absorbance of the sample was measured at 544 nm in 1-cm path-length cells. A correction was applied for the reagent blank before the calibration graph was plotted. Samples were analysed in an identical manner.

FIA method. The general procedure for preparation of the calibration graph and analysis of unknown thiol solutions consisted of the manual reactions for *S*-nitroso derivative formation, steps (1) and (2), followed by flow-injection analysis of the product from step (2).

RESULTS AND DISCUSSION

This method of determining thiols by their *S*-nitrosation should be of general applicability to a wide variety of thiols. Since each mole of thiol reacts with one mole of nitrous acid and that nitrous acid is subsequently released by the mercury-catalyzed hydrolysis, all thiol assays utilize the same final reaction (*i.e.*, the azo-dye determination of nitrous acid), so widely differing thiols should all yield the same standard calibration graph.

Although mercury(II), copper(II) and silver(I) all catalyze the hydrolysis of *S*-nitrosothiols, the use of mercuric chloride is recommended since it forms colorless water soluble mercaptides (RSHgCl) in the presence of excess of reagent. Copper mercaptides may be colored³⁰ and these colors can interfere in the measurement of the azo-dye. Many of the silver mercaptides are insoluble and their precipitation could cause interference with the spectrophotometric assay and could also plug the FIA tubing.

The final step of the assay is diazotization of an aromatic primary amine by the liberated nitrous acid and the formation of an azo-dye by coupling to another amine or phenolic

compound. Theoretically, any delay in the addition of amine to the hydrolyzed solution of *S*-nitrosothiol could cause a partial loss of the nitrous acid, owing to a reaction with the ammonium sulfamate present. However, when we used a mixed reagent containing both mercuric chloride and sulfanilamide there was no evidence of a loss of nitrous acid by this side-reaction.

Batch method

With this method, the absorbance (A) of the azo-dye formed was a linear function of concentration (C , μM) of thiol in the final solution; over the range 1–35 μM the observed regression equation was $A = 0.002 + 0.0413C$. The results for assay of fourteen different thiols (Table 1) demonstrate that this method has broad applicability and is precise. The mean molar absorptivity was $4.11 (\pm 0.12) \times 10^4 \text{ l. mole}^{-1} \cdot \text{cm}^{-1}$.

The method has been used for the assay of primary, secondary and tertiary thiols in the presence of other reactive groups such as aliphatic primary amino, tertiary amino, hydroxyl, carboxyl or amide groups. In general, such groups did not cause any interference (see Table 2). Tryptophan was an exception, probably because its indole nucleus reacts with nitrous acid to yield a diazo compound that also couples (though relatively slowly) with *N*-(1-naphthyl)ethylenediamine.^{31,32} Organic sulfides (*e.g.*, methionine) and disulfides (*e.g.*, cystine) do not interfere. Urea, ascorbic acid, hydrazine, ammonium ion, guanine, adenine and 2-aminopyridine do not affect the color reaction but rapidly consume nitrous acid in step (1). A sufficient excess of sodium nitrite should be added in step (1) when these compounds are known to be present. A 10-fold molar ratio of hydrogen sulfite to thiol does not interfere with the reaction. Methanol and ethanol form nitrite esters which are not completely destroyed by the addition of ammonium sulfamate, step (2). The alcohol nitrite esters do decompose under the conditions of step (3), however, and thus at high concentrations they interfere with the thiol assays. Thus we did not use alcohols as solvents for water-insoluble thiols, and used acetonitrile instead.

This assay technique did not give acceptable results for sterically hindered thiols (*e.g.*, triphenylmethane thiol), dithiols (*e.g.*, D,L-dithiothreitol and 2,5-dimercaptopyridic acid), and thiol-thione tautomers (*e.g.*, benzothiazol-2-thiol, benzoxazole-2-thiol, benzimida-

severe noise in FIA systems.³³ Thus we did not attempt the nitrosation and the destruction of nitrous acid in the flow system, but performed these steps manually.

We made a preliminary optimization of the flow-injection system, varying the parameters in the ranges given below in parentheses. The final configuration of the three-channel FIA manifold (Fig. 1) had a 50-cm hydrolysis coil (L1) (30–150 cm) and a 100-cm coupling coil (L2) (60–200 cm). The flow-rate in each channel was 1 ml/min (1–3 ml/min). Maximum peak absorbances were obtained with the reagent concentrations given in the recommended procedure. Further increases in the reagent concentrations had no effect on the peak heights obtained over the thiol concentration ranges reported. With a 50- μl loop (20–200 μl), the *S*-nitroso derivatives could be assayed with a sample throughput of 180 per hr. Typical calibration peaks for 1.25–12.50 μM homocysteine standards are shown in Fig. 2. The regression equation obtained for the 1–15 μM thiol range was $A = 0.0018 + 0.0104C$. The slope of the FIA system response was about a quarter of that for the batch method. This loss of sensitivity was apparently due to the dispersion of the sample plug. The dispersion coefficient,

D ,³⁴ found for potassium dichromate injected into the flow system described in Fig. 1, was 4.

Generally, the application and limitations of FIA methods parallel those of batch procedures. However, a significant tolerance was found for the presence of as much as 50-fold molar ratio of tryptophan to thiol in the FIA method, whereas even trace amounts caused severe interference in the batch method.

We have also made preliminary studies on the use of the FIA method for the assay of thiol groups in bovine serum albumin (molecular weight 6.6×10^4). The levels of free thiol groups are known to vary from sample to sample, depending on the prior history of the sample. With our FIA assay we found 0.65 (1.1% RSD) thiol groups per albumin "molecule", and 0.68 (1.4% RSD) by use of the Ellman reagent³⁵ when we assayed the sample of bovine serum albumin. We believe that our technique has significant potential for the assay of thiols in proteins and peptides.

SIMPLE UNSEGMENTED FLOW CONFIGURATIONS FOR SIMULTANEOUS KINETIC DETERMINATIONS

M. ROMERO-SALDANA, A RIOS, M D. LUQUE DE CASTRO and M. VALCARCEL

Department of Analytical Chemistry, Faculty of Sciences, University of Córdoba, Córdoba, Spain

(Received 25 August 1989 Revised 18 April 1990 Accepted 3 September 1990)

Summary—Two unsegmented-flow manifolds were designed for simultaneous determinations based on differences in the kinetic behaviour of two analytes with the same reagent. The determination of Fe(III) and Co(II), based on displacement of Fe(III) and Co(II) from their EGTA complexes by PAR, was used as a model system. The displacement reactions were photometrically monitored at 510 nm

Simultaneous determinations are of interest because they reduce analytical cost and time. In addition a high degree of automation can be achieved by using flow-injection systems.^{1,2} There are three basic ways of implementing simultaneous determinations in flow-injection analysis (FIA) with single-channel configurations.

(a) By using fast scan detectors, when the optical^{3,4} or electroanalytical^{5,6} features of the analytes (or reaction products) are suitable, the detector performing a complete scan at the maximum of the FIA peak.

(b) By using stopped-flow methods,⁵ when the two analytes react with the same reagent to yield similar products, but at different rates (optical detectors are most frequently used for this purpose). Differential kinetic methods can be applied to determine the analyte concentration.

(c) By altering the manifold to obtain more than one signal per injection. Proportional equation methods are normally applied in this case.

The last option is the most interesting from the point of view of economy and design, and offers several possibilities, such as use of a very large sample volume,⁶ use of manifolds with splitting and merging points,⁷ internally coupled valves,⁸ and open-closed configurations.⁹ Additional information about these alternatives can be found in monographs on FIA.^{2,10} In all cases, signals at different reaction times are obtained, which can be used for kinetic determinations.

This paper reports two manifolds which were evaluated by means of the well-known ligand-

displacement reaction between EGTA complexes and PAR, based on the different reaction rates of the EGTA complexes of Fe(III) and Co(II).¹¹ This chemical system was selected because its kinetic features make it suitable for checking the performance of the proposed automated operational modes. The manifolds allow two absorbance signals to be obtained at different reaction times, the values of these forming the basis for the simultaneous determinations.

EXPERIMENTAL

Reagents

The reagents used were aqueous $1 \times 10^{-3} M$ ethyleneglycol bis(β -aminoethyl ether)-*N,N,N',N'*-tetra-acetic acid (EGTA) and 2 mg/ml 4-(2-pyridylazo)resorcinol (PAR) monosodium salt monohydrate solutions. The pH of the EGTA solution was adjusted to 10.1 with sodium hydroxide. Standard stock solutions (1.000 g/l.) of iron(III) and cobalt(II) were also used.

Apparatus

A Pye-Unicam SP-500 single-beam spectrophotometer with a Hellma 178.12-QS flow-cell (inner volume 18 μ l), a Gilson Minipuls peristaltic pump, a Rheodyne 5041 injection valve, a Tecator TM-III chemifold and a Radiometer REC-80 recorder were used. The tubing of the reactor lines had an internal diameter of 0.5 mm.

RESULTS AND DISCUSSION

Manifolds

Both configurations allow the sample solution to react with the reagent for two reaction times.

Fig 1 Manifolds designed for the simultaneous determination of Fe(III) and Co(II) (I), With injection valve; (II), with selecting valve

The longer residence time is different for the two manifolds and results in different types of signal, transient for the configuration with the injection valve and a plateau for the configuration with the selecting valve.

Function of the manifold(I) with injection valve and reagent injection. The sample containing both analytes is continuously merged with a $1 \times 10^{-3} M$ EGTA stream (pH 10.1) and mixed within the reactor R_1 [Fig. 1(I)]. When the loop of the injection valve, I.V., is being filled with $7.8 \times 10^{-5} M$ PAR (pH 9.82), the stream is merged with the main channel at a point between R_2 and R_3 . This configuration allows the displacement reaction to take place within R_3 while the injection valve is in the filling position and yields a continuous signal that is the sum of the contributions of both analytes. Switching I.V. to the load position inserts a plug of PAR between R_1 and R_2 , giving a longer duration of the displacement reaction and a corresponding change in the contributions of the two analytes to the total signal provided by the detector, resulting in a sharp peak superimposed on the

continuous signal [Fig. 2(a)]. The difference in the contributions of the two analytes to the continuous and transient signals allows a set of simultaneous equations to be established for the system.

Function of the manifold(II) with a selecting valve. Replacement of the injection valve with a selecting valve, S.V. [Fig. 1(II)] allows the two streams (sample + EGTA, and PAR) to be diverted differently, depending on its position. In one position, the sample-EGTA mixture is selected and PAR inserted at point B (in this case the reaction takes place only in reactor R_3). In the other position, the PAR stream is selected and the sample-EGTA mixture is inserted at point A; the reaction takes place in reactors R_2 and R_3 before detection. The two continuous signals or plateaux obtained [Fig. 2(b)] allow the mixture to be resolved.

There are major differences between the two flow schemes. The simpler configuration I has the following shortcomings: (i) the volume of PAR injected must be large enough ($250 \mu l$) to prevent the degree of reaction from being offset by the high dispersion; (ii) the mixing of the sample with the injected reagent is not very efficient; (iii) the signal is disturbed by the merging of the injected plug of PAR with the continuous PAR stream entering at point P, this disturbance being increased by the large injected volume (this effect is especially important with coloured reagents (e.g., PAR, or with solutions containing organic solvents).

Manifold II eliminates these shortcomings and was therefore selected for developing the analytical method.

Kinetics of the process

The chemical reactions used were the instantaneous formation of the M-EGTA complex [M = Fe(III) or Co(II)] in basic medium and the displacement reaction with PAR:

which occurs at different rates for Fe(III) and Co(II), as shown in Fig. 3. The absorbance-time recordings were obtained with the manifold II, and a very short R_2 (12 cm). The rate constants (k) of these reactions were calculated from plots of $\log(A_\infty - A_t)$ vs. time (A_∞ being the final absorbance and A_t that at a given reaction time), the slopes being $-k/2.303$. The values $k_{Fe} = 5.1 \text{ min}^{-1}$ ($r = 0.9994$) and $K_{Co} = 2.1 \text{ min}^{-1}$ ($r = 0.9988$) show the faster displacement undergone by the Fe(III)-EGTA complex.

Fig. 2 Recordings obtained with, (a) manifold I, (b) manifold II. A_1 and A_1' are the signals obtained at residence time t_1 , A_2 and A_2' are those obtained at residence time t_2

Fig. 3 Absorbance-time curves obtained by stopping the flow immediately after mixing the reactants. Concentration of Fe(III) and Co(II) 2.0 $\mu\text{g/ml}$

Effect of variables

The optimum values found for the chemical variables were those stated in the experimental section. Because of the higher stability of the PAR complexes, the concentration of this reagent was kept lower than that of the EGTA to ensure the maximum possible difference in kinetic behaviour between the two chemical systems.

The optimum injection volume for manifold I was 270 μl . The influence of the flow-rate and reactor lengths was similar for both manifolds. Figure 4a shows the effect of flow-rate on the absorbance difference between the signals at the two residence times. The behaviour of the two analytes was similar and a flow-rate of 1.3 ml/min was found to be optimum. The length of R_1 is not significant, as the formation of the EGTA complexes is instantaneous, so it was fixed at 45 cm. R_3 must be short enough (50 cm) to ensure a short residence time corresponding to the first signal; on the other hand

Fig. 4 Influence of (a) the flow-rate and (b) the length of R_2 on the difference (ΔA) between the signals obtained at the two residence times

the length of R_2 is important since it must ensure an adequate difference between the two residence times. Figure 4b shows an optimum length of 150 cm for iron(III) (the faster reaction) and 300 cm for cobalt(II). A compromise of 250 cm was chosen for R_2 .

Calibration curves

Fe(III) and Co(II) (each in the absence of the other) can be determined by measuring (a) the absorbance of the first signal (measured at residence time t_1), (b) the absorbance of the second signal (residence time t_2) or (c) the difference between them.

Table 1 summarizes the features of the calibration curves obtained. As the Fe(III)-EGTA displacement reaction was rather fast, the calibration curve based on method (c) had poor sensitivity [0.010 ($\mu\text{g/ml}$)], and was clearly unsuitable for the determination of this analyte;

Table 1 Features of the individual determination of Fe(III) and Co(II)

Parameter*	Equation†	Regression coefficient	Linear range, $\mu\text{g/ml}$
A_1	$A_1 = 0.2765[\text{Fe}^{3+}] - 0.2047$	0.9998	1.0-5.0
A_1	$A_1 = 0.0375[\text{Co}^{2+}] - 0.0093$	0.9985	1.0-12.0
A_2	$A_2 = 0.2775[\text{Fe}^{3+}] - 0.063$	0.9982	1.0-5.0
A_2	$A_2 = 0.0975[\text{Co}^{2+}] + 0.031$	0.9996	0.5-7.0
ΔA	$\Delta A = 0.060[\text{Co}^{2+}] + 0.040$	0.9951	0.5-8.0

* A_1 = absorbance at residence time t_1

A_2 = absorbance at residence time t_2

$\Delta A = A_2 - A_1$

†Concentrations in $\mu\text{g/ml}$

hence it does not appear in Table 1. This type of measurement was very suitable for Co(II), however, the sensitivity being twice that obtained by method (a).

Effect of other metal ions

The influence of various metal ions on the proposed method was studied. Alkali-metal and alkaline-earth metal ions, Ni(II), Cd(II), Hg(II) and Pb(II) did not interfere, at least in a 1:1:10 (Fe(III): Co(II):foreign ion) ratio. Zn(II), Cu(II), Al(III), MoO_4^{2-} and WO_4^{2-} gave positive and Mn(II), Sn(II) and Cr(III) negative interferences. Mn(II), Cu(II) and Cr(III) were tolerated at a 1:1.1 ratio, while Zn(II), MoO_4^{2-} and WO_4^{2-} gave positive (between 10–20%), and Al(III) and Sn(II) higher negative errors at that ratio.

Simultaneous determination of Fe(III) and Co(II)

When both analytes are present the signals are not linearly additive. To solve this problem, calibration curves for Co(II) were run in the presence of constant amounts of Fe(III).¹² Thus, the general equation for Co(II) measured at residence time t_1 was:

$$A_1 = m[\text{Co}^{2+}] + n$$

where the slope, m , and the intercept, n , are linear functions of the concentration of Fe(III) in the sample.

$$m = 0.0215[\text{Fe}^{3+}] - 0.0123 \quad (r = 0.9965)$$

$$n = 0.1675[\text{Fe}^{3+}] - 0.026 \quad (r = 0.9955)$$

From the signals measured at t_2 , calibration curves for Fe(III) in the presence of constant amounts of Co(II) were constructed. The slopes found were very similar and their average was

$$m' = 0.1612$$

and the intercept was a linear function of the Co(II) concentration:

$$n' = 0.006625[\text{Co}^{2+}] + 0.095 \quad (r = 0.9896)$$

The final set of equations was

$$A_1 = (0.0215[\text{Fe}^{3+}] - 0.0123)[\text{Co}^{2+}]$$

$$+ 0.1675[\text{Fe}^{3+}] - 0.026$$

$$A_2 = 0.1612[\text{Fe}^{3+}] + 0.0662[\text{Co}^{2+}] + 0.095$$

which were solved with the aid of a simple BASIC program which requires input of the

Table 2 Analysis of mixtures of Fe(III) and Co(II)

Added, $\mu\text{g/ml}$		Found, $\mu\text{g/ml}$	
Fe(III)	Co(II)	Fe(III)	Co(II)
3.00	1.00	2.98	1.09
3.00	3.00	3.03	3.18
4.00	1.00	4.00	0.91
4.00	3.00	4.03	2.89
1.00	2.00	1.16	1.91
1.00	4.00	0.95	3.95
2.00	1.00	2.01	1.08
2.00	3.00	2.05	3.12
2.00	4.00	2.03	4.02

coefficients of these equations and the A_1 and A_2 values for each sample.

Table 2 lists the results obtained for some synthetic samples. The precision, expressed as r.s.d., was 2.4% for Fe(III) and 3.6% for Co(II) (for $n = 11$, $P = 0.05$ and $2.0 \mu\text{g/ml}$ of analyte in both cases). The sampling frequency was 25/hr.

CONCLUSIONS

Two novel manifold configurations are proposed for simultaneous determinations based on the different kinetic behaviour of two analytes with a single reagent.

KINETIC DETERMINATION OF EDTA AND CITRATE BY THE DISPLACEMENT OF FLUORIDE FROM Al³⁺-F⁻ COMPLEXES AND USE OF A FLUORIDE ION-SELECTIVE ELECTRODE

J. G. PENTARI, C. E. EFSTATHIOU* and T. P. HADJIIOANNOU

Laboratory of Analytical Chemistry, University of Athens, Panepistimiopolis (Kouponia),
Athens 157 71, Greece

(Received 1 May 1990 Revised 11 July 1990 Accepted 25 July 1990)

Summary—The displacement of fluoride from its aluminium complexes by the action of EDTA, citrate and other ligands is a relatively slow process which can be monitored potentiometrically with a fluoride ion-selective electrode. Some characteristics of these reactions are presented. There is evidence that [AlF]²⁺ reacts with the competitive ligand faster than the simple free (hydrated) Al³⁺ species does. The relative rates of release of fluoride by the action of various aminopolycarboxylic acids have been determined. Potentiometric reaction-rate methods have been developed for the determination of 0.2–1.5 μmole of EDTA and 0.1–1.0 μmole of citric acid, with average relative errors of ~3%.

Aluminium forms a series of complexes with fluoride of the general type [AlF_n(H₂O)_{6-n}]⁽³⁻ⁿ⁾⁺ where *n* = 1–6. For simplicity, water molecules will be omitted from the formulae for the aluminium species shown below. Baumann,¹ using potentiometric data obtained with a fluoride ion-selective electrode (ISE), has calculated the successive formation constants of the lower (*n* = 1–4) Al–F complexes, whereas Agarwal and Moreno,² using the same sensor, have calculated the formation constants of these complexes under a wide range of conditions (at ionic strengths 0.05–0.5, and in the temperature range 25–37°).

Aluminium ion reacts slowly with almost all ligands, including fluoride and aminopolycarboxylic acids. Srinivasan and Rechnitz³ have investigated the kinetics of the formation of the complexes [FeF]²⁺ and [AlF]²⁺, by using the fluoride ISE. They have also used the electrode for indirectly studying the kinetics of the reaction between Fe(III) and iodide, by monitoring the rate of release of fluoride according to the overall scheme⁴

As equilibrium (1) is quickly established and [FeF]²⁺ is inactive towards iodide, monitoring

the rate of release of fluoride provides an indirect, but adequate, means of monitoring reaction (2), since the rate of release of fluoride will be governed by the rate of reaction (2).

In the present study, the fluoride ISE has been used for monitoring the release of fluoride from its complexes with aluminium after the addition of a competitive complexing reagent (an aminopolycarboxylic acid or α-hydroxy-acid) in a buffered (acetate) medium. The overall displacement reaction can be written

Since the equilibria for reactions Al³⁺ and F⁻ are established slowly, the rate of fluoride release cannot be considered as indicative of the rate of reaction (4). Furthermore, the direct displacement reaction

cannot be excluded, and experimental data, presented in this study, reveal that it proceeds faster than the direct complexation of “fluoride-free” aluminium species with L^{m-}.

The overall rate of release of the fluoride, as the result of numerous parallel reactions, has only comparative value and may serve as a measure of the effectiveness of L as a “fluoride demasking reagent”. It should be stressed that

*Author for correspondence

the rate and completeness of the fluoride displacement reaction is of particular importance for the potentiometric determination of total fluoride in samples containing elevated concentrations of aluminium (*e.g.*, tooth-pastes, mineral waters and industrial effluents). The treatment of such samples with solutions containing competitive complexing reagents such as DCTA or tartrate must always precede the measurement step.^{5,6}

In this study, the conditions of the reactions between the Al-F complexes and the complexing reagents were investigated and optimized to obtain potential recordings with a slope ($\Delta E/\Delta t$) proportional to the amount of the complexing reagent. A kinetic procedure based on these displacement reactions was developed and 0.2–1.5 μmole of EDTA was determined with an average relative error of $\sim 3\%$. Other complexing reagents (DCTA, citrates and isocitrates) readily displace fluoride from Al-F complexes, but the initial fast release of fluoride is followed by its slow recombination with the excess of aluminium, resulting in a minimum in the potential-time recordings. It was found that the depth of the minimum can be linearly related to the logarithm of the amount of the complexing reagent. A kinetic procedure based on this observation was developed for the determination of 0.1–1.0 μmole of citrate with an average relative error of $\sim 3\%$.

EXPERIMENTAL

Apparatus

A potentiometric rate measurement system consisting of a digital electrometer (Orion 801 pH-pIon meter) interfaced to a microcomputer (Amstrad CPC-6128) was used. A brief description of the system hardware and the control program KINMOD can be found elsewhere.⁷ Alternatively, the potential of the fluoride ISE can be conventionally recorded.

A combination fluoride electrode (Orion Model 96-09) was used and all measurements were performed in a constant-temperature ($25 \pm 0.2^\circ$) reaction cell with continuous magnetic stirring. The electrode was stored in 1.0M fluoride solution when not in use.

Reagents

All solutions were prepared from analytical grade reagents and demineralized distilled water was used throughout. The following stock solutions were prepared: 0.1000M sodium fluoride

(stored in a polyethylene bottle), 0.0500M aluminium nitrate, 2.50M sodium nitrate and acetate buffer solutions (0.10M total acetate) over the pH range 3.8–5.5.

The following aminopolycarboxylic acid solutions (0.0500M) were used: nitrilotriacetic acid (NTA), ethylenediamine-*N,N,N',N'*-tetra-acetic acid (EDTA), *N*-hydroxyethylethylenediamine-*N,N',N'*-tetra-acetic acid (HEDTA), *trans*-1,2-diaminocyclohexane-*N,N,N',N'*-tetra-acetic acid (DCTA), 2,2'-ethylenedioxybis(ethyliminodiacetic acid) (EGTA), diethylenetriamine-*N,N,N',N'',N''*-penta-acetic acid (DTPA), triethylenetetramine-*N,N,N',N'',N''',N'''*-hexa-acetic acid (TTHA). These solutions were prepared by the addition of small volumes of 5M sodium hydroxide to a vigorously stirred suspension of the free acid, maintaining the pH at 6–7, and diluting to volume after complete dissolution.

Solutions (0.0500M) of the following α -hydroxy-acids or their sodium or potassium salts were used: glycollic, pyruvic, lactic, α -hydroxyisobutyric, mandelic, malic, tartaric, citric and isocitric. These solutions were stored in a refrigerator.

Standard $\text{Al}^{3+}/\text{F}^-$ solutions, at a given pH and ionic strength, were prepared by mixing the appropriate volumes of fluoride stock solution, acetate buffer, and sodium nitrate stock solution in a standard flask, adding the required volume of aluminium stock solution (diluted with almost enough water to make up the total volume needed), with vigorous shaking (to eliminate the possibility of formation of insoluble aluminium salts by local excess of aluminium) and finally diluting to the mark. Standard solution A was 0.625mM $\text{Al}(\text{NO}_3)_3$, 1.00mM NaF, pH 4.1 (total acetate 2.50mM), 0.100M NaNO_3 .

Standard solution B was prepared in the same way as solution A but was 0.750mM in $\text{Al}(\text{NO}_3)_3$. These standard solutions were stored in polyethylene bottles and it was found potentiometrically that their fluoride activities remained stable for at least a week.

Working standard solutions of EDTA (in the range 0.2–1.5mM) and citrate (in the range 0.1–1.0mM) were prepared daily from the stock solutions by dilution with water.

Procedures

General studies. A 10.00-ml volume of standard $\text{Al}^{3+}/\text{F}^-$ solution was transferred into the reaction cell. The stirrer was started and after

the potential had stabilized (20–30 sec) the reaction was initiated by the rapid injection of 10–50 μl of the stock solution of the complexing reagent. The reaction was followed for about 30–60 sec and its course was monitored by the microcomputer. The potential–time ($E-t$) data were stored on magnetic disks for later use. The cell was emptied and washed with two 10-ml portions of the $\text{Al}^{3+}/\text{F}^-$ solution.

Kinetic measurement of EDTA. A 10.00-ml volume of standard solution A was transferred into the reaction cell. The stirrer was started and, after the potential had been stabilized (about 30 sec), the reaction was initiated by the rapid injection of 1.00 ml of working standard or sample solution of EDTA in the concentration range 0.20–1.5mM. The reaction was followed for about 30–60 sec and its progress was monitored by the microcomputer. The analytical signal ($\Delta E/\Delta t$, mV/sec) was automatically calculated by the program by linear regression of the $E-t$ data obtained between 10 and 30 sec after sample injection. The cell was then emptied and washed as above.

Calibration graphs of $\Delta E/\Delta t$ vs. C_{EDTA} were constructed by using standard solutions of EDTA.

Kinetic measurement of citrate. A modified version of the KINMOD program was used to facilitate the measurement of the peak height, ΔE , of the potential–time plot ($\Delta E = E_{\text{eq}} - E_{\text{peak}}$), where E_{peak} was the lowest potential obtained after the addition of the citrate sample, and E_{eq} was the equilibrium potential prior to the addition of the citrate sample.

A 10.00-ml volume of standard solution B was transferred into the reaction cell. The stirrer was started and after the potential had stabilized the reaction was initiated by the rapid injection of 1.00 ml of working standard or sample solution of citrate (Cit) in the concentration range 0.10–1.0mM. The reaction was followed for 60 sec and the analytical signal (ΔE , mV) was automatically calculated by the program. The cell was then emptied and washed as above.

Calibration graphs of ΔE vs. $\log C_{\text{Cit}}$ were constructed by using standard solutions of citrate.

RESULTS AND DISCUSSION

Kinetic characterization of the $\text{Al}^{3+}/\text{F}^-/\text{EDTA}$ system

Although aluminium forms very stable complexes with EDTA ($K_f = 1.3 \times 10^{16}$) and other

aminopolycarboxylic acids, its direct titration with these compounds (except DCTA)⁸ is virtually impossible in the presence of high concentrations of neutral electrolytes.⁹

The influences of parameters such as the analytical concentrations of aluminium (C_{Al}) and fluoride (C_{F}), pH, ionic strength, and temperature were examined. With each set of parameters, the rate of displacement of the fluoride ion from Al–F complexes (expressed in terms of $-\Delta E/\Delta t$) was measured with various amounts of EDTA. In each case the linearity of the recordings obtained was evaluated to establish conditions for reproducible measurement of $\Delta E/\Delta t$. The linearity and slope of the resulting calibration graphs were also examined.

With a constant analytical concentration of fluoride, the concentration of each aluminium species and the concentration of uncomplexed fluoride are dependent on the analytical concentration of aluminium. From the equilibria

and the relevant mass-balance equations for aluminium and fluoride, the following implicit function of $[\text{F}^-]$ is obtained:

$$[\text{F}^-] \left(1 + \frac{[\text{H}^+]}{K_{\text{HF}}} \right) + \frac{\sum_{i=1}^4 \left(i [\text{F}^-]^i \prod_{j=1}^i K_j \right)}{1 + K_h/[\text{H}^+] + \sum_{i=1}^4 \left([\text{F}^-]^i \sum_{j=1}^i K_j \right)} C_{\text{Al}} = C_{\text{F}} \quad (12)$$

Equation (12) is solved numerically for $[\text{F}^-]$ by using the Newton–Raphson iterative procedure.¹⁰ The concentrations of all other species are calculated from their explicit functions obtained from the relevant equilibrium expressions. The mole fractions of all aluminium species, and $\log [\text{F}^-]$, are shown as functions of C_{Al} in Fig. 1.

The successive formation constants (K_i) used for the calculations were $K_1 = 2.8 \times 10^6$, $K_2 = 1.6 \times 10^5$, $K_3 = 6.2 \times 10^3$, $K_4 = 1.5 \times 10^3$ (calculated at 25° and ionic strength 0.1).² The dissociation constant of HF, K_{HF} , and the

Fig 1 Calculated mole fractions of aluminium species and values of $\log [F^-]$ (dashed line) as functions of C_{Al} , C_F 1.00mM, pH 4.1, ionic strength 0.10, temperature 25°

hydrolysis constant of Al^{3+} , K_h , were taken as 5.9×10^{-4} and 1.1×10^{-5} , respectively.^{2,11}

Standard Al^{3+}/F^- solutions with C_{Al} in the range 0.125–1.25mM and fixed $C_F = 1.00mM$ were prepared. The concentration of free fluoride in each of these solutions was measured potentiometrically and found to be in excellent agreement with the calculated values (the experimental points are shown in Fig. 1). This fact confirms that the acetate (total acetate concentration 2.50mM), added to increase the buffer capacity of the standard Al^{3+}/F^- solutions, does not participate to any great extent in the overall Al–F equilibria.

Calibration graphs, for amounts of EDTA corresponding to final analytical concentrations in the range 0.025–0.125mM, were prepared

Fig 2 Effect of the analytical concentration of aluminium (C_{Al}) on the recorded curves of the fluoride ISE potential during the reaction of the Al^{3+}/F^- standard solutions with EDTA at $25.0 \pm 0.2^\circ$, C_{Al} as shown on recordings, C_F 1.00mM, C_{EDTA} 0.150mM, pH 4.1 (total acetate 2.50mM), ionic strength 0.10 (NaNO₃), INJ = injection of EDTA solution

with each standard solution and it was found that optimum linearity and sensitivity were obtained at $C_{Al} = 0.625mM$. At this analytical concentration of aluminium, the predominant aluminium species are $[AlF]^{2+}$ and $[AlF_2]^+$, with mole fractions of 0.40 and 0.55, respectively.

Typical curves recorded during the reaction of the Al^{3+}/F^- standard solutions with the same amount of EDTA, are shown in Fig. 2. The recordings obtained with the standard solution with $C_{Al} = 0.625mM$ had an extensive linear portion and the highest (absolute) slope. The initial potential change is especially pronounced for $C_{Al} > 0.625mM$, where the doubly-charged complex $[AlF]^{2+}$ predominates. Probably, $[AlF]^{2+}$ reacts much faster with the negatively charged species of EDTA than the other complexes do, owing to the stronger attractive coulombic forces. Apparently, the solution is quickly depleted of $[AlF]^{2+}$, because of the slow re-establishment of the equilibria among the Al–F complexes.

In an attempt to enhance the sensitivity of the kinetic determination of EDTA, the previous experiments were repeated with C_F fixed at 0.250mM and C_{Al} in the range 0.04–0.40mM. The optimum C_{Al} was found to be $\sim 0.25mM$, but no improvement in sensitivity or linearity of the calibration graph was observed. Furthermore, lower fluoride concentrations resulted in a much slower stabilization of the potential of the fluoride ISE.

For standard solutions with $C_{Al} = 0.625mM$, $C_F = 1.00mM$ and pH values in the range 4.1–5.6, recordings were obtained with various EDTA concentrations as before. It was found that the slope of the initial portion of the potential recordings increased with increasing

Fig 3 Recorded curves of the fluoride ISE potential during the reaction of the $\text{Al}^{3+}/\text{F}^-$ standard solution with various aminopolycarboxylic acids (L) at $25.0 \pm 0.2^\circ$, C_F 1.00 mM, C_{Al} 0.625 mM, C_L 0.100 mM, pH 4.1 (total acetate 2.50 mM), ionic strength 0.10 (NaNO_3), INJ = injection of aminopolycarboxylic acid solution

pH, but the absence of extended linear portions of these recordings dictated the use of pH 4.1. Replacing acetate by monochloroacetate and repeating the measurements in the pH range 3.5–4.0 resulted in linear potential recordings, but no increase in the slope of the calibration graph was achieved.

The rate of the fluoride displacement by EDTA was examined with standard $\text{Al}^{3+}/\text{F}^-$ solutions with ionic strengths in the range 0.1–1.0 (adjusted with sodium nitrate). The rate of fluoride release decreased when the ionic strength was increased, denoting a rate-determining step between species of opposite charge. It is known that the reaction of aluminium with EDTA is retarded by high ionic strength.⁸ Although the absence of ionic background would result in enhanced sensitivity of the kinetic determination of EDTA, an ionic strength of 0.10 was selected to overcome small variations in the ionic strength of the samples.

The rate of the displacement reaction increased with temperature. From the slopes of the calibration graphs obtained at temperatures in the range 23–32° (normalized for the temperature effect on the pre-logarithmic factor of the Nernst equation), an activation energy of 16.0 ± 0.8 kcal/mole was calculated. However, it should be noted that the consistent curvature observed on the relevant Arrhenius plots denotes that more than one rate-determining reaction step is involved.

Kinetic measurement of EDTA

The EDTA contents of 1.00-ml samples of aqueous solutions containing 0.2–1.5 μmole of

EDTA were measured by the reaction rate method. Calibration graphs were obtained with four standard solutions. A typical calibration graph is described by the equation

$$-\Delta E/\Delta t (\text{mV/sec}) = -0.014 + 0.232(\text{EDTA}, \mu\text{mole}), \quad r = 0.999 \quad (13)$$

The average absolute and relative errors of the measurement (single measurements) were 0.02 μmole and 3.1%, respectively. The relative standard deviations of repetitive measurements of samples containing 0.40 and 1.20 μmole of EDTA were 3.0 and 2.4%, respectively ($N = 9$).

Comparison of EDTA with other aminopolycarboxylic acids

Other aminopolycarboxylic acids were examined to determine the relative rates of their displacement reactions. Typical recordings are shown in Fig. 3.

DCTA reacts much faster than the others, resulting in a non-monotonic release of fluoride. Probably, the following reactions take place ($\text{H}_4\text{Y} = \text{DCTA}$):

Reaction (16) must be much slower than reaction (14), otherwise a monotonic release of fluoride would occur. Probably, partial complexation of aluminium with fluoride weakens the polymeric structure of hydrated aluminium ions, making them more reactive.

The relative rate of release of fluoride by each of the aminopolycarboxylic acids examined was determined from the slopes of the calibration plots obtained by varying the amount of complexing reagent. The extended reaction curves were used for preparing the calibration plots except in the case of DCTA, where the initial slopes of the recordings were used. The rates for the aminopolycarboxylic acids examined, relative to that for EDTA, are:

DCTA	EDTA	NTA	TTHA	DTPA	HEDTA	EGTA
9.0	1.00	0.75	0.74	0.70	0.33	0.20

These values justify the customary use of DCTA, rather than EDTA, in total ionic

strength adjustment buffer (TISAB) formulations for fluoride ISE applications in the presence of aluminium.

Kinetic characterization of the system $Al^{3+}/F^-/citrate$

Citrate readily replaces fluoride from Al-F complexes. The fluoride ions released recombine with the excess of Al^{3+} , resulting in non-monotonic trough-shaped recordings even sharper than those obtained with DCTA. It soon became apparent that the depth of the minimum of the potential-time recordings could serve as an analytical signal for the determination of small amount of citrate and was a linear function of the logarithm of the amount of citrate added.

The reaction conditions were optimized with regard to high sensitivity and linearity, as described above for EDTA.

Typical recordings obtained with C_F fixed at 1.00mM and C_{Al} in the range 0.25–1.50mM, at pH 4.1 and ionic strength 0.10, are shown in Fig. 4. The sharpest and deepest troughs were obtained at C_{Al} 0.750–1.00mM, a concentration range in which $[AlF]^{2+}$ is the predominant species (Fig. 1).

As in the case of EDTA, the effect of pH was examined by repeating the measurements with $C_{Al} = 0.750mM$ over the pH range 3.5–5.5. Sharp potential troughs appeared at pH 4.1–4.5, whereas at pH > 5.0 only a relatively small potential change was observed. It was found that increasing ionic strength results in a flatter change in potential.

The effect of temperature was examined over the range 25–38° and at various analytical concentrations of citrate. The thermal coefficient was found to be 0.1 mV/deg or less. Therefore, small temperature fluctuations will not have a noticeable effect on the measurements.

Kinetics measurement of citrate

The citrate contents of 1.00-ml samples of aqueous solutions containing 0.1–1.0 μ mole of citrate were measured from the maximum change in potential (ΔE). Calibration graphs were obtained with four standard solutions. A typical calibration graph is described by the equation

$$\Delta E(mV) = 14.70 + 10.04 \log(Cit, \mu\text{mole})$$

$$r = 0.99992 \quad (17)$$

Fig. 4 Effect of the analytical concentration of aluminum (C_{Al}) on the recorded curves of the fluoride ISE potential during the reaction of the Al^{3+}/F^- standard solutions with citrate at $28.0 \pm 0.2^\circ$; C_{Al} as shown on recordings, C_F 1.00mM, C_{Cit} 0.030mM, pH 4.1 (total acetate 2.50mM), ionic strength 0.10 ($NaNO_3$), INJ = injection of citrate solution

The average absolute and relative errors of the measurement (single measurements) were 0.01 μ mole and 2.7%, respectively. The relative standard deviations of repetitive measurements of samples containing 0.10 and 0.75 μ mole of citrate were 2.0 and 1.9%, respectively ($N = 10$).

Comparison of citrate with other α -hydroxy-acids

Other α -hydroxy-acids were similarly examined. It was found that the monocarboxylic acids (glycollic, pyruvic, lactic, α -hydroxyisobutyric and mandelic) did not displace fluoride from its aluminium complexes. The dicarboxylic acids (malic and tartaric) displaced fluoride by an initially fast reaction which quickly subsided. Reaction curves obtained with isocitrate were similar to those obtained with citrate. Taking the analytical sensitivity (slope of the calibration graph) for the determination of citrate as unity the analytical sensitivities of the four reactive α -hydroxy-acids are

Isocitric	Citric	Malic	Tartaric
1.05	1.00	0.38	0.20

CONCLUSIONS

The displacement of fluoride from its complexes with aluminium by the action of EDTA, citrate and other related compounds is relatively slow, and easily monitored potentiometrically. The determination of individual reaction

rate constants is virtually impossible by exclusive monitoring of free fluoride. However, semi-quantitative inspection of the experimental data shows that fluoride is displaced quickly from the $[AlF]^{2+}$ species, and this complex reacts faster with DCTA, citrate and isocitrate than uncomplexed aluminium species do.

The applicability of the described kinetic procedures for the determination of EDTA and citrate is limited owing to the great number of interferents. Some kinetic discrimination may be possible. Ions forming complexes with fluoride, EDTA or citrate that are more stable than those of aluminium, or that form precipitates with fluoride or aluminium, should be considered as potential interferents. However, monitoring of the displacement reaction by means of a fluoride ion-selective electrode may serve as a sufficiently sensitive scheme for the post-column

detection of complexing reagents in LC and FIA systems.

KINETIC SPECTROPHOTOMETRIC DETERMINATION OF NANOGRAM AMOUNTS OF CYANIDE

A. VELASCO, M. SILVA and M. VALCARCEL

Department of Analytical Chemistry, Faculty of Sciences, University of Córdoba, 14004 Córdoba, Spain

(Received 9 November 1989 Revised 18 September 1990 Accepted 19 September 1990)

Summary—A sensitive kinetic method for determination of nanogram amounts of cyanide is reported. It is based on the measurement of the induction period imposed by cyanide on the copper(II)-catalysed oxidation of 3-hydroxybenzaldehyde azine (3-OHBAA) by potassium peroxydisulphate. Kinetic data are recorded spectrophotometrically at 465 nm, the maximum absorption wavelength of the oxidation product of 3-OHBAA. From the kinetic study and other experimental tests it may be concluded that the cyanide ion undergoes copper(II)-catalysed oxidation during the induction period. The calibration plot is linear in the range 150–600 ng/ml cyanide and the detection limit is 50 ng/ml. The precision of the method, expressed as the relative standard deviation, is 3.2% for 350 ng/ml cyanide. Good recoveries are obtained in applying the method to analysis for cyanide in water samples.

The determination of inorganic anions by their catalytic effect on redox reactions is less common than that of metal ions. Many anions act as inhibitors in metal-catalysed reactions because they can form stable complexes with metal ions, but this facilitates their determination by kinetic or catalytic titration methods.¹

Despite the great ability of cyanide to form stable complexes with transition metal ions, few kinetic methods have been developed for its determination. Two types of method have been used: direct determination of cyanide based on its catalytic effect on redox^{2,3} and decomposition⁴ reactions and indirect determination on the basis of its inhibitory effect on metal-catalysed reactions⁵⁻⁷ and on one uncatalysed reaction.⁸ Catalytic titrations have scarcely been used for cyanide determination.^{9,10}

The kinetic determination of cyanide reported in this paper is based on the copper(II)-catalysed oxidation of 3-hydroxybenzaldehyde azine (3-OHBAA) by potassium peroxydisulphate in ammoniacal medium, an indicator reaction previously used for the kinetic determination of nanogram amounts of copper in a large variety of samples.¹¹ In this reaction, the cyanide interacts with the potassium peroxydisulphate rather than with copper(II), imposing an induction period (proportional to the amount of cyanide present in the sample) in the absorbance vs. time plots recorded at the maximum absorption wavelength of the oxidation product of 3-OHBAA. The proposed method

permits the determination of ng/ml levels of cyanide with appreciable selectivity (*e.g.*, in the presence of large amounts of thiocyanate) and its application to the analysis of water samples with good results.

EXPERIMENTAL

Reagents

All chemicals used were of analytical-reagent grade. A 3-hydroxybenzaldehyde azine solution (3 mg/ml) was prepared in ethanol. The reagent was synthesized according to the procedure of Luque de Castro and Valcárcel.¹² A standard cyanide solution (1.0 mg/ml) was prepared by dissolving 2.5 g of potassium cyanide (equivalent to 1 g of cyanide) in 1 litre of 0.05M sodium hydroxide, and standardized argentometrically.¹³ A standard copper solution (1.000 mg/ml) was made by dissolving 1.000 g of pure electrolytic copper in the minimum volume of nitric acid (1 + 1) and diluting to exactly 1 litre with 1% v/v nitric acid.

Apparatus

All spectrophotometric measurements were made with a Perkin-Elmer Lambda 5 double-beam spectrophotometer furnished with an automatic recorder and a dry thermostat (Peltier system) with 1-cm cells. A Radiometer PHM62 pH-meter furnished with a combined glass-calomel electrode was also used.

Procedure

To a 10-ml standard flask add 2.0 ml of ethanolic 3-OHBA solution, 4.0 ml of ethanol, 1.0 ml of distilled water, 100 μ l of 1.000 μ g/ml copper(II) solution, appropriate volumes of cyanide solution to give a final concentration of cyanide between 150 and 600 ng/ml, 1.0 ml of 0.1M potassium peroxydisulphate and 0.8 ml of concentrated ammonia solution. Make up to volume with distilled water, mix, and after 10 min, transfer a portion to a 1-cm spectrophotometric cell kept at $25 \pm 0.1^\circ$. Wait for 30 sec before starting to record the absorbance (at 465 nm) as a function of time against a blank containing no cyanide or copper (uncatalysed reaction). Calculate the induction period from the kinetic curve; it should be proportional to the concentration of cyanide in the sample.

RESULTS AND DISCUSSION

Copper(II) catalyses the oxidation of 3-hydroxybenzaldehyde azine by potassium peroxydisulphate in ammoniacal solutions. The oxidation product formed gives rise to an intense band centred at 465 nm. In the presence of cyanide this band is again present but there is an induction period in the absorbance *vs.* time plot (Fig. 1). After this delay time, the catalytic reaction exhibits the same kinetic behaviour (initial rate) as in the absence of the cyanide ion. This can be attributed to an interaction between cyanide and potassium peroxydisulphate rather than with the catalyst. In fact, taking into account the experimental results reported in this paper, it appears that the cyanide ion is oxidized

Fig. 1. Modifying effect of cyanide on the copper(II)-catalysed oxidation of 3-OHBA by potassium peroxydisulphate. (I) reaction catalysed by 10 ng/ml copper(II), (II) as for (I), but in the presence of 300 ng/ml cyanide. Reaction conditions as described in "Procedure"

by the potassium peroxydisulphate in a reaction which is also catalysed by copper(II). Thus, the start of the copper(II)-catalysed oxidation of 3-OHBA (once cyanide has been completely oxidized) is marked by an increase in the absorbance at 465 nm (Fig. 1).

Influence of reaction variables

The effect of temperature on the oxidation of cyanide was examined in the range $15\text{--}40^\circ$ (Fig. 2). Although the induction period was longer at low temperatures (giving higher sensitivity in the kinetic determination of cyanide), the initial rate of the 3-OHBA/S₂O₈²⁻/Cu²⁺ system was lower and graphical errors in the determination of the induction period were therefore larger. Thus, the temperature was fixed at 25° (room temperature) for subsequent experiments, taking into account the appreciable extent of the induction period and the ease with which this temperature can be achieved in the spectrophotometer cell compartment.

To optimize the concentration of potassium peroxydisulphate the initial value was varied in the range $3 \times 10^{-3}\text{--}1.3 \times 10^{-2}M$, while keeping the concentrations of the other reactants constant [Fig. 3(a)]. From the results, we established the kinetic dependence of the oxidation of the cyanide ion on the concentration of potassium peroxydisulphate. Thus, if a pseudo first-order dependence was assumed, the corresponding rate equation could be written as

$$-d[\text{CN}^-]/dt = k[\text{S}_2\text{O}_8^{2-}] \quad (1)$$

As the oxidant concentration was in large excess with respect to the cyanide concentration,

Fig. 2. Absorbance/time curves recorded at different temperatures for the 3-OHBA/S₂O₈²⁻/Cu²⁺ system in the presence of 250 ng/ml cyanide. Other conditions as described in "Procedure"

Fig 3 Effect of chemical variables on the kinetic determination of 500 ng/ml cyanide (a) $S_2O_8^{2-}$, (b) 3-OHBAAs, (c) NH_3 ; (d) Cu^{2+}

it could be assumed to be constant, and integration of equation (1) over the limits $[CN^-]_0 - [CN^-]_f$, corresponding to $t = t_0$ (start of the reaction) and $t = t_f$ (end of the cyanide oxidation reaction), would yield:

$$[CN^-]_0 - [CN^-]_f = k[S_2O_8^{2-}](t_f - t_0) \quad (2)$$

which, assuming $t_f - t_0 = IP$ (induction period) and $[CN^-]_f \rightarrow 0$ can be simplified to

$$[CN^-]_0 = k[S_2O_8^{2-}]IP \quad (3)$$

from which, taking into account that $[CN^-]_0$ was constant in all the experiments concerned, equation (3) can be rewritten as:

$$IP = k'/[S_2O_8^{2-}] \quad (4)$$

where $k' = [CN^-]_0/k$.

This theoretical dependence was experimentally confirmed by the straight line ($r = 0.994$, $n = 6$) obtained in the plot of the induction period against the reciprocal of the oxidant concentration. From these studies, the optimum oxidant concentration was taken to be $0.01M$ (corresponding to 1 ml of $0.1M$ potassium peroxydisulphate in the reaction mixture).

The effect of the concentration of 3-OHBAAs on the induction period is reflected in Fig. 3(b). Although the 3-OHBAAs does not take part in the oxidation of cyanide ion, the results suggest that the 3-OHBAAs/ $S_2O_8^{2-}$ / Cu^{2+} system exerts an accelerating effect on this oxidation reaction.

In order to increase the sensitivity we used a 3-OHBAAs concentration of $2.5 \times 10^{-3}M$ (2.0 ml of 3-mg/ml ethanolic solution in 10 ml) in the reaction.

The effect of the ammonia concentration on the length of the induction period was studied by following the proposed procedure and adding between 0.4 and 2.0 ml of concentrated ammonia to a series of 10-ml standard flasks containing cyanide and the other reactants. A $1.08M$ ammonia concentration was chosen as optimal since although lower concentrations would give longer induction periods and use of higher concentrations would be less sensitive to loss of ammonia, in both cases the graphical determination of the induction period proved more troublesome.

The influence of pH was examined at a fixed initial concentration of ammonia ($1.08M$) by adding dilute hydrochloric acid or sodium hydroxide. A zero-order kinetic region was found at pH values of about 10.8–13.2, so a pH of 11.9, which was accomplished by addition of 0.8 ml of concentrated ammonia solution to the reaction mixture, was selected.

The variation of the induction period was studied as a function of the copper(II) concentration in the range 10–30 ng/ml [Fig. 3(d)]. The dependence of the induction period on the concentration of copper was found to be similar to that on the concentration of the oxidant,

which suggests a pseudo first-order dependence of the rate of oxidation of cyanide on the copper(II) concentration:

$$-d[\text{CN}^-]/dt = k_1[\text{Cu}^{2+}] \quad (5)$$

If copper(II) does exert a catalytic effect on this reaction, its concentration must be kept constant during the determinations. Direct dependence between the induction period and the reciprocal of the copper(II) concentration is indicated by integration of equation (5) similarly to equation (1). The straight line obtained ($r = 0.9988$, $n = 6$) for the experimental relationship confirms this dependence and the catalytic effect of copper(II) on the oxidation of cyanide by potassium peroxydisulphate. The copper(II) concentration selected was 10 ng/ml [100 μ l of 1.000 μ g/ml copper(II) solution].

Increase in the ethanol concentration between 20 and 65% v/v linearly increased the length of the induction period by a factor of up to 2.8. Thus, the cyanide oxidation reaction was markedly hindered by increased ethanol contents. According to the Kirkwood equation,¹⁴ the rate of reaction between two ions with the same charge sign increases with increasing dielectric constant of the medium. Therefore, we may assume an interaction of two ions with the same charge sign to be the rate-determining step in the copper(II)-catalysed oxidation of cyanide by potassium peroxydisulphate. From this study, a 60% v/v ethanol concentration was chosen as optimum.

Finally, the length of the induction period was found to increase non-linearly with the cyanide concentration [Fig. 4(a)]. In order to account for this behaviour, we may assume a kinetic dependence of order -1 between the oxidation rate of cyanide and its concentration:

$$-d[\text{CN}^-]/dt = k_0/[\text{CN}^-] \quad (6)$$

Integration of equation (6) between the limits $t_1 = t_0$, $[\text{CN}^-]_1 = [\text{CN}^-]_0$ and $t_2 = t_f$, $[\text{CN}^-]_2 = [\text{CN}^-]_f$ gives

$$[\text{CN}^-]_0^2 - [\text{CN}^-]_f^2 = 2k_0(t_f - t_0) = 2k_0\text{IP} \quad (7)$$

$[\text{CN}^-]_f$ can be neglected and equation (7) can be rewritten as

$$\text{IP} = k'_0[\text{CN}^-]_0^2 \quad (8)$$

where $k'_0 = 1/2k_0$

This relation between the induction period and the cyanide concentration was experimentally confirmed, as shown in Fig. 4(b).

Fig. 4 Kinetic determination of cyanide (a) effect of the cyanide concentration on the induction period, (b) linear calibration function used for the determination of cyanide

In consistence with the study above, the following rate equation is suggested for the copper(II)-catalysed oxidation of cyanide by potassium peroxydisulphate, in which the 3-OHBAAs/S₂O₈²⁻/Cu²⁺ system acts as a "developing reaction":

where K is the rate constant.

Oxidation of cyanide, and catalytic effect of copper(II)

According to the results found in the kinetic study, we may assume the 3-OHBAAs/S₂O₈²⁻/Cu²⁺ system to be subject to an induction period in the presence of cyanide ion, which is oxidized by potassium peroxydisulphate in a reaction also catalysed by copper(II). Although the kinetic dependence on copper(II) is indicative of its catalytic effect, four further assays were made to confirm this point: (a) oxidation of 3-OHBAAs by potassium peroxydisulphate catalysed by 10 ng/ml copper(II); (b) the same reaction in the presence of 450 ng/ml cyanide; (c) preparation of the sample as in (b) but with the 3-OHBAAs added after 7 min [*i.e.*, once the cyanide had been oxidized by S₂O₈²⁻ in the presence of copper(II) as catalyst]; (d) preparation of the

sample as in (b), but with both the 3-OHBAA and copper(II) added after 7 min.

The results are listed in Table 1. The absence of an induction period in (c) and its occurrence in (d) clearly confirm the catalytic effect of copper(II) on the oxidation of cyanide by potassium peroxydisulphate. The small difference between the induction periods in (b) and (d) can be attributed to slight oxidation of cyanide in the delay time (7 min) before addition of the copper.

In summary, the kinetic curve recorded has two distinct parts: (1) an induction period in which the cyanide is oxidized by potassium peroxydisulphate in a reaction catalysed by copper(II) according to:

and (2) the typical absorbance *vs.* time response, measured at 465 nm, corresponding to the oxidation of 3-OHBAA by potassium peroxydisulphate, also catalysed by copper(II).

Kinetic determination of cyanide

Under the experimental conditions given above, the plot of the induction period against the square of the concentration of cyanide was essentially linear between 150 and 600 ng/ml cyanide. The sensitivity, expressed as the slope of the calibration function, was 62.8 min.ml².ng⁻². The detection limit (50 ng/ml) was evaluated as the concentration corresponding to three times the standard deviation of the induction period for 30 determinations of low analyte concentration¹⁵ (200 ng/ml cyanide). The reproducibility of the method was checked on 11 replicate determination of 350 ng/ml cyanide. The relative standard deviation obtained was 3.2%.

The effect of various anions generally accompanying cyanide was studied at a cyanide concentration of 300 ng/ml. The results obtained

Table 1 Catalytic effect of copper(II) on the oxidation of cyanide

Experiment	Induction period, sec
(a) Cu ²⁺ + 3-OHBAA + S ₂ O ₈ ²⁻	—
(b) 3-OHBAA + Cu ²⁺ + CN ⁻ + S ₂ O ₈ ²⁻	370
(c) Cu ²⁺ + CN ⁻ + S ₂ O ₈ ²⁻ + wait 7 min + 3-OHBAA	—
(d) CN ⁻ + S ₂ O ₈ ²⁻ + wait 7 min + 3-OHBAA + Cu ²⁺	340

Table 2 Influence of foreign anions on the kinetic determination of 0.3 µg/ml cyanide

Anion added	Tolerate ratio, w/w
F ⁻ , Cl ⁻ , Br ⁻ , BrO ₃ ⁻ , SO ₄ ²⁻ , CO ₃ ²⁻ , NO ₃ ⁻ , SCN ⁻ , ClO ₄ ⁻ , PO ₄ ³⁻ , B ₄ O ₇ ²⁻ , acetate, tartrate	100
SO ₃ ²⁻ , AsO ₄ ³⁻ , SeO ₃ ²⁻ , citrate	50
CrO ₄ ²⁻ , I ⁻ , ClO ₃ ⁻ , IO ₃ ⁻ , S ₂ O ₃ ²⁻	20
C ₂ O ₄ ²⁻	10
IO ₄ ⁻	5

are listed in Table 2, in which the tolerated ratio of each foreign anion is the largest amount yielding an error less than ±5% in the induction period. The maximum level tested was 30 µg/ml (tolerated anion to cyanide weight ratio = 100).

The results indicate a good tolerance to common anions such as fluoride, chloride, bromide, bromate, nitrate, sulphate, *etc.*, and especially to thiocyanate, which is a serious interferent in several methods for the determination of cyanide. The effect of common metal ions was also tested. The maximum tolerated ratio of metal ions to cyanide were calcium and magnesium, 100, iron and aluminium, 20; lead, 10; cadmium, 5. Manganese, zinc, silver, mercury, cobalt and nickel interfered when present in 1:1 weight ratio to cyanide, owing to their ability to form strong complexes with it; this behaviour can be exploited for their determination and resolution in mixtures with copper(II)¹⁶

Determination of cyanide in water samples

Cyanide, as a water pollutant, may enter the environment from many sources. Thus, as it is used extensively in many industrial processes, it may be present in wastes and wastewaters as well as in streams receiving uncontrolled and unpurified industrial effluents. Because cyanide is highly toxic even at low concentrations, monitoring of low cyanide levels is required within sewage treatment works in order to improve the quality of the effluent. In this context, and in order to validate the proposed kinetic method, it was applied to analysis for cyanide in water samples.

Water samples were spiked with 0.28–0.50 µg/ml cyanide and analysed directly by the procedure described. As can be seen from the results obtained (Table 3), the recoveries ranged from 97.7 to 100.7%, with an average of 99.5%

Table 3 Recovery of cyanide added to water samples

Sample	Cyanide content, $\mu\text{g/ml}$		Recovery, %
	Added	Found*	
Drinking water	0.300	0.302	100.7
	0.400	0.399	99.7
	0.500	0.491	98.2
River water	0.280	0.276	98.6
	0.350	0.342	97.7
	0.450	0.447	99.5
		Mean	99.1
	Standard deviation	1.2	

*For three separate determinations

for drinking water and 98.6% for river water. The relative standard deviation for the overall procedure was 1.2%. These recoveries show the good performance of the proposed kinetic method in the determination of cyanide in this type of sample.

(Received 16 July 1990 Revised 27 August 1990 Accepted 5 September 1990)

Summary—The kinetics of the dissolution of copper metal in an aqueous solution containing copper(II) and an unsaturated organic ligand was followed by using an automated flow-injection analysis technique to determine the concentration of copper(I) in solution as a function of time. The results suggest that the rate of dissolution of the copper metal is dependent on electron transfer between the copper(II) and copper atoms on the surface of the copper metal, and on the stabilization of copper(I) by the unsaturated organic ligand in solution.

Copper(I) has long been known to form stable π -complexes with olefinic ligands. This property has been exploited for the determination of copper(I) in the presence of copper(II),¹ for the removal of trace levels of impurities from copper metal,² for the purification of olefins^{3,4} and in an investigation of the kinetics of reduction of copper(II) by copper metal in the presence of allyl alcohol.⁵ In the kinetic study it was found that the rate of oxidation of copper metal was first order with respect to the copper(II) concentration, the pH of the solution and the allyl alcohol concentration. The reaction was followed by periodically withdrawing samples from the reaction vessel with a microsyringe and determining the concentrations of copper(I) and copper(II). This manual sampling was tedious and introduced errors caused by the difficulty in withdrawing samples at reproducible time intervals. An obvious solution to this problem is to automate the sampling procedure.

In the work described in this paper, flow-injection analysis (FIA), was used to automate the sampling process.⁶ FIA has high reproducibility and sample throughput, and is relatively easy to automate. The kinetics of the oxidation

of copper metal to copper(I) in the presence of a variety of unsaturated ligands was investigated by an FIA technique. In these reaction systems, the reaction rates were sufficiently rapid to enable us to obtain adequate kinetic data within minutes.

EXPERIMENTAL

Materials

Copper granules (20–30 mesh) were washed with dilute perchloric acid, rinsed with distilled demineralized water, rinsed with acetone, and dried prior to the experiment. The ethyl alcohol used to make up solutions was refluxed over solid potassium hydroxide and aluminum powder for 8 hr and distilled prior to use. The allyl alcohol and allyl cyanide (Aldrich), acrylamide, propionitrile and butyronitrile (Eastman Kodak), acrylonitrile and acetonitrile (Mallinckrodt), were of reagent grade purity and all were used without further purification.

Apparatus

The apparatus used is shown in Fig. 1. It consisted of a main pump (#1, Buchler Polystaltic), a sample recirculation pump (#2, Cole-Palmer Masterflex #7014), an air-actuated sample-injection valve system with a sample loop volume of $\sim 100 \mu\text{l}$ (Rheodyne 5020 Teflon Rotary Valve, 50-01 Pneumatic Actuator, and 7163 Solenoid), and a Gilford Model 240

*Present address California Public Health Foundation, Hazardous Materials Laboratory, 2151 Berkeley Way, Berkeley, CA 94704, U S A

Fig 1 Schematic representation of the flow-injection analysis system for the automated determination of complexed copper(I) in solution

spectrophotometer fitted with a flow-cell (NSG Precision Cells # 513). All tubing was 0.8 mm bore Teflon and the flow-rate in the FIA system was 5.5 ml/min. The temperature of the 300-ml reaction vessel was kept constant at 25°.

An LSI-11 personal computer programmed with Fortran IV was used to perform the data acquisition, open and close the injection valve, and analyse the data. A Data Translation DT2781 was used to perform the analog to digital conversion and to provide digital I/O to toggle the injection valve. The DT2781 provided 12-bit conversion, and was used in the bipolar mode. The range was ± 1 V.

Procedure

The reaction mixture (~35 ml) consisted of 3 ml of copper(II) perchlorate solution, the ligand, and 25 ml of 0.1M sodium perchlorate. The pH of the solution was adjusted with perchloric acid. Dissolved oxygen was removed from the solution by passage of nitrogen which had been freed from traces of oxygen by bubbling through an alkaline pyrogallol solution. The reaction was started by adding 15 g of the copper granules to the reaction mixture, which was recirculated through the sample injection valve, and injected into the carrier stream (50% v/v ethanol-water) at a rate of four injections per minute. The carrier stream was merged with a 0.1% solution of 2,9-dimethyl-

1,10-phenanthroline (dmp) in 50% v/v ethanol-water. The absorbance of the $\text{Cu}(\text{dmp})_2^+$ complex formed was measured at 450 nm.

The effect of various unsaturated ligands on the rate of oxidation of copper metal was determined in a system in which the initial copper(II) concentration, pH and surface area of the copper metal were kept constant and the concentration of the unsaturated ligand was varied. The rate of oxidation of copper metal, expressed as $-\text{d}[\text{Cu}^{2+}]/\text{d}t = \frac{1}{2}\text{d}[\text{Cu}^+]/\text{d}t$ was determined by the initial rate method.

RESULTS

The effect of the initial copper(II) concentration, pH, and allyl alcohol concentration on the rate of oxidation of copper metal was investigated. The effect of the initial copper(II) concentration is shown in Fig. 2. Each experimental point in Fig. 2 was obtained from the average of a large number of measurements of the initial rate. It was found that the reaction was first order with respect to the initial copper(II) concentration up to $2.5 \times 10^{-3}M$, at pH 2.25 and an allyl alcohol concentration of 0.41M.

The effect of pH on the reaction rate is shown in Table 1. The results show that the reaction rate increases by more than a factor of two, with increase in pH from 0.7 to 4.8.

Table 2 shows that the rate of reaction increases linearly with allyl alcohol concentration

Fig 2 Effect of copper(II) concentration on the reaction rate, at pH 2.25 and 0.41M allyl alcohol concentration

up to about $1.47 \times 10^{-2}M$, and then becomes constant.

The effect of various unsaturated ligands on the reaction rate was investigated and the results are shown in Table 2. As in the case of allyl alcohol, the reaction rates initially increased linearly with ligand concentration and subsequently leveled out.

DISCUSSION

The following sequence of reactions is proposed for the dissolution of copper metal in the presence of an unsaturated ligand, L. Copper(II) ions are adsorbed on the surface of the copper metal and the resultant species is represented as Cu^0-Cu^{II} . This species on the surface of the copper metal is in equilibrium with the species Cu^I-Cu^I , as a consequence of electron transfer. In the presence of the ligand in contact with the surface of the copper metal, the species Cu^IL_n is formed in the solution phase. The rate constants, k_1 , k_2 , k_3 , that are involved in this series of reactions are shown in the reaction scheme.

and are given by the following rate equations:

$$-\frac{d}{dt} [Cu^0-Cu^{II}] = k_1 [Cu^0-Cu^{II}] - k_2 [Cu^I-Cu^I] \quad (2)$$

$$\begin{aligned} \frac{d}{dt} [Cu^I-Cu^I] &= k_1 [Cu^0-Cu^{II}] \\ &- k_2 [Cu^I-Cu^I] \\ &- k_3 [Cu^I-Cu^I][L]^n \quad (3) \end{aligned}$$

Table 1 Effect of initial pH on the rate of reaction at an initial copper(II) concentration of $2 \times 10^{-3}M$ and allyl alcohol concentration of 0.41M

pH	Rate $\times 10^4$, mole. l ⁻¹ min ⁻¹
0.70	2.4
1.01	2.6
1.40	3.0
2.01	3.7
3.01	3.7
3.60	4.0
4.10	4.5
4.75	5.6

$$\frac{d}{dt} [Cu^IL_n] = k_3 [Cu^I-Cu^I][L]^n \quad (4)$$

Since the reaction rates were found to be first order with respect to the ligand L, the value of n in equations (3) and (4) is unity. Under steady-state conditions, when $[Cu^I-Cu^I]$ is constant,

$$\frac{d}{dt} [Cu^I-Cu^I] = 0, \quad (5)$$

$$[Cu^I-Cu^I] = \frac{k_1 [Cu^0-Cu^{II}]}{k_2 + k_3 [L]} \quad (6)$$

Table 2 Effect of the initial concentration of unsaturated ligand on the reaction rate at pH 3.01 and $[Cu(II)] = 1.05 \text{ mM}$

Ligand	Concentration, mM	Rate $\times 10^4$, mole l ⁻¹ min ⁻¹
Allyl alcohol	2.94	1.1
	5.88	1.6
	14.7	2.3
	29.2	2.3
	118	2.2
Acrylamide	1.00	0.34
	4.00	1.2
	10.0	2.1
	20.0	2.9
	60.0	2.8
	120	3.0
	Acrylonitrile	3.04
6.08		0.38
15.2		0.60
30.4		1.3
60.8		1.5
122		21.6
Acetonitrile	3.77	0.24
	19.0	0.33
	38.0	0.59
	75.9	1.8
	152	2.2
	228	2.8
	304	2.7
Allyl cyanide	4.97	0.88
	12.4	1.2
	24.9	1.6
	49.7	1.6
	99.4	1.8

Table 3. Calculated ratios of the rate constants, k_3/k_2 , [equation (10)] from the experimental values of S and C [equations (8) and (9)]

Unsaturated ligand	$S \times 10^2$	$C \times 10^4$	$r \times 10^{-2} = \frac{k_3}{k_2} \times 10^{-2}$
Allyl alcohol	0.40	2.0	2.0
Acrylamide	3.6	3.0	1.2
Allyl cyanide	0.54	2.0	0.27
Acrylonitrile	0.49	1.6	0.31
Acetonitrile	0.15	2.8	0.54
Propionitrile	0.16	2.5	0.62
Butyronitrile	0.18	0.9	0.20

Hence, the rate of the reaction is given by

$$\frac{d}{dt} [\text{Cu}^{\text{I}}\text{L}] = \frac{k_1 k_3 [\text{L}] [\text{Cu}^0 - \text{Cu}^{\text{II}}]}{k_2 + k_3 [\text{L}]} \quad (7)$$

When $k_3[\text{L}] \ll k_2$, the initial slope, S , of a plot of the rate of the reaction *vs.* $[\text{L}]$ is given by

$$S = \frac{k_1 k_3}{k_2} [\text{Cu}^0 - \text{Cu}^{\text{II}}] \quad (8)$$

When $k_2 \ll k_3[\text{L}]$ in equation (7), a plot of the rate of the reaction *vs.* $[\text{L}]$ is a constant, C , given by

$$C = k_1 [\text{Cu}^0 - \text{Cu}^{\text{II}}] \quad (9)$$

The ratio of the rate constants k_3 and k_2 can be calculated from the ratio, r , of the experimental values of S and C :

$$r = \frac{S}{C} = k_3/k_2 \quad (10)$$

The larger the numerical value of r , the greater the tendency for the forward reaction, *i.e.*, dissolution of copper metal, to occur [equation (1)]. Since the total surface area of the copper metal and the concentration of the copper(II) remain constant during the course of an experiment, it may be deduced from equation (9) that the higher the value of C , the greater the value of the rate constant, k_1 . The values of S , C , and r for the various unsaturated ligands investigated are shown in Table 3. The variation in the value of r in the series of ligands reflects the stability of the species $\text{Cu}^{\text{I}}\text{L}$.

HYDROLYSIS OF GADOLINIUM(III) IN LIGHT AND HEAVY WATER

L. GARCIA RODENAS and S J. LIBERMAN

Comisión Nacional de Energía Atómica, Avda del Libertador 8250, Buenos Aires 1429, Argentina

(Received 17 May 1989 Revised 18 July 1990. Accepted 3 September 1990)

Summary—The hydrolysis constants of Gd^{3+} and the solubility products of $Gd(OH)_3$ and $Gd(OD)_3$ in nitrate solutions at 25 and 70° in H_2O and D_2O have been determined because of their importance in nuclear technology. The constants are defined (charges omitted for clarity) as $*K_{11} = a_{GdOH} a_H / a_{Gd}$, $*K_{21} = a_{Gd(OH)_2} a_H^2 / a_{Gd}$, $*K_{30} = a_{Gd} / a_H^3$. The values for the H_2O system were $p*K_{11} = 7.87 \pm 0.02$, $p*K_{21} = 15.16 \pm 0.09$, $p*K_{30} = -19.32 \pm 0.03$ at 25° and $p*K_{11} = 7.55 \pm 0.03$, $p*K_{21} = 13.04 \pm 0.03$, $p*K_{30} = -16.16 \pm 0.04$ at 70°. For the D_2O system they were $p*K_{11}^D = 8.17 \pm 0.01$, $p*K_{21}^D = 16.00 \pm 0.09$, $p*K_{30}^D = -21.18 \pm 0.04$ at 25° and $p*K_{11}^D = 7.84 \pm 0.02$, $p*K_{21}^D = 13.95 \pm 0.02$, $p*K_{30}^D = -17.34 \pm 0.04$ at 70°. The mean enthalpy changes of the reactions were also calculated.

Our interest in the stability of Gd^{3+} species in light and heavy water is due to the use of gadolinium as a neutron-absorber in the control of reactivity in CANDU nuclear reactors. Gadolinium nitrate solution is added to the moderator heavy water circuit, where the temperature is about 70°. The use of this additive requires the heavy water to be kept slightly acidic to avoid hydrolysis, and precipitation of gadolinium deuterioxide.

Calculation of the solubility limit of $Gd(NO_3)_3$ as a function of pD in CANDU nuclear reactors requires not only knowledge of the solubility product of the gadolinium deuterioxide but also of the first and second hydrolysis constants of Gd^{3+} in heavy water at the temperatures of interest in the reactor (25–70°). At present there seems to be no reliable information in the literature. It is also of interest to compare the behaviour in heavy and light water in order to enlarge knowledge of the properties of electrolyte solutions in both media.

Hydrolysis constants of Gd^{3+} in H_2O at 25° have been reported in the literature. The $*\beta_{qp}$ values ($*\beta_{qp} = [Gd_p(OH)_q]^{(3p-q)+} [H^+]^q / [Gd^{3+}]^p$) were determined at different ionic strengths, so to make a comparison between them, we calculated the $*K_{qp}$ values ($*K_{qp} = a_{Gd_p(OH)_q}^+ a_H^q / a_{Gd^{3+}}^p$) listed in Table 1 from the literature data by means of the Pitzer equation.¹

The spread in the $*pK_{11}$ values is considerable, some methods being more reliable than others;⁶ however, the values in the range 7.8–8.0 fit closely with the trends of the hydrolysis

constants for the other lanthanide ions.¹¹ The solubility product in H_2O at 25° has also been determined by several authors under different conditions, for different aging times, and the $p*\beta_{30}$ values ($*\beta_{30} = [Gd^{3+}] / [H^+]^3$) range from -21.7 to -15.1.^{2,6,11-17} In some instances, over-simplifications were made in which hydrolysis was not considered.¹²⁻¹⁵ In Table 1 we list only the $p*\beta_{30}$ values obtained by the best defined experimental and calculation procedures.^{2,6} We also include the $*K_{30}$ value ($*K_{30} = a_{Gd^{3+}} / a_H^3$) from an empirical relation¹¹ derived for aged lanthanide hydroxides.

For polynuclear complex formation, Ngo and Burkov found results compatible with $Gd_2(OH)_4^{2+}$ ($p*\beta_{22} = 14.23$),² and Kragten and Decnop-Weever postulated the existence of the species $Gd_3(OH)_4^{3+}$ ($p*\beta_{43} = 19.0$).⁶ These poly-complexes have not been characterized by other means.

The studies of gadolinium in heavy water solutions are limited; Amaya *et al.*⁹ reported $p*K_{11}^D = 6.82$ at 25°, and Baumann,¹³ disregarding hydrolysis, reported $p*\beta_{30}^D$ to be -19.96 for a precipitate aged for 7 days.

In the present study the hydrolysis constants of Gd^{3+} and the solubility product of $Gd(OH)_3(s)$ or $Gd(OD)_3(s)$ in light or heavy water at 25 and 70° were determined by potentiometric measurements, under experimental conditions reasonably close to those existing in the moderator system in the CANDU nuclear reactor. The thermodynamic parameters of the Gd^{3+} species in both media were also examined.

EXPERIMENTAL

All reagents were analytical grade and the solutions were prepared with triply distilled light or heavy water (99.8% pure). Gadolinium nitrate [$\text{Gd}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$, 99.9% pure], from Nucor Research Chemicals, was used without further purification. Solutions were saturated with nitrogen to eliminate carbon dioxide.

Potentiometric titrations were performed at $25.00 \pm 0.02^\circ$ and $70.00 \pm 0.02^\circ$ with a Metrohm 654 pH-meter provided with a glass combined electrode standardized with standard buffer solutions at pH values (conventional activity scale) of 4.00 ± 0.02 and 7.00 ± 0.02 at 25° and 4.11 ± 0.02 and 6.98 ± 0.02 at 70° . For heavy water solutions, the electrode was standardized with phosphate and carbonate buffers prepared in heavy water. The pD values given by Bates¹⁸ for these solutions are 7.43 ± 0.02 and 10.74 ± 0.02 at 25° and 7.39 ± 0.02 and 10.44 ± 0.02 at 70° .

The titrations were performed with standardized sodium hydroxide solution, and gadolinium nitrate concentrations of $1.00 \times 10^{-2} \text{ M}$ for H_2O at 25 and 70° and 1.00×10^{-2} and $8.00 \times 10^{-3} \text{ M}$ for D_2O at 25 and 70° , respectively, for determination of the hydrolysis constants. For the solubility product measurements the concentrations were 0.920×10^{-3} and $0.732 \times 10^{-3} \text{ M}$ in H_2O and 0.857×10^{-3} and $0.953 \times 10^{-3} \text{ M}$ in D_2O at 25 and 70° respectively. The pH or pD of the solutions reached a constant value within about 5 min after addition of base. No supporting electrolyte was added, so that the conditions would be close to those in the CANDU moderator system.

Evaluation of the thermodynamic constants

For evaluation of the hydrolysis constants $*K_{11}$ and $*K_{21}$ and the solubility product $*K_{s0}$ in aqueous or deuteroaqueous solutions of Gd^{3+} , equations (1)–(3) were considered (charges are omitted in the subscripts, for the sake of clarity):

together with the mass-balance relationships (4) and (5):

$$c = [\text{Gd}^{3+}] + [\text{GdOH}^{2+}] + [\text{Gd}(\text{OH})_2^+] + [\text{Gd}(\text{OH})_3] + n_s / (V_0 + V) \quad (4)$$

$$c_b = (V c_{\text{OH}}) / (V_0 + V) = [\text{GdOH}^{2+}] + 2[\text{Gd}(\text{OH})_2^+] + 3[\text{Gd}(\text{OH})_3] + 3n_s / (V_0 + V) + [\text{OH}^-] \quad (5)$$

where a_i is the activity of species i , $a_{\text{Gd}(\text{OH})_3(\text{s})} = 1$, c , c_{OH} and c_b are the molar concentrations of gadolinium nitrate, sodium hydroxide and base in the solution, n_s is the number of moles of $\text{Gd}(\text{OH})_3$ precipitated and V_0 and V are the volumes (in litres) of the $\text{Gd}(\text{NO}_3)_3$ solution and added base respectively. The slight influence of $\text{Gd}^{3+} - \text{NO}_3^-$ ion-association is discussed below; volume changes due to reaction are negligible at the concentrations used. From these equations, as shown in the Appendix, equations (6) and (7) were derived, in which the constants $*K_{11}$, $*K_{21}$ and $*K_{s0}$ can be evaluated from the experimental results:

$$y = *K_{11}x + *K_{21} \quad (6)$$

where

$$n_s = 0, [\text{Gd}(\text{OH})_3] = 0, c \gg c_b, [\text{OH}^-] \ll c_b,$$

$$y = (c_b / 2c) a_{\text{H}}^2 \gamma_{\text{Gd}(\text{OH})_2} / \gamma_{\text{Gd}}$$

$$x = a_{\text{H}} \gamma_{\text{Gd}(\text{OH})_2} / 2 \gamma_{\text{GdOH}}$$

$$y_s = *K_{s0} x_s \quad (7)$$

where

$$y_s = 3c - c_b, c_b / c < 3$$

$$x_s = 3a_{\text{H}}^3 / \gamma_{\text{Gd}} + 2*K_{11} a_{\text{H}}^2 / \gamma_{\text{GdOH}} + *K_{21} a_{\text{H}} / \gamma_{\text{Gd}(\text{OH})_2}$$

The activity coefficients of species i were calculated at the given ionic strengths by both the Davies equation (8)¹⁹ and equation (9) derived by the mean spherical approximation (MSA) for aqueous electrolyte mixtures:²⁰

$$\log \gamma_i = Az_i^2 \{ [\sqrt{I} / (1 + \sqrt{I})] - 0.30I \} \quad (8)$$

$$\ln \gamma_i = \ln \gamma_i^{\text{elec}} + \ln \gamma_i^{\text{hs}} \quad (9)$$

In (8), z is the charge of species i , I is the ionic strength and A is the Debye–Hückel constant. The A values for H_2O and D_2O are 0.5115 and 0.5155 at 25° and 0.5625 and 0.5691 at 70° . In (9), the first and second terms are the electrostatic and the hard-sphere contributions respectively.

The complete sets of explicit equations to calculate these terms are given by Corti.²⁰ The only parameters involved in this calculation are charge, concentration of ionic species and radii of hydrated ions. For the latter we have chosen the following values: Gd^{3+} 0.335, $GdOH^{2+}$ 0.30, $Gd(OH)_2^+$ 0.30, OH^- 0.18, NO_3^- 0.175, Na^+ 0.158 nm.

Equation (6) is valid in a pH or pD range low enough to avoid the presence of $Gd(OH)_3$ and $Gd(OH)_3(s)$ or their deuterated analogues, and equation (7) must be applied at higher pH or pD values when solid is present. This method provides an independent determination of $*K_{11}$ and $*K_{21}$ from $*K_{30}$.

RESULTS AND DISCUSSION

Hydrolysis constants

Figure 1 shows the pH and pD measurements in light and heavy water solutions of $Gd(NO_3)_3$, as a function of the fraction of added base, c_b/c , at 25 and 70°. The ionic strength, 0.048M in D₂O solutions at 70° and 0.06M in all the others, was constant within 0.6%. The activity coefficients calculated by the Davies equation and the MSA approximation agree within 0.05%.

Least-squares calculations of the slope and intercept of the linear equation (6) with these experimental results gave the values for $*K_{11}$ and $*K_{21}$ listed in Table 2 (with their standard deviations). The theoretical curves calculated with these values give a good fit to the experimental data, as shown in Fig. 1.

The presence of polynuclear species is not consistent with our results: the species $Gd_2(OH)_2^{4+}$ ($p^*\beta_{22} = 14.23$ at $I = 3M$) postulated by Ngo and Burkov² would be formed at higher Gd^{3+} concentration, and $Gd_3(OH)_4^{5+}$ ($p^*\beta_{43} = 19.00$ at $I = 1M$) postulated by Kragten and Decnop-Weever⁶ does not fit with our data.

From Tables 1 and 2, comparison of our p^*K_{11} values with published data indicates good agreement with the results of Ngo and Burkov,² Usherenko and Skorik,³ Frolova *et al.*⁴ and the empirical correlation of Kumok and Serebrennikov,⁵ but not with those of Kragten and Decnop-Weever,⁶ Guillaumont *et al.*,⁷ Amaya

Table 2 Hydrolysis constants and solubility product for Gd^{3+} in light and heavy water

25	7.87 ± 0.02	15.16 ± 0.09	-19.32 ± 0.03	8.17 ± 0.01	16.00 ± 0.09	-21.18 ± 0.04
70	7.55 ± 0.03	13.04 ± 0.03	-16.16 ± 0.04	7.84 ± 0.02	13.95 ± 0.02	-17.34 ± 0.04

et al.,^{8,9} and Moeller.¹⁰ The results obtained by the last three sets of authors are subject to rather large uncertainties: Guillaumont *et al.* used a not too reliable solvent extraction method, Amaya *et al.* reported hydrolysis constants for several lanthanide ions besides Gd^{3+} , all lower than those found in the literature,¹¹ and Moeller gave $*K_{11}$ values which depended on the concentration. The procedure used by Kragten and Decnop-Weever is accurate and gives results coincident with those of the Kumok and Serebrennikov method, as well as with reliable literature data for other lanthanides,^{21,22} but not for Gd^{3+} . We cannot elucidate the discrepancy.

With respect to $*K_{21}$, again our result is lower than that of Kragten and Decnop-Weever,⁶ but not too far away from the prediction made by Baes and Mesmer¹¹ that $p*K_{21}$ is approximately twice the $p*K_{11}$ values, as for most other lanthanides.

With regard to the results for the D_2O system, the values of $*K_{11}^D$ and $*K_{12}^D$ are slightly lower than $*K_{11}$ and $*K_{12}$. This effect is consistent with that found in the literature for other cations.²³ Again, the $p*K_{11}^D$ value reported by Amaya *et al.*⁹ is higher than ours.

The hydrolysis constants increased with temperature for both solvents, as expected.

The constants in Table 2 were calculated by assuming that $[GdNO_3^{2+}]$ was negligible compared with $[Gd^{3+}]$ at $[Gd(NO_3)_3] = 0.01M$; this is true only to a certain extent. The $Gd^{3+}-NO_3^-$ ion-association constants β_1 ($\beta_1 = [GdNO_3^{2+}]/[Gd^{3+}][NO_3^-]$) given in the literature refer to higher concentrations than those in the present study: 2.33 for the $Gd(NO_3)_3$ concentration range 0.23–2.17M,²⁴ and between 6.40 and 2.38 for 0.05–0.35M $Gd(NO_3)_3$.²⁵ These values give an estimate of the extent of the association but are not precise enough to be used in our calculations. Equation (I) in the Appendix shows the corrections to be made to $*K_{11}$ and $*K_{21}$ to allow for the association. If we assume $\beta_1 = 2$, the constants will increase by 6% and $p*K_{11} = 7.84$ and $p*K_{21} = 15.13$ will be obtained. The corresponding corrections for the D_2O system should be similar to these.

Solubility product

Figure 2 shows the pH and pD measurements in light and heavy water solutions of $Gd(NO_3)_3$ at 25 and 70° as a function of c_b/c until hydroxide precipitation occurs.

Least-squares fitting of these results to equation (7) gives the $*K_{30}$ values listed in Table 2.

Because the ionic strength did not remain constant during the titrations, the true activity coefficients of the species were calculated by an iterative procedure until two successive $*K_{30}$ values were the same. The activity coefficients calculated by the Davies equation¹⁹ and the MSA approximation²⁰ agreed within 0.05%. The theoretical curves in Fig. 2, calculated with the $*K_{11}$, $*K_{12}$ and $*K_{30}$ values from Table 2, gave a good fit to the experimental data.

The solubility product of $Gd(OH)_3$ is higher than that of $Gd(OD)_3$, in agreement with Baumann's results for the aged hydroxides.¹³ The solubility products also increase with temperature, which seems to be in contradiction with the results of Meloche and Vrátný¹² over the range 10–40°. However, these authors did not take into account the change in the ionic product of water with temperature. Making the proper corrections to their results, we found not only an increase in the solubility product with temperature for $Gd(OH)_3$, but also the hydroxides of Pr, Nd, Sm and Y.

The $p*K_{30}$ value from our experiments is smaller than any of those listed in Table 1; the difference is even larger at $I = 0$. This discrepancy perhaps should be attributed to the longer aging times used in the earlier work. On the other hand, from the standard free energy of reaction (3), 110.3 kJ/mole, calculated from the $*K_{30}$ value in Table 2 by using the relationship $\Delta G_3^0 = -RT \ln *K_{31}$, and the standard free energies of formation –688 kJ/mole for $Gd^{3+}(aq)$ and –237 kJ/mole for H_2O ,²⁶ the value –1289 kJ/mole is derived for the standard free energy of formation of $Gd(OH)_3(s)$, in close agreement

Fig. 2. Potentiometric titrations of $Gd(NO_3)_3$ solutions for solubility product evaluations. \circ , $0.920 \times 10^{-3}M$; \square , $0.857 \times 10^{-3}M$; \bullet , $0.732 \times 10^{-3}M$; \blacksquare , $0.953 \times 10^{-3}M$. The lines are calculated from the least-squares fit to the experimental data [equation (7)]

Table 3 Mean standard enthalpy change of reactions (1)–(3) (kJ/mole)

	ΔH_{11}^0	ΔH_{21}^0	ΔH_{31}^0
H ₂ O	14 ± 2	92 ± 5	138 ± 3
D ₂ O	14 ± 1	89 ± 5	167 ± 4

with the value -1288 kJ/mole reported in the literature.²⁶

The influence of $\text{Gd}^{3+}-\text{NO}_3^-$ ion-association on the $*K_{s0}$ values in Table 2 could be estimated by use of equation(II) in the Appendix. If we consider $\beta_1 = 2$, $*K_{s0}$ will decrease by 5% and a value of $p*K_{s0} = -19.30$ will be obtained. It is clear that the main source of error in the values of the constants given in Table 2 is the lack of information regarding $\text{Gd}^{3+}-\text{NO}_3^-$ association.

From the data in Table 2, thermodynamic functions for the equilibria involved can be derived. Table 3 shows the mean standard enthalpy change $\Delta H_{qp}^0 = RT^2 \ln *K_{qp}/dT$ for reactions (1)–(3) in the temperature range 25–70° in H₂O and D₂O. The values are positive and, within experimental error, identical for both solvents with the exception of ΔH_{31}^0 , which is more endothermic for D₂O medium.

In Fig. 3, the distribution of Gd^{3+} species is plotted as a function of pD at 70° for $10^{-4}M$ Gd^{3+} , the maximum concentration of this "poison" used in the moderator circuit to shut down the reactor. The species distribution at 25°, corresponding to the period during which the reactor is not under operation, is also included. The concentrations in this diagram were calculated by taking into account the changes in the activity coefficients with pD, by application of the iterative procedure used for the $*K_{s0}$ calculation. The vertical lines correspond to the pD for initial precipitation at each temperature

This stability diagram indicates that pD in the CANDU moderator circuit should be kept

Fig 3 Speciation in $10^{-4}M$ $\text{Gd}(\text{NO}_3)_3$ solution in heavy water, — 25°, ---- 70°

below 7.36 (for safety reasons the pD is much lower) to avoid precipitation of the hydroxide after the liquid shut-down system has operated. When the moderator cools down to room temperature the pD should be below the precipitation value (9.20).

Acknowledgements—We are indebted to Dr H. Corti for his assistance in the application of the MSA method

APPENDIX

Equation (6) is derived as follows. Equations (4) and (5) are expressed in terms of $[\text{Gd}^{3+}]$ and equated

$$c_b[1 + *K_{11}\gamma_{\text{Gd}}/a_{\text{H}}\gamma_{\text{GdOH}} + *K_{21}\gamma_{\text{Gd}}/a_{\text{H}}^2\gamma_{\text{Gd(OH)}_2}] = c[*K_{11}\gamma_{\text{Gd}}/(a_{\text{H}}\gamma_{\text{GdOH}}) + 2*K_{21}\gamma_{\text{Gd}}/a_{\text{H}}^2\gamma_{\text{Gd(OH)}_2}]$$

Rearrangement gives

$$c_b/c = (1 - c_b/c) * K_{11} \gamma_{Gd} / a_H \gamma_{GdOH} \\ + (2 - c_b/c) * K_{21} \gamma_{Gd} / a_H^2 \gamma_{Gd(OH)_2}$$

If c_b is negligible compared with c , then

$$c_b/c = *K_{11} \gamma_{Gd} / a_H \gamma_{GdOH} + 2 *K_{21} \gamma_{Gd} / a_H^2 \gamma_{Gd(OH)_2}$$

and multiplying by $a_H^2 \gamma_{Gd(OH)_2} / \gamma_{Gd}$ gives

$$(c_b/2c) a_H^2 \gamma_{Gd(OH)_2} / \gamma_{Gd} = *K_{11} a_H \gamma_{Gd(OH)_2} / 2 \gamma_{GdOH} + *K_{21}$$

which is identical to equation (6)

Equation (7) is derived as follows $[Gd(OH)_3]$ and $n_s / (V_0 + V)$ are eliminated by means of equations (4) and (5), to give

$$3c - c_b - [OH^-] = 3[Gd^{3+}] + 2[GdOH^{2+}] + [Gd(OH)_2^+]$$

Then $[OH^-]$ is treated as negligible compared with c_b , and $[Gd^{3+}]$, $[GdOH^{2+}]$ and $[Gd(OH)_2^+]$ are replaced by functions

of $*K_{11}$, $*K_{21}$ and $*K_{30}$, giving

$$3c - c_b = *K_{30} [3a_H^3 / \gamma_{Gd} + 2 *K_{11} a_H^2 / \gamma_{GdOH} + *K_{21} a_H / \gamma_{Gd(OH)_2}]$$

which is the same as equation (7).

The $Gd^{3+} - NO_3^-$ ion-association reaction

could be taken into account by including $[GdNO_3^{2+}]$ in the mass balance equation (4). Then, instead of equations (6) and (7), the following equations can be derived by a procedure similar to that above

$$(c_b/2c) a_H^2 \gamma_{Gd(OH)_2} / \gamma_{Gd} \\ = *K_{11} / (1 + \beta_1 [NO_3^-]) a_H \gamma_{Gd(OH)_2} / 2 \gamma_{GdOH} \\ + *K_{21} / (1 + \beta_1 [NO_3^-]) \quad (I)$$

and

$$3c - c_b = *K_{30} (3a_H^3 / \gamma_{Gd} + 2 *K_{11} a_H^2 / \gamma_{GdOH} \\ + *K_{21} a_H / \gamma_{Gd(OH)_2} + \beta_1 [NO_3^-] 3a_H^3 / \gamma_{Gd}) \quad (II)$$

ION FLOTATION OF RHODIUM(III) AND PALLADIUM(II) WITH ANIONIC SURFACTANTS

HE XING-CUN

Department of Chemistry, Guangxi Normal University, Guilin, Guangxi, People's Republic of China

(Received 19 March 1990 Revised 18 August 1990 Accepted 28 August 1990)

Summary—The ion flotation of rhodium(III) and palladium(II) with some anionic surfactants has been investigated. Two flotation procedures are proposed for the separation of some platinum metals, based on differences in the kinetic properties of the chloro-complexes of rhodium(III), palladium(II) and platinum(IV). The first involves the selective flotation of $\text{Rh}(\text{H}_2\text{O})_6^{3+}$ from PdCl_4^{2-} and PtCl_6^{2-} in dilute hydrochloric acid with sodium dodecylbenzenesulfonate (SDBS). After precipitation of the hydroxide and redissolution in dilute acid, the Rh(III) is converted into $\text{Rh}(\text{H}_2\text{O})_6^{3+}$, Pd(II) and Pt(IV) remaining as PdCl_4^{2-} and PtCl_6^{2-} respectively, and separation is achieved by floating the $\text{Rh}(\text{H}_2\text{O})_6^{3+}$ with SDBS. The second is for separation of Pd(II). Prior to flotation, the solution of PdCl_4^{2-} and PtCl_6^{2-} is heated with ammonium acetate to convert PdCl_4^{2-} into $\text{Pd}(\text{NH}_3)_4^{2+}$. The chloro-complex of Pt(IV) is unaffected. The complex cation, $\text{Pd}(\text{NH}_3)_4^{2+}$, is then selectively floated with SDBS. The procedures are fast, simple and do not require expensive reagents and apparatus.

In recent years, there has been considerable interest in ion flotation, leading to the development of a number of methods for separation of numerous cationic and anionic complexes.¹⁻¹¹ The ion flotation properties and separation of the anionic chloro-complexes of some platinum metals have been studied systematically,¹²⁻¹⁷ but no flotation studies of the cationic complexes of platinum metals have been noted in the literature.

The platinum metals have similar chemical properties. In many cases several of these metals are present in the sample, and interferences may occur in determinations. It is important to separate the platinum metals from each other in their determination and purification. The differences in kinetic properties of the platinum group metals in the formation of cationic, anionic and neutral species have been widely used for their separation. Though many studies have indicated considerable success in separation of some platinum metals by ion-exchange and solvent extraction methods, the advantage of the differences in their labile character could be further utilized. In this paper, we describe use of the charge selectivity of surfactants to achieve separation by adjustment of the initial solution conditions so that the complex ions of interest are opposite in charge sign. Our results show that the rapid formation of $\text{Rh}(\text{H}_2\text{O})_6^{3+}$ can be used in the flotation procedure. The aquo-cation of Rh(III) can be obtained by precipitation of

the hydroxide and its redissolution in dilute acid, and can then be floated with sodium dodecylbenzenesulfonate (SDBS) from Pd(II) and Pt(IV) which remain as PdCl_4^{2-} and PtCl_6^{2-} respectively. Our results also indicate that the rate of formation of the cationic ammine-complex of Pd(II) from its chloro-complex is sufficiently different from that of the Pt(IV) complex to permit isolation of the Pd(II) complex by flotation. The complete conversion of PdCl_4^{2-} into $\text{Pd}(\text{NH}_3)_4^{2+}$ can be achieved by heating the solution with ammonium acetate. Pt(IV) does not form an ammine-complex under these conditions. The $\text{Pd}(\text{NH}_3)_4^{2+}$ can then be floated from PtCl_6^{2-} with SDBS. In this paper, the influence of several factors on the flotation is reported, and the optimum ion flotation conditions are presented.

EXPERIMENTAL

Apparatus

The flotation cell is made by joining a G4(3-4 μm nominal pore size) sintered-glass funnel to a glass tube. A hole is drilled in the funnel 1 cm above the sintered glass disc and fitted with a rubber stopper for sample removal. Nitrogen saturated with water is passed through the sintered-glass disc. The flow-rate is controlled by a regulator valve.

A Shimadzu model UV-240 spectrophotometer was used to obtain the spectra of the

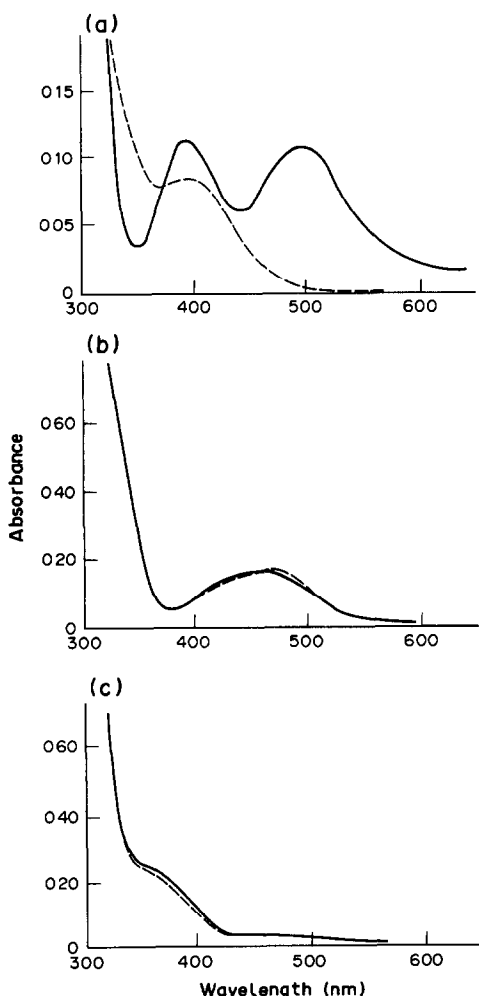

Fig 1 The spectra of Rh(III), Pd(II) and Pt(IV) (a) Rh(III) (b) Pd(II) (c) Pt(IV) The dotted lines mean the spectra after pretreatment

complex ions of Rh(III), Pd(II) and Pt(IV). A model 72 spectrophotometer (Shanghai Analytical Instrument Factory) and a Hitachi model 180/80 atomic-absorption spectrometer were used for determination of the metals.

Reagents

Tetrachloropalladate(II) and hexachloroplatinate(IV) stock solutions were prepared by dissolving high-purity palladium and platinum in *aqua regia*, repeatedly evaporating the solutions to dryness with hydrochloric acid, and making up to known volume in 2M hydrochloric acid. Hexachlororhodate(III) stock solution was prepared by dissolving $\text{Rh}_2\text{O}_3 \cdot 5\text{H}_2\text{O}$ (99.9% pure) in concentrated hydrochloric acid, refluxing the solution for 2 hr to ensure that all the rhodium was present as RhCl_6^{3-} , and making up the final solution in 2M hydrochloric acid. The anionic surfactants sodium dodecyl-

benzenesulfonate (SDBS), sodium dodecyl-sulfonate (SDS) and sodium lauryl sulfate (SLS) were prepared and $5 \times 10^{-3}M$ stock solutions in water were made. All other chemicals used were analytical reagent grade.

Procedures

Sample pretreatment. To convert RhCl_6^{3-} into $\text{Rh}(\text{H}_2\text{O})_6^{3+}$, the sample solution was treated in the following manner. Sodium hydroxide solution was added to the sample solution until Rh(III) hydroxide was completely precipitated. After standing for 2 hr at pH 2, the precipitate was dissolved in 0.5M hydrochloric acid to yield $\text{Rh}(\text{H}_2\text{O})_6^{3+}$. When treated in the same way, Pd(II) and Pt(IV) were reconverted into PdCl_4^{2-} and PtCl_6^{2-} respectively. For the complete conversion of PdCl_4^{2-} into $\text{Pd}(\text{NH}_3)_4^{2+}$ the solution of PdCl_4^{2-} was heated with ammonium acetate until the brownish-red color of PdCl_4^{2-} disappeared; the chloro-complex of Pt(IV) was unaffected.

Flotation experiments. Solutions were prepared for flotation by pipetting sufficient of the pretreated sample solutions into 50-ml standard flasks to give a final metal concentration of $1 \times 10^{-4}M$, followed by addition of 4 ml of surfactant solution and 0.3 ml of absolute ethanol and dilution to volume. The solutions were then mixed for 10 min. Each was then transferred to the flotation cell, and nitrogen saturated with water was passed through it at a controlled flow-rate of 30 ml/min for 25 min.

Measurement techniques. After the maximum flotation was achieved, the foam was collected with a sampling tube described by Mizuike and Hiraide,² and collapsed by addition of a small amount of ethanol. The floated metals were recovered from the sublates by wet ashing with nitric acid, followed by repeated heating to dryness with a few drops of concentrated hydrochloric acid. Finally, the residues were taken up in dilute hydrochloric acid and the amounts recovered were measured by atomic-absorption spectrometry. The progress of the flotation was monitored by measurements on samples removed from the cell at appropriate intervals. Spectrophotometric measurements were also used to supplement the tracer studies. Both palladium and platinum were determined with 2-(5-bromo-2-pyridylazo)-5-diethylamino-phenol in the presence of poly(ethyleneglycol)-octylphenyl ether.¹⁸

Fig 2 The spectra of (a) Pd(II) and (b) Pt(IV) The dotted lines mean the spectra after pretreatment

RESULTS AND DISCUSSION

Oxidation states of Rh, Pd and Pt after pretreatment

The solutions of Rh, Pd and Pt, after pretreatment as described above, were examined spectrophotometrically and the absorption spectra are given in Fig.1. For comparison, the absorption spectra of RhCl_6^{3-} , PdCl_4^{2-} and PtCl_6^{2-} are also shown. It was observed that after pretreatment the spectra of the Pd(II) and Pt(IV) species were the same as those of PdCl_4^{2-} and PtCl_6^{2-} . This indicated that the Pd(II) and Pt(IV) remained as PdCl_4^{2-} and PtCl_6^{2-} respectively. The case of Rh(III) was different. After the hydrolysis and acidification, the pink color of the solution of Rh(III) changed to a yellowish color. Figure 1(a) shows the change in the spectra. The absorption peak at 396 nm confirmed the presence of $\text{Rh}(\text{H}_2\text{O})_6^{3+}$ (${}^1\text{A}_{1g} - {}^1\text{T}_{1g}$).¹⁹

When the solution of Pd(II) was heated with ammonium acetate, the brownish-red color of PdCl_4^{2-} disappeared, and a colorless ammine-complex of Pd(II) was formed. This colorless ammine-complex of Pd(II) was regarded as $\text{Pd}(\text{NH}_3)_4^{2+}$.^{20,21} The differences in the spectra of PdCl_4^{2-} and $\text{Pd}(\text{NH}_3)_4^{2+}$ are shown in Fig. 2(a). However, the chloro-complex of Pt(IV) was not affected by the presence of ammonium acetate. The color and spectrum [shown in Fig. 2(b)] of the solution of Pt(IV) did not change.

Reactions of $\text{Rh}(\text{H}_2\text{O})_6^{3+}$ and $\text{Pd}(\text{NH}_3)_4^{2+}$ with surfactants

It was found that white precipitates were formed in the bulk solutions when $\text{Rh}(\text{H}_2\text{O})_6^{3+}$ and $\text{Pd}(\text{NH}_3)_4^{2+}$ were mixed with SDBS, SDS or SLS. However, $\text{Rh}(\text{H}_2\text{O})_6^{3+}$ and $\text{Pd}(\text{NH}_3)_4^{2+}$ do not form precipitates with cationic surfactants such as tetradecyldimethylbenzylammonium

chloride, cetylpyridinium chloride and cetyltrimethylammonium bromide. No rhodium or palladium remained in the solutions after the precipitates were filtered off. Thus flotation procedures seem reasonable choices for recovering these elements.

As Rh(III) and Pd(II) formed cationic complexes after pretreatment, anionic surfactants should be used as collectors in the flotation. The flotation curves for $\text{Rh}(\text{H}_2\text{O})_6^{3+}$ and $\text{Pd}(\text{NH}_3)_4^{2+}$ with different surfactants are presented in Fig. 3. It can be seen that SDBS is the most efficient collector. The reason for this may be that SDBS has a longer hydrocarbon chain than SDS and SLS, that stability of the foam layer is proportional to the chain length, and stable foam is necessary to support the sublate. Thus, SDBS was chosen for further experimentation.

Effects of surfactant and metal concentrations

It is important to know whether variations in the initial concentrations of either the surfactant or metal ion result in significant differences in flotation efficiencies. For the first series of experiments, the metal concentration was fixed at $1 \times 10^{-4} \text{M}$ and the surfactant concentration was varied. For the second series, the molar ratio of SDBS to metal ion was held at 4:1, and the metal ion concentration was varied.

As the sublate salt has a stoichiometric ratio of colligend to collector, to obtain complete flotation of bivalent and trivalent ions, the surfactant must be present in at least 2:1 and 3:1 molar ratio respectively, to these ions. The experimental results confirmed that quantitative flotation was obtained only when there was an excess of collector. However, a large excess of collector, which produces a large volume of foam, should be avoided. Suitable molar

Fig 3 The effects of flotation time and surfactants (a) The flotation curves of $\text{Rh}(\text{H}_2\text{O})_6^{3+}$, (b) The flotation curves of $\text{Pd}(\text{NH}_3)_4^{2+}$. The concentrations of metals and surfactants were 1×10^{-4} and $4 \times 10^{-4}M$, respectively A SDBS B SDS, C SLS

ratios of SDBS to metal ion in the initial solution were found to be 3.5–5.0. The initial concentration of SDBS used in this work was therefore fixed at $4 \times 10^{-4}M$.

The results of the second series of experiments indicated that satisfactory flotation efficiencies with SDBS were obtained if the concentrations of Rh(III) and Pd(II) were in the range 2×10^{-5} – $4 \times 10^{-4}M$. If the concentrations of Rh(III) and Pd(II) were higher than $4 \times 10^{-4}M$, large amounts of SDBS were needed, and flotation was incomplete. The decrease in flotation efficiencies was attributed to the formation of micelles which rendered the substrate hydrophilic.

Effect of ethanol

It was observed in the flotation experiments that addition of a small amount of ethanol increased the flotation efficiencies. The reason for this was that the addition of ethanol reduced the coagulation of gas bubbles and produced a stream of numerous tiny bubbles. Bubbles having diameters below 0.5 mm are easily captured by precipitates, and therefore flotation was more efficient in the presence of a small amount of ethanol. However, it was of importance to control the amount of ethanol added. A large amount should be avoided, since it destroys the foam layer and causes partial redispersion of the substrate into the solution. A suitable amount of

ethanol was found to be 0.1–0.5 ml in 50 ml of sample solution.

Effects of bubbling time and gas flow-rate

Bubbling time and gas flow-rate should be carefully optimized. If the gas flow-rate is too low, it would take a long time to achieve complete flotation. If it is too high, the stability of the foam layer decreases, and moreover some bulk solution will be captured in the foam layer. From the flotation curves shown in Fig. 3, it can be seen that the best flotation efficiencies were obtained by the passage of nitrogen for 20 min at 30 ml/min flow-rate. In the flotation experiments, 25 min and 30 ml/min were chosen as the bubbling time and flow-rate, respectively.

Effect of ammonium ion on the separation of Rh(III) and Pd(III)

It was observed that the presence of ammonium ion in the initial sample interfered with the separation of Rh(III) and Pd(II). When the pH is adjusted for precipitation of the Rh(III), the ammonia will be liberated and form an ammine complex with the Pd(II). This complex is so stable that it is not decomposed by the addition of dilute hydrochloric acid. Since not only $\text{Rh}(\text{H}_2\text{O})_6^{3+}$ but also $\text{Pd}(\text{NH}_3)_4^{2+}$ can be floated by SDBS, if ammonium ion is originally present the separation of Rh(III) and Pd(II) is incomplete and even impossible. Therefore, ammonium ion must be absent from the original sample, or removed from it chemically, e.g., by evaporation to low bulk and heating with concentrated nitric acid.²²

Separation tests

Binary mixtures of the ions were separated. Rh(III) was floated by the first procedure from two binary mixtures under conditions similar to those for Rh(III) alone. Pd(II) was floated by

Table 1 Recovery data for flotation separation of binary mixtures of Rh(III), Pd(II) and Pt(IV) (each 500 μg per 50 ml)

Mixture	Recoveries, %			
	Floated		Not floated	
	Rh	Pd	Pd	Pt
Rh(III)–Pd(II)	94.0		99.8	
Rh(III)–Pt(IV)	91.2			99.1
Pd(II)–Pt(IV)		88.3		99.4

the second procedure from a binary mixture under conditions similar to those for Pd(II) alone. The results presented in Table 1 indicate that binary mixtures of these three platinum metals can be satisfactorily separated.

As osmium and ruthenium are easily converted into their tetroxides, which can be distilled, it was not considered necessary to examine their behavior in the system. Iridium was also not examined, because of its complicated oxidation and complexation behavior.

CONCLUSIONS

(a) The cationic complexes of rhodium(III) and palladium(II) can be floated with SDBS. (b) The differences in the kinetic properties of platinum metals can be used in their separation by ion flotation. (c) Satisfactory separations of binary mixtures of Rh(III), Pd(II) and Pt(IV) can be achieved by the proposed flotation procedures. (d) The proposed flotation procedures are fast, simple and do not require expensive reagents and apparatus. They may be useful for both laboratory and industrial separations of these three platinum metals.

(Received 6 June 1990 Revised 12 September 1990 Accepted 20 September 1990)

Summary—Electrothermal atomic-emission spectrometric determination of lithium with use of a tungsten tube has been investigated. Lanthanum nitrate is used as a matrix modifier to eliminate the interference of Al, Ca, Cu, Fe, K, Mg, Na, Pb and Zn. Lithium in biological samples has been determined by the method. The recovery of lithium in the samples was >91%.

Electrothermal atomic-emission spectrometry with graphite furnaces and metal tubes¹⁻¹² is very useful as an analytical method for some elements. However, the high levels of background radiation emitted by graphite furnaces are a drawback. We have found atomic-emission spectrometry with a metal-tube atomizer to be a useful alternative.⁶⁻¹⁰

Lithium is an essential element in the life processes of organisms. Some workers have reported the trace determination of lithium in food as well as somatic and biological samples by electrothermal atomic-absorption spectrometry^{2,11-14} with graphite furnaces but there is severe chemical interference.^{1,2,15,16}

In this paper, we report on the effect of lanthanum as a matrix modifier in lithium emission spectrometry. A relatively simple and sensitive method for trace determination of lithium in biological samples is demonstrated.

EXPERIMENTAL

Instrumentation

The atomic emission was measured with a Nippon-Jarrell Ash Ebert-type monochromator fitted with an R 928 photomultiplier (Hamamatsu Photonics Co.), run at 680 V, a dc amplifier, an oscilloscope (Iwatsu MS-5021), and a microcomputer (Sord M223). The slit-width was chosen so as to give a spectral band-pass of 0.02 nm. The time constant of the detection system was 4 msec. The signal from the computer was recorded with a plotter (Graphtec WX4675). A lithium hollow-cathode

lamp (Hamamatsu Photonics Co.) was used for alignment of the atomic-emission line at 670.78 nm. The small tungsten tube (2-mm internal diameter, 35 mm long and 0.05-mm wall) used as an excitation source was made from high-purity tungsten sheet (99.95%, Goodfellow Metals Ltd.). Two legs for supporting the tube at both ends were made from molybdenum sheets (0.1-mm thickness, 99.95% purity, Rembar Co.). The power for heating the metal tube atomizer was applied by a step-down transformer (TP-Y, Takabayashi Electric Co. Ltd.) and a volt-slider (3 kVA, Yamabishi Co.). The arrangement of the tube atomizer, condensing lenses, light apertures, and detection system was described earlier.¹⁰ The temperature signal from the tube wall, which was preliminarily calibrated with an optical pyrometer (Chino Works), was obtained from a photodiode (S641, Hamamatsu Photonics Co.) and fed to the microcomputer with the simultaneous emission signal. A glass micropipette (1 μ l) with a Teflon tip was calibrated gravimetrically with a microbalance (Mettler H20).

Water used in the study was purified four times by demineralizing and distilling, with an autodistiller (Isuzu Works), a demineralizer (Monopet type, Organo Co.) and a superpurifier (FS-1 type, Fujiwara Works).

Reagents

A standard 1 mg/ml stock solution of lithium was prepared by dissolving lithium carbonate in 0.15M nitric acid. A lanthanum stock solution (10 mg/ml) was prepared by dissolving lanthanum nitrate [La(NO₃)₃·6H₂O] in water.

*Author for correspondence

Matrix solutions were prepared from the metal nitrates. All working solutions were prepared from the stock solutions just before use.

Analytical-reagent grade chemicals were used throughout.

Procedure

Hydrogen at a flow-rate of 20 ml/min was added to the argon purge gas (flow-rate 480 ml/min) to protect the metal tube from oxidation by traces of oxygen in the system. This mixture was selected on the basis of a previous study.⁹ Since lithium may be present at trace levels in glassware and laboratory apparatus, Teflon and plastic ware cleaned with acid and fourfold purified water was used. The voltage supplied to the photomultiplier was 680 V.

A 1 μ l-aliquot (10 pg of Li) of sample solution was placed in the metal tube by micropipette, dried at 360 K for 10 sec, pyrolysed at 570 K for 20 sec and atomized by heating to 2620 K (at a ramp rate of 5.0 K/msec). Molecular emission generated by decomposition or vaporization of concomitant species was characterized by heating the interferent alone and measuring the emission at the lithium atomic resonance line (670.78 nm).

RESULTS AND DISCUSSION

Reproducibility and detection limit

The detection limit (0.02 ng/ml, $S/N = 2$) for plasma-emission determination is poorer than that of flame emission determination (1 pg/ml, $S/N = 2$),¹⁷ because a large fraction of the lithium atoms will be ionized in an inductively coupled plasma having a gas temperature of 9000–10000 K.¹⁸ The detection limit by atomic-fluorescence spectrometry with ICP as an atom cell has been reported as 0.3 ng/ml.¹⁹ The mass detection limit in the graphite-funace emission method is 0.5 pg,^{15,16} corresponding to 0.025 ng/ml. However, the detection limit in our metal-tube atomizer system, defined as the weight of lithium giving an emission signal equal to three times the standard deviation of the background signal, is 0.04 pg (corresponding to 0.004 ng/ml in a 10- μ l injection). Even though the efficiency of the small tube for emission measurements is limited, owing to the short residence time of the atomic vapour, the detection limit is comparable to that of flame emission.

Fig 1 CRT display showing the effect of lead on atomic emission of lithium (a) 10 pg of lithium, (b) 10 pg of lithium and 10 ng of lead, (c) 10 ng of lead, (d) temperature trace, a.u. = arbitrary units

The relative standard deviation (RSD) calculated from 9 measurements of 10 pg of lithium was 8%. The RSD for lithium (10 pg) in the presence of 50 ng of lanthanum was 5% (10 measurements). The RSD in the presence of organic matrix and 50 ng of lanthanum was 18–32% for three replicates.

Interference and matrix modifier study

Biological material, in general, contains large amounts of Al, Ca, Cu, Fe, K, Mg, Na, Pb and Zn (particularly Ca, K and Mg). The effect of these elements on the lithium emission profile was investigated by injection of a mixture of 10 pg of lithium and 10 ng of interferent into the metal atomizer (Table 1). A typical interference is shown in Fig 1. The results show that all these elements except iron caused a reduction in peak height. When the interferences caused by Ca, K and Mg in 100 ng amounts were further investigated, the lithium signals were found to be decreased to 35–40% of the signal in the absence of interferent.

Lanthanum is one of the most popular matrix modifiers for determinations of alkali and alkaline-earth metals by flame and electrothermal atomization atomic-absorption spectrometry.^{20–24} The effect of 50 ng of lanthanum on the lithium emission signal is shown in Fig. 2. It was found that the second peak in the emission signal for lithium alone was suppressed when lanthanum was present, and the lithium signal was slightly depressed and shifted to a lower temperature region. The second peak (in the signal for lithium alone) is thought to be due to molecular emission.

Table 1 Effect of lanthanum on interferences in determination of lithium (10 pg)*

Interfering element (10 ng)	Peak height†		Peak area†	
	Without La	With La	Without La	With La
(Li)	8 08 ± 0 64	6 11 ± 0 31	6700 ± 210	4790 ± 530
Al	6 79 ± 0 12	6 15 ± 0 32	5950 ± 210	4370 ± 130
Ca	5 95 ± 0 31	6.73 ± 0 32	2750 ± 320	7210 ± 1200
Cu	7.17 ± 0 20	6.15 ± 0 37	3509 ± 300	6480 ± 1180
Fe	8 08 ± 0 21	6 22 ± 0 33	9071 ± 1540	6210 ± 780

*3-10 measurements in each case

†Arbitrary units

The effect of lanthanum as a matrix modifier for suppressing the interferences was investigated. Figure 3 shows the effect of lanthanum (50 ng) on the lithium emission signal in the presence of lead. The emission signal for lead in the presence of lanthanum was negligible, and so was the effect of lead on the signal for lithium. The addition of lanthanum modified the interferences with respect to peak height (Table 1) but all the interferents except potassium, sodium and lead caused the lithium signal to be broader and to shift to a higher temperature region. The appearance temperature of the lithium signal, which is defined as the temperature of the atomizer at the time when an emission signal can first be perceived above the baseline noise, and the temperature for maximum emission were similar in the presence or absence of K, Na or Pb when lanthanum was added as matrix modifier. The presence of 100 ng of Ca, K or Mg lowered the lithium signal by about 25%.

Though lanthanum is known to act as a releasing agent for metal ions by preferential formation of compounds with interfering anions,²⁰⁻²³ and has been used as a radiation buffer in determination of calcium in phosphate rocks,²⁴ the mechanism in the present case is less obvious. It has been reported, however, that when lithium nitrate and lanthanum nitrate are heated together for 10 hr at 800° a compound LiLaO_2 is produced.²⁵ This reaction should proceed much more rapidly at the higher temperatures attained in the tungsten tube, and the modifying effect of the lanthanum may be due to "protection" afforded by formation of this compound.

Determination of lithium in biological materials

Biological samples were dried in an electric oven at 350 K for 4 hr and a 0.1-g sample was weighed and transferred into a Uni-seal vessel; 4 ml of concentrated nitric acid and 1 ml of 30%

hydrogen peroxide were added and the sealed vessel was heated for 3 hr in an electric oven at 390 K. After the digestion, the solution was transferred to a Teflon beaker and evaporated to dryness in a poly(ethylene glycol) bath at 380 K. The residue was dissolved in about 2 ml of 1M nitric acid and the solution was evaporated to dryness. This cycle was repeated, then the residue was taken up in 1 ml of the acid, the requisite amount of matrix modifier was added, and the solution was transferred to a 10-ml standard flask and made up to the mark with water. When necessary the solution was further diluted with water.

For atomic-emission measurements, $1 \mu\text{l}$ of the solution was introduced into the excitation tube by pipette after the addition of lanthanum. The emission signal was measured and a calibration graph was obtained by use of standard solutions (containing lanthanum); it was linear up to 10 pg of lithium.

Some studies with known quantities of lithium added to the samples indicated good recovery (Table 2). A result compared with a certified value is also listed in Table 2 and found to be almost quantitative.

The method presented requires only acid digestion of the biological sample. With lanthanum as matrix modifier, atomic emission spectrometry with a metal tube offers a simple and sensitive technique for the determination of

lithium in biological materials. The main disadvantage at present is the lack of a suitable commercial instrument, and this restricts wider use of the technique, despite its obvious applicability.

DETERMINATION OF TEN RARE-EARTH ELEMENTS AND YTTRIUM IN SILICATE ROCKS BY ICP-AES WITHOUT SEPARATION AND PRECONCENTRATION

M. S. RATHI, P. P. KHANNA* and PULOK KUMAR MUKHERJEE

Spectra Laboratory, Wadia Institute of Himalayan Geology, 33 General Mahadeo Singh Road,
Dehra Dun 248 001, India

(Received 20 October 1989 Revised 25 July 1990. Accepted 19 September 1990)

Summary—Lanthanum, cerium, neodymium, samarium, europium, gadolinium, dysprosium, erbium, ytterbium, lutetium and yttrium have been determined in 8 international rock standards by inductively coupled plasma atomic emission spectrometry (ICP-AES) without prior ion-exchange separation and preconcentration. The results for La, Ce, Nd, Eu, Dy, Yb and Y were in good agreement with the reported values, whereas those for Sm, Gd, Er and Lu were less accurate. However, the results for Sm, Gd, Er and Lu can also be used for studies of petrogenesis.

Rare-earth element (REE) geochemistry has been established as one of the most powerful tools for petrogenetic studies of rocks. REEs (except for Ce) are comparatively inert towards secondary geological processes, and hence their relative abundances even in altered rocks, give valuable information about the origin of rocks.¹

High-resolution ICP-AES has become a widely used and popular technique for measurement of major and trace elements, including REEs,³⁻⁸ in analytical geochemistry. However, preparation of samples for ICP-AES determination of the REEs in rock samples generally involves separation of REE fractions by cation-exchange, followed by concentration by evaporation.³⁻⁸ This procedure is quite tedious and thus hinders the routine production of REE data.

The aim of the present investigation was to find whether the separation and preconcentration steps can be avoided by calibrating the instrument with standards having a chemical matrix similar to that of the samples.

EXPERIMENTAL

Dried samples (0.5 g) were digested with a hydrofluoric-perchloric acid mixture in open PTFE beakers. The digestion was repeated 5 or 6 times with evaporation to perchloric acid fumes after each, in order to ensure complete dissolution, and the final solution was made up accurately to 50 ml. The instrumentation used

was a Jobin Yvon model JY 70 Plus ICP, with a 1-m focal length Czerny-Turner, holographic grating, 3600 grooves/mm, and a Meinhard concentric glass nebulizer "type C". The RF generator was a 40.68 MHz single-phase unit, with power stable to better than 0.01%. The gas flow-rates (l./min) were: outer (coolant) 12; intermediate (auxiliary) 0; central (carrier + sheath) 0.55.

A set of four rock standards (Syenite STM-1, Quartz latite QLO-1, Diabase W-2, supplied by U.S.G.S. and Granite GS-N, supplied by A.N.R.T., France) and a blank were used for calibration in order to cover a wide compositional range of geological materials. Six rock standards (Basalt BE-N, from A.N.R.T., Basalt BHVO-1, Mica schist SDC-1, Granite G-2, Rhyolite RGM-1 and Granodiorite GSP-1 from U.S.G.S.) were treated as unknown samples and analysed for REE and Y. A validation test was done with a different set of standards for calibration (SDC-1, BE-N, BHVO-1, W-2, and Gabbro MRG-1, supplied by C.C.R.M.P., Canada) and a blank, for measurement of REEs and Y in QLO-1, GS-N, G-2, RGM-1 and GSP-1. The results are summarized in Table 1.

RESULTS AND DISCUSSION

The concentrations of the REEs and Y in the reference rock standards were taken from the latest compilation by Govindaraju.⁹ Some of the REE values for these reference rocks are not

well characterized and are proposed only for information (they are marked with an asterisk in Table 1).

A comparison of our results (Table 2) with those obtained by use of a separation technique^{6-8,10,11} and also with the consensus values,⁹ shows that those for La, Ce, Nd, Eu, Dy, Yb, and Y are in good agreement. Agreement for Sm, Gd, Er and Lu is rather poor, but most of the differences are within the acceptable limits of error for petrogenetic purposes. Some of our measurements (underlined in Table 2) are in better agreement with the reported values than are those obtained by using a separation technique.

The values found for Er were always lower than the reported values, whereas those for Sm were always high. The accuracy of the results for these two elements was better for basic rocks than for granitic rocks. The reason for this is unclear, but is possibly spectral interference by elements such as Ba, Sr, Zr, etc. which are generally present in granitic

rocks at levels as much 10-100 times those in basic ones.

The cation-exchange methods do not give complete separation of the REEs from the other rock components, some elements, such as Ba, Ca, Sr, Ti and Zr, being incorporated in the REE fraction.^{3,7} In our method, however, rock standards were used instead of salt standards for calibration, and as these are chosen so that their matrices are similar to those of the samples, there is some degree of compensation of chemical and spectral interferences. The results obtained for G-2, RGM-1 and GSP-1 differed, however, according to which set of calibration standards was used. All the calibrations were found to satisfy a first order fit. The slopes and intercepts obtained for both calibration sets are given in Table 3. The major component composition of the standards is given in Table 4.

In summary, it may be concluded that separation and preconcentration of REEs is not essential for their determination in silicate rock

Table 4 Major component composition (%) of the standards used for calibration

Standard	SiO ₂	Al ₂ O ₃	Fe ₂ O ₃	FeO	MnO	MgO	CaO	Na ₂ O	K ₂ O	TiO ₂	P ₂ O ₅

samples. It is difficult to determine Pr, Tb, Ho and Tm by this method, but the rest of the REEs and Y can be measured with reasonable accuracy in a 10-mg/ml rock solution by using high-resolution ICP-AES. The accuracy achieved is sufficient for the purpose of geological interpretation. The results could probably be further improved by using calibration standards that all closely match the samples in chemical composition.

(Received 27 May 1989 Revised 28 June 1990 Accepted 10 October 1990)

Summary—Coulometric generation of H⁺ and D⁺ ions in aqueous media by the oxidation of hydrogen and deuterium dissolved in palladium, is described. Hydrogen and deuterium dissolved in palladium were found to be oxidized at more negative potentials than the oxidation potentials of water and other components present. The H⁺ and D⁺ ions generated were used for the titration of tris(hydroxymethyl)aminomethane, piperidine, triethylamine and sodium tetraborate, the end-point being determined potentiometrically with a glass electrode and an SCE. In titrations of 0.001–0.1 M solutions of the bases, the current efficiency was 100%.

In previous work,¹⁻³ we have generated H⁺ ions in non-aqueous media by anodic oxidation of hydrogen dissolved in palladium. Titrations of organic bases with the ions generated in this way showed that the current efficiency in the generation was 100%. Therefore, we considered it interesting to investigate the generation of H⁺ and D⁺ ions in aqueous media by anodic oxidation of hydrogen and deuterium, dissolved in palladium. No data on the coulometric generation of D⁺ ions have hitherto been reported.

EXPERIMENTAL

Reagents

All chemicals used were of analytical reagent grade (Merck and Fluka). Tris(hydroxymethyl)aminomethane⁴ and sodium tetraborate were prepared as primary standard solutions. Piperidine and triethylamine solutions were standardized by potentiometric titration with standard perchloric acid solution. The supporting electrolyte was 1 M sodium perchlorate or sulphate in water. Deuterium oxide (heavy water), 99.8%, was purchased from the Radioisotope Division of IGN Chemicals.

Electrodes

The electrode for generating D⁺ was a palladium plate (1 × 2 × 0.5 cm) saturated with deuterium obtained by electrolysis of heavy water. The other electrodes used, the apparatus and the procedure were as described earlier.³

RESULTS AND DISCUSSION

Although hydrogen and deuterium dissolved in palladium have been extensively studied,⁵⁻⁸ no data are reported on their practical application as sources of H⁺ and D⁺ ions for quantitative determination of bases in aqueous media.

Previous direct coulometric titrations of organic bases with H⁺ ions generated by the oxidation of water at a platinum anode were not successful, as the bases titrated were oxidized as well.

By recording the current-potential curves for water, the bases to be titrated, and hydrogen and deuterium dissolved in palladium (Fig. 1) we found that in 1M aqueous solutions of sodium sulphate or perchlorate, hydrogen and deuterium dissolved in palladium were oxidized at potentials more negative (slightly above 0V) than those for oxidation of the bases and water.

In order to establish whether the reactions $H_2/Pd \rightarrow 2H^+ + 2e^-$ and $D_2/Pd \rightarrow 2D^+ + 2e^-$ are quantitative, we titrated solutions of tris(hydroxymethyl)aminomethane (THAM), piperidine, triethylamine and sodium tetraborate, with H⁺ and D⁺ ions obtained by the oxidation of hydrogen and deuterium. The results obtained under the optimum experimental conditions are presented in Table 1. Under the optimum conditions the current efficiency was 100%.

Since the oxidation potentials of hydrogen and deuterium dissolved in palladium are only slightly above 0V, these species can be used for generation of H⁺ and D⁺ for titrimetric determination of organic bases, with 100% current efficiency.

The palladium plate used (1 × 2 × 0.5 cm) can be utilized for the generation of H⁺ (D⁺) ions in water for more than 80 hr at a current of 0.015 A. After consumption of the hydrogen (deuterium) dissolved in the palladium, the electrode can again be saturated with hydrogen (deuterium).

From the results presented in Table 1 it may be concluded that hydrogen and deuterium dissolved in palladium are ideal for the coulometric generation of H⁺ and D⁺ ions in water; their oxidation potentials are low and they can be quantitatively oxidized. Furthermore, their application brings no foreign organic compounds into the solution under investigation.

INDICATOR CHARACTERISTICS OF BROMOTHYMOLO BLUE DERIVATIVES

J. B. PUSCHETT and B. S. RAO

(Received 3 January 1990 Revised 5 September 1990 Accepted 10 September 1990)

Summary—Some Bromothymol Blue derivatives with a nitro, amino, isothiocyanato or sulfonamide group substituted on the sulfonated ring of the dibromothymolsulfonephthalein have been studied spectrometrically. All the dyes have two characteristic absorption peaks which can be used to measure pH in the physiological range. The molar absorptivities, wavelengths of maximum absorption and pK_a values have been determined from the absorbances, and are similar for all four dyes.

Indicator dyestuffs can be used to measure pH spectrophotometrically, by use of the Henderson-Hasselbalch equation.¹ The scope of this method can be widened by the use of fiber optics in measuring the absorbance of the dyestuff. Light is transmitted by a fiber to a chemically sensitive dye immobilized at the fiber tip. The fraction of the light absorbed by the dye is determined by measuring the absorbance or reflectance by carrying the appropriate radiation through another fiber to a detector. Several pH sensors based on this principle have been reported.²⁻⁷ In these systems, the dye was immobilized on a cross-linked hydrophilic copolymer, attached to glass fibers. One of the disadvantages of these methods is that the reagent is not covalently bound to the fiber and may be leached out. Some applications may require high flexibility of the fibers and high resistance to breakage on bending and twisting. Glass fibers are much more fragile than plastic fibers. It is also difficult to miniaturize some of these devices.

Zemel and co-workers^{8,9} reported the use of a pair of twisted plastic fibers, which gave a high degree of mechanical flexibility combined with very small size and a low cost construction of a disposable probe.

In our work on development of a fiber optic sensor for *in vivo* pH measurements, it was of

interest to prepare flexible plastic optical fibers with dye molecules covalently bound to their surface.¹⁰ For the construction of such a probe, phenolsulfonephthalein and 3,3'-dibromothymolsulfonephthalein (Bromothymol Blue, BTB) are among the most suitable dyes, because they are sensitive to pH in the physiological range.

Attachment of dye molecules to the optical fibers requires the presence of reactive functional groups on the fiber surface as well as on the dye itself. Introduction of groups other than the hydroxyl group into Bromothymol Blue offers a possibility for immobilization of the indicator on a plastic optical fiber. We have therefore prepared derivatives of Bromothymol Blue containing nitro (NBTS), amino (ABTS), isothiocyanato (IBTS) and sulfonamide (SBTS) groups on the sulfonated ring of Bromothymol Blue.

3-Nitro-2-sulfobenzoic anhydride was condensed with thymol in the presence of anhydrous zinc chloride to yield 3-nitrothymolsulfonephthalein (NTS), which was then

*Author for correspondence

brominated in acetic acid to afford 3-nitro-3',3''-dibromothymolsulfonephthalein (NBTS). This compound was catalytically reduced, by using palladium on charcoal, and hydrazine hydrate, to obtain the corresponding 3-amino-3',3''-dibromothymolsulfonephthalein (ABTS), from which the isothiocyanato (IBTS) and *p*-toluenesulfonamide (SBTS) derivatives were prepared.¹⁰ ABTS and IBTS were subsequently covalently attached to plastic fibers with functional groups on their surface, *e.g.*, amino groups on the surface of poly(methylmethacrylate) fiber cladding¹⁰ and sulfonyl chloride groups on the surface of the polystyrene fibers. It is hence important to know how such chemical modification affects the indicator characteristics of the dyes. SBTS was used as a model for predict-

ing the behavior of ABTS attached to chlorosulfonated polystyrene fibers.

The synthesis and characterization of the dyes used are described elsewhere.¹¹

EXPERIMENTAL

An IBM 9430 spectrophotometer and a Fisher Accumet Model 805MP pH meter were used. For each dye, a stock solution of known concentration was prepared in dilute alkali, and divided into several portions. Various small amounts of hydrochloric acid were added to these portions to yield solutions of different pH. The change in volume resulting from addition of the acid was negligible. The spectrum of each solution over the 300–700 nm range was then recorded and the pH was measured.

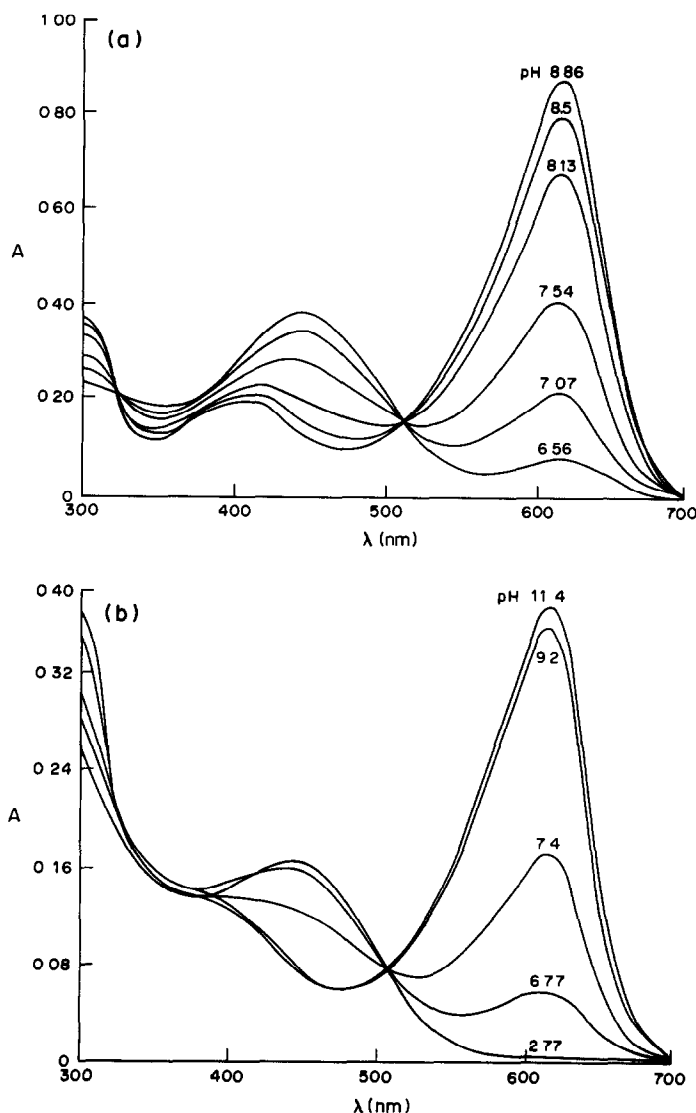

Fig. 1 Spectra at various pH values and 25° for (a) $2.0 \times 10^{-5} M$ IBTS in water, (b) $0.76 \times 10^{-5} M$ SBTS in water

RESULTS AND DISCUSSION

The effect of pH on the spectra of IBTS and SBTS over the 300–700 nm range is shown in Fig. 1. For both dyes, two absorption peaks are seen, the peak at about 600 nm being the more sensitive in the pH range 6.5–8.5. The isosbestic points at ~ 500 nm indicate quantitative transformation without any side products. A similar effect of pH was also observed for NBTS and ABTS. The occurrence of two absorption peaks and the observed effect of pH on the spectrum can be explained on the basis of the work of Blow and Rich,¹² who postulate the following structures for BTB:

At low pH the sultone form exists as a yellow neutral species, which on addition of alkali is ionized to the blue form and its canonical forms, which can be further deprotonated at high pH. The short wavelength peak for the derivatives (Fig. 1) can be attributed to the corresponding yellow form and the long wavelength peak to the quinonoid form. In the pH range of interest, the first equilibrium shifts to the right when alkali is added, resulting in an increase in the

Fig 2 Dependence of the absorbance of $2.0 \times 10^{-5} M$ IBTS at $\lambda_{\max} = 615$ nm (temperature 25°)

Fig 3. Dependence ratio of the absorbances at the two maxima, on pH, for IBTS, ABTS, and SBTS in water, at 25°

concentration of the phenolate ion (due to neutralization of the phenolic proton). At lower pH the neutral form predominates. It is clearly seen from Fig. 1 that the absorbances of the two peaks, which are proportional to the concentrations of the relevant species, vary with pH. Similar results were observed for NBTS and ABTS.

Since there is a sharp isosbestic point in the spectra (Fig. 1) the ratio of the absorbance at the long wavelength peak to that at the isosbestic point is independent of the dye concentration and is a function of only the pH. Likewise, the ratio of the absorbances at the short and long wavelength peaks will be a function of only pH. For ABTS, IBTS and SBTS, these ratios are plotted against pH in Fig. 2. This property is the basis of the spectrophotometric determination of the pH of solutions.¹³ ABTS and IBTS give almost the same values as each other for the ratio over the pH range examined. For SBTS, however, the ratio is much lower for pH above 8.

The pK_a values were estimated by the Brode procedure.¹³ For each dye, the absorbance at the long wavelength peak was plotted as a function of pH. The abscissa of the point of inflexion gave an estimate of pK_a . A typical plot for IBTS is shown in Fig. 3. The pK_a of IBTS at 25° was estimated as 7.6, in good agreement with the reported value of 7.1 for BTB.

Table 1 lists the pH sensitivity ranges, pK_a values, wavelength maxima, molar absorptivities and color changes for various Bromothymol Blue derivatives, and pertinent literature information on TS and BTB. The molar absorptivities were determined from the absorbances, at the long wavelength maximum, of alkaline

Table 1 Wavelength maxima, pH sensitivity ranges and color changes for various dyes

Dye	pH range	pK _a	λ_{\max} , nm	ϵ^* , 10 ⁴ l mole ⁻¹ .cm ⁻¹	Color change
TS	8.0–9.6	8.9	594	4.6	yellow–blue
NTS	8.0–10.0	9.0	592	2.2	yellow–violet blue
BTB	6.2–7.6	7.1	617	4.9	yellow–blue
NBTS	7.5–9.5	8.5	607	1.6	yellow–blue
ABTS	6.5–8.5	7.6	612	3.5	yellow–blue
IBTS	6.5–8.5	7.6	615	5.4	yellow–blue
SBTS	6.5–8.5	7.7	612	4.2	yellow–blue

*At the longer wavelength maxima and the highest pH

solutions of known concentrations. The pH transition range of 8–10 observed for NTS is in excellent agreement with the pH range 8.2–9.6 reported earlier.¹⁴

From the tabulated data, the effect of substituents on the indicator characteristics can be assessed. Substitution on the sulfonated ring appears to shift the pH transition range to slightly higher values. From comparison of the pK_a values of TS and NTS and of BTB and NBTS, it can be seen that the nitro group, which has a strong electron-withdrawing character, on the sulfonated ring slightly increases the pK_a values. Similar results have been reported for some phenolsulfonephthaleins with halogen substituents on the sulfonated ring.¹⁵ In contrast, the introduction of bromine atoms into the thymol moiety of TS lowers the pK_a from 8.9 for TS to 7.1 for BTB. Thus, the electron-withdrawing group attached to the phenol rings has an opposite and stronger effect on the pK_a value than when it is attached to the sulfonated ring. These apparently anomalous effects can be reconciled by considering entropy effects,¹⁶ by analogy with the chloroacetic acids. When the electron-withdrawing groups are on the sulfonated ring, the effect will be to increase the degree of localization of negative charge on this ring and hence increase the ordering effect on the water solvation shell, which in turn makes the entropy of solvation less positive and hence the free-energy change of ionization more positive, thus increasing pK_a. When the groups are on the phenol ring however, the charge on the anion is more uniformly distributed over the ion, the entropy of solvation is more positive and hence pK_a is reduced. Similar results have been reported for phenolsulfonephthaleins prepared from substituted phenols.¹⁵

In conclusion, the results of the present study indicate that the introduction of a

functional group on the sulfonated ring of BTB or further sulfonamide derivatization does not change the absorption wavelength or the high sensitivity of TS and BTB, which can be conveniently used as spectrophotometric pH probes with the low cost He–Ne laser (wavelength 632 nm). Further work on the surface modification and the covalent attachment of indicator molecules to optical fibers as well as the probe construction and pH sensing by laser optics is under way

SYNTHESIS AND CHARACTERIZATION OF 2-(3,5-DICHLORO-2-PYRIDYLAZO)-5-DIMETHYLAMINO- PHENOL AS A REAGENT FOR DETERMINATION OF LANTHANUM

LILIANA FERNANDEZ and ROBERTO OLSINA

Department of Analytical Chemistry, Faculty of Chemistry, Biochemistry and Pharmacy,
University of San Luis, Argentina

(Received 16 October 1989 Revised 11 September 1990 Accepted 19 September 1990)

Summary—2-(3,5-Dichloro-2-pyridylazo)-5-dimethylaminophenol (3,5-diCIDMPAP) has been synthesized and its spectral properties, acid-base equilibria, physical constants, and solubility and stability are presented. This reagent is highly promising for the determination of lanthanides. The influence of Triton X-100 on the dissociation constant has been investigated and the association constant between the reagent and the surfactant determined. Analytical data for the 3,5-diCIDMPAP complexes with La(III), Eu(III), Gd(III), Er(III) and Yb(III) are given, La(III) in synthetic samples has been determined with 3,5-diCIDMPAP.

The lanthanides have a wide range of industrial applications, especially in the preparation of catalysts, in alloys and as geochemical tracers, and there has been much interest in development of organic reagents for their determination.¹⁻⁹

The reagents of azo-type, particularly the pyridylazo compounds,⁶⁻⁹ give colored lanthanide complexes that are suitable for spectrophotometric determination. Introduction of halogens into the pyridine ring should considerably increase the sensitivity,¹⁰ so in the present work 2-(3,5-dichloro-2-pyridylazo)-5-dimethylaminophenol (3,5-diCIDMPAP) was examined as a reagent for spectrophotometric determination of some lanthanides. To enhance the sensitivity further, a surfactant was added to the reaction mixture.

EXPERIMENTAL

Apparatus

A Varian 634-UV spectrophotometer was used with 1-cm path-length glass cells. An Orion 701-A pH-meter equipped with a combination glass-calomel electrode was used for pH measurement.

Reagents

Reagents were of analytical quality, except for those used in the synthesis of 3,5-diCIDMPAP, which were purified before use.

Synthesis of reagent

3,5-Dichloro-2-aminopyridine was synthesized by the method of Shibata *et al.*¹¹ A solution of 10 g of the purified product in 150 ml of benzene was placed in a 500-ml glass flask fitted with a reflux condenser and a tube for introduction of a gas. The solution was deaerated by passage of nitrogen through it for 5 min. Sodium amide (3 g) dispersed in benzene that had been deaerated was then introduced, and the mixture was refluxed for about 1 hr under an atmosphere of nitrogen; 15 ml of recently prepared isoamyl nitrate were then added¹² and the mixture was refluxed for 5 hr with continuous passage of nitrogen. The condenser was removed, and the mixture was evaporated to half its volume, then cooled. The light yellow precipitate of diazotate was filtered off by gentle suction and washed with small portions of diethyl ether. A solution of 12 g of diazotate in 70 ml of distilled water and a solution of 5 g of recently purified 3-dimethylaminophenol in 30 ml of ethanol were placed in a 500-ml glass flask fitted with a reflux condenser and bubbler tube, and the mixture was refluxed at a temperature not above 65° for 5 hr, with passage of a slow stream of carbon dioxide. When the solution was cooled, a dark red product was obtained, and filtered off with a sintered glass filter.

The product was purified by repeated recrystallization from chloroform. Analysis gave C 50.1%, H 4.0%, N 17.9%; $C_{13}H_{12}N_4OCl_2$ requires C 50.18%, H 3.99% and N 18.01%. The melting point was 191° .

RESULTS AND DISCUSSION

Spectral studies

The mass spectrum was taken and had a peak at $m/z = 310$, for the ^{35}Cl isotopic compound. The proton NMR spectrum was in agreement with that reported by Nakamura *et al.*¹³

The reagent should exhibit three acid-base equilibria. Starting with the species present in very acid solution, these equilibria are

corresponding to deprotonation of the pyridinium ring, followed by

for deprotonation of the quaternary ammonium group, and finally

An absorptometric method was used to evaluate the constants.¹⁴ In all cases the solvent used was 15% v/v ethanol and the ionic strength was kept constant at 0.1M.

Azo-reagents are widely applied in the determination of metal ions. Solvent mixtures such as ethanol-water are frequently used to dissolve the reagent and the complexes formed. Additives such as surfactants are also used to stabilize and/or solubilize the complexes and increase the sensitivity of the method. Triton X-100, a non-ionic poly(ethylene oxide) surfactant, was used in the present work.

The acidity constants in the presence of the surfactant were determined in conditions analogous to those described above, with the concentration of Triton X-100 kept constant at 0.4% v/v ($\approx 7 \times 10^{-3}M$), which permits the existence of micelles (the cmc is $2 \times 10^{-4}M$). Table 1 shows the values obtained in the presence and absence of Triton X-100

The presence of the surfactant slightly changes the absorption spectra of the various reagent forms. In the case of the ROH species, there is a red shift of 5 nm and an absorbance decrease of 19%. This is related to changes in the probability of the transitions of the π -electrons present in the chromophores^{15,16}

Table 1 Acidity constants of 3,5-diCIDMPAP

Constant	Conditions	Value
pK_{a1}	15% v/v ethanol	-1.2
pK_{a2}	15% v/v ethanol	1.7
	0.4% v/v Triton X-100,	
	15% v/v ethanol	0.9
pK_{a3}	15% v/v ethanol	11.6
	0.4% v/v Triton X-100,	
	15% v/v ethanol	11.8

Association constant of the reagent with Triton X-100

The acid-base properties of 3,5-diCIDMPAP are strongly modified by the presence of micellar additives. The lanthanide complexes of the reagent are generally formed at $pH > 7$, so the reagent form generally involved is ROH. The variation of pK_{a3} with Triton X-100 concentration was studied in the absence of ethanol. To determine the association constant the expression¹⁵

$$1/K_{a(app)} = 1/K_{a(H_2O)} + C_D D_{HA}/K_{a(H_2O)}$$

was used, where $K_{a(app)}$ is the dissociation constant of the phenolic OH group in the presence of the surfactant, $K_{a(H_2O)}$ is the same constant for aqueous medium, K_{HA} is the constant for association of the reagent anion and the micelles, and C_D is the concentration of surfactant present in micellar form.

$$(C_D = C_T - cmc)$$

Figure 1 shows the results obtained. The value of K_{HA} is 6.1×10^{-3} .

Fig 1 Determination of the association constant C_T (M) 1, 2×10^{-4} , 2, 1.5×10^{-3} , 3, 2.8×10^{-3} , 4, 3.6×10^{-3} , 5, 6.3×10^{-3} , 6, 1.7×10^{-2}

Determination of lanthanides

Table 2 presents some experimental conditions for the spectrophotometric determination of lanthanides with 3,5-diCIDMPAP, and the molar absorptivities obtained.

The main advantage of the reagent, however, is that all its lanthanide complexes except that with lanthanum can be extracted into benzene. Thus if the lanthanides can be separated from the elements accompanying them in rocks, etc., 3,5-diCIDMPAP can be used to determine lanthanum in the aqueous phase after extraction of its complexes with the other lanthanides. Methods such as that of Crock *et al.*¹⁷ can be

Table 3 Determination of La(III) in synthetic samples

Sample	Composition, %	La(III) found,* %
La(III)	40.0	40.2 ± 0.6
Other REE	60.0	CL = 40.0 ± 0.4
La(III)	3.0	3.03 ± 0.07
Other REE	97.0	CL = 3.03 ± 0.06
La(III)	90.0	89.7 ± 0.6
Other REE	10.0	CL = 89.7 ± 0.05

*Mean ± standard deviation of σ determinations, and 95% confidence limits (CL _{$\alpha=0.05$})

used for the initial separation of the lanthanides from the matrix elements.

The method has a sensitivity equal to that of atomic-absorption spectrometry with electrothermal atomization and four orders of magnitude better than that of flame atomic-absorption spectrometry.

Table 3 shows some results for analysis of synthetic mixtures of lanthanides.

SPECTROPHOTOMETRIC DETERMINATION OF ANTIMONY WITH VANILLYLFLUORONE IN THE PRESENCE OF POLY(VINYL ALCOHOL)

ITSUO MORI,* YOSHIKAZU FUJITA, MINAKO TOYODA, KEIJI KATO,
KAZUMI FUJITA and YUJI OKAZAKI

Osaka University of Pharmaceutical Sciences, Matsubara-shi, Osaka 580, Japan

(Received 12 June 1989 Revised 26 January 1990 Accepted 30 August 1990)

Summary—Antimony in the range up to 2.5 $\mu\text{g/ml}$ in the final solution is determined spectrophotometrically with vanillylfluorone in the presence of poly(vinyl alcohol) in acidic media. The method is compared with that using *o*-hydroxyhydroquinonephthalein (Qnph). It is simple, rapid and sensitive, without need for heating or solvent extraction, and the apparent molar absorptivity (ϵ) is $5.0 \times 10^4 \text{ l mole}^{-1} \text{ cm}^{-1}$ at 545 nm, for the Qnph method ϵ is $2.8 \times 10^4 \text{ l mole}^{-1} \text{ cm}^{-1}$ at 520 nm. Tests with an artificial wastewater gave 99–103% recovery.

High-purity antimony is used in the manufacture of semiconductors, and the antimony levels in the urine of workers in the factories should be monitored.¹

Numerous xanthene and triphenylmethane dyes such as phenylfluorone and its derivatives,²⁻⁴ Gallein,^{5,6} Bromopyrogallol Red⁷ and Brilliant Green,^{8,9} have been used for spectrophotometric determination of antimony, and the effect of surfactants on some of these methods has been examined.^{5,7,10-12} However, the purity of commercial phenylfluorones is variable and their solutions in methanol are not always stable.

Vanillylfluorone (2,6,7-trihydroxy-9-vanillylxanthene-3-one, Vfl), is reported to be superior in ease of purification and stability in organic solvents.¹³

In this paper, the colour reaction of Vfl with antimony in the presence and absence of dispersion agents is compared with the corresponding reaction with *o*-hydroxyhydroquinonephthalein (Qnph), which is also recommended^{14,15} as superior to phenylfluorone. A simple, rapid and sensitive spectrophotometric method for the assay of antimony with Vfl in the presence of poly(vinyl alcohol), PVA, is proposed and compared with the corresponding method employing Qnph.

EXPERIMENTAL

Reagents

A $1.0 \times 10^{-3} \text{ M}$ Vfl solution in methanol was prepared, and a Qnph solution as described earlier.^{14,15} Antimony stock solution ($1.0 \times 10^{-2} \text{ M}$) was prepared by dissolving antimony metal (Mitsuwa Chemical Co., Ltd., 99.999% pure) in concentrated sulphuric acid, cooling and diluting with water to give 20% v/v sulphuric acid in the final solution. A $5.0 \times 10^{-4} \text{ M}$ antimony working solution was prepared by dilution of the stock solution with 20% v/v sulphuric acid.¹⁶ A 1.0% solution of PVA ($n = 500$, Kishida Chemical Co., Ltd.) in water was prepared, and 20% v/v sulphuric acid was used for adjustment of acidity. All reagents and materials were of analytical-reagent grade. Demineralized water was used throughout.

Spectrophotometric procedure

Pipette various volumes of standard antimony solution, to give up to 25 μg of antimony, into a series of 10-ml standard flasks. Add 1.5–3.0 ml of 20% v/v sulphuric acid, 2.0 ml of 1.0% PVA solution and 1.5 ml of $1.0 \times 10^{-3} \text{ M}$ Vfl solution. Mix thoroughly and dilute to the mark with water. After about 10 min measure the absorbance at 545 nm against a reagent blank prepared in the same way. Analyse sample solutions similarly.

A similar procedure can be used with Qnph, with measurement at 520 nm.

*Author for correspondence

Fig 1 Absorption spectra of Qnph, Vfl, and their antimony complexes in the presence of PVA. Antimony $5.0 \times 10^{-5}M$, Qnph or Vfl $5.0 \times 10^{-5}M$, PVA 0.2%, reference water. A, Qnph solution, B, Vfl solution, C, Qnph-antimony solution, D, Vfl-antimony solution

RESULTS AND DISCUSSION

Of the reagents Pyrogallol Red, Bromopyrogallol Red, phenylfluorone derivatives, Gallein, Xylenol Orange and Vfl, the last was best in terms of sensitivity, stability and reproducibility. Though Vfl gave good colour development in the presence of a cationic surfactant such as hexadecylpyridinium chloride, the product was somewhat lacking in stability and gradually precipitated. However, the colour developed in the presence of PVA (as a dispersion or stabilizing agent) was more stable and reproducible than that in its absence. Figure 1 shows the absorption spectra of the Vfl-antimony and Qnph-antimony complexes and of Vfl and Qnph, and shows the greater sensitivity of the Vfl system.

Maximal and constant absorbance was obtained at 4–8% v/v final sulphuric acid concentration for the Vfl-antimony complex, and at pH 1.1–1.5 (obtained with 0.5–3.0 ml of 1.0% v/v sulphuric acid, for the Qnph-antimony complex.

A final PVA concentration of 0.1% was optimal, and PVA was superior to Triton X-100, Brij 35, poly(*N*-vinyl-2-pyrrolidone) and gelatine for the purpose. Maximal absorbance for a fixed amount of antimony was obtained with 1.4–3.0 ml of $1.0 \times 10^{-3}M$ Vfl, so final concentrations of $2.8 \times 10^{-4}M$ Vfl and 0.1% PVA were selected for use. Beer's law holds over the concentration range 0–2.5 $\mu\text{g/ml}$ antimony in the final solution with Vfl and 0–6.0 $\mu\text{g/ml}$ with Qnph. The apparent molar absorptivity was $5.0 \times 10^4 \text{ l.mole}^{-1}.\text{cm}^{-1}$ for Vfl, and $2.8 \times 10^4 \text{ l.mole}^{-1}.\text{cm}^{-1}$ for Qnph. The relative standard deviation was 0.5% for 1.05 $\mu\text{g/ml}$ antimony (5 replicates).

Interferences

Tin(IV) interfered seriously in the assay of antimony with Vfl, giving a positive error, and thorium and bismuth gave negative errors. Other cations tested, such as aluminium, cobalt(II), indium, tantalum, manganese(II), iron(III), did not interfere, nor did anions such as iodide, fluoride and cyanide, at 100-fold molar ratio to antimony, but thiosulphate caused interference.

Table 1 shows the tolerance levels for these ions. The Vfl method is less prone to interference than the Qnph method, and is more sensitive than the phenylfluorone, Bromopyrogallol Red, Gallein and Brilliant Green methods.³⁻⁹

Table 1. Effect of foreign ions on determination of 1.22 $\mu\text{g/ml}$ antimony

Ion	Added, $\mu\text{g/ml}$	Molar ratio (ion/antimony)	Absorbance at 520 nm	Tolerance ratio for Vfl method relative to Qnph method
—	—	—	0.500	
Sn(IV)	0.3	0.25	0.499	10
Bi(III)	20.9	10	0.488	10
Th(IV)	23.2	10	0.459	20
Al(III)	80.9	300	0.501	10
In(III)	34.3	300	0.505	20
Fe(III)	55.8	100	0.514	1000
Mn(II)	54.9	100	0.510	10
Cu(II)	63.6	100	0.490	2
Co(II)	176.8	300	0.500	5
Ni(II)	176.1	300	0.495	10
$\text{S}_2\text{O}_3^{2-}$	5.6	5	0.485	5
F^-	38.0	100	0.498	10
Tartrate	1200	1000	0.496	10
NTA	1711	1000	0.491	5

The reaction between Vfl and antimony can be prevented by masking the antimony with tartrate, but the reaction with tin(IV) is not affected, so Vfl can be used for the determination of tin in the presence of antimony. The composition of the Vfl-antimony complex in the presence of PVA was found to be 1:1 by the continuous-variation and molar-ratio methods. The molar ratio of Vfl to PVA was not investigated. The recovery of antimony from an artificial wastewater containing antimony, cobalt(II), aluminium, magnesium, iron(III), was found to be 99–103%.

DETERMINATION OF SOME SULPHUR COMPOUNDS WITH *N*-BROMOIMIDES

C MOHANA DAS

Department of Chemistry, St Joseph's College, Bangalore 560001, India

(Received 12 January 1990 Revised 1 August 1990 Accepted 7 September 1990)

Summary—Two stable oxidants, *N*-bromophthalimide and *N*-bromosaccharin are proposed as reagents for the visual and potentiometric titrimetric of thioureas, isothiocyanates, xanthates, dithiocarbamates, thiols, sulphur, thiosulphate, thiocyanate and thiocarbonate. The results are precise within 0.1–0.3%.

The *N*-haloimides have evoked interest as sources of halonium cations, hypohalite species and imide anions, and some have been used as redox titrants,^{1–11} but their instability is a disadvantage. Recently *N*-bromophthalimide and *N*-bromosaccharin (abbreviated to NBP and NBSA) have been developed as oxidimetric titrants and are reported to be more stable than most of the related *N*-halo compounds.^{7,11–13} These two compounds have been used for the determination of a wide range of compounds,^{14–18} but only a few sulphur compounds. This paper extends the range of sulphur compounds examined.

N-Bromophthalimide
(NBP)

N-Bromosaccharin
(NBSA)

The half-cell for these oxidants (denoted by RNBr) is:

EXPERIMENTAL

Reagents

NBP and NBSA were prepared by bromination of phthalimide and saccharin, respectively, as reported earlier.¹⁵ They are fairly soluble in glacial acetic acid and the stock solutions were prepared by dissolving 11.3 g of NBP (or 13.1 g of NBSA) in 1 litre of anhydrous acetic acid and were kept in amber bottles. The solutions were standardized iodimetrically as for dichloramine-T.¹

Xanthates were prepared by reaction of the corresponding sodium alkoxides with carbon disulphide. The products were dissolved in acetone, the solutions were filtered, and the compounds precipitated by addition of petroleum ether (b.p. 60–80°).¹⁹ Sodium diethyldithiocarbamate was a commercial product and the other dithiocarbamates were prepared by the usual methods.^{20–22} Amines, commercial grade, were distilled before use. All other chemicals used were of reagent grade. The sulphur compounds were standardized by established methods.

Procedure for thioureas

Thioureas are quantitatively oxidized to sulphate:

Thiosemicarbazide reacts as follows

A known volume of the test solution is taken in a 100-ml beaker and 1 g of sodium acetate and 2 or 3 drops of Quinoline Yellow indicator are added. If a sample is dissolved in an organic solvent, enough water is added to make the initial organic solvent concentration 50–60% v/v. The sample is titrated with 0.025*M* oxidant until the yellow colour disappears. For potentiometric titrations the apparatus described earlier³ was used.

Procedure for isothiocyanates

Organic isothiocyanates are quantitatively converted into thioureas with n-butylamine in dimethylformamide at room temperature:

A known volume of a solution of organic isothiocyanate in dimethylformamide is taken in a 100-ml beaker and 3 ml of n-butylamine are added. The solution is diluted to 10 ml with dimethylformamide and after 15 min for completion of the reaction, is titrated in the same way as for thioureas.

Procedure for dithiocarbamates and xanthates

In acetonitrile medium dithiocarbamates and xanthates are quantitatively oxidized according to:

A known volume of the sample solution is dissolved in 20 ml of acetonitrile. About 30 ml of methanol and 50 mg of potassium iodide are added and the mixture is titrated until the colour of iodine appears. The concentration of the organic solvent should be 60–70% v/v.

Procedure for thiols and thiosulphate

Thiols and thiosulphates are quantitatively oxidized to the disulphides and tetrathionate, respectively, according to:

A known volume of sample solution is taken in a 100-ml beaker and diluted with water to make the concentration of organic solvent < 50% v/v; about 50 mg of potassium iodide is added and the analyte is titrated. For visual titrations, the appearance of a pale yellow colour is taken as the end-point

Procedure for elemental sulphur

Elemental sulphur (3–20 mg) is first converted into thiosulphate by dissolving it completely in chloroform or n-heptane (3–5 ml), and adding 5 ml of 1M sodium sulphite. Ethanol is added in small quantities, with shaking of the mixture, until a homogeneous liquid is obtained. The thiosulphate produced is titrated as above, after the addition of 10 ml of 40% formaldehyde solution to mask the excess of sulphite.

Procedure for thiocyanate

An aliquot of sample solution is taken in a beaker, 5 ml of concentrated hydrochloric acid are added and the mixture is titrated. For visual titration 2 or 3 drops of Methyl Orange indicator are added; the indicator is decolorized at the end-point. Oxidation takes place according to:

*Procedure for thiocarbonate*

Thiocarbonate is oxidized to sulphur in the presence of hydrochloric acid and iodide:

A known volume of sample solution is diluted with acetic acid (75% v/v) and 10 ml of 10% v/v hydrochloric acid are added along with 50 mg of potassium iodide. The solution is titrated to appearance of a pale yellow colour.

Procedure for sulphite

Sulphite is oxidized to sulphate according to the equation:

Excess of oxidant is added to a sample of the reductant solution and the surplus is determined by titration with thiosulphate after the addition of 10 ml of 10% potassium iodide solution.

RESULTS AND DISCUSSION

Results of the determinations are given in Table 1. The coefficients of variation show all the methods are precise, but problems arise with certain compounds. In the case of phenyl thiourea, the results were high (but so was the result obtained by the reference method). Allyl thiourea does not react stoichiometrically. Dithiocarbamates and xanthates react with NBP and NBSA in aqueous organic medium, but the reactions are sluggish and the stoichiometry variable. If iodide is present, however, the reaction is rapid and stoichiometric. The apparently low value obtained for diethyldithiocarbamate is presumably due to low purity of the starting material, since the comparison method gave a correspondingly low value. The results for thiols show that the use of aqueous organic media gives sufficiently accurate results, but 3-mercaptopropionic and mercaptosuccinic acid are oxidized beyond the disulphide stage in an unaccountable fashion, and the method is

Table 1 Determination of some sulphur compounds with *N*-bromocompounds

Compound	Range studied, mmole	Recovery,*		Mean recovery by comparison method,† %

not recommended for these compounds. Thio-sulphate reacts quantitatively with NBP or NBSA only in presence of iodide. Elemental sulphur can be determined after conversion into thiosulphate. Thiocyanate can be determined only in the presence of hydrochloric acid, and thiocarbonate is oxidized quantitatively in the presence of hydrochloric acid and iodide. For sulphite no auxiliary agent is needed, but in the direct titration, the results may be low owing to aerial oxidation, so a back-titration procedure is recommended. As is generally the case for oxidants, the selectivity of the methods is largely governed by the redox potentials of the analytes and there is typical interference from Fe(II), As(III), Sb(III), ascorbic acid, hydrazine, semicarbazide and isoniazid.

BOOK REVIEWS

Thermal Analysis: Proceedings of the Fourth European Symposium on Thermal Analysis and Calorimetry, Jena, GDR, 23-28 August 1987 (2 volumes). D SCHULTZE, (editor), Wiley, Chichester, and Akadémiai Kiadó, Budapest, 1988. Pages 1297 \$60 00

These two volumes of the Proceedings of ESTAC 4 contain, bound together in hard covers, the material in the four issues of Vol 33 of the *Journal of Thermal Analysis* devoted to the lectures and papers presented at the symposium. As such, it is in a convenient form for libraries, and others, who may wish to keep Conference Proceedings together and separate from normal journal issues or who do not receive the relevant journal but wish to have a complete set of Proceedings. In addition to reproducing plenary (14) and award (2) lectures, the volumes have sections devoted to papers on theory (17), instrumentation (16), earth sciences and materials (8), solid-state reactions (18), inorganic chemistry, glass, ceramics (55), pharmacy, biology, medicine (34) and final section devoted to assessments (6) of some of the advances recorded. The texts of the plenary and award lectures are given in full and the lengths of the other papers range from 4 to 8 pages, 6 being the most common. All the papers are in English and, being typeset rather than the more common offset from typescript, are very easy to read: the diagrams, too, are very clearly reproduced. However, the paper used in some parts of the volumes is of rather poor quality, with the result that some of the half-tones are not as clear as they might be. An unusual feature is that each plenary lecture is accompanied by a photograph of the lecturer, taken during its delivery—an innovation that, to this reviewer, makes the volumes much less formal and conveys the spirit of friendliness always found among thermal analysts and calorimetrists. It would be invidious to select any of the papers for comment here: suffice it to say that many new ideas and novel approaches are proposed, although, as is usual at conferences, not all papers are of the same scientific standard. Having already been published as parts of a journal, abstracts of all the papers have already appeared in the relevant abstract journals. The quality of the English expression is generally high throughout, indicating careful editing. Moreover, the two volumes have very useful author and subject indexes. Disappointingly, however, the title of the books appears nowhere on the cloth board covers, even on the spine, with the result that once the dust covers are worn or removed, the volumes will be incognizable. Despite this, these two very useful volumes are likely to appear on the bookshelves of many more thermal analysts and calorimetrists than the original parts of the journal, especially so in view of the very moderate cost.

R C MACKENZIE

Thin-Layer Chromatography—Reagents and Detection Methods, Volume 1a: H JORK, W FUNK, W FISCHER and H WIMMER, VCH, Weinheim, 1990. Pages xv + 464. DM148 00

This is an ideal laboratory handbook of reagents and detection methods currently available for use in thin-layer chromatography (TLC). In the first part of the book the theory and methodology of spectrophotometric and, in particular, spectrofluorimetric methods of detection and their use in both qualitative and quantitative analysis are given. The presentation here, which is also characteristic of the rest of the book is clear, simple, logical and easy to follow and understand. *In situ* Pre-chromatographic derivatization techniques such as reactions involving oxidation, reduction, halogenation and danylation are summarized in tabular form. This has enabled the authors to put a large number of illustrative examples into a few pages. Each example quoted is referenced and a brief description of the method, reagent and end-products is given. The judicious selection of examples means that the wide range of applications covered should cater for all interests. In the section on post-chromatographic detection techniques attention is rightly focused on the advantages and disadvantages of the various ways of processing the chromatograms and on the possible errors involved. The concluding section on documentation is essential reading for those involved with, in particular, quality control.

The second part of the book gives in alphabetical order a list of the most commonly used chemical detecting reagents. For each reagent its preparation, the compounds with which it reacts, the reaction, and the method of use are all given. Particularly commendable is the fact that the authors have tested every procedure in their laboratories and have included the results of their tests in full. A good index means that it is relatively easy to find the appropriate reagent for a particular compound or class of compound.

All chapters in both parts of the book are very well referenced. This very up-to-date compact book contains a wealth of readily accessible information which will be of value to any experimentalist involved in TLC.

Chemical Sensors and Microinstrumentation: R W MURRAY, R E DESSY, W R HEINEMAN, J JANATA and W R SEITZ (editors), ACS, Washington, DC, 1990. Pages xii + 410. \$89 95

In considering a book such as this, that is, one devoted to a rapidly advancing field and compiled from the reports of work in progress submitted at a Symposium, (the 196th Meeting of the American Chemical Society, Los Angeles, California,

1988) it is salutary to refer back to accounts of earlier Symposia. If the International Meeting on Chemical Sensors held in Fukuoka, Japan, 1983 is selected for this purpose it can be seen that most of the fundamental concepts were well known at that time, but there have been considerable advances in the technology of construction and instrumentation. Indeed, the papers collected in the present work may be said to be based on three well established techniques, those based on electrochemical measurements, those utilizing piezoelectric crystal oscillators and those using conventional spectrophotometric techniques combined with the use of optical fibres. The most significant developments reported are concerned with the microminiaturization of probes, and so successful have been the attempts to produce microelectrodes that spatial resolutions of the order of $1\ \mu\text{m}$ have been achieved. With such equipment it has been possible to study the concentration gradients in solutions such as those encountered in flow analysis. A further advance has been in the combination of biochemical systems, such as enzymes and polymers, with electrodes so as to produce electrical signals from biologically active molecules, and there have been similar developments in probes based on optical signals. Probably the most interesting research dealt with in the present volume is the modification of piezoelectric devices so as to optimize their response to a particular chemical vapour by stimulating the production of surface acoustic waves. The value of such devices in environmental monitoring is self-evident, one paper reports such an application and it is to be expected that there will be many more. The book is recommended to all practising analytical chemists who may find their work in the future increasingly dependent on the use of chemical sensors.

J. R. MAJER

Instrumental Effects in Homodyne Electron Paramagnetic Resonance Spectrometers: R. CZOCH and A. FRANCIK, Horwood, Chichester, 1989. Pages 395 £45.00

Several factors are contributing to a growth in the usage of EPR spectrometers. These include diagnosis of certain cancers, characterization and quantification of irradiation dosages in foods, and the development of EPR imaging. The appearance of a new book on practical aspects of the technique will therefore arouse considerable interest. Most commercial EPR spectrometers are of the homodyne type and this book is devoted to an examination of the instrumental errors and distortions which can affect the resonance signals. The first three chapters introduce the basic theory and technique and catalogue the main types of random and systematic instrumental effects. Chapters 4–8 deal in detail with particular effects such as those due to saturation and modulation. The heart of the book is a particularly thorough treatment of adsorption and dispersion including sample control distortions from the AFC system. Microwave detection errors, e.g., delay effects, errors of digital processing and truncation errors, background effects and inhomogeneity are also analysed in these chapters. The final part of the book in chapters 9 and 10 describes methods of optimizing instrumental variables and testing the resolution, sensitivity and reproducibility of spectra.

The book has been well translated and provides access to the literature from Russian and Polish sources. It contains an interesting description of an EPR spectrometer produced commercially by the Institute of Telecommunication and Acoustics of the Technical University of Wrocław, which few in the West will have had the opportunity to see. Some of the facts mentioned in this book are quite enlightening. For example, the wings of a Lorentzian line are truncated by random noise and this can lead to errors in the double integral as great as 19% even for S/N ratios of 250! A useful table for the estimation and correction of this error is given.

The authors present detailed mathematical analysis of many of the distortions but, sadly for the non-specialist, few references to computer algorithms are given. This book will appeal to technically minded EPR exponents and should be a useful reference text for those engaged in quantitative analysis by EPR.

J. C. WALTON

Data Analysis in the Chemical Industry: Volume 1, Basic Techniques: R. CAULCUTT, Horwood, Chichester, 1989. Pages 231 £45.00

This book is the first of a series based on the author's manuals for his short courses on applied statistics for industry. However, it has been redesigned as a self-study text, and the author states that he believes many people will learn more by studying the book than they would by attending a four- or five-day course.

The book offers a completely practical approach to statistics, with the use of diagrams and worked examples to explain the aims of the tests described. It is ideal for a chemist who feels intimidated by the equations in a normal statistical text.

The topics covered included quality assessment (mean, standard deviation, confidence limits, confidence interval, tolerance limits), comparisons (combined standard deviation, confidence interval for the difference between two population means), regression, significance testing (t -tests, normal probability plots, outliers, Dixon's test, Wilcoxon's matched pairs test, non-parametric tests), more significance tests and confidence intervals (Wilcoxon's rank sum test, Tukey's quick test, chi-squared test, one-sided and two-sided significance tests), and detecting sudden changes (cusum analysis). All the necessary statistical tests are included.

I recommend this book as an excellent introduction to the practical application of statistics in the chemical industry, and I look forward to the rest of the Series.

MARY MASSON

1988) it is salutary to refer back to accounts of earlier Symposia. If the International Meeting on Chemical Sensors held in Fukuoka, Japan, 1983 is selected for this purpose it can be seen that most of the fundamental concepts were well known at that time, but there have been considerable advances in the technology of construction and instrumentation. Indeed, the papers collected in the present work may be said to be based on three well established techniques, those based on electrochemical measurements, those utilizing piezoelectric crystal oscillators and those using conventional spectrophotometric techniques combined with the use of optical fibres. The most significant developments reported are concerned with the microminiaturization of probes, and so successful have been the attempts to produce microelectrodes that spatial resolutions of the order of $1\ \mu\text{m}$ have been achieved. With such equipment it has been possible to study the concentration gradients in solutions such as those encountered in flow analysis. A further advance has been in the combination of biochemical systems, such as enzymes and polymers, with electrodes so as to produce electrical signals from biologically active molecules, and there have been similar developments in probes based on optical signals. Probably the most interesting research dealt with in the present volume is the modification of piezoelectric devices so as to optimize their response to a particular chemical vapour by stimulating the production of surface acoustic waves. The value of such devices in environmental monitoring is self-evident, one paper reports such an application and it is to be expected that there will be many more. The book is recommended to all practising analytical chemists who may find their work in the future increasingly dependent on the use of chemical sensors.

Ion-Selective Electrodes, 5: E PUNGOR, (editor), Pergamon Press, Oxford, 1989. Pages xv + 675. £85 00, \$135 00

This volume includes the invited lectures, the papers, and an account of all the (sometimes very lively) discussions from the Fifth Symposium on Ion-Selective Electrodes held at Matrafured, Hungary, 9–13 October 1988. The papers, which cover a very wide range of interesting topics, are reproduced from camera-ready copy. The author list includes most of the well known names in the field of ion-selective electrodes. Also included are a tribute to Professor Ernő Pungor, on the occasion of his 65th birthday, by H. Malissa, and some Reflections of the History of Analytical Chemistry in Hungary, by the Historian of Analytical Chemistry, F Szabadváry.

MARY MASSON

Spectrometric Titrations: J POLSTER and H LACHMANN, VCH, Weinheim, Germany, 1989. Pages xvi + 433. DM196.0, £66 00

The title "Spectrometric Titrations" conveyed the wrong message to me about the subject matter of this monograph, however, the sub-title "Analysis of Chemical Equilibria" clarifies matters. The authors choose to distinguish between a photometric titration, in which a spectrophotometer is used to locate the end-point of what we would normally consider to be a titration, and a spectrophotometric titration, which aims to investigate, for the example, the pH-dependence of an absorption spectrum, in order to obtain information about the number and type of dissociable groups in a substance, or establish the corresponding dissociation constants. The authors admit that their use of the word titration is inconsistent with the IUPAC definition, and give their own definition as "controlled displacement of a chemical equilibrium by means of a titration reagent (R), the titrant". My personal opinion is that analytical chemists would be happier without re-definition of well accepted terms such as "titration".

The actual subject matter of the book is a very mathematical treatment of the analysis of the various chemical equilibria that can be studied by making spectrophotometric measurements of a solution at each step in a "titration". The material is nicely presented, with many clear diagrams, aided sometimes by the use of a second colour. There are three main parts, a brief introduction on "The Theoretical and Methodological Basis of Spectrophotometric Titration", a major second one on "The Formal Treatment and Evaluation of Titration Systems", and a shorter final one on the "Instrumental Methods" that can be used to provide the data. Listings of two computer programs for use in data analysis are also included.

Fuel Science and Technology Handbook: J G SPEIGHT (editor), Dekker, New York, 1990. Pages xii + 1193. \$195 00 (U S A & Canada), \$234 00 (rest of the world)

Any reader new to this topic cannot fail to be impressed by its breadth, and all readers will undoubtedly be impressed by the huge amount of information, much of it very recent, which Dr Speight and his team of eight other writers have assembled together in one volume. There are five major sections, dealing with Petroleum (315 pages), Tar sands (119), Coal (355), Oil shale (358) and Natural gas (113). Each section deals with Origin, occurrence and recovery, Terminology and classification, Composition and properties, and Chemicals from each source. Much of the material will be of interest to chemical engineers, but there are substantial sections relevant to pure chemists and also to analytical chemists.

One of the big hurdles for a writer in this field to surmount is that it is impossible to generalize time and again we read "may be as big as, or as little as" as each writer struggles to present an impression of the magnitude of a problem in production, the minimum economic scale for a process or a well, or the estimated-size of known resources. The reader will have to be patient—there is no simple answer to these questions, and likewise, to each simple question there will be as many answers as there are questioners. The authors usually try to give illustrative examples, as in the chapter on natural gas, with typical compositions of "wet" and "dry" gas as a guide and no more.

I found the chapters light on the chemical aspects of production, certainly of gas and oil where there is a lot of chemistry and a widespread use of chemicals in the production processes, but perhaps this was compensated for by the detail in the technology for processing and converting the fuels—gasification and liquefaction of coals, retorting of shales and so on—and also, as in the chapters on natural gas and on petroleum, on the compilation of methods (API and ASTM) for characterizing the materials and measuring their properties. Interesting references are made to the Fischer retorting method for shales, and the extent to which industrial processes can often obtain higher yields than this "standard" analytical method.

Sections on processing tend to have rather many line diagrams which are not particularly informative for most readers, and on pages 52 and 123 we find the same figure for the constituents of petroleum reproduced. While the book is generally well referenced, it is annoying, especially in the introductory chapter, to find frequent reference to earlier works by the editor, rather than to original sources.

A large book, at a large price, and a "mine" of information for engineers in fuel technology, it will be helpful to the analytical chemist first encountering problems in the fuel industries, because it will create a background awareness of the processes and the terminology. For the analytical methods themselves the reader will have to look elsewhere.

I L MARR

Analytical Artifacts GC, MS, HPLC, TLC and PC: B. C. MIDDLEDITCH, Elsevier, Amsterdam, 1989. Pages xxiv + 1033. \$241.50, Dfl 495.00

This catalogue is Volume 44 in the Elsevier Journal of Chromatography Library and contains information on impurities, by-products, contaminants and other artifacts that the analytical chemist may encounter.

Each substance or topic is covered in alphabetical order in an individual monograph. The general format of each substance monograph is common name, nominal mass, mass spectrum, structure, Chemical Abstracts Service name and registry number, Merck Index reference number, synonyms, occurrence of artifact, mass spectra of derivatives and cross-references. Not all substances are given equal treatment and the information can range from a few lines to a few pages of text. A retention index for most toxicologically relevant substances is given pertaining to retention on SE-30 or OV-1 chromatography columns.

Interdispersed between the substance monographs are very useful topics related to general areas of consideration. Examples of contaminants from plastic wash bottles, parafilm, Pasteur pipettes, grease, resins, syringes, filter paper, etc., are mentioned. Cautionary tales of, *e.g.*, changes in trade-names, unusual chromatography results (rat peaks, ghost peaks, pink beards), handling of lunar samples, blood collection devices and turpentine poisoning are mentioned.

It is hoped that the information in this reference work will help prevent publication of analytical reports that draw the wrong conclusions.

For example, an article once claimed to have identified the pheromone emitted by bitches in season to attract male dogs. However, this was later shown to be only a widely used antimicrobial agent.

Some monographs in the text are limited in their content but the excellent indexes and full literature citations make this a very useful compilation—especially for those involved with trace analysis and GC-MS.

KINETIC FLUOROMETRIC FIA DETERMINATION OF TOTAL ASCORBIC ACID, BASED ON USE OF TWO SERIAL INJECTION VALVES

H. K. CHUNG and J. D. INGLE, JR.*

Department of Chemistry, Oregon State University, Gilbert Hall 153, Corvallis, OR 97331-4003, U.S.A.

(Received 30 August 1990. Accepted 27 October 1990)

Summary—The kinetic determination of total ascorbic acid with a flow-injection analysis system is described. The sample is loaded into two serial sample injection valves and injected into a carrier system containing mercuric chloride and *o*-phenylenediamine. The formation of a fluorescent product is monitored. The single-point and double-point kinetic methods are compared by using both peak height and peak area as the analytical signal. A detection limit of 0.1 $\mu\text{g/ml}$ for vitamin C was achieved with a sample throughput rate of 30 per hour.

Several methods have been proposed to use flow-injection analysis (FIA) for analytical kinetic measurements of relatively slow reactions. These methods include the single-point methods in which the peak height or area is taken as proportional to the amount of product formed in a fixed time period,^{1,2} a two-point kinetic assay based on the difference in signals from two flow-through detector cells,³ the stopped-flow technique in which the dispersed sample zone is stopped for a predetermined period when it reaches the detection cell, during which the reaction-rate measurement is performed,⁴ a two-point kinetic method based on the simultaneous injection of the sample with two serial injection valves into one reagent carrier stream,⁵ and a multiple-point method based on an array of detectors along an observation tube.⁶ The single-point kinetic method does not provide the advantages of a true kinetic method because an absolute signal rather than a change in signal is measured. Also, if the sample contains a non-reacting species which contributes to the detector response, an error will result.

Fernandez *et al.*⁷ demonstrated that kinetic information can be obtained in a single-line manifold by injecting a relatively large sample volume (*e.g.*, 1000 μl) into the reagent stream. Two reaction zones and two peaks are produced, because little or no reagent/sample mixing occurs in the middle of the sample zone. The kinetic determinations are based on the

difference in peak heights or areas. Chung and Ingle⁸ proposed a kinetic method also based on injection of a relatively large volume of sample into a single-line manifold, the FIA profile being normalized with respect to sample dispersion. Under proper conditions, the normalized signal increases from the center to the edge of the profile and rate information can be extracted.

Most of the FIA techniques suggested^{1,2,9,10} for determination of ascorbic acid (AA) are single-point methods with electrochemical or spectrophotometric detection.

The purposes of this paper are to demonstrate that a fluorometric kinetic procedure developed for the determination of total ascorbic acid in a conventional fluorometric cell¹¹ is adaptable to FIA measurements, and also to compare kinetic FIA measurements made with the single-point method and a two-point method based on two serial injection valves. The effects of non-reacting interferences and peak height *vs.* peak area measurements are also considered.

EXPERIMENTAL

Instrumentation

All measurements were performed with a microcomputer-controlled single-line FIA manifold and a fluorescence detection system that have already been described.¹² The FIA manifold consists of a valveless positive-displacement carrier-stream pump, two sample-loop injection valves separated by a reaction coil of 400-cm length, and a flow cell (20- μl volume,

*Author for correspondence.

1-mm path-length) for fluorescence measurement. Another pump is used to aspirate sample solutions into the sample loops from the sample reservoir. All connecting tubing in the main line is 0.5-mm i.d. Teflon tubing. The length of tubing between the second injector and the flow cell was approximately 50 cm.

The microcomputer controls the pumps and load/injection position of the sample-injection valves, and the data acquisition, after which it calculates and reports the heights and areas for both peaks and the differences in these quantities. For both valves, the sample-loop volume was 30 μ l, and both sample loops were filled with the same test solution and switched to the injection position simultaneously under microcomputer control. Two FIA peaks are obtained. If a slow reaction occurs between the analyte and reagent carrier stream, the second peak is larger because the sample plug is in contact with the reagent stream for a longer period of time (*i.e.*, there is longer reaction time) and the system can be used to obtain kinetic information.

Solutions and measurement conditions

This FIA system was evaluated for the determination of AA by means of a fluorescence reaction developed for use in a conventional sample cell.¹¹ This reaction involves the rapid oxidation of AA by mercuric chloride to dehydro-*l*-ascorbic acid, which then reacts with *o*-phenylenediamine (OPDA) over a period of several minutes to form a fluorescent quinoxaline. A carrier solution of 1mM mercuric chloride and 50mM OPDA in pH-4.75 acetate buffer was used. Calibration data were obtained from 3 repetitive injections for each standard. A 1- μ g/ml quinine sulfate solution in 0.05M sul-

Fig. 1. Baseline-corrected FIA peaks for the ascorbic acid standards: (a) blank, (b) 1 μ g/ml, (c) 5 μ g/ml, (d) 6.25 μ g/ml, (e) 10 μ g/ml. Injected sample, 30 μ l; flow-rate, 1 ml/min.

Table 1. Calibration data for the determination of ascorbic acid

Quantity*	Magnitude \dagger , counts	Slope \dagger , counts . ml . μ g ⁻¹	Intercept \S , counts
$(S_2)_m$	6995 (0.7)	343 (6.9)	71.7 (40)
A_2	81207 (1.8)	8055 (98)	596 (560)
ΔS_m	2703 (1.5)	284 (5.0)	-134 (29)
ΔA	71014 (1.7)	7150 (70)	-519 (400)

* $(S_2)_m$ = maximum signal for second peak; A_2 = area of second peak; $\Delta S_m = (S_2)_m - (S_1)_m$; $\Delta A = A_2 - A_1$.

\dagger For 10- μ g/ml AA; RSD (%) in parentheses.

\dagger The standard error of the slope is given in parentheses.

\S The standard error of the intercept is given in parentheses.

furic acid was used for calibrating the loop volumes. For measurements of AA, the excitation wavelength was 366 nm (17-nm spectral bandpass) and the emission wavelength was 435 nm (21-nm spectral bandpass). Quinine sulfate (QS) measurements were made under the same conditions except that the emission wavelength was 460 nm.

RESULTS AND DISCUSSION

Figure 1 shows the baseline-corrected FIA peaks. Calibration data are summarized in Table 1 for the second peak (single-point kinetic method) and as rates calculated from the difference in peak heights and peak areas. The calibration plots are linear up to at least 10 μ g/ml AA. Typically, RSD values are 1–2%. The detection limits for AA estimated for all four methods are not significantly different and range between 0.05 and 0.1 μ g/ml. The proposed FIA method provides a simple means to determine vitamin C that should be applicable to pharmaceutical samples. The sample throughput with the present manifold is about 30 samples per hour.

It is important to note that if the sample already contains a fluorophore that does not react in the system but gives a signal under the excitation and emission conditions used, the single-point methods based on peak height or peak area will not discriminate between this signal and the one from the AA reaction. However, the two-point kinetic method does provide partial or complete discrimination against such interferents, depending on the situation. If the volumes of the two sample loops could be made exactly equal, the areas of the two peaks for a non-reacting fluorophore would be identical. This assumption was tested with 1- μ g/ml QS solution. The ratio of the peak areas ($r_A = A_2/A_1$) was 1.012. For the sample loop

volumes used, such a species would contribute only 1.2% of its signal to the ΔA signal for AA. Complete discrimination can be achieved by calculating a corrected difference in area ($\Delta A'$) based on $\Delta A' = A_2/r_A - A_1$.

The effect of non-reacting interferents on the difference in peak heights is much more serious as it depends on the difference in the sample loop volumes and in the dispersion for the two peaks. From the peaks obtained by injecting the 1- $\mu\text{g/ml}$ QS standard, the ratio of the baseline-corrected peak heights (r_p) was 0.342. The dispersion coefficients at the peak maximum are 2.95 and 8.50 for the first and second peaks, respectively. Hence a non-reacting interferent, yielding a maximum signal of S_2 for the second peak, would contribute a signal equal to $-1.92S_2$ to the peak height difference (ΔS_m) for AA. A compensated value ($\Delta S'_m$) can be obtained by calculating from $\Delta S'_m = (S_2)_m / r_p - (S_1)_m$. This possibility was not realized in the original work on the dual-injection kinetic method.⁷

KINETIC DETERMINATION OF ZINEB IN AGRICULTURAL SAMPLES BY CONTINUOUS ADDITION OF REAGENT

M. C. QUINTERO, M. SILVA and D. PEREZ-BENDITO

Department of Analytical Chemistry, Faculty of Sciences, University of Córdoba, 14004 Córdoba, Spain

(Received 16 January 1990. Revised 2 November 1990. Accepted 3 November 1990)

Summary—The technique of automatic continuous addition of reagent has been applied for the determination of zineb in pesticides. The method is based on photometric monitoring of the fast complexation reaction between zinc(II) and Zincon. The special feature of the technique is the direct kinetic measurement, which provides a highly selective determination of zineb at $\mu\text{g/ml}$ levels. The sampling rate of 140 samples/hr makes the method very useful in routine analysis for this pesticide in vine and olive leaves.

The degree of automation achieved in mixing of reagents and samples, and in acquisition and processing of data, has roused increasing interest in kinetic methods of analysis.^{1,2} In this context, the continuous addition of reagent (CAR) technique permits direct rate measurements to be made for systems having half-reaction times in the millisecond region. The theoretical and practical aspects of this technique have recently been discussed.³ It permits continuous recording of the signal as a function of time, and thus provides a kinetic curve. It is a useful alternative to the stopped-flow technique inasmuch as it requires very much simpler (and readily available) instrumentation and is particularly suitable for routine analysis. The feasibility of this approach has been shown for photometric³ and fluorimetric⁴ methods, and has been applied to determination of sulphonamides in pharmaceuticals.⁵

In this work we extend the technique to the determination of zineb, a dithiocarbamate-type pesticide and fungicide used for treatment of fruit and vegetables. In the EEC and U.S.A., tolerance levels are set for dithiocarbamate fungicides, and methods for their determination are important.

Most methods for the determination of zineb are based on its decomposition by digestion with hot acid, and determination of the carbon

disulphide released. Photometric,⁶⁻⁹ gas chromatographic,¹⁰⁻¹² and precipitation titrimetric¹³ methods have been used for the final determination, but these methods are non-specific since any dithiocarbamate pesticide (such as maneb, mancozeb, nabam and amoban) yields carbon disulphide on acid decomposition. Methods based on the determination of the organic component of the pesticide, such as that based on the conversion of zineb into the molybdenum ethylenedithiocarbamate complex,¹⁴ are subject to various interferences. The methods based on analysis for zinc generally use dithizone as the chromogenic reagent, either in homogeneous medium¹⁵ or with liquid-liquid extraction,¹⁶ but will be subject to interference by other heavy-metal dithiocarbamate pesticides such as maneb and mancozeb.

The proposed kinetic method for the determination of zineb is based on acid decomposition of the pesticide and complexation of the liberated zinc with Zincon (2-carboxy-2'-hydroxy-5'-sulphoformazylbenzene), monitored by the CAR technique. It gives a sensitive (dynamic linear range 0.25–3.0 $\mu\text{g/ml}$) and selective determination of zineb that is applicable to commercial formulations and their residues on vegetables. This method is not specific for zineb, as there is interference by other Zn-containing fungicides, such as propineb and ziram, which can be similarly determined. It can be used, of course, to determine the sum of any Zn-containing fungicides present. The potential interference of maneb [since manganese(II) is also complexed by Zincon] is avoided owing to the

special features of the CAR technique, which can be used for the simultaneous kinetic determination of both pesticides, as will be shown in a future report.

EXPERIMENTAL

Reagents

All chemicals were of analytical-reagent grade. All dilute solutions were prepared immediately prior to use. Zineb (Chem. Service Inc., West Chester, PA) was used as supplied. A 250 mg/l. standard solution was prepared by dissolving 25 mg of the pesticide in 2.0 ml of concentrated nitric acid, heating until dissolution was complete and diluting to volume with distilled water in a 100-ml standard flask. The zinc content of this solution was determined by EDTA titration. A stock solution of Zincon ($2.95 \times 10^{-3}M$) was prepared by dissolving 130.0 mg of the chemical in 2.0 ml of 0.1M sodium hydroxide and diluting to 100 ml with distilled water. A 0.1M sodium borate/boric acid buffer of pH 9.0 was also prepared.

Apparatus

The instrumental arrangement has already been described.³ A Radiometer PHM62 pH-meter equipped with a combined glass-calomel electrode was used for pH measurements.

Procedures

Determination of zineb. To the reaction vessel of the CAR system were added a known volume of the standard zineb solution, containing between 15 and 180 μg of the pesticide, and 5.0 ml of 0.1M sodium borate/boric acid buffer of pH 9.0, followed by accurate dilution to 60 ml with distilled water. Then $7.4 \times 10^{-4}M$ Zincon was continuously added at 35 ml/min, with stirring at 200 rpm. The absorbance at 620 nm was monitored. The computer system recorded the full absorbance *vs.* time curve and calculated the initial rate (over a period of about 1 sec) and the zineb concentration.

Analysis of formulations. About 400 mg of sample was weighed accurately into a beaker, 8 ml of concentrated nitric acid were added, and when the brisk evolution of brown fumes had ceased, the solution was heated gently to complete the dissolution, then cooled and diluted to volume with distilled water in a 1-litre standard flask. Suitable volumes were analysed as above.

Analysis of plant residues. Known volumes (0.25–3.0 ml) of ZZ-azul triple micro-formu-

lation suspension (400 mg/l.) were added to vine and olive leaves. The leaves were then dried in the sun and later in the shade. Each sample was extracted with two 25-ml portions of chloroform; the combined extracts were evaporated to dryness and the residue was treated with 2 ml of concentrated nitric acid. When the brisk effervescence of nitrogen dioxide had ceased, the solution was evaporated to low bulk to remove nitrous fumes and most of the acid, diluted to 40 ml with water, adjusted to pH 6–8, placed in the reaction vessel and after addition of 5.0 ml of the pH 9.0 buffer was diluted to 60 ml and analysed as above.

RESULTS AND DISCUSSION

Zineb was determined through its metal constituent, by formation of the complex between zinc(II) and Zincon, which has been widely used for the photometric determination of zinc(II) in a variety of samples.¹⁷ Its application to the determination of zineb requires mineralization of the pesticide, which can easily be done with concentrated nitric acid.

The formation of the Zn-Zincon complex is so fast that its pseudo first-order reaction rate constant could not be determined even by the stopped-flow technique. This accounts for the fact that zinc(II) has not hitherto been determined kinetically by direct complexation with this ligand, but only by ligand-exchange reactions.¹⁸ The singular feature of the CAR technique that allows the kinetic determination of zinc(II) with Zincon is that the reaction then conforms to pseudo second-order kinetics³ and hence the reaction rate is somewhat slower.

The method involves continuous addition of Zincon solution at constant rate to a stirred zinc(II) solution and monitoring of the absorbance of the complex as a function of time, to produce a kinetic curve. The kinetic data thus generated are acquired by the computer at a collection rate of 20 points per second. The slope of the initial linear portion of the curve (initial rate method) is proportional to the analyte concentration and is used as the measurement parameter. Figure 1 shows a typical curve. The slight increase in absorbance at longer reaction times (≥ 3 sec) is due to absorption of light by the excess of ligand. The contribution of Zincon to the initial absorbance changes is negligible.

As the method is based on the reaction of Zincon with free zinc ions, it is necessary to

Fig. 1. Typical absorbance vs. time plot for the determination of zineb ($3.0 \mu\text{g/ml}$) with Zincon. Experimental conditions as described in the text.

mineralize the sample, and preliminary experiments showed that this could best be done by treatment with concentrated nitric acid, which was found to be quantitative.

Effect of variables

The influence of both chemical and instrumental variables on the determination of zineb was evaluated by examining plots of initial rate as a function of the variable. All concentrations quoted are the initial concentration in the autoburette or in the reaction vessel; the effects of dilution were considered small enough to be ignored.

The effect of rate of addition of the Zincon solution was examined over the range 5–45 ml/min. As expected from the theory of the method,³ the initial rate increased linearly with the rate of addition. A rate of 25 ml/min, giving an initial rate midway along the linear portion of the plot, was selected for use, but as the effect of this variable is closely related to that of the Zincon concentration used, both were re-optimized later. The stirring rate is another critical variable. The maximum precision of the initial rate was achieved with a stirring speed of 200 rpm, which gave adequate mixing and avoided eddies (which could result in spurious signals). The effect of the initial volume of sample solution in the cell was studied over the range 60–100 ml. As the amount of zinc taken in the reaction vessel was the same in all the experiments, the initial rate decreased with in-

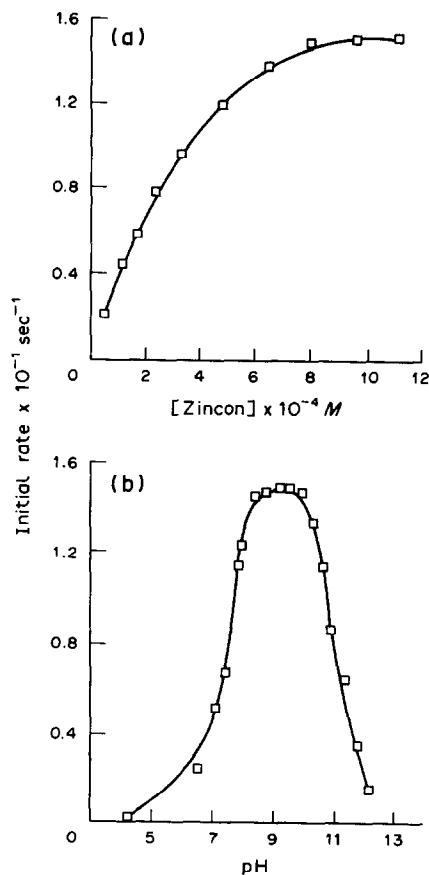

Fig. 2. Dependence of the initial rate on (a) the Zincon concentration and (b) the pH. [Zineb] = $3.0 \mu\text{g/ml}$. Experimental conditions as described in the text.

creasing initial volume. An initial volume of 60 ml was selected as a compromise between that needed to give the maximum initial rate and that needed to accommodate the stirrer and the optical probe so that no bubbles or eddies were produced by the stirring, and the light-path of the probe was filled with solution.

The effect of chemical variables such as the Zincon concentration, the sample pH and the analyte concentration were also examined. Figure 2(a) shows the results obtained by varying the Zincon concentration between 2.95×10^{-5} and $1.03 \times 10^{-3} M$. The initial rate increased with the Zincon concentration up to about $7.5 \times 10^{-4} M$, and then remained constant. A concentration of $7.4 \times 10^{-4} M$, which resulted in the maximum reliability and sensitivity and yielded the best reagent mixing throughout the reaction vessel, was selected. With this reagent concentration, use of an addition rate of 35 ml/min improved the sensitivity. The effect of pH on the initial rate was studied over the range 4–12 and Fig. 2(b) shows that the initial rate

Fig. 3. Experimental (○) and simulated (—) curves for the zinc(II)-Zincon system.

was almost unchanged in the pH range 8.5–9.6. A pH of 9.0 was selected, and was obtained by inclusion of 5.0 ml of 0.1M boric acid/sodium borate buffer (pH 9.0) in the final volume of 60 ml.

Under the optimal conditions thus established, the initial rate was found to be linearly related to the zineb concentration over the range 0.25–3.0 $\mu\text{g/ml}$.

Determination of the pseudo second-order rate constant

The pseudo second-order rate constant of the complexation reaction between zinc(II) and Zincon was determined by using the integrated rate equation governing the method.³ The average value obtained was $k = (9.9 \pm 0.5) \times 10^4 \text{ l. mole}^{-1} \text{ sec}^{-1}$ for use of $7.4 \times 10^{-4} \text{ M}$ Zincon, an addition rate of 35 ml/min and an initial sample volume of 60 ml. To check the validity of the proposed equation a simulated kinetic curve was constructed by using the integrated rate equation and the experimental k value and gave good agreement with the experimental kinetic curve (Fig. 3).

Analytical figures of merit

The initial rate method was applied to absorbance *vs.* time plots recorded for different zinc (or equivalent zineb) concentrations. The features of the analytical method are summarized in Table 1. The sensitivity was taken as the slope of the calibration graph, the detection

limit was calculated according to IUPAC¹⁹ and the precision was determined from analysis of 11 samples each containing 1.0 $\mu\text{g/ml}$ zineb. The throughput was calculated from the time required for three replicate analyses, including the period needed to refill the reaction vessel, and was very high because the kinetic curve is rapidly computed.

The dynamic linear range for determination of zinc(II) was found to be 0.06–0.72 $\mu\text{g/ml}$, which is narrower than that for the conventional photometric determination of zinc(II) with Zincon²⁰ (0.1–2.4 $\mu\text{g/ml}$), but has a lower determination limit.

Interferences

As the pesticide sample is decomposed to release its metal content, pesticides containing no metal ion cannot cause interference and only maneb and copper(II) were tested as interferences, as they often accompany zineb in commercial formulations. Solutions of zineb and maneb (both mineralized with nitric acid) or of copper(II) were mixed to obtain samples containing the equivalent of 1 $\mu\text{g/ml}$ zineb and up to 100 $\mu\text{g/ml}$ interferent. The tolerance ratio of interferent to zineb was taken as the largest giving an error of less than $\pm 3.0\%$ in the initial rate for 1.0 $\mu\text{g/ml}$ zineb. For maneb the ratio was 50, but the CAR technique can be adapted for simultaneous determination of zineb and maneb (to be reported later). For copper(II) (added as the oxychloride) the ratio was 2 but could be increased to 4 by addition of 5 $\mu\text{g/ml}$ cyanide, which is adequate to allow the determination of zineb in commercial formulations containing copper oxychloride. Analysis of samples containing free zinc(II) as well as zineb requires extraction of the fungicide into an organic solvent as described below.

Analysis of commercial formulations and agricultural samples

Zineb, like other dithiocarbamate fungicides, is widely used in agriculture, and is an active ingredient of various formulations used to control leaf diseases in vegetables. The present procedure was applied to the routine determination of zineb in formulations and in vine and olive leaves.

To avoid interference by any free zinc(II) present in the samples, the zineb was extracted into chloroform, and the organic phase was then treated as described above for analysis of plant residues. It was confirmed that all the

*Determination in presence of 0.5 µg/ml cyanide.

free zinc(II) remained in the aqueous phase (the average recovery of zineb in the organic phase was 98.3%).

The method was applied to determination of zineb in a commercial formulation, namely ZZ-azul triple micro (dust, 15% zineb, 20% maneb and 15% copper as oxychloride). Recoveries close to 100% for added zineb were obtained (Table 2). The zineb content in the formulation was found to be $15.4 \pm 0.1\%$, in good agreement with the nominal value given by the manufacturers.

For determination of zineb on vine and olive leaves treated with this pesticide we tested the recoveries from leaves treated with known amounts of ZZ-azul triple micro, and found them to be close to 100% (Table 3).

From the limit of determination by the method (0.25 µg/ml zineb), the initial sample volume in the reaction cell (60 ml) and the mean weight of one vine leaf (0.350 g) or three olive leaves (0.250 g), the limit of determination of

zineb can be estimated as 43 and 60 mg/kg for vine and olive leaves, respectively.

CONCLUSIONS

Zineb concentrations at mM level can be determined by the CAR technique and direct complexation of zinc(II) (released from zineb by nitric acid treatment) with Zincon. The blue complex is rapidly formed and its absorbance can be readily monitored by this new approach, which affords direct rate measurements on the msec time scale. The suitability of the technique for routine determination of zineb in agricultural samples has been demonstrated.

QUANTIFICATION OF VOLATILE SOLVENTS IN BLOOD BY STATIC HEADSPACE ANALYSIS

RUSSELL L. DILLS,* STUART D. KENT, HARVEY CHECKOWAY and DAVID A. KALMAN

Department of Environmental Health, School of Public Health and Community Medicine, University of Washington, Seattle, WA 98195, U.S.A.

(Received 8 August 1990. Revised 19 September 1990. Accepted 5 October 1990)

Summary—A static headspace method for determination of volatile solvents in blood was developed. The solvents determined were 1,1,1-trichloroethane, toluene, xylene (*o*-, *m*- and *p*-), ethylbenzene, styrene, α -methylstyrene and 4-methylstyrene at concentrations ranging from 0.01 to 1 $\mu\text{g/ml}$. Internal standard calibration was used. Parameters affecting sensitivity and precision were determined and optimized.

Volatile organic solvents are common contaminants in the environment and work place. Recent human exposure to these contaminants is most accurately assessed by monitoring the concentration of individual solvents in the blood. One method of quantifying solvent concentration in blood is headspace analysis, in which analytes dissolved in blood are partitioned between the blood and air in a closed system and the concentrations of analytes in the airspace (headspace) over the blood are determined. The concentrations of analytes in the headspace are proportional to their concentrations in the blood.¹

As part of our research in monitoring exposures to environmental and work place contaminants, we wanted a general screening method for blood that could detect low levels of common solvents. The desired quantification limit was approximately the level expected in an average human exposed to a concentration equal to 1% of the occupational guideline suggested by the American Conference of Governmental Industrial Hygienists. Ramsey *et al.*^{2,3} have developed a method for screening volatile organic compounds in blood by headspace analysis. Their method was created for diagnostic use in high-exposure situations occurring with solvent abuse and acute poisoning. They used low-resolution (packed-column) gas chromatography (GC) and did not automate the method. We have therefore developed and validated an automated method for headspace analysis of blood from humans with low-level exposure to solvents.

The method described in this report differs from previously published analyses in that: (a) the quantification limit is lower (as low as 0.01 $\mu\text{g/ml}$ in blood); (b) the system is fully automated, permitting up to 20 hr of unattended operation; (c) the range of volatility for analytes is wide (b.p. 12–170°); and (d) high-resolution gas chromatography is used, permitting discrimination between xenobiotics and background agents.

EXPERIMENTAL

Materials

“Nanograde” toluene was obtained from Mallinckrodt (St Louis, MO). 1,1-Difluoro-1,2,2-trichloroethane was purchased from PCR (Gainesville, FL). 1,1,1-Trichloroethane (TCE), ethylbenzene, *p*-xylene (gold label; inhibited with 10–15 ppm 4-*tert*-butylcatechol), *m*-xylene, *o*-xylene (HPLC grade), styrene (gold label; inhibited with 10–15 ppm 4-*tert*-butylcatechol), 4-chlorofluorobenzene, α -methylstyrene (inhibited with 15 ppm 4-*tert*-butylcatechol), and 4-methylstyrene (inhibited with 0.1% by weight hydroquinone) were bought from Aldrich Chemical Company (Milwaukee, WI). Dimethylsulfoxide (DMSO) was obtained from Burdick and Jackson (Muskegon, MI). Analytical-reagent grade chemicals were used unless otherwise indicated. The styrenes and 1,1-difluoro-1,2,2-trichloroethane were kept refrigerated because of their tendency for slow degradation. The chemicals used for standards were analyzed by gas chromatography/mass spectrometry (GC/MS) for impurities. We noticed some variation of purity in the chemicals,

*Author for correspondence.

depending on source and lot. The sources and grades indicated above were satisfactory.

Gas chromatography

A capillary gas chromatograph with a flame ionization detector (Hewlett-Packard model 5880A; Avondale, PA) was used. The nitrogen make-up gas flow to the detector was approximately 30 ml/min. The detector temperature was 250°. Liquid carbon dioxide was the coolant for sub-ambient temperature programming and was controlled by the sub-ambient temperature control-option available for the 5880A gas chromatograph. The oven temperature control was turned off for the duration of the analyte transfer (5 min), by commands in the run table.

The multi-ramp oven temperature program was as follows: -10° for 5.2 min initial temperature; heating to 40° at 15°/min followed by an 8-min isothermal period; heating to 65° at 4°/min; ballistic heating to 220° followed by a 6-min isothermal period (for post-analysis column conditioning).

A DB-WAX capillary column (30 m × 0.32 mm i.d., 0.25 mm film thickness; J&W Scientific, Folsom, CA) was directly connected to the transfer line of the headspace sampler with a zero dead-volume union (ZU.5TJ with graphite ferrules; Valco Instruments Company, Inc., Houston, TX). If the union became cooled, during sub-ambient temperature programming, for example, split peaks were observed in the chromatogram. To prevent this, the union was placed inside the heated zone of the capillary injector, ensuring that the union remained at 150°. The linear velocity of the helium carrier gas was 20 cm/sec at 150°.

Headspace sampler

A Hewlett-Packard 19395A headspace sampler was used with an 18906A constant heating-time accessory. The headspace sampler hardware and operation have been described by Wylie,⁴ as has the constant heating-time apparatus.⁵ In brief, the headspace sampler maintained samples at a constant temperature for a preselected period prior to sampling. To sample the headspace, the sample vial was first pressurized with helium admitted through a needle piercing the septum of the vial. The vial was then vented, whereby a positive-pressure transfer of the helium/headspace mixture was made to a volumetric injection loop (1 ml). When the loop had been filled, it was switched into the

carrier gas stream and its contents swept into the gas chromatographic column. Operational parameters for analyses with the headspace sampler are shown in Table 1.

Cryotrap

The cryotrap was a brass tube (13 × 0.635 cm o.d.) suspended in the gas chromatograph oven. The gas chromatographic column was centered in the brass tube with graphite ferrules swaged onto the tube ends. When there was a tight seal between the column and the ferrules, multiple split peaks were observed in the chromatogram. We attributed this phenomenon to the existence of cold spots where the column contacted the ferrules. To avoid this phenomenon, the holes drilled in the ferrules were oversized.

Liquid nitrogen was the coolant for the cryotrap and entered it counter-current to the gas chromatographic column carrier-gas flow. The liquid-nitrogen supply was controlled by a solenoid valve that was activated when the headspace sampler probe descended. The cryotrap was cooled for 7 min and then warmed by compressed air until the trap temperature reached approximately 40°. The compressed air was controlled by a solenoid valve activated through the run table.

The coolant flow was regulated to maintain a temperature of -120° (temperature controller, Model 310; Omega Engineering, Stamford, CT). The thermocouple (type J) was attached to a brass screw opposite the liquid-nitrogen inlet. A second thermocouple (type K) was used to monitor the outer surface temperature of the trap. This thermocouple was wired to the "auxiliary temperature 2" sensor input on the 5880A gas chromatograph.

Sample preparation

The recommendations of the Centers for Disease Control for the handling of blood were

Table 1. Operational parameters for headspace analyses

Vial venting duration	2 sec
Injection duration	5 min

*Above atmospheric pressure.

followed.⁶ Blood samples were taken in "vacutainers" containing sodium citrate as an anti-coagulant. Samples were kept at approximately 4° until sample preparation. The "vacutainers" were filled as completely as possible, to minimize the headspace above the blood sample.

To prepare a sample for analysis, 2 ml of water containing 2 mg of sodium azide were placed in a 10-ml crimp-top vial (23 mm o.d., 47 mm in height; Alltech Associates, Deerfield, IL) and frozen. When the ice in the vial began to thaw slightly, 1 ml of blood was pipetted onto the ice with an Eppendorf Combitips pipettor (Brinkman Instruments, Westbury, NY) and an 18-gauge needle. A Teflon-lined butyl rubber septum (Hewlett-Packard, part no. 9301-0976) and an aluminum seal (20-mm o.d. seal without centers; Alltech Associates) were immediately placed on the vial and the seal was crimped. We found that these septa are the most resistant to gas leakage. Once sealed, the vials were stored at 4° until analysis.

Immediately prior to analysis, 10 μ l of an internal standard (a solution of 61 μ g of 4-chlorofluorobenzene and 78 μ g of 1,1-difluoro-1,2,2-trichloroethane per ml in DMSO) were added to the prepared blood sample. The internal standard solution was carefully injected under the surface of the blood-water mixture with a 500- μ l syringe (gas-tight, Luer tip; Hamilton Company, Reno, NV), a PB-600 repeating dispenser (Hamilton), and a 26-gauge needle. The final concentrations of internal standards in the blood were 0.61 μ g of 4-chlorofluorobenzene and 0.77 μ g of 1,1-difluoro-1,2,2-trichloroethane per ml.

Standard preparation

For method validation experiments, standard curves and blanks, out-of-date human blood was used as the matrix. Out-of-date blood was obtained from a local blood bank and was one or two days past its expiry date. The blood was not hemolyzed or septic.

With each set of samples, a set of spiked blood standards was analyzed and a standard curve constructed. The blood was spiked by the same procedure as described for the addition of internal standard to samples. The concentrations of each analyte in the spiking solutions were approximately 1.0, 5.0, 10, 50 and 100 μ g/ml which gave, respectively, concentrations of 0.01, 0.05, 0.1, 0.5 and 1.0 μ g/ml in the blood. Along with the spiked blood standards, a blood

sample containing only internal standard was analyzed as a blank. The result from this blank analysis was used as the zero point in the standard curve.

Standard curves

Standard curves were prepared daily. Peak-area ratios (of analyte to internal standard) were computed. Weighted least-squares linear regression of blood concentration of analyte *vs.* area ratios yielded the slopes and intercepts. When non-weighted linear regression was used, the highest concentration data points had undue influence, causing poor fits of the regression lines at the lower concentration data points. The square-root of the reciprocal of the concentration was used as the weighting factor. Heteroscedasticity was reduced by this weighting scheme. Regressions were performed with the MGLH module of Systat (Systat, Inc., Evanston, IL).

RESULTS AND DISCUSSION

GC parameters

The choice of satisfactory columns was limited. Our primary criterion for chromatographic separation was resolution of the xylene isomers and ethylbenzene. Only columns with a polyethylene glycol stationary phase achieved resolution of these solvents. Columns of 0.25 mm i.d. occasionally became blocked with ice, a problem that was avoided by using 0.32 mm i.d. columns (as had been reported by others^{4,7}). A film thickness of 0.25 μ m was chosen to maximize resolution between the xylenes. Though a DB-wax column afforded resolution of the solvents tested, it did not resolve the most volatile components (Fig. 1).

The connection of the transfer line from the headspace sampler to the gas chromatographic column had considerable influence on the sensitivity and precision of the headspace analysis. When the transfer line was inserted into the split/splitless injector port through the septum, and the injector was operated in the split mode as recommended in the headspace sampler manual,⁸ the sensitivity was not sufficient for our needs. As the split ratio was decreased, the sensitivity increased. However, the precision decreased, and at a split ratio of 10 the coefficient of variation was approximately 20–30%. When the injector was used in the splitless mode, no increase in sensitivity was

Fig. 1. Chromatogram of a spiked blood sample. The concentration of the analytes was approximately $0.1 \mu\text{g/ml}$. Transfer of analytes to the gas chromatographic column was between 0 and 5.7 min. A = 1,1,1-trichloroethane; B = 1,1-difluoro-1,2,2-trichloroethane; C = toluene; D = ethylbenzene; E = *p*-xylene; F = *m*-xylene; G = *o*-xylene; H = 4-chlorofluorobenzene; I = styrene. The methylstyrenes were eluted between 20 and 25 min. 1,1-Difluoro-1,2,2-trichloroethane and 4-chlorofluorobenzene were used as internal standards.

gained, because slow transfer of the analytes from the large volume injector into the capillary column caused gross tailing and distortion of the chromatographic peaks. The solution to the sensitivity and precision problem was to connect the column and transfer line directly. This increased the sensitivity while maintaining the precision at acceptable levels (coefficient of variation $< 10\%$).

Because the gas chromatograph inlet was bypassed by direct connection of the gas chromatographic column to the transfer line, the headspace sampler supplied the gas chromatograph with carrier gas. Assuming continuous and instantaneous mixing of the contents of the 1 ml sample loop with carrier gas incoming at a flow-rate of 1.0 ml/min, the time required for transfer of 99% of the analytes to the column (4.6 min) was calculated by use of a gas dilution equation.⁹ This calculation neglected the small dead volume of the transfer line (0.13 ml). Therefore, the transfer time (injection time) was set at 5 min.

Cryotrap

Because of the 5 min transfer of the headspace mixture, a cryotrap was necessary to focus the analytes that were more volatile than *m*-xylene into a narrow region of the gas chromatographic column. Without the cryotrap, *p*-xylene, *m*-xylene and ethylbenzene were poorly resolved, toluene was not resolved from endogenous volatile compounds in blood, and TCE was not detectable.

The optimum arrangement of coolant flow and heating-air flow was determined. Peak width was minimized when the coolant flow was counter-current to the carrier-gas flow and heating-air flow. Kolb *et al.*⁷ noted that this configuration formed a temperature gradient in the column and reduced the peak width.

Occasionally analytes escaped collection in the cryotrap. This was typically caused by coolant supply problems and was evidenced by breakthrough of the untrapped compounds during the sample transfer. Compounds re-

tained on the column at room temperature, such as styrene, were unaffected by trap failure.

Headspace sampler parameters

The optimum conditions for headspace sampling were determined in a series of experiments with either blood or water as the sample matrix. Blood was used as the matrix when the matrix was likely to influence the optimization. Both response and precision were evaluated during the optimization. The parameters optimized were heating time, sample temperature, the method used to fill the sample loop, equilibration time for headspace vial pressurization, the overpressure and pressurization time.

The sensitivity of headspace analyses has been improved by heating the sample matrix, which increases the concentration of analytes in the gas phase.¹ To determine the effect of sample temperature on the sensitivity and precision, vials containing either 3 ml of water or 1 ml of blood and 2 ml of water were spiked and the headspace concentrations of the analytes were determined. Sample temperature had different effects upon the response for analytes in blood or water as matrix (Fig. 2). For water, the response increased with temperature over the range 40–90° while for blood, the response was maximal at 60°. At higher temperatures, blood coagulated prior to sampling. The partitioning of analyte from a solid (coagulated blood) to air was less efficient than from a liquid to air. The precision, in all cases, was inversely proportional to the response.

To evaluate the effect of sample heating time on the response and precision, replicate headspace vials containing toluene, the xylenes, internal standard and styrene in a water matrix

Fig. 2. The effect of sample temperature on the response for styrene. Headspace samples were equilibrated for 80 min prior to analysis. Two different sample matrices, water and a 1:2 mixture of blood and water, were examined in this experiment. Similar results for other analytes were observed in these two matrices.

Fig. 3. The effect of heating time on response and precision for styrene. Headspace samples were prepared at room temperature and then heated. The heating time is the length of time the sample remained at 60° prior to analysis. Thermal equilibrium was achieved in approximately 5 min. Three replicate analyses were performed for each heating time. Other analytes exhibited similar trends in response and precision. (●) Coefficient of variation; (○) peak area.

were prepared and analyzed with the headspace sampler. As the headspace vials warmed to 60°, a new equilibrium concentration of analyte vapor in the headspace was approached. The vials reached thermal equilibrium in approximately 5 min. However, the concentration of analyte vapor in the headspace continued to rise for at least 80 min (Fig. 3). The coefficient of variation was inversely proportional to the concentration of analyte vapor (Fig. 3). Experiments with blood as matrix showed similar behavior. Thus, the optimum heating time for a sample would be at least 80 min.

Because of the mechanics of the constant heating-time apparatus, the heating time was required to be some multiple of the run time. Each sample was heated for two runs (74 min). Although a longer heating time would have allowed the analytes to reach equilibrium, the next allowable duration (111 min) would have significantly decreased the number of samples analyzed per day. Even though the analytes in the headspace vial were not in complete thermodynamic equilibrium between the phases, reproducible measurements could be made with the constant heating-time apparatus, because the heating period before sampling of the headspace was the same for each vial.⁵

A hyperbolic relationship between response and overpressure was derived from the basic gas laws. Response was proportional to the concentration in the headspace sample (C_s), in this case,

$$C_s = C_i \left(\frac{P_i}{P_i + P_a} \right) \quad (1)$$

where C_i is the concentration of analyte in the headspace prior to pressurization, P_i the initial headspace pressure (atmospheric), and P_a the overpressure (pressurization above atmospheric). This relationship was confirmed experimentally (data not shown). In order to deliver at least 1 ml of helium/headspace mixture to the sample loop, P_a had to be greater than approximately 0.2 bar. There was no discernible relationship between the precision and overpressure.

We confirmed that more analyte was contained in the sample loop when the loop and vial were not completely depressurized as indicated in the instrument manual.⁸ Therefore, the duration of sample venting was set to 2 sec, an insufficient time for complete depressurization. However, we noted that better reproducibility was achieved if P_a was 0.8–1.2 bar, which was higher than the overpressure optimum for sensitivity.

The optimum duration for pressurization and the time allowed for pressure equilibration in the sample vial were determined by replicate analysis of water spiked with analytes. Pressurization required at least 30 sec; shorter times resulted in poor precision and reduced sensitivity. Equilibration time did not affect the sensitivity. However, precision was highest with equilibration times greater than 30 sec.

Sample preparation

For valid measurements, the septum sealing the headspace vial must not allow analyte to escape. By pressurizing the vial and then submerging it under water, we evaluated the integrity of the septum seal, for silicone rubber–Teflon and butyl rubber–Teflon composite septa. Silicone rubber septa leaked after a single puncture with the 26-gauge needle used to add internal standard to the sample. Furthermore, this type of septum did not always form an air-tight seal. However, the butyl rubber–Teflon septa performed excellently and did not leak under 3 bar pressure even after the vial had been punctured five times. Gill *et al.*³ studied the loss of analytes from headspace vials and concluded that either Teflon- or aluminum-lined septa offered the best stability.

The effect of sample volume on response was determined experimentally. Blood (10 ml) was spiked with toluene, ethylbenzene, the xylenes, styrene, α -methylstyrene, and 4-methylstyrene, and a series of headspace vials was prepared, with different volumes of spiked blood. The

samples were then analyzed according to the standard procedure.

The response changed with blood volume as expected, but the magnitude of the change and the optimum volume were dependent on the analyte (Fig. 4). Apparently the compounds that are partitioned to the greatest extent into the air were most affected by the blood volume. Small variations in the blood volume dispensed would be more likely to affect the precision for compounds with a lower affinity for blood.

The relationship between blood volume and response was derived from the mass balance equation describing the partitioning of analyte between the two phases in the headspace vial. The mass balance equation is:

$$V_b C_i = V_b C_b + V_a C_a \quad (2)$$

where V_b is the volume of blood and water mixture in the headspace vial, C_i the concentration of analyte in the blood before partitioning, C_b the concentration of analyte in the blood after partitioning, V_a the volume of air (gas phase) in the headspace vial and C_a the concentration of analyte in the gas phase of the headspace vial after partitioning. By definition the partition coefficient between the blood and water mixture and air ($k_{b/a}$) is given by $k_{b/a} = C_b/C_a$, and the total vial volume is $V_i = V_b + V_a$; substituting these variables in equation (2) and solving for C_a gives:

$$C_a = \frac{V_b C_i}{V_b(k_{b/a} - 1) + V_i} \quad (3)$$

Fig. 4. The effect of sample volume on response. The blood was spiked with a solvent mixture (0.1 $\mu\text{g/ml}$) and various volumes were analyzed according to the procedure described. The standard volume of blood analyzed was 1 ml, to which 2 ml of water were added. The relationship between the blood volume and response is given by equation (3), but as $k_{b/a}$ was not known, least-squares non-linear regression was used to fit an equation of the form $C_a = V_b/(aV_b + b)$, where a and b are constants, to the results. The lines are the regression lines. Similar relationships held for all compounds analyzed. (●) Toluene; (○) styrene; (□) 4-methylstyrene.

The liquid phase is the blood-water mixture.

The sensitivity in headspace analyses can be increased by adding compounds that increase partitioning of the analyte into air. Inorganic salts have greatly increased the sensitivity of analyses for polar chemicals, such as alcohols^{1,10-12} and water-miscible ketones and aldehydes.¹ However, there is very little effect, if any, with non-polar chemicals.^{1,13,14} We have examined several additives which alter the physico-chemical structure of blood. In these experiments, 1 ml of blood was placed in a headspace vial with 2 ml of an additive. Additives were 0.9% saline water, 8M urea, 1M aluminum sulfate and 1 ml of water followed by 1 ml of 4.0M ammonium sulfate. Unadulterated blood (1 ml) was analyzed as a control. Three replicates were analyzed for each additive and control.

The additives which caused the blood to coagulate, ammonium sulfate and aluminum sulfate, increased the variability (Table 2). The importance of preventing blood from coagulating was noted previously, but without explanation.¹⁵ The additives which lysed the blood cells, *i.e.*, water and 8M urea, decreased the variability, as did saline which, in essence, thinned the blood. The response was increased most by addition of water to the blood. The concentrations of chloroform, toluene and styrene in the headspace were previously shown to be increased by hemolysis of blood by water.¹⁶ Hemolysis probably increased the response because it retarded coagulation of the blood. Solid-gas phase partitioning of analytes is less efficient than liquid-gas phase partitioning. In addition, hemolysis probably increased the availability of analytes from the blood cells,

which apparently contain higher concentrations of solvents than the surrounding plasma does.^{17,18}

The effect of sample storage upon response was evaluated. Replicate samples of spiked blood were prepared according to the standard procedure and stored at 4°. Sets of samples were analyzed on the day of preparation, and then 24 and 72 hr later. The response did not decrease during 72 hr of storage. Gill *et al.*³ showed that samples stored without headspace in bottles with Teflon-lined caps did not lose analyte during storage for 30 days.

Standard preparation

Four methods have previously been used to spike blood: direct addition of neat analyte to blood, addition of an aqueous solution of analyte to blood, addition of a blood solution of analyte to blood and addition of analyte in a water-miscible vehicle to blood. The primary goals in preparing standards for headspace analysis were quantitative transfer of the analyte into the liquid phase and rapid achievement of physicochemical equilibrium. Not all these methods could achieve these objectives.

Equilibrium was reached slowly (>24 hr) when immiscible liquids were mixed to prepare standards of halogenated hydrocarbons^{19,20} and aromatic hydrocarbons²⁰ in water. Furthermore, Radzikowska-Kintzi and Jakubowski¹⁵ indicated that introduction of μl volumes of undissolved hydrocarbons into blood samples caused problems with precise dosage. Formation of a micro-emulsion of immiscible solute dispersed in aqueous solution was discussed by Sanemasa *et al.*²¹ Solutions of analytes in blood have been used to spike samples.^{3,15} This ap-

Response was the mean peak area from three replicate analyses. Two ml of additive were added to 1 ml of blood prior to the analyses, except for $(\text{NH}_4)_2\text{SO}_4$ [where 1 ml of water was added, followed by 1 ml of $(\text{NH}_4)_2\text{SO}_4$ solution]. Aqueous solutions were: 0.9% saline, 4.0M $(\text{NH}_4)_2\text{SO}_4$, 1.0M $\text{Al}_2(\text{SO}_4)_3$, and 8M urea. CV is the coefficient of variation.

proach appeared to give good results, with a reported stability of 3 weeks for solutions of aromatic hydrocarbons and TCE. However, storage of blood solutions is problematic for some solvents, because of blood-induced degradation, for example, of esters²² and ethanol.¹¹ Furthermore, blood deteriorates during storage and this is accelerated by sepsis.

We prefer to use a spiking solution made with a water-miscible vehicle. Addition of a second solute to water, in this case the vehicle, has been shown to change the solute-vapor equilibrium constant.^{21,23} These secondary solutes have an influence only when their mole fraction is greater than 5×10^{-3} .²³ For this reason, we used 10 μ l of vehicle, which corresponded to a DMSO mole fraction of 1.5×10^{-3} in the aqueous phase of the headspace vial.

We initially used methanol as the vehicle but found it unsatisfactory because it was eluted early in the chromatogram and interfered with the quantification of TCE and toluene. Therefore, we evaluated several water-miscible solvents as substitutes, namely formamide, DMSO, dimethylformamide, 3,3'-oxydipropionitrile, hexamethylphosphoramide and propylene glycol. Formamide and dimethylformamide contained impurities and the solutions were not stable. A major peak, possibly for a contaminant in the solvent, appeared early in the chromatogram when 3,3'-oxydipropionitrile was used. Their high viscosity made it difficult to transfer solutions in propylene glycol. Hexamethylphosphoramide caused baseline disturbances on the chromatogram and posed additional handling problems because of its toxicity.

DMSO proved satisfactory as the vehicle. It was eluted very late in the chromatogram and did not interfere with any of the analytes. Solutions of the analytes in DMSO were stable when stored frozen at 4°. Freezing and thawing of DMSO solutions of analytes did not affect the analyte concentration. The DMSO solutions used contained only minor (<0.1%) impurities or decomposition products which were eluted before TCE. The impurities were identified by GC/MS as dimethylsulfide and methylsulfide.

Because the internal standard was used to correct for recoveries of analytes, it had to behave similarly to the analytes. We found that one potential internal standard, 4-chlorofluorobenzene, behaved similarly to all the aromatic analytes in method development experiments, but TCE and 4-chlorofluoroben-

zene exhibited different recovery and response as the experimental parameters were changed. To find an internal standard for TCE we therefore examined compounds structurally related to it. Few compounds satisfied the constraint of being chromatographically resolvable from the analytes and common blood components and not being present as an environmental or work place contaminant. 1,1-Difluoro-1,2,2-trichloroethane satisfied these constraints but was not ideal, owing to its slow degradation in aqueous solution at elevated temperatures (60°).

Analytical performance

Standard curves were obtained for six levels of analyte in spiked samples of human blood: 1, 0.5, 0.1, 0.05, 0.01 and 0 μ g/ml. Over this range the standard curve was linear (Table 3). TCE was not reliably quantified below 0.1 μ g/ml because of interference from the peaks of endogenous blood substances. Styrene and toluene had measurable background concentrations; these concentrations fluctuated, depending on the batch of blood used for standard preparation, but were less than 0.1 μ g/ml. The precision of response was calculated for each calibration point (Table 4). The coefficient of variation was generally less than 5%.

CONCLUSIONS

Static headspace analysis is an accurate and useful method for quantifying solvents in blood. Studies performed during development of the method showed that the headspace methodology must be optimized specifically for blood, rather than by use of parameters derived from headspace experiments with aqueous media. For example, procedures used to increase sensitivity in water analyses, such as salting-out, decreased the sensitivity for blood analyses because of their coagulative effects on blood.

Table 3. Linearity of the calibration curves [peak-area ratio, analyte to internal standard, plotted *vs.* concentration (μ g/ml)]

Compound	Intercept*	Slope*	r^2
TCE	0.014 \pm 0.004	0.41 \pm 0.01	0.981

For optimum sensitivity and precision, standards and samples must be prepared and manipulated in a way that minimizes loss of the volatile analytes. For valid quantification with the internal standard method of calibration, the physicochemical properties of the internal standard must be closely matched to those of the analytes; an internal standard that would be adequate for all the compounds investigated could not be found.

ELECTRODEPOSITION ON PYROLYTIC GRAPHITE PLATFORMS FOR ELECTROTHERMAL ATOMIC-ABSORPTION SPECTROSCOPIC DETERMINATION OF LABILE LEAD IN SALINE WATER

(Received 31 October 1989. Revised 25 July 1990. Accepted 3 August 1990)

Summary—A technique for the determination of labile Pb in sea-water has been developed which uses co-deposition with mercury on 6–14-mg pyrolytic graphite platforms, followed by electrothermal atomization of the deposit. Optimization of the applied voltage, pH and sodium chloride concentration with respect to the deposition efficiency yielded a detection limit of 0.15 $\mu\text{g/l}$. Pb for 120-sec depositions with a single platform. As the amount of deposit increases linearly with deposition time up to 5 min and the simultaneous use of two platforms increases the analytical signal by a factor of 1.73, a further improvement is possible. Near-shore sea-water and estuarine water samples containing lead in the concentration range 0.4–1.3 $\mu\text{g/l}$. were analysed with an RSD better than 10%. Background correction was not required as the technique eliminates spectral interferences due to molecular absorption.

Although various techniques can be used for removing or suppressing interferences in electrothermal atomic-absorption spectrometry (ETAAS) methods, there are always limitations to their use, especially when dealing with high-salt matrices. Selective volatilization to remove the interferents prior to atomization is applicable when there is sufficient difference between the volatilities of the analyte and the interferents.¹ For determination of some elements, Zeeman background correction (with platform atomization), chemical modification, selective volatilization and use of peak integration are some of the possibilities for dealing with high-salt matrices.^{2–4} The modification of furnace design has also shown some potential for solving the problems arising from high-salt matrices. However, without separation of the salts from the analyte before the introduction of samples into the furnace, salt build-up at the cool ends of the furnace by condensation can occur rapidly after a few firings.⁵ Moreover, when very low concentrations, close to the detection limit, are involved, which is most

likely for trace metals in sea-water, preconcentration is often necessary.

Of the many preconcentration methods available, those which also separate the analyte from the matrix, such as solvent-extraction, sorption methods and electrodeposition, are more desirable for combination with ETAAS techniques.

Electrodeposition has many advantages in terms of sample size required, concentration factor, simplicity and freedom from contamination. The use of preconcentration by electrodeposition coupled with AAS methods was reported as early as 1967 by Brandenberger and Bader, who concentrated mercury from urine on a copper spiral electrode which was subsequently transferred to the absorption tube for atomization of the deposited mercury.^{6,7} They later extended the technique to determine Cd, Zn, Pb, Tl, Cu, Ag, Au and Pt, using tungsten or platinum wires⁸ in the same manner. Fairless and Bard have successfully used hanging mercury drop electrodes⁹ for electrodeposition and subsequent atomization. The hanging mercury drop electrode was not easy to handle and the mercury drop could not be reproducibly positioned in the graphite furnace, although its

*Author for correspondence.

transfer to a carbon filament was satisfactory. Jensen *et al.* overcame the problem by using a graphite boat to keep the drop in position.¹⁰ The wire methods, which were often followed by electrical heating in a cool inert atmosphere for atomization,^{6-8,11-15} suffer, like the wire loop¹⁶ and carbon rod¹⁷ methods, from recombination and condensation, which reduce the atomic population and cause background absorption. In addition, the residence time of the atoms in the light-path is often very short and spatial inhomogeneity of the atomic population makes selection of the measuring zone critical.¹⁸ Heating the wire (with deposit) in the hot reducing environment of a hydrogen flame^{15,19,20} or a graphite furnace²¹ overcame these problems. Czobik and Matousek²¹ deposited lead from sea-water or a blood digest on a thin tungsten wire, which was then inserted vertically into the centre of a graphite furnace for atomization. This approach combined the advantages of the graphite furnace technique with preconcentration and separation by electrodeposition. However, only a very thin wire was employed, in order to maximize the heating rate and minimize light-loss; the wire had a surface area of 0.012 cm². Thomassen *et al.*²² employed exhaustive electrolysis on a graphite rod, which was then ground and placed in the graphite furnace for atomization. This approach has the advantage of determination of several elements in the ground sample, but is time-consuming and prone to contamination from the several steps involved.

A more elegant development is direct deposition from a recirculated sample onto the inner surface of a graphite furnace tube, as proposed by Batley and Matousek²³ and Volland *et al.*²⁴ This technique was later applied to chemical speciation of chromium in natural water²⁵ and also served as a sampling technique²⁶ by *in situ* deposition of lead and cadmium from sea-water. After the deposition, the graphite tubes can be transported to the laboratory for immediate measurement or stored for later investigation, without any change in the amount of deposit. The efficiency of deposition on the graphite tube inner wall was improved threefold when a nylon insert was used to produce a thin layer flow-through cell configuration, as reported by Frick and Tallman,²⁷ who employed an HGA-2100 graphite tube for the determination of mercury in water samples. The improvement in sensitivity was explained by the increased linear velocity of the solution passing through the

electrode, which resulted in reduced thickness of the hydrodynamic diffusion layer. Toris *et al.*²⁸ designed a flow system for *in situ* deposition on a glassy-carbon furnace cup in the same manner. Only a very narrow linear range (up to 0.02 absorbance) was reported.

In this work, electrodeposition of labile lead from sea-water on a thin pyrolytic graphite platform has been examined. The electrodeposition step was followed by ETAAS determination in a tubular graphite furnace. This approach obviates the need to remove and replace the furnace tube for each determination. Since selectivity is not a problem in the ETAAS method, a simple two-electrode electrochemical system with a fixed applied voltage was used (rather than electrolysis at a cathodic potential controlled with a potentiostat). The effects of electrolysis conditions and atomization parameters have been studied, as well as the possibility of using more than one platform, to increase the sensitivity.

EXPERIMENTAL

Apparatus

A Varian Techtron AA-5 atomic-absorption spectrometer fitted with a Varian Techtron model 90 CRA furnace was used. For time-resolved measurements, the signal from the photomultiplier was processed by a simple current amplifier with an *RC* time constant of 10 msec, and was fed into a Tracor Northern TN-1505 signal averager.

The standard pyrolytic graphite-coated tubular furnaces were positioned between the support rods so that the sample injection hole was blocked by one of the rods to reduce diffusional loss of atoms. Thin platforms with dimensions 6.5 × 2.3 × 0.18 and 6.5 × 2.3 × 0.43 mm were machined from a solid pyrolytic graphite block (Ringsdorff). The finished platforms weighed approximately 6 and 14 mg, respectively.

Electrodeposition

Electrodepositions were done with a regulated d.c. supply with a voltage range of 0–12 V. A Perspex cell equipped with a magnetic stirrer (Fig. 1) was used. The electrode holder (Fig. 2) was machined from Teflon and a nylon screw was used to hold the platform. The platinum wire anode and cathode were inserted through holes drilled through the Teflon holder.

Fig. 1. Perspex cell for electrodeposition.

Reagents

Acetate buffer solutions and mercury(II) nitrate solutions were prepared from Merck "Suprapur" grade chemicals. Isopiastically distilled nitric acid and doubly distilled Milli-Q filtered water (referred to as Milli-Q water) were used throughout. A standard lead solution was prepared from analytical-grade chemicals and diluted with Milli-Q water when needed.

Samples of near-shore sea-water (Sydney) and estuarine water (Port Stephens) were collected in acid-washed polyethylene bottles, filtered through 0.45- μm membrane filters and stored at 4° until analysed.

Procedure

The cell, electrode holder and all glassware were soaked overnight in 1.0M nitric acid and cleaned with distilled and Milli-Q water before use.

A 10-ml sea-water sample was pipetted into the cell, followed by 0.10 ml of $1.5 \times 10^{-2}M$

Fig. 2. Electrode holder.

mercury(II) nitrate solution and 0.05 ml of 1M acetic acid/2M sodium acetate buffer. With Teflon-tipped tweezers, one or two platforms were placed in position in the electrode holder and the nylon screw was tightened. The voltage supply was then switched on and the electrode holder (with platforms) submerged in the stirred solution for the required time. On completion of electrolysis, the assembly was quickly transferred into a beaker containing Milli-Q water, without disconnection of the electrical circuit, and was left there for 15 sec. The platforms were then detached, gently touched with filter paper to remove adhering water, and transferred to the furnace for atomization.

RESULTS AND DISCUSSION

Effect of electrode washing on AA signals

Electrodeposition in the presence of mercury(II) results in formation of a very thin film of mercury with trace metals co-deposited. The thin film is not very stable and can be removed by strong rubbing with a filter paper or by dissolution in acid solution, as confirmed by ETAAS determination of mercury before and after such treatment (Fig. 3). The mercury deposit was virtually unaffected when washed in water, with or without disconnection of the circuit, but traces of sodium chloride remained on the platform, as indicated by the second

Fig. 3. Stability of the thin mercury film, monitored by AA at 253.6 nm. Platform with deposit washed with: A; Milli-Q water; B; Milli-Q water (and then rubbed with filter paper); C; 0.1% HNO_3 ; D; 0.1% HNO_3 , circuit disconnected; E; 1.0% HNO_3 ; F; 1.0% HNO_3 , circuit disconnected. Traces T_w and T_p represent the atomizer wall and platform temperatures, respectively, as measured with a radiational thermometer.

(sodium chloride molecular absorption) peak in trace A.

The effect of acid leaching was confirmed by the results for lead determination after different treatments, as shown in Fig. 4. Pure metallic lead could not be obtained, even with thorough washing of the deposit obtained from sodium chloride solution, because a small amount of sodium chloride was always found to be present on the platform, as manifested by the shift of appearance of the lead peak. For this reason, the peak for metallic lead (trace A in Fig. 4) was obtained by depositing lead from 25 $\mu\text{g/l}$. lead solution in 0.01% nitric acid without any other reagents added, and the platform washed with water thoroughly after deposition. The peak for metallic lead appeared to slightly precede the peak for lead in nitric acid solution, in agreement with the results of Czobik and Matousek.²¹

Figure 4 indicates that treatment with acid reduces the lead signals considerably. The shift to low temperature of the peak in trace B in Fig. 4 is due to residual sodium chloride, since the peak coincided with the lead peak originating from lead nitrate in the sodium chloride matrix (trace D). According to the procedure, the electrode is transferred to the wash solution with approximately 0.05 ml of sample solution

Fig. 4. AA peak appearance for Pb in various forms, measured at 217.0 nm with use of a 14-mg platform. Lead atomized from: A; metallic form; B; deposit following the proposed procedure; C; as for B, but washed with 1.0% HNO_3 ; D; 1 ml of 0.24 mg/l. Pb aqueous standard solution in 100 mg/l. NaCl; E; 1 μl of 0.10 mg/l. Pb in 1.0% HNO_3 . T_w and T_p represent atomizer wall and platform temperatures, respectively, as measured with a radiational thermometer.

adhering to the holder, which is diluted to about 100 mg/l. sodium chloride concentration in the 20 ml of wash water. Attempts to wash the platforms more thoroughly, with running water, to leave only the lead amalgam (which should give a peak appearing at the same temperature as in trace A) were unsuccessful, resulting in poor reproducibility, reduction of the peak height, and inconsistent peak appearances and shapes. Washing by immersion in Milli-Q water was therefore considered suitable, not only for these reasons, but also because of the freedom from contamination.

Effect of pH and applied voltage

The pH of the sample solution and the applied voltage have an important effect on the deposition efficiency in that they influence the degree of hydrogen evolution. Hydrogen evolution could increase the deposition efficiency of lead by contributing to the stirring action, thus reducing the diffusion layer thickness and improving the efficiency, but could also decrease the efficiency by reducing the surface available for lead deposition. In addition, the pH of the sample solution determines the amount of labile lead in the sea-water sample and thus affects the deposition efficiency.

The influence of applied voltage on electro-deposition efficiency was investigated over a wide pH range (Fig. 5). The results showed a sharp increase in the response at above 1.5 V, followed by an equally sharp decrease at above 3.5 V, which may have been caused by hydrogen covering the electrode, as hydrogen bubbles were clearly visible at this stage. The results showed that the optimum signals were obtained at between 2.0 and 3.0 V and these limits were used for the remainder of the experiments. At these applied voltages, the AA signals were only slightly affected by variations of pH between 3.0 and 6.1. The downward shift of the curves for pH 6.8 and 7.5 resulted from the lower availability of labile lead species at these pH values.

Metals in natural systems can occur in various forms, both labile and non-labile, depending on the pH. Batley and Florence have developed an anodic stripping voltammetry (ASV) speciation scheme for heavy metals in natural waters,^{29,30} with a pH of 4.8 as a boundary for labile form discrimination. For this reason, the same pH was used for electro-deposition in order to deposit the metals from their labile forms.

Fig. 5. The effects of applied voltage and pH on Pb AA signals measured at 217.0 nm. Sea-water pH was adjusted by adding μl amounts of 10% v/v HNO_3 , and 10-ml samples were electrolysed in the presence of $1.5 \times 10^{-4} \text{M}$ $\text{Hg}(\text{NO}_3)_2$ for 30 sec.

Effect of mercury(II) nitrate concentration

Mercury-plated electrodes have been shown to improve sensitivity and resolution in ASV analysis,^{31,32} and have found practical use in the determination of amalgam-forming elements by analytical methods employing preliminary electrodeposition, such as voltammetry and chronopotentiometry,³³ ASV³⁴ and a.c. voltammetry.³⁵ The advantage of mercury-plated over unplated electrodes (made of the same material) arises from the increased rate of the electrode processes, owing to amalgam formation. Florence³⁶ obtained the same advantage, for ASV analysis, by simultaneous deposition of mercury and trace metals from sample solutions to which mercury(II) nitrate had been added.

As co-deposited mercury causes no apparent interference in ETAAS analysis, mercury(II) nitrate was added to the sample solution to

maximize the efficiency of electrodeposition. The optimum amount of mercury(II) nitrate was investigated; a $1.5 \times 10^{-4} \text{M}$ concentration was considered to be sufficient for obtaining maximum signals with the present experimental arrangement.

Standard-addition technique with sea-water

Sea-water and estuarine water samples were analysed for lead by the standard-addition technique. The standard-addition plot was linear up to 0.2 absorbance and then only slightly curved up to 0.3 absorbance. The reagent blank was checked by doubling the concentrations of the added reagents and was found to be negligible.

To evaluate the accuracy of the proposed method, the samples were also analysed by ASV (Table 1). The two approaches gave comparable results, considering the ultratrace levels and the difficult matrix. As in some earlier work^{23,26} however, the electrodeposition-ETAAS technique appears to yield consistently higher results. The fact that the ASV analyses were performed under clean-room conditions and this facility was unavailable for the ETAAS work, could be a contributing factor.

It was pointed out by Florence and Batley³⁷ that the recovery of the trace metals added to natural waters cannot be determined by measuring the recovery of an ionic spike unless the water has first been treated to convert all forms of the metal into the free metal ions. It is unlikely that lead will be adsorbed on inorganic colloids at pH 6.0,^{38,39} but lead in sea-water can be adsorbed on organic colloids at the pH employed. For this reason, the standard-addition technique was also applied for lead in 3.5% sodium chloride solution for comparison with the standard-addition plot for sea-water. The slopes in both cases were the same within experimental error, which indicated that the lead added to the sea-water was present in the labile form. In practical terms, this means that analyses can be done with lead standards prepared in 3.5% sodium chloride solution instead of by the more time-consuming standard-addition technique.

Table 1. Results of Pb determination in saline water

Sample	Pb content, $\mu\text{g/l}$.	
	This method*	ASV†
Sea-water (Coojee Bay, Sydney)	0.44 ± 0.05	0.38 ± 0.03
Estuarine water 1 (Port Stephens)	0.65 ± 0.08	0.62 ± 0.05
Estuarine water 2 (Port Stephens)	1.32 ± 0.14	1.20 ± 0.10

*Deposition for 120-sec at 2.0 V, performed in triplicate.

†ASV at pH 4.8 performed in triplicate by G. E. Batley.

However, sea-water from different sources may contain colloidal organic matter which could strongly bind, adsorb or occlude the added lead at the pH used. Accordingly, it is important to realize that the proposed method is limited to the determination of labile lead. Total lead can be determined by digesting the sea-water samples with nitric acid, adjusting the pH and following the method described.

Deposition efficiency

Under certain electrolysis conditions the electrochemical properties of the electrolyte are related to the electrolysis time and the ratio of the original and final concentrations of the analyte, according to equation (1):^{40,41}

$$\log\left(\frac{C_0}{C_t}\right) = \frac{0.43 DA t}{V\Delta} \quad (1)$$

where D is the diffusion coefficient (cm^2/sec) of the species being reduced, A the electrode area (cm^2), Δ the diffusion layer thickness (cm), t the electrolysis time (sec), V the electrolyte volume (ml) and C_0 and C_t the original and final (at time t) concentrations, respectively.

Equation (1) can be rearranged to give

$$\frac{C_0}{C_t} = \exp(DAt/V\Delta)$$

$$\frac{(C_0 - C_t)V}{C_0V} = 1 - \exp(Kt/V) \quad (2)$$

where $K = DA/\Delta$.

In this equation the term $(C_0 - C_t)V$ represents the amount of metal deposited, and the term C_0V signifies the original amount of the analyte metal. It follows that the amount of metal deposited will be proportional to the original amount as long as Kt/V is kept constant. This means that not only exhaustive electrolysis but also substoichiometric electrolysis can be employed.

To increase the deposition efficiency, some of the parameters above were investigated. The diffusion layer thickness was minimized by vigorous mechanical stirring of the electrolyte in the deposition step, and slow stirring during washing of the platform helped to minimize any possible deposition from the wash solution and to protect the deposited film.

Use of a small volume of electrolyte increases the relative concentration factor (C_0/C_t) when the other parameters are kept constant. This alters the concentration of the remaining sol-

ution (C_t) considerably, so repeated deposition from the same sample solution is not feasible. Furthermore, the use of small sample volumes for deposition causes non-linearity in the dependence of deposited amount on time, as can be seen below.

From equation (2)

$$\frac{C_0 - C_t}{C_0} = \frac{Kt}{V} - \frac{K^2t^2}{2V^2} + \dots \quad (3)$$

From the relationship $C_0/C_t = \exp(Kt/V)$, $Kt/V \rightarrow 0$ when C_0/C_t is ~ 1 , so

$$\frac{C_0 - C_t}{C_0} = \frac{Kt}{V} \quad (4)$$

This result implies that the amount deposited is a linear function of time when C_0/C_t is close to unity. This is true for larger volumes of electrolyte. On the other hand, if V is small, C_0/C_t will be greater than unity and the terms following Kt/V in equation (3) cannot be neglected. Under these circumstances, the graph of amount deposited *vs.* time becomes non-linear.

It can be concluded from the reasoning above that although any constant V and t can be employed for preconcentration by electrodeposition, a wider linear relationship between the amount of deposit and time is obtained with larger sample volumes. In addition, repeated depositions can be made from the same solution.

To determine the fraction of lead deposited on the platform when 10 ml of sample solution was electrolysed for 60 sec, the result from direct injection of 1 μl of 0.24 mg/l. lead (0.24 ng) in 100 mg/l. sodium chloride solution onto the platform was compared with the signal obtained by the electrodeposition procedure. On this basis, it was established that under the experimental conditions employed the amount electrodeposited was 0.3% of the total lead content of the sample.

Effect of deposition time

The sensitivity of the electrodeposition-ETAAS method can be increased by extending the deposition period. Theoretically, the amount of metal deposited increases linearly with time when C_0/C_t is close to unity [equation (4)]. This was confirmed experimentally, as a linear relationship was obtained for deposition times of up to 5 min. A longer period of time was not tested, because of the practical consideration of limiting the analysis time, but C_0/C_t can

be calculated from equation (1) to predict whether C_0/C_t will be a non-linear function of t at any deposition time. For example, for 30-min deposition, the fraction deposited will be 8.6% compared with the 0.3% for 1-min deposition, giving a 4.2% deviation from linearity at 30 min in the plot of amount of deposit *vs.* time. The characteristic concentration found for the determination of lead in sea-water with deposition for 120 sec was $0.04 \mu\text{g/l}$.

Effect of sodium chloride concentration

As the sodium chloride concentration influences both the diffusion coefficient (D) and the diffusion layer thickness (Δ) in equation (1), its effect on the slope of the standard-addition plots was investigated. The results (Fig. 6) showed a decrease in the slope with decreasing sodium chloride concentration. These changes are apparently due to the composite effect of D and Δ . The thickness of the diffusion layer decreases with decreasing viscosity. Changes in the sodium chloride concentration can influence speciation of the analyte, and thus the concentration, nature and size of the diffusing species, which alter the value of D . Lead, at the pH employed for sea-water analysis, is present mostly in the form of chloro-complexes.⁴² The lead species in the absence of sodium chloride are likely to be aquo-complexes or free ions. From the results presented in Fig. 6, it is evident that the chloro-complexes have larger diffusion coefficients. This result agrees with the observations of Meites,⁴³ who reported the diffusion current constant (proportional to $D^{1/2}$) to be

greater for lead in 1M hydrochloric acid than in 1M nitric acid.

There are some additional factors influencing D and Δ , such as temperature, but it is not the purpose of this work to examine these aspects in detail. However, the samples to be electrolysed were always brought to room temperature to minimize effects due to temperature variations.

Enhancement of sensitivity with multiple platforms

As the electrodeposition efficiency depends on the surface area of the platform used, the sensitivity of the method can be enhanced either by increasing the surface area of one platform or by atomization of deposits from several platforms. In this work, a two-platform system was investigated. The result obtained by the standard-addition technique with two platforms used simultaneously, agreed with that of the single-platform approach, as shown in Fig. 7. There would be the disadvantage of light-loss by use of more platforms, owing to the obstruction of the light-path, and also difficulty in handling. It was observed in this experiment that light-losses of 3 and 9% occurred for use of two and three platforms, respectively, whereas one platform caused no perceptible loss. The sensitivity achieved with the two-platform system was 1.73 times better than that with a single platform. This is less than the theoretical value of 2, because the heating rate of the two platforms is lower than that of the single platform at the same furnace-temperature setting.

Fig. 6. Effect of NaCl concentration on the slope of standard-addition plots. Sea-water was diluted to various degrees: (□) 100%, (○) 60%, (●) 30%, (△) 0% sea-water. Sea-water (10 ml) containing $1.5 \times 10^{-4}M$ $\text{Hg}(\text{NO}_3)_2$ and acetate buffer (pH 4.8) was electrolysed at 2.0 V for 60 sec.

Fig. 7. Comparison of standard-addition plots for (△) single-platform and (○) two-platform atomization. Experimental conditions are the same as for Fig. 6, except for use of 30-sec deposition time.

Interference effects

Interference effects in this method can originate from both the electrodeposition and atomization steps. In the atomization step, under optimum experimental conditions no molecular absorption was observed, as confirmed by the use of a hydrogen lamp, and, therefore, background correction was not required. However, the small amount of sodium chloride remaining on the platform, though causing no spectral interference, did shift the appearance of the peak to lower temperatures, as seen in Fig. 4. Good reproducibility of peak-height measurements confirmed that a small variation in the amount of sodium chloride adhering to the platform before atomization did not influence the ETAAS determinations. The co-deposited mercury should not cause any interference in the atomization of lead, since it evaporates and atomizes at a temperature well below the appearance temperature of lead. Other metals likely to be co-deposited along with lead from sea-water include Bi, Cu, Cd, Zn, Tl, In, Sb, Mn and Ag. Thomassen *et al.*²² found no interference effect on 50 $\mu\text{g/l}$. lead in the presence of a thousandfold ratio of Cd, Mg, Fe, Mn, Zn or Ni, with exhaustive electrolysis on a carbon rod.

By analogy with the deposition step in thin-film ASV techniques, interference with electrodeposition in this method can occur as a result of competitive reduction of other elements co-existing in the sample solution. Florence⁴⁴ has examined such effects on each of eight species [Bi, Sb(III), Cu, Pb, In, Cd, Tl and Zn] in the presence of all the others plus Ni, Mn and Fe, at 10 times their normal concentration levels in sea-water. He found that the stripping current for Zn was depressed by Cu and Ni as a result of the formation of intermetallic compounds, but no other interferences were observed for ASV of the remaining elements.

Table 2. Reproducibility of the electrodeposition-ETAAS method

Pb concentration in sea-water, $\mu\text{g/l}$.	Mean absorbance (10 replicates)	RSD, %
0.65	0.075	5.7
1.40	0.146	9.3

These observations appear to be confirmed by the present work, as the results for standard addition of lead showed a linear plot and identical slopes for sea-water samples and 3.5% sodium chloride solution.

Reproducibility and detection limit

The reproducibility of the electrodeposition-ETAAS method was evaluated by obtaining the standard deviations for 10 determinations at two different concentration levels (Table 2). The detection limit, defined as the concentration that gives a reading equal to three times the standard deviation of a series of 10 determinations at or near blank level, was calculated to be 0.15 $\mu\text{g/l}$. for 120-sec deposition and use of a single platform. This detection limit is adequate only for the determination of lead in estuarine or near-shore sea-water from polluted areas. For the determination of open-ocean sea-water with lower lead concentration levels, a double-platform system combined with an extension of the deposition time would be necessary.

CONCLUSIONS

This work uses electrodeposition for preconcentration and separation of lead onto thin pyrolytic graphite substrates and then platform atomization for detection by atomic-absorption spectrometry.

Table 3 compares the sensitivity of several methods which use electrodeposition and graphite furnace atomization. The normalized

Table 3. Comparison of characteristic concentrations and electrode surface areas for some electrodeposition-furnace AAS techniques

Technique	Estimated electrode surface area, cm^2	Characteristic concentration, with 5 min deposition, $\mu\text{g/l}$.	Normalized characteristic concentration, $\mu\text{g/l}$.
W wire ²¹	0.012	0.15	0.002

(two platforms)	0.60	0.009	0.0054

*Normalized for 1 cm^2 surface area of electrode.

sensitivity was obtained by assuming linear relationships between the amount of deposit and time, and the amount of deposit and surface area. This assumption was justified in this case, as can be seen from equation (1). The normalized sensitivities for the pyrolytic graphite coated tube and the glassy-carbon cup methods show comparable values, whereas the platform method increased the sensitivity by a factor of about four. This improvement could originate from variations in many factors, such as atomization of lead from different compounds and under different electrodeposition conditions (effects of temperature and electrolyte mobilization). Furthermore, in direct deposition on the furnace tube and cup,^{29,33} the metals are distributed evenly along the furnace length or cup depth, which results in reduced residence time in the light-path for the atoms deposited at the furnace ends. In addition, the cup configuration gives a different pattern of atom loss during atomization.

The tungsten wire method²¹ appears to offer the highest sensitivity. The faster heating rate due to the small mass of the wire and possibly to the high thermal conductivity of tungsten is considered to play an important role in this context. Therefore, for elements with low atomization temperatures, deposition on a tungsten platform followed by atomization in a graphite furnace could give improved results.

DETERMINATION OF LEAD IN HOUSEHOLD REFUSE FLY-ASH BY X-RAY FLUORESCENCE SPECTROMETRY AND A MODIFIED STANDARD-ADDITION TECHNIQUE

MARIT ANDERSSON and ÅKE OLIN*

Department of Analytical Chemistry, Uppsala University, P.O. Box 531, S-751 21 Uppsala, Sweden

(Received 26 April 1990. Accepted 9 October 1990)

Summary—Lead in fly-ash from a garbage incinerator has been determined by X-ray fluorescence spectrometry (XRFS) and a modified standard-addition method. To keep the attenuation properties of the spiked samples constant, decreasing amounts of an attenuation modifier [mercury (II) acetate] were added together with increasing amounts of the standard (lead nitrate). Linearity between fluorescence intensity and amount of lead was thus obtained, so the amount of lead in the sample could be evaluated by linear regression. The amount of modifier needed could be calculated from a simple expression. The method was validated by comparison with the results obtained by applying atomic-absorption spectrometry (AAS) to solutions made by leaching the fly-ash with strong acid. For 8 fly-ash samples, containing between 0.8 and 1.35% lead, the largest absolute difference between the two sets of results was 0.03%. Theoretical calculations based on a simplified version of the Sherman equation were performed to confirm the linearity of the modified standard-addition curves.

The standard-addition method is often used in analysis by instrumental methods when the matrix affects the sensitivity. For most instrumental techniques the relationship between the analytical signal and the amount, or concentration, of the analyte is linear or can be made linear by a simple transformation. The standard-addition function, *i.e.*, the relationship between the analytical signal and the standard addition, can then be evaluated by linear regression to yield the analytical result.

The relationship between line intensity and concentration is non-linear in X-ray fluorescence spectrometry (XRFS).¹ At low analyte concentrations, however, the relationship approaches linearity and the standard-addition method can be used.^{2,3} The concentration range in which linearity can be expected depends on the properties of the analyte as well as on those of the matrix.⁴ The heavier the analyte and the lighter the matrix, the more restricted will the linear range be.

A non-linear variant of the standard-addition function was used previously for the determination of lead in fly-ash from a garbage incinerator.⁵ This analysis represents the case of a heavy absorber in a light matrix. A three-parameter standard-addition function was used

to evaluate the lead concentration from the measurements. The results agreed well with those found by atomic-absorption spectrometry (AAS) applied to solutions obtained by digestion of the samples with strong acid. The method is time-consuming, however, since an increased number of standard additions must be made, owing to the increased number of parameters. Also, the result seemed to be sensitive to small experimental errors, but this was not more closely investigated. We have, therefore, been looking for a method which yields a linear standard-addition plot. The results of this investigation are presented here.

THEORY

In the standard-addition method, additions, b_i , of a standard (B) are made to portions, a_i , of the analytical sample (A) where $i = 1, 2, \dots, N$ is the running number of a portion. The weights of A and B taken can be denoted by a_i and b_i , respectively.

In the "normal" standard-addition method, as applied, for instance, to an AAS analysis of an aqueous sample, the sample portions are of equal size. The portion of sample plus the added standard is diluted to a fixed volume in order to guarantee that the concentrations of the interferences are equal in all solutions used to generate the standard-addition curve. In the standard-

*Author for correspondence.

addition method proposed here for XRFs, such restrictions are unnecessary. Since solid samples are analysed in XRFs, it would be inconvenient to have to weigh out exactly equal amounts of sample. The variation in sample size is allowed for by using the weight taken (a_i) in the derivation of the equations used for the method. The only restrictions on a_i are that the weights can be determined with acceptable accuracy and that the amount is sufficient to make a disk for the fluorescence measurement.

For a heavy element in a light matrix there is no enhancement of the XRF signal and the line intensity, I , can be written as⁶

$$I_i = Q(C_x + y_i C_0) \int_{\lambda_0}^{\lambda_{edge}} \frac{\mu_x(\lambda) J(\lambda) d\lambda}{\mu_A^*(\lambda) + y_i \mu_B^*(\lambda)} \quad (1)$$

where Q is a constant of proportionality, $\mu_x(\lambda)$ the mass-attenuation coefficient of the analyte, $\mu_A^*(\lambda)$ and $\mu_B^*(\lambda)$ are the effective mass-attenuation coefficients of the sample and standard, $J(\lambda)$ is the intensity of the tube spectrum and y_i the ratio b_i/a_i . The integral is taken from the short-wavelength end of the spectrum to the absorption edge of the analytical line.

When the analyte is present at low concentration in the sample, the concept of an equivalent wavelength, λ_e , that is largely independent of small changes in the sample composition, may be applied.⁷ Equation (1) can then be written as

$$I_i = \frac{Q'(C_x + y_i C_0) \mu_x(\lambda_e)}{\mu_A^*(\lambda_e) [1 + y_i \mu_B^*(\lambda_e) / \mu_A^*(\lambda_e)]} \quad (2)$$

where Q' now includes the constant intensity of the excitation radiation. The equation contains three unknown parameters [$Q' \mu_x(\lambda_e) / \mu_A^*(\lambda_e)$; $\mu_B^*(\lambda_e) / \mu_A^*(\lambda_e)$; C_x] and was used in the previous method for the determination of lead in household fly-ash.⁵ The non-linearity of the standard-addition function $I = f(y)$, is caused by the term $y \mu_B^* / \mu_A^*$ in the denominator. Only when this term is small compared to unity, will the function be linear. By dilution of the sample with a diluent, and use of the same size of a_i , y can be made smaller, since smaller standard additions are required. However, for many samples, the addition of a diluent also diminishes μ_A^* , so $y \mu_B^* / \mu_A^*$ might then still inflict a curvature on the standard-addition line.

If additions to the sample can be made so that the denominator of the integrand in equation (1) remains constant, the curvature would be removed. This might be achieved by adding not only the standard but also a second compound,

called the (absorption) modifier. The modifier will be denoted by M and it does not contain the analyte. Equation (1) would then read

$$I_i = Q \left(C_x + \frac{b_i}{a_i} C_0 \right) \times \int_{\lambda_0}^{\lambda_{edge}} \frac{\mu_x(\lambda) J(\lambda) d\lambda}{\mu_A^*(\lambda) + \frac{b_i}{a_i} \mu_B^*(\lambda) + \frac{m_i}{a_i} \mu_M^*(\lambda)} \quad (3)$$

Proportionality between I and the factor involving concentrations will be obtained if the value of the integral can be made constant, *i.e.*, independent of b_i , by a suitable choice of m_i . This would be the case if, for each excitation wavelength, the quantity $z_i(\lambda)$ given by

$$z_i(\lambda) = \frac{\mu_x(\lambda)}{\mu_A^*(\lambda) + \frac{b_i}{a_i} \mu_B^*(\lambda) + \frac{m_i}{a_i} \mu_M^*(\lambda)} = \frac{\mu_x(\lambda)}{\mu_i^*(\lambda)} \quad (4)$$

can be made independent of b_i .

The largest addition of standard, b_N , is usually chosen so that the analyte concentration is increased by a factor of 2–4. This addition will give the denominator of equation (4) its greatest value, $\mu_N^*(\lambda)$, and no modifier is added ($m_N = 0$). The modifier should be added to the other sample mixtures so that $\mu_i^*(\lambda)$ equals $\mu_N^*(\lambda)$. Thus

$$\begin{aligned} \mu_A^*(\lambda) + \frac{b_i}{a_i} \mu_B^*(\lambda) + \frac{m_i}{a_i} \mu_M^*(\lambda) \\ = \mu_A^*(\lambda) + \frac{b_N}{a_N} \mu_B^*(\lambda) \end{aligned} \quad (5)$$

or

$$\begin{aligned} m_i(\lambda) = \frac{\mu_B^*(\lambda)}{\mu_M^*(\lambda)} \left(\frac{a_i b_N}{a_N} - b_i \right) \\ = r(\lambda) \left(\frac{a_i b_N}{a_N} - b_i \right) \end{aligned} \quad (6)$$

For the amount of modifier to be independent of the exciting wavelength, the quotient $\mu_B^*(\lambda) / \mu_M^*(\lambda)$ must be independent of λ . The quotient can be written

$$r(\lambda) = \frac{\mu_B^*(\lambda)}{\mu_M^*(\lambda)} = \frac{\mu_B(\lambda) + G \mu_B(\lambda_f)}{\mu_M(\lambda) + G \mu_M(\lambda_f)} \quad (7)$$

where λ_f is the fluorescence wavelength and G a constant. An approximately constant value of $r(\lambda)$ can be expected only if $\mu_B(\lambda) / \mu_M(\lambda) \sim \mu_B(\lambda_f) / \mu_M(\lambda_f)$. Hence, the modifier and the analyte must absorb the exciting radiation between absorption edges of the same notation. This must also be the case for the analytical line.

Therefore the analyte and the modifier elements in general must be close together in the same period of the periodic table, with the atomic number of the modifier lower than that of the analyte. The factor $\mu_x(\lambda)J(\lambda)$ in the integrand of equation (3) determines the wavelength range in the tube spectrum that is of importance for excitation. In certain cases, only a limited range need be considered and in the limit the exciting spectrum can be replaced by a narrow wavelength range centred around λ_c . In this case $r(\lambda)$ will be given by

$$r(\lambda_c) = \frac{\mu_B(\lambda_c) + G\mu_B(\lambda_r)}{\mu_M(\lambda_c) + G\mu_M(\lambda_r)} \quad (8)$$

and the previous restrictions on the modifier can be slackened.

The value of $r(\lambda)$ can be calculated from equation (7) without knowledge of the composition of the sample. It should also be noted that the modifying element may be present in the original sample. These attributes follow from the additivity of absorption. Once a tentative value of $r(\lambda)$ has been calculated from equation (7) or (8), equation (3) can be used to test by theoretical calculations whether proportionality between I and amount of analyte is indeed achieved.

The value of $r(\lambda)$ is obtained by calculation and an error in $r(\lambda)$ will lead to a systematic error in C_x . The values of the mass attenuation coefficients may vary by up to 10% between different sources. Fortunately, quotients between coefficients, as needed here, are more consistent. An estimate of the error caused in the analytical result by an uncertainty in $r(\lambda)$ is needed. It will be developed for the case when only a single standard addition is made. Excitation by monochromatic radiation will be assumed, in order to simplify the equations. The intensity will then be

$$I_1 = \frac{Q''C_x}{\mu_A^* + rb_2\mu_M^*/a_2} \quad (9)$$

Index 1 refers to the portion to which only modifier is added, and index 2 to the portion to which only the standard is added. The calculated value of $r(\lambda)$ is denoted by r .

In a two-point standard addition, C_x is calculated from

$$C_x = \frac{I_1 \Delta C}{I_2 - I_1} \quad (10)$$

where ΔC is b_2C_0/a_2 , equation (3).

From equations (9) and (10) we obtain

$$\frac{dC_x}{dr} = \frac{dI_1 dC_x}{dr dI_1} = -\frac{C_x I_2 \alpha}{(I_2 - I_1)(1 + \alpha r)} \quad (11)$$

where $\alpha = b_2\mu_M^*/a_2\mu_A^*$. The relative error in C_x , $\Delta C_{x,rel}$, is

$$\Delta C_{x,rel} = -\frac{I_2 \alpha r \Delta r_{rel}}{(I_2 - I_1)(1 + \alpha r)} \quad (12)$$

The influence of moderate values of Δr_{rel} on I_1 is small and the first factor in equation (12) may be regarded as constant. Hence the relative error in C_x is largely determined by, and diminishes with, αr . From equation (7) and the definition of α we find $\alpha r \sim b_2\mu_B^*/a_2\mu_A^*$. This suggests that the standard addition should be kept as small as possible after due consideration of the error in C_x introduced by the uncertainties in the measurement of I_1 and I_2 .

EXPERIMENTAL

Fly-ash samples

The fly-ash samples were obtained from the garbage incinerator in Uppsala, Sweden. The samples, which contained about 1% lead, were homogenized in a mixer. Nitric acid digests of the samples⁵ were used for the AAS determinations.

Reagents

The lead standards were prepared from lead nitrate and contained 80.0 or 40.0 g/l. lead. Solid mercury(II) acetate was used as the modifier. The reagents were of *p.a.* quality.

Apparatus

The X-ray measurements were made with a Philips PW 1410 X-ray spectrometer equipped with a PW 1710 processor. The PbL_α and PbL_β lines and the backgrounds on both sides of a line were measured by use of a scandium/molybdenum dual-anode X-ray tube operated at 60 kV/45 mA, a lithium fluoride crystal (200) and a scintillation detector. The counting time was 5 sec for each line and background measurement. The measurement sequence of background 1, peak, background 2 was repeated three times. Unless spurious peaks appeared, the average from the three repetitions was used to calculate the net intensity.

Sample preparation

Standard additions of lead were made by pipetting 0–2 ml of an aqueous lead standard onto about 4 g of the sample in a Teflon container, drying in a microwave oven, and adding the calculated amount of solid mercury(II) acetate as modifier. Then two steel balls were added and the container was shaken mechanically for 3 min. The disks for the X-ray measurements were prepared as described earlier.⁵ The pressure on the die was 130 MPa and not 11 MPa as erroneously reported previously.

Calculations

The theoretical calculation of the integral in equation (3) and of related quantities was performed as described in a previous communication.⁸

RESULTS AND DISCUSSION

Figure 1 shows the intensities from a fly-ash sample to which standard additions of lead (as the nitrate) had been made. The curvature of the standard-addition graph is clearly visible. An attempt to determine the lead content of the fly-ash by linear regression leads to a gross error. As described earlier,⁵ the lead concentration can be obtained by fitting equation (2) to the data by non-linear regression. This method, however, is sensitive to small experimental errors. It also requires an inconveniently large number of standard additions since three parameters are involved in the regression. Experimental linearization of the standard-addition function as described above was therefore tested.

Mercury, added as the acetate, was chosen as the modifying element. The value of $r(\lambda)$ in equation (7) is 1.07 for the PbL_α line when calculated from the attenuation coefficient

Fig. 1. Line intensity, I , as a function of the ratio between the weights of added lead nitrate and sample, y ; \circ , without modifier; $+$, with modifier.

expression given by Thinh and Leroux.⁹ It is almost independent of the exciting wavelength between the K and L_{III} absorption edges. For the PbL_β line, $r(\lambda)$ varies with the excitation wavelength since this line is absorbed by mercury between the K and L edges but not between the L and M edges (as the PbL_α line is). Hence PbL_α was chosen as the analytical line. Figure 1 also shows the effect of the modifier; the same standard additions were made as in the experiment without modifier. The amount of modifier was calculated from equation (6). A straight line was fitted to the points and the analytical result thus obtained differed by 2% from the result obtained by non-linear regression. In this and similar experiments the correlation coefficient was 0.9999 or better.

A number of experiments were performed to test the concordance of the results obtained with the technique. In one set of experiments the concentration interval of the standard additions was decreased from 4 to 2% but the standard procedure with five additions was maintained.

Table 1. Analytical results obtained with different standard-addition schemes applied to the same specimen of fly-ash; in all experiments mercury(II) acetate was added as an absorption modifier

8	1	4.0	0.771	0.768–0.773
			mean 0.768 ± 0.005	

*An extra 50 mg of mercury(II) acetate was added to each aliquot of fly-ash.

In another set the performance with single standard additions was studied. The results are summarized in Table 1. Ranges rather than relative standard deviations are presented since there were only four replicates. The results demonstrate that the precision of the method is good; the largest deviation from the mean is about 2%. There is no significant difference in results between the various addition modes. The decrease in precision expected for use of small additions (experiments 4–8) does not show up.

The imprecision of a single intensity measurement can be estimated from the primary data to be about 0.5% and seems to be largely independent of the size of the standard addition. It probably arises from the preparation of the disks and their presentation to the spectrometer. The contribution from counting statistics to the imprecision is small, considering that the average of three measurements on each disk was used in the calculation. A calculation of error on the assumption of a constant relative imprecision of 0.5% in the intensity measurement yields an estimated imprecision in the analytical result amounting to 2% for the smallest and 1% for the largest standard addition.

Experiment 2 shows that presence of the modifier in the original sample does not affect the analytical result.

The accuracy of the results was estimated by determination of lead in 8 fly-ash samples, by the single-addition variant, with an addition of 3% of lead. A comparison was made with the results from AAS measurements. The lead con-

tent of the samples varied from 0.8 to 1.35%. The mean absolute difference between the XRFS and AAS results was 0.016% and the largest difference 0.03%. This indicates that the accuracy of the method is good. The results from the XRFS measurements were systematically higher, which might indicate that a small fraction of the lead could have been left behind in the digestion step of the AAS procedure, but this was not further investigated.

The influence of an error in the quantity of modifier was tested, by the single standard-addition variant. To portions of fly-ash (4.00 g) amounts of mercury(II) acetate were added that corresponded to an error of 0, ± 5 , ± 10 , ± 20 , and $\pm 25\%$ in $r(\lambda)$. The intensities from these samples correspond to I_1 in equation (9). These intensities were then combined with measurements, I_2 , on similar samples to which 0.256 g of lead nitrate had been added. The apparent lead concentration of the sample was evaluated from equation (10). The relative error in the result was calculated on the premise that the result obtained with the theoretical r -value was correct. The errors are presented in Table 2 together with the estimates from equation (12). The ratio μ_B^*/μ_A^* needed for the calculation of these estimates was obtained experimentally. Equation (2) was fitted to standard-addition measurements made without modifier, and the parameter μ_B^*/μ_A^* was found to be 2.7 by non-linear regression. The central value of αr is thus 0.17. The agreement between the experimentally determined and estimated errors is fairly good, and most important, the data indicate that the accuracy of the analytical result is not very sensitive to errors in r .

As previously mentioned, $r(\lambda)$ is not constant for the PbL_β line. A computer simulation showed, however, that the exciting radiation is centred around the MoK_α line (0.71 Å), which is close to the absorption edges for lead. The r -value for this wavelength, calculated from equation (8), is 0.55. Calculations indicated that this value of $r(\lambda)$ should yield a linear standard-addition function. This was confirmed by experiment. A linear standard-addition plot (corr. coeff. = 0.9999) was obtained for five additions of lead in the range 1–4%. The lead concentration found from linear regression was 0.775%, which differs by 0.008% (1% relative) from the result obtained with the PbL_α line ($r = 1.07$). As expected, the standard-addition graph for PbL_α was slightly curved for $r = 0.55$. The analytical result from linear regression was in error by about 15%.

Table 2. Relative error ($\Delta C_{x,rel}$) in the analytical result, caused by a relative error (Δr_{rel}) in the value of $r(\lambda)$ used to calculate the amount of absorption modifier from equation (6); the true value of $r(\lambda)$ ($\Delta r_{rel} = 0$; $\Delta C_{x,rel} = 0$) is assumed to be 1.07, as calculated from equation (7) for lead nitrate as standard and mercury(II) acetate as modifier; the experimental conditions are given in the text and C_x was calculated from equation (10) and the estimated relative error in C_x from equation (12)

Δr , %	C_x , %	$\Delta C_{x,rel}$, %

*No modifier added.

CONCLUSIONS

This study indicates that this modified standard-addition method can be used to obtain a linear standard-addition function in XRFS for matrices and analyte concentrations that otherwise would yield a non-linear function. The results also show that good precision is achieved with only one standard addition at an analyte level of about 1%. Compared to dilution techniques, the method suffers only a small reduction in line intensity, which is a distinct advantage.

ADSORPTIVE VOLTAMMETRIC BEHAVIOUR OF IMMUNOGLOBULIN M

JOSE M. FERNANDEZ ALVAREZ¹, MALCOLM R. SMYTH^{1,*} and RICHARD O'KENNEDY²

¹School of Chemical Sciences and ²School of Biological Sciences, Dublin City University, Dublin 9, Ireland

(Received 26 January 1990. Revised 28 May 1990. Accepted 19 September 1990)

Summary—The adsorptive voltammetric behaviour of immunoglobulin M (IgM) has been investigated at the static mercury drop electrode. The stripping process yields an analytically useful signal and the detection limit is $1.2 \times 10^{-10} M$. The adsorptive voltammetric behaviour of IgM has been compared with that of IgG and streptavidin.

Immunoglobulin M (IgM) is a macroglobulin with an approximate molecular weight of 9×10^5 and it accounts for about 10% of the serum immunoglobulin pool.¹ Electron microscope studies of IgM proteins from various species have led to the accepted structure of IgM as a circular pentameric molecule stabilized by disulphide linkages and the presence of an additional peptide J (joining) chain which is thought to assist the process of polymerization prior to secretion by the antibody-producing cell.² Monomeric IgM also exists in low concentrations in normal serum, but can occur in higher concentrations in certain disease states (e.g., systemic lupus erythematosus and Waldenstrom's macroglobulinaemia). Although IgG is by far the predominant antibody produced in most *secondary* antibody responses, IgM is the major class of antibody secreted into the blood in the early stages of a *primary* antibody response.

Adsorptive stripping voltammetry has received much attention in recent years for the determination of a variety of inorganic and organic species which can undergo adsorptive accumulation at electrode surfaces, either directly or following a suitable complexation reaction.^{3,4} We have reported on the adsorptive voltammetric behaviour of a series of proteins^{5–11} and have made use of this technique to monitor different immunological reactions^{5–7} and to assess the stability of chemically modified enzymes.¹⁰ We now present the adsorptive voltammetric behaviour of bovine IgM

and compare it with the behaviour of the monomeric Y-shaped IgG and the globular protein streptavidin.

EXPERIMENTAL

Apparatus

Voltammetric experiments were performed with a Princeton Applied Research Corporation (PARC) Model 303A Static Mercury Drop Electrode (SMDE) (drop area 0.025 cm^2) coupled to a PARC Model 264A Polarographic Analyser and a PARC Model 305 Magnetic Stirrer. Voltamperograms were recorded on a Houston Instruments Model 2000 X–Y Recorder. A platinum wire was used as auxiliary electrode and all potentials were measured *vs.* an Ag/AgCl/satd. KCl reference electrode.

Reagents

Bovine IgM, purified by precipitation and gel filtration, was obtained from Sigma as a 1.1 mg/ml stock solution in 0.05M Tris–HCl, 0.15M NaCl, 0.01M glycine medium with 0.1% sodium azide as preservative. A 0.025M phosphate buffer (pH 7.4) was used as background electrolyte and distilled water was purified using a Waters Milli-Q water purification system. All chemicals used were of analytical reagent grade.

Procedure

Before each voltammetric experiment the electrolyte was purged with oxygen-free nitrogen for 15 min. After addition of the sample the solution was purged for a further 30 sec. The potential was then set at the required accumu-

*Author for correspondence.

lation potential, E_{acc} , for the required accumulation time, t_{acc} , with stirring at 400 rpm. The stirring was stopped automatically and, after a 15 sec equilibrium time, the potential was scanned in the differential pulse (DP) mode in the cathodic direction, with a pulse amplitude of 50 mV, and a scan-rate of 10 mV/sec. A scan-rate of 100 mV/sec was used for linear sweep voltammetry (LSV) and cyclic voltammetric (CV) experiments.

RESULTS AND DISCUSSION

The cyclic voltammetric behaviour of 55 mg/l. IgM at the static mercury drop electrode (SMDE) is shown in Fig. 1. A potential scan performed under solution-phase conditions ($t_{acc} = 0$ sec) gave rise to a very small response, the magnitude of which is close to that of curve *c* in Fig. 1. On the other hand, a symmetrical and well defined peak was obtained when a preconcentration step preceded the potential scan, proving that the substance could be accumulated at the SMDE. The peak potential, E_p , was -0.58 V and the width at half height, $W_{1/2}$, was 60 mV. It can also be seen that the process is irreversible in nature and the peak current

Fig. 1. Multicyclic voltamperograms for a 52.4 mg/l. solution of bovine IgM. Curve *a* was obtained after a t_{acc} of 300 sec; curves *b* and *c* are successive scans at the same drop. Scan-rate 100 mV/sec.

Fig. 2. Effect of the accumulation potential, E_{acc} , (●) and of the starting potential (□) (accumulation at open circuit) on the DP voltammetric responses for a 5.5 mg/l. solution of IgM; t_{acc} 180 sec.

decreases on repetitive scanning at the same drop.

Stripping peaks obtained for a 26.8 mg/l. solution of IgM with accumulation for 120 sec and increasing scan-rates showed the existence of a linear relationship between the current intensity, i_p , and the scan-rate, v , in the range 5–100 mV/sec ($r = 0.9998$; $n = 5$), as expected for an adsorption-controlled process.

Different preconcentration schemes and potential scan modes were examined. Differential pulse voltammetry (DPV) provided analytical signals that were twice as sensitive as those achieved by linear sweep voltammetry (LSV). Accordingly, the DPV mode was selected for the rest of the study. Preconcentration experiments performed under both electrolytic and open-circuit conditions revealed that in both instances IgM was adsorbed at the SMDE.

The influence of the accumulation potential, E_{acc} , on the peak intensity is shown in Fig. 2, where the influence of the starting potential for open-circuit preconcentration experiments is also shown. The use of an E_{acc} of +0.2 V provided the optimum signals, with respect to both the peak intensity and the peak morphology. Under these conditions well defined and symmetrical peaks ($W_{1/2} = 90$ mV) were obtained, whereas for other values of E_{acc} the peaks were broader and somewhat distorted.

It is worth emphasizing that the pattern exhibited by i_p as a function of E_{acc} is closely resembled, but in an inverse way, by the graph of $W_{1/2}$ vs. E_{acc} (Fig. 3). Moreover, when the preconcentration step is performed at open circuit, the peak intensity remains approximately

Fig. 3. Effect of the accumulation potential, E_{acc} , (●) and of the starting potential (□) (accumulation at open circuit) on the peak width at half height, $W_{1/2}$, of the DP voltammetric responses for IgM. Conditions as for Fig. 2.

constant regardless of the potential value at which the scan is started. The magnitude of this peak equals that obtained with electrolytic pre-concentration at $E_{acc} = +0.1$ V, and again the widths of these two peaks are practically the same (Fig. 3).

The range of pH values within which immunoglobulins are active is very limited and, accordingly, the effect of pH on the adsorptive behaviour of IgM was restricted to the range from 7.0 to 8.0. Although there was not a dramatic effect on the peak intensity, a trend to increasing current response with increasing pH was observed. Furthermore, the optimum E_{acc} values were seen to decrease as the pH was lowered and the best analytical signals were obtained for an E_{acc} of +0.15 V at pH 7.4 and for an E_{acc} of +0.05 V at pH 7.0. The pI (isoelectric point) values for immunoglobulins are not known precisely, but they lie in the range 8–9. Besides the hydrophobicity of certain regions of the molecule, the adsorption onto the electrode involves electrostatic interactions,¹² and when the pH is increased towards the pI value, the overall positive charge on the molecule is reduced. In other words, as the pH approaches pI, more of the negatively polarized portions of the molecule become available, favouring adsorption onto an increasingly positively charged electrode.

As expected, the use of increasing pulse amplitudes and larger drop sizes gave rise to an increase in the current. However, larger background currents accompanied the use of higher pulse amplitudes, and optimum operational conditions were established as a trade-off be-

tween sensitivity and signal discrimination. As a consequence, a pulse amplitude of 50 mV and a large drop size were used for further studies.

The effect of increasing accumulation times on the peak currents obtained for increasing concentrations of IgM are shown for three cases in Fig. 4(a). As expected, i_p showed a steady increase with t_{acc} for each concentration until monolayer saturation of the electrode was reached. In addition, there was a linear relationship between the slopes of the accumulation curves and the corresponding concentration, as shown in Fig. 4(b). It is interesting to note that monolayer coverage of the electrode is reached for the pentameric IgM structure at a t_{acc} of ~ 300 sec [Fig. 4(a), curve 3], in contrast to the linear increase of current response up to $t_{acc} = 900$ sec obtained for a similar concentration of IgG.⁶ On the other hand, the first peak observed for IgG⁶ is clearer than that for IgM, indicative of different conformations of the molecules in the adsorbed state, and consequently a different availability of certain regions of each protein to the electrode surface. The fact that the accumulation curves have different intercepts indicates that the adsorption of IgM at the SMDE does not proceed according to a simple Langmuir isotherm. Indeed, a recent paper by Lin *et al.*¹³ has shown that the adsorption of IgG at a clean mica surface occurs through a co-operative process, depending on the formation of aggregates. These workers further demonstrated that isolated molecules are rapidly desorbed from the surface, that ridges of adsorbed molecules are formed during the formation of a monolayer, and that for-

Fig. 4. (a) Effect of the accumulation time, t_{acc} , on the DP voltammetric current for (○) 5.50 mg/l., (□) 8.25 mg/l. and (●) 11.00 mg/l. solutions of IgM. (b) Variation of the slope of the accumulation curves in a with the concentration of IgM. $E_{acc} = +0.1$ V.

mation of subsequent layers does not take place until monolayer formation is nearly complete.

By preconcentrating IgM at the SMDE for 300 sec at the optimum E_{acc} (+0.2 V), and subsequently stripping the adsorbate in the DPV mode under the optimized experimental conditions, a detection limit of 0.11 mg/l. ($1.2 \times 10^{-10} M$) was obtained. The calibration graph was linear between 0.28 and 6.60 mg/l. (3.1×10^{-10} and $7.3 \times 10^{-9} M$) ($r = 0.9996$; $n = 9$) with a slope of 150 ng.l.mg^{-1} . Typical calibration voltamperograms are shown in Fig. 5.

The larger number of disulphide linkages existing in the molecule of IgM^{1,2} could account for the detection limit being lower than that for IgG, even when a shorter t_{acc} was used. However, the linear span of the calibration is one order of magnitude for both molecules, and,

Fig. 5. Effect of concentration on the DP voltammetric current for IgM: 0, blank; 1, 0.11 mg/l. (limit of detection); 2, 0.28 mg/l.; 3, 0.55 mg/l.; 4, 0.83 mg/l.; 5, 1.10 mg/l.; 6, 2.20 mg/l. $E_{acc} + 0.2 \text{ V}$; t_{acc} 300 sec.

which is more important, the slopes of the calibration plots are very similar (150 and 160 nA.l.mg^{-1} for IgM and IgG, respectively) implying that the current produced per unit of concentration is the same.

In conclusion, it is difficult to agree with the assumption usually made in the literature¹⁴⁻¹⁶ that reduction of the disulphide linkages is the only process responsible for the electrochemistry of this type of protein. Recently, we have reported on the electrochemistry of streptavidin, a globular protein which is completely devoid of sulphur-containing amino-acid residues^{17,18} but still undergoes an electrode process at the same potential as the disulphide-containing proteins.¹¹ Emons *et al.*¹⁹ have recently suggested that the voltammetric signal for IgG is due to an interfacial process connected with reversible protein re-orientations in the adsorbed layer and, possibly, with fast faradaic reactions of both adsorbed redox states of the immunoglobulin. It is clear that much more work is required to elucidate the origin of the voltammetric response produced by these proteins.

ACCURACY IN THE PRECISE COULOMETRIC TITRATION OF AMMONIA AND AMMONIUM ION WITH ELECTROGENERATED HYPOBROMITE

AKIHARU HIOKI,* MASAOKI KUBOTA and AKIRA KAWASE

National Chemical Laboratory for Industry, 1-1, Higashi, Tsukuba-shi, Ibaraki 305, Japan

(Received 20 December 1989. Revised 26 October 1990. Accepted 31 October 1990)

Summary—A precise and accurate method in which ammonia and ammonium ions are coulometrically titrated with electrogenerated hypobromite was studied. Through the measurement of the current efficiency for generating hypobromite and the dependencies of titration results on electrolysis current and delay time between sampling and starting electrolysis, precision and accuracy of 0.01 and 0.02%, respectively, were obtained. The accuracy of the titration was compared with that of acidimetric coulometric titration of ammonia.

Since ammonia or ammonium ions can be formed from many nitrogen compounds¹⁻⁵ and water or hydrogen in various materials,^{6,7} the present study is important as a basis of wide application. Coulometric titration is an absolute method, based on Faraday's law, and can yield high precision and accuracy, without the need for a reference material.⁸⁻¹³

Ammonia or ammonium ions react with hypobromite in weakly alkaline solution¹⁴⁻¹⁶ to give nitrogen and bromide, and this reaction has been used in coulometric titration of ammonium ions with electrogenerated hypobromite,¹⁷⁻²¹ which has been applied to determination of some nitrogen compounds.^{20,22-24} The best precision reported¹⁷ was 0.1% for 230 μg of ammonia.

In the present study the dependence of the current efficiency of hypobromite generation on the current density was measured, and the loss of ammonia or ammonium ions, during both the electrolysis and the delay time after sampling, was estimated, and corrections for these factors allowed the total ammonia concentration to be measured with high precision and accuracy. To validate the accuracy, a solution of ammonia in excess of sulphuric acid was prepared, and its oxidimetric coulometric titration was compared with a coulometric acidimetric titration. The coulometric oxidative titration was also used to determine the purity of high-grade ammonium chloride.

EXPERIMENTAL

Reagents

Demineralized water was further purified by isopiestic distillation. Reagent-grade chemicals were used unless otherwise stated. Analytical-reagent grade ammonia solution and ultrapure sulphuric acid were used.

Approximately $2.54 \times 10^{-2} m$ ($m \equiv$ mole per kg of solution) sulphuric acid was used for preparing a solution of ammonia (*ca.* $5.9 \times 10^{-3} m$) in *ca.* $1.27 \times 10^{-2} m$ sulphuric acid. Ammonium chloride was dried for 6 hr at 50° under reduced pressure. An ammonium chloride solution (*ca.* $6.68 \times 10^{-3} m$) was prepared by diluting a solution containing *ca.* 7.16 g of the dried ammonium chloride in 1 kg of water. Each sample solution was kept in a Teflon-PFA bottle. Buoyancy corrections were always applied.

Apparatus

The constant-current source was a model 220 type (Keithley, Cleveland). The electrolysis currents were determined by measuring the voltage drop across a standard resistor (10 or 100 Ω , Type 2792, Yokogawa, Tokyo) in series with the source. The voltage drop was read with a digital voltmeter (Model 8800A, John Fluke, Seattle) calibrated against an unsaturated Weston standard cell (Type 2749, Yokogawa). The linearity of the voltmeter response was confirmed by the fact that ten times the ratio of the voltage drop across the 10- Ω resistor to that across the 100- Ω resistor was unity at different currents. The

*Author for correspondence.

current measurements were accurate to within 0.01% with no dummy load and the error in measuring the electrolysis time was less than 0.001%. The density of the solutions was determined to within 0.00005 g/ml with a DA-101B densimeter (Kyoto Electronics, Kyoto).

The coulometric titration cell (Fig. 1) was equipped with silicone rubber stoppers and a bubble trap to exclude air. The temperature of the solutions was $25 \pm 3^\circ$. Pure nitrogen was

always passed through the solution in the counter-electrode chamber to remove dissolved oxygen.

For the oxidimetry the cell shown in Fig. 1(a) was used. The generation medium was 120 ml of 1M sodium bromide containing 10 g/l. borax and was adjusted to pH 8.5^{17,19}. The solution in the counter-electrode chamber was 80 ml of 10 g/l. borax solution at pH 9.0. The end-point was detected by dead-stop titration with a dual

platinum-plate electrode. The voltage impressed across the two plates [each of surface area *ca.* 2 cm² (one side)] was 150 mV supplied by a d.c. voltage source (E-150A, TOA, Tokyo). The indicator current was obtained as the output of a μ A meter (TR-8641, Takeda Riken, Tokyo), averaged for 5 sec with a digital integrator (RD-202, Tokyo Kagaku, Tokyo) to improve the precision of end-point detection.

For the acidimetry a cell with two centre compartments²⁵ [Fig. 1(b)] was used. The generating chamber contained 100 ml of 1M potassium chloride and the counter-electrode chamber contained 90 ml of 1M potassium chloride and some solid barium carbonate.²⁶ Use of this electrolysis cell eliminates loss of ammonium ions into the counter-electrode chamber.²⁵ The indicator electrode was a combination pH electrode (GST-5211C, TOA), used with a D-150A pH-meter (TOA).

Oxidimetric coulometric titration with hypobromite

Pure nitrogen was passed through the generation medium for 30 min, then the solution, stirred at constant rate, was electrolysed until the indicator current was *ca.* 4 μ A (a stable current was attained in 1–2 min). A 5-g portion of sample solution (weighed to 0.1 mg) was introduced from a gravimetric burette through the sample-inlet tube, which was then rinsed with 5.0 ml of water added dropwise from a transfer pipette. The solution was electrolysed with a continuous current until just before the end-point, and then with successive 1-sec pulses of 10 mA until the indicator current was *ca.* 4 μ A. The generating efficiency of the pulses was $\geq 99.7\%$ of that of the continuous current, and this slight difference caused only a negligible error. A stable indicator current was attained after 1–2 min. The indicator current exhibited slight upward curvature just before the end-point and the intersection of extrapolations of the linear portions was used as the end-point. Five successive measurements were made in the same batch of generation medium, resulting in successive decreases in the sodium bromide concentration from (12/13)M for the first titration to (12/17)M for the last. The Faraday was taken as 96485 C/equivalent.^{27–29} Any systematic error in the end-point determination was regarded as self-cancelling in this method.^{17,19,30,31} By treating the first of the five measurements as a pretitration, the effect of impurities in the generation medium was minimized.³¹ Formation of hypo-

bromite from bromide by oxygen is negligible, so any oxygen produced in the generation medium during electrolysis or present dissolved in the sample solution could be ignored. The time elapsed between the addition of sample solution and the start of electrolysis was recorded.

Acidimetric coulometric titration

The inflexion point on the titration plot can be regarded as the equivalence point in this case.^{32,33} For sulphuric acid, the end-point was taken as being indicated by a pH of 7.00, which was sufficiently close to the inflexion point. Pure nitrogen was continuously passed through the generation medium at pH 5.2, and after 1 hr the electrolysis was conducted with 1-sec pulses of 10 mA until the pH rose to *ca.* 8. A stable pH value was obtained in 2 min. A 25-g portion of the sample solution was then introduced through the sample-inlet tube, which was rinsed with 5.0 ml of water. The solution was electrolysed with a continuous current of 50 mA until the pH reached 5.4, corresponding to *ca.* 99.7% completion of the titration, nitrogen being continuously passed over the solution. Nitrogen was passed through the solution for a further hour, and the titration was then completed with 1-sec pulses of 10 mA. The efficiency of the pulse was 99.7% of that of the continuous current and this difference could be neglected. The generation medium was used for only one measurement. For titration of a solution of ammonia in excess of sulphuric acid, the inflexion point was used to locate the second end-point.

RESULTS AND DISCUSSION

Current efficiency

According to Bishop,³⁴ the efficiency of coulometric generation of hypobromite is close to 100%. Current density and electrode potential measurements have been utilized to ascertain the efficiency of coulometric generation.^{35–37} The relation between the anode potential measured with respect to an SCE (HC-205C, TOA) and the current was determined. A Luggin capillary filled with agar gel (30 mg/ml agar in 4M potassium chloride) was used as a liquid junction and kept *ca.* 2 mm from the anode surface. The potential was measured in the region where the anode was closest to the sintered glass disk.

When five successive additions of 5 g of $6.68 \times 10^{-3}m$ ammonium chloride and 5.0 ml of

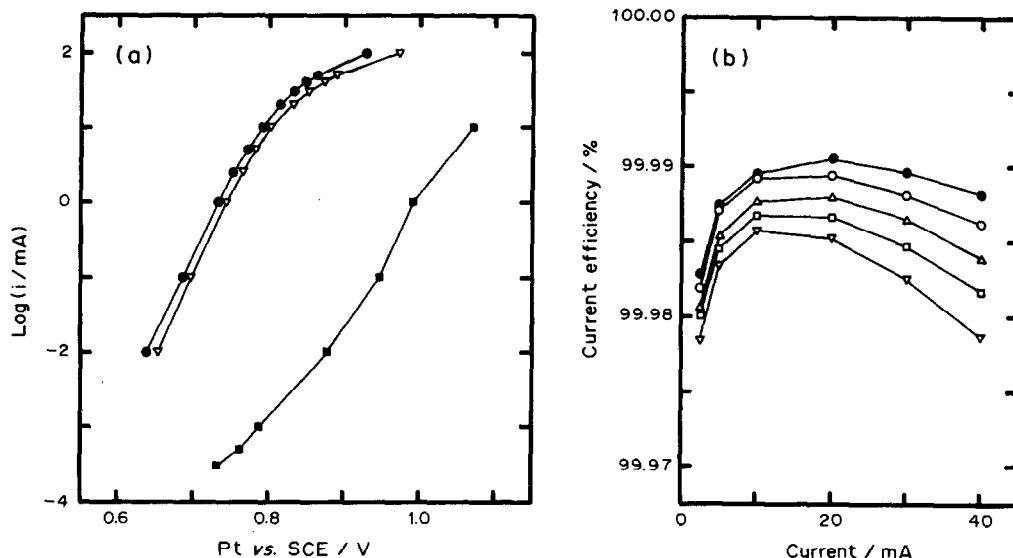

Fig. 2. (a) Relation between current and electrode potential. (b) Dependence of the current efficiency on the current. ●: $[\text{NaBr}] = (12/13)M$; ○: $[\text{NaBr}] = (12/14)M$; △: $[\text{NaBr}] = (12/15)M$; □: $[\text{NaBr}] = (12/16)M$; ▽: $[\text{NaBr}] = (12/17)M$; ■: $[\text{NaBr}] = 0$. Anode area (one side), 20 cm^2 .

water were made to the 120 ml of generation solution containing sodium bromide, the anode potential [Fig. 2(a)] and the solution pH were practically unaffected by the degree of dilution. The anode potential in the 10 g/l. borax solution, (adjusted to the same pH, 8.5, as that in the presence of sodium bromide) was also independent of dilution with water, but the pH decreased to 8.4 after addition of 50 ml of water. The efficiency of hypobromite generation can be calculated from the ratio between the currents in the presence and absence of sodium bromide at a given anode potential.³⁷ Figure 2(b) shows the dependence of the generation efficiency on both the current and the dilution. Corrections were applied on the basis of Fig. 2(b).

Oxidimetry of ammonium ions in sulphuric acid medium

Figure 3(a) shows the effect of the generation current on the oxidation of ammonium ions in sulphuric acid medium, when the delay time was 5 min. The ordinate represents the concentration found relative to the mean value ($5.86089 \times 10^{-3}M$) found by electrolysis at 20 mA. There is a maximum variation of about 0.06% for replicate determinations at a given degree of dilution of the sodium bromide solution. The repeatability of 7 determinations [electrolysis current 20 mA, delay time 5 min, and sodium bromide concentration $(12/14)M$] corresponding to the maximum variation gives an sd of 0.019%. Since the values shown in

Fig. 3(a) decrease approximately linearly with the time needed for electrolysis [Fig. 3(b)], it is thought that the values obtained at the lower currents might be smaller owing to loss of ammonia by volatilization or diffusion into the counter-electrode chamber. If ionic migration of ammonium ions were the cause of the lower values in Fig. 3(a), the loss should depend only on the total quantity of electricity and be independent of the time needed for the electrolysis. The ionic migration of the ammonium ion should depend on its ability to transfer charge during the electrolysis, *i.e.*, it depends on the ionic mobility³⁸ of sodium, bromide and ammonium ions, and on the concentration ratio between the ammonium ion and sodium bromide. The error caused by ionic migration was estimated as less than 0.005%, in terms of loss of ammonia during the electrolysis.

The parameters for the individual regressions [Fig. 3(b)] are as follows: numbers of data, slopes (%/min) and intercepts (%) for the dilution steps 2, 3, 4 and 5 are 11, -2.15×10^{-3} (0.29×10^{-3}) and 100.013 (0.008), 8, -1.52×10^{-3} (0.32×10^{-3}) and 100.005 (0.007), 9, -1.63×10^{-3} (0.24×10^{-3}) and 100.026 (0.006), and 8, -1.26×10^{-3} (0.32×10^{-3}) and 100.000 (0.012), respectively, where values in parentheses are the corresponding standard deviations. Since the intercepts did not differ significantly, the regression lines in Fig. 3(b) were recalculated on the basis of a common intercept (100.011%, s.d. 0.004%) for the

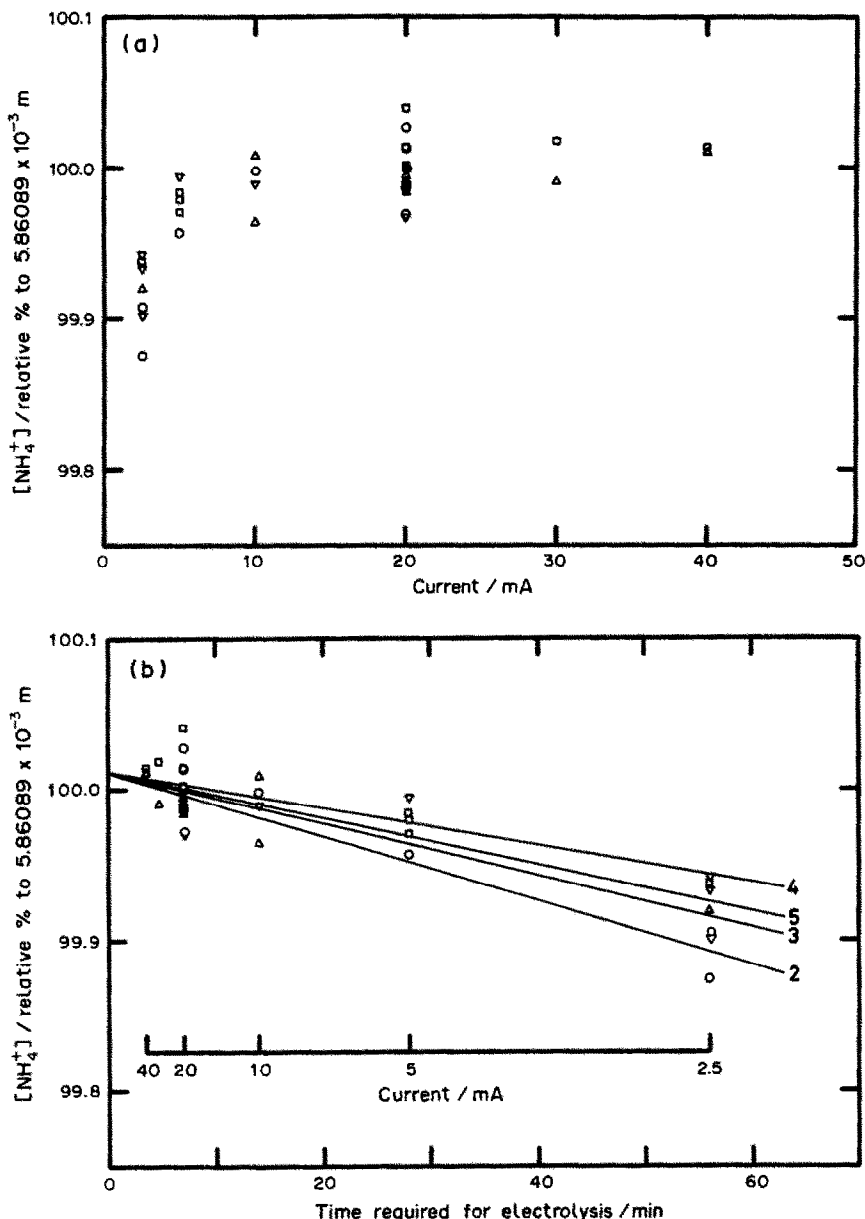

Fig. 3. Dependence of the results for the solution of ammonia in sulphuric acid, obtained by coulometric titration with hypobromite ions, on (a) the electrolysis current and (b) the time required for electrolysis. \circ : $[\text{NaBr}] = (12/14)M$; \triangle : $[\text{NaBr}] = (12/15)M$; \square : $[\text{NaBr}] = (12/16)M$; ∇ : $[\text{NaBr}] = (12/17)M$ [corresponding to 2, 3, 4 and 5, respectively, on the calculated lines in Fig. 3(b)]. Delay time before starting electrolysis, 5 min.

data of the four steps of dilution, and the slopes (%/min) for the dilution steps 2, 3, 4 and 5 became -2.11×10^{-3} (0.23×10^{-3}), -1.71×10^{-3} (0.31×10^{-3}), -1.21×10^{-3} (0.26×10^{-3}) and -1.52×10^{-3} (0.19×10^{-3}), respectively. At currents > 10 mA, there is little difference among the results obtained for the successive runs.

Figure 4 represents the effect of the delay time on the results obtained for the sulphuric acid solution of ammonia, with electrolysis at 20

mA. The loss of ammonium ions was directly proportional to delay time.

The parameters for the regressions were calculated as for Fig. 3(b): the numbers of data, slopes (%/min) and intercepts (%) for the dilution steps 2, 3, 4 and 5 are 11, -6.68×10^{-3} (0.71×10^{-3}) and 100.022 (0.009), 8, -6.41×10^{-3} (0.77×10^{-3}) and 100.019 (0.012), 8, -7.56×10^{-3} (0.57×10^{-3}) and 100.048 (0.009), and 8, -5.60×10^{-3} (0.75×10^{-3}) and 100.016 (0.014), respectively.

Fig. 4. Dependence of the results for the ammonia solution in sulphuric acid, obtained by coulometric titration with hypobromite ions, on the delay time before starting the electrolysis. Electrolysis current, 20 mA. Symbols *etc.* as for Fig. 3.

The regression lines in Fig. 4 were calculated on the basis of a common intercept (100.025%, s.d. 0.006%) for the data of the four steps of dilution, and the slopes (%/min) for the dilution steps 2, 3, 4 and 5 are -6.87×10^{-3} (0.60×10^{-3}), -6.75×10^{-3} (0.58×10^{-3}), -6.45×10^{-3} (0.54×10^{-3}) and -5.99×10^{-3} (0.47×10^{-3}), respectively.

The total concentration of ammonia was obtained by correcting the intercept for the loss of 0.011% occurring during the electrolysis at 20 mA, and found to be $(5.8630 \pm 0.0008) \times 10^{-3}m$. The accuracy was estimated from the sd (0.0056%) of the intercept in Fig. 4, the sd (0.003%) of the loss at 20 mA, estimated from Fig. 3(b), the error (less than 0.005%) of measuring the 20-mA current, and the negative error (less than 0.005%) due to ionic migration. The addition of the sample solution caused little change of pH, and the indicator current was scarcely changed by the presence of free sulphuric acid. The slope of the plot of indicator current *vs.* time, after the end-point, was decreased in approximately the same proportion as the degree of dilution.¹⁹

Acidimetric coulometric titration

Since the titration of the sulphuric acid solution of ammonia is the reverse of the titration of a monoacidic base with a strong acid, the change in the hydrogen-ion concentration near

the equivalence point is expressed by equation (1),^{32,33}

$$a = 1 - p_1/[H] + p_2[H] \quad (1)$$

where p_1 and p_2 are constants and a is the degree of titration defined as

$$a = (t_0 + t_i - t)/t_0 \quad (2)$$

where t is an arbitrary electrolysis time at a certain current, t_i is the electrolysis time needed to reach the equivalence point, and t_0 is the time interval corresponding to neutralization of one equivalent of the base. Equation (3) is derived from equations (1) and (2):

$$t = t_i + p_1 t_0 \gamma_H 10^{\text{pH}} - p_2 t_0 \gamma_H^{-1} 10^{-\text{pH}} \quad (3)$$

where γ_H is the hydrogen-ion activity coefficient. It is believed that γ_H is constant during the course of the coulometric titration. The value of t_i is derived from the experimental data (pH *vs.* t) by a non-linear least-squares method^{39,40} applied to the three parameters t_i , $p_1 t_0 \gamma_H$ and $p_2 t_0 \gamma_H^{-1}$ in equation (3).

From titrations of the sulphuric acid solution of ammonia and the sulphuric acid solution alone (four determinations for each) the total concentration of ammonia in the former was estimated as $(5.8620 \pm 0.0019) \times 10^{-3}m$. The error was estimated from the sd values of both sets of results for the same solutions. The difference from the concentration obtained by oxidimetry is *ca.* 0.02%, which is within the

Fig. 5. Dependence of the results for the ammonium chloride solution, obtained by coulometric titration with hypobromite ions, on the delay time before starting the electrolysis. Electrolysis current, 20 mA. Symbols as for Fig. 3.

estimated precision. Thus the accuracy of oxidimetry by hypobromite generation was further established.

Ammonium chloride solution

Figure 5 shows the dependence of the oxidimetric results obtained for the ammonium chloride solution (*ca.* $6.68 \times 10^{-3}m$) on the delay time, when the current used was 20 mA. The ordinate represents the concentration found titrimetrically, relative to that based on the weight of ammonium chloride used. The uncertainty in the chemical formula weight (53.4910 ± 0.0009) is less than 0.002%.⁴¹ As it was expected from Fig. 4 that hardly any difference would be made by the four dilution steps, all the data in Fig. 5 were used for extrapolation. The number of data, slope (%/min) and intercept (%) are 14, -7.63×10^{-3} (0.72×10^{-3}) and 100.014 (0.008), respectively. As the ammonium chloride concentration is similar to the total ammonia concentration in the sulphuric acid solution of ammonia and the slope in Fig. 5 is reasonably close to that in Fig. 4, the exact concentration of ammonium chloride, $(6.6847 \pm 0.0010) \times 10^{-3}m$, was obtained by correcting for the loss during the course of the electrolysis (0.011% at 20 mA) estimated from Fig. 3. This concentration is 100.02%, relative to that based on the weight taken, and its inaccuracy was estimated as 0.02% at most, from the s.d. (0.0084%) of the

intercept in Fig. 5, the s.d. of the loss during the course of electrolysis at 20 mA, the accuracy of determining the 20-mA current, the negative error due to ionic migration, and the uncertainty in the formula weight of ammonium chloride.

In the oxidimetric coulometric titration of ammonium ions presented in this paper, high accuracy will be obtained if the current efficiency and the loss of the sample are taken into consideration. The determination of ammonium ions by this method can be utilized for determining the purity of reference materials. The method should also be useful for determination of nitrogen as ammonia or ammonium ions after pretreatment such as Kjeldahl digestion.⁴²

(Received 9 October 1990. Accepted 15 November 1990)

Summary—The products arising from the reaction of α -protected lysine with glucose have been studied by different techniques, *viz.* high-performance liquid chromatography (HPLC) with UV detection, fast atom bombardment (FAB) mass spectrometry (MS), and HPLC/MS. Most of the analytical data were obtained by the last approach and allowed identification of many molecular species for a thorough knowledge of possible reaction pathways or structural data already available in the literature.

Accumulation of brown advanced glycation products in proteins has been proposed as relevant to the development of long-term complications of diabetes mellitus.^{1,2} In the past, the structure of these products has been studied, starting from glycated proteins, by means of chemical and enzymatic hydrolysis and other separative and analytical techniques.³⁻⁵ New information has been added to that already known by Njoroge *et al.*, who demonstrated that chemical hydrolysis can lead to artifacts.⁶ In a recent study⁷ we compared data from chemical and enzymatic hydrolysis and were able to confirm these earlier⁶ findings.

However, since the structure of the brown products in the complex hydrolysis mixture is difficult to determine by those techniques, we decided to take a different approach, namely to study the products of the chemical reaction of glucose and protected lysine. This approach is expected to provide useful information about the mechanism of this reaction and form a promising starting point for future studies *in vivo*.

EXPERIMENTAL

Synthesis of N- α -acetyl-L-lysine methyl ester

N- α -Acetyl-L-lysine methyl ester was prepared and purified according to Irving and Gutmann.⁸ It was a dense yellow oil. The protected lysine (100 mg) and D-glucose (5 g) were dissolved in 5 ml of sodium phosphate buffer (pH 7.5, 0.05M Na) and the solution was incubated for 28 days at 37°, and then was lyophilized.

HPLC separation

A Perkin-Elmer series 3B liquid chromatograph connected to an LC-75 spectrophotometric detector was used. The detector wavelength was set at 320 nm. A μ -Bondapak C-18 reverse phase column was used for the separation. Each sample was diluted tenfold with distilled water before injection. Gradient elution at a flow-rate of 2 ml/min was used, with a mixture of acetonitrile and water in ratio progressively changed from 1:99 to 20:80 in 30 min.

Mass spectrometric measurements

Fast atom bombardment (FAB) measurements were made with a VGZAB 2F mass spectrometer.⁹ Glycerol solutions of the sample were bombarded with 8 keV Xe atoms. GC/MS was performed on a Finnigan ITD 800 system operating in electron ionization mode (100 eV, 100 μ A), with a fused-silica capillary column (25 m long, i.d. 0.32 mm) coated with a 0.4- μ m layer of SE54. The temperature was programmed to rise from 70 to 250° at 7°/min. HPLC/MS measurements were performed with a VG ZAB-VE instrument operating under plasma-spray conditions with a probe temperature of 250° and a source temperature of 240°. The HPLC conditions were as described above.

RESULTS AND DISCUSSION

The HPLC chromatogram of the reaction of protected lysine and glucose is shown in Fig. 1. There are three main peaks, with retention times of 6, 11 and 12 min respectively. GC/MS analysis of each peak led to unsatisfactory results, possibly owing to the high polarity of the compounds investigated. However, FAB MS of the whole reaction mixture, shown in Fig. 2a, gave a spectrum which differed from that of the pure protected lysine (Fig. 2b). For the mixture, ions at m/z 285 and 263 were detectable (with a

Fig. 1. HPLC chromatogram obtained by detection at 320 nm.

Fig. 3. Daughter ion spectra: (a) ion at m/z 285; (b) ion at m/z 263.

signal/chemical background ratio of about 20). Daughter ion spectra (Fig. 3) suggested that these species had structures 1 and 2 respectively (Scheme 1).

The very high chemical noise observed under the FAB conditions suggests the presence of many other molecular species. For this reason, HPLC/MS measurement was the method of choice. The reconstructed total ion chromatogram

obtained under the same HPLC conditions is shown in Fig. 4. Practically no chromatographic resolution was obtained. However, mass spectra obtained at different elution times led to an effective description of the molecular species present in the complex mixture. Figure 5 shows the spectra obtained for scans 18, 25 and 37. In the first, many different ionic species are easily detected in the range m/z

Scheme 1

Fig. 4. Reconstructed ion chromatogram for HPLC/MS analysis of reaction mixture under plasma-spray conditions.

150–500, and in the third new molecular species becomes detectable at m/z 324.

Neither GC/MS analysis of every component obtained by preparative HPLC runs, nor mass spectrometric analysis of the whole mixture by FAB was satisfactory. No compound related to the Amadori reaction could be detected by GC/MS, possibly because of the high polarity of such molecules. The FAB mass spectrum of the whole reaction mixture differed from that of protected lysine (Fig. 2b), mainly by the presence of ions at m/z 285 and 263 (Fig. 2), but it must be stressed that this spectrum is quite unsatisfactory. Ionic species are present at every m/z

value. Also the ions of interest have a signal/chemical background ratio of about 20, which suggests many other molecular species may be present but are concealed by the chemical background. For the ions at m/z 285 and 263, the daughter ion spectra (Fig. 3) suggest the structures 1 and 2 (in Scheme 1) which could originate from lysine and glucose (Schiff's base) with subsequent Amadori rearrangement and decarboxylation. Both compounds 1 and 2 show the formal loss of H_3O^+ (possibly from sequential losses of H^+ and H_2O) in the daughter spectra, leading to ions at m/z 244 and 266 respectively.

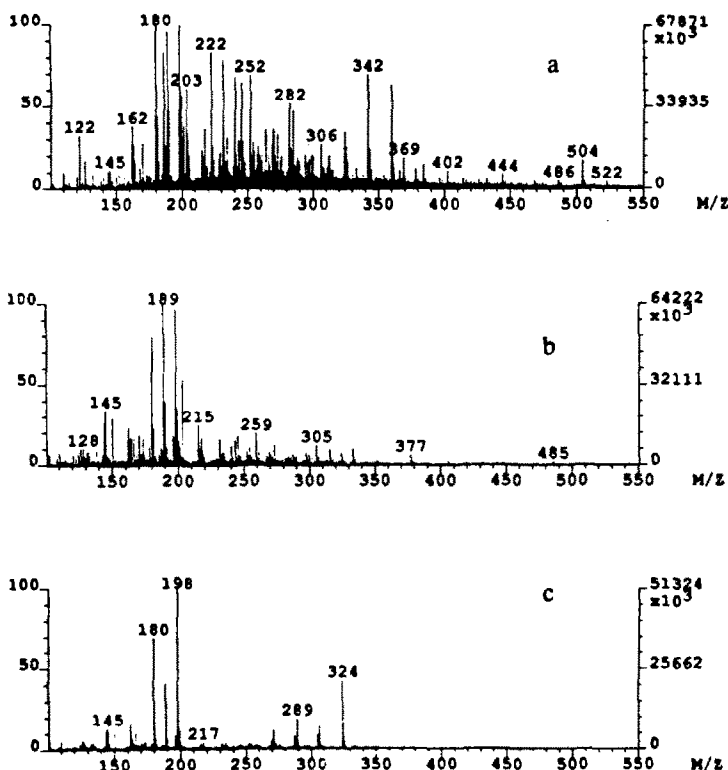

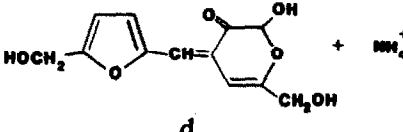

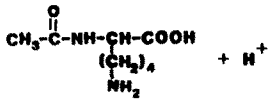

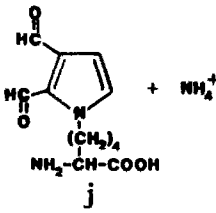

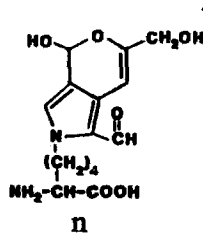

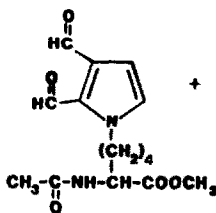

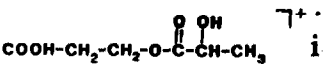

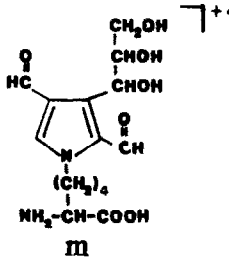

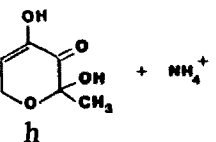

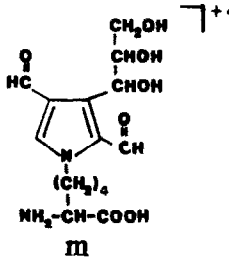

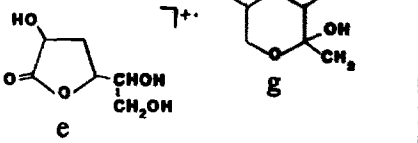

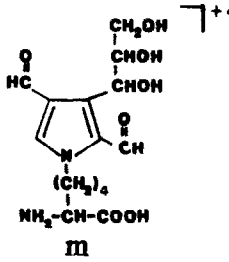

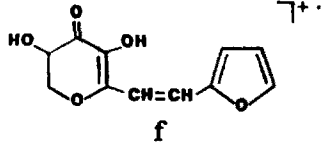

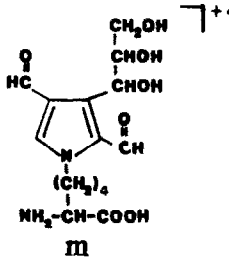

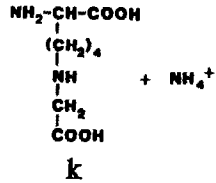

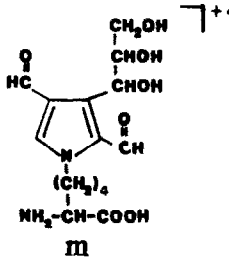

Fig. 5. Mass spectra obtained at different elution times by HPLC/MS analysis: (a) mass spectrum of scan No. 18, (b) mass spectrum of scan No. 25, (c) mass spectrum of scan No. 37.

To obtain more satisfactory results, we performed a series of HPLC/MS measurements. Under the HPLC conditions described we obtained the total ion chromatogram reported in Fig. 4. The practically complete loss of resolution in comparison with UV detection

Table 1. Possible structures detected by plasma-spray HPLC/MS

<i>m/z</i>	Structures	<i>m/z</i>	Structures
180	Glucose γ^+	270	 d
189	 + H ⁺	 + NH ₄ ⁺ j	
198	Glucose + NH ₄ ⁺	324	 n
162	 b	326	 + NH ₄ ⁺ o
	 i	342	 m
	 h	342	 m
	 e	342	 m
222	 f	360	 m
	 + NH ₄ ⁺ k	360	 m
240	f + NH ₄ ⁺	360	m + NH ₄ ⁺

shows that the latter is artificially selective, in that it can detect those components containing the chromophoric moiety but not describe the real composition of the mixture. In contrast, the mass spectra obtained at different elution times

can give an effective description of the molecular species in the complex mixture (*e.g.*, Fig. 5). The spectrum for scan 18 corresponding to the maximum of the reconstructed total ion current (Fig. 4) shows many different ionic species in the

Scheme 2, Part 1.

Scheme 2, Part 2.

Scheme 2. Possible pathways leading to structures compatible with the molecular weight found in HPLC/MS analysis, where $\text{R} = -(\text{CH}_2)_4-\text{CH}(\text{NH})-\text{COOH}$.

range m/z 150–500. Though some of them are easily attributable to molecules present in the reaction mixture (as for example m/z 180 and 198 corresponding to $\text{M}^{+\cdot}$ and $[\text{M} + \text{NH}_4]^+$ for glucose, respectively), others are rather difficult to account for, since their structure is inferred only from their molecular weight. For these reasons we propose for them isobaric structures already suggested and/or described in the

literature, as intermediate and final glycation products. At longer retention times most of the ionic species shown in scan No. 18 disappear, but new molecular species at m/z 324 become detectable.

In recent years many efforts have been made to obtain a general view of the possible patterns related to the Maillard reaction. Some useful results have been obtained either from theoretic-

cal or experimental approaches. The structures deduced from HPLC/MS data were proposed on the basis of studies of the Maillard reaction under physiological conditions. Our own opinion is that structure assignment based solely on molecular weight can sometimes give misleading results, but at this stage of the present research, reliable information on the molecular weights of the Maillard products is important.

Possible pathways leading to structures compatible with the molecular weights found by HPLC/MS are reported in Scheme 2. Loss of lysine from the Schiff's base arising from the reaction of glucose and lysine (Scheme 2, structure *a* proposed by Paulsen and Pflughaupt³) can lead at first to two different structures (*b* and *c* in Scheme 2). Such behaviour was already proposed by Anet,¹⁰ Kato¹¹ and Beck *et al.*,¹² and, considering the reaction conditions seems more than reasonable. Both structures *b* and *c* undergo further rearrangements with losses of neutral moieties such as furan-2-aldehyde and analogous products. By this pathway structures *d*, *e* and *f* are obtained; they have been well described by Ledl and co-workers^{4,13,14} and Sengl.¹⁵ It is significant that several ions, at *m/z* 252 (*d*), 222 (*f*) and 162 (*e*) are present in the mass spectrum reported in Fig. 5a. The further rearrangement of compound *c* to *c'*, favoured from a thermodynamic point of view, accounts for the formation of both compounds *g* and *h* (molecular weights 162 and 144 respectively). The latter, in aqueous solution, readily adds water to yield the compound with molecular weight 162. The pathways described above, leading to compounds *c'*, *g*, *h* and *i*, have already been described by Ledl and Severin,⁵ Sengl¹⁵ and Mills *et al.*¹⁶

The right-hand part of Scheme 2 shows the reaction of compound *b* with *a* through condensation and further cleavage of the polyol chain, followed by oxidation. This process leads to compound *j*, the molecular ion of which is still present in the spectrum in Fig. 5a at *m/z* 252. The formation of such a compound has already been proposed by Krönig.¹⁷ Also the formation of carboxymethyl-lysine (compound *k*), described by Ahmed *et al.*,¹⁸ cannot be excluded. In fact, the ion at *m/z* 222, shown in Fig. 5a, could be due to the cationization of compound *k* with NH_4^+ , as often observed under plasma-spray conditions. All these findings are shown in Table 1, where the possible structures related to the most abundant ionic species in the spectra shown in Fig. 5 are proposed.

In addition to the ionic species which can be attributed to the structures described above and already reported in the literature, we detected some other molecular ions of unknown structure. Thus, the ions at *m/z* 342 and 360 can be attributed to structures *m* and *m* + NH_4^+ respectively (Table 1). These structures easily originate from selective oxidation of the side alcohol chain of molecule *l* (Scheme 2).¹⁹⁻²¹ The ions at *m/z* 324 are not so easily identified. Structure *n* in Table 1 can be tentatively proposed.

In conclusion, by comparing HPLC, GC/MS, FAB and HPLC/MS data for the products arising from the interaction of glucose and protected lysine we were able to identify many different molecular species, most of which have the same molecular weight as the products described in the literature. Other compounds, not reported in the literature, were assigned a structure on a mechanistic basis.

THE RATE OF REDUCTION OF SELENIUM(VI) TO SELENIUM(IV) IN HYDROCHLORIC ACID

JEAN PETTERSSON* and ÅKE OLIN

Department of Analytical Chemistry, Uppsala University, P.O. Box 531, S-751 21 Uppsala, Sweden

(Received 9 February 1990. Revised 9 May 1990. Accepted 1 October 1990)

Summary—The reduction of selenium(VI) to selenium(IV) in 4, 5 and 6M hydrochloric acid was studied at temperatures between 50 and 95°. The reaction rate was determined by measurement of the selenium(IV) formed, by continuous-flow hydride-generation atomic-absorption spectrometry. The most notable feature of the reaction is the strong increase in rate with increasing hydrogen-ion concentration and temperature. The rate increases initially with chloride concentration at constant acidity (mixtures of hydrochloric and perchloric acid) but levels off to an almost constant value at high chloride concentrations.

A number of methods are available for the determination of selenium at trace level. Those most frequently used determine only the selenium(IV) present in the final sample. This applies to procedures that are based on the formation of piaszelenols (molecular fluorescence and gas chromatography), hydrogen selenide (atomic spectroscopy), or selenides (stripping voltammetry). Any selenium(VI) present in the original sample or formed during pretreatment of the sample must therefore be transformed into the quadrivalent state if determination of total selenium is required. Reduction by chloride in strongly acidic medium,¹⁻³ photolysis in slightly alkaline medium,⁴ and reduction to elemental selenium and subsequent reoxidation to selenium(IV) by a bromine/bromide buffer⁵ have been used for the conversion of selenium(VI) into selenium(IV).

Reduction by 4–6M hydrochloric acid at elevated temperatures is by far the most commonly used method. A number of recommendations, sometimes conflicting, for performing the reaction can be found in the literature. This prompted Bye and Lund⁶ to investigate the rate of the reaction between selenate and hydrochloric acid. They determined the time necessary for complete reduction at various temperatures and concentrations of acid. Their results indicated that the reaction is first-order with respect to selenium(VI) and that the activation energy is 83 kJ/mole. They pointed out that the reaction rate may be matrix-dependent, and that the

conflicting results reported may be due to matrix effects.

This paper presents the results from a study of the kinetics of selenate reduction in hydrochloric acid, a flow-injection technique being used for sampling. The reaction can be followed more efficiently in this way than by the batch technique used previously.⁶ Rate constants at various temperatures and the activation energy have been determined. The influence of chloride on the reaction rate was also investigated.

EXPERIMENTAL

Reagents

All chemicals used were of analytical grade. Standard solutions of selenium(VI) and (IV) were prepared as described earlier.⁷

Apparatus

The hydride-generation atomic-absorption spectrometry (HG-AAS) equipment has been described elsewhere.⁸ The signal from the AAS instrument was evaluated with an integrator (Shimadzu C-R3A).

The kinetic experiments were done with the sample in a beaker covered by a Teflon lid and fitted into a central boring in an aluminium cylinder provided with an aluminium lid. The cylinder was heated on a hot-plate and the temperature controlled to $\pm 0.2^\circ$ by a resistance thermometer fitted through the lid. Holes were also drilled for addition of reagents and for tubing to collect samples. The reaction mixture was stirred with a magnetic bar. Sampling was

*Author for correspondence.

generally done by continuously pumping the reaction mixture from the beaker through Teflon tubing (i.d. 0.7 mm) to the sample loop (0.5 ml) of the HG-AAS apparatus. Just after emerging from the thermostat the tubing passed through a cooling device, which lowered the temperature to 17° in less than 10 sec. At this temperature the reaction rate is negligible.

Procedure

Hydrochloric acid (200 ml) of the appropriate concentration was transferred to the beaker. When the desired reaction temperature had been reached and had stabilized, 1 ml of selenium(VI) solution in hydrochloric acid was added to yield a concentration of about 5 ng/ml in the reaction mixture. At the instant of mixing, the pump and a timer were started. The timer controlled the injection valve of the HG-AAS apparatus and a measurement was generally made every 30 sec. Calibrations were performed with standard solutions of selenium(IV) before, during and after the kinetic run.

At low reaction rates, sampling and analysis were controlled manually. The interval between samplings was increased as the reaction progressed. Standards were run between determinations, to allow a correction to be made for changes in the sensitivity of the HG-AAS apparatus.

RESULTS AND DISCUSSION

The equilibrium constant of the reaction

has been found⁹ to be $K_1 = 7.1 \times 10^{-10}$ atm.kg⁵.mole⁻⁵. The reduction of selenate at trace level by chloride is more appropriately written as

The equilibrium constant of reaction (2) can be found by combining K_1 with the constant for $\text{Cl}_2(\text{g}) \rightleftharpoons \text{Cl}_2(\text{aq})$. This constant was estimated from the solubility of chlorine in water¹⁰ to be 0.1 mole.kg⁻¹.atm⁻¹. The constant for reaction (2) is then $K_2 = 7.1 \times 10^{-11}$ kg⁴/mole⁴. A calculation of K_2 from standard potentials¹¹ yields $K_2 = 4.9 \times 10^{-11}$ l.⁴/mole⁴. The standard enthalpy change for reaction (2) was calculated to be 110 kJ/mole.¹² The value of K_2 at 80°, an average

Fig. 1. Recorder tracing of a kinetic run of 5 µg/l. selenate in 5M hydrochloric acid at 85°. —|—| Calibrations.

temperature for the kinetic experiments, can then be estimated to be 6×10^{-8} l.⁴/mole⁴. The conditional constant in 4–6M hydrochloric acid can be estimated to be larger by a factor of 10–500. The estimate of K_2 indicates that reaction (2) would be quantitative at a selenium(VI) concentration of 1×10^{-7} M (8 ng/ml). The reverse reaction can therefore be neglected in our experiments.

Kinetic measurements were made for 4, 5 and 6M hydrochloric acid media in the temperature range 50–95°, depending on the medium. Figure 1 shows the recorder trace for a kinetic run. The data were evaluated on the assumption that the formation of selenium(IV) at constant hydrochloric acid concentration followed a rate law which was first-order with respect to selenium(VI), *i.e.*,

$$C = C_0(1 - e^{-kt}) \quad (3)$$

where C is the concentration of selenium(IV), C_0 the concentration of selenium(VI) at $t = 0$, and k is the pseudo first-order rate constant. The value of k was obtained by fitting the function

$$C = A - Be^{-kt} \quad (4)$$

to the data by non-linear regression. The reason for using a more general function is due to some complications introduced by the experimental set-up: (i) a delay between sampling and time of analysis; (ii) an uncontrolled period at the start of the reaction before the reaction mixture is homogeneous; (iii) continued progress of the reaction in the cooler; (iv) the fact that the analytical result is an average concentration for the time interval during which the sampling loop is filled. Provided that the pumping rate and the temperature profile in the cooler remain constant during an experiment and that plug flow can be assumed, it can be shown that equation (4) should be valid.

Fig. 2. Fit of the equation $C = A - Be^{-kt}$ to the data in Fig. 1.

A comparison of equations (3) and (4) shows that A should be equal to C_0 , which also should be the value of C at $t = \infty$, C_∞ . This was checked now and then by letting the reaction go to completion. A and C_∞ generally agreed within 5%. The intercept on the t -axis of the fitted function formally corresponds to a delay time, which was usually less than 15 sec. The fit of equation (4) to the data in Fig. 1 is shown in Fig. 2.

From a practical point of view, the most pronounced feature of the reduction of selenium(VI) by hydrochloric acid is the marked dependence of the rate on temperature and acidity. This is demonstrated in Fig. 3 where $\ln k$ is shown as a function of $1/T$. Reasonably straight lines can be drawn for each concentration of the acid, and the mean of the activation energy, E_A , is 126 ± 10 kJ/mole. The observed half-lives (min), $t_{1/2}$, can be reproduced by the empirical relationship

$$t_{1/2} = 2.8 \times 10^{-14} \{\text{HCl}\}^{-3.73} e^{126000/RT} \quad (5)$$

where $\{\text{HCl}\}$ is the mean molar activity of the hydrochloric acid medium at 25° .¹³ The ratio of the half-lives calculated from equation (5) to the observed values was 0.97 ± 0.15 . The tempera-

Fig. 3. Values of $\ln k$ as a function of $1/T$ for \square , $4M$; \triangle , $5M$; \circ , $6M$ hydrochloric acid media.

tures needed to reach 99.9% reduction in about 30 min are 105 , 85 and 65° for 4 , 5 and $6M$ hydrochloric acid, respectively. This result agrees with the findings by Bye and Lund.⁶ Their value of E_A is, however, 40 kJ/mole less than ours.

The difference in activation energy could be a medium effect, since Bye and Lund measured the rate in 10:1 v/v mixtures of hydrochloric acid (2 – $10M$) and concentrated perchloric acid. The reported value of E_A was determined from experiments with a medium made up from $4M$ hydrochloric acid. A measurement in this medium with our equipment at 80° yielded a value of $1.04 \times 10^{-3} \text{ sec}^{-1}$ for k . Bye and Lund reported $3.3 \times 10^{-4} \text{ sec}^{-1}$. To find whether this difference in the rate constant was due to our experimental technique, the determination was repeated in the batch mode. A 110-ml volume of the medium was heated to 80° and then selenium(VI) was added at temperature equilibrium. The reaction mixture was sampled at intervals and the samples were treated as described earlier.⁶ The value of k obtained was $1.08 \times 10^{-3} \text{ sec}^{-1}$. The two experimental techniques thus resulted in closely agreeing values for the rate constant.

We next repeated the measurement by the procedure described in detail by Bye and Lund.⁶ When the water-bath was set at 80° a smaller value of k was obtained ($4.7 \times 10^{-4} \text{ sec}^{-1}$). It was noted, however, that the reaction mixture attained its final temperature about 15 min after the start of an experiment and this temperature was about 4° below that of the water-bath. When the temperature of the water-bath was increased so that the temperature of the medium was 80° and the selenium(VI) was not added until temperature equilibrium was reached, the experiment yielded $k = 1.05 \times 10^{-3} \text{ sec}^{-1}$, in agreement with the previous values.

The medium investigated was a $3.6M$ hydrochloric/1.1M perchloric acid mixture. It will be demonstrated later that exchange of chloride for perchlorate at high chloride concentrations and constant acidity will have only a minor effect on the rate constant. If we therefore assume that the medium behaves like $4.7M$ hydrochloric acid, k is estimated from equation (5) to be $1.3 \times 10^{-3} \text{ sec}^{-1}$, in fair agreement with our experimental result. The value of k obtained at 60° differed only by 20% from the value obtained by Bye and Lund. We are therefore inclined to believe that the difference in E_A is mainly due to uncertainties in temperature rather than to a difference in medium.

Fig. 4. The selenium(IV) signal as a function of time at three chloride concentrations in mixtures of hydrochloric and perchloric acid. The total acid concentration was $5M$ and the temperature 54° . The rate was determined by linear regression. $[Cl^-]$: \times , 0.2 ; \triangle , 0.4 ; \circ , $0.8M$.

A strongly acid digest containing no chloride ions is obtained when the analytical sample is decomposed with mixtures of strong acids. It is therefore of interest to study the influence of the chloride concentration on the reaction rate. Such a study was performed at 54° with mixtures of hydrochloric and perchloric acid; the sum of the acid concentrations was kept constant at $5M$. The chloride concentration was varied from 0.05 to $5M$. The measurements were made at a high (usually 1000 ng/ml) initial concentration of selenium(VI), C_0 . The rate constant was evaluated from the initial rate of the reaction R .

Fig. 5. The rate constant as a function of the chloride concentration, determined by use of equation (6). The curve corresponds to equation (7).

$$R = \frac{d[Se(IV)]}{dt} = kC_0 \quad (6)$$

R was obtained from the slope of a plot of selenium(IV) concentration vs. time.

Figure 4 shows the results of some experiments and Fig. 5 the variation of k with the chloride concentration. The rate increases rapidly with chloride concentration up to about $2.5M$, then levels off. The maximum in k at high chloride concentration is not unique to the $5M$ medium. It was observed in similar measurements with a total acidity of $4M$. A plot of $\log k$ vs. $\log [Cl^-]$ for $[Cl^-] < 0.8M$ indicated a reaction order of 1.75 . The observed rate constant (sec^{-1}) roughly follows the relationship

$$k = \frac{6.85 \times 10^{-5} [Cl^-]^{1.75}}{1 + 0.45 [Cl^-]^{1.75}} \quad (7)$$

which indicates a multi-step reaction.

The weak dependence of the rate on chloride concentration above $\sim 3M$ is not peculiar to a total acid concentration of $5M$. Experiments with mixtures of hydrochloric and perchloric acid, with lithium chloride, and lithium perchlorate to keep the ionic strength constant at $5M$, also yielded rates at 80° that were almost independent of the concentration of chloride in the ranges $2M < [Cl^-] < 5M$; $3M < [H^+] < 5M$. From a practical point of view these results indicate that the addition of chloride to an acid digest should be limited to give a concentration of about $2.5M$.

The dependence of the reaction rate on the hydrogen-ion concentration is very marked. The reaction order was almost 5 at constant chloride concentration (5 or $4M$) and a constant ionic strength of $5M$. The high order is in agreement with results reported by Brimmer *et al.*¹⁴ The order of reaction is thus greater than the stoichiometric coefficient for H^+ in reaction (2). The high dependence of the reaction rate on acidity indicates that some kind of selenate-proton cluster might be formed before the selenium atom is attacked by chloride.

EFFECT OF pH ON THE REACTION OF TRIS(2,2'-BIPYRIDYL)RUTHENIUM(III) WITH AMINO-ACIDS: IMPLICATIONS FOR THEIR DETECTION

STEPHEN N. BRUNE and DONALD R. BOBBITT*

Department of Chemistry and Biochemistry, University of Arkansas, Fayetteville, AR 72701, U.S.A.

(Received 18 June 1990. Revised 10 July 1990. Accepted 26 July 1990)

Summary—A new technique for the detection of amino-acids is described, which is based on their chemiluminescence reaction with tris(2,2'-bipyridyl)ruthenium(III). The pH-dependence of this reaction has been investigated and found to be the key experimental parameter in application of this reaction as a detection technique. The chemiluminescence emission obtained is maximal at pH values higher than the N-terminal amino group pK_a of the amino-acid. The background reaction between the ruthenium reagent and hydroxide ion does not occur with the same efficiency as the amino-acid reaction and the optimum signal to noise ratio is obtained at pH 10. A limit of detection of 30 picomole was found for valine and the response was shown to be linear over two orders of magnitude.

New advances in protein sequencing and amino-acid analysis are critical for the continued development and future progress of a variety of emerging biomedical technologies, including those involving recombinant DNA procedures and gene cloning.¹ Most modern techniques for amino-acid analysis require either pre- or post-column derivatization to enhance detection. These methods involve reaction of the amino-acid with ninhydrin,² dansyl chloride,³ *o*-phthal-aldehyde,⁴ 1-fluoro-2,4-dinitrobenzene,² or dimethylaminoazobenzenesulfonyl chloride,⁵ followed by detection of the derivative by conventional ultraviolet or fluorescence spectrometry. Derivatization techniques can suffer from poor sensitivity as a result of incomplete reaction. Derivatization also adds complexity to the technique and may become time and labor intensive. Further, the derivative may not be stable and must therefore be determined immediately. Finally, derivatization limits the separation/detection procedure in that it must be based on the characteristics of the derivative rather than those of the free amino-acid. Frequently, the reagent moiety added to the analyte dominates the chromatographic properties of the derivative, thereby affecting separation efficiency and resolution.

One way to circumvent these limitations inherent in derivatization techniques would be to use a chemiluminescence reaction to detect

amino-acids directly. Chemiluminescence techniques offer many advantages over techniques based on fluorescence and ultraviolet absorption. Further, chemiluminescence detection requires no excitation source and the reaction is usually fairly selective. In addition, the theoretically zero background expected in the absence of analyte suggests that chemiluminescence techniques would be extremely sensitive.

There have been several recent reports which deal with the chemiluminescence (CL) detection of amino-acids.⁶⁻¹¹ Many of the CL techniques have detection limits in the femtomole range.^{6,8,11} However, most of these techniques require precolumn derivatization, which can result in increased analysis time. Of the techniques that do not require derivatization, the reaction of l-amino-acids with l-amino-acid oxidase provides a response for only eight of the amino-acids.⁷ The amperometric method described by Kok *et al.*¹² and the chemiluminescence method presented by Koerner and Nieman⁹ both involve the complexation of amino-acids with copper(II) ions and have detection limits in the picomole range.

It can be postulated that the ideal chemiluminescence detection system would possess the following characteristics: (1) fast reaction kinetics to facilitate miniaturization of the detection system; (2) high reaction efficiency to enhance selectivity; (3) the capability to generate the reagent at the site of reaction, to avoid the need for precolumn chemistry. The methods

*Author for correspondence.

discussed above do not detect the free amino-acid directly but rather through some property of a reagent such as copper(II) or a specific derivatizing agent. Therefore, one way to improve the detection limits for amino-acids would be to find a chemiluminescence reagent capable of reacting directly with the amino-acid. One reagent which might satisfy these requirements and undergo a direct chemiluminescence reaction with amino-acids is tris(2,2'-bipyridyl)ruthenium(III), $\text{Ru}(\text{bpy})_3^{3+}$. Electro-generated $\text{Ru}(\text{bpy})_3^{3+}$ has been observed by Rubinstein *et al.*¹³ to produce CL upon reaction with a variety of molecules, including oxalate ions. Similarly, Noffsinger and Danielson¹⁴ observed CL when electrogenerated $\text{Ru}(\text{bpy})_3^{3+}$ was reacted with primary, secondary and tertiary amines. Detection limits of 0.28 and 2.4 picomole were found for tripropylamine and oxalic acid, respectively. The method was found to be 60 times more sensitive for tertiary than for primary amines and this was attributed to differences in the first ionization potentials of the different classes of compounds. The mechanism for this reaction has been outlined for the oxalate system¹³ and it is believed that the amines react by a similar mechanism. Both Rubinstein *et al.*¹³ and Hoffinger and Danielson¹⁴ found that the ruthenium-based CL reaction was dependent upon the pH of the reaction mixture. In both studies maximum chemiluminescence was obtained between pH 4 and 6, although pH values above 7 were not investigated because hydroxide ions are known to produce CL with $\text{Ru}(\text{bpy})_3^{3+}$. No chemical or theoretical explanation was given for this pH response. From the reported correlation of chemiluminescence intensity with the ionization potential of the first non-bonding orbital (*i.e.*, the lone pair of electrons on a nitrogen atom) it would be expected that a neutral amine group would be more easily ionized than a protonated one. Thus, it would appear that the maximum CL signal should occur at a pH at which the NH_3^+ group is substantially deprotonated (*i.e.*, $\text{pH} > \text{pK}_a$). However, the relative CL intensities produced by reaction with primary, secondary, and tertiary amines should still be controlled by their ionization potentials.

In the present work, the pH-dependence of the reaction of $\text{Ru}(\text{bpy})_3^{3+}$ with amino-acids was investigated. It was found that the maximum CL signal for amino-acids occurs at pH values above 7. The generality of this technique was found to hold for amines as well as amino-acids

and the implications of this for detection in HPLC or FIA will be discussed.

EXPERIMENTAL

Apparatus

$\text{Ru}(\text{bpy})_3^{3+}$ was generated by using a PAR (Princeton, NJ) model 363 Potentiostat/Galvanostat with a standard three-electrode arrangement consisting of a platinum gauze working electrode, a silver-wire quasi-reference electrode, and a platinum-wire auxiliary electrode. The auxiliary electrode was separated from the $\text{Ru}(\text{bpy})_3^{3+}$ solution by a glass frit to prevent formation of ruthenium metal at the electrode surface. A 1.5mM $\text{Ru}(\text{bpy})_3(\text{ClO}_4)_2$ solution (in 0.4M sodium sulfate as supporting electrolyte) was used for all studies. The potential at the working electrode was set at 1.10 V *vs.* the Ag wire. The electrolysis was run for 20 min per 50 ml of ruthenium solution. When the electrolysis had run to completion the ruthenium solution had changed in color from orange to a clear green, corresponding to the formation of $\text{Ru}(\text{bpy})_3^{3+}$. The $\text{Ru}(\text{bpy})_3^{3+}$ was then pumped to the detection cell by means of a Gilson (Middleton, WI) Minipuls 3 peristaltic pump. To keep the volume in the electrolysis cell constant, $\text{Ru}(\text{bpy})_3^{3+}$ was pumped into the electrolysis cell at the same rate at which $\text{Ru}(\text{bpy})_3^{3+}$ was removed. The electrolysis was operated continuously, to provide a constant concentration of $\text{Ru}(\text{bpy})_3^{3+}$ to the detection cell. Tests with a standard sample over a period of 1 hr showed that there was less than 5% variation in the measured signal, confirming that a steady-state concentration of $\text{Ru}(\text{bpy})_3^{3+}$ was produced. The detection cell consisted of a small coil of clear poly(vinyl chloride) tubing (*i.d.* 0.76 mm) positioned in front of a Hamamatsu (Hamilton, NJ) R928 photomultiplier tube. An ISCO (Lincoln, NE) LC-5000 syringe pump was coupled to the detector through a Rheodyne (Cotati, CA) 7010 injector fitted with either a 20 or a 750 μl loop.

The PMT current was monitored with a Keithley (Cleveland, OH) 485 picoammeter, the output of which was sent to a personal computer through an IEEE-488 interface (Model PC-2A; National Instruments, Austin, TX). The experimental configuration is shown schematically in Fig. 1.

Reagents

All amino-acids were purchased from Sigma (St. Louis, MO) and used without further purifi-

SP, syringe pump; IN, injection system; LDS, light detection system (detection cell coupled to a photomultiplier tube); HV, photomultiplier power supply; PA, picoammeter; DP, data procurement and display; PP, peristaltic pump; RR, ruthenium(II) reservoir; MS, magnetic stirrer; EC, electrochemical cell; PS, potentiostat.

cation. $\text{Ru}(\text{bpy})_3\text{Cl}_2$ was purchased from Aldrich (Milwaukee, WI) and converted into the perchlorate before use. All other chemicals were reagent grade and used as received.

Amino-acid solutions were analyzed within 3 days after preparation. The buffers used were 0.05M KH_2PO_4 at pH 6, 7 and 8, 0.05M H_3BO_3 at pH 9 and 10, and 0.025M K_2HPO_4 at pH 11 and 12.

Procedure

The pH studies were performed by injecting a 750 μl plug of buffer followed by either the amino-acid or amine buffered at the same pH. The carrier stream containing the sample plug was merged with the $\text{Ru}(\text{bpy})_3^{3+}$ stream at the detection cell. Since the efficiency of transport of the $\text{Ru}(\text{bpy})_3^{3+}$ was not determined, all pH studies were conducted with at least a 10:1 mole ratio of $\text{Ru}(\text{bpy})_3^{3+}$ to amine or amino-acid to ensure that an excess of ruthenium reagent was available. The flow-rates of the $\text{Ru}(\text{bpy})_3^{3+}$ and the amino-acid solutions were 0.6 and 0.5 ml/min, respectively.

RESULTS AND DISCUSSION

As already mentioned, the development of techniques for the detection of underivatized amino-acids is an important area of investigation. Previous studies by Bard and co-workers have shown that $\text{Ru}(\text{bpy})_3^{3+}$ will react with a variety of compounds including oxalate¹³ and other organic acids,¹⁵ to yield chemiluminescence. From its reactivity, as determined from these studies, it appeared that $\text{Ru}(\text{bpy})_3^{3+}$ might

be capable of reacting with a variety of amino-acids to yield chemiluminescence and serve for their sensitive detection. However, the technique appeared to have limited analytical utility as initial studies had shown that the reaction does not occur with great efficiency under the usual conditions suggested for $\text{Ru}(\text{bpy})_3^{3+}$ studies (*i.e.*, at $\text{pH} \leq 7$).

A previous study¹⁶ of the oxidation of amino-acids by hexacyanoferrate(III) suggested that the reactive species was the anion of the amino-acid. If the reaction mechanism is similar with $\text{Ru}(\text{bpy})_3^{3+}$, the reaction should be faster at pH values equal to or greater than the pK_a of the N-terminal amine of the amino-acid, but a complication is that hydroxide ion also reacts with $\text{Ru}(\text{bpy})_3^{3+}$ to yield chemiluminescence. However, this approach would still have analytical merit if the reaction of the ruthenium complex with an amino-acid occurred with greater efficiency than that with hydroxide ion. The pH-dependence of the $\text{Ru}(\text{bpy})_3^{3+}$ /amino-acid reaction was therefore investigated to test this hypothesis.

Table 1 contains a summary of the pH-dependence of the reaction of $\text{Ru}(\text{bpy})_3^{3+}$ with glutamic acid. It is clear that at $\text{pH} < \text{pK}_a$ for glutamic acid (9.2), the amino-acid reaction does not produce sufficient chemiluminescence to be distinguishable from the buffer blank. However, at $\text{pH} > 8$, the reaction of $\text{Ru}(\text{bpy})_3^{3+}$ with the amino-acid occurs with greater facility than that with hydroxide. The chemiluminescence increases dramatically over the pH range 9–11. Besides glutamic acid (GLU, carboxylic acid side-chain), valine (VAL, hydrocarbon side-chain) and triethylamine (TEA) were tested in the pH range 6–11; pH values > 11 were not investigated because at pH 12 the hydroxide ion concentration was larger than the $\text{Ru}(\text{bpy})_3^{3+}$ concentration. The tertiary amine was chosen in order to compare the results of this study with a previous study of the reaction of amines with

Table 1. Luminescence signal vs. pH

pH	Luminescence signal		
	GLU	VAL	TEA

10	0.75	0.84	0.80
11	1.0	1.0	0.79

*Corrected for background and normalized to largest signal within a given data set.

$\text{Ru}(\text{bpy})_3^{3+}$.¹⁴ The results are summarized in Table 1.

From the data in Table 1 it is clear that pH is an important experimental variable in the amino-acid/ $\text{Ru}(\text{bpy})_3^{3+}$ reaction. Figure 2 clearly illustrates this. In Fig. 2, the signal for glutamic acid (a) is plotted along with the signal (b) for the buffer blank at each pH tested. It is evident that the amino-acid response is much greater than the signal from the hydroxide reaction. From the noise measured on the background signal, the signal-to-noise ratio (SNR) at each pH was determined and normalized, and is also plotted in Fig. 2c. The highest SNR, which corresponds to the optimum detectability, occurs at approximately pH 10, corresponding to the pH at which the nitrogen site in the amino-acid is appreciably deprotonated. The apparent slight decrease in the SNR at pH 11 is indicative of the fact that most (86%) of the amino-acid is deprotonated at pH 10. Thus, in going from pH 10 to 11, a substantial increase in the background signal is observed because the hydroxide ion concentration increases from 10^{-4} to $10^{-3}M$. At the same time, the fraction of amino-acid in the deprotonated form increases only from 86 to 98%. However, the background noise increased in proportion to the background signal with increase in pH, resulting in a decrease in SNR at pH values $> \sim 10$.

The pH-dependence of the reaction of $\text{Ru}(\text{bpy})_3^{3+}$ with amino-acids should also hold for the reaction with amines, but this would contradict a previous study¹⁴ which suggested that $\text{Ru}(\text{bpy})_3^{3+}$ reacts optimally with amines at between pH 4.5 and 6.0. To determine the origin of this discrepancy, the pH-dependence of the reaction of triethylamine with $\text{Ru}(\text{bpy})_3^{3+}$ was

Fig. 2. Effect of pH on the chemiluminescence of glutamic acid. (a) Background-corrected glutamic acid signal; (b) background signal from OH^- reaction; (c) SNR obtained from (a) and the noise measured on (b), at each pH. Concentration of $\text{Ru}(\text{bpy})_3^{3+}$ was $1.5mM$ in $0.4M$ Na_2SO_4 supporting electrolyte.

studied. In the previous study¹⁴ maximum chemiluminescence occurred at pH 6, whereas in the present work (Table 1) it was obtained at pH 9. A possible explanation is that in the previous study both the $\text{Ru}(\text{bpy})_3^{3+}$ and the amine solutions were buffered at the pH to be tested. Bard¹³ has shown that $\text{Ru}(\text{bpy})_3^{3+}$ solutions are most stable at $\text{pH} < 6$. Therefore, as the pH is increased to 7, some decomposition of the $\text{Ru}(\text{bpy})_3^{3+}$ solution would be expected, resulting in a diminished amount of the reagent available for the chemiluminescence reaction. In the previous study¹⁴ the results would be very sensitive to the amount of $\text{Ru}(\text{bpy})_3^{3+}$ available, since an approximately 10:1 molar ratio of amine to $\text{Ru}(\text{bpy})_3^{3+}$ was used. The optimum pH measured under such conditions would therefore represent a trade-off between the availability of the analyte in its most reactive form and the stability of the $\text{Ru}(\text{bpy})_3^{3+}$ reagent.

To avoid this problem, we used an unbuffered $\text{Ru}(\text{bpy})_3^{3+}$ solution and buffered only the amine or amino-acid to be tested. In addition, the $\text{Ru}(\text{bpy})_3^{3+}$ was used in at least 10-fold molar ratio to the amine or amino-acid. By measuring the pH of the solution after the reaction had occurred, it was ascertained that no significant pH change occurred as a result of either the dilution or the reaction.

Noffsinger and Danielson¹⁴ related the observed chemiluminescence for the reaction of $\text{Ru}(\text{bpy})_3^{3+}$ with amines to the first ionization potential of the non-bonding orbital of the nitrogen atom. In such a model, the observed chemiluminescence results from the formation of an amine radical by reaction of the amine with $\text{Ru}(\text{bpy})_3^{3+}$. The radical then reacts with a second $\text{Ru}(\text{bpy})_3^{3+}$ ion, producing an excited $\text{Ru}(\text{bpy})_3^{2+*}$, which subsequently decays to the ground state with the emission of a photon. Support for this model has been offered by Laloo and Mahanti¹⁶ who investigated the reaction of hexacyanoferrate(III) with amino-acids. By consideration of these studies, a mechanism can be offered for the reaction of $\text{Ru}(\text{bpy})_3^{3+}$ with amino-acids. The sequence is outlined below. It should be noted that in this mechanism, the deprotonation at the amine site is very important.

Therefore, on the basis of the $\text{p}K_a$ values alone, the normalized CL should be at a maximum at pH values slightly above the $\text{p}K_a$ of the protonated amine group. Thus, for the amino-acids, the optimum signal would be expected at $\text{pH} > 9$, and for triethylamine at $\text{pH} > 11$. Only the amino-acids showed the expected pH-dependence, however, triethylamine giving an optimal signal at a pH of approximately 9, well below its $\text{p}K_a$ value of 11.

A possible explanation for this requires consideration of the ionization potentials of amines and amino-acids. In general, it would be expected that the higher the ionization potential of the nitrogen site, the more important is the state of protonation at that site, in terms of the ability of the nitrogen atom to donate an electron. Thus donation of an electron by triethylamine, a tertiary amine with an ionization potential of only 8.0 eV,¹⁷ would be expected to be less dependent on the state of protonation than would be the case for the amino-acids, which are primary amines with ionization potentials of approximately 9.5 eV for the non-bonding electron on the nitrogen atom.¹⁸ This would result in a less straightforward dependence of the chemiluminescence reaction on pH. In support of this, for the reaction of $\text{Ru}(\text{bpy})_3^{3+}$ with ethylamine, $\text{p}K_a$ 11 and ionization potential 9.5 eV,¹⁹ it was found that the optimum signal was obtained at a pH of approximately 11 (highest pH tested), lending credence to the idea that the pH-dependence is related to the ionization potential of the nitrogen site.

The analytical capabilities of the $\text{Ru}(\text{bpy})_3^{3+}$ chemiluminescence technique were investigated by using a flow-injection system. Figure 3 shows the reproducibility of multiple injections of methionine over an order of magnitude range of injected mass. For multiple injections of the same standard, the reproducibility was better than 5%. A plot of normalized peak height *vs.* normalized mass of amino-acid injected was a straight line with a slope of 0.98 ± 0.04 , an intercept of 0.03 ± 0.03 and a correlation coefficient of 0.998 (5 points). For valine, a linear response was obtained from 1×10^{-10} to 100×10^{-10} mole. Linear plots were also obtained for arginine, glutamic acid and methion-

Fig. 3. Chemiluminescence response *vs.* methionine concentration. Multiple 20 μl injections of (a) 0.5, (b) 0.2, (c) 0.1 and (d) 0.05M methionine buffered at pH 10. $\text{Ru}(\text{bpy})_3^{3+}$ flow-rate 0.6 ml/min; pH 10 (borate, 0.05M) buffer flow-rate 0.5 ml/min. Ruthenium concentration as for Fig. 2.

ine over the range from 1.5×10^{-10} to 100×10^{-10} mole. After system optimization an injection of 1×10^{-10} mole of valine buffered at pH 10 gave a signal of 5.3 μA , and the root mean square noise in the buffer blank was found to be 0.50 μA . From these values, the minimum measurable injected quantity for the $\text{Ru}(\text{bpy})_3^{3+}$ system was calculated to be 3×10^{-11} mole of amino-acid ($3\sigma_{\text{blank}}$ criterion). The system was found to be stable for periods of several hours, as determined by repeated injections of the same standard.

To investigate the generality of this approach, eight different amino-acids were tested, representing the different side-chains found in the naturally occurring amino-acids. The results are summarized in Table 2. It is interesting that tryptophan, a secondary amine, gave no more chemiluminescence than the primary amine amino-acids, whereas secondary amines would be expected¹⁴ to give greater chemiluminescence than primary amines. It is possible that the aromatic ring in tryptophan may provide some delocalization of the electrons on the nitrogen atom, thereby diminishing the chemiluminescence.

Table 2. Relative luminescence for eight different amino-acids

Amino-acid	Side-chain type	Relative* luminescence
VAL	Hydrocarbon	1.00
MET	Sulfur-containing	0.79
PHE	Aromatic	0.71
GLU	Carboxylic acid	0.57
TRP	Aromatic amine	0.35
ARG	Basic/amine	0.28
GLY	Hydrogen	0.06
THR	Alcohol	0.04

*Normalized to valine.

As is evident, the $\text{Ru}(\text{bpy})_3^{3+}$ system provides an extremely sensitive way to detect amino-acids without derivatization. The relative response for the different amino-acids varies widely, but even in the least sensitive case (threonine), the limit of detection is estimated to be approximately 0.9 nmole of injected amino-acid. The optical system was not optimized, since the reaction chemistry was the primary reason for the investigation. With the pH-dependence resolved, optical optimization may provide significant improvements in the detectability. For example, visual observation of the reaction coil has shown that the amino-acid emission is localized in a region smaller than that sampled by the present detection system, but the background emission arising from the reaction with hydroxide ion occurs in a much larger region of the detection coil. Thus, more of the background signal than necessary is being sampled and optical imaging may help to isolate the analyte emission region while excluding regions of emission due only to the background hydroxide reaction.

In summary, the pH-dependence of the reaction of amino-acids with $\text{Ru}(\text{bpy})_3^{3+}$ has been investigated in terms of its implications for the detection of underivatized amino-acids separated by HPLC or introduced into a flow-injection system. It has been shown that the optimum chemiluminescence emission for amino-acids is observed at a pH between 10 and 11, which corresponds to the pH at which a significant percentage of the amino-acid exists in the anionic form. A background reaction between the $\text{Ru}(\text{bpy})_3^{3+}$ reagent and hydroxide ion has been observed to be less pH-dependent and it does not limit the technique. The method gives a linear response to amino-acid over a range of two orders of magnitude, and a minimum measurable quantity of 30 pmole of valine has been attained with a flow-injection system. These limits are already significant, considering that they were obtained with underivatized

amino-acid, but improvements are expected from optimization of the optical system. Studies to identify the relative importance of various parameters in the reaction chemistry are currently under investigation, including the role of the α -hydrogen atom on the reaction efficiency, and the importance of steric considerations at the nitrogen site.

EQUILIBRIUM CONSTANTS AND ASSAY OF BASES IN ACETONITRILE

JOSE BARBOSA, VICTORIA SANZ-NEBOT and ELENA TORRERO

Department of Analytical Chemistry, University of Barcelona, 08028 Barcelona, Spain

(Received 14 February 1990. Revised 3 July 1990. Accepted 24 October 1990)

Summary—The acid–base equilibria of a series of bases of pharmaceutical interest have been studied in acetonitrile medium and used to investigate the possibility of the use of this solvent to determine basic substances with complex and diverse structure. The pK_{HB} values of a series of cardiovascular compounds have been determined. From these values, simple potentiometric and visual titrations in acetonitrile media are proposed for the assay of bases in pharmaceutical formulations.

Acetonitrile is one of the most important dipolar aprotic solvents. It is used extensively as a reaction medium in synthesis and for mechanistic studies, as well as in electrochemistry, spectrophotometry and liquid chromatography. It owes its manifold applications in such diverse fields to a combination of physical properties,¹ particularly its high polarity ($\pi^* = 0.75$)² accompanied by only modest “chemical” solvating power towards many polar and ionic solutes. In common with all other dipolar aprotic solvents,³ acetonitrile typically behaves as a very weak electrophile. It is a much weaker hydrogen-bond donor than water ($\alpha = 0.19$)² but unlike protophilic dipolar aprotic solvents,³ it is also a weak hydrogen-bond acceptor ($\beta = 0.31$).² In consequence, many solutes have high and strongly differentiated reactivities (both kinetically and thermodynamically) in acetonitrile.

Acetonitrile is a much more differentiating solvent than water, reflected by its much smaller autoprotolysis constant⁴ ($pK_{ap} = 33.6$). Nevertheless, the dielectric constant of acetonitrile is high enough ($\epsilon = 36.0$) to allow extensive electrolytic dissociation of ionic solutes. However, many of the potential benefits of acetonitrile as a reaction medium are not fully realized because in the majority of cases the selection of this solvent was largely based on trial and error, as little information was available about the exact nature of the various solute species present and their interactions in this solvent.

The acid–base equilibria of a series of benzodiazepines in acetonitrile have previously been studied.⁴ In the present work, the dissociation constants of the protonated bases in another

series of cardiovascular compounds, the β -blockers, have been determined.

β -Adrenergic blocking agents are widely used in the treatment of cardiac arrhythmias, hypertension, angina and thyrotoxicosis and, because they are also used as doping agents in sport, these substances have been added to the list of substances forbidden by the International Olympic Committee (I.O.C.).

Although methods for the determination of β -adrenergic blocking drugs in urine or other biological fluids are of importance,⁵ rapid and simple quality-control methods for their assay in pharmaceutical formulations are also of interest.

This paper discusses acid–base equilibria in acetonitrile and proposes simple potentiometric and visual titrations for the assay of bases in pharmaceutical preparations.

EXPERIMENTAL

Apparatus

For potentiometric titrations, a Crison Digilab 517 pH-meter equipped with a Radiometer G202C glass electrode and the Pleskov (Ag/0.01M AgNO₃ in acetonitrile) reference electrode, with 0.1M tetraethylammonium perchlorate in acetonitrile as salt bridge, was used.⁶ This perchlorate was used on the assumption that the liquid-junction potential introduced would remain essentially constant.⁷ The titrant was added with a Metrohm 655 Multi-Dosimat automatic burette with a 2-ml exchangeable unit. Sample solutions were titrated in a double-walled vessel maintained at $25.0 \pm 0.1^\circ$ by circulating water, with magnetic stirring, under a continuous flow of nitrogen.

Reagents

Acetonitrile (Merck, for chromatography); nitromethane (Fluka, analytical grade); perchloric acid (Carlo Erba, RPE-ACS grade), 0.1M solution in nitromethane; picric acid (Doesder, analytical grade, vacuum-dried); tetraethylammonium perchlorate (Carlo Erba, RS grade) and tetrabutylammonium hydroxide (TBAH), 0.1M solution in propan-2-ol (Carlo Erba, RPE grade).

All β -blocker drugs were purified materials kindly supplied by Lab. Esteve (propranolol and metoprolol), Almirall (atenolol), Fides (alprenolol and sotalol), Squibb Ind. Farm, (nadolol), Ciba-Geigy (oxprenolol), Hoechst (penbutolol) and Rhône-Poulenc (acebutolol), pharmaceutical laboratories from Barcelona and Madrid.

Structure and nomenclature

Most β -adrenergic blocking agents can be structurally generalized by the formula shown in Fig. 1(a); they are oxypropanolamines which

(a)

(b)

Fig. 1. (a) General structure of β -adrenergic blocking agents. (b) Structure of sotalol, *N*-(4-[1-hydroxy-2-[(1-methylethyl)amino]ethyl]phenyl)methanesulphonamide.

differ in polarity because of the different aryl groups. Among the β -blockers studied, sotalol differs from the general structure and is shown in Fig. 1(b). The substituents at key positions of the compounds studied may be found in Table 1.

Determination of the dissociation constants

The dissociation constants were determined by potentiometry at $25.0 \pm 0.1^\circ$.

From the dissociation constant value of 10^{-11} found for picric acid in a careful study by

Table 1. Structure of β -adrenergic blocking agents

Substance	Ar	R	Systematic name
Acebutolol	$\text{CH}_3 - \text{CH}_2 - \text{CH}_2 - \text{CO} - \text{NH} - \text{C}_6\text{H}_4 - \text{CO} - \text{CH}_3$	—H	<i>N</i> -[3-Acetyl-4-(2-hydroxy-3-[(1-methylethyl)amino]propoxy)phenyl]butanamide
Alprenolol	$\text{CH}_2 = \text{CH} - \text{CH}_2 - \text{C}_6\text{H}_4$	—H	1-[(1-Methylethyl)amino]-3-[2-(2-propenyl)phenoxy]-2-propanol
Atenolol	$\text{NH}_2 - \text{CO} - \text{CH}_2 - \text{C}_6\text{H}_4$	—H	4-(2-Hydroxy-3-[(1-methylethyl)amino]-propoxy)benzeneacetamide
Metoprolol	$\text{CH}_3 - \text{O} - \text{CH}_2 - \text{CH}_2 - \text{C}_6\text{H}_4$	—H	1-[4-(2-Methoxyethyl)phenoxy]-3-[(1-methylethyl)amino]-2-propanol
Nadolol		—CH ₃	5-(3-[(1,1-Dimethylethyl)amino]-2-hydroxypropoxy)-1,2,3,4-tetrahydro-2,3-naphthalenediol
Oxprenolol	$\text{CH}_2 = \text{CH} - \text{CH}_2 - \text{O} - \text{C}_6\text{H}_4$	—H	1-[(1-Methylethyl)amino]-3-[2-(2-propenyloxy)phenoxy]-2-propanol
Penbutolol		—CH ₃	1-(2-Cyclopentylphenoxy)-3-[(1,1-dimethylethyl)amino]-2-propanol
Propranolol		—H	1-[(1-Methylethyl)amino]-3-(1-naphthyl)oxy)-2-propanol

Kolthoff and Chantooni,⁸ the standard potential of the cell was determined by titration of $5 \times 10^{-5} M$ picric acid in acetonitrile with TBAH, and the computer program ACETERISO⁹ was used to calculate the autoprotolysis constant of the medium as reported previously.^{6,10} In picrate-picric acid solutions in acetonitrile, water and alcohols up to $0.5 M$ have no effect on the pH,³ because the picrate ion has practically no hydrogen-bond acceptor properties.

The dissociation constants of the bases were determined by potentiometric titration of their $5 \times 10^{-3} M$ solutions in acetonitrile with $0.1 M$ perchloric acid in nitromethane. For atenolol, propranolol and sotalol, the constants were also determined in acetonitrile-water solutions (water approximately 0.025 and $0.05 M$). The electrode came to equilibrium very quickly after each addition of titrant.

The dissociation constant, K_{HB^+} , of the protonated base is given by

$$K_{HB^+} = a_{HS^+} \frac{[B]y_B}{[HB^+]y_{HB^+}} \quad (1)$$

where a represents activity and y the molar activity coefficient.

From the standard potential of the cell, a_{HS^+} can be calculated from the Nernst equation and the pH is defined by $pH = -\log a_{HS^+} \cdot [HB^+]$ and $[B]$ are computed from the analytical concentration of the base; y_B is assumed to be 1 and the activity coefficient of HB^+ is calculated from the "reduced" Debye-Hückel equation⁷

$$\log y_{HB^+} = -355z_i^2 \epsilon^{3/2} I^{1/2}$$

where z_i is the ionic charge, ϵ the dielectric constant and I the ionic strength. With these values, the pK_{HB^+} of the base is computed from each point of the titration.⁶

RESULTS AND DISCUSSION

Equation (1) was used in the manner described earlier⁴ to determine the pK_{HB^+} values of β -adrenergic blocking agents in acetonitrile. The results are shown in Table 2, together with literature data for the other bases. We estimate

Table 2. Equilibrium constants of bases: dissociation constants (pK_{HB^+}) and effective acidities (pK'_{HB^+}) in acetonitrile; formation constant of perchlorate salt ($\log K_{f,HA_c}^{BHClO_4}$) in acetic acid and dissociation constants (pK_{H_2O}) in water

that the pK_{HB^+} values in Table 2 should be accurate to better than ± 0.10 . This table includes only bases for which pK_{HB^+} and the formation constant of the perchlorate salt in acetic acid medium, $K_{\text{f,HAc}}^{\text{BHCIO}_4}$,^{14,15} are known, but additional data are available.^{4,6,11-15}

In solvents of relatively high dielectric constant, such as acetonitrile, in which perchlorate salts can be considered to be completely dissociated, the pH at 50% neutralization, pH_{HNP} , is equal to pK_{HB^+} if activity coefficients are neglected, even though homoconjugated species are present.³ In our work, however, activity coefficients are taken into consideration, *e.g.*, for sotalol the potential $E_{\text{HNP}} = -385.2$ mV, which corresponds to $\text{pH}_{\text{HNP}} = 17.55$ compared with $pK_{\text{HB}^+} = 17.46$.

All the protonated bases studied are much weaker acids in acetonitrile than in water. The factors contributing to the $\Delta pK_{\text{AN-H}_2\text{O}}$ values in Table 2 are illustrated by comparing the following equilibria:

and

where the subscripts indicate solvation by water (W) or acetonitrile (AN). Although the influence of the solvent is complex, taking into account the ability of acetonitrile to solvate cations but not anions, the dominant factor must be the much lower proton-acceptor power of acetonitrile compared with that of water.

In a study of the K_{HB^+} values of a large number of base cations in acetonitrile and water, Coetzee and Padmanabhan¹¹ found that ΔpK for aliphatic amines, pyridine, pyrrolidine and piperidine varied between 7.2 and 8.3, the average being 7.6. For the aromatic amines aniline and *p*-toluidine they found a difference of about 6 (Table 2). Similarly, Leffek *et al.*¹³ found that for a series of 30 phenyl-substituted derivatives of 2-phenyl-1,1,3,3-tetramethylguanidine (PhTMG) the mean value of ΔpK was 8.1 ± 0.5 the same as we find for β -blockers. The values reported⁴ for the benzodiazepines are in line with these results, with an average ΔpK value of 7.6.

The difference in pK_{HB^+} between acetonitrile and water in terms of transfer activity coefficients is expressed¹⁶ by equation (2):

$$\begin{aligned} {}^{\text{AN}}\Delta^{\text{W}}pK_{\text{HB}^+} &= (pK_{\text{HB}^+})_{\text{AN}} - (pK_{\text{HB}^+})_{\text{W}} \\ &= p\gamma_{\text{W} \rightarrow \text{AN}}^{\text{t}}(\text{HB}^+) - p\gamma_{\text{W} \rightarrow \text{AN}}^{\text{t}}(\text{H}^+) \\ &\quad - p\gamma_{\text{W} \rightarrow \text{AN}}^{\text{t}}(\text{B}) \end{aligned} \quad (2)$$

in which $\gamma_{\text{W} \rightarrow \text{AN}}^{\text{t}}(i)$ is the transfer activity coefficient from water to acetonitrile for species *i*. The symbol $\gamma_{\text{W} \rightarrow \text{AN}}^{\text{t}}$ is preferred here to the alternative one, ${}^{\text{AN}}\gamma_i^{\text{O}}$, approved by IUPAC.¹⁷

The transfer activity coefficient is closely related to $\Delta G_{\text{W} \rightarrow \text{AN}}^{\text{t}}(i)$, the standard free energy of transfer of 1 mole of species *i* from water to acetonitrile.

$$\log \gamma_{\text{W} \rightarrow \text{AN}}^{\text{t}}(i) = [\Delta G_{\text{W} \rightarrow \text{AN}}^{\text{t}}(i)]/2.303RT$$

A recent review¹⁸ discussed the various extrathermodynamic assumptions made in finding transfer activity coefficients. In the present work the $\log \gamma_{\text{W} \rightarrow \text{AN}}^{\text{t}}(\text{H}^+)$ value of 8.1 reported by Kolthoff and Chantooni¹⁹ is used, based on the "Parker" (or "tetraphenylborate") assumption that $\gamma^{\text{t}}(\text{AsPh}_4^+) = \gamma^{\text{t}}(\text{BPh}_4^-)$, which appears to yield more accurate $\gamma_{\text{W} \rightarrow \text{AN}}^{\text{t}}(i)$ values than any other assumption.²⁰ There is no uniform agreement on the sign convention. In this work a value of $\log \gamma_{\text{W} \rightarrow \text{AN}}^{\text{t}}(\text{H}^+)$ of 8.1 means that a solute giving a hydrogen-ion activity of 1 in acetonitrile would give an activity of $10^{-8.1}$ in water. Therefore, positive values of $\log \gamma^{\text{t}}$ indicate that the solvent-solute interactions are greater for the solute in water than in the solvent.

Taking into account that the $\Delta pK_{\text{AN-H}_2\text{O}}$ values determined are close to 8.1 (Table 2), the influence of the proton-transfer activity coefficient value on the difference in pK_{HB^+} values could be important [equation (2)].

Even though acetonitrile is much more inert than water, it still solvates ammonium ions significantly, since in acetonitrile, as in water, tertiary ammonium ions are generally stronger acids than the corresponding secondary or primary ammonium ions.

Aromatic ammonium ions (anilinium and *p*-toluidinium ions) are considerably stronger acids in acetonitrile than would be predicted from the strength of protonated aliphatic amines. This fact indicates probably either decreased solvation of aromatic amines or increased solvation of aromatic ammonium ions by water.^{11,21}

On the other hand, in the case of derivatives of the PhTMG bases¹³ there is no hydrogen bonding to stabilize the base and consequently $\Delta pK_{\text{AN-W}}$ is practically equal to $\log \gamma_{\text{W} \rightarrow \text{AN}}^{\text{t}}(\text{H}^+)$.

Even in solvents with very poor hydrogen-bonding donor ability, such as acetonitrile,² hydrogen-bonding with acids is strong enough to make dimerization of the acids very small and

virtually negligible in dilute solution.³ However, particularly in protophobic solvents such as acetonitrile, hydrogen-bonding between an anion and its conjugate acid (homoconjugation) has a large effect on the slope of the titration curve and makes acetonitrile not very suitable for successive titrations of acids in mixtures, although it is a solvent with good resolving power for acids.³ The corresponding complexes AHA^- formed between Brønstad acids and their anions are more stable than the BHB^+ complexes.¹¹ This difference reflects the fact that the solvation of cations rather than anions is more marked for acetonitrile than for water.²² The formation constants of hydrogen-bonded complexes between free and protonated bases, BHB^+ , in acetonitrile have been determined and their values in general are very small.^{4,11} In this paper the formation constants of the BHB^+ homoconjugated complexes for the β -blockers are evaluated by the method of Coetzee *et al.*²² from plots of $(E^0 - E) - g \log y_{\text{HB}^+}$ vs. $\log (c_b/c_s)$, where E^0 and E are the standard potential and the potential of the cell respectively, $g = 2.303RT/F$ and c_b and c_s are the analytical concentrations of the base and salt, respectively. Plots for several β -blockers are shown in Fig. 2.

It follows from the Nernst equation that a plot of $(E^0 - E) - g \log y_{\text{HB}^+}$ vs. $\log ([\text{B}]/[\text{HB}^+])$ will be linear with a slope of 59 mV/decade at 25°. If no complexation occurs between B and HB^+ , $[\text{B}]$ and $[\text{HB}^+]$ are given by c_b and c_s respectively, but otherwise the plot will deviate from linearity, increasing the slope.

Figure 2 shows no evidence for formation of BHB^+ complexes for β -blockers under

Fig. 2. Plot of $(E^0 - E) - g \log y_{\text{HB}^+}$ vs. $\log (c_b/c_s)$ for several β -blockers. \square , Sotalol; \triangle , oxprenolol; \diamond , nadolol; \times , atenolol; $+$ propranolol.

Fig. 3. Plot of pK_{HB^+} in acetonitrile vs. $pK_{\text{H}_2\text{O}}$ for bases numbered as in Table 2. \square , From references (4) and (6); \triangle , from reference (11); \times , from reference (13); \diamond , β -blockers.

the experimental conditions used, since in all cases linear plots with slopes close to 59 mV/decade were obtained. The curves for the neutralization of β -blockers with perchloric acid in acetonitrile can therefore be calculated in the same way as for aqueous media, since homoconjugation is negligible in dilute solutions, as is usually the case for bases.²³

In order to study the effects of hydrogen-bond donors such as water on the pK_{HB^+} values of β -blockers in acetonitrile, the representative β -blockers atenolol, propranolol and sotalol were also studied in acetonitrile containing low concentrations of water (up to 0.05M). The results were not significantly different from those in Table 2, which can be explained by these bases having very low homoconjugation constants.³

Analytically, resolution of acid strength in dipolar aprotic solvents is very important. For acids of a given class, HB^+ , the resolution R in acetonitrile is given by the relationship

$$(pK_{\text{HB}_2^+} - pK_{\text{HB}^+})_{\text{AN}} = R(pK_{\text{HB}_2^+} - pK_{\text{HB}^+})_{\text{W}}$$

in which the left-hand side is the difference in pK_{HB^+} values in acetonitrile, and the right-hand side is the difference in water, multiplied by R .³

For the substituted benzoic acids and for non-*ortho*-substituted phenols, the values of R in acetonitrile were 2.60 and 2.24, respectively.³ However, a plot of pK_{HB^+} values of bases in acetonitrile vs. the pK_{HB^+} values in water is roughly linear, as shown in Fig. 3, with a slope of 1.06. Figure 3 also shows all the pK_{HB^+} literature data from references 4, 6, 11 and 13.

This low value of R is in agreement with the observation that aprotic solvents do not much improve the resolution of acid strength of cationic acids, in contrast to the case for uncharged acids.³

From equation (2), the difference between ${}^{\text{AN}}\Delta^{\text{w}}\text{p}K_{\text{HB}_2^+}$ and ${}^{\text{AN}}\Delta^{\text{w}}\text{p}K_{\text{HB}_1^+}$, (${}^{\text{AN}}\Delta\Delta^{\text{w}}\text{p}K_{\text{HB}_2^+}^{\text{HB}_1^+}$), can be expressed in terms of the transfer activity coefficients:³

$$\begin{aligned} {}^{\text{AN}}\Delta\Delta^{\text{w}}\text{p}K_{\text{HB}_2^+}^{\text{HB}_1^+} &= [\text{p}\gamma_{\text{W}\rightarrow\text{AN}}^{\text{HB}_2^+}] \\ &\quad - \text{p}\gamma_{\text{W}\rightarrow\text{AN}}^{\text{HB}_1^+}] \\ &\quad - [\text{p}\gamma_{\text{W}\rightarrow\text{AN}}^{\text{B}_2}] \\ &\quad - \text{p}\gamma_{\text{W}\rightarrow\text{AN}}^{\text{B}_1}] \end{aligned}$$

From this expression, it appears that the resolution R is independent of the proton transfer activity coefficient.

In the case of uncharged acids, the main reason for the resolution obtained could be that the capacity of acetonitrile to solvate anions is very weak.³ Acetonitrile has practically no hydrogen-bond donor capacity, whereas water has a high hydrogen-bonding donor capacity with a solvatochromic parameter of 1.17.² Thus, acids such as carbon acids, the anions of which are not hydrogen-bonded in hydrogen-bond donating solvents, do not exhibit resolution of acid strength between amphiprotic and aprotic solvents³ and no difference was found in the resolution of acid strength between non-hydrogen-bond donor solvents such as acetonitrile, *N,N*-dimethylformamide and dimethylsulphoxide.²⁴

The difference in hydrogen-bond accepting capacity between acetonitrile ($\beta = 0.31$)² and water ($\beta = 0.47$)²⁵ is much smaller, however, than the difference in their hydrogen-bond donor capacities, and acetonitrile solvates HB^+ cations much better than A^- anions. This explains why the resolution of acid strengths of cationic acids HB^+ is very much smaller than for uncharged acids HA .

Traditional $\text{p}K$ measurements reflect the degree of dissociation of a species in a given solvent, but do not provide a valid measure of the relative proton activity.²⁶ One of the main purposes of studies dealing with the influence of solvents on acid–base equilibria is to obtain a solvent-independent acidity or basicity scale. By referring the acid–base character of non-aqueous solvents to the same aqueous standard state, an “absolute” pH' scale is obtained which allows the acidity and

basicity of aqueous solutions to be compared directly:²⁷

$$\text{pH}' = \text{pH} + \text{p}\gamma_{\text{W}\rightarrow\text{S}}^{\text{H}^+}$$

The transfer activity coefficient represents the acid end of the solvent-independent pH' scale in each distinct solvent S , with ultimate reference to the familiar aqueous pH scale and physical comparability with the latter. The basic limit of the pH' scale in any solvent is conventionally defined by its autoprotolysis constant.²⁸

For an aprotic solvent such as acetonitrile, the dissociation constants are translated into the absolute scale by the equation

$$\text{p}K'_{\text{HB}^+} = \text{p}K_{\text{HB}^+} + \text{p}\gamma_{\text{W}\rightarrow\text{AN}}^{\text{H}^+}$$

The effective acidity ($\text{p}K'_{\text{HB}^+}$) provides a measure of both the proton activity in non-aqueous media and the ability to catalyse proton-induced reactions.²⁹ The values of $\text{p}K'_{\text{HB}^+}$ shown in Table 2 provide a measure of the effective acidity of the protonated bases, irrespective of the medium.

On the other hand, the autoprotolysis constant defines the normal range of pH in the solvent and also has important bearings on acid–base titrations in non-aqueous media, where the “ pH jump” at the equivalence point is larger, the greater the $\text{p}K_{\text{ap}}$ value. This value is a composite function of the intrinsic acidic and basic strengths of the solvent and its relative permittivity.³⁰

Then, in the titration of a base

where H_5^+ denotes the solvated proton, the weaker the solvent is as a base and as an acid, the further to the right the equilibrium lies and the larger the “ pH jump” at the equivalence point. For these reasons, very weak bases such as urea and lormetazepam^{4,6} are titrated in acetonitrile, because the formation constant of HB^+ increases and K_{HB^+} decreases with decreasing acid–base strength of the solvent.

Although acetic acid has been a popular solvent for the titration of bases,^{1,14,15,31} the formation constants of HB^+ are much larger in acetonitrile [$K_{\text{f}}(\text{HB}^+) = 1/K_{\text{HB}^+}$] than in acetic acid ($K_{\text{f},\text{HAc}}^{\text{BHClO}_4}$),¹⁴ as shown in Table 2. Hence the break in pH at the end-point is much greater for titration in acetonitrile than in acetic acid. Titration in acetonitrile extends the potential range at the basic end to several hundred mV below that for acetic acid.⁴ The difference in the

"pH jump" is approximately equal to the difference between pK_{HB^+} and $\log K_{f,HAc}^{BHClO_4}$.

Furthermore, for the differentiating titration of two or more bases of different strengths, it is frequently necessary to avoid the levelling effect of acetic acid. This may be done by titration in a non-levelling solvent such as acetonitrile, with perchloric acid dissolved in nitromethane.^{4,6}

The usefulness of acetonitrile for the titration of mixtures of bases was tested in this work and earlier^{4,6} and we conclude that binary mixtures of bases differing in pK_{HB^+} by ≥ 2.5 can be successfully titrated with perchloric acid in nitromethane with potentiometric detection of the end-point. Some mixtures are of great pharmaceutical interest, *e.g.*, trimethoprim and sulfa-methoxazole, potentiometric titration provides a differentiating assay with errors of less than 2%.

$K_{f,HAc}^{BHClO_4}$ values¹⁵ are plotted against the respective dissociation constants of the protonated bases in acetonitrile in Fig. 4. Most of the bases investigated, despite their marked structural differences and the fact that their equilibrium constants were estimated under different experimental conditions, fall into one of two groups, each with reasonable linearity. Only sulphamethoxazole seems not to conform.

The vertical straight line can certainly be attributed to the levelling properties of anhydrous acetic acid. Thus, bases with a pK_{HB^+} value in acetonitrile greater than ~ 12.5 or a pK_{H_2O} value greater than ~ 5 are levelled in acetic acid medium.¹⁵ In contrast, levelling of the strongest bases does not occur in acetonitrile, as this solvent is too weak an acid.¹¹

Fig. 4. Plot of pK_{HB^+} values in acetonitrile vs. $\log K_{f,HAc}^{BHClO_4}$ for bases, numbered as in Table 2.

It is of interest that for bases that are not levelled in acetic acid medium, there is a negative correlation between the formation constants, $\log K_f(HB^+)$, in acetonitrile, acetic acid and water and their solvatochromic parameters E_T^N ,³² if their pK_{H_2O} values are greater than 1.5.

The intrinsic acidic and basic strengths of the solvent and its relative permittivity have an influence on $K_f(HB^+)$, *i.e.*, on the pH change at the end-point of a titration.^{29,30} Acetonitrile, acetic acid and water are similar in basic strength, since their β values are not very different.^{2,25} However, they are very different in polarity and acidic strength. The correlation of $\log K_f(HB^+)$ and E_T^N for these three solvents can be explained by the fact that the E_T^N parameter is a measure of the polarity-polarizability of the solvent and its hydrogen-bond donor acidity.³²

The answer to how strong a base must be to give a satisfactory potentiometric titration end-point in acetonitrile is that pK_{HB^+} must be approximately 6 or greater. This theoretical principle has been tested.

Hence, titration graphs with sharp and reproducible inflection points, and $< 2\%$ error were obtained in acetonitrile for all the bases investigated (Table 2), even for the extremely weak bases urea and lormetazepam, which cannot be titrated potentiometrically in acetic acid medium with any degree of accuracy.

On the other hand, those organic bases employed in pharmaceutical preparations and which show a sharp break in the titration curve, may be determined by the more rapid indicator method with the same accuracy and precision as by the potentiometric method.

The change in pH near the equivalence point can be calculated from the dissociation constant of the protonated base, so it is possible to predict which indicators (I) will give sharp colour changes in the equivalence range, since the pK_{HI^+} values and the quality of colour change in acetonitrile are known.^{10,33} The β -blockers were visually titrated with errors $< 2\%$, the indicator selected on the basis of pK_{HI^+} and the quality of colour change being Tropaeolin 00. For visual titrations of bases in acetonitrile we suggest the use of the previously reported series of indicators for the acid-base scale in acetonitrile,¹⁰ from which it is easy to select the best indicator for a specific titration.^{10,33}

STUDIES ON METAL CARBONATE EQUILIBRIA—PART 21* STUDY OF THE U(VI)–H₂O–CO₂(g) SYSTEM BY THERMAL LENSING SPECTROPHOTOMETRY

G. BIDOGLIO, P. CAVALLI, I. GRENTHE,† N. OMENETTO,‡ PAN QI§ and G. TANET

(Received 29 January 1990. Revised 18 June 1990. Accepted 30 October 1990)

Summary—Equilibria in the U(VI)–H₂O–CO₂(g) system in 0.5M sodium perchlorate medium at 25° have been studied. By using thermal lensing spectrophotometry (TLS) and a very low total concentration of U(VI) ($4 \times 10^{-6}M$) information could be obtained on equilibria involving $UO_2(CO_3)_2^{2-}$ without complications due to formation of the trimer $(UO_2)_3(CO_3)_6^{6-}$. The experimental data allowed a precise determination of the equilibrium constant $\log K_3 = 6.35 \pm 0.05$ for the reaction $UO_2(CO_3)_2^{2-} + CO_3^{2-} \rightleftharpoons UO_2(CO_3)_3^{4-}$. The interpretation of TLS data is briefly discussed, as well as the potential use of this technique for studies of the speciation of trace elements in natural water systems.

Uranium(VI) forms strong complexes with the carbonate ion. The following species have been identified:¹ UO_2^{2+} , $UO_2CO_3(aq)$, $UO_2(CO_3)_2^{2-}$, $UO_2(CO_3)_3^{4-}$, and the trimer $(UO_2)_3(CO_3)_6^{6-}$. $UO_2(CO_3)_3^{4-}$ is the limiting complex, *i.e.*, it contains the maximum number of co-ordinated carbonate ions per UO_2^{2+} ion. The trimer is very stable and the equilibrium constant for the reaction

in 0.5M sodium perchlorate medium is $\sim 10^{7.6}$. As a result, the concentration of the trimer is much larger than that of the monomer $UO_2(CO_3)_2^{2-}$, except at a very low total concentration of U(VI), *i.e.*, $10^{-5}M$ or lower. Special experimental methods must be used to detect and study the properties of $UO_2(CO_3)_2^{2-}$. Solubility experiments may give the desired information provided that the solubility of the solid phase is sufficiently low. This is the case for $UO_2CO_3(s)$.¹ Conventional spectrophotometry was used by Scanlan² to study the equilibrium between $UO_2(CO_3)_3^{4-}$ and $UO_2(CO_3)_2^{2-}$. Despite the low total concentration of U(VI) used,

$10^{-4}M$, the concentration of $(UO_2)_3(CO_3)_6^{6-}$ was not negligible.

Thermal lensing spectrophotometry (TLS)³ has many of the characteristics of conventional spectrophotometry but much higher sensitivity. In previous communications^{4,5} we have outlined how this method may be used for the quantitative study of equilibria in solution.

Spectrophotometry is a quick and reliable experimental method, but its use in equilibrium analysis is complicated by the need to determine the equilibrium constants *and* the molar absorptivities for the various complexes, *cf.* Rossotti and Rossotti.⁶ There are many reports on the use of graphical⁶ and numerical methods^{7,8} for the evaluation of spectrophotometric equilibrium data. To establish a unique chemical model it is generally necessary to rely on experimental data of high precision and to vary the concentrations of the reactants over as large a concentration range as possible. When this is not possible there will invariably be ambiguities in the interpretation.

TLS and laser-induced photoacoustic spectroscopy (LIPAS) have been proposed as possible tools for the determination of the chemical form of trace elements (speciation) in ground water systems.⁹⁻¹³ Both methods have the required high sensitivity but, as will be outlined in this work, this is in general not sufficient to determine the speciation of a trace element in a multiligand system such as ground water.

This communication describes the experimental technique used to obtain TLS data, and their chemical interpretation. Some remarks on the use of TLS (which can also be applicable to other laser techniques) for the study of speciation of trace elements in ground waters will also be made.

EXPERIMENTAL

Chemicals

All chemicals used were of reagent grade. The various stock solutions of HClO_4 , NaClO_4 , NaHCO_3 and $\text{UO}_2(\text{ClO}_4)_2$ were prepared and analysed as described before.¹⁴ Carbon dioxide (100%) and a 10.33% CO_2/N_2 gas mixture were obtained from SIO, Milan, and analysed by them.

TLS equipment

The excimer laser and the dye laser systems were the same as described before.¹⁵ The measurements were made at 448 nm, obtained by using Coumarin 450 dissolved in spectroscopically pure methanol. The total concentration of U(VI) was $4 \times 10^{-6} \text{M}$. The overall efficiency of the system was only about 40% of that obtained in our previous studies,^{4,5} mainly because of the lower performance of the excimer laser. The maximum energy available from the dye was $\sim 1 \text{ mJ/pulse}$. The TLS signals, obtained by boxcar averaging of 30 laser firings, were displayed on a chart recorder. These signals were then normalized by means of an

external reference solution (a dilute aqueous solution of potassium dichromate) which was measured immediately before and after the test solutions. This procedure allowed correction for unavoidable random drifts and variations in the efficiency of the system, which were not simply due to fluctuations in the laser power, which was constantly monitored with a pyroelectric detector. For each test solution, the measuring sequence was external standard, test solution, external standard. The experimental results obtained at 25° are collected in Table 1, together with their estimated random error.

Carbonate concentrations from 10^{-9} to 10^{-4}M must be studied to cover the entire complex-formation range in the U(VI)- H_2O - $\text{CO}_2(\text{g})$ system. It is advantageous to use a titration technique as described previously.⁵ This system was modified slightly by the addition of a gas trap after the filter, to prevent the gas-bubbles released by the pressure drop over the filter from reaching the cuvette. This device worked quite well, although some gas-bubbles occasionally entered the cuvette and caused extensive random deflections of the probe laser beam. When this happened the measurements were repeated.

The carbonate concentration was varied by titrating an initial solution of composition 20.00mM NaHCO_3 , 0.480M NaClO_4 , $4 \times 10^{-6} \text{M}$ U(VI) with a solution of composition 200.0mM HClO_4 , 0.300M NaClO_4 , $4 \times 10^{-6} \text{M}$ U(VI). The total concentration of U(VI) was thus kept constant, throughout the

titration and $[H^+]$ and $[CO_3^{2-}]$ varied. The partial pressure of $CO_2(g)$ was kept constant throughout the titrations by bubbling CO_2 through the test solutions. The hydrogen-ion concentration was measured with a glass electrode, calibrated by means of the known hydrogen-ion concentration in the initial solution, which was calculated from the known value of $\log K_{a1} = -7.607$, the equilibrium constant for the reaction $CO_2(g) + H_2O \rightleftharpoons H^+ + HCO_3^-$ in the given ionic medium and at the temperature used.²⁰ The titrant was added by use of calibrated Eppendorf pipettes. The experimental results are given in Table 1 and in Fig. 1.

Interpretation of data

The chemical equilibria in the U(VI)- H_2O - $CO_2(g)$ system can be described by

where $(OH)CO_2^-$ represents HCO_3^- and $(OH)_2CO_2^{2-}$ represents CO_3^{2-} .

From previous work¹ it is known that the complexes formed under the conditions used in this study are mononuclear and contain only CO_3^{2-} as the ligand (the latter point being verified by the fact that the data in Fig. 1 were independent of P_{CO_2}). It follows that equation (2) can be written as

Fig. 1. Experimental TLS data points for S^*/BS_3 vs. $\log(P_{CO_2}/[H^+]^2)$ and normalized curves for R vs. $\log u$. The full line is the best normalized curve, shown in the position of best fit (obtained by using $S_2/S_3 = 0.2$, $S_1/S_3 = 0.15$, $S_0/S_3 = 0.1$, $L = 0.15$, $M = 10^{-3}$). The dotted line was similarly calculated but with $L = 0.10$. From the position of best fit we obtain (for $\log u = 0$):

$$\log K_3 = 17.25 - \left(\log \frac{P_{CO_2}}{[H^+]^2} \right)_{\log u = 0} = 6.35 \pm 0.05$$

The TLS signal (S^*) corrected for the effect of the solvent is given by

$$S^* = S - S_{\text{solv}} = B \left(\frac{S_3 \beta_3 a^3 + S_2 \beta_2 a^2 + S_1 \beta_1 a + S_0}{\beta_3 a^3 + \beta_2 a^2 + \beta_1 a + 1} \right) \quad (4)$$

where S and S_{solv} are the TLS signals for the test solution and the solvent, respectively, B is total concentration of U(VI), S_n is the molar value of the TLS signal for $UO_2(CO_3)_n^{2-2n}$ (S_n is analogous to the molar absorptivity), β_n is the equilibrium constant for reaction (3), and a is the free carbonate concentration. By introducing the normalized variables $1/u = \beta_2/\beta_3 a$; $L = \beta_1 \beta_3 / \beta_2^2$ and $M = \beta_3^2 / \beta_2^3$ we can transform equation (4) into

$$S^* = BS_3 \left[\frac{1 + (S_2/u + S_1 L/u^2 + S_0 M/u^3)/S_3}{1 + 1/u + L/u^2 + M/u^3} \right] \equiv BS_3 R \quad (5)$$

From equation (4) it is obvious that $S^*/BS_3 \rightarrow 1$ with increasing a . In Fig. 1 we have plotted the experimental data S^*/BS_3 as a function of $\log(P_{CO_2}/[H^+]^2)$ (the latter quantity is proportional to $\log a$).

The experimental data can be compared with model functions $R(u, L, M, S_n)$ where the function R is as defined in equation (5). The shape of the model function depends on L , M and S_n . By comparing graphs of R vs. u with the experimental plots for S^*/BS_3 vs. $\log(P_{CO_2}/[H^+]^2)$ (or $\log a$), we can, in principle, determine the parameters in equation (4). At the position of best fit, we obtain (at $\log u = 0$)

$$\log \frac{\beta_3}{\beta_2} = \log K_3 = 17.25 - \left(\log \frac{P_{CO_2}}{[H^+]^2} \right)_{\log u = 0}$$

where $17.25 = -\log K_{a2}$.²⁰ For further details refer to the literature.^{5,16-18} From Fig. 1 it is obvious that the largest variations in the experimental quantity occur in the region where the complexes $UO_2(CO_3)_3^{4-}$ and $UO_2(CO_3)_2^{2-}$ are predominant. The variations are much smaller in the range where UO_2^{2+} and $UO_2CO_3(aq)$ are present. Hence, we should be able to obtain the most precise information for the reaction

with equilibrium constant $K_3 = \beta_3/\beta_2$, as is indeed the case.

The value of S_3 is obtained from the initial solution in the absence of $CO_2(g)$. The carbon-

ate concentration is then so high that all U(VI) is present as $\text{UO}_2(\text{CO}_3)_3^{4-}$.

RESULTS AND DISCUSSION

As seen from Table 1, the precision in the individual determinations of S^*/BS_3 was fairly good, but repeating the experiments gave a much larger scatter in the results (*cf.* Fig. 1). An uncertainty of ± 0.02 in S^*/BS_3 therefore seems to be a better estimate than the values obtained for the individual test solutions. In the present experiment the absolute error obtained was the same for all the solutions investigated. The large relative error in S^*/BS_3 in the range where UO_2^{2+} and $\text{UO}_2\text{CO}_3(\text{aq})$ predominate means that we can only determine the equilibrium constants β_1 and β_2 with a low degree of accuracy.

The experimental data can be described quite well with just equilibrium reaction (6). A least-squares refinement gave $\log K_3 = 6.42$ and $S_2/S_3 = 0.11$. However, from previous experiments it is known that $\text{UO}_2\text{CO}_3(\text{aq})$ and UO_2^{2+} will be present in non-negligible amounts in some of the test solutions at the lower values of $-\log [\text{H}^+]$. Hence, we preferred to make the curve-fitting by using the complete equation (5), but with S_1/S_3 and S_0/S_3 as fixed parameters estimated as described below. The variables L and M were also assigned a fixed value. By comparing the experimental data with plots for different model functions R *vs.* $\log u$, we obtained, in the position of best fit, $\log K_3 = 6.35 \pm 0.05$ by using a curve with $S_2/S_3 = 0.20 \pm 0.05$; $S_1/S_3 = 0.15$; $S_0/S_3 = 0.1$; $L = 0.15 \pm 0.05$; $M = 10^{-3}$.

The value of $\log K_3$ is not very sensitive to the values of the other parameters, with the exception of S_2/S_3 . The full line in Fig. 1 is the normalized curve in the position of best fit. The dotted line was obtained by using $L = 0.1$, with the other parameters the same as for the full line. By comparing the two curves we estimate the error in L to be ± 0.05 .

The ratio S_0/S_3 was estimated from the experimental curve to be approximately 0.1 at low values of $\log(P_{\text{CO}_2}/[\text{H}^+]^2)$. From the experimental data we observe that S^*/BS_3 increases as UO_2^{2+} is transformed into $\text{UO}_2\text{CO}_3(\text{aq})$. Hence the value of S_1/S_3 should be larger than the value of S_0/S_3 (*i.e.*, > 0.1) but smaller than S_2/S_3 (*i.e.*, < 0.2), so we have chosen $S_1/S_3 = 0.15$.

We can now compare the results obtained in this TLS investigation with previous results, *cf.*

Table 2. The agreement between the equilibrium constants is satisfactory. The ratio S_2/S_3 can also be calculated from the spectra given by Bidoglio *et al.*⁴ In that case, in the solution denoted " $\text{UO}_2(\text{CO}_3)_3^{4-}$ ", about 90% of the uranium was present as $\text{UO}_2(\text{CO}_3)_3^{4-}$, and the rest as $\text{UO}_2(\text{CO}_3)_2^{2-}$; the solution denoted " $\text{UO}_2(\text{CO}_3)_2^{2-}$ " contained approximately equal concentrations of $\text{UO}_2(\text{CO}_3)_3^{4-}$ and $\text{UO}_2(\text{CO}_3)_2^{2-}$. Using this information and the TLS signals reported in the previous study,⁴ we obtain $S_2/S_3 \sim 0.2$, in good agreement with our result.

To calculate the various β_n values we need information not only on K_3 and L but also on M . The latter quantity can only be obtained from the data at the lower end of the S^*/BS_3 *vs.* $\log a$ curve, where the experimental errors are the largest. Hence, no precise value can be obtained for M in this study; a model with $M = 0$ and $S_2/S_3 = 0.12$ will fit the experimental data as well as the one proposed. However, even this model gives $\log K_3 = 6.35$ and $S_1/S_3 = 0.2$. Other mononuclear models do not give a satisfactory fit. If noticeable quantities of $(\text{UO}_2)_3(\text{CO}_3)_6^{6-}$ had been formed, the experimental (and model) curve would have been much steeper.¹⁹ Thus, at the level of precision attained in this study, we can safely exclude the formation of quantities of the oligomer $(\text{UO}_2)_3(\text{CO}_3)_6^{6-}$ larger than 5%, but not smaller quantities of this or other complexes than those postulated. The limitations just discussed are not characteristic for the TLS method, but for *any* solution chemical method.

Information about the speciation of trace elements in natural water systems is of interest for several reasons. The chemical form of the trace metal may influence its toxicity or its beneficial effects. The chemical form may also influence the rate of transport of the trace elements, *e.g.*, by affecting their sorption on the solid phases encountered along the transport path. The speciation is often derived indirectly

Table 2. Comparison between equilibrium data and spectroscopic information obtained in this study with some literature data

†Calculated from the TLS spectra⁴ as discussed in the text.

by calculating the species distribution from known analytical data for the water (*e.g.*, pH, redox potential, total concentration of ligands and concentrations of the major cations), and a suitable thermodynamic database for the elements in question. The quality of the calculation is no better than the quality of the database. TLS and other laser techniques, such as LIPAS, are important experimental tools because they allow us to study chemical equilibria in the laboratory at concentrations closer to those found in nature. This is particularly important for elements which may form polynuclear complexes when "ordinary" experimental methods (which in general require total concentrations of $10^{-4}M$ or larger) are used, but form mononuclear complexes at the very low total concentrations usually encountered in surface and ground water systems. One example is the hydrolysis of metal ions,⁵ another is the oligomerization of $UO_2(CO_3)_2^{2-}$, as discussed in this communication. The laser methods thus make it possible to improve the databases used for equilibrium ("speciation") calculations.

The laser techniques may also be useful for on-line investigations of trace elements, either at a fixed wavelength or at several different wavelengths. In order to obtain information on speciation in systems containing more than one ligand it is necessary to have rather large differences in the spectra of the complexes. This is rarely the case for inorganic ligands. However, elements such as the actinides have quite different spectra in each oxidation state. The laser techniques then offer a convenient way to obtain information on the oxidation states, as exemplified by the work of Pollard *et al.*¹³

STUDIES OF POLYFUNCTIONAL *O*-LIGANDS: FORMATION AND STABILITY OF Mg^{2+} AND Ca^{2+} COMPLEXES OF 1,2,4,5-BENZENETETRACARBOXYLIC ACID IN AQUEOUS SOLUTION AT 25°

ALESSANDRO DE ROBERTIS and CONCETTA DE STEFANO

Istituto di Chimica Analitica dell'Università, Salita Sperone 31, P.O. Box 30,
I-98166 S. Agata di Messina, Messina, Italy

(Received 21 February 1990. Revised 5 November 1990. Accepted 9 November 1990)

Summary—The stabilities of the Ca^{2+} and Mg^{2+} complexes with 1,2,4,5-benzenetetracarboxylic acid (pyromellitic acid) were studied potentiometrically, at 25°. The species ML , MHL , MH_2L , and M_2L [L = pyromellitate⁴⁻; M = Ca^{2+} , Mg^{2+}] were found to be present in solution (for Mg^{2+} the species MH_3L was also found). The dependence of the formation constants on ionic strength, and the stability trends of the Ca^{2+} and Mg^{2+} complexes with carboxylate ligands, are discussed.

Magnesium and calcium cations form not very strong complexes with carboxylate ligands.¹⁻⁹ As an example, monocarboxylate ligands form CaL^+ complexes (L = acetate, phenoxyacetate, salicylate) with a mean stability constant $\log K = 0.9$ ($I = 0M$, $T = 25^\circ$)^{4,6,8} and dicarboxylate ligands form CaL complexes (L = malonate, maleate, succinate and phthalate) with a mean stability constant $\log K = 2.4$ ($I = 0M$, $T = 25^\circ$).^{5,6} Increasing the number of carboxylate groups rapidly enhances the stability of the Mg^{2+} and Ca^{2+} complexes [citrate, $\log K = 4.9$ ($I = 0M$, $T = 25^\circ$) and 4.7 ($I = 0M$, $T = 25^\circ$) for calcium and magnesium, respectively⁹].

Since polycarboxylate ligand complexes represent the first step for understanding the complexing ability of several polyelectrolytes and natural ligands (such as humic and fulvic acids), we have studied previously the formation of the alkali-metal complexes of 1,2,4,5-benzenetetracarboxylic acid (H_4L , pyromellitic acid);¹⁰ the solubility and thermal stability of the alkali-metal and alkaline-earth metal salts of pyromellitic acid;¹¹ and the stabilities at different temperatures and ionic strength of alkali-metal and alkaline-earth metal ion complexes with citrate.^{12,13}

Here we report a potentiometric determination of the stability of Mg^{2+} and Ca^{2+} pyromellitate complexes at 25°, in aqueous solution.

EXPERIMENTAL

Materials

Tetraethylammonium iodide (Et_4NI , Fluka) and tetramethylammonium hydroxide (Me_4NOH , Fluka) were recrystallized as described by Perrin *et al.*;¹⁴ Me_4NOH was standardized against potassium hydrogen phthalate, and hydrochloric acid (C. Erba, concentrate ampoules) against sodium carbonate. The solutions of calcium and magnesium chlorides were prepared from the analytical-grade reagents (Fluka) and standardized with EDTA.¹⁵ Lithium chloride solution was prepared from the analytical-grade salt (Fluka), dried under vacuum. All the solutions were prepared by using doubly distilled water and grade A glassware.

Potentiometric equipment and procedure

The free hydrogen-ion concentration was measured with a potentiometer (Metrohm E600) connected to a Ross combination pH electrode model 8102, supplied by Orion. The titrant was delivered by an Amel model 882 dispenser, readable to 1 μl . The measurement cell was maintained at $25 \pm 0.2^\circ$; a magnetic stirrer was employed, and purified nitrogen was bubbled through the solution during the titration.

*Mean ionic strength. The ionic strength varies throughout the titration, and this was taken into account by the computer program STACO.

†Number of points in the titration.

The test solutions (see Tables 1 and 2) containing the ligand and magnesium chloride or calcium chloride were titrated with standard 0.4M Me_4NOH . The E° value for all the solutions was calculated from separate titrations of 0.010M hydrochloric acid at the same ionic strength as the solution under study. For the solutions containing Mg^{2+} the self-medium method was used, whereas for those containing Ca^{2+} the titrations were done in the presence of 1M lithium chloride. Protonation constants and Li^+ complex formation constants were obtained from titrations of the pyromellitic acid in the presence of $LiCl$ and Et_4NI , by a method already reported for studying weak complexes.⁶ We used Me_4NOH as titrant in order to avoid the formation of other complex species with Na^+ and K^+ , and because Me_4N^+ ions do not form complex species with carboxylate ligands.⁶

Calculations

Protonation constants and the ligand purity were calculated by the computer program ESAB.^{16,17} Formation constants of the Mg^{2+} and Ca^{2+} complexes were calculated by the computer program STACO.¹⁸ The formation constants of weak Li^+ complexes were calculated by using the computer program ES2WC.^{6,19} All these programs are based on non-linear least-squares methods. In the calculations, the association of Mg^{2+} and Ca^{2+} with Cl^- was taken into account, by using the formation constants reported previously.²⁰ Distribution diagrams were calculated by using the computer program ES4EC.²¹⁻²³

The dependence of the protonation and complex formation constants on ionic strength was taken into account by using the equation^{6,24}

$$\log \beta = \log^T \beta - z^*[\sqrt{I}/(2 + 3\sqrt{I}) + 0.1I^{3/2}] + CI \quad (1)$$

§Empirical parameter of equation (1).

where ${}^T\beta$ is the overall formation constant at infinite dilution,

$$z^* = \Sigma(\text{charge})_{\text{reactants}}^2 - \Sigma(\text{charge})_{\text{products}}^2,$$

and C is an empirical parameter. The program STACO is able to calculate C in addition to the formation constants.

The protonation constants of pyromellitic acid and the formation constants of the Li^+ complexes, reported in Table 3, are in agreement with previous findings.⁴⁰

RESULTS AND DISCUSSION

The analysis of the potentiometric data indicates the formation of the species MgL^{2-} , $MgHL^-$, MgH_2L , MgH_3L^+ and Mg_2L . In the calculations, the formation of the $MgCl^+$ species was also considered. In Table 4, we report the formation constants calculated by the program STACO, together with the empirical parameter C [equation (1)], which accounts for the dependence of $\log \beta$ on ionic strength. In Fig. 1 we show the distribution of Mg^{2+} -pyromellitate species *vs.* pH. The stability of the Mg^{2+} -pyromellitate complexes is quite high: at $pH \geq 6.5$, the fraction of pyromellitate present as MgL^{2-} and Mg_2L in the solution (in the conditions of Fig. 1) is over 90%.

For the determination of the stability of Ca^{2+} -pyromellitate complexes it was not possible to use the self-medium method, because of the low solubility of Ca_2L and CaH_2L ($pK_{s0} = 11.85$ and 17.71 , respectively).¹¹ Therefore, we decided to use a constant medium with

†Calculations did not consider the formation of species $CaCl^+$.

‡Calculations did consider the formation of species $CaCl^+$.¹⁰

$I = 1M$ (LiCl). Lithium chloride was chosen as background for two reasons: (i) Li^+ and Cl^- do not interact significantly²⁵ (and therefore the calculated ionic strength is, in practice, the effective ionic strength); (ii) Li^+ forms quite well-defined complexes with pyromellitate. The analysis of the potentiometric data indicates the formation of the species CaL^{2-} , $CaHL^-$, CaH_2L and Ca_2L (Table 5). It was impossible to find the species CaH_3L , in contrast to the Mg^{2+} system, owing to the lower metal concentrations. The chloride complex $CaCl^+$ was also taken into consideration. In Fig. 2 we show the distribution of Ca^{2+} -pyromellitate species *vs.* pH. Apparently, the degrees of formation of Ca^{2+} -pyromellitate complexes are lower than those for the corresponding complexes of Mg^{2+} (Fig. 1), but this apparent difference is due to the presence of $1M Li^+$ which forms complexes having a stability that is unusual for alkali-metal complexes. Attempts to find mixed Li^+ - Ca^{2+} pyromellitate complexes were unsuccessful*.

On comparing the stability of the complexes studied here with those of citrate^{9,13} [$\log K(ML)$

Fig. 1. Distribution of the Mg^{2+} -L ($L = \text{pyromellitate}^{4-}$) complex species *vs.* pH, at 25°, $I = 0.1M$ ($MgCl_2$). In this diagram, only Mg^{2+} species are reported. $C_{Mg} = 0.033M$; $C_L = 0.005M$. Species: 1, $MgLH_3$; 2, $MgLH_2$; 3, $MgLH$; 4, MgL ; 5, Mg_2L .

*Varying the LiCl concentration in the experiments might allow the species $LiCaL^-$ to be found, so the formation constants of Table 5 must be regarded as conditional ones, *i.e.*, valid only in $1M$ LiCl medium.

Fig. 2. Distribution of the Ca^{2+} -L ($L = \text{pyromellitate}^{4-}$) complex species vs. pH, at 25° , $I = 1M(\text{LiCl})$. In this diagram, only Ca^{2+} species are reported. $C_{\text{Ca}} = 0.02M$; $C_L = 0.005M$. Species: 1, CaLH_2 ; 2, CaLH ; 3, Ca_2L ; 4, CaL .

$= 4.7$ ($I = 0M$, $T = 25^\circ$), 4.9 ($I = 0M$, $T = 25^\circ$) and $\log K(\text{MHL}) = 2.4$ ($I = 0M$, $T = 25^\circ$), 2.8 ($I = 0M$, $T = 25^\circ$) for magnesium and calcium, respectively] we observe that with citrate the unprotonated complexes are more stable than the monoprotated complexes, whereas the reverse is the case with pyromellitate. This behaviour can be explained, for pyromellitate unprotonated complexes by the simultaneous presence of the binuclear M_2L species, and for the monoprotated complexes by the presence of a residual negative charge on the ligand. Nevertheless, these comparisons, though widely used in the literature, can often be misleading, in particular when dealing with polyfunctional ligands.

Fig. 3. Fraction of Mg^{2+} in complexed form, $(\Sigma\%)_L$, vs. $p\text{Mg}$. Ligands (L): 1, acetate; 2, malonate; 3, pyromellitate; 4, citrate.

Fig. 4. Fraction of Ca^{2+} in complex form, $(\Sigma\%)_L$, vs. $p\text{Ca}$. Ligands (L): 1, acetate; 2, malonate; 3, pyromellitate; 4, citrate.

Stability constants for a metal-ligand system can be of interest in several fields of chemistry, one of which, related to the speciation of multi-component fluids, is the analytical study of the sequestering ability of a series of ligands for a particular metal ion. In this case the fraction of metal present in the form of complexes in solution (as the sum of the fractions for the individual complexes) is the best parameter for comparing the stabilities of different systems. As an example, in Figs. 3 and 4 we report the sum of percentages of Mg^{2+} and Ca^{2+} complexes of acetate, malonate, citrate and pyromellitate, as a function of the total metal concentration pM ($= -\log [\text{Mg}]$ or $-\log [\text{Ca}]$), at pH 5 and 8. The curves indicate clearly (and quantitatively) the stability of each metal-ligand system, with a parameter independent of the type of species formed. Moreover, calculations performed at different pH values show how the differences in the sequestering ability of ligands for a metal ion are dependent on pH. As can be seen in Figs. 3 and 4, the sharp difference at pH 8 between the Mg^{2+} and Ca^{2+} citrate complexes, (compared with the corresponding pyromellitate complexes) disappears in practice at pH 5.

In the introduction we stated that increasing the number of carboxylate groups rapidly enhances the stability of Mg^{2+} and Ca^{2+} complexes. This is not true for the unprotonated citrate and pyromellitate complexes. Therefore,

‡Extrapolated values.

§Values calculated by using, for the ionic strength dependence of formation constants, the parameters determined for the system Mg²⁺-pyromellitate.

the statement must be revised. In fact, we can say that the stability increases with the number of carboxylate groups only if they are effective in the co-ordination, and this is not true for pyromellitate. This ligand can be considered to be similar to phthalate, with additional groups that are not involved in the co-ordination. Additional alkaline-earth metal-carboxylate ligand systems are being studied in this laboratory, to provide information for a model of the stability of the complexes formed in such systems.

The dependence of the Mg²⁺ complex formation constants on ionic strength (Table 4) is in good agreement with previous findings for several complex systems.^{6,24} In Table 6 we report the formation constants of Mg²⁺ and Ca²⁺ complexes at different ionic strengths for the Ca²⁺ complexes; the C values [equation (1)] found for the Mg²⁺ complexes were used.

(Received 14 August 1989. Revised 30 May 1990. Accepted 9 October 1990)

Summary—The synthesis, physicochemical properties and interactions with metal ions of three new reagents of the *N*-phenylthiosemicarbazone family, namely pyridoxal phenylthiosemicarbazone, 3-hydroxypyridine-2-aldehyde phenylthiosemicarbazone and 2,6-diacetylpyridine bis(phenylthiosemicarbazone), as well as their ionization constants and the spectral features of their complexes with transition-element cations are reported. A photometric determination of cobalt with pyridoxal phenylthiosemicarbazone in perchloric acid medium is proposed and has been used in analysis of steels.

Thiosemicarbazones and phenylthiosemicarbazones generally react as chelating ligands with transition metal ions by bonding through the sulphur and hydrazine nitrogen atoms,^{1,2} but occasionally behave as terdentate ligands and bond through an additional co-ordinating group. As a rule, phenylthiosemicarbazones are more advantageous than thiosemicarbazones, as their complexes have much higher absorptivities.³

So far, pyridine-2-aldehyde,^{4,5} 2-acetylpyridine,⁶ 2-benzoylpyridine⁷ and di-2-pyridyl ketone phenylthiosemicarbazones⁸ as well as diacetyl⁹ and dipyridylglyoxal diphenylthiosemicarbazones¹⁰ have been used as spectrophotometric reagents. Likewise, the diphenylthiosemicarbazones of 1,2-cyclohexanedione and its 2-methyl and 5,5'-dimethyl derivatives have been used in the non-catalytic kinetic determination of copper(II).¹¹⁻¹³

This paper reports on the synthesis, physicochemical properties and analytical behaviour of three new phenylthiosemicarbazones, *viz.* pyridoxal (PPT), 3-hydroxypyridine-2-aldehyde (3-OH-PAT) and 2,6-diacetylpyridine bis(4-phenylthiosemicarbazone) (2,6-DAPT). These compounds, not studied so far, feature quite different structures and properties. We have made a comprehensive photometric study of the complexes they form with a variety of transition metal ions, to evaluate and compare their potential analytical applications.

EXPERIMENTAL

Reagents

The chelation study was made with 0.05 and 0.1% solutions of the compounds in question in dimethylformamide (DMF). Analytical reagent grade chemicals were used throughout. All metal ion solutions were standardized.

Synthesis of the compounds

PPT. 1 g of pyridoxal hydrochloride was dissolved in 15 ml of water and mixed in a flask with 0.8 g of 4-phenylthiosemicarbazide dissolved in 50 ml of ethanol. The resulting solution was neutralized with sodium acetate and heated under reflux for 30 min. It was allowed to stand at room temperature until yellow crystals were formed; these were then recrystallized from ethanol. The melting point of the product obtained was 150° (decomposition).

3-OH-PAPT. A solution of 1.5 g of 3-hydroxy-2-hydroxymethylpyridine hydrochloride in 150 ml of water was heated together with 0.8 g of manganese dioxide and 200 ml of chloroform at 60° under reflux for 30 min, after which 50 ml of 0.3M sulphuric acid were added dropwise to the mixture. After 10 min of further heating, the solution was cooled gently and the layers formed were decanted. The chloroform solution was dried over sodium sulphate and then evaporated in a rotating film evaporator at

30–40°. The remaining white solid, 3-hydroxypicolinaldehyde, was dissolved in 30 ml of ethanol and added to a solution containing 1 g of 4-phenylthiosemicarbazide in 50 ml of ethanol. The mixture was heated under reflux for 6 hr and then allowed to cool to room temperature. The yellow crystals obtained were recrystallized from methanol. Their melting point was 155° (decomposition).

2,6-DAPT. A 1.1 g amount of 2,6-di-acetylpyridine was dissolved in the minimum volume of absolute ethanol and mixed in a round-bottomed flask with 2.2 g of 4-phenylthiosemicarbazide in ethanol. The mixture was heated under reflux for 3 hr and then allowed to stand at room temperature for 12 hr. The crystals obtained were filtered off, washed with several portions of cold ethanol and then recrystallized from ethanol. Their melting point was 152°.

The purity of the products obtained was confirmed by elemental analysis.

Chelation study

The solutions used in this study were prepared in 25-ml standard flasks with different concentrations of the metal ions, 5 ml of a solution of the reagent in question in DMF, 10 ml of buffer and dilution with distilled water to the mark.

Absorbances were measured against a reagent blank.

Determination of cobalt with PPT in perchloric acid medium

To 3 ml of 0.5 mg/ml PPT solution in dimethylformamide in a 25-ml standard flask, add a known volume of cobalt solution containing between 12.5 and 100 µg of cobalt, 2 ml of dimethylformamide, 0.05 g of ascorbic acid and 5 ml of 60% perchloric acid, and dilute to volume with water. Measure the absorbance at

430 nm against a reagent blank prepared at the same time as the sample. Construct calibration graphs with standard solutions treated in the same way.

Determination of cobalt in steels

Dissolve 0.1–1.0 g of steel in 20–50 ml of *aqua regia* under reflux. Remove the excess of acid by heating. Dilute the solution to 100 ml in a standard flask with distilled water. Analyse an aliquot of this solution by the procedure described above. Any silica or tungstic acid precipitated should be filtered off.

RESULTS AND DISCUSSION

We recorded the infrared spectra of the three compounds by the potassium bromide pellet technique and assigned the corresponding bands to —NH—, C=N and C=S stretching vibrations. We also obtained the ¹H NMR spectra of solutions of the compounds in a mixture of CHCl₃-d₁, DMSO-d₆ and MeOH-d₄. The mass spectra were also recorded and the molecular peaks were found to be consistent with the expected molecular weights. Spectral data are summarized in Table 1.

The ultraviolet spectra of the reagents in various solvents showed intense *n* → *π** bands between 250 and 360 nm, as expected for these systems. The wavelengths of the bands decreased (blue shift) with an increase in the solvent polarity.¹⁴

Acid–base behaviour

The reagents PPT and 3-OH-PAPT both have one protonation constant and two dissociation constants, which, on comparison with those of similar compounds, can be assigned to the protonation of the pyridine nitrogen atom (*K*₁), release of the proton of the hydroxyl group (*K*₂), and release of the proton of the —SH group,

Table 1. Physicochemical properties of the ligands

Property	PPT	3-OH-PAPT	2,6-DAPT
Solubility in ethanol, g/l.	3.20	1.60	0.13
Solubility in water, g/l.	0.40	0.20	0.04
Solubility in dimethylformamide, g/l.	18.50	25.40	1.04
C=N frequency (stretch), cm ⁻¹	1600 m	1600 s	1590 s
C=S frequency (stretch), cm ⁻¹	1040 s	1070 s	1080 m
Aromatic —CH— protons (NMR), ppm	7.1–7.8	7.1–8.2	7.1–8.5
CH ₃ protons, ppm	2.4		2.7–2.9
Imine proton, ppm	8.5	8.5	
Molecular peak (mass spectrum) <i>m/z</i>	316	272	
p <i>K</i> ₁ (protonation of pyridine N atom)	3.25	3.25	1.80
p <i>K</i> ₂ (OH group)	7.75	7.70	—
p <i>K</i> ₃ (SH group)	10.50	11.85	10.50

(which is in tautomeric equilibrium with the C=S group) (K_1); this last process is typical of all thiosemicarbazones and phenylthiosemicarbazones. On the other hand, besides its protonation constant 2,6-DAPT has only one dissociation constant although it has two phenylthiosemicarbazide chains; presumably, as with other dithiosemicarbazones,⁹⁻¹¹ this arises because of the long distance between the two —SH groups, which may make their dissociations spectrophotometrically indistinguishable. The protonation constants (Table 1) were calculated by plotting the absorbance values as a function of pH and applying the customary Stenström and Goldsmith¹⁵ and Sommer¹⁶ methods. As can be seen, pK_1 for 2,6-DAPT is smaller than that for the other two compounds and also smaller than the usual value for pyridine compounds; this is also the case with pyridine 2,6-dialdehyde dithiosemicarbazone,¹⁷ and probably arises from the steric hindrance exerted by the two chains at positions 2 and 6 which block access of protons to the pyridine nitrogen atom through the so-called "face strain effect".

Reaction with metal ions

We studied the reactivity of the three reagents towards 40 cations at concentrations up to 100 ppm and at different pH values. As(III) and (V), Sn(II) and (IV), Al, Cr(III), Be, U(VI), Th, La, Ce(III), W(VI), Mo(VI), alkali-metal and alkaline-earth metal ions did not react with any of the three to an appreciable extent. The most sensitive reactions were with Co(II), Fe(II) and (III), Ni, Cu(II), Zn(II) and Cd(II).

We made a spectrophotometric study of the complexes formed and determined their optimum pH ranges and molar absorptivities, which are listed in Table 2. As can be seen, the values obtained for DAPT were lower than those for the other two compounds; hence its potential analytical interest is smaller.

One of the most outstanding features of these reagents is the high stability of their Co(II) complexes, which are formed even in perchloric acid media, unlike other complexes. This allows their use in the selective determination of traces of cobalt in acid media as the products show no appreciable tendency to decompose in such acidic media. The best results were obtained with PPT, which was therefore chosen for the selective photometric determination of cobalt.

Table 2. Photometric properties of complexes

Ligand	Metal ion	λ , nm	Optimum pH	$\epsilon \times 10^4$ l.mole ⁻¹ .cm ⁻¹
PPT	Co(II)	430	1	1.35
	Co(II)	450	4.5-6.5	1.40
	Ni(II)	430	4-6	1.90
	Cu(II)	440	2.5-5.5	2.17
	Zn(II)	430	5-6	1.62
	Cd(II)	405	4.5-5.5	8.60
	Fe(II)	440	4-6	2.45
	Fe(III)	420	3-5.5	2.40
3-OH-PAPT	Co(II)	435	1-2	2.75
	Co(II)	450	8.5-11	2.60
	Ni(II)	440	8.5-11.5	3.45
	Cu(II)	450	7.5-9	2.10
	Zn(II)	430	10-12	3.83
	Cd(II)	435	5.5-8.5	3.56
	Fe(II)	440	2-3.5	2.12
	Fe(III)	470	8-10	2.57
2,6-DAPT	Co(II)	400	2.5-5	1.93
	Ni(II)	390	4.5-7.5	1.66
	Cu(II)	380	5-10	1.44
	Zn(II)	385	4-9	1.85
	Cd(II)	380	6-10.5	1.60
	Fe(II)	380	4-8	2.97
	Fe(III)	385	3.5-8.5	3.48

Study of the cobalt(II)-PPT complex

The Co(II)-PPT complex was found to have 1:2 stoichiometry. We studied its formation in a perchloric acid medium and found the absorbance did not vary significantly up to an acid concentration of 1.2M. To avoid precipitation of the reagent the DMF content of the final solution must not be below 20%. The optimum order of addition is cobalt-reagent-DMF-ascorbic acid-perchloric acid.

Determination of cobalt

A method for the determination of cobalt with PPT in perchloric acid medium has been developed. Beer's law is obeyed over the range 0.5-4.0 ppm, with a molar absorptivity of 1.35×10^4 l.mole⁻¹.cm⁻¹ at 430 nm. The minimum error zone in a Ringbom graph was between 1.2 and 3.6 ppm.

The method was subject to few interferences as the complexes of most of the potential interferences are either not formed or are decomposed in the strongly acidic medium used. The tolerated levels of the different species tested are listed in Table 3.

The technique described above has been applied to the determination of cobalt in steels. Standard steels were supplied by CENIM. The compositions of these steels were as follows, Steels 1, 2 and 3: Ni, 3.878-3.893%; Mo, 0.490-0.492%; Mn, 0.580-0.583%; Cr, 1.046-1.048%; C, 0.158-0.159%; Si, 0.290-0.291%; S, 0.01%;

Table 3. Interference of foreign ions in the determination of cobalt with PPT

Ion	Tolerance ratio, w/w
Ni(II), Cd(II), Zn(II), Pb(II), Mn(II), Bi(III), Hg(I), Zr(IV), Sb(III), Ca(II), Sr(II), Be(II), Mg(II), Ba(II), Li(I), Tl(I), K(I), Na(I), Fe(II) or (III) (in the presence of ascorbic acid), sulphite, sulphate, phosphate, bromide, thiocyanate, nitrite, oxalate, iodide, chloride, ascorbic acid	> 100

(Received 1 February 1990. Revised 27 June 1990. Accepted 31 October 1990)

Summary—The protonation of 3-amino-1,2,4-triazole was studied potentiometrically (glass electrode) in sodium chloride and calcium chloride solutions, $0.13 \leq I \leq 0.92M$, at 10, 25, 37 and 45°. The effect of the background electrolyte on the protonation constants is explained by a complex formation model. The species CaL^+ , $CaHL^{2+}$ and H_2LCl ($HL = 3\text{-amino-1,2,4-triazole}$) are proposed. Stability constants, together with their dependence on temperature (ΔH°) and on ionic strength, are reported for the protonated and complex species.

The speciation of natural fluids, *i.e.*, the determination of all the species present in the fluid (free metal ions and ligands, hydrolytic species, stable and weak complexes), requires knowledge of accurate thermodynamic parameters for the metal-ligand interactions. Since pesticides are often involved in complexation reactions, the study of the thermodynamics of formation of pesticide complexes would be highly desirable, particularly for the speciation of ground waters. Moreover, transport and plant uptake of pesticides can be favoured by complexation with cations present in the ground, and therefore the knowledge of the stability of these complexes is important also for pesticide transport and uptake models.

As a further contribution to our studies on complexing ability of pesticides and related compounds,¹⁻⁴ we chose, as an interesting nitrogen-containing ligand, the herbicide 3-amino-1,2,4-aminotriazole (AmitroleTM). Here we report a potentiometric study of the protonation of this ligand in sodium chloride and calcium chloride aqueous solution, at different temperatures and ionic strengths. Salt effects are tentatively explained by a complex formation model.

EXPERIMENTAL

Materials

3-Amino-1,2,4-triazole (Aldrich) of >99.5% purity (standardized by acidimetric titration); sodium chloride (Carlo Erba RPE, standardized by argentometric titration) and calcium chloride dihydrate (Carlo Erba RPE, standardized by EDTA titration), were used without further purification.

Potassium hydroxide and hydrochloric acid stock solutions were prepared by diluting the contents of Merck or Carlo Erba ampoules of concentrates, and standardized against potassium hydrogen phthalate and sodium carbonate respectively.

Apparatus

Potentiometric measurements were performed with a Metrohm 654 pH-meter coupled with Orion glass-saturated calomel electrodes, with an instrumental resolution of ± 0.1 mV. The titrant solution (potassium hydroxide) was delivered by a Metrohm model 654 dispenser (minimum reading 0.01 ml). An IBM PC XT and a Honeywell printer were coupled with the pH-meter and the dispenser in order to add

preselected volumes of titrant and to print out the corresponding e.m.f. values. The measurement cells (25 ml) were kept within 0.2° of the required temperature. All titrations were done with magnetic stirring, and purified nitrogen passed through the solution.

Procedure

Each solution to be investigated was prepared by mixing, in a 250-ml standard flask, ~1M hydrochloric acid, a weighed amount of 3-amino-1,2,4-triazole and a suitable volume of ~5M sodium chloride or ~1.7M calcium chloride, so that the concentration of organic ligand was approximately 10mM, that of hydrochloric acid 20mM and the ionic strength about

0.1, 0.5 or 1.0M according to the added amount of salt. The solution obtained was titrated with standard potassium hydroxide solution. The electrode couple was standardized, in terms of pH = -log[H⁺], by titrating 10mM hydrochloric acid containing the same sodium chloride or calcium chloride concentration as the solution under study. The excess of hydrochloric acid allowed the internal E° and the liquid-junction potential⁵ to be determined.

Calculations

Calculations of protonation constants and ligand purity were performed by the non-linear least-squares computer program ESAB2M.^{5,6} The dependence of the protonation constants on temperature and ionic strength was calculated by the REGIS⁷ program. Weak complex formation constants, and their dependence on temperature and ionic strength, were calculated by the non-linear least-squares program ES2WC⁸ and distribution diagrams were calculated by the ES4EC program.^{9,10} Previously reported pK_w values¹¹ for different temperatures and ionic strengths were used in the calculations. Protonation constants were expressed as

$$K_j^H = [H_j L] / ([H][H_{j-1} L])$$

(primes will be used to indicate conditional protonation constants, see results).

Concentrations, and hence the thermodynamic parameters, were always expressed on the molarity scale. Throughout the paper, uncertainties are given as three times the standard deviation.

RESULTS AND DISCUSSION

Protonation constants calculated without allowing for weak interactions are given in Table 1. The dependence of the formation

Table 2. Ionic strength dependence of protonation constants [see equation (1)] of 3-amino-1,2,4-triazole in NaCl and CaCl₂ media (I = 0.1–0.9M)*

constants on ionic strength can be taken into account by using the equation¹²⁻¹⁴

$$\log \beta = \log {}^T \beta - z^* A \sqrt{I} / (1 + B \sqrt{I}) + CI + DI^{3/2} \quad (1)$$

where

- β = generic formation constant;
- ${}^T \beta$ = formation constant extrapolated to zero ionic strength;
- $z^* = \Sigma (\text{charge})_{\text{reactants}}^2 - \Sigma (\text{charge})_{\text{products}}^2$;
- $A = 0.5115 + 9.123 \times 10^{-4} (T - 25) + 4.93 \times 10^{-6} (T - 25)^2$;
- $B = 1.5$ or 1^\dagger .

A and B are the parameters of the Debye-Hückel equation, C and D are empirical parameters, and T is the centigrade temperature.

In Table 2 we report the numerical values of the empirical parameters together with their dependence on ionic strength. Extrapolation to

\dagger The parameter B assumes the value 1.5 when the dimensional parameter a in the Debye-Hückel equation is $\sim 5 \text{ \AA}$. In some cases, particularly when weak interactions are neglected, it is better to use $B = 1$. This is the case for the protonation constants of aminotriazole determined in CaCl_2 medium (see below).

\ddagger When dealing with systems where weak interactions are studied, the association of the background electrolyte has to be considered, in our opinion, since small differences in the assumptions made in deriving formation constants may drastically change the picture of the solution under study. On the other hand, high uncertainties affect the association constants for the background, as in our case for the species NaCl and CaCl^+ . In any case, it is of great importance to give clearly in the paper all the information that allows the reader to know exactly the assumptions under which thermodynamic parameters are calculated.

Fig. 1. Dependence of protonation constants on ionic strength, calculated without allowing for weak-complex formation. $y = \log K^H (I=0) - \log K^{H'} (I)$. 1, $\log K_1^{H'}$ (NaCl); 2, $\log K_1^{H'}$ (CaCl_2); 3, $\log K_2^{H'}$ (NaCl); 4, $\log K_2^{H'}$ (CaCl_2).

zero ionic strength gave the thermodynamic parameters, reported in Table 3, together with ΔH° and ΔC_p° values obtained from the dependence of the protonation constants on temperature, (by using the equation of Clarke and Glew¹⁵). Figure 1 shows the function $\log K^{H'}$ vs. I .

When analysing salt effects on the protonation of 3-amino-1,2,4-triazole, we must consider (i) the complex formation between the protonated form H_3L and Cl^- , as for similar systems,¹⁶⁻¹⁸ and (ii) the formation of weak complexes with Ca^{2+} , as suggested by the fact that the protonation constants in calcium chloride medium are significantly lower than those in sodium chloride medium (see Fig. 1). By making the same assumption as in preceding papers on salt effects on the protonation of amines,^{16,20} and by using calculation procedures for weak complexes,^{8,12} we found the formation of the species H_2LCl , CaL^+ and CaHL^{2+} ($\text{HL} = 3\text{-amino-1,2,4-triazole}$), the formation constants of which, extrapolated to zero ionic strength, are reported in Table 4. To calculate the dependence of the formation constants of these species on ionic strength, it is necessary to decide whether association of the background electrolyte should be considered. \ddagger

We performed the relative calculations with and without considering the association of background (for the species NaCl and CaCl_2 we

†For parameters for the ionic strength dependence of formation constants, see equation (1).

used formation constants obtained in previous work⁷), and in Table 5 we report the results. At $I = 0.75M$, in the case of the H_2LCl and CaL^+ species, quite different results are obtained with the two types of calculations.

In Fig. 2 we report the distribution diagram of the system $Ca^{2+}-Cl^-$ -3-amino-1,2,4-triazole. Errors in formation percentages, arising from errors in formation constants,^{9,10} are compatible with correct speciation. For example, at $I = 0.75M$, $C_{Ca} = 0.25M$, $C_{Cl} = 0.5M$ and $C_L = 0.005M$, the maximum percentages are: H_2LCl $21 \pm 4\%$, at pH 2; CaL^+ $50 \pm 6\%$, at pH 11; $CaHL^{2+}$ $11 \pm 6\%$, at pH 7.

Complex-formation constants are slightly dependent on temperature, and we calculated for the chloride complexation:

$$\Delta H^\circ = 15 \pm 7 \text{ kJ/mole}$$

and for calcium complexation:

$$\Delta H^\circ = -9 \pm 5 \text{ kJ/mole.}$$

No comparison can be made with the literature for the thermodynamic parameters reported in this work, but in Table 6 we report some formation constants found for Ca^{2+} and Cl^- complexes with pyridine,^{16,19} imidazole,¹⁷

ethylenediamine²⁰ and other amines.¹⁸ The stability of these complexes (similar reactions for different ligands are taken into account) is quite close, indicating similar side-reactions. The conditions of the distribution diagram in Fig. 2 were chosen to show a hypothetical system where all the interactions are significant. Concentrations in natural (irrigation) waters are much lower²¹⁻²³ (average values $0.45mM$, $0.82mM$ and $5.4\mu M$ for Cl^- , Ca^{2+} and amino-triazole, respectively; $I \sim 3mM$). In these conditions, as reported in Fig. 3, the only important species is HL . On the other hand, in some particular situations, the concentrations may be

higher, and the formation constants reported here for different temperatures and ionic strengths allow the speciation of aminotriazole in the presence of Ca^{2+} and Cl^- , under a wide range of conditions. Furthermore, interactions between amines and Mg^{2+} , SO_4^{2-} and other cations and organic anions should be considered, and are under study in our laboratories.

(Received 18 December 1989. Revised 29 October 1990. Accepted 31 October 1990)

Summary—The protonation constants of 1,3-propanediamine-*N,N'*-diacetate-*N,N'*-di-3-propionate (1,3-pddadp) were determined in sodium nitrate solution of various concentrations and in 0.1M potassium nitrate medium. The values of the thermodynamic functions (ΔG , ΔH and ΔS) for the successive protonation equilibria, in 0.1M (Na)NO₃ medium, at 25°, are also reported.

In the recent past, attention has been paid to aminopolycarboxylic acids structurally related to ethylenediaminetetra-acetic acid (EDTA), owing to their importance in chemistry,¹⁻³ medicine⁴ etc.

Aminopolycarboxylic acids form strong complexes with many metal ions;⁵ the high values of the stability constants of such complexes may be attributed to the presence of the basic secondary or tertiary amino groups, the large negative charge of the acid anion, and the formation of five- or six-membered chelate rings.¹

To investigate the effect of chelate ring size on the stability of metal complexes in solution, numerous substituted and structurally related EDTA-type ligands have been tested,^{1,2}

The ligand studied here (abbreviated as 1,3-pddadp or simply pddadp) is a newly synthesized aminopolycarboxylic acid^{6,7} capable of forming three six-membered (one diamine and two 3-propionate) chelate rings and two five-membered (glycinate) rings with metal ions. Its protonation constants have not previously been reported in the literature. In this work, they

have been determined in (Na)NO₃† and K(NO₃) medium at 15, 20, 25, 30 and 35° from potentiometric measurements with the glass electrode.

Reagents

The 1,3-pddadp was prepared by condensation of 1,3-propanediamine-*N,N'*-diacetic acid with 3-chloropropionic acid in aqueous potassium hydroxide solution as described previously.⁶⁻⁸ Elemental analysis gave C 45.6%, H 6.2%, N 8.5%; C₁₃H₂₂O₈N₂ requires C 46.70%, H 6.63%, N 8.38%. A stock solution was prepared by dissolving a weighed amount of the acid, previously dried at 80° for 3 hr and stored in a desiccator, in doubly distilled water. A stock solution of nitric acid, 'Suprapur' (Merck) was standardized against tris(hydroxymethyl)aminomethane. Carbonate-free sodium hydroxide and potassium hydroxide p.a. (Merck) were standardized against potassium hydrogen phthalate, by using a Gran plot. Stock solutions of sodium nitrate p.a. (Merck) and potassium nitrate p.a. (Fluka) were prepared by dissolving the doubly recrystallized salt in doubly distilled water. The salt content was determined by evaporation of a known volume of solution to dryness at 150° and weighing the residue.

*Author for correspondence.

†Notation of the medium is in accordance with Sillén and Martell.⁵

Apparatus

Potentiometric measurements were made on solutions in a double-walled glass vessel at 15.00, 20.00, 25.00, 30.00 and $35.00 \pm 0.02^\circ$, with a commercial Beckman (39501 B8U) combined electrode. The emf was measured with a Beckman model 4500 digital pH-meter with a precision of ± 0.1 mV. The temperature was controlled by circulation of water through the jacket, from a VEB model E3E ultrathermostat bath and maintained within $\pm 0.02^\circ$. Purified nitrogen was bubbled through the solution in order to maintain an inert atmosphere. Efficient stirring of the solution was achieved with a magnetic stirrer. All test solutions (TS) were prepared in a constant ionic medium, 0.1, 0.5, 1.0M (Na)NO₃ or 0.1M (K)NO₃ by mixing the appropriate amounts of ligand, nitric acid, and sodium nitrate (or potassium nitrate) solutions. The concentration of hydrogen ion was decreased by the addition of sodium hydroxide (or potassium hydroxide), prepared in the ionic medium used for the test solution. At each medium concentration, at least 6 titrations with various concentration ratios of H₄-1,3-pddadp to nitric acid (1.0–5.0mM pddadp and 10.0–20.0mM HNO₃) were performed, over the pH range 1.0–11.0. Approximately 150 points were collected in each titration.

The concentration of free hydrogen ion, h , at each point of the titration was calculated from the measured emf, E , of the cell RE/TS/GE (RE and GE denote the reference and glass electrode, respectively) from the Nernst equation:

$$E = E_0 + Q \log h \quad (1)$$

where E_0 is a constant which includes the standard potential of the glass electrode, and Q is the slope of the glass electrode response. The value of E_0 for the electrode was determined from a separate titration of nitric acid with sodium hydroxide, both of known concentration, under the same temperature and medium conditions as for the test solution titration. The data so obtained were analysed by the program MAGEC.⁹ During the MAGEC calculation the auto-protolysis constant of water, K_w , was refined until the best value for Q was obtained. The values of Q at various temperatures were found to be: at 15°, 57.0 mV; 20°, 58.1 mV; 25°, 59.0 mV; 30°, 60.1 mV; 35, 61.0 mV. The results obtained indicate the reversible Nernstian response of the glass electrode used.

These values were employed in all subsequent calculations. The E_0 values obtained from strong acid–strong base titrations were used in conjunction with the data obtained for titration of H₄-1,3-pddadp with strong base, in the program SUPERQUAD¹⁰ for refining the values of the protonation constants of the ligand. In the SUPERQUAD calculation, the total ligand, total proton and strong base concentrations were kept constant and E_0 and the protonation constants of the ligand were varied. When the resulting statistics and standard deviations were acceptable, the refined values of E_0 did not deviate by more than 1% from the initial values. When the statistics and residuals were unacceptable, the total proton concentration was also refined, which mostly led to a much improved set of statistics and a reasonably good scatter of residuals. However, the results were accepted only if the changes in E_0 and total proton concentration did not exceed 1% of the initial values. Otherwise, the titration was rejected. Standard deviations of protonation constants obtained from SUPERQUAD calculations reflect the random errors inherent in experiments. The errors which may arise from temperature variations, standardization of reagents, electrode calibration and sample weighing and dilutions were estimated from the corresponding instrumental precision, and used in the calculation of the total absolute errors of the protonation constants. It was found that the total absolute errors of the protonation constants corresponded to an error of < 0.05 in $\log K$.

Proton magnetic resonance spectra of 1,3-pddadp solutions were recorded on a Varian FT-80A High Resolution Spectrometer operating at 80 MHz, with samples kept at $30.0 \pm 0.5^\circ$. All solutions were made in D₂O in order to provide an internal lock signal. Chemical shifts are reported in ppm and measured relative to sodium-3-(trimethylsilyl)-1-propanesulphonate (tms*). Typically 50–100 transients were accumulated.

RESULTS AND DISCUSSION

The protonation equilibria of 1,3-pddadp may be represented by

(where charges are omitted for simplicity). The successive protonation constants, K_n ,

of the various protonated forms are defined as

$$K_n = \frac{[H_n L]}{[H][H_{n-1} L]} \quad L = 1, 3\text{-pddadp}$$

The constants were calculated by minimizing the error-square sum, U , of the potentials:

$$U = \sum w_i (E_{\text{obs}} - E_{\text{calc}})^2 \quad (2)$$

where E_{obs} and E_{calc} refer to the measured potential and that calculated from equation (1). The weighting factor w_i is defined as the reciprocal of the estimated variance of measurement:

$$w_i = 1/\sigma^2 = 1/[\sigma_E^2 + (\delta E/\delta V)\sigma_V^2]$$

where σ_E^2 and σ_V^2 are the estimated variances of the potential and volume readings, respectively. The minimization in equation (2) was performed with the aid of SUPERQUAD.¹⁰ The quality of fit was judged by the values of the sample standard deviation, s , and the goodness of fit, χ^2 , (Pearson's test). At $\sigma_E = 0.1$ mV and $\sigma_V = 0.005$ ml, the values of s in different sets of titrations were between 1.0 and 1.8, and χ^2 was between 12.0 and 13.0. The scatter of residuals ($E_{\text{obs}} - E_{\text{calc}}$) vs. pH was reasonably random, without any significant systematic trends, thus indicating a good fit of the experimental data.

The calculated values of the protonation constants in various concentrations of the (Na)NO₃ medium at 25° are shown in Table 1. It can be seen that the influence of the medium on the protonation constants of 1,3-pddadp is not very pronounced and is much lower than in the case of EDTA.¹¹ Variations of $\log K_n$ with the medium concentration may be attributed to changes in only the activity coefficients. That is, it appears that any complexation of 1,3-pddadp with Na⁺ can be neglected. A distribution diagram of the various protonated forms of 1,3-pddadp, calculated by using the SPECIES¹² program indicates that the formation of the 1,3-pddadp⁴⁻ anion starts at pH ~ 9.0 and sharply increases with increasing pH.

In Table 2 the protonation constants of ethylenediaminetetra-acetate (EDTA) ethylene-

diaminetetra-3-propionate (edtp), ethylenediamine - *N,N'*-diacetate - *N,N'*-dipropionate (eddadp), 1,3-propanediaminetetra-acetate (pdta) and 1,3-pddadp, in the same media, are presented together.

The values for the first and second protonation constants, $\log K_1$ and $\log K_2$ respectively, of 1,3-pddadp are similar to the corresponding constants of pdta and are quite close to the protonation constants of 1,3-propanediamine ($\log K_1 = 10.62$, $\log K_2 = 8.64$).¹⁵ This suggests that the two constants, K_1 and K_2 , refer to protonation of the nitrogen atoms. The constants for the third and fourth protonation steps of 1,3-pddadp, $\log K_3$ and $\log K_4$ respectively, differ very little from the corresponding constants for eddadp and edtp, so they may be ascribed to protonation of the propionic carboxylate groups.

The increase in the values of $\log K_1$ for the series edtp, eddadp, pddadp and EDTA arises from the increasing concentration of negative charge on the basic nitrogen atoms, leading to an increase in the binding energy for H⁺ ions. The second protonation constant ($\log K_2$) of pddadp is approximately two units higher than the corresponding value for eddadp, and the difference between these two values roughly corresponds to the difference between the $\log K_2$ values of 1,3-propanediamine and 1,2-ethylenediamine¹⁵ (1.65). Comparison of the $\log K_3$ values of pdta and pddadp (2.47 and 3.75) shows that their difference is approximately equivalent to the difference between the $\log K_2$ values of 3-aminopropionic and 2-aminoacetic acid¹⁵ (1.19). Bearing in mind the structures of the chelating agents involved, the explanation of the differences discussed may be found in the greater electrostatic inductive effect of the =N—H group on the second nitrogen atom in eddadp or the acetate carboxyl group in pdta, in comparison with the same groups in pddadp. From the electrostatic point of view, the stabilization of the groups where the electropositive

log K_4	2.98	2.79	2.87

nitrogen atom is separated by two carbon atoms from the group to be protonated is higher than in the case where the separation is by three carbon atoms. Therefore, in eddadp and pdta the second nitrogen atom and the acetic carboxyl group respectively, are more acidic than in pddadp.

The existence of protonated nitrogen atoms in the molecule of 1,3-pddadp indicates that it has a zwitterionic structure:

That the ion has this structure in solution is also indicated by the values of the protonation constants obtained in a 50% v/v water-ethanol mixture, and given in Table 3.

Comparing the values of the protonation constants of 1,3-pddadp in 0.1M (K)NO₃ water solution (Table 2) and at the same salt concentration but in mixed water-ethanol solution (Table 3) it can be seen that in ethanolic solution the values of the protonation constants remain the same (log K_1 and log K_2) or are only slightly raised (log K_3 and log K_4) compared with those for aqueous medium. Such behaviour is common for amino-acids¹⁵ and characterizes dipolar ions.¹⁶

The data presented in Table 3 can conveniently be discussed in terms of $\Delta G_{(\text{ion.})}$ defined as $2.303RT (\log K^{(w)} - \log K^{(s)})$, *i.e.*, the difference between the standard free energies of ionization in the mixed solvent and in water.¹⁶ The ionization process can be represented by the general equation:

where S denotes a molecule of solvent. Since the solutes involved in the ionization are charged,

log K_4	3.06	3.05

then of the two basic steps in solute-solvent interactions, *i.e.*, charge transfer and charge separation,¹⁶ only the first will be dominant. Therefore, although the difference in dielectric constant between pure water and the water-ethanol mixture is appreciable (78.3 *vs.* 49.0 at 25°), it will have little effect on the protonation constants of the solutes. Also, the solvation in mixed ethanol-water as solvent should not differ much from that in water, since

the structures of the two solvents are similar. Consequently the two effects will result in relatively small values of $\Delta G_{(\text{ion.})}$.

In order to confirm the zwitterionic structure of 1,3-pddadp in solution, the proton nmr spectrum, at various pH values of the ligand were recorded. The nmr spectrum of 1,3-pddadp over the pH range 2.7-13.0 consists of a sharp singlet for the acetate methylenic protons, a triplet-like pattern for the protons of the two nitrogen-bound methylenic groups of the propanediamine part of the ligand (2.45 ppm, pH 12) a broad quintet-like pattern for the protons of the central methylenic group of the propanediamine part of the ligand (1.85 ppm, pH 12) and a complex multiplet for the protons from the two propionate groups (2.95 ppm, pH 12). The chemical shifts of all resonances of the ligand are pH-dependent, as illustrated by the chemical shift data for the acetate methylenic protons in Table 4.

On the basis of the chemical shifts of structurally related protons in other aminopolycarboxylic acids¹⁷⁻²⁰ it can be concluded that the two nitrogen atoms in 1,3-pddadp are protonated first, followed by protonation of the propionate groups.

The values obtained for the thermodynamic functions ΔG^0 , ΔH^0 , and ΔS^0 associated with the protonation reactions investigated are pre-

Table 4. The pH-dependence of the chemical shifts of the acetate methylenic protons in 1,3-pddadp

pH	2.80	6.00	12.00	13.00
δ , ppm	3.85	3.75	3.35	3.10

Table 5. Thermodynamic quantities, $\log K_n$, ΔG_n^0 (kcal/mole), ΔH_n^0 (kcal/mole) and ΔS_n^0 (cal. mole⁻¹. K⁻¹) for the stepwise protonation reaction $nH + L = H_nL$ (L = pddadp, EDTA, pdta, ida)

	1,3-pddadp [0.1M (Na)NO ₃ medium]					ΔG_{298}^0	ΔH^0	ΔS_{298}^0
	15°	20°	25°	30°	35°			
$\log K_1$	10.16	10.12	10.06	10.00	9.93	-13.7	-4.5	31
$\log K_2$	8.34	8.27	8.24	8.17	8.13	-11.2	-4.1	24
$\log K_3$	3.69	3.72	3.73	3.77	3.79	-5.1	+1.7	23
$\log K_4$	2.94	2.97	2.98	3.01	3.00	-4.1	+0.1	14
EDTA (0.1M KNO ₃) ²¹								
$\log K_1$			10.19			-13.9	-5.6	27.9
$\log K_2$			6.13			-8.4	-4.2	14.1
$\log K_3$			2.69			-3.7	+1.4	17.1
$\log K_4$			1.99			-2.7	+0.3	10.1
pdta (0.1M KNO ₃) ²²								
$\log K_1$		10.46				-14.02	-5.16	30.2
$\log K_2$		8.02				-10.75	-4.43	21.6
ida (0.1M KNO ₃) ²²								
$\log K_1$		9.45				-12.67	-8.15	15.4

sented in Table 5 for 1,3-pddadp and some other complexones.

Within experimental error the values of ΔH^0 for all the protonation steps are reasonably constant over the entire temperature range from 15 to 35°. Thermodynamic quantities were calculated from the equation²³

$$\ln K = -\frac{\Delta H^0}{RT} + \frac{\Delta C_p}{R} \ln T + \frac{\Delta S_0 - \Delta C_p}{R}$$

by plotting $\log K$ against $1/T$ and taking $\Delta C_p = 0$ over the temperature range used.

From Table 5 it can be seen that the heat of the first protonation step decreases in the order ida, EDTA, pdta, pddadp. Since for the protonation of ammonia,²³ $\Delta H^0 = -12.4$ kcal/mole it may be concluded that increasing the substitution on the nitrogen atom causes the binding energy for H⁺ to decrease.

Values of ΔH^0 for pdta, EDTA and pddadp are about half of those for glycine and β -alanine (~ 10 kcal/mole).⁵ Such lowered values may

partly arise from the formation of a hydrogen bond between the proton from the =N—H group and the nearest negatively charged oxygen atom from the carboxyl group, resulting in weakening of the bond between the nitrogen atom and the proton. Owing to steric hindrance in pddadp, hydrogen bonds may be formed only with the negatively charged oxygen atoms in the acetate groups (Scheme 1).

The entropy change of the first protonation step for all ligands in Table 5 is large and may be attributed to the decrease in the negative charge of the ligands and consequent redistribution of water molecules in the first solvation sphere.

BOOK REVIEWS

Physical Chemistry: P. W. ATKINS, 4th Edition, OUP, Oxford, 1990. Pages xii + 995. £40.00 (hardback), £19.50 (softback).

The author of this very popular textbook is now producing a new edition every four years and the many chemists who have contributed material will be pleased with this current tome.

The arrangement of topics is very similar to that in previous editions, with the three major divisions, equilibrium, structure and change, encompassing 30 chapters. Many excellent diagrams are included in the text and each chapter is prefixed by a check-list of key ideas and concluded with a bibliography for further reading. The number of worked examples in the text has been increased and this is to be welcomed. The student can quickly grasp concepts through such exercises, provided of course that the workings are correct. Additional exercises—the simpler ones—plus additional problems are also grouped together at the end of each chapter. As with previous editions a separate solutions manual is available.

In Part 1 the concepts of thermodynamics are covered comprehensively and applied to changes of state. Where the student may find the mathematics difficult, help is provided by careful explanations and—where deemed necessary—by reverting to basics, as with partial derivatives. In this sense a gentle but firm guide through the mathematics is provided. Ideal and real solutions, phase diagrams and electrochemical cells are included in this section.

Whereas the equilibrium section is dominated by thermodynamics, the more extensive structure section is dealt with from the viewpoint of quantum mechanics. Again, theoretical aspects are treated very clearly and comprehensively even to the point of straying into what some might call inorganic chemistry. The author's own interests are evident here, as he has also produced the well received text *Molecular Quantum Mechanics*. Applied diffraction methods, spectroscopy (the discussions of magnetic resonance and the use of lasers have both been extended), statistical thermodynamics and electrical and magnetic properties of molecules are also covered in this section.

Part 3 is concerned with change and hence chemical kinetics, dynamic electrochemistry and surface processes are much in evidence. Here, as in Part 2, thermodynamics is included where appropriate.

All in all, the book is a comprehensive account of physical chemistry with the emphasis on the theory rather than the applied nature of the subject. The suggestions for further reading should suffice for those who consider their own special interests scantily served. Academics will now have to remember to change the edition number associated with this textbook, on their lists of recommended books for students of chemistry.

P. J. COX

Mass Spectrometry of Biological Materials: C. N. MCEWEN and B. S. LARSEN (eds.), Dekker, New York, 1990. Pages xiii + 515. \$125.00 (U.S. and Canada), \$150.00 (elsewhere).

The large number of books and other publications relating to mass spectrometry is indicative of the necessity to gain information on the structure of chemical compounds. Included among these compounds are biologically active molecules and this book deals with the use of mass spectrometry in the structural elucidation and analyses of such molecules.

The book is comprised essentially of two sections, the first dealing with the use of mass spectrometry in the analysis of proteins (including protein sequencing), glycoproteins, and peptides. The second section is dedicated to mass spectrometry of biological materials such as lipids, steroids, bile acids, pesticides and nitrogen-containing compounds, including amines, indoles and their metabolites.

Although the contributors assume that the reader has a reasonably detailed knowledge of the ionization techniques used in mass spectrometry, it is gratifying to note that descriptions are given of the theories and practicalities of techniques such as fast atom bombardment, plasma desorption, desorption chemical ionization and other innovations in ionization methods. In addition, clear explanations are given of the principles and use of tandem mass spectrometry, linked scanning, Fourier-transform techniques, and gas chromatography and liquid chromatography linked to mass spectrometry.

In most of the chapters, methods are described for the isolation, extraction and derivatization of compounds prior to mass spectrometry, and this aspect will be of considerable benefit to those who require a general reference guide for application to their own work.

The contributors and editors are to be congratulated for the manner in which the chapters are written and presented in clear, unequivocal terms. The book is designed primarily as a working manual rather than as a review of various topics and it will be an extremely useful addition to the laboratories (in addition to libraries) of those who are actually engaged in the use of mass spectrometry in the analysis of biological compounds in the course of their work.

A. SMITH

Spectroscopy of Biological Molecules—New Advances: E. D. SCHMID, F. W. SCHNEIDER and F. SIEBERT (eds.), Wiley, Chichester, 1988. Pages xvii + 509. £52.50.

This book is compiled from the proceedings of the Second European Conference on the Spectroscopy of Biological Molecules, Freiburg, Germany, 1987, covering the applications of vibrational spectroscopy to this field.

A. SMITH

Spectroscopy of Biological Molecules—New Advances: E. D. SCHMID, F. W. SCHNEIDER and F. SIEBERT (eds.), Wiley, Chichester, 1988. Pages xvii + 509. £52.50.

This book is compiled from the proceedings of the Second European Conference on the Spectroscopy of Biological Molecules, Freiburg, Germany, 1987, covering the applications of vibrational spectroscopy to this field.

The book commences with a very useful review section on recent advances and then continues to look at applications of several techniques to study of protein structure, biomembranes, chromophore-containing systems, and nucleic acids, and is completed by a most informative section on the medical and pharmaceutical applications, including *in vivo* studies.

Each paper is reproduced in its original form, and as a reference text for those working in this field the book will prove most valuable.

S. M. MACMANUS

Liquid Chromatography/Mass Spectrometry—Applications in Agricultural, Pharmaceutical and Environmental Chemistry: M. A. BROWN (ed.), ACS, Washington, D.C., 1990. Pages xii + 298. \$64.95.

The ACS Symposium Series No. 420 provides a useful monograph on applications of LC/MS and contains papers on agricultural, pharmaceutical and environmental chemistry which are in camera-ready form and reviewed under the supervision of the editor, Mark Brown, with the assistance of the Series Advisory Board. Unfortunately, there is a wide variation in the standard of presentation in this format which detracts somewhat from the overall quality of the book.

Eighteen papers formed into chapters deal progressively with agrochemicals, pesticide metabolism and degradation (2–7), pharmaceuticals and metabolism (8–12), and environmental analysis (13–18). These applications of LC/MS are preceded by Chapter 1, a short review of the development of LC/MS techniques by Cairns and Siegmund. This paper highlights the advantages of LC/MS over GC/MS in the analysis of molecules that are either thermally labile, or of low volatility or high polarity. Although not an in-depth review, it does form a useful, limited introduction and deals with the practicalities, advantages and disadvantages of the various LC/MS interfaces that have been developed.

Because of the stereotyped format, there is some inevitable overlap and repetition in description and practical aspects from paper to paper. However, the applications provide a good indication of the wide use of LC/MS techniques in these fields.

The first category of papers describes techniques for enhancing structural information, confirmation of pesticide residues by LC/Tandem MS, the use of solvent ions to confirm structure of selected herbicides with thermospray (TSP), chlorinated herbicide analysis by LC/MS, multi-residue analysis of thermally labile sulphonylurea herbicides in crops, and the application of negative-ion MS in studies of herbicide metabolism.

The second category considers structural elucidation of xenobiotic conjugates obtained from either biological fluids or from enzymatic/chemical synthesis by positive-ion TSP, LC/MS and LC/MS/MS; exploratory qualitative analysis of novel pharmaceuticals, nemadectins and tetracyclines in fermentation broths by TSP/LC/MS; quantification of components of human plasma, endogenous retinoic acid, by LC/NCI-MS at picogram levels; LC/MS in bioanalysis dealing with three aspects, namely, optimization strategy for TSP, and two applications (i) confirmatory evidence for aminotrazepam in blood, involving TSP LC/MS and MS/MS and (ii) analysis after chiral separation of metoprolol enantiomers with a phase system switching approach and MB/LC/MS; monitoring of *in vivo* cyclic acetylation and deacetylation of anticonvulsants by TSP/LC/MS.

The third section highlights aspects of applications in environmental analysis. Two papers deal with target and non-target pollutants in hazardous wastes and phenols, and their sulphates and conjugates utilizing particle beam MS. Vestal, a leader in the development of TSP, describes a combination ion source for the detection of environmentally important compounds. DLI and FAB LC/MS are applied to the analysis of metabolites of benzo(a)pyrene. The use of ion-exchange TSP tandem MS for polar urinary metabolites and use of LSIMS (caesium ion) for structural studies of *in vitro* alkylation of haemoglobin by electrophilic methods, *viz.* with styrene-7,8-oxide, are also presented. The latter paper highlights the powerful application of a four sector (EBEB) MS/MS instrument for the sequencing of tryptic peptides isolated from human globins.

In conclusion, this monograph provides valuable and exemplary information on the wide use of a range of LC/MS techniques for qualitative, quantitative and structural analyses and is a useful addition to the literature dealing with this important subject.

P. J. BAUGH

Inorganic Chemistry: D. F. SHRIVER, P. W. ATKINS and C. H. LANGFORD (eds.), OUP, Oxford, 1990. Pages xiii + 706. £40.00 (hardback), £16.50 (softback).

A single text dealing with inorganic chemistry must be extensive, as the discipline covers over a hundred elements and extends into many other branches of science. Inevitably this new work will be compared with *Advanced Inorganic Chemistry* by Cotton and Wilkinson and *Chemistry of the Elements* by Greenwood and Earnshaw. It is aimed at the undergraduate student and is keenly priced.

The approach adopted by the authors is selective and interpretative rather than comprehensive. The 19 chapters of the book are arranged under five section headings: structure, reactions, *s*- and *p*-block elements, *d*- and *f*-block elements and interdisciplinary topics (which comprise catalysis, structure and properties of solids and bioinorganic chemistry). Not all chapters are strictly sequential and it would be possible to move directly from say Chapter 3 on *d*-metal complexes to Chapter 14 on bonding and spectra of complexes. There are several worked examples together with additional problems, and short answers are supplied to all exercises; these will be useful to both teacher and student. A separate publication, *Guide to Solutions*, by Prof. S. Strauss accompanies the text but has not been seen by this reviewer. Suggestions for further reading (supplementary books) are given at the end of each chapter. In the text the columns in the periodic table are numbered from 1 to 18 and (for the main groups) from I to VIII, so that the oxygen group is Group VI/16 and the chromium group is Group 6.

The book commences with a very useful review section on recent advances and then continues to look at applications of several techniques to study of protein structure, biomembranes, chromophore-containing systems, and nucleic acids, and is completed by a most informative section on the medical and pharmaceutical applications, including *in vivo* studies.

Each paper is reproduced in its original form, and as a reference text for those working in this field the book will prove most valuable.

Because of the stereotyped format, there is some inevitable overlap and repetition in description and practical aspects from paper to paper. However, the applications provide a good indication of the wide use of LC/MS techniques in these fields.

The first category of papers describes techniques for enhancing structural information, confirmation of pesticide residues by LC/Tandem MS, the use of solvent ions to confirm structure of selected herbicides with thermospray (TSP), chlorinated herbicide analysis by LC/MS, multi-residue analysis of thermally labile sulphonylurea herbicides in crops, and the application of negative-ion MS in studies of herbicide metabolism.

The second category considers structural elucidation of xenobiotic conjugates obtained from either biological fluids or from enzymatic/chemical synthesis by positive-ion TSP, LC/MS and LC/MS/MS; exploratory qualitative analysis of novel pharmaceuticals, nemadectins and tetracyclines in fermentation broths by TSP/LC/MS; quantification of components of human plasma, endogenous retinoic acid, by LC/NCI-MS at picogram levels; LC/MS in bioanalysis dealing with three aspects, namely, optimization strategy for TSP, and two applications (i) confirmatory evidence for aminotrazepam in blood, involving TSP LC/MS and MS/MS and (ii) analysis after chiral separation of metoprolol enantiomers with a phase system switching approach and MB/LC/MS; monitoring of *in vivo* cyclic acetylation and deacetylation of anticonvulsants by TSP/LC/MS.

The third section highlights aspects of applications in environmental analysis. Two papers deal with target and non-target pollutants in hazardous wastes and phenols, and their sulphates and conjugates utilizing particle beam MS. Vestal, a leader in the development of TSP, describes a combination ion source for the detection of environmentally important compounds. DLI and FAB LC/MS are applied to the analysis of metabolites of benzo(a)pyrene. The use of ion-exchange TSP tandem MS for polar urinary metabolites and use of LSIMS (caesium ion) for structural studies of *in vitro* alkylation of haemoglobin by electrophilic methods, *viz.* with styrene-7,8-oxide, are also presented. The latter paper highlights the powerful application of a four sector (EBEB) MS/MS instrument for the sequencing of tryptic peptides isolated from human globins.

In conclusion, this monograph provides valuable and exemplary information on the wide use of a range of LC/MS techniques for qualitative, quantitative and structural analyses and is a useful addition to the literature dealing with this important subject.

Inorganic Chemistry: D. F. SHRIVER, P. W. ATKINS and C. H. LANGFORD (eds.), OUP, Oxford, 1990. Pages xiii + 706. £40.00 (hardback), £16.50 (softback).

A single text dealing with inorganic chemistry must be extensive, as the discipline covers over a hundred elements and extends into many other branches of science. Inevitably this new work will be compared with *Advanced Inorganic Chemistry* by Cotton and Wilkinson and *Chemistry of the Elements* by Greenwood and Earnshaw. It is aimed at the undergraduate student and is keenly priced.

The approach adopted by the authors is selective and interpretative rather than comprehensive. The 19 chapters of the book are arranged under five section headings: structure, reactions, *s*- and *p*-block elements, *d*- and *f*-block elements and interdisciplinary topics (which comprise catalysis, structure and properties of solids and bioinorganic chemistry). Not all chapters are strictly sequential and it would be possible to move directly from say Chapter 3 on *d*-metal complexes to Chapter 14 on bonding and spectra of complexes. There are several worked examples together with additional problems, and short answers are supplied to all exercises; these will be useful to both teacher and student. A separate publication, *Guide to Solutions*, by Prof. S. Strauss accompanies the text but has not been seen by this reviewer. Suggestions for further reading (supplementary books) are given at the end of each chapter. In the text the columns in the periodic table are numbered from 1 to 18 and (for the main groups) from I to VIII, so that the oxygen group is Group VI/16 and the chromium group is Group 6.

The book is extremely well produced, with wide margins which contain many excellent diagrams. In particular there are numerous structures which emphasize the three-dimensional nature of the subject. However, I did notice that one structure of tin referred to in the formula index was actually a polymer of sulphur (S_n). Bonding and mechanistic models are explained clearly and co-ordination chemistry is well surveyed. Periodic trends rather than isolated treatments of elements are emphasized, *e.g.*, the inorganic chemistry of phosphorus is mentioned in various chapters, *viz.* those on the nitrogen and oxygen groups, the structures of solids, molecular structure, Brønsted acids and bases, Lewis acids and bases, oxidation and reduction, hydrogen and its compounds, main group organometallics, and *d*- and *f*-block organometallics. Also, uranium is not mentioned in the general index but some uranium chemistry is scattered here and there in the text. The terms "*d*-orbital splitting" and "crystal field theory" are also absent but "ligand field splitting" and "ligand field theory" are present, along with "frontier orbital energy level" diagrams.

As a general introductory text with a structural bias it certainly succeeds in its interpretative approach.

P. J. COX

Dictionary of Drugs—Chemical Data, Structures and Bibliographies: J. ELKS and G. R. GANELLIN (eds.), Chapman & Hall, London, 1989. £675.

This 2-volume work provides a concise up-to-date reference source on structures, physical properties and pharmacological properties of more than 6000 drugs of current interest. The compilation brings together essential data that are otherwise difficult to retrieve, and together with additional references allows a rapid access to original data.

The main work is clearly presented in the style of the *Dictionary of Organic Compounds* with extensive cross-referenced indexing. The Structure Index, however, though providing a source of rapid scanning for structural recognition, is confusingly condensed.

This will be a key source for scientists of many disciplines working with pharmaceuticals as well as for the industry itself. The editors are to be commended on their labours, but not surprisingly for such a specialized publication the cost is high. It will be of interest to see whether the high standard of these volumes is to be maintained in subsequent additions.

(Received 20 July 1989. Revised 30 November 1990. Accepted 14 December 1990)

Summary—The methodological aspects of the use of HPLC in determination of metals in the form of their chelates are discussed. Rational schemes for the analysis of complex environmental and industrial samples are presented, including choice of chelating reagent, chelate preparation, metal concentration, separation method and detection method. Examples of the application of HPLC of metal chelates to environmental, production and quality control are presented.

To ensure ecological safety and improve production processes, special attention should be paid to determination of heavy metals in environmental and technological samples. Automated HPLC systems can serve this purpose because of their speed, throughput, reproducibility and repeatability, and, ease of automation. In combination with computer systems, they are almost ideal sensors for environmental monitoring and process control.

When metals are determined in the form of chelates,¹ another advantage of HPLC is the diversity of possible separation methods, and hence of approaches for solving the analytical problem.

The present paper is devoted to developing the chemical fundamentals and methodology of the HPLC of metal chelates, and their use for the analysis of environmental and industrial samples.

EXPERIMENTAL

Instrumentation

The work was done with high-performance liquid chromatographs manufactured in the USSR (Milikhrom, Tsvet 306 and 3006, KhZh 1305) and equipped with spectrophotometric detectors. Steel columns of standard size and microcolumns (2 mm i.d.) packed with appropriate sorbents were used. Preconcentration

was performed in glass columns (usually 5 × 100 mm) filled with Teflon FT-4 (0.10–0.25 μm) treated with an organic solvent or a solution of a chelating reagent (extraction–chromatographic preconcentration), or in steel columns (4 × 50 mm) packed with silanized silica gel or a high-capacity ion-exchanger (sorption and ion-exchange preconcentration, respectively).

Reagents

Standard metal solutions were prepared from salts or the metals (analytical-reagent grade) and standardized by conventional methods. Chelating reagents (sodium diethyldithiocarbamate, potassium dibutyldithiophosphate, 8-hydroxyquinoline (Fluka), 4-(2-pyridylazo)resorcinol and 1-(2-pyridylazo)-2-naphthol (Reanal, Hungary) were purified by recrystallization, sublimation or extraction,¹⁻³ and used as aqueous or ethanol solutions or in solid form.

The chelates were obtained by mixing the aqueous analyte solution with the reagent, by extraction or by extraction chromatography.

Other chemicals were of analytical-reagent grade. Doubly distilled or demineralized water was used.

The organic solvents (hexane, chloroform, dichloromethane, benzene, toluene, acetone, 2-propanol, acetonitrile, etc.) of “pure for chromatography” or analytical-reagent grade were used without further treatment.

*Author for correspondence.

RESULTS AND DISCUSSION

Types of chelates used in HPLC

Depending on the electronic structure of the analyte metal M, the type of chelating reagent HL, and the complex formation conditions, different types of complexes can be formed, including (1) neutral chelates ML_n ; (2) cationic ML_n^+ or anionic ML_n^- chelates; (3) mixed-ligand chelates ML_mX_{n-m} (X = a singly charged unidentate or bidentate ligand). In the presence of hydrophobic ions of opposite charge, charged complexes can form ion-associates, *e.g.*, $ML_n^- B^+$.

All these forms of complexes have been used in metal determination by HPLC, and the separation method used is determined by the type of metal chelate (Table 1).

Selection of the chelating reagent

In general, reagents designed for separation and determination of metals by HPLC should fulfil the following requirements.

(1) Neutral or charged complex formation with a large number of metals (*i.e.*, the reagent should have a sufficiently mobile electronic or geometric structure).

(2) Formation of a single well defined co-ordinatively saturated complex under the conditions used, with high stability in the chromatographic system and sufficient solubility in the mobile phase.

(3) Comparatively low hydrophobicity.

These properties can be achieved by tailoring the reagent molecule by varying the chelating

group structure, insertion of substituents with different numbers of carbon atoms, and different electronic and steric effects, insertion of electron-acceptor atoms and ionogenic groups, and by optimizing the complex formation conditions and the mobile phase composition.

The following should also be taken into account.

(1) The kinetics of complex formation (especially during the chromatographic process or post-column detection).

(2) The stability of the reagent under the conditions of complex formation.

(3) The possibility of metal preconcentration and removal of reagent excess.

(4) Adequate sensitivity (*e.g.*, high molar absorptivity) and difference in the characteristics of the complexes and the reagent.

(5) Ready availability and/or simplicity of synthesis.

(6) Specificity for the analytical problem being solved.

(7) Material and labour costs.

Chelate preparation

Several techniques are used for formation of metal chelates for analysis by HPLC.^{4,5}

(1) Complex formation in aqueous medium, followed by extraction with an organic solvent, or extraction of metals from an aqueous solution with a solution of the chelating reagent in an organic solvent.

(2) Complex formation in aqueous medium, followed by sorption on a column of an inert

Table 1. Determination of metals in the form of different types of chelates

Type of chelate	Example	Method of preparation (concentration)	Chromatographic variant	Species determined
ML_n	$Cu(DEDTC)_2$ $Co(Ox)_3$	Extraction, extraction chromatography, sorption	Normal- or reversed-phase adsorption	Cu, Ni, Co, Zn, Cd, Hg, Fe, Pb <i>etc.</i> Co(III), Cr(III), Mo(VI), W(VI), platinum metals
$ML_{n-m}X_m$	$Pt(PAN)Cl$	Extraction, extraction chromatography	Normal- or reversed-phase adsorption	Pt, Pd, Rh Cu, Ni, Co
ML_n^+	$Fe(DAM)_3^+$	Extraction, extraction chromatography	Normal-phase adsorption	Fe, Ti, Zr, rare-earth elements
ML_n^- $ML_n B_m$	$Zn(PAR)_2^-$ $Ni(PAR)_2(R_4N)_2$	Direct mixing, ion-exchange Direct mixing, extraction, extraction chromatography	Ion-exchange Ion-pair	Co, Cu, Ni, Zn, Fe <i>etc.</i> Fe, Co, Ni, Cu, Zn, Ga <i>etc.</i>

*DEDTC = diethyldithiocarbamate; Ox = 8-hydroxyquinoline; DAM = diantipyrylmethane; PAN = 1-(2-pyridylazo)-2-naphthol; PAR = 4-(2-pyridylazo)resorcinol; R_4N = quaternary ammonium ion.

support coated with an organic solvent, or passage of the sample solution through a column of an inert support coated with a solution of the chelating reagent in an organic solvent.

(3) Chelate formation in aqueous medium with subsequent sorption on a column of a hydrophobic sorbent, a polymeric support or a high-capacity anion-exchanger.

(4) Formation of the chelates by passing the sample through a precolumn of silica gel coated with octadecylsilane and loaded with the reagent.

(5) Direct injection of the chelate mixture in aqueous or homogeneous water-organic medium into the analytical column.

(6) Precolumn on-line formation by injection of the sample into an eluent containing the chelating reagent.

(7) On-column formation with the sample injected directly into the column, the reagent being present in the mobile phase.

Only the first four variants permit simultaneous concentration of the metals, and are to be preferred. In a number of cases, however, a simpler and faster formation of the complexes can be achieved by direct mixing of the metal and reagent solutions or by on-column formation (see below). The choice of chelate preparation technique is partly dependent on the nature of the metals to be determined. For example complexes of kinetically inert metals can only be obtained under static conditions.

Concentration

As a rule, preconcentration is necessary in the determination of traces of metals by HPLC.⁶

Liquid-liquid extraction, the most widely used group separation method in inorganic analysis (including HPLC),⁴ also offers the possibility of relative concentration of metals. This makes concentration by extraction indispensable in the determination of trace elements in the presence of large amounts of matrix components. However, the concentration factors achieved rarely exceed 100.

Extraction chromatography (the dynamic mode of extraction) can give a degree of concentration that is about twice that attainable in static (batch) extraction. Further, performance of the concentration stage in a closed system practically eliminates the risk of metal losses and contamination. The same advantages are inherent in sorption concentration, and the

capacity of columns of hydrophobic sorbents is substantially higher, which allows separation of larger amounts of metals, at a higher flow-rate.

In general, extraction and extraction chromatographic concentration are better combined with normal-phase chromatography, whereas sorption concentration is more suitable for reversed-phase and ion-pair chromatography.

Ion-exchange concentration of metals is conducted on a small precolumn (which may have a back-flush facility) or directly on a separation column. The latter possibility is due to the low elution power of water, as a result of which much greater sample volumes can be used in ion-exchange chromatography than in the other HPLC methods (up to 500 μl or, on average, larger by a factor of 50).

The choice of concentration technique is determined not only by the chromatographic mode and the concentration of the analyte, but also by the nature of the sample. For instance, in sorption concentration of samples with a high salt background the matrix components are partially eluted by the polar solvent (acetonitrile or methanol) used to elute the concentrate from the column. Therefore, for analysis of mineral salts, extraction concentration is recommended, but for solutions which contain a large amount of low-polarity organic compounds, sorption concentration is preferable.

Chelate separation mechanism

As mentioned above, the choice of HPLC method and therefore the separation mechanism is primarily determined by the type of metal chelate (see Table 1).

The retention mechanism of neutral chelates ML_n in adsorption chromatography has been comprehensively discussed by Timerbaev and Petrukhin.⁴ In the case of co-ordinatively saturated chelates (the complexes of choice) retention is determined by the formation of hydrogen bonds with the surface hydroxyl groups (normal-phase variant) or with the mobile phase polar molecules (reversed-phase variant). The energy of these interactions is proportional to the total electronegativity of the ligand donor atoms: the higher the electronegativity the stronger the adsorption on specific sorbents and the weaker on non-polar sorbents. In turn, the effective charge on the donor atoms is proportional to the effective charge on the metal ion. In reversed-phase chromatography the contribution of non-specific chelate-sorbent interactions and, especially, the solvophobic

effect caused by disordering of the water structure, can become appreciable.⁷

The same features are observed for the cationic chelates ML_n^+ . However, a distinguishing feature of their chromatographic behaviour is the influence of the nature of the counter-ion B^- on the retention of different chelates of the same metal. In mixed-ligand chelates $ML_{n-m}X_m$, if X^- is a unidentate ligand it can affect the electron density distribution in the chelate ring and thereby the proton-acceptor ability of the donor atoms. As a consequence, the ability of such compounds to participate in specific intermolecular interactions also depends on the anionic composition of the medium. Anionic chelates ML_n^- can be retained in ion-pair HPLC by both ion-exchange and adsorption. The relative contributions of these mechanisms then strongly depend on the mobile phase composition (mainly on the eluting strength and concentration of the organic modifier), and under certain conditions a mixed retention mechanism may occur. This is why the elution sequence of complexes can vary considerably and even be completely reversed.

When separation is performed on organic anion-exchangers, anionic chelates, because of their rather high hydrophobicity, are retained simultaneously by ion-exchange and hydrophobic adsorption.

Detection

Since most metal chelates are highly coloured, spectrophotometric detection is generally used.⁴ For consecutive determination of all the components, with comparable sensitivity, close similarity of the spectral characteristics of the metal chelates (wavelength of absorption maxima, and molar absorptivity) is desirable. On the other hand, if there is sufficient difference in the chelate absorption spectra, there is a possibility of determining one metal in the presence of large amounts of another.⁸ Thus the selectivity can be increased, and interferences eliminated by appropriately changing the detection wavelength.

Detectors of the other types (electrochemical, atomic-emission, atomic-absorption, fluorescence) have various drawbacks, compared with spectrophotometric detectors, and are rarely used.⁴

Sample analysis

The advantages of HPLC as a multielement method are manifested in the analysis of multi-

component mixtures in which the analytes are present at comparable concentrations. The method is particularly useful for complex water samples containing traces of metals (natural water, treated waste water). Moreover, since only a comparatively short time is required for the treatment of such samples, another advantage of HPLC—speed of analysis—becomes prominent.

A number of analytical problems, however, require selective determination of one or several metals in the presence of large amounts of macrocomponents. Characteristic examples are the determination of trace platinum metals in the presence of non-ferrous metals,^{3,8} determination of cobalt in nickel salts,⁸ or analysis of waste water from wash tanks in electroplating works.⁹

The selectivity of HPLC determination of metals can be increased in several ways.

- (1) By choice of chelating reagent.
- (2) By choice of chelate preparation conditions (pH control, use of masking agents, kinetic effects *etc.*).
- (3) By varying the separation conditions, utilizing the differences in the chromatographic stability of the complexes, and changing the separation mechanism.
- (4) By changing the spectrophotometric detection conditions or using a selective detection method (atomic-emission spectrometry, atomic-absorption spectrometry, *etc.*)⁴

PRACTICAL APPLICATIONS

Some examples of applications to various analytical problems will now be given, with an outline of the methods used, and some typical results (Table 2).

Environmental samples

To demonstrate the possibilities of HPLC in environmental control, natural samples of three different types have been chosen: mineral (ground) waters, surface (lake) waters, and soils.

*Mineral waters.*¹⁰ To determine heavy metals, the sample (up to 500 ml) was made 0.1M in hydrochloric acid and 0.3M in sodium chloride, and 20–70 mg of potassium dibuthyldithiophosphate was added. The complexes formed were concentrated on a glass column containing 2 g of FT-4 impregnated with 1 ml of toluene, and then eluted with toluene (the total volume eluate is 3 ml). A 10- μ l portion of the eluate was analysed on a column (62 \times 2 mm) of 5- μ m

‡Mean ± standard deviation of 4-9 determinations.

Silasorb-600 (Lachema) with toluene-hexane (70:30 v/v) mixture (flow-rate 1 ml/min), followed by spectrophotometric detection at 300 nm.

Surface waters.⁸ To determine molybdenum and tungsten, a 70–100 ml sample of lake water was adjusted to pH 4 with 0.1M hydrochloric acid, 30 mg of crystalline 8-hydroxyquinoline were added and the mixture was left to stand overnight. It was then passed through a glass column (100 × 3 mm) containing 0.2 g of FT-4 treated with 1M 8-hydroxyquinoline solution in chloroform, at a flow-rate of 0.5 ml/min. The concentrate was eluted with 0.5 ml of chloroform and the eluate was washed with 0.1M hydrochloric acid [to remove the excess of reagent and eliminate interferences by Fe(III), Al(III), Cu(II) and other ions]. A 10- μ l aliquot was chromatographed on the same Silasorb column with a dichloromethane-isopropyl alcohol (95:5 v/v) mixture as the mobile phase, and spectrophotometric detection at 254 nm was used.

Soils.⁹ A finely ground sample (5 g) was stirred with 50 ml of acetate buffer (pH 4.8) for 1 hr. The suspension was filtered (filter paper) and after adjustment to pH 8 with 1M ammonia solution was treated with 4 mg of sodium diethyldithiocarbamate. The mixture was passed through a glass column filled with 2 g of FT-4, the concentrate was eluted with 3 ml of acetonitrile, and a 4- μ l aliquot of the eluate was analysed on a column (64 × 2 mm) of 10- μ m Separon C₁₈ (Chemapol) by elution with acetonitrile-water-chloroform (70:28:2 v/v) at a flow-rate of 100 μ l/min. The absorbance of the eluate at 280 nm was measured.

Waste waters

Waste waters from electroplating plants are a potential source of environmental pollution with toxic heavy metals. This type of waste water is analysed before and after purification. In this case the analysis data allow simultaneous control of the ecological safety of a given production process and the efficiency of the purification systems.

Four procedures have been developed,^{2,9–11} based on (a) combination of extraction-chromatographic concentration by normal-phase HPLC of metal dibutyldithiophosphates, (b) sorption concentration and reversed-phase HPLC of metal diethyldithiocarbamates, (c) ion-pair HPLC and (d) anion-exchange HPLC of metal pyridylazoresorcinol (PAR) complexes.

Purified waters. In procedure (a) the metals were determined as dibutyldithiophosphates by the procedure used for analysis of mineral waters.¹⁰

In method (b) the sample (100–400 ml) was adjusted to pH 8 with 1M ammonia solution, 10 mg of sodium diethyldithiocarbamate were added, and the mixture was passed through a column of 2 g of FT-4 or C₁₆-phase. The concentrated complexes were desorbed with 5 ml of acetone, the eluate was evaporated to dryness, and the residue was dissolved in 1 ml of acetonitrile. A 2- μ l aliquot of this solution was chromatographed on the Separon column with acetonitrile-water-chloroform (70:29:1 v/v) as mobile phase (flow-rate 100 μ l/min), followed by detection at 280 nm. Figure 1 shows chromatograms of waste water samples before and after four stages of electroflotation treatment.¹²

Untreated waters. Analysis of waste water from electroplating wash tanks can be performed without preconcentration.

Ion-pair HPLC was used in two different ways. In the first, 1 ml of acetate buffer (pH 5), 1 ml of acetonitrile and 0.6 ml of 5 × 10⁻³M PAR were added to a known volume of sample, and a 10- μ l aliquot of the mixture was analysed on a column (62 × 2 mm) of Nucleosil RP-18 (Merck), with a mobile phase consisting of

Fig. 1. Chromatograms of waste water samples: (a) before treatment, (b) after purification. For chromatographic conditions see text.

40:60 v/v acetonitrile–acetate buffer (pH 5) mixture containing 0.01M cetyltrimethylammonium bromide, at a flow-rate of 100 μ l/min. In the second, 10 ml of 2×10^{-3} M PAR were added to the sample and 50 μ l of this mixture were injected into a column (100 \times 6 mm) of 10- μ m Silasorb-600 C₁₈, and the analytes were eluted with acetonitrile–water (20:80 v/v) or acetone–water (30:70 v/v) containing 6×10^{-3} M tetrabutylammonium hydroxide and 0.1M sodium carbonate (pH 11.5) (flow-rate 1.5 ml/min).

In the anion-exchange HPLC, a corresponding excess of 1×10^{-3} M PAR was added to the sample, and 100 μ l of the mixture were chromatographed on a column (200 \times 6 mm) of the low-capacity surface-modified resin-based anion-exchanger XIKS-1 (USSR), with a mixture (40:60 v/v) of acetone and 0.04M sodium carbonate (pH 12) as eluent (flow-rate 2 ml/min), followed by spectrophotometric detection at 500 nm (Fig. 2).

When the iron content was high [e.g., in the purification of effluents by co-precipitation of metals with hydrous iron(III) oxide], modification of the anion-exchange chromatography by on-column formation of the metal PAR complexes proved to be effective. In contrast to other metals, the iron(III) does not form a complex under these conditions, probably for kinetic reasons,¹³ and does not interfere.

Industrial samples

There are two objectives with this type of sample: quality control in metallurgical and other industries (analysis of steels, alloys, metals, etc.) and monitoring of technological

Fig. 2. Anion-exchange separation of metal PAR chelates. For chromatographic conditions see text.

solutions and intermediate products to control or improve the technological process.

Steels, metals.² A sample (0.1 g) of steel or metallic nickel was dissolved by heating with *aqua regia* and the solution was evaporated to a moist residue, which was dissolved in 0.1M hydrochloric acid and accurately diluted with water to 250 ml. A 0.1–0.5 ml portion was adjusted to pH 5, and the determination was performed as in the analysis of waste waters (ion-pair variant).

Alloys, catalysts.^{3,8} These samples may contain traces of platinum metals.

To determine palladium(II), platinum(II) and rhodium(III) in a copper alloy (0.01% of platinum metals), the sample (0.5 g) was dissolved by heating with 10 ml of *aqua regia*. The solution was carefully evaporated to minimum volume, then diluted with concentrated hydrochloric acid and again evaporated. This operation was repeated until destruction of nitroso compounds was complete and all the metals were present as their chlorides. The precipitate of silver chloride was filtered off on paper, and washed with 10-mg/ml sodium chloride solution. The filtrate and washings were diluted to 25 ml, 5 g of sodium sulphate and 5–7 ml of 6M sulphuric acid were added and the mixture was boiled until dissolution of metal hydroxo- and oxo-chlorides was complete, then cooled and diluted accurately to 20 ml with 0.1M sulphuric acid. A 10-ml aliquot was buffered with 4M sodium acetate and 1M sulphuric acid to pH 3, one drop of 1-(2-pyridylazo)-2-naphthol solution (PAN, 1 mg/ml solution in dimethylformamide) was added and then 0.25M EDTA saturated with isopentanol, until copper was completely masked (colour change from violet to green). The solution obtained was heated to 85° and passed through a steel column (140 \times 5 mm) packed with FT-4 (1 g) impregnated with PAN solution in isopentanol and kept at 85° (flow-rate 0.25 ml/min). The column was washed with 2 ml of 0.01M EDTA and cooled, then the concentrate was eluted with 2 ml of chloroform–isopropyl alcohol mixture (2:1 v/v) and 10 μ l of the eluate was analysed on a column (200 \times 2 mm) 5- μ m Spherisorb CN (Merck) or (250 \times 4.6 mm) 5- μ m Silasorb-600 with a mobile phase of acetonitrile–0.1M sodium perchlorate (40:60 v/v, pH 4) or benzene–isopropyl alcohol (90:10 v/v), respectively, followed by spectrophotometric detection at 440 nm (Fig. 3).

A 10–20 mg sample of carbon fibre-based catalyst was dissolved in 3 ml of

Fig. 3. Chromatogram of a mixture of palladium, platinum and rhodium PAN chelates. Chromatographic conditions: column, 5- μ m Spherisorb CN, 200 \times 2 mm; mobile phase, acetonitrile/0.1M sodium perchlorate, pH 4, (40:60 v/v); flow-rate, 1 ml/min; detection at 440 nm.

concentrated sulphuric acid and 1 ml of 3% hydrogen peroxide solution, heated till the solution became colourless, and then cooled. One ml of *aqua regia* was added and the solution was heated until sulphur trioxide fumes appeared. The solution was cooled, and to remove nitrogen oxides 1 ml of concentrated hydrochloric acid was added and evaporated to a moist residue, this operation being repeated three times. After cooling, the residue was dissolved in water and diluted to 25 ml. One ml of 50 mg/ml ascorbic acid solution was added to 1–2 ml of this solution (accurately measured) and the pH was adjusted to 4.8 with acetate buffer. Then 8-hydroxyquinoline (30 mg; was added, followed by heating on a boiling water-bath for 2 hr. After cooling, the platinum metal chelates were extracted with 2 ml of chloroform. The extract was washed with 0.1M sodium hydroxide (to remove the reagent excess), and a 10- μ l aliquot was sorbed on a Silasorb column and the chelates were eluted with dichloromethane-isopropyl alcohol mixture (97:3 v/v) at a flow-rate of 100 μ l/min (Fig. 4). Under these conditions it is possible to determine all the

Fig. 4. Determination of platinum in carbon fibre-based catalyst as 8-hydroxyquinolate. Detection at 254 nm. For chromatographic conditions see text.

platinum metals in the sample in less than 12 min.¹⁴

Salts.⁸ The content of colour-producing metals, such as cobalt and chromium, in raw materials (alkali metal salts) should be controlled in the production of optical glasses.

A 10-g sample of sodium chloride or nitrate was dissolved in 30 ml of acetic buffer (pH 4.5) and 8-hydroxyquinoline (30 mg) was added. After heating on a boiling water-bath for 30 min the mixture was cooled and then shaken with 5 ml of chloroform for 5 min. The extract was washed twice with 0.1M hydrochloric acid, then evaporated to dryness. The residue was dissolved in 0.1 ml of the eluent to be used (95:5 v/v dichloromethane-isopropyl alcohol) and a 5 or 10 μ l aliquot was chromatographed on a Silasorb column.

Technological solutions.¹⁵ For determination of molybdenum, tungsten, cobalt and chromium in

Fig. 5. Chromatogram of technological solution sample. Mobile phase, dichloromethane/isopropyl alcohol (95:5 v/v). Other conditions as for Fig. 4.

the leaching solutions from oxidized and sulphide copper ores (Fig. 5), the same procedure was used as for salt analysis. Mo and W in the technological solutions of ore processing were determined under the same chromatographic conditions. The sample was heated with 10 ml of concentrated sulphuric acid and 6 ml of concentrated nitric acid on a sand-bath and the solution was then evaporated to dryness. The residue was dissolved in 2% v/v nitric acid and diluted accurately to 100 ml with water. A 1–5 μ l portion of this solution was taken for HPLC analysis.

Copper was determined in the technological solutions of plastics production by a procedure similar to the one described above for analysis of mineral waters. Non-ionic surfactants present in considerable amounts in the sample did not interfere.

Comparison of different HPLC methods

The data in Table 2 and other metrological and analytical characteristics can be used to compare the analytical possibilities provided by the HPLC methods reported above for analysis of metal chelates.

The detection limits for the metals are on average about 1 ng. With a 10- μ l volume of sample injected this corresponds to 0.1 μ g/ml in the final test solution. With preconcentration the detection limit will be about 1 ng/ml, which for many metals is comparable with the sensitivity of such instrumental methods as atomic-absorption, X-ray fluorescence and X-ray emission spectrometry, and others.

The sensitivity depends on the molar absorptivity of the metal chelates and on the separation efficiency. The dispersion of the chromatographic zones, under conditions of comparable sorbent characteristics, flow-rates and sorbate molecular size, is determined by the nature of the mobile phase. Because of this, the lowest detection limits are observed in normal-phase HPLC, where less viscous eluents are used.

The linear calibration range covers 2–3 orders of magnitude, and the absolute determination limit primarily depends on the degree of metal concentration.

Reproducibility (in terms of relative standard deviation) varies on the average from 3 to 7% for trace and environmental analysis but can be somewhat worse when multicomponent mixtures are analysed (owing to peak overlap)

or when the sample has a complex composition (soils, technological solutions).

The accuracy of the results, provided separation of the reagent excess is complete (at the sample treatment or the chromatographic stage), is sufficiently high. The separation time usually does not exceed 10–15 min.

Nevertheless, each chromatographic variant has its own analytical peculiarities.

The HPLC of neutral chelates, which is at present better developed both theoretically and methodologically, is characterized by higher selectivity. However, adsorption chromatography has the disadvantage of the more strict requirements for the stability and kinetic inertness of metal chelates.¹⁶ The dissociation of low-stability and labile complexes in the mobile and stationary phases leads to a decrease in the number of metals that can be determined and worsens the metrological characteristics of the determination.

Ion-pair and ion-exchange HPLC are distinguished by the ability to use spectrophotometric reagents (dyes, metallochromic indicators) which form highly coloured chelates with numerous metals, as well as to vary the separation selectivity within wide limits by changing the mobile phase composition. Moreover, the metal chelates formed by this type of multi-dentate reagent are rather stable in the chromatographic process. The increased sensitivity often makes the metal preconcentration stage unnecessary, which speeds up and simplifies the analysis. The somewhat lower sensitivity of ion chromatography (because of the lower efficiency of the available ion-exchangers) is compensated by the higher sample volumes that can be used.

Thus, at present the different HPLC modifications do not compete but complement each other.

With regard to the competitiveness of HPLC of metal chelates as a whole, we should note that its advantages over the other analytical methods follow from (a) the possibility of multi-element determination, (b) consecutive determination of metals in different oxidation states and in different chemical forms, as well as non-metals (anions, including metal oxo-anions) and organic compounds (both neutral and charged); (c) the possibility of being combined with various metal preconcentration methods; (d) low dependence of the analysis results on sample treatment; (e) good technical equipment.

CONCLUSIONS

High-performance liquid chromatography as a method of inorganic analysis came into being in the middle 1970s. In metal analysis an important role is played by the HPLC of metal chelates, the progress of which is connected with the development of its main field of practical application—the analysis of complex water samples. At present, however, there is rapid development of other chromatographic techniques in which complex formation is utilized to a greater or lesser extent. These are cation-exchange HPLC with post-column reaction detection, ion chromatography of metal cyanide complexes and HPLC on chelating bonded phases. The future will show which chromatographic variants will become the most competitive, and when.

(Received 24 July 1990. Revised 19 October 1990. Accepted 3 November 1990)

Summary—Diprotic acid dyes [H_2A : Bromophenol Blue (BPB), Bromochlorophenol Blue (BCPB), Bromocresol Purple (BCP), Bromocresol Green (BCG), Bromothymol Blue (BTB)] can be extracted as 1:1 ion-associates Q^+HA^- and 1:2 ion-associates $(Q^+)_2A^{2-}$ with quaternary ammonium cations (Q^+) into chloroform. The extraction constants ($\log K_{ex}$) of the 1:1 and 1:2 ion-associates have been determined. Linear relationships between $\log K_{ex}$ and the number of methylene groups in the quaternary ammonium ions were observed; from the slope of the line, the contribution of a methylene group to $\log K_{ex}$ was found to be $\sim 0.43-0.65$. The extractability with alkyltrimethylammonium cations was larger than that with symmetrical tetra-alkylammonium cations, for both the 1:1 and 1:2 ion-associates. From the extraction constants obtained, the extractability of acidic dyes was in the order $BTB > BCG > BPB > BCPB > BCP$.

The extraction behaviour of ion-associates of triphenylmethane dyes such as Methylene Blue, Ethyl Violet and Crystal Violet, with various monovalent anions has been widely studied.¹⁻³ Although acidic dyes, such as Bromophenol Blue, Bromocresol Purple and Bromocresol Green, have frequently been used for the extraction-spectrophotometric determination of amines and quaternary ammonium compounds,⁴⁻⁶ the extraction behaviour of the acidic dyes themselves has not been examined in detail. In the present work, the extraction constants for the ion-associates of five acidic dyes [Bromophenol Blue (BPB), Bromochlorophenol Blue (BCB), Bromocresol Purple (BCP), Bromocresol Green (BCG) and Bromothymol Blue (BTG)] with quaternary ammonium counter-ions distributed between an aqueous phase and chloroform were determined and correlated with the numbers of carbon atoms in the counter-ions. A parameter related to the extractability of the acidic dyes was determined from the extraction constants obtained. Such a parameter will be useful for prediction of the extractability of ion-associates with the acidic dyes and the design of new extraction systems.

EXPERIMENTAL

Apparatus

Absorbances were measured with a Japan Spectroscopic Uvidec-430 spectrophotometer with fused-silica cells of 10-mm path-length. The pH values were measured with a Hitachi-Horiba Model F-8 dp pH meter. An Iwaki Model V-SX type KM shaker was used for horizontal shaking of the 25-ml stoppered test-tubes used for the extractions.

Reagents

Acidic dye solutions were prepared by dissolving the appropriate amounts of dyes (see Fig. 1) in 0.01M sodium hydroxide and diluting to 200 ml with distilled water.

Stock solutions of quaternary ammonium ions were prepared by dissolving accurately weighed amounts of the chlorides listed in Table 1, in distilled water. Working solutions were prepared by diluting the stock solutions before use.

Sulphuric acid, acetic acid, acetate buffer solution, phosphate buffer solution, ammoniacal buffer solution and sodium hydroxide solution

Bromocresol Green	H	Br	Br	CH ₃	BCG
Bromothymol Blue	CH ₃	CH(CH ₃) ₂	Br	H	BTB

(0.05M) were used to adjust the pH of the solutions to 2.3–12.5.

A 0.33M sodium sulphate solution was used to adjust the ionic strength of the aqueous solution to a final value of $\mu = 0.2$.

Chloroform was used without further purification, and was saturated with distilled water before use.

All reagents were of analytical-reagent grade and were used without further purification.

Procedure for the determination of extraction constants

A 5-ml volume of an aqueous solution containing $1.2 \times 10^{-5}M$ acidic dye, 0.01M buffer solution, sodium sulphate solution and an appropriate amount of aqueous quaternary ammonium salt solution ($\mu = 0.2$) was mechanically shaken with 5 ml of chloroform for a fixed time at 25.0°. After phase separation, the absorbance of the organic phase was measured at the wavelength of the absorption maximum of the ion-associate.

Calculation of the extraction constants

A diprotic acid dye (H_2A) dissociates protons to form two kinds of anion, HA^- and A^{2-} . An extraction system in which a quaternary ammonium cation (Q^+) reacts with HA^- and A^{2-} to form the ion-associates Q^+HA^- and $(Q^+)_2A^{2-}$ respectively, in the aqueous phase, involves the following equilibria, provided that the extracted ion-associates do not dissociate or aggregate:

where the subscript org refers to the organic phase and the aqueous phase is unmarked. The extraction constants, K_{ex1} and K_{ex2} , for equations (1) and (2) are given by:

$$K_{ex1} = [Q^+HA^-]_{org} / [Q^+][HA^-] \quad (3)$$

$$K_{ex2} = [(Q^+)_2A^{2-}]_{org} / [Q^+]^2[A^{2-}] \quad (4)$$

1:1			(1.03)	3.9	5-20 (10)	416

*The figures in parentheses are the values of α_{HA⁻} in equation (8).

†The figures in parentheses are the shaking times used for the determination of the extraction constants.

‡Molar absorptivity, 10⁴ l. mole⁻¹. cm⁻¹.

The concentration of the ion-associate in the organic phase was calculated from equation (5)

$$A_{X(o)} = \epsilon_{X(o)} C_{X(o)} \quad (5)$$

where $A_{X(o)}$, $\epsilon_{X(o)}$ and $C_{X(o)}$ are the absorbance, molar absorptivity and concentration of the ion-associate (X) in the organic phase, respectively. In application of equation (5), the $\epsilon_{Q^+HA^-(o)}$ and $\epsilon_{(Q^+)_2A^{2-}(o)}$ values obtained by using TDTMA or TAA as a counter-cation were used. The distribution ratios of HA⁻ and A²⁻, D_{HA^-} and $D_{A^{2-}}$, are given by the following equations:

$$D_{HA^-} = [Q^+HA^-]_{org}/[HA^-] = K_{ex1}[Q^+] \quad (6)$$

$$D_{A^{2-}} = [(Q^+)_2A^{2-}]_{org}/[A^{2-}] = K_{ex2}[Q^+]^2 \quad (7)$$

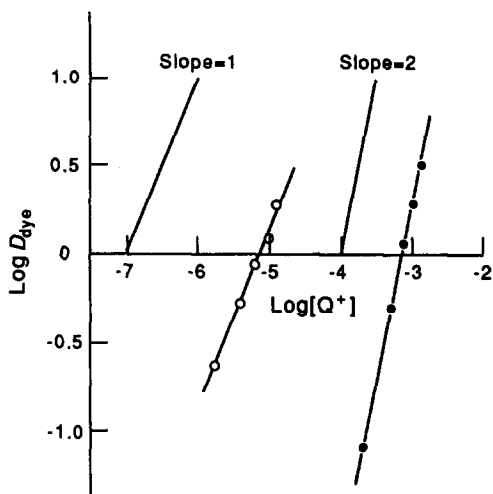

Fig. 2. Plots of log D_{dye} vs. log $[Q^+]$. Dye, BCP; Q^+ , DTMA; \circ , 1:1 ion-associate; \bullet , 1:2 ion-associate. The pH values are those in Table 2.

The side-reaction coefficient for HA⁻, α_{HA⁻}, is given by

$$\begin{aligned} \alpha_{HA^-} &= [HA^-]/[HA^-] \\ &= ([HA^-] + [A^{2-}])/[HA^-] \\ &= 1 + [A^{2-}]/[HA^-] \\ &= 1 + K_2/[H^+] \end{aligned} \quad (8)$$

where $[HA^-]$ is the total concentration of dye anion that is not bound in ion-associates with Q^+ , and K_2 is the apparent second dissociation constant of a diprotic acid dye (see Table 2). $[HA^-]$ can be calculated from the α_{HA⁻} values in Table 2 and the following equation:

$$[HA^-] = [HA^-]/\alpha_{HA^-} \quad (9)$$

The side-reaction of quaternary ammonium ions shown in equation (10) does not occur.

This was confirmed by the calculation with the extraction constant⁷ for the quaternary ammonium ion with chloride ion.

RESULTS AND DISCUSSION

Effect of shaking time

The effect of the shaking time on the extraction of the ion-associate was examined by varying the time from 1 to 20 min (30 min for the 1:2 ion-associate of BCG). The shaking times required to reach extraction equilibrium are summarized in Table 2. The wavelengths of maximum absorption and the molar absorptivities of the ion-associates in the organic phase are also given in Table 2.

Table 3. Extraction constants for 1:1 and 1:2 ion-associates

Determination of the extraction constants

The plots of $\log D_{HA^-}$ and $\log D_{A^{2-}}$ against $\log [Q^+]$ for the extraction system with DTMA and BCP are shown in Fig. 2. As expected from equations (6) and (7), straight lines with a slope of +1 for 1:1 ion-associates and +2 for 1:2 ion-associates were obtained. This result supports the extraction equilibria shown in equations (1) and (2).

The five acidic dye anions in Fig. 1 and the seven quaternary ammonium cations in Table 1 (other than TDTMA) were examined, and the extraction constants were calculated from equations (3) and (4): the results obtained are summarized in Table 3.

Fig. 3. Relationship between $\log K_{ex1}$ and the number of carbon atoms in the alkyltrimethylammonium ions. Counter-anion: (1) HBTB⁻, (2) HBCG⁻, (3) HBPB⁻, (4) HBCPB⁻, (5) HBCP⁻. Q⁺: (a) OTMA, (b) DTMA, (c) DDTMA (see group I in Table 1).

Relationship between the extraction constants and number of carbon atoms in the quaternary ammonium ion

As shown in Figs. 3–6, for the same carbon number the extractability with long-chain alkyltrimethylammonium ions (group I) is larger than that with tetra-alkylammonium ions (group II). This indicates that the cations of group I, with their longer alkyl chains, make the ion-associates more hydrophobic and more soluble in chloroform. The plots of $\log K_{ex}$ vs. number of carbon atoms in the quaternary ammonium ion are linear; the slopes are listed in Table 4. The contribution of a methylene group to the extraction constant ($\log K_{ex}$) was

Extractability of acidic dyes

The possibility of estimating an extraction constant has been examined.^{7,13} The intercepts on the ordinate, obtained by extrapolating the straight lines in Fig. 3 to zero carbon atoms in the alkyltrimethylammonium cation, can be used to give a parameter (A) related to the extractability of an anion. To obtain a parameter, C , related to the extractability of a cation, the hypothetical cation,

an alkyltrimethylammonium cation with no alkyl groups, was assigned the value $C = 0$. Therefore C values for any alkyltrimethylammonium cation in 1:1 ion-associates can be calculated from equation (11):

$$C = 0.58n \quad (11)$$

where n is the number of carbon atoms in Q^+ and 0.58 is the contribution of a methylene group to the extraction constant (π_{CH_2}). The value of $\log K_{ex}$ for 1:1 ion-associates was considered to be the sum of two quantities, C and A :

$$\log K_{ex} = C + A \quad (12)$$

Values of A for each univalent dye anion, calculated from $\log K_{ex}$ in Table 3, and equations (11) and (12) are listed in Table 5.

Table 5. Values of A for dye anions

Anion	A^*
HBTB ⁻	-0.69
HBCG ⁻	-0.75 ± 0.01 (2)
HBPB ⁻	-1.43 ± 0.01 (2)

HBCP ⁻	-2.57 ± 0.19 (3)
BCG ²⁻	-9.19 ± 0.14 (3)
BPB ²⁻	-9.35 ± 0.15 (3)
BCPB ²⁻	-9.98 ± 0.20 (3)
BCP ²⁻	-10.70 ± 0.12 (3)

*Mean value. The figures in parentheses are the numbers of measurements.

From the plots of $\log K_{\text{ex}}$ vs. n in Fig. 4, we can say that the C values for tetra-alkylammonium cations in 1:1 ion-associates are given by equation (13):

$$C = 0.43n + a \quad (13)$$

where 0.43 is π_{CH_2} and a is a constant for a cation, 0.99, which was determined from $\log K_{\text{ex}}$ in Table 3, the A values in Table 5, and equations (12) and (13). From the finding that the slope of the plot of $\log K_{\text{ex}}$ vs. n for 1:2 ion-associates is about twice that for 1:1 ion-associates for both the alkyltrimethylammonium and the tetra-alkylammonium cations in Table 4, the value of $\log K_{\text{ex}}$ for 1:2 ion-associates can be expressed as equation (14).

$$\log K_{\text{ex}} = 2C + A \quad (14)$$

The C and A values in equation (14) were estimated similarly to those for equation (12). The C values for alkyltrimethylammonium and tetra-alkylammonium cations in 1:2 ion-associates can be calculated from equations (15) and (16), respectively:

$$C = 0.65n \quad (15)$$

$$C = 0.52n + 0.59 \quad (16)$$

where 0.65 in equation (15) and 0.52 in equation (16) are π_{CH_2} ; and 0.59 in equation (16) was determined from $\log K_{\text{ex}}$ (except for BCP) in Table 3, A values in Table 5 and equation (14). The A values for each bivalent dye anion, calculated from $\log K_{\text{ex}}$ in Table 3 and equations (14) and (15), are listed in Table 5.

From the A values obtained, it was found that the extractability of the acidic dyes was in the order BTB > BCG > BPB > BCPB > BCP in both the 1:1 and 1:2 ion-associates. This order in the extractability of the dyes may be explained as due to two factors: the increase of the hydrophobic effect on introduction of alkyl groups, and the effective distribution of the electrons in dye molecules, caused by the introduction of an electron-attracting halogen group.

(Received 21 April 1989. Revised 24 October 1990. Accepted 16 November 1990)

Summary—The extraction of Pd(II) by tri-isobutylphosphine sulphide, TIBPS (Cyanex 471x), in toluene from aqueous chloride solutions (containing small amounts of thiocyanate) has been investigated. The extraction is enhanced by the presence of thiocyanate, owing to formation of mixed-ligand Pd(II)-Cl⁻-SCN⁻-TIBPS complexes. Analysis of the metal distribution suggests the formation of PdCl(SCN)·TIBPS, PdCl(SCN)₂·2TIBPS, Pd(SCN)₂·TIBPS and Pd(SCN)₂·2TIBPS in the organic phase. The equilibrium constants are logK₁₁₁ = 9.56, logK₁₁₂ = 12.70, logK₁₂₁ = 14.73 and logK₁₂₂ = 17.17, respectively. The ultraviolet absorption spectra of the organic phase support the hypothesis of formation of mixed-ligand complexes.

Solvent extraction has been widely used for the separation of palladium,¹ especially with sulphur-containing extractants, which are known to be highly selective for extraction of metals classified as "soft acids".

Cyanex 471x is a phosphine sulphide reagent, the active component of which is tri-isobutylphosphine sulphide (TIBPS). It has been reported as effective for extraction of Pd(II),²⁻⁵ Ag(I)⁶ and Hg(II)⁷ and the separation of Pd(II)-Pt(IV) mixtures. However, the slow rate of the extraction of Pd(II) is one of the major problems in the separation of the platinum group metals.⁸

Al-Bazi and Freiser⁹ reported a large increase in the rate of extraction of Pd(II) by Kelex 100 [7-(1-vinyl-3,3,5,5-tetramethylhexyl)-8-quinolinol] when sodium thiocyanate was present in the aqueous phase, and regarded this as due to the *trans*-effect in Pd(SCN)₃Cl²⁻ produced in the aqueous phase.

The aim of the present work was to investigate the effect of thiocyanate on the Pd(II)-Cl-TIBPS system and to explain the role of thiocyanate in enhancement of the extraction rate.

EXPERIMENTAL

Reagents

Tri-isobutylphosphine sulphide, TIBPS, was obtained from Cyanex 471x (kindly supplied by the American Cyanamid Co.) by recrystallization from an ethanol-water mixture,³ and used to prepare a stock 1 × 10⁻³M solution in toluene (Merck p.a.) which had been successively washed with 0.5M sodium hydroxide, distilled water, 0.5M hydrochloric acid and doubly distilled water before use. Sodium chloride (Merck p.a.) was purified as previously described.¹⁰ Sodium thiocyanate solutions were standardized by titration with silver nitrate, iron(III) ammonium sulphate being used as indicator.

A stock solution of Pd(II) (3 × 10⁻³M, pH = 1) was prepared by dissolving the required amount of the chloride (Spanish Society of Precious Metals) in 0.1M hydrochloric acid, and was standardized gravimetrically with dimethylglyoxime.¹¹

In the aqueous phases the total concentrations of Pd(II) used were 3 × 10⁻⁵, 1.2 × 10⁻⁴ and 2.3 × 10⁻⁴M. The total thiocyanate concentration was varied between 2.5 × 10⁻⁵ and 1 × 10⁻³M. The pH was kept constant at 2.5 to avoid hydrolysis of palladium. The total chloride concentration was 1M.

*Author for correspondence.

The total TIBPS concentration was varied in the range from 2×10^{-4} to $1 \times 10^{-3}M$.

Apparatus

A Bausch and Lomb Spectronic 2000 spectrophotometer was used.

Procedure

Aqueous solutions with a total chloride concentration of $1.0M$ and various concentrations of palladium and thiocyanate were prepared. Equal volumes (10 ml) of the organic and aqueous phases were mixed in stoppered glass tubes and shaken for 90 min on a rack rotating at 40 rpm and kept at $22 \pm 1^\circ$. Preliminary work had shown that shaking for 90 min was adequate for equilibrium to be reached (Fig. 1).

The mixture was then centrifuged and the phases were separated. Excess of thiocyanate was added to the aqueous phase and the absorbance at 310 nm was measured to determine the palladium.¹² For several sets of conditions the Pd(II) mass balance was checked by stripping the palladium from the organic phase with $0.1M$ sodium thiocyanate and measuring the absorbance of the resulting aqueous phase.

RESULTS AND DISCUSSION

The palladium distribution coefficient, D , is given by

$$D = \frac{[\text{Pd(II)}]_{\text{org}}}{[\text{Pd(II)}]_{\text{aq}}} \quad (1)$$

where $[\text{Pd(II)}]_{\text{org}}$ and $[\text{Pd(II)}]_{\text{aq}}$ are the total palladium concentrations in the organic and aqueous phase, respectively.

Figure 2 gives the palladium distribution coefficient as a function of the total TIBPS concentration for total Pd(II) concentrations of 3.2,

Fig. 1. Palladium concentration in the aqueous phase, plotted against time, for different SCN^- concentrations. $[\text{Pd(II)}]_{\text{tot}} = 3.0 \times 10^{-5}M$; $[\text{TIBPS}]_{\text{tot}} = 7.0 \times 10^{-4}M$.

Fig. 2. Experimental distribution data, $\log D$ vs. $\log [\text{TIBPS}]_{\text{tot}}$ at different SCN^- levels. $[\text{Pd(II)}]_{\text{tot}}$: (a) $3.0 \times 10^{-5}M$; (b) $1.2 \times 10^{-4}M$; (c) $2.3 \times 10^{-4}M$.

12.8 and 24.8 ppm and different thiocyanate concentrations and Fig. 3 shows the data in the form $\log D$ vs. $\log [\text{SCN}^-]_{\text{tot}}$.

Taking into account that in our case ($[\text{Cl}^-] = 1.0M$), in the absence of SCN^- the Pd(II) in the aqueous phase will be present as the PdCl_4^{2-} complex, equation (1) can be expressed as:

$$D = \frac{[\text{Pd(II)}]_{\text{org}}}{[\text{PdCl}_4^{2-}](1 + \sum K_i [\text{SCN}^-]^i / [\text{Cl}^-]^i)} \quad (2)$$

Fig. 3. Experimental distribution data, $\log D$, plotted against $\log [\text{SCN}^-]_{\text{tot}}$. $[\text{Pd(II)}]_{\text{tot}} = 3.0 \times 10^{-5} \text{M}$. Solid lines are the calculated curves based on the proposed model.

where the K_i values are the equilibrium constants of the reactions

with $i = 1, 2, 3$ and 4 . The values of K_i obtained from the literature¹³ were $\log K_1 = 6.03$, $\log K_2 = 10.93$, $\log K_3 = 14.52$ and $\log K_4 = 17.55$.

Likewise, the general extraction reaction when SCN^- is added could be expressed as:

where $q = 0-2$. The equilibrium constant can be termed K_{exp} . Since TIBPS is a neutral extractant,⁵ it follows that its role in the extraction is solely solvation of the palladium complex extracted, which itself must therefore be neutral.

The solubility of TIBPS in aqueous solution was determined by equilibrating hydrochloric acid with a solution of TIBPS in toluene, and analysing the aqueous phase for TIBPS by ICP spectrometry and HPLC. The solubility of TIBPS in aqueous solution was found to be $< 1.10 \times 10^{-6} \text{M}$.

To evaluate the composition of the extracted species as well as the corresponding formation constants, the experimental data were analysed numerically with the LETAGROP-DISTR program,¹⁴ which is based on minimization of the error-square sum, U :

$$U = \sum_N (\log D_{\text{cal}} - \log D_{\text{exp}})^2 \quad (5)$$

where D_{exp} are the experimental values of the distribution coefficient and D_{cal} are the corresponding values calculated from the relevant

mass-balance equations for a proposed model: N is the total number of experimental points.

Our proposed models include the mixed-ligand complexes present in the aqueous phase [equation (3)] and protonation of thiocyanate as a constant set in all calculations. The results of the LETAGROP-DISTR calculations for different models tested, based on equation (4), are summarized in Table 1. Polynuclear species of Pd(II) were also tested but were always rejected. It is interesting that the results obtained for extraction of PdCl_2 solvated with TIBPS, model I, are far from agreement with the experimental data, and when mixed species are included in the model (e.g., VII), the PdCl_2 species is rejected. A binuclear species is also rejected in the calculations (models VI and IX).

As seen from Table 1, model X, consisting of the species $\text{PdCl}(\text{SCN}) \cdot \text{TIBPS}$, $\text{PdCl}(\text{SCN}) \cdot 2\text{TIBPS}$, $\text{Pd}(\text{SCN})_2 \cdot \text{TIBPS}$ and $\text{Pd}(\text{SCN})_2 \cdot 2\text{TIBPS}$ formed in the organic phase gives the best fit to the experimental data. Thus, the chemical reactions regarded as responsible for the extraction seem to be

Figures 4 and 5 show the distributions of the species proposed in this model, as a function of the total TIBPS and thiocyanate concentrations, respectively. As seen, the species containing $\text{Pd}(\text{SCN})_2$ predominate under most conditions, and although $\text{Pd}(\text{SCN})_2 \cdot \text{TIBPS}$ is predominant in the range of extractant concentrations studied, $\text{Pd}(\text{SCN})_2 \cdot 2\text{TIBPS}$ becomes more important as the concentration of TIBPS increases (as might be expected).

In additional experiments the ultraviolet absorption spectra of the organic phases obtained

Table 1. Results of numerical calculations for the species $\text{PdCl}_{r(2-q)}(\text{SCN})_q \cdot p\text{TIBPS}$ [equation (4)] by the program LETAGROP-DISTR; n (number of experimental points) = 89

The standard deviation $\sigma(\log D)$ is defined as $\sigma(\log D) = (U/(N - N_k))^{1/2}$ where N_k is the number of constants to be adjusted. The error in the constants vs is given as $\pm 3\sigma(\log K)$ but for $\sigma(K) > 0.2K$, the "best" value of $\log K$ and the maximum value $[\log(K + 3\sigma(K))]$ are given.

by extraction of aqueous Pd(II) solutions (in the presence and absence of thiocyanate) with a toluene solution of TIBPS were recorded. For the extraction without thiocyanate present the shaking time was extended to a week to ensure that equilibrium was reached. The spectra are shown in Fig. 6(a). As seen, there is a blue-shift of the absorbance maximum when the extraction is done with thiocyanate present in the

aqueous phase, whereas there is a red-shift in the spectrum of the initial aqueous phases when thiocyanate is added, Fig. 6(b). The blue-shift seems to be a consequence of the change in medium as well as the ligand-exchange (and is analogous to the spectral differences between palladium thiocyanate species in aqueous medium and in molten salts¹²) and the red-shift

Fig. 4. Distribution diagram of metal species vs. $[\text{TIBPS}]_{\text{tot}}$. $[\text{Pd(II)}]_{\text{tot}} = 3.0 \times 10^{-5}M$; $[\text{SCN}^-]_{\text{tot}} = 1.0 \times 10^{-4}M$.

a consequence of ligand-exchange in aqueous medium.^{15,16}

A comparison of these results with those reported by Walker and Bautista² and by Inoue and co-workers³⁻⁵ leads to conclusions different from theirs. Walker and Bautista,² explain the extraction of Pd(II) by TIBPS in xylene, in the absence of thiocyanate, as due to formation of Pd(TIBPS)_2 species in the organic phase, and Inoue and co-workers consider that a binuclear 2:2 complex also contributes to the extraction into toluene. In both systems metal extraction is assumed to occur by a solvating mechanism. Neither Walker and Bautista nor Inoue and co-workers give values for the reaction constants. The main difference from our results is related to the formation of the binuclear species reported by Inoue and co-workers, and this may be due to the different ranges of Pd(II) concentration used, which in our case were limited by the solubility of Pd(II) in aqueous solutions containing thiocyanate. Furthermore, thio-

cyanate provides a different chemical environment, which may result in a different speciation.

Species with 1:2 metal:extractant stoichiometry are also found when triphenylphosphine in 1,2-dichloroethane is used as the extractant (in the absence of thiocyanate).¹⁷ Our results also partially agree with those reported in the literature for the extraction of different metals with Cyanex 471x, e.g., Ag(I) is extracted from nitrate solutions as $\text{AgNO}_3 \cdot 2\text{TIBPS}$,⁶ and Hg(II) from chloride media as $\text{HgCl}_2 \cdot 2\text{TIBPS}$,⁷ and a recent study concerning Au(III) extraction from hydrochloric acid media with Cyanex 471x showed that the species $\text{AuCl}_3 \cdot \text{TIBPS}$ and $\text{AuCl}_3 \cdot 2\text{TIBPS}$ are responsible for the gold extraction.¹⁸

In our study the effect of thiocyanate on the extraction of Pd(II) from chloride solutions has been shown to be related to the formation of mixed-ligand complexes $\text{PdCl}_{4-i}\text{SCN}_i^{2-}$ in the aqueous phase, which react more rapidly than the corresponding tetrachloro-complex PdCl_4^{2-} . As a result an increase in the rate of Pd(II) extraction is obtained (see Fig. 1). The trends observed at the different thiocyanate concentrations may be related to the similar trend in the relative concentrations of the species $\text{PdCl}_2(\text{SCN})_2^{2-}$ and $\text{PdCl}(\text{SCN})_3^{2-}$ under the corresponding experimental conditions.

Such behaviour has previously been explained as a catalytic process based on a *trans*-ligand effect.⁹ However, taking into account our findings that thiocyanate is present in the extracted metal species, the effect of the thiocyanate should now be considered as a particular case of synergism rather than catalysis, although a *trans*-effect of the thiocyanate in the mixed-ligand aqueous complexes may well be important in formation of the metal species finally extracted.

TRACE MEASUREMENTS OF RHODIUM BY ADSORPTIVE STRIPPING VOLTAMMETRY

JOSEPH WANG and ZIAD TAHA

Department of Chemistry, New Mexico State University, Las Cruces, NM 88003, U.S.A.

(Received 14 August 1990. Revised 12 September 1990. Accepted 21 September 1990)

Summary—A sensitive stripping voltammetric procedure for quantifying rhodium is described. The complex of rhodium with chloride ions is adsorbed on the hanging mercury drop electrode, and the reduction current of the accumulated complex is measured during a negative-going scan. Cyclic voltammetry is used to characterize the interfacial and redox behaviors. The effect of pH, chloride concentration, accumulation potential and other variables is discussed. The detection limit is $1 \times 10^{-8} M$ (~ 1 ng/ml) with 5-min accumulation. A linear current-concentration relationship is observed up to $7 \times 10^{-7} M$ and the relative standard deviation (at the $2 \times 10^{-7} M$ level) is 3.0%. Possible interferences by co-existing metals are investigated.

Because of the importance of rhodium, a sensitive method is required for its reliable measurement. In particular, the quantification of rhodium at trace levels is desired for geological surveys, catalytic applications and materials science. Spectroscopic procedures have been proposed for measuring low levels of rhodium, after solvent extraction,¹ liquid chromatography² or preferential complexation.³ Such schemes, however, are time-consuming and costly.

The present paper describes a sensitive stripping voltammetric procedure for trace measurement of rhodium. The polarographic behavior of rhodium has been explored by different groups.⁴⁻⁷ These studies elucidated the redox mechanism of rhodium in the presence of various complexing agents. The quantification of rhodium by coulometry⁶ or catalytic polarography⁷ has also been reported. However, the utility of stripping analysis (the most sensitive electrochemical technique⁸) for rhodium has not been reported. The combination of the voltammetric activity of rhodium chloro-complexes with their surface-active properties results in an effective adsorptive stripping procedure, the characteristics of which are described in this paper.

EXPERIMENTAL

Apparatus

A PAR Model 264 voltammetric analyzer was used with a PAR Model 303 static mercury drop electrode.

Reagents

All solutions were prepared with doubly distilled water. A 1000 mg/l. rhodium stock solution (atomic absorption standard; Aldrich) was diluted as required for standard additions. Potassium chloride solutions were prepared by dissolving the reagent in water and adjusting the pH with hydrochloric acid or sodium hydroxide solution.

Procedure

Potassium chloride solution (10 ml, pH 1.3) was pipetted into the polarographic cell and purged with nitrogen for 4 min. The preconcentration potential (-0.20 V) was applied to a fresh mercury drop while the solution was stirred. After the preconcentration, the stirring was stopped and 15 sec later the background voltamperogram obtained by applying a negative-going scan terminating at -0.60 V. A known volume of rhodium standard was then added and the adsorptive and stripping cycle was repeated with a new mercury drop.

RESULTS AND DISCUSSION

Repetitive cyclic voltamperograms for 50 ng/ml rhodium in 2.5M potassium chloride (pH 1.3) were used to evaluate the interfacial and redox behavior (Fig. 1). In the absence of prior accumulation only a small peak from the reduction of the rhodium chloro-complex was observed, at -0.52 V (Fig. 1, B). When the

experiment was repeated with a 120-sec stirring period (at -0.20 V) a large peak was observed at -0.52 V in the first negative-going scan. Subsequent scans gave a much smaller peak (of approximately constant height), indicating desorption of the product from the surface (Fig. 1, A). According to the work of Van Loon and Page,⁶ the complex adsorbed under these experimental conditions should be mainly RhCl_2^- .

Figure 2 shows that for a 20 ng/ml rhodium solution, the longer the preconcentration time, the more metal complex is adsorbed on the surface, and the larger is the peak current. For example, with 120-sec preconcentration (Fig. 2, e) there is a fivefold enhancement of the peak current relative to that obtained without preconcentration (Fig. 2, a). As a result, excellent signal-to-background characteristics are obtained which permit measurements at nanomolar concentration levels. Also shown in Fig. 2 (inset) are plots of peak current *vs.* preconcentration time at two levels of rhodium [(A) 20 and (B) 40 ng/ml]. In both cases the current increases linearly with time. The slopes are 9.6 nA/sec (A) and 26.2 nA/sec (B) (correlation coefficients, 0.999 and 0.996, respectively).

Fig. 1. Repetitive cyclic voltamperograms for 50 ng/ml rhodium, in 2.5M KCl (pH 1.3) solution, (A) with and (B) without 120-sec preconcentration (at -0.20 V), with 400 rpm stirring; scan-rate, 50 mV/sec.

Fig. 2. Differential pulse voltamperograms for 20 ng/ml rhodium after different preconcentration times: (a) 0, (b) 30, (c) 60, (d) 90, (e) 120 sec, and 400 rpm stirring. Inset are current *vs.* preconcentration time plots for (A) 20 ng/ml and (B) 40 ng/ml Rh. Conditions: 2.5M KCl (pH 1.3); accumulation at -0.20 V; scan-rate 10 mV/sec; pulse amplitude, 25 mV.

The stripping current depends strongly on the solution pH (Fig. 3A). Increasing the pH from 3 to 7 results in a sharp decrease in peak height. This could be explained by the affinity of Rh^{3+} for hydroxide ions at high pH.⁶ A similar pH-current profile was obtained for polarographic work. A sharp increase in the peak width was observed as the pH was increased from 4 to 7 (Fig. 3B). The effect of convection mass transport was also evaluated.

Fig. 3. Effect of pH on the adsorptive stripping current (A) and the peak half-width (B): 50 ng/ml Rh; preconcentration time, 60 sec; other conditions as for Fig. 2.

Accumulation of rhodium chloro-complexes from a stirred solution gave rise to a peak current 2.2 times as large as that obtained with the quiescent solutions.

The chloride ion concentration has a pronounced effect on the stripping current (Fig. 4A). The stripping peak for 50 ng/ml rhodium increases linearly with increasing potassium chloride concentration between 1 and 2.5M, and then decreases. As the chloride concentration increases, the mole fraction of RhCl_6^{3-} increases, giving rise to a higher signal. According to the work of Shlenskaya *et al.*,⁹ this increase is almost linear between 1.5 and 2.5M potassium chloride, in agreement with the signal trend shown in Fig. 4A. At low chloride concentration aquo-chloro mixed-ligand complexes are formed.^{4,6} The dependence of the stripping current on the preconcentration potential over the range from +0.10 to -0.40 V was examined (Fig. 4B). The response increased sharply between 0.00 and -0.20 V and then decreased at more negative potentials. The optimal conditions for rhodium measurements are there-

Fig. 4. Dependence of the adsorptive stripping current on (A) the KCl concentration and (B) the accumulation potential: 50 ng/ml Rh; other conditions as for Fig. 2.

Fig. 5. Stripping voltamperograms obtained for solutions of increasing rhodium concentration over the range 10–30 ng/ml (a–c). Preconcentration for 45 sec; other conditions as for Fig. 2. Inset are calibration plots for different accumulation times: (A) 45 and (B) 90 sec.

fore 2.5M potassium chloride as supporting electrolyte (pH 1.3) and a preconcentration potential of -0.20 V.

Figure 5 shows stripping voltamperograms obtained for 10–30 ng/ml rhodium solutions after a 45-sec preconcentration time. Calibration plots over a wider concentration range (10–60 ng/ml), obtained by using different preconcentration times, are also shown in Fig. 5 (inset). The response is linear over this range [slopes, (A) 24.7 and (B) 54.8 nA.ml.ng⁻¹, both with correlation coefficients of 0.997]. The detection limit was estimated to be 10nM (1 ng/ml) with a 5-min accumulation ($S/N = 3$). The precision was estimated from eight successive measurements of 50 ng/ml rhodium solution (90-sec preconcentration); the mean peak current was 1426 nA (range 1360–1470 nA and relative standard deviation 3.0%).

The following metal ions (20 ng/ml) were tested and found not to affect the 20 ng/ml rhodium peak: Ag(I), Ni(II), Zn(II), Co(II), Pd(II), Au(III), Ti(IV), Fe(II), Fe(III), Pb(II) and Cu(II). A decrease in the rhodium stripping peak was observed in the presence of Mn(II) and Sn(II). Hence, a separation step would be required in the presence of these metals. The effects of several anions were also examined. No interference was observed in the presence of 2mM nitrate or bromide. An additional peak was observed in the presence of 2mM iodide, at ca. 140 mV negative to the peak of interest, but did not affect the determination of rhodium.

In conclusion, the method described provides a simple approach for the determination of trace levels of rhodium. The interfacial accumulation results in a substantial enhancement of the voltammetric response, permitting convenient quantification at the ng/ml level. Depending on the sample matrix, a separation step may be required to isolate rhodium from interfering metals.

THE SYNTHESIS OF SOME LIPOPHILIC TETRA-ARYLBORATES FOR USE IN MEMBRANE ELECTRODE PREPARATION

AGNES YOO and CARL E. MOORE
Loyola University, Chicago, Illinois 60626

(Received 24 July 1990. Revised 19 October 1990. Accepted 3 November 1990)

Summary—Synthetic methods for preparing four lipophilic tetra-arylborates considered suitable candidates for use in membrane electrodes are described. Qualitative precipitation tests were performed with several cations. The sodium salts of the four tetra-arylborates were found to have limited stability but the cesium salts were relatively stable.

The tetrakis-*p*-chlorophenylborate anion, first reported in 1965,^{1,2} has found use in the fabrication of membrane electrodes^{3,4} suitable for sensing certain large cations. It seems likely that the activity of tetrakis-*p*-chlorophenylborate as the active agent in membrane electrodes is due in large part to the lipophilic character of the *p*-chlorophenyl moiety. Private communications with workers in the field of membrane electrodes have revealed an interest in, and a need for, additional tetra-arylborate ionophores suitable for the formulation of cation-sensing membranes.

We have attempted to meet this need by the synthesis of a number of tetra-aryl borates which have an unbranched aliphatic chain in the position *meta* to the carbon atom bonded to the boron atom. The study required the preparation of several new compounds as well as the resynthesis of a few compounds previously prepared in this laboratory. Our choice of the *meta*-position for the alkyl-substituent was predicated on our experience—and that of others⁵⁻⁹—with other tetra-arylborates that alkyl-substituents placed in the *para*-position relative to the carbon-boron bond yield compounds of lower stability than their *meta*-substituted analogs.

The following salts were prepared and supplied to other laboratories for membrane electrode studies.

1. Cesium tetrakis(*m*-methylphenyl)borate
2. Cesium tetrakis(*m*-ethylphenyl)borate
3. Cesium tetrakis(*m*-propylphenyl)borate
4. Cesium tetrakis(*m*-butylphenyl)borate

Synthesis of sodium tetrakis(m-alkylphenyl)borates

The *in situ* synthetic procedure of Vandenberg¹⁰ was used, which proceeds according to the equation:

As in all Grignard syntheses, the apparatus and reagents must be completely free from water. To achieve this, the *m*-alkylphenyl halide was dried over anhydrous CaSO₄ overnight, anhydrous diethyl ether was dried over sodium metal overnight, magnesium turnings were dried at 120°, and sodium tetrafluoroborate was dried at 120° overnight.

All apparatus was dried overnight at 120°. A 500-ml three-necked round-bottomed flask was fitted with a magnetic stirring bar, a reflux condenser, a 60-ml dropping funnel, and a glass tube and stopcock for introduction of nitrogen. The dropping funnel was stoppered, a drying tube attached to the condenser and the cooling water turned on. Nitrogen was passed through the flask and the flame of a Bunsen burner swept over the flask until there was no visible condensation of moisture in the condenser. An additional dropping funnel can be added (with a suitable adapter) for the addition of diethyl ether.

The following procedure is scaled for the use of 0.1 mole of alkylphenyl halide starting material.

Weigh 2.8 g of sodium tetrafluoroborate into the reaction flask. To expose a fresh metal

surface, grind 2.5 g of magnesium turnings with a dry mortar and pestle. Add the magnesium to the flask, then just sufficient anhydrous diethyl ether to cover the solid reagents. Dissolve 0.1 mole of the alkylphenyl halide in approximately 20 ml of anhydrous diethyl ether and introduce it into the dropping funnel. Add about 5 ml of the alkylphenylhalide solution to the reaction flask, from the dropping funnel. Stir the solution while gently warming it with a heating mantle. The appearance of turbidity signifies the beginning of the reaction. The reaction mixture bubbles vigorously, and turns yellow, green or brown. When the reaction has started, add sufficient anhydrous diethyl ether to the flask to bring the volume to approximately 200 ml. Let the remaining alkylphenyl halide solution drip into the flask. The Grignard reaction usually takes from 5 to 45 min to start. Addition of the alkylphenyl halide solution requires approximately an hour. The drop rate must be regulated throughout, to avoid an excessively vigorous reaction. If the reaction becomes too energetic, the flask should be immersed in an ice-water bath. After all the alkylphenylhalide has been added, stir for an additional 3 hr with sufficient heating to maintain a gentle reflux. During the reaction there will be a considerable loss of ether by evaporation.

Work-up of the product

The tetra-arylborates are easily decomposed by acids and by the free radicals produced by ether hydroperoxides. The use of basic solutions and peroxide-free ether in the work-up will minimize these problems.

Prepare 200 ml of ice-water and make it slightly basic with dilute sodium hydroxide solution. Pour the reaction mixture into the ice-water, with stirring. Add 0.5 g of anhydrous sodium carbonate and stir. Wash the reaction flask with peroxide-free diethyl ether and add the washings to the aqueous mixture. Separate the ether layer, which contains the crude sodium salt of the tetrakis (*m*-alkylphenyl)borate. Saturate the aqueous layer with sodium chloride and extract it with three 30-ml portions of peroxide-free ether.

Preparation of cesium tetrakis-alkylphenylborates

The reaction proceeds as follows:

Add the combined ether extracts of the

sodium salts dropwise to about 600 ml of 1% cesium chloride solution containing $10^{-4}M$ aluminum sulfate to promote coagulation of the precipitate. Heat the solution to about 40° and stir it vigorously during the addition. When the addition is complete, continue the stirring for 1 hr. Then chill the precipitate and supernatant liquid in an ice-water bath for 1 hr, filter and wash the product twice with chilled demineralized water.

Suspend the product in 100 ml of xylene and filter. Repeat this step, then air-dry the product. Dissolve it in 0.7–1.5 l. of redistilled acetone containing 5% v/v demineralized water. Warm the solution slightly (maximum 30°) and filter to remove foreign particles. Evaporate with a rotary evaporator in a 35–40° water-bath, to a volume of 100–200 ml. Chill the solution and filter. Dry the precipitate under vacuum for 12 hr.

RESULTS AND DISCUSSION

Study of properties of the sodium salts

Qualitative precipitation tests. One ml of 0.1M aqueous cation solution was mixed with 10–15 drops of the ether solution of the reagent (sodium salt). The cations tested were Li^+ , K^+ , Rb^+ , Cs^+ , Tl^+ , NH_4^+ , $(\text{CH}_3)_3\text{NH}^+$, $(\text{CH}_3)_4\text{N}^+$, Ba^{2+} , Sr^{2+} , Pb^{2+} , Cd^{2+} , Mn^{2+} , Zn^{2+} , Ni^{2+} and Ca^{2+} . The reactions of interest are summarized in Table 1.

Stability tests. A portion of the combined ether extracts from the work-up step was stored in a stoppered test-tube at 5–10°. A second portion was purged with nitrogen before similar storage in the refrigerator. A third portion in a stoppered test-tube was left at room temperature. Each was tested at intervals by qualitative precipitation with rubidium. Failure to produce a precipitate indicated that an appreciable amount of decomposition had occurred during storage.

The ether solution of the sodium salts was found to be stable for about two days. No significant differences in stability were observed between ether solutions kept under nitrogen and in air. Use of ether that had been redistilled in the presence of lithium aluminum hydride appeared to increase the stability of the reagent.

Because the pure sodium salts were not stable in solid form, attempts to obtain them were unsuccessful. The cesium salts are considerably more stable, however, and could be easily pre-

pared. Their infrared and NMR spectra were consistent with the structures expected for the compounds, and analysis for carbon, hydrogen and boron gave results in agreement with those expected (Table 2). The compounds were found to be soluble in dimethylsulfoxide (DMSO). Saturated solutions of the salts were prepared in acetone, acetonitrile, and water by warming for 30 min, in a warm water-bath, in glassware washed and rinsed with demineralized water, DMSO, and acetone. The resulting solutions were allowed to equilibrate for two days at room temperature. Measured volumes were taken, the solvent was evaporated, and the residue was dried at 120° and cooled in a desiccator. The molar solubilities were determined by dissolving the residue in a 90/10 v/v DMSO–water mixture and analysis for boron by DC-plasma emission spectrometry.¹¹ The results are given in Table 3.

The solubility of cesium tetraphenylborate in water was found to be more than an order of magnitude higher than the value previously reported.¹² An intriguing zig-zag pattern occurred in a plot of solubility *vs.* chain length of

the alkyl group. The solubilities were lower for the odd-numbered alkyl side-chain derivatives than for the even-numbered alkyl side-chain compounds. Within each group (odd or even number of carbon atoms) the compounds with longer alkyl chains were more soluble than those with shorter chains.

Three of the tetra-arylborates synthesized are new compounds, the *m*-methyl analog, prepared for comparative purposes, having been previously described. Increasing the length of aliphatic chains is known to enhance the lipophilicity of ionophores. The degree of lipophilicity of the reagent that is incorporated into the PVC matrix, in addition to whatever effects it may have on the selectivity and solubility, is of paramount importance in the preparation of ion-sensing membrane electrodes, because it controls the amount of reagent that leaches out of the membrane.

The sodium salts of the *m*-ethyl, *m*-*n*-propyl, *m*-*n*-butyl, and *m*-methyl compounds were found to be of limited stability in aqueous solution. In peroxide-free diethyl ether solution the period of stability increased to 2–3 days.

Table 2. Elemental analysis of the cesium tetrakis(*m*-alkylphenyl)borates

Alkyl	Found, %			Theory, %		
	C	H	B	C	H	B
None	63.5	4.48	2.44	63.76	4.46	2.39
Methyl	66.0	5.59	2.18	66.17	5.55	2.13
Ethyl	68.5	6.53	1.87	68.10	6.43	1.92
Propyl	70.1	7.25	1.79	69.69	7.15	1.74
Butyl	71.3	7.71	1.62	71.05	7.70	1.60

Table 3. Solubilities of cesium tetrakis(*m*-alkylphenyl)borates at room temperature

Alkyl	Acetone,	Acetonitrile,	Water,*
	10 ⁻² M	10 ⁻² M	10 ⁻⁴ M
None	2.7	1.5	4
Methyl	0.2	0.2	3
Ethyl	2.4	0.9	5
Propyl	1.3	0.6	2
Butyl	2.2	1.2	4

These sodium salts, because of their solubility in ether, can be incorporated into PVC membrane electrodes, where they may have sufficient stability in the PVC matrix to warrant further study.

Generally, the longer the alkyl chain, the greater the selectivity of the anion toward the larger cations. For example, tetrakis(*m*-*n*-butylphenyl)borate formed heavy precipitates only with cesium and rubidium. Cesium can be separated from rubidium by precipitation with tetrakis(*m*-*n*-butylphenyl)borate if the concentration of the reagent solution is suitably adjusted (*cf.* Table 1).

NUCLEATION IN PREMICELLAR AGGREGATION

CHRISTOPHER P. LORAN and RAY VON WANDRUSZKA*

Department of Chemistry, University of Idaho, Moscow, ID 83843, U.S.A.

(Received 13 August 1990. Revised 17 October 1990. Accepted 3 November 1990)

Summary—The role of a nucleating agent (cholesterol) in the premicellar aggregation of sodium lauryl sulfate (SLS), cetyltrimethylammonium bromide, Triton X-405 and Brij 35 has been investigated. The I_1/I_3 ratios of pyrene in the solutions indicate that SLS is strongly nucleated by cholesterol, but the other detergents appear to be so to a lesser extent. However, quenching studies show that premicellar Brij 35 also forms nucleated aggregates that protect the probe from the quencher. Energy transfer data with Triton X-405 suggest that such aggregates have a more open structure than self-assembling ones and are more accessible to water.

The formation of surfactant aggregates at concentrations below the critical micelle concentration (cmc) has been reported.¹⁻³ It can be deduced from fluorescence measurements involving probes associated with these aggregates. Specific methods suitable for these investigations include the assessment of polarity from spectral features, fluorescence quenching and energy transfer. In the present study all three are used to evaluate the role of nucleation of detergent by a relatively hydrophobic species (cholesterol) in the premicellar aggregation process.

Relative band intensities in the vibronic structure of the fluorescence emission spectrum of pyrene have previously been used to assess the polarity of the environment of the fluorophore in premicellar and micellar media.⁴⁻⁹ The ratio of the peak heights of the first and third emission bands (I_1/I_3) is a sensitive gauge of the nature of the immediate surroundings of the probe. The higher the ratio the greater is the polarity of the microenvironment and this in turn indicates the association of the probe with nonpolar entities in aqueous solution and hence the existence of such aggregates.

The fluorescence of polyaromatic hydrocarbons is quenched by some anionic species¹⁰⁻¹⁴ if the quenching species can come into direct physical contact with the fluorophore. The quenching mechanism may be collisional (dynamic quenching) or involve ground-state complex formation (static quenching). Either may be prevented by isolation of the fluorophore from the quenching species and this may be achieved by association of the fluorophore with detergent aggregates. Protection arising from hydrophobic interactions between probe and

detergent is especially effective against hydrophilic ionic quenchers such as bromide. This shielding effect leads to a notable increase in fluorescence intensity.¹⁵

Rothenberger *et al.* have shown that micellar systems allow for efficient energy transfer if the donor and acceptor species are sufficiently close to each other.¹⁶ The donor and acceptor may both be extraneous species that have penetrated the nonpolar micellar interior, or, as in this study, the donor may be the species forming the micelle. Kalyanasundaram and Thomas have studied the transfer of excitation energy from the phenyl groups of micellar Igepal C-630 to solubilized molecules of pyrene,¹⁷ and efficient energy transfer has been shown to occur between sodium phenylundecanoate micelles and naphthalene.¹⁸ Previous work in our laboratory has demonstrated micellar sensitization in the benzyltrimethylhexadecylammonium chloride (BDCH)/naphthacene, Triton X-405 (TX-405)/pyrene and TX-405/Brij 35 systems.¹⁹

EXPERIMENTAL

Pyrene (98% pure) (Sigma) was recrystallized twice from absolute ethanol and sublimed onto a cold finger. TX-405 (70% aqueous solution), sodium lauryl sulfate (98% pure), Brij 35 and cholesterol (Sigma) were used without further purification. Potassium bromide (analytical grade, J. T. Baker) was used as supplied. The water used in all solutions was distilled and treated with a 0.22- μ m Millipore filter system to give 18 M Ω .cm resistivity.

An aqueous stock solution of pyrene was prepared by adding a 4- μ l aliquot of a

5.1-mg/ml ethanolic solution to a dry 1000-ml standard flask. The solvent was then evaporated and about 800 ml of water was added. After sonication for 4 hr the flask was filled to the mark to make a $1.0 \times 10^{-7} M$ pyrene solution. Stock solutions with the surfactants [SLS, Brij 35, CTAB (cetyltrimethylammonium bromide) and TX-405] were prepared from the pyrene solution in a similar manner, with surfactant concentrations ranging from 1.00×10^{-7} to $0.01 M$. Cholesterol solutions were all saturated ($5.16 \times 10^{-6} M$). Fluorescence spectra were recorded with a Perkin-Elmer MPF 66 spectrofluorimeter equipped with a temperature-controlled sample compartment. This instrument gives corrected excitation and emission spectra through the use of a built-in Rhodamine 101 quantum counter. Excitation and emission slit-widths were set for 5 and 2 nm bandpass, respectively, and all measurements were corrected for a blank. The fluorescence intensity values reported are the averages of triplicate measurements. Unless otherwise stated, readings were taken at 24° .

RESULTS AND DISCUSSION

Polarity effects

When small amounts of cholesterol are added to SLS solutions containing pyrene, the conductivity and surface tension values measured are not affected. These techniques lack the sensitivity necessary to record relatively subtle alterations in the solution environment. The I_1/I_3 ratio of the pyrene emission spectrum can be effectively used to monitor the polarity of the immediate environment of the fluorophore.¹⁹ A direct relationship exists between the ratio and the polarity. In Fig. 1, for the solution free from cholesterol the critical micelle concentration

Fig. 1. Variation of I_1/I_3 ratio of pyrene emission with SLS concentration with (Δ) and without (+) cholesterol ($5.16 \times 10^{-6} M$) present.

Fig. 2. Variation of I_1/I_3 ratio of pyrene emission with CTAB concentration with (---) and without (—) cholesterol present.

(cmc) is reached at about $10^{-3} M$ SLS, the concentration at which the I_1/I_3 ratio begins to decrease sharply. In the presence of cholesterol, a lower ratio persists at SLS concentrations up to about $5 \times 10^{-3} M$, indicating that the microenvironment of pyrene is considerably less polar in this case. This effect is not observed when cholesterol and pyrene are together in a solution without surfactant, suggesting that SLS associates with dissolved cholesterol even at very low detergent concentrations, and that pyrene exists in a relatively nonpolar environment within these aggregates.

A similar study with CTAB gave very different results. Figure 2 shows the variation of the I_1/I_3 ratio with CTAB concentration. Cholesterol had a negligible effect on the measured values. A similar lack of preaggregation was observed when Brij 35 was used as the detergent.

Aggregates of SLS that have formed around a nucleus of cholesterol are notably more sensitive to temperature than those of pure SLS (Fig. 3). In the presence of cholesterol the I_1/I_3 ratio of pyrene is consistently greater at the higher temperature, indicating that the cholesterol/SLS aggregate is thermally disturbed in the warmer solution. The values of the ratio at different temperatures are relatively close together at the extremities of the graph: at very low SLS concentrations the extent of aggregation is small, and so temperature change has less effect; at high SLS concentrations micelles are formed which have less thermal lability than the premicellar aggregates. The temperature effects are minimal in the absence of cholesterol.

Bromide quenching

Micellar aggregates afford protection from fluorescence quenching by species such as

Fig. 3. Variation of I_1/I_3 ratio of pyrene emission with SLS concentration at different temperatures: (---) 22.2°; (—) 58.0°. (A) Without cholesterol; (B) with $5.16 \times 10^{-5} M$ cholesterol present.

bromide ions, by providing the probe with a hydrophobic environment that is inaccessible to the hydrophilic quencher. The assessment of fluorescence quenching can expose surfactant aggregation behavior that may not be evident from the I_1/I_3 ratio measurements.

The successive addition of $2\text{-}\mu\text{l}$ increments of $0.01 M$ potassium bromide to $10^{-7} M$ pyrene solution with and without $5.16 \times 10^{-5} M$ cholesterol present gives a steady decrease in the ratio of quenched to unquenched intensity (I_q/I_0), as shown in Fig. 4, A. The effect of cholesterol is small when no detergent is present and in the presence of CTAB and SLS. However, for Brij 35 a consistently higher I_q/I_0 ratio is observed in the presence of cholesterol, Fig. 4, B–D.

The data indicate various degrees of protection of the fluorophore by premicellar detergents in the presence of cholesterol. Though cholesterol enhances protection in all cases, the effect is minor with the cationic surfactant CTAB present. This may be partially due to the attraction of a "halo" of bromide by this detergent, as reported before from this laboratory.³ However, the observation that the I_1/I_3 ratio is not affected by CTAB suggests that the detergent does not form extensive premicellar

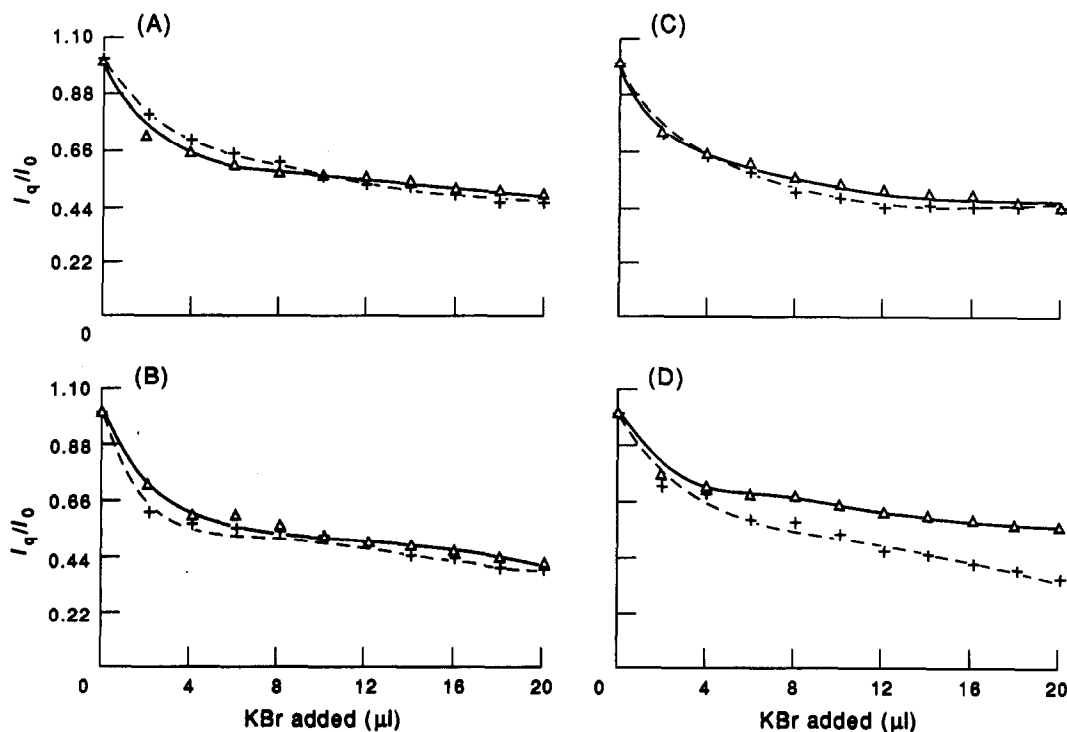

Fig. 4. Variation of the ratio of quenched to unquenched fluorescence intensity (I_q/I_0) in detergent solutions with added ($0.01 M$) KBr with (—) and without (---) cholesterol present. (A) No detergent; (B) $1 \times 10^{-3} M$ CTAB; (C) $1 \times 10^{-4} M$ SLS; (D) $5 \times 10^{-6} M$ Brij 35.

aggregates with dissolved cholesterol as nucleus. In the case of SLS it can be concluded from both the I_1/I_3 ratio data and the quenching measurements that such nucleation takes place to a significant extent. Brij 35 presents an interesting case since the I_1/I_3 ratio measurements suggest no nucleated premicellar aggregation, but the quenching measurements indicate strong protection. This apparent dichotomy may be ascribed to the nature of the Brij molecule. It consists of two relatively long linked chains: one is a hydrocarbon (the "dry" portion), and the other a polyoxyethylene ether (the "wet" portion). It has been reported that the latter is distended with water even in Brij micelles.¹⁹ A loose premicellar association between Brij 35 and dissolved cholesterol can provide a protective environment for pyrene with regard to bromide, especially for dynamic (collisional) quenching. If the probe is close to the polar portion of the detergent moiety, its I_1/I_3 ratio may not be significantly lowered.

Energy transfer

Energy transfer from TX-405 to pyrene has been shown to occur in micellar solutions of the detergent.¹⁹ The phenyl group of TX-405 is excited at 292 nm, and the characteristic pyrene emission at 373 nm is monitored. Most of the observed emission is due to energy transfer, and only a small fraction is caused by direct excitation (and this can be effectively eliminated by spectral subtraction of the emission from pyrene excited at 292 nm).

The I_1/I_3 ratio can again be used to monitor the polarity of the microenvironments of the sensitized fluorophore. In this case emission is observed only from pyrene molecules that are located sufficiently close to the aromatic center of TX-405 to allow for energy transfer. Fluorescence was observed from sensitized pyrene in premicellar solutions of both TX-405 alone and TX-405 with cholesterol. Figure 5 shows that the I_1/I_3 ratio in the latter case was higher up to a detergent concentration of about $2.9 \times 10^{-4} M$, at which the ratios became the same as those corresponding to the cmc.

To interpret these results it should first be noted that excitation energy transfer takes place in premicellar TX-405, as reported in an earlier communication from this laboratory.¹ The presence of cholesterol appears to create a more polar environment for pyrene associated with these aggregates. It may be postulated that this is due to the size of the nucleated aggregates and

Fig. 5. Variation of I_1/I_3 ratio of sensitized pyrene with TX-405 concentration, with (—) and without (---) cholesterol present.

their accessibility to water compared to the self-assembling ones. In order to make sensitization feasible, the pyrene must be located in a similar position relative to the detergent phenyl group, in both types of aggregates. This rules out greater proximity of the polyoxyethylene ether portion of the TX-405 agglomerate as the cause of the higher I_1/I_3 ratio. Detergent aggregation around a cholesterol molecule as nucleus may, however, form a larger, more open structure, with a greater amount of associated water. Thus the pyrene experiences a more polar environment, as reflected in an increase in the I_1/I_3 ratio. When the cmc is reached, the aggregate contracts while forming the micelle, squeezing out the water and reducing the polarity around the pyrene probe. The I_1/I_3 ratios in the two types of aggregate therefore become the same at the cmc, as shown by the convergence of the plots in Fig. 5.

CONCLUSIONS

While it may be expected that detergents attach themselves to hydrophobic species in aqueous solution in the process of solubilizing them, the fluorescence data presented here indicate that this type of nucleated premicellization occurs to varying degrees. In some cases it provides a hydrophobic environment for the probe at very low detergent concentrations. However, the nucleated aggregates have a relatively open structure, probably with detergent chains somewhat separated around a central cholesterol core, with water penetrating between them. The formation of premicellar aggregates appears to be generally promoted by the presence of a nucleating species.

PRECONCENTRATION OF NICKEL AND COBALT ON ALGAE AND DETERMINATION BY SLURRY GRAPHITE-FURNACE ATOMIC-ABSORPTION SPECTROMETRY

MO SHENGJUN* and JAMES A. HOLCOMBE†

Department of Chemistry and Biochemistry, The University of Texas at Austin, Austin, TX 78712, U.S.A.

(Received 28 August 1990. Revised 20 November 1990. Accepted 10 December 1990)

Summary—Unicellular green algae have been utilized to preconcentrate Ni²⁺ and Co²⁺ ions from sea-water and riverine water samples. Studies have shown that rinsing the algae with 0.12M hydrochloric acid improves the adsorption of nickel and cobalt, and the optimum range of pH of extraction is wide. The maximum extraction efficiencies were 84 and 73% for Ni and Co, respectively, at ng/ml levels. The sea-water matrix and relatively small amounts of many impurities reduce the adsorption efficiency for both nickel and cobalt. The preconcentration is achieved by mixing 6 mg of algae with 50–100 ml of sample, and subsequently isolating the algae by centrifugation. The pellet of algae is then resuspended in 1 ml of 0.08M nitric acid, and analyzed as a slurry by graphite-furnace atomic-absorption spectrometry. The values found for nickel and cobalt in riverine (SLRS-1) and sea-water (CASS-1) standard reference materials are within the limits of certification.

Graphite-furnace atomic-absorption spectrometry (GFAAS) is in routine use for the determination of ultratrace amounts of nickel and cobalt. However, considerable difficulty can be encountered in the direct determination of nickel and cobalt in complex samples owing to matrix interferences, and because the concentrations are at or below the limits of detection. Chelation and solvent extraction or immobilized-ligand separation combined with GFAAS have been used to determine nickel and cobalt in such samples, but poor selectivity and time-consuming procedures are inherent in many of these approaches.

Biological organisms have the potential ability to adsorb selectively specific elements without preconcentrating the matrix.^{1–6} Unicellular green algae have been used successfully to separate and preconcentrate copper from a sea-water sample,⁶ but no reports consider the preconcentration of nickel and cobalt by algae. Mahan *et al.*¹ have studied the ability of three unicellular algae strains to adsorb thirteen elements, including nickel and cobalt. The possibility of preconcentrating nickel and cobalt from dilute

solutions was indicated. However, the concentrations in this study were in the µg/ml range and no attempt was made to preconcentrate the metals from complex samples.¹ In the present work, the conditions for preconcentration of nickel and cobalt by the algae have been studied and the method has been applied to the analysis of riverine and sea-water samples. The results show that when the algae are not washed with 0.12M hydrochloric acid, the recovery is critically dependent on the pH of the solutions, especially for cobalt extraction. However, if the algae are washed initially in 0.12M hydrochloric acid, adsorption of nickel and cobalt by the algae is nearly constant between pH 6 and pH 9, with extraction efficiencies for Ni and Co of 84 and 73%, respectively. When the concentration of the metal ion is between 1 and 16 ng/ml, the uptake efficiency on the algae is independent of the concentration of metal. The sea-water matrix and relatively small amounts of many impurities reduce the adsorption efficiency. Therefore, for complex samples it was necessary either to prepare a calibration curve after determining the extraction efficiencies from matrix-matched standards, or to use standard-addition methods with the unknown samples.

Although there have been several studies of metal uptake by algae, little is known regarding the binding mechanism. Christ *et al.*⁷ have

*On leave from the Department of Chemistry, South China Normal University, Guangzhou, People's Republic of China.

†Author for correspondence.

considered the functional groups that may be available for ion-exchange or metal binding. These included amine and carboxyl groups from both amino-acids and polysaccharides, although no experimental verification was made. Majidi and co-workers⁸ have presented direct evidence of binding of Cd^{2+} by using ^{113}Cd NMR as a probe, and concluded that the site for cadmium binding was probably a carboxyl group. Mahan and co-workers^{1,9} have shown through Langmuir plots that multiple binding sites probably exist. Similar non-Langmuirian adsorption isotherms can be inferred from similar studies by other researchers.

In short, there have been few studies that elucidate the binding mechanism or the chemical nature of the exterior cell wall. Certainly, a polysaccharide structure is known to exist, but there are also several protein groups. Of course, it is not known which of these might be present on the surface under the conditions in which the algae are grown.

EXPERIMENTAL

Preparation of algae

The algae used in this study were a form of unicellular green *Chlorella*. Preparation and cultivation of the algae have been described previously.⁶ Before use, 6 mg of algae were added to 10 ml of 0.12M hydrochloric acid (Mallinckrodt, analytical reagent grade), then the mixture was agitated, centrifuged, and the supernatant decanted and discarded. The pellet of algae was then washed with 5 ml of demineralized water and centrifuged again. After discard of the rinse solution, the algae were ready for use.

Apparatus

All experiments utilized an AA-875 spectrophotometer equipped with a GTA-95 graphite-furnace atomizer (Varian Techtron). The operational conditions and temperature programs for the determination of nickel and cobalt are listed in Table 1. The analytical wavelengths

used for nickel and cobalt were 232.0 and 240.7 nm, respectively. The spectral bandpass of the monochromator was 0.2 nm. All studies were performed with deuterium-lamp background correction and wall atomization, with a 10- μl aliquot of the slurry suspension or supernatant. All data were recorded as peak areas. The algae did not represent a complex matrix, even though the original solution composition might have contained a high concentration of dissolved salts. As a result, simple wall atomization was adequate for matrix-free analysis and no platform was employed.

Procedure

The sample was prepared by adding 6 mg of algae to 10 ml of a solution containing nickel or cobalt. The pH of each solution was adjusted to between 6 and 8 by dropwise addition of hydrochloric acid or sodium hydroxide solution. The mixture was agitated for 20 min and centrifuged. The supernatant was decanted and the pellet of algae was resuspended in 2 ml of 0.08M nitric acid. This slurry was then transferred to an autosampler sampling vial for analysis. Three replicates were run for each experiment, and a distilled water blank was run through the extraction and analysis for all experiments. When a significant blank value was detected, it was subtracted from the corresponding sample signal. Typical blank values are shown later in the paper.

After the algae had been washed with hydrochloric acid, the procedure required about 40 min for the preconcentration of six samples. All reported extraction efficiencies are based on concentrations derived from calibration graphs prepared for simple aqueous cobalt and nickel standards in 0.08M nitric acid.

RESULTS AND DISCUSSION

Dependence of adsorption on pH

Nickel and cobalt were present as trace minerals in the growth medium and might be

Table 1. Furnace operating conditions

Fig. 1. The effect of pH on adsorption of cobalt by algae. Before use, the algae were either washed in $0.12M$ hydrochloric acid (curves a, b) or not washed (c, d). Both $\text{Co(NO}_3)_2$ (b, d) and CoCl_2 (a, c) were tested in the analytical solution. The cobalt concentration was 5 ng/ml for all starting solutions, and all final suspensions were $0.08M$ in nitric acid.

contained within the intercellular material or adsorbed on the cell wall. In an attempt to minimize the blank, the algae were washed in dilute acid ($0.12M$ hydrochloric acid). In previous studies with copper, a difference in the metal uptake efficiency had been found to occur as a result of an acid wash.⁶ Figures 1 and 2 show similar effects for nickel and cobalt and also display the uptake efficiencies as a function of solution pH.

The mechanism of removal of metal by the acid wash could be as simple as a displacement process at ion-exchange sites on the surface, or as complicated as a partial denaturation of complex proteins that bind with these metals.

In the two figures, curves a and b denote the algae that were washed with $0.12M$ hydrochloric acid; curves c and d represent the algae that were not washed. Both NiCl_2 and CoCl_2 (curves a and c) and $\text{Ni(NO}_3)_2$ and $\text{Co(NO}_3)_2$ (curves b and d) were tested in the analytical solutions. The pH was adjusted by dropwise addition of sodium hydroxide or acid. When acid was added, either hydrochloric or nitric acid was used, depending on the anion of the analyte salt being studied. Nickel and cobalt concentrations were 10 and 5 ng/ml , respectively, for these test solutions. The final biomass pellet was suspended in $2.0 \pm 0.1 \text{ ml}$ of $0.08M$ nitric acid.

Figures 1 and 2 clearly demonstrate the importance of the preliminary wash with hydro-

Fig. 2. The effect of pH on adsorption of nickel by algae. Before use, algae were either washed in $0.12M$ hydrochloric acid (curves a, b) or not washed (c, d). Both $\text{Ni(NO}_3)_2$ (b, d) and CoCl_2 (a, c) were tested in the analytical solution. The nickel concentration was 10 ng/ml for all starting solutions, and all final suspensions were $0.08M$ in nitric acid.

‡Composite matrix.

chloric acid. When the algae were not washed with acid, the efficiency of adsorption showed a stronger dependence on pH. Figure 1 shows that adsorption of cobalt by the unwashed algae increases gradually up to pH 7, then decreases gradually. However, nickel adsorption by the unwashed algae increases continuously with pH (Fig. 2, curves c and d). After the acid wash, the efficiency of adsorption is relatively constant between pH 6 and 9.

The data also show that the acid wash especially improves the efficiency of adsorption when the chlorides of the analytes are present. The maximum extraction efficiencies are 84.0% for NiCl₂, 66.4% for Ni(NO₃)₂, 73.0% for CoCl₂, and 64.8% for Co(NO₃)₂, in contrast to 65.6%, 60.8% and 46.5%, 41.6%, respectively, for samples without acid washing. These results are similar to those reported previously for Cu.⁶

Effect of sea-water matrix

The data in Tables 2 and 3 show that adsorption of nickel and cobalt, in contrast to that of lead and copper,^{6,10} is more sensitive to the presence of concomitants in the solution. However, the adsorption appears to be less affected by the common alkali-metal and alkaline-earth metal salts than indicated by previous reports for zinc and cadmium.^{2,10} Zinc adsorption was shown to be negligible in the presence of 0.2M

sodium chloride or magnesium nitrate in the solution,¹⁰ and cadmium adsorption was dramatically decreased by the sea-water matrix so that the attempted preconcentration of cadmium from sea-water was not successful.² Table 2 shows that even with a 2×10^6 -fold ratio of sodium chloride present, a 59% recovery of nickel was still obtained. A 4×10^6 -fold ratio of the same salt yielded a 56% recovery for cobalt, which is 23% less than that obtained in the absence of a matrix. Though it is thought that this might be due to competitive binding of matrix cations at the algae sites, the data do not preclude possible influence by complexation with the matrix anion, e.g., Cl⁻ or NO₃⁻. It is also interesting that the interference from mixed matrices was not significantly more than that observed when a single matrix salt was used, which confirms that the interference is not a simple cumulative effect.

The interference by the sea-water matrix on nickel adsorption was generally less than that for cobalt. For example, when the concentration of potassium chloride was 1 and 0.5 mg/ml, the relative decrease in the nickel adsorption was 2 and 14% whereas the corresponding decrease for cobalt was 30 and 21%. Concentrations of sodium chloride less than 1 mg/ml gave no effect on nickel adsorption by the algae, but the effect on cobalt adsorption was obvious.

†Composite matrix.

The effect of combinations of agents

The effects of two organic ligands and one ionic surfactant on nickel and cobalt adsorption were considered. The adsorption was inhibited entirely by the presence of either 0.2% sodium citrate or 0.1% ethylenediaminetetra-acetic acid (EDTA). Dodecyl sodium sulfate (0.01%) decreased the nickel and cobalt adsorption by 38 and 30%, respectively, relative to that observed for simple aqueous solutions; this behavior is unlike the results obtained previously for copper, where little effect was observed.⁶ The stability of the analyte complex may play an important role in some instances, since the EDTA complexes are very stable: Ni-EDTA ($K_f = 4.16 \times 10^{18}$), Co-EDTA ($K_f = 2.04 \times 10^{16}$). The citrates are less stable, with typical K_f values of ca. 10^5 .

The effects of impurities

Several elements which may be capable of displacing nickel or cobalt (by competitive binding at the algae adsorption sites) were also considered. They are Pb²⁺, Cu²⁺, Cd²⁺, Mn²⁺ and V³⁺. The results shown in Tables 4 and 5 indicate that the effects on the adsorption are variable and complicated. For example, adsorption of Pb²⁺ by algae was shown previously to be stronger than adsorption of V³⁺,¹ but the impact of Pb²⁺ on Ni²⁺ and Co²⁺ adsorption is less than that of V³⁺. From previous studies, the

strength of Cu²⁺ and Mn²⁺ adsorption by the algae should be between that for Pb²⁺ and V³⁺, but the effect of 1000 ng/ml Cu²⁺ and Mn²⁺ on nickel and cobalt adsorption is larger than that of the other elements tested.

Explanation of the observed effects of these sets of elements at different concentrations is complicated. The situation for each element appears to be different. For example, the effect of 100 ng/ml manganese appears to be negligible, but a lower concentration of Mn (10 ng/ml) measurably reduces both nickel and cobalt adsorption. The reason for differences in the effects of 10–1000 ng/ml cadmium on cobalt adsorption is not obvious. The situation is even more complicated, because of the presence of other trace elements in the sample solution. With the exception of Pb²⁺ as a concomitant, the general effect of added metal salts was similar for both nickel and cobalt.

Concentration by uptake of nickel and cobalt

A series of nickel and cobalt solutions (1–16 ng/ml) was prepared, and a 10-ml aliquot of each was used to prepare 1 ml of preconcentrated slurry. The concentrations of nickel and cobalt in these concentrates were then determined from a working curve prepared from aqueous standards. In these experiments the extraction efficiencies for nickel and cobalt were $84 \pm 5\%$ and $73 \pm 5\%$, respectively. There

Table 6. The effect of sample volume on adsorption of nickel and cobalt by algae

Element	Initial sample volume, ml	Final slurry volume, ml	Concentration factor	Recovery, %	Average, %
Ni	10	2	5	84.0	82.8
	50	1	50	78.7	
	100	1	100	85.6	
Co	10	2	5	73.0	72.3
	50	1	50	70.4	
	100	1	100	73.4	

does not appear to be any consistent trend with changing concentration; the variations probably reflect uncertainty in the method. The results show that adsorption of nickel and cobalt on the algae does not depend on their initial solution concentrations.

Preconcentration factor and sampling volume

One of the potential advantages of extracting nickel and cobalt from sample solutions is the improvement of analytical sensitivity as well as reduction of interference by the original sample matrix. Although the magnitude of the preconcentration is independent of the nickel and cobalt concentrations in the original sample, it remains to be determined whether some variation in extraction efficiency is caused by the preconcentration factor, *i.e.*, the ratio of initial to final volume.

To evaluate the effect of sample volume on extraction efficiency, 6 mg of algae were added to 20, 50 and 100 ml of solution containing a total of 160 ng of nickel and 80 ng of cobalt. The solutions were preconcentrated to a final volume of either 1.0 or 2.0 ml. The extraction efficiency results given in Table 7 represent a range of preconcentration factors from 5 to 100. The results show that with different sample volumes and different preconcentration factors, the recoveries of nickel and cobalt remain nearly constant, with no obvious dependence on the initial sample volume.

Riverine and sea-water analysis

To study the capability of these algae for

†Standard-addition method necessary.

preconcentrating nickel and cobalt in environmental samples, two standard reference solutions were preconcentrated and analyzed: near-shore sea-water (CASS-1) and riverine water (SLRS-1) (National Research Council of Canada). The algae were acid-washed in batches by the procedure described previously. Before preconcentration, the samples were neutralized by dropwise addition of sodium hydroxide solution to raise the pH to 7 ± 1 . The sample volumes were 100 ml for CASS-1 and 50 ml for SLRS-1, so the preconcentration factors were 100 and 50, respectively, with a final solution volume of 1.0 ml. A blank solution was carried through the same procedure and the signal obtained was subtracted from the corresponding sample signal. Typical metal concentrations in the algae suspensions and a 100-ml blank solution were 3.7 ± 0.2 ng/ml nickel and 3.3 ± 0.5 ng/ml cobalt. The source of the metal is not the algae but most likely impurities in the sodium hydroxide.

The calibration graph method was used to analyze the sea-water sample. The method of standard additions was used for analysis of SLRS-1 to compensate for sample-dependent variations in extraction efficiency rather than to correct for interferences in the GFAA analysis. The concentrations in the riverine water were obtained from the value found by the standard addition method, by dividing it by the preconcentration factor. Table 7 shows the results obtained for the SLRS-1 riverine water, and these were in good agreement with the certified values. The concentrations found for nickel and cobalt in SLRS-1 were both low if a simple calibration curve prepared from aqueous standards was used, and a previously determined extraction efficiency was assumed.

In sea-water the main matrix components are sodium, potassium, magnesium and calcium chlorides. The uptake efficiency (75 and 62% for nickel and cobalt) in the presence of the synthetic sea-water matrix was used, in conjunction with a calibration graph prepared with aqueous

standards. This approach is simpler, faster and conserves sample. The concentration read from the calibration graph was divided by the preconcentration factor and the extraction efficiency to yield the results listed in Table 7, which are within the limits of the certified values. The standard-addition method was also tried for the sea-water sample, but only one sample was used owing to a shortage of the reference material. The results were 0.26 ng/ml for nickel and 0.022 mg/ml for cobalt.

CONCLUSION

This study has demonstrated that unicellular green *Chlorella* algae can be used to separate and preconcentrate nickel and cobalt from sea-water and riverine water samples. The extraction efficiencies for nickel and cobalt from aqueous solutions are 84 and 73%, respectively, and appear relatively insensitive to solution pH in the range 6–9 (if the algae have been washed with 0.12M hydrochloric acid) and to the ratio of solution volume to mass of algae, at least in the range 0.8–16 ml per mg. However,

the extraction efficiency appears sensitive to the presence of high concentrations of the alkali and alkaline-earth metal salts, and to low concentrations of many accompanying impurities.

INDIRECT SPECTROPHOTOMETRIC DETERMINATION OF TRACE CYANIDE WITH CATIONIC PORPHYRINS

HAJIME ISHII* and KATSUNORI KOHATA

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira, Aoba-ku, Sendai, 980 Japan

(Received 13 July 1990. Revised 25 October 1990. Accepted 20 November 1990)

Summary—Three highly sensitive methods for the determination of cyanide have been developed, based on the fact that the complexation of silver ions with three cationic porphyrins, 5,10,15,20-tetrakis(1-methyl-2-pyridinio)porphine [T(2-MPy)P], 5,10,15,20-tetrakis(1-methyl-3-pyridinio)porphine [T(3-MPy)P] and 5,10,15,20-tetrakis(1-methyl-4-pyridinio)porphine [T(4-MPy)P], in alkaline media is inhibited by cyanide and the decrease in absorbance of the silver(II) complex is proportional to the cyanide concentration. Sensitivities of the procedures developed are 0.133, 0.126 and 0.234 ng/cm², respectively for an absorbance of 0.001. Cadmium(II), copper(II), mercury(II), zinc(II), iodide and sulfide interfere with the cyanide determination. One of the proposed methods was applied to the determination of cyanide in waste-water samples, with satisfactory results.

It has been reported¹ that three cationic porphyrins, 5,10,15,20-tetrakis(1-methyl-2-pyridinio)porphine [T(2-MPy)P], 5,10,15,20-tetrakis(1-methyl-3-pyridinio)porphine [T(3-MPy)P] and 5,10,15,20-tetrakis(1-methyl-4-pyridinio)porphine [T(4-MPy)P], react rapidly with silver(I) at pH 9.6–12.0 to form yellow complexes which are oxidized by dissolved oxygen to the corresponding stable red silver(II) complexes within several minutes at room temperature. These complexation reactions are applicable to the spectrophotometric determination of trace amounts of silver. It was also reported that the reactions are strongly inhibited by cyanide, the decrease in absorbance of the silver(II) complexes being directly related to the cyanide concentration, which suggests the possibility of the indirect spectrophotometric determination of micro-amounts of cyanide.

In the present work, the fundamental conditions for the determination of cyanide in this way have been investigated and three highly sensitive methods for cyanide determination have been developed.

EXPERIMENTAL

Reagents

All reagents used were of analytical-reagent grade unless stated otherwise. All solutions were prepared with distilled, demineralized water.

T(2-MPy)P, *T(3-MPy)P* and *T(4-MPy)P* solutions, 1.6×10^{-4} M. Prepared by dissolving the required weight of porphyrin tosylate in water. The tosylates were synthesized and purified by a method described in the literature.^{2,3}

Standard cyanide solution, 0.5 mg/ml. Potassium cyanide (0.125 g) was dissolved in 100 ml of water and the solution was stored in a polyethylene bottle. This solution was unstable, and was therefore prepared every second day and standardized titrimetrically with silver nitrate.⁴ Working solutions were prepared just before use, by diluting this solution with water.

Standard silver(I) solution, 1.0×10^{-2} M. Prepared by dissolving 170 mg of silver nitrate (dried at 110°) in 50 ml of 0.1M nitric acid and diluting to 100 ml with water. Working solutions were prepared by dilution of this solution with water and addition of enough aqueous ammonia solution to give an ammonia concentration of 0.5M. The solutions thus obtained were stable for more than one month, when stored in amber bottles.

Lead(II) solution, 5×10^{-4} M. Prepared by dissolving 0.17 g of lead nitrate in 1 litre of water and adding sufficient nitric acid to give a pH of about 2.

Procedures

Procedure A, with T(3-MPy)P. To a known volume of sample containing up to 3.2 µg (0.12 µmole) of cyanide ion, in a 25-ml standard flask, add 1 ml of 1.9×10^{-4} M silver(I) solution

*Author for correspondence.

with ammonia concentration adjusted to 0.5*M*, a sufficient amount of 0.1*M* sodium hydroxide or 0.1*M* nitric acid to adjust the pH to about 12, and 2 ml of 1.6×10^{-4} *M* T(3-MPy)P solution. After allowing to stand for about 10 min, add 1 ml of 5×10^{-4} *M* lead(II) and 3 ml of 2*M* sodium nitrate, and dilute to the mark with water. Measure the difference in absorbance (ΔA) at 427 nm (10-mm path-length cells) between the resultant colored solution and a reagent blank solution similarly prepared.

Procedure B, with T(2-MPy)P. Prepare the colored solution as in procedure A, but adjusting the pH to about 10.6 and using 2 ml of 1.6×10^{-4} *M* T(2-MPy)P solution instead of T(3-MPy)P solution. Measure ΔA at 423.5 nm.

Procedure C, with T(4-MPy)P. Take an aliquot containing up to 5.8 μg (2.2×10^{-7} mole), of cyanide ion and prepare the colored solution as in procedure A, but adjust the pH to about 11.4 and use 2 ml of 1.6×10^{-4} *M* T(4-MPy)P solution instead of T(3-MPy)P solution. Measure ΔA at 431 nm.

RESULTS AND DISCUSSION

Absorption spectra

The complexation of silver ions with porphyrins in alkaline media is suppressed by cyanide, the decrease in absorbance of silver(II)–porphyrin complexes being proportional to the cyanide concentration. As has been reported,¹ whichever porphyrin is used, the Soret band of the silver(II)–porphyrin complex considerably overlaps that of the porphyrin itself in alkaline media, whereas the Soret band of the lead(II)–porphyrin complex is well separated from that of the porphyrin and its silver(II) complex. Hence, the absorbance of the silver(II) complex should be measured after any free porphyrin has been converted into its lead(II) complex.

Figure 1 shows the spectral change in the Soret region of the T(3-MPy)P–silver(II)–cyanide–lead(II) system when the cyanide concentration is increased. The absorbance of the silver(II)–T(3-MPy)P complex at 427 nm decreases and that of the lead(II)–T(3-MPy)P complex at 471 nm increases. The reason is that with increasing cyanide concentration, the amount of the silver(II)–T(3-MPy)P complex formed decreases, so that the amount of T(3-MPy)P available to form the complex with lead(II) increases. It can also be seen that the difference between the absorbances of a solution

Fig. 1. Spectral change of the T(3-MPy)P–silver(II)–cyanide–lead(II) system with increasing cyanide concentration. T(3-MPy)P, 6.4×10^{-6} *M*; Ag(I), 3.0×10^{-6} *M*; Pb(II), 9.3×10^{-6} *M*; NaNO₃, 0.24*M*; pH, 12.0; reference, water. CN⁻/Ag(I)—A, 0.00; B, 0.56; C, 1.12; D, 1.68; E, 2.41; F, 3.35; G, 4.50; H, 6.50.

containing cyanide and of those containing no cyanide (and hence the sensitivity is higher) is larger at 427 nm than at 471 nm. Similar spectral changes were observed when T(2-MPy)P and T(4-MPy)P were used instead of T(3-MPy)P.

The effect of pH on the cyanide determination is shown in Fig. 2. The optimum pH and wavelength for absorbance measurements in each procedure are shown in Table 1.

Effect of ammonia concentration

Usually, to avoid interference by various ions in the determination of cyanide, hydrogen cyanide is distilled from acidified sample solution and trapped in a sodium hydroxide solution, which is then analysed.⁴ If silver ions are added to this alkaline solution, they are hydrolysed, so it is better to add the silver as its

Fig. 2. Effect of pH on the cyanide determination. Wavelength (nm)—A, 427; B, 423.5; C, 431. A, B and C correspond to procedures A, B and C, respectively.

Table 1. Optimum pH values, wavelengths for absorbance measurements, calibration equations and apparent molar absorptivities (ϵ)

Procedure	Porphyrin to be used	Optimum pH	Wavelength, nm	Calibration equation	ϵ , l.mole ⁻¹ .cm ⁻¹
A	T(3-MPy)P	12.0	427	CN ⁻ (ng/ml) = 126 ΔA	2.04×10^5
B	T(2-MPy)P	10.6	423.5	CN ⁻ (ng/ml) = 133 ΔA	1.95×10^5
C	T(4-MPy)P	11.4	431	CN ⁻ (ng/ml) = 234 ΔA	1.11×10^5

ammine complex, which undergoes ligand substitution by cyanide. Figure 3 shows the effect of the ammonia concentration on this ligand substitution in the cyanide determination with T(3-MPy)P. At ammonia concentrations $<0.02M$ in the final solution ΔA decreases, presumably because hydrolysis of the silver ions increases, and at concentrations $>0.02M$ the ammonia binds the surplus silver ions more strongly and interferes with the porphyrin reaction. At a final ammonia concentration of about $0.02M$ the influence of both effects is minimal.

Effect of other variables

The effects of the concentrations of silver(I), porphyrin and lead(II) were examined. The results revealed that a constant and maximum ΔA value is obtained in all three procedures provided that more than an equimolar ratio of silver(I) to cyanide, more than 1.5-fold molar excess of the porphyrin relative to silver(I), and more than 1.5-fold molar excess of lead(II) relative to the porphyrin are added.

Under the recommended conditions, the formation of the silver(I) ammine and porphyrin complexes was instantaneous and that of the lead(II)-porphyrin complexes rapid, but formation of the stable silver(II)-porphyrin complexes took about 10 min at room temperature.

Adsorption of the porphyrins and their silver(II) complexes on the inner surface of the

glassware could be suppressed almost completely by the presence of at least $0.2M$ sodium nitrate in the final solution.

Composition of the silver(I)-cyanide complex

A computer calculation of the distribution of species in the cyanide-silver(I)-ammonia system showed that the 1:2 complex $Ag(CN)_2^-$ should be formed irrespective of the molar ratio of silver to cyanide present, and the surplus silver will be present as the $Ag(NH_3)_2^+$ complex under the conditions for the determination of cyanide. A plot of the absorbances at 427 and 471 nm, as a function of the concentration ratio of cyanide to silver (Fig. 4) confirmed this point.

Calibration graph and precision

Calibration graphs for the cyanide determination were prepared for all three procedures and gave straight lines which conformed to Beer's law. The regression equations and the apparent molar absorptivities calculated from them are summarized in Table 1. Of the methods developed, procedure A has the highest sensitivity, but procedure B is almost as sensitive.

Seven standard solutions containing 44.4 ng/ml cyanide were analysed by procedure A. The results had a relative standard deviation of 1.6%.

Fig. 3. Effect of the ammonia concentration in procedure A. CN⁻, 44.4 ng/ml; T(3-MPy)P, $5.1 \times 10^{-6}M$; Ag(I), $3.0 \times 10^{-6}M$; Pb(II), $9.3 \times 10^{-6}M$; NaNO₃, $0.24M$; pH, 12.0; wavelength, 427 nm.

Table 2. Tolerance limits for various ions in the determination of 38.4 ng/ml CN⁻ by procedure A with T(3-MPy)P

Ion	Tolerance limits
Cl ⁻	600 µg/ml
Br ⁻	0.6 µg/ml
I ⁻	Strong interference
SCN ⁻	4.5 µg/ml
S ²⁻	Strong interference
NO ₃ ⁻	31000 µg/ml*
SO ₄ ²⁻	48000 µg/ml*
Mg(II)	800 ng/ml
Ca(II)	280 ng/ml
Fe(III)	170 ng/ml
Cu(II)	Strong interference
Zn(II)	Strong interference
Cd(II)	Strong interference
Hg(II)	Strong interference

*Maximum tested.

Interferences

Interferences were studied by preparing solutions containing a fixed amount of cyanide and various amounts of other ions and applying the procedures developed. An error of $\pm 3\%$ in the absorbance reading was considered tolerable. Table 2 shows the influence of other ions on procedure A. Similar results were obtained with the other two porphyrins. Cadmium(II), copper(II), mercury(II), zinc(II), iodide and sulphide interfered seriously with the cyanide determination because of reaction with the porphyrin or silver(I). The tolerance limits for bromide and thiocyanate are also not high. However, as already mentioned, cyanide is usually determined after it has been separated from interfering ions by distillation, so these interferences should not arise.

Table 3. Determination of cyanide in wastewater samples

Sample	Cyanide added, Cyanide found,	
	ng/ml	ng/ml
A	0.0	0.0
	44.4	44.8
	88.8	88.3
B	0.0	0.2
	44.4	44.1
	88.8	88.4

Application to real samples

Cyanide in wastewater samples was determined by procedure A, after isolating it from co-existing ions by distillation.⁴ The results are given in Table 3.

Comparison with other methods

The proposed methods for the determination of cyanide are rapid and simple. The sensitivities of the methods are higher than those of any current spectrophotometric methods for cyanide.⁴⁻⁷

RAPID DISSOLUTION OF CHROMITE WITH SULPHURIC ACID-LITHIUM SULPHATE MIXTURE CONTAINING CERIC SULPHATE, MANGANESE DIOXIDE OR PERIODATE, AND SPECTROPHOTOMETRIC DETERMINATION OF CHROMIUM

NOBUTAKA YOSHIKUNI

Laboratory for Analytical Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba, Japan

(Received 7 July 1989. Revised 7 December 1990. Accepted 14 December 1990)

Summary—Cr₂O₃ and chromite ore can be dissolved in H₂SO₄-Li₂SO₄-Ce(SO₄)₂ (20/10/1 v/w/w), H₂SO₄-Li₂SO₄-MnO₂ (20/10/1 v/w/w) and H₂SO₄-Li₂SO₄-KIO₄ (20/10/2 v/w/w) mixtures. The turbid solution produced can be clarified by treatment with H₂O₂ or solvent extraction and the chromium determined spectrophotometrically at 614 nm.

The chief ore of chromium is chromite, which is one of the most refractory minerals with respect to chemical dissolution. The chromite can be fused with alkali metal borate but dissolution of the cooled melt in mineral acid is slow (and impossible if boron trioxide is used as the fusion flux).¹ Previous studies² have shown that a sulphuric acid-lithium sulphate mixture can easily dissolve refractory oxides such as hafnium oxide, titanium dioxide and zirconium oxide but not the more refractory chromium(III) oxide. However, if a strong oxidizing reagent such as ceric sulphate, manganese dioxide, potassium permanganate or potassium periodate is added to the sulphuric acid-lithium sulphate mixture, chromium(III) oxide can be dissolved. This paper demonstrates the dissolution of chromium(III) oxide and chromite in this way and that the chromium in the resultant solution is present as chromium(III) and chromium(VI). The chromium(VI) can then be reduced to chromium(III) with hydrogen peroxide in sulphuric acid medium and the chromium(III) determined spectrophotometrically.

EXPERIMENTAL

Reagents

Chromium(III) oxide, ceric sulphate tetrahydrate, 30% hydrogen peroxide, manganese dioxide, sulphuric acid, lithium sulphate monohydrate, potassium periodate, potassium permanganate and potassium dichromate were Wako Pure Chemical Co. analytical grade. All

other reagents were also of analytical grade. Demineralized distilled water was used throughout. A chromium stock solution was prepared by dissolving 0.9527 g of potassium dichromate in 150 ml of 6.0M sulphuric acid in a beaker, transferring the solution into a 200-ml standard flask, and rinsing the beaker and diluting to the mark with 6.0M sulphuric acid.

Chromite sample

Chromite ore was obtained from Steelport, Transvaal, Republic of South Africa, and ground with a mortar and pestle.

Dissolution procedures

Dissolution of chromium(III) oxide and chromite with H₂SO₄-Li₂SO₄-Ce(SO₄)₂ mixture. Accurately weigh approximately 100 mg of Cr₂O₃ or 50 mg of very finely powdered chromite and transfer it into a dry 100-ml Kjeldahl flask. Weigh out roughly 10 g of Li₂SO₄·H₂O and 1 g of Ce(SO₄)₂·4H₂O, and add them to the flask. Add 20 ml of concentrated sulphuric acid to the flask in such a way that any solid caught in the neck is washed down. Place a small short-stemmed funnel in the neck of the flask and heat the flask with a Bunsen burner in a well-ventilated fume-hood, with the flask at 45° from the vertical. Start with a strong flame, rapidly increasing the temperature until the acid begins to fume. Rotate and shake the flask, and continue the heating until a clear brown solution is obtained. Let the flask stand for about 5 min, then cautiously add

about 50 ml of water little by little, and then 30% hydrogen peroxide until reduction of the ceric sulphate is complete. Cool, filter through a glass microfibre filter (e.g., Whatman GF/A, 7.0 cm diameter) into a 100-ml standard flask and dilute to the mark with water.

For 100 mg of chromite double the quantity of lithium sulphate and ceric sulphate should be used, with 20 ml of concentrated sulphuric acid. This mixture can easily dissolve 100 mg of chromite.

Dissolution with H_2SO_4 - Li_2SO_4 - MnO_2 mixture. The procedure is the same as that described above, but with 1 g of manganese dioxide instead of the ceric sulphate, and with 20 ml of concentrated sulphuric acid and 10 g of $Li_2SO_4 \cdot H_2O$ for 100 mg of sample. The fuming is continued for only 3–4 min.

Dissolution with H_2SO_4 - Li_2SO_4 - KIO_4 mixture. For 100–200 mg of Cr_2O_3 or chromite (in a 100-ml Kjeldahl flask) use 20 ml of concentrated sulphuric acid, 10 g of $Li_2SO_4 \cdot H_2O$ and 2 g of potassium periodate, and gently heat for 5 min with a Bunsen burner. Increase the temperature until the acid fumes, rotate and shake the flask, and continue the heating for 10–15 min. After cooling, add 50 ml of water, transfer the solution to a 200-ml separatory funnel, add 50 ml of carbon tetrachloride and shake the funnel for 1 min to extract the iodine produced. Discard the organic phase. Filter the aqueous phase into a 100-ml standard flask and dilute to the mark with water.

*Decomposition of chromite by fusion with NaOH and Na_2O_2 .*³ Accurately weigh 100–250 mg of finely powdered chromite into a nickel crucible, add 3 g of sodium hydroxide and 3 g of sodium peroxide, fuse the mixture for 20 min, cool, dissolve the product in 3.6*M* sulphuric acid, transfer the solution into a 100-ml standard flask and dilute to the mark with 3.6*M* sulphuric acid.

Spectrophotometric determination of chromium

Take 1–10 ml portions (accurately measured) of chromium standard solution or the sample solution and evaporate them to dryness in beakers on a hot-plate and dissolve the residues with 15 ml of 11.5*M* sulphuric acid. Then add 1 ml of 30% hydrogen peroxide to each, cover the beakers, and heat them on a hot-plate. Repeat the addition of peroxide three times. If potassium periodate was used, continue addition of hydrogen peroxide until all the periodate has been decomposed, and evaporate the

solution to about 15 ml. When the colour has changed from the blue of the sample solutions or the orange of the standard solutions to deep green, cool, and transfer the solutions into 25-ml standard flasks. Add 6.0 ml of concentrated sulphuric acid to each and dilute to the mark with water. Measure the absorbance at 614 nm against a reagent blank prepared under the same conditions.

RESULTS AND DISCUSSION

Dissolution of chromium(III) oxide and chromite

Chromite is one of the most refractory minerals with respect to chemical dissolution. However, if a strong oxidizing reagent such as potassium permanganate is used in conjunction with concentrated sulphuric acid or its mixture with lithium sulphate, chromite and chromium(III) oxide can easily be decomposed, but such mixtures can be explosive when heated.

The effect of other powerful oxidizing reagents, such as ceric sulphate, manganese dioxide, potassium periodate, nitric acid, potassium bromate and potassium peroxodisulphate, in sulphuric acid and sulphuric acid–lithium sulphate media, on the dissolution time of chromium(III) oxide has therefore been examined (Table 1).

Chromium(III) oxide (100 mg) can be dissolved in a few minutes by heating with 20 ml of concentrated sulphuric acid and 1 g of ceric sulphate in a Kjeldahl flask, but the cerium(III) products (the oxide or oxysulphate) cannot be completely dissolved on addition of water.

However, if lithium sulphate (10 g) is also present, the decomposition is complete in 1 min or less, and the cerium(III) is in a form that is readily soluble in water. The colour of the solution is changed from brown to clear blue by the addition of 1 ml of 30% hydrogen peroxide.

Chromium(III) oxide (100 mg) can be completely dissolved by heating for a few minutes with H_2SO_4 - KIO_4 (20 ml, 2 g) or H_2SO_4 - Li_2SO_4 - KIO_4 (20 ml, 10 g, 2 g) mixture in a Kjeldahl flask. For chromite, only the H_2SO_4 - Li_2SO_4 - KIO_4 mixture is efficient, but heating for 15–20 min is required. Iodine is generated in this method, and if it is not completely volatilized during the heating, must be removed by extraction with carbon tetrachloride, to prevent its interference in the chromium(III) determination. Silica and silicates are not decomposed and must be filtered off (glass microfibre filter). MnO_2^{4-6} or manganese ore⁴ can

*Spectrophotometric determination after removal of iron.

$\text{H}_3\text{PO}_4\text{-HNO}_3$ system, though successful when used in a beaker, proved unsuitable when used in a Kjeldahl flask, unless more nitric acid was added from time to time. Chromium(III) oxide cannot be dissolved in $\text{H}_2\text{SO}_4\text{-Li}_2\text{SO}_4$ mixture with the aid of other oxidizing agents such as potassium bromate or potassium peroxodisulphate.

In the dissolution with the $\text{H}_2\text{SO}_4\text{-Li}_2\text{SO}_4\text{-Ce}(\text{SO}_4)_2$ system, the iron(II) in the chromite ore reduces some of the cerium(IV) and it is necessary either to use a smaller sample (50 mg) or double the amounts of lithium sulphate and ceric sulphate if a 100-mg sample is used. The $\text{H}_2\text{SO}_4\text{-Li}_2\text{SO}_4\text{-Ce}(\text{SO}_4)_2$ system can be heated rapidly to a high temperature and chromite can

be decomposed in a few minutes, but other metal oxides such as iron oxide dissolve more slowly (10–15 min).

After heating for 10–15 min, the colour of the $\text{H}_2\text{SO}_4\text{--Li}_2\text{SO}_4\text{--Ce}(\text{SO}_4)_2$ system is changed from the initial turbid yellow to a clear yellowish brown, and to a clear brown if heated with chromite. After dilution with water the chromium(VI) in the solution is readily reduced by addition of 1 ml of 30% hydrogen peroxide. In this mixed system the ratio of lithium sulphate to ceric sulphate is of importance because the lithium sulphate appears to prevent the formation of insoluble cerium oxide or oxysulphate. Any silica or silicate present in the chromite ore cannot be dissolved by this method and has to be filtered off, with a glass microfibre filter.

Heating with the $\text{H}_2\text{SO}_4\text{--Li}_2\text{SO}_4\text{--MnO}_2$ (20 ml, 10 g, 1 g) system decomposes 100 mg of chromite in about 5 min. The turbid solution is black or deep violet, and is readily changed to sky blue by the addition of a few drops of 30% hydrogen peroxide. Any silica or silicate is left undissolved and must be removed (glass microfibre filter).

Spectrophotometric determination of chromium

The chromate and diphenylcarbazide methods^{7,8} are widely used for spectrophotometric determination of chromium. The atomic-absorption photometric determination of trace and moderate amounts of chromium in ores, rocks and other materials was studied by Donaldson.^{8,9} However, these methods are unsuitable for determination of chromium in chromite ores because they are highly sensitive and the samples must be extensively diluted. To overcome this drawback the possibility of using the less sensitive absorbance measurement of chromium(III) in a high concentration of sulphuric acid was examined. In 11.5M sulphuric acid, Cr(III) exhibits absorption peaks at 432 and 614 nm (Fig. 1). Iron(III) interferes with the measurement at 432 nm, so the 614 nm peak is used for chromite analysis. The calibration graph obeys Beer's law from 10 to 500 $\mu\text{g/ml}$ Cr(III). In reduction of chromium(VI) by treatment with hydrogen peroxide the sulphuric acid

concentration must be kept in the range 10.5–12.5M because there is a slight red-shift of the chromium absorption spectrum with increase in sulphuric acid concentration.

Determination of chromium in chromium(III) oxide and chromite

Table 2 gives the results obtained for analysis of Cr_2O_3 and chromite ore under the recommended conditions. The dissolution of Cr_2O_3 with the $\text{H}_2\text{SO}_4\text{--Li}_2\text{SO}_4\text{--Ce}(\text{SO}_4)_2$, $\text{H}_2\text{SO}_4\text{--Li}_2\text{SO}_4\text{--MnO}_2$ and $\text{H}_2\text{SO}_4\text{--Li}_2\text{SO}_4\text{--KIO}_4$ systems is complete and the procedure can be recommended for determination of chromium. Decomposition with $\text{H}_2\text{SO}_4\text{--MnO}_2$ mixture gave low results.

For chromite, analysis after fusion of the sample with $\text{NaOH--Na}_2\text{O}_2$, gave 28.3% chromium (standard deviation 0.9%), which is comparable to the results obtained (grand average 28.4%, standard deviation 0.8%) by using the dissolution method with $\text{H}_2\text{SO}_4\text{--Li}_2\text{SO}_4$ mixture containing one of the oxidizing agents $\text{Ce}(\text{SO}_4)_2$, MnO_2 or KIO_4 (see Table 2).

This is a very easy and rapid dissolution method for chromium oxide and chromite ore under atmospheric conditions, and a very simple method for determination of chromium. It seems particularly useful for rapid evaluation of the quality of chromium ores.

THE INFLUENCE OF HYDROGEN PEROXIDE AND pH ON THE MOHR TITRATION

REIKO FUJITA

Department of Chemistry, School of Liberal Arts and Sciences, Iwate Medical University,
Honcho-dori 3-16-1 Morioka, Japan 020

(Received 6 November 1989. Revised 26 November 1990. Accepted 14 December 1990)

Summary—The official Japanese method for determination of chloride in hot-spring waters requires any H_2S present to be oxidized with hydrogen peroxide in ammoniacal medium. When this was done, and the solution was titrated with silver nitrate at pH 9.7, the indicator colour changed from yellow to brownish grey, owing to reduction of silver ions to the metal by hydrogen peroxide. The effect can be eliminated by adjusting the pH to 7.0–7.5 before the titration.

Almost all hot-spring waters contain dissolved H_2S , and this interferes with the determination of chloride by various analytical methods, including the Mohr titration. This interference is due to the formation of Ag_2S , which causes a positive error for chloride. The official Japanese *Analytical Methods of Mineral Spring Water*,¹ therefore specifies oxidation of the sulphide by treatment with hydrogen peroxide in ammoniacal medium.

However, it is known that in the presence of ammonium salts a positive error arises from formation of $Ag(NH_3)_2^+$ unless the pH is sufficiently low.²⁻⁵ Moreover, hydrogen peroxide reduces Ag_2O to silver in alkaline medium. Therefore, to develop an accurate method for titration of chloride in hot-spring water containing soluble H_2S , it was felt necessary to study the interaction between pH, Ag^+ , and H_2O_2 to elucidate potential interference in the titration.

The goals of the present work were to elucidate the interference mechanisms in titration of chloride with silver nitrate and find a satisfactory modification of the pretreatment in which soluble H_2S is removed by oxidation with hydrogen peroxide.

EXPERIMENTAL

Reagents

A 0.36M stock chloride solution was prepared by dissolving 2.1038 g of sodium chloride in 100 ml of distilled water, and working solutions (approximately 320 $\mu g/ml$ chloride) were prepared from it by dilution. Hydrogen peroxide solution were prepared as required, by addition of a 30% stock solution. H_2S -water

was prepared by saturating distilled water with H_2S , and the solution was standardized.⁶

Determination of Cl^- by the Mohr method

Potassium chromate indicator (0.25M) was added to 20 ml of chloride solution, which was then titrated with 0.1M silver nitrate (with stirring by magnetic stirrer). A blank solution was similarly titrated and a correction applied for the value obtained.

Relationship between the concentration of H_2O_2 and the oxidation of H_2S

Kunimi hot-spring water (20 ml) with and without H_2S -water (20 ml) was mixed with hydrogen peroxide in a flask to give a range of peroxide concentrations from 0.42mM to 1.8M. After 10 min the residual H_2S was determined as follows.⁶

Acetic acid was added to the sample solution, containing 3–4 mg of sulphide, until the pH was lowered to about 2, then 5–10 ml of 50 mg/ml cadmium acetate solution were added. The flask was sealed and shaken, then the precipitate was filtered off, washed with 1% v/v acetic acid and dissolved in 3M hydrochloric acid. The solution was accurately diluted to 50 ml and a 5–20 ml portion was heated at 60–80° for 10 min, then cooled. The pH was adjusted to 10 by addition of 3M ammonia solution, Cu–PAN indicator was added, and the cadmium present (which corresponded to the sulphide in the original solution) was titrated with 0.01M EDTA.

Modified method for the oxidation of sulphide

The pH of a sample solution (50 ml) containing 0–150 ppm H_2S was adjusted to 10–11 by

the addition of 1M sodium hydroxide. This solution was oxidized by the addition of 30% v/v hydrogen peroxide (1 ml), and then boiled for 10 min. After cooling, the pH of the solution was lowered to 7.0–7.5 by the addition of sulphuric acid (with monitoring by pH-meter). Leakage of chloride from the reference electrode was found to correspond to less than 1 ppm in the test solution, in 5 min.

RESULTS AND DISCUSSION

The Japan official method for removing soluble H_2S consists of oxidation with hydrogen peroxide in ammoniacal medium.¹ When, in the present work, the method was applied to two kinds of hot-spring water containing 83–151 ppm H_2S , before their titration with silver nitrate to determine chloride, detection of the end-point was difficult, and accurate determination of the chloride impossible. The colour changes at the end-point were as follows. The yellow of the chromate solution changed to a turbid brownish green immediately after each addition of titrant and also just before the end-point. In addition, many bubbles occurred at the same time that the colour changed. If these solutions were filtered after the production of bubbles ceased, a greyish black precipitate was collected and a clear yellow solution obtained. The absorption spectrum of this solution was the same as that of potassium chromate. Since Ag_2S is black, the colour change was thought to be due to precipitation of Ag_2S formed from Ag^+ and residual H_2S . Hence, the relationship between the concentration of H_2O_2 used and the oxidation of sulphide was investigated, with the result shown in Fig. 1. No sulphide could be detected in either Kunimi

hot-spring water or H_2S -water when the peroxide concentration used was $\geq 18mM$, which was lower than the concentration specified in the standard method. This suggested that all the sulphide had been oxidized and that the precipitate was not Ag_2S . In fact, qualitative analysis showed that the precipitate was metallic silver. Since it was found that precipitation of silver did not occur if the solution was adjusted to a neutral pH after oxidation with peroxide, the relationship between $[Ag^+]$, $[H_2O_2]$ and pH was further studied. It was found that the excess of peroxide did not influence titrations done at pH 7.0–7.4.

The effect of H_2O_2 over the pH-range 6.9–11.3 [adjusted with sodium hydroxide instead of ammonia, to avoid formation of $Ag(NH_3)_2^+$] was investigated. In the presence of peroxide at pH > 10.0, chloride could not be determined by the Mohr method, since gas was evolved when silver nitrate was added, and the colour of the solution changed to greyish black because a precipitate of metallic silver was formed.

It is known that hydrogen peroxide reacts with Ag_2O but not with Ag^+ , and acts as a reductant:

According to calculations based on the relevant constants, a precipitate of Ag_2O should not form at pH < 11.0 under the conditions of the Mohr method. However, Ag was formed even at pH 10.0, which is lower than the upper pH limit (10.5) recommended for use of the Mohr method. This is presumably due to the non-equilibrium conditions existing at the point of entry of the titrant into the chloride solution, where the resulting local concentration of Ag^+ could be high enough to produce a small amount of Ag_2O , which would react with the peroxide and perhaps induce the well-known Haber–Weisz chain reaction for decomposition of peroxide.

It follows that if peroxide is present, it is essential to keep the pH sufficiently low to prevent localized formation of Ag_2O . The requirement for oxidation of sulphide with peroxide at relatively high pH and titration at lower pH can be met by first adjusting the pH to 10–11 with sodium hydroxide for the oxidation reaction, and then lowering the pH to 7–7.5 by addition of sulphuric acid. The Mohr titration can then be applied.

†Added chloride: 205 μg/ml.

‡Added chloride: 160 μg/ml.

Application of the Mohr method

The following experiment was planned to confirm the effectiveness of the modified method of oxidation of H₂S. The samples used were H₂S-water and two kinds of hot-spring water, each containing chloride. A known amount of sodium chloride solution was added to the hot-spring water, and the results for these solutions were compared with those for hot-spring water to which no chloride had been added. The experiment was repeated five times with the same samples, and the results are shown in Table 1. The determination of the added Cl⁻ was acceptably accurate (98–101% recovery). The modified method was evidently suitable for the determination of chloride in hot-spring water containing substantial amounts of H₂S.

(Received 13 November 1989. Revised 9 November 1990. Accepted 19 November 1990)

Summary—A rapid, simple and reliable routine method for the determination of total sulphur in zinc concentrates, roasted products and leached residues from zinc smelters is described. The method involves the fusion of the sample with sodium peroxide and sodium carbonate or routine acid decomposition and dissolution to give soluble compounds. The absorbance of the barium sulphate suspension produced by the addition of barium chloride powder to a dilute hydrochloric acid solution of the sample, containing cetyltrimethylammonium bromide solution as a dispersing agent, is measured at 420 nm. The results obtained for some zinc concentrates and other products are compared with those obtained by the conventional gravimetric barium sulphate method. Results for a reference zinc concentrate and other samples with various matrices and the results obtained with standard additions to the samples are good.

Sulphur is present mostly as sulphide in zinc concentrates and during roasting is converted into sulphur dioxide, which is used to manufacture sulphuric acid in most "roast-leach-electro-win" hydrometallurgical plants. The roasted product and leached residues contain unreacted sulphides and sulphates in amounts which depend on the roasting conditions, and this severely affects the leaching efficiency, precious-metal recovery, sulphate balance and recovery efficiency of the plant operations, so their analytical control is essential at all levels.

The total sulphur content in zinc plant samples varies from 2 to 32%. Our laboratory uses a uniform method for the determination of sulphur by the usual nitric acid decomposition in the presence of potassium bromate and a solution of bromine in carbon tetrachloride to form soluble sulphate, followed by the conventional gravimetric method.¹⁻³ Titrimetric, potentiometric and polarographic methods have been reported in the literature for the determination of sulphate in certain samples, but these methods are not suitable for zinc concentrates and other residues, owing to the complexity of the samples.

For simpler and more rapid determination of total sulphur, modification of the decomposition technique for converting all the sulphur

compounds into soluble sulphates is needed and the gravimetric barium sulphate method must be replaced. The universal technique proposed by Bhargava *et al.*⁴ for rapid dissolution of materials encountered in the steel industry has not hitherto been tried for these types of zinc plant samples, though it seems well suited for the purpose. For determination of low levels of sulphate the use of nephelometry^{5,6} or turbidimetry⁷ has been found advantageous. Hence it seemed to us that combination of the alkaline fusion technique with turbidimetric determination would provide a rapid and useful method for use in production control.

In the proposed method, the sample is fused with sodium peroxide and sodium carbonate in a nickel crucible, and the cooled fusion cake is leached with water and dissolved completely in hydrochloric acid, the sulphur species in the sample all being in soluble sulphate form. Powdered barium chloride is added to the solution, the barium sulphate suspension produced being stabilized by cetyltrimethylammonium bromide. The absorbance is measured at 420 nm.

This method is simple, rapid and reliable, and the results are comparable with those of the standard gravimetric method. The decomposition brings the major and minor constituents into solution, providing in a single operation a sample solution suitable for complete analysis.

EXPERIMENTAL

Reagents

All reagents used were of analytical grade.

Standard sulphate solution (2 mg/ml). Dissolve 2.958 g of anhydrous sodium sulphate in sulphate-free demineralized water and dilute the solution exactly to 1000 ml.

Cetyltrimethylammonium bromide (CTAB) solution. Dissolve 2.00 g of CTAB in 100 ml of 6M hydrochloric acid. Dilute 2 ml of this stock solution to 1000 ml with demineralized water.

Bromine solution in carbon tetrachloride. Mix 20 ml of bromine and 30 ml of carbon tetrachloride in an amber glass-stoppered bottle.

Barium chloride powder. Grind the reagent and sieve it, collecting the fraction (< 300 μ m particle size) passing through a BSS 52-mesh sieve.

Apparatus

A JASCO double-beam UVIDEK 430 spectrophotometer, a magnetic stirrer with built-in speed regulator, and Teflon-coated stirrer bars (10 mm diameter, 25 mm length) were used.

Sample preparation

Acid decomposition. To 1.000 g of powdered (100-mesh) sample in a dry 400-ml beaker add 3–4 g of potassium bromate. Cover the beaker with a dry watch-glass, and swirl it to mix the sample with the potassium bromate. Add 8–10 ml of the carbon tetrachloride solution of bromine and let stand for 15 min. Add 10 ml of concentrated nitric acid and stand the beaker on an asbestos pad on a hot-plate, for slow reaction and evaporation. Remove the cover and evaporate the solution to dryness. Cool, add 10–15 ml of concentrated hydrochloric acid, evaporate to

dryness and slightly bake the residue. Repeat this acid treatment twice to decompose the sample completely. To the baked sample add 2–3 g of sodium chloride and disperse it over the sample. Add 50 ml of 6M hydrochloric acid and heat to dissolve the soluble salts. Filter (Whatman 12.5-cm No. 1 filter paper) and wash the residue with 6M hydrochloric acid, collecting the filtrate and washings in a 250-ml standard flask. Make up to the mark with 6M hydrochloric acid.

Alkaline fusion. Cover 1.000 g of powdered sample in a 50-ml zirconium or nickel crucible with 8 g of sodium peroxide and 2 g of sodium carbonate. Fuse the mixture over a Méker burner or in a muffle furnace at 700° until the melt is cherry red and clear. Cool. Extract with the minimum (10 ml) of water. After the effervescence has ceased, empty the crucible into a beaker, add 10 ml of concentrated hydrochloric acid to the crucible and empty it into the beaker. Rinse the crucible with the minimum amount of water, collecting the washings in the beaker. Boil the solution for 5 min, then let it cool. If any residue is found, filter (Whatman 12.5-cm No. 1 filter paper) and wash the residue with 6M hydrochloric acid. Transfer the solution into a 250-ml standard flask and dilute to volume with 6M hydrochloric acid.

Turbidimetric determination

Pipette a volume of sample solution containing up to 2.5 mg of sulphate into a 100-ml standard flask, and dilute to volume with CTAB solution. Transfer the solution to a 150-ml beaker, add a stirrer bar and place the beaker on the magnetic stirrer. Stir the solution at constant speed (500–700 rpm). Add 0.25 g of barium chloride powder and continue stirring for 1 min.

Immediately transfer some of the suspension into a 10-mm path-length cell and measure the absorbance at 420 nm against a blank similarly prepared. Prepare a calibration graph, with standards prepared in the same way, covering the range up to 3.0 mg of sulphate per 100 ml.

RESULTS AND DISCUSSION

The method was validated by analysing various samples generated at the zinc smelter, as well as a certified zinc concentrate reference sample (Tables 1 and 2). Various amounts of sulphate were added at the measurement stage to determine the efficiency of dispersion under the experimental conditions for different matrices and the results obtained are reported as % recovery in Table 2.

The results obtained for total sulphur in solutions prepared by the two decomposition methods and analysed by both methods (gravimetric and turbidimetric) were in good agreement. Both methods of determination were applied to each sample solution. The alkaline fusion decomposition method was found to be

more effective and much faster than the acid decomposition. Although silica is also brought into solution in the alkaline fusion decomposition, there is no effect on the sulphur values obtained.

Since the sample solution is also used for determination of various major and minor constituents, especially lead and silver, to save time in these determinations a 6M hydrochloric acid concentration is used.

The reagent blanks must be run through the entire procedure, including the decomposition step, because the minor constituents are determined by atomic-absorption spectrophotometry, and contamination from the crucible used for the fusion must be allowed for. With zirconium crucibles no difficulty has been encountered.

The proposed method is very simple, rapid and accurate for zinc plant samples of various types and is a useful alternative to the standard gravimetric method, which is long and tedious.

Barium sulphate suspensions prepared in CTAB solution were found to have maximum absorbance at 420 nm. The calibration graph

was linear up to 2.5 mg of sulphate in 100 ml of solution.

Copper, cadmium, zinc, iron and chloride cause practically no interference.

The barium chloride should be thoroughly ground to pass a 52-mesh sieve, to provide uniform particle size, and this has been found effective for producing the barium sulphate dispersion in CTAB solution. The amount added is based on the practical requirement of reaction with all the sulphate present, without leaving undissolved reagent dispersed in the solution; 0.25 g in 100 ml of solution was found satisfactory. Equal amounts of the barium chloride powder, with uniform particle size, must be used for all samples, standards and blanks, since turbidimetric methods require production of reproducible particle size distributions.

Dilute CTAB solution is used as the stabilizer to keep the barium sulphate in suspension. Too high a CTAB concentration causes frothing, however. Another conditioning agent, glycerol in hydrochloric acid,⁸ was also tried as the stabilizer but did not give satisfactory results. Toennies and Bakay used an ethanol-dipropylene glycol mixture as stabilizer⁶ but its efficacy was not tested in the present work.

The absorbance measurement should be made immediately after a constant time has elapsed after addition of the barium chloride. Generally 1 or 2 min is sufficient to attain a uniform suspension of barium sulphate in the CTAB solution.

A FIBER-OPTIC CYCLODEXTRIN-BASED SENSOR

J. P. ALARIE and T. VO-DINH*

Advanced Monitoring Development Group, Health and Safety Research Division, Oak Ridge National Laboratory, Oak Ridge, TN 37831-6101, U.S.A.

(Received 29 August 1990. Revised 14 November 1990. Accepted 24 November 1990)

Summary—This paper describes the development of a fiber-optic cyclodextrin-based (FCD) sensor. The device uses laser excitation and fluorescence detection with β -cyclodextrin as the reagent phase, immobilized at the tip of an optical fiber. The sensitivity of the FCD sensor is 14 times as great as that of a bare optical fiber when measurements are made with the fiber immersed in a buffer after a 10-min incubation period. The selectivity of the sensor is illustrated with pyrene as the model compound and 5,6-benzoquinoline as the interferent. An interference study with a contaminated environmental ground water sample is used to illustrate the usefulness of the FCD device.

An important class of fiber-optic chemical sensors relies on the interaction of the analyte with a reagent phase immobilized at the sensing end of the optical fiber to produce a spectroscopic signal. Antibodies and enzymes are often used as the reagent phases in fiber-optic sensors because of their high specificity toward the analyte of interest.¹⁻⁵ Cyclodextrins (CDs) have lower specificity than antibodies and enzymes but because of their ability to form complexes with various molecules have been utilized in chromatographic separation of organic and inorganic compounds.⁶

Cyclodextrins are sugar molecules having the structure of a hollow truncated cone with a hydrophobic cavity. Their complexation ability has been attributed to four factors.⁷ (1) Van der Waals interaction, (2) hydrogen-bonding, (3) displacement of high-energy water molecules from the cavity, and (4) release of the strain energy of the CD on inclusion of the guest molecule. The hydrophobicity of the guest molecule also plays a key role in the stability of the complex. The stoichiometry of the complexes is not necessarily 1:1; instances of 2:1 and 1:2 complexes are known.^{7,8} Complexation with cyclodextrins also enhances the fluorescence⁹ and phosphorescence of certain analytes¹⁰⁻¹⁴ and for this purpose CDs have been used on immobilized quartz plates in a fiber-optic probe.¹⁵

This work involves the development of a CD-based fiber-optic chemical sensor with β -

CD immobilized at the distal face of an optical fiber, that combines the selectivity of the CD with enhancement of the fluorescence of the complexed molecule. The polynuclear aromatic hydrocarbon (PAH) pyrene is used as the model compound. The complexation ratio for pyrene has been shown to be 1:1 for concentrations below $10^{-6}M$,^{8,16} which is the case for all pyrene solutions used in this work. The performance of the FCD sensor (analytical curve and response time) is described, and its selectivity has been investigated by using 5,6-benzoquinoline as an interferent, together with a ground water spiked with pyrene, and containing other PAHs as contamination.

EXPERIMENTAL

Materials

β -Cyclodextrin, glycidoxypropyltrimethoxysilane (GOPS), sodium hydride, pyrene and 5,6-benzoquinoline were obtained from Aldrich (Milwaukee, WI). Toluene, *N,N*-dimethylformamide (DMF), methanol and ethanol were obtained from EM Science (Cherry Hill, NJ). Phosphate-buffered saline (PBS) was obtained from Sigma (St. Louis, MO). The optical fiber was a multimode fused-silica 600- μ m diameter fiber purchased from General Fiber Optics (Cedar Grove, NJ). Fluorescence spectra were obtained with a Perkin-Elmer model MPF-43A spectrofluorimeter.

Procedures

β -CD was immobilized on the optical fiber by a method described previously.⁶ In this study, a

*Author for correspondence.

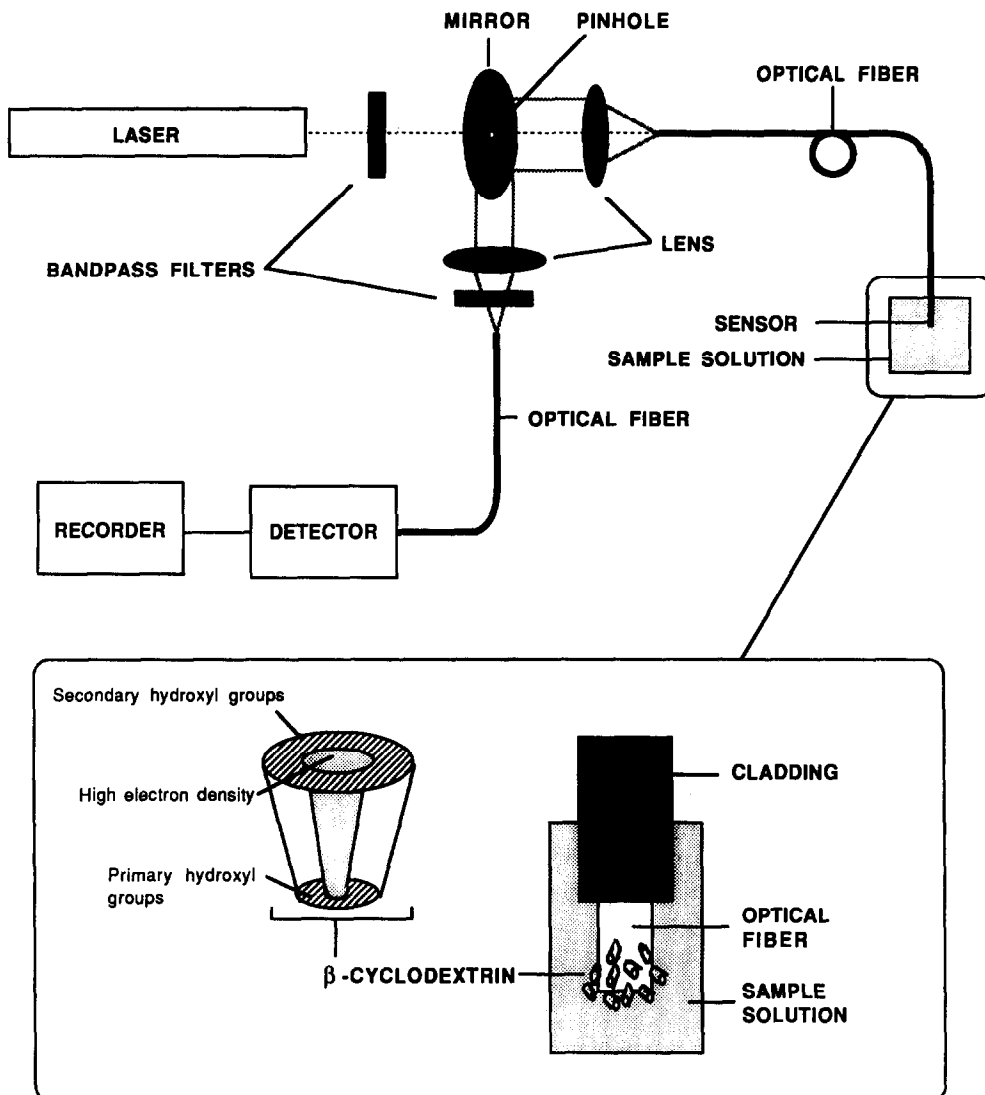

Fig. 1. Schematic diagram of the fiber-optic cyclodextrin (FCD) based sensor.

1-cm length of cladding was stripped from the fiber end and the fiber was heated overnight at 100°. The stripped tips (of several fibers) were then modified by immersing them in a 10% v/v GOPS solution in toluene, which was then refluxed for 3 hr.

The distal ends were washed with toluene and then methanol, and the fibers were heated overnight at 100°. Under an atmosphere of nitrogen, 500 mg of β -CD (heated overnight at 60°) was dissolved in 30 ml of DMF, sodium hydride (125 mg) was added, and the mixture was allowed to react for 15 min. The excess of sodium hydride was filtered off (still under a nitrogen atmosphere) and the solution refluxed for 2 hr with the fiber tips immersed in it. The fiber tips were then washed with DMF, methanol, toluene,

water and methanol in succession and heated overnight at 60°. They were then ready for use.

Apparatus

The optical configuration of the FCD sensor is straightforward and is shown schematically in Fig. 1. A brief description of the instrumental system is as follows. The 325-nm line of an He-Cd laser (Omnichrome, Chino, CA) was focused onto the untreated end of the optical fiber after passing through a beam-splitter consisting of a mirror with a 2-mm pinhole through its center. The fluorescence emitted by the sensor/analyte system was transmitted back through the fiber, reflected by the mirror and focused onto a collection fiber after passing through a 380–420 nm bandpass filter. The

Fig. 2. Response curves for: a, bare fiber; b, FCD at $t = 0$ and c, FCD at $t = 10$ min.

collection fiber was connected to a photomultiplier (Hamamatsu, model R760), the current from which was processed by a Keithley model 485 autoranging picoammeter.

Measurements

All measurements were performed as follows. The samples were pyrene solutions for calibration and a pyrene/5,6-benzoquinoline mixture for the interference study. The sensor end of the fiber was immersed in the sample solution for a 10-min incubation period, then transferred into a fresh PBS solution. Measurements were taken when the fiber was first placed in the sample solution ($t = 0$), after 10 min (*i.e.*; immediately prior to removal ($t = 10$), and immediately it was placed in the PBS solution ($t = \text{post-incubation}$). The fiber could be reused after rinsing with a 60:40 v/v methanol/water mixture until the baseline signal was restored (generally in less than 1 min). In the interference study, the solutions were stirred.

Fig. 3. Temporal response of the FCD sensor.

Fig. 4. Response curves for bare fiber, post-incubation, and FCD, post-incubation.

RESULTS AND DISCUSSION

Direct measurements in sample solutions

The performance of the β -CD derivatized fibers was evaluated by establishing response graphs for a pyrene concentration range of 8.5×10^{-9} – $2.7 \times 10^{-7} M$. Four response plots were obtained to characterize the β -CD fibers. The first was for the response of an underivatized optical fiber, *i.e.*, a blank (Fig. 2, curve a). The second and third lines (b and c in Fig. 2) were for the response of the β -CD fibers at incubation times $t = 0$ and $t = 10$ min. The linearity of these three response plots was excellent over the concentration range investigated, with correlation coefficients of (a) 0.9986, (b) 0.9986 and (c) 0.9980. However, the β -CD fibers are much more sensitive than the underivatized fiber, owing to the fluorescence enhancement obtained when pyrene molecules are complexed by β -CD. The measurement at $t = 0$ produces an enhancement factor of 2.7 and that at $t = 10$ min improves the factor to 3.1. Further improvement by measurement after incubation for more than 10 min would be minimal, as the response of the FCD levels off after about 10 min (Fig. 3).

The fourth response plot was for the post-incubation measurements and is shown in Fig. 4. This would be the actual working calibration plot since only the pyrene molecules complexed by the β -CD would be measured, which was not the case for the measurements at $t = 0$ and $t = 10$ min (Fig. 2), because the optical fiber, when in the analyte solution, "saw" beyond the β -CD layer and therefore non-complexed pyrene molecules in the solution as well as any interferents were also measured.

Fig. 5. Interference study. Detection of pyrene in the presence of 5,6-benzoquinoline.

When the fiber is removed from the sample solution and placed in the PBS solution, however, only molecules (of analyte or interferent) bound by the β -CD are measured. Figure 4 also shows the result of leaving (for 10 min) a bare fiber in pyrene solutions of the same concentrations as those used with the β -CD fibers, and measuring the post-incubation signal. This indicates that some of the signal from the FCD may be due to non-specific adsorption. With the limit of detection (LOD) defined as the concentration of pyrene which yields an S/N ratio of 4 (noise = 0.8 nA), the LOD for the FCD is

$1.9 \times 10^{-8} M$ pyrene. The LOD may be extended to lower concentrations by increasing the amount of β -CD immobilized on the optical fiber, therefore allowing a longer incubation period without saturation of the β -CD.

The sensitivity of the FCD post-incubation measurements is 14 times that of the bare fiber post-incubation measurements. This enhancement occurs because more pyrene molecules are complexed by the FCD than are adsorbed by the bare optical fiber. The enhancement is also larger than that achieved by the solution measurements (at $t = 0$ and $t = 10$ min) as only complexed pyrene molecules (and no free pyrene molecules in solution) are being measured.

Reproducibility

The reproducibility was investigated by repetitive measurements of $6.8 \times 10^{-8} M$ pyrene solutions. For a total of 10 measurements ($t = 0$ signal), an average signal of $46.2 \pm 3.4 \mu A$ was obtained, producing a relative standard deviation (RSD) of 7.3%. This RSD value may include variations due to incomplete rinsing (with 60:40 methanol/water mixture) between measurements, as well as to fluctuations in the pyrene concentration in the field of view of the optical fiber. When signal variations from fiber to fiber are also taken into account the RSD is estimated to be 15%.

Fig. 6. Fluorescence emission spectra of pyrene, a ground water blank, and the ground water sample spiked with pyrene.

Interference studies

An interference study was performed with pyrene as the model compound and 5,6-benzoquinoline as the interferent. Owing to the hydrophobic nature of the internal cavity of the β -CD, 5,6-benzoquinoline, which contains a nitrogen atom (see Fig. 5), is not expected to form stable complexes with β -CD, as homocyclic pyrene does. The concentration of the 5,6-benzoquinoline was $1.3 \times 10^{-7} M$ and the pyrene concentration was $3.4 \times 10^{-8} M$. Figure 5 shows the signals for the individual pyrene and 5,6-benzoquinoline solutions and for a mixture of the two compounds, at $t = 0$ and post-incubation (following a 10-min incubation period). When they are determined individually, at $t = 0$, the pyrene and 5,6-benzoquinoline samples yield similar fluorescence signals, which are approximately additive for a mixture. However, when the FCD is used in post-incubation mode, the 5,6-benzoquinoline signal is practically zero whereas the signal for pyrene and the mixture are 8.5 and 8.7 nA respectively. The result illustrates the selectivity of the FCD sensor in the presence of non-complexing or weakly complexing interferents. The selectivity in this case is based on the reduced ability of 5,6-benzoquinoline to form stable complexes inside the β -CD cavity. Pyrene, which forms stable complexes in the hydrophobic cavity, can be measured by the FCD sensor in the presence of a 4-fold molar ratio of 5,6-benzoquinoline.

The selectivity of the FCD was also analyzed by using a ground water sample spiked with pyrene. This ground water sample was known from synchronous luminescence measurements

to have PAH contamination.¹⁷ The extent of contamination was not further examined either qualitatively or quantitatively. Figure 6 shows the fluorescence emission spectra of pyrene ($1.4 \times 10^{-7} M$), a ground water blank, and a ground water sample spiked with pyrene, excitation at 325 nm. The results of analysis with the FCD are shown in Fig. 7. For measurement at $t = 0$, the ground water blank signal is higher than the pyrene signal, and that for the spiked ground water signal is approximately the sum of the signals from the individual samples. For the post-incubation measurements, the ground water blank signal is almost negligible and the pyrene and spiked ground water sample yield practically identical signals. This indicates that there are no other interferents present in the ground water sample which can be complexed by β -CD. This also illustrates the ability of the FCD to measure pyrene selectively in a complex mixture.

CONCLUSION

The analytical properties of a simple fiber-optic chemical sensor utilizing the selectivity of immobilized β -CD have been described. Besides being used to detect analytes in an unknown mixture, the FCD may also be utilized to study the complexation of cyclodextrins with select fluorophors. Other uses might include further studies of the fluorescence enhancement effect, along with determination of formation constants and other bonding characteristics.

SYNTHESIS OF NEW MICROSENSOR COATINGS AND THEIR RESPONSE TO TEST VAPORS

2,4,6-TRISUBSTITUTED-1,3,5-TRIAZINE DERIVATIVES

ALAN R. KATRITZKY,* JAMSHED N. LAM and HASSAN M. FAID-ALLAH

(Received 6 June 1990. Revised 30 October 1990. Accepted 3 November 1990)

Summary—Novel 1,3,5-triazine derivatives were spray-coated onto surface acoustic wave (SAW) devices and exposed to vapors of dimethyl methylphosphonate (DMMP), chloroethyl ethyl sulfide (CEES) and water. Changes in chemiresistor and SAW responses were monitored and recorded by computer-controlled data-acquisition techniques. All the derivatives tested showed little or no chemiresistor or SAW responses to water vapor. The largest reversible chemiresistor response to DMMP vapor was observed with the dicarboxylic acid derivative. The largest SAW response to DMMP was with the dithione, and the dichloro-octylthio derivative showed the largest response to CEES.

The need to design instruments to detect airborne contaminants has increased rapidly in recent years. The need to detect contaminants in parts per million (ppm) concentrations for gas leaks, chemical warfare (CW) agents and illicit drug manufacture makes the use of GC/MS (which has been used for the detection of atmospheric pollutants) and other large monitoring devices impractical.

Microelectronics and computer design have been used in the fabrication of selective and sensitive vapor detectors which are small in size and are applicable to military, industrial and environmental use. These devices include chemiresistor,^{1,2} surface acoustic wave (SAW)³⁻⁵ and bulk-wave piezoelectric quartz crystal sensors.⁶ The chemiresistor and SAW devices are both manufactured from piezoelectric quartz with an interdigitated electrode array (usually gold) lithographically deposited on the surface of the quartz crystal.¹ It is this similarity between the two devices that allows resistance (chemiresistor) and frequency (SAW) measurements to be made simultaneously.⁷ The principles of operation of SAW devices^{3,8} as well as those of chemiresistors¹ have already been described in detail. Details of the system used in our laboratory and its modes of operation have been published in two reviews by our group^{9,10} and will not be discussed here. The work described in this report is part of a project involving rapid

preliminary screening of heterocyclic derivatives and the behavior of various classes of compounds in an attempt to utilize these microsensors to their full potential. Heterocyclic systems tested so far include benzimidazole,¹¹ pyridine and pyrylium,¹² thiadiazole,¹³ nicotinamide,¹⁴ acridinium betaine,¹⁵ and phosphorus¹⁶ derivatives. It is hoped that acquisition of such data will provide valuable insight into the vapor/coating interactions and afford a better understanding of the effects of various functional groups on the device responses. In this paper, we report the responses of a variety of trisubstituted-1,3,5-triazines to DMMP (a nerve-agent simulant), CEES (a sulfur mustard-gas simulant) and water (an interferent).

EXPERIMENTAL

Simultaneous chemiresistor and SAW measurements were performed while exposing the device to water, CEES and DMMP vapors in turn. The results were usually reproducible to within 5%. The dual 52-MHz surface acoustic wave apparatus used (Microsensor Systems, Inc.), has been described in detail previously.^{9,11,15}

The resonant frequency was monitored with a digital frequency counter, Phillips Model PM 6674 universal frequency counter (550 MHz). The conductivity measurements were made by the application of a 1-V bias to either of the two remaining electrodes, and measurement of the current with a precision current-to-voltage

*Author for correspondence.

converter consisting of an operational amplifier and a switch-selectable feedback resistor.

SAW and chemiresistor data-acquisition was controlled by an Apple II computer with an IEEE-488 interface, connected to the frequency counter and an electrometer (Keithley 617 Programmable Electrometer).

The coatings were dissolved in a volatile organic solvent, typically spectroscopic grade chloroform, and the device was spray-coated with an air brush, with dry nitrogen as the propellant. The coating thickness was monitored with the frequency counter until a frequency shift of *ca.* 50 kHz was obtained. The frequency shifts caused by the coating were recorded as an indication of coating thickness. Test vapors were generated by passing a regulated flow of nitrogen through the neat liquid at 0°, in a vapor bubbler equipped with a gas dispersion tube. The flow-rate over the device was controlled with a flowmeter and was found to be 7.5 ml/min by use of a bubble meter. The absolute concentrations of the test vapors were calculated by methods described previously.¹⁵ Thus at 0°, the vapor pressures of DMMP, CEES and water afforded concentrations of 5.2, 30.7 and 4.8 g/m³ respectively.

Initially the system was purged with nitrogen for 5 min to establish a baseline curve. The device was then exposed to the vapor for 40 min, followed by a nitrogen purge for 50–60 min. If a response was irreversible, the SAW device was cleaned and recoated before exposure to the next test vapor.

The SAW devices used were rinsed with acetone between runs, followed by ultrasonic cleaning for 15 min in spectroscopic grade 2-propanol.

Melting points were determined on a Thomas-Hoover capillary melting point apparatus, and were uncorrected. ¹H NMR spectra were recorded on a Varian Model EM 360L spectrometer with tetramethylsilane (TMS) as the internal standard. ¹³C NMR spectra were recorded at 25 MHz on a JEOL Model JNM-FX 100, with solvent peaks (CDCl₃, δ77.0 or (CD₃)₂SO δ39.5) as internal references.

Synthesis of coating materials

2,4-Dichloro-6-octylthio-1,3,5-triazine (5), b.p. 140–145°/5 mmHg, literature value¹⁷ 146–148°/0.4 mmHg, and 2,4-dichloro-6-dodecylthio-1,3,5-triazine (8), literature value¹⁷ m.p. 23–26° (see Tables 1 and 2) were prepared by known literature procedures.

Preparation of 2,4-dioctylamino-6-octylthio-1,3,5-triazine (2). A solution of 2,4-dichloro-6-octylthio-1,3,5-triazine (15.0 g, 50 mmole) in acetone (50 ml) and water (20 ml) was cooled to 0–5°. Octylamine (13.1 g, 110 mmole) was added dropwise while the temperature was maintained at 0–5°. Cooling was continued as aqueous sodium hydroxide solution (2*M*, 50 ml) was slowly added. The mixture was then stirred for 24 hr at ambient temperature and the precipitate was filtered off, washed with water and dried. Crystallization from dilute methanol resulted in colorless plates (22.5 g, 93%), m.p. 56° (see Tables 1 and 2).

*Preparation of 2-octylthio-1,3,5-triazine-4(3*H*),6(5*H*)-dithione (3).* A solution of 2,4-dichloro-6-octylthio-1,3,5-triazine (8.0 g, 27 mmole) and thiourea (4.0 g, 54 mmole) in acetone (100 ml) was heated under reflux for 1 hr. The reaction mixture was then cooled to 0° and aqueous sodium carbonate solution (0.5*M*, 200 ml) was added slowly, with the temperature kept below 5°. The mixture was then stirred at room temperature overnight, the precipitate filtered off and the filtrate neutralized with 5% v/v hydrochloric acid. The product was filtered off, washed with water and dried (see Tables 1 and 2).

Preparation of 2,4-di(carboxymethylthio)-6-octylthio- (6) and 2,4-di(carboxymethylthio)-6-dodecylthio- (9) 1,3,5-triazines. A solution of (5) or (8) (50 mmole) in acetone (100 ml) was cooled to 0–5°. Mercaptoacetic acid (9.3 g, 100 mmole) and then collidine (13.5 g, 110 mmole) were added dropwise while the temperature was maintained at 0–5°. The mixture was stirred for 24 hr at ambient temperature, poured into water (100 ml) and extracted with diethyl ether (3 × 75 ml). The ethereal solution was dried over anhydrous sodium sulfate and evaporated under reduced pressure to yield the products, as white solids (see Tables 1 and 2).

General procedure for the synthesis of tris(dialkylaminoethylthioethoxy)-1,3,5-triazines (7a–c)

The appropriate dialkylaminoethanethiol hydrochloride (140 mmole) was added to a solution of cyanuric chloride (4) (8.7 g, 47 mmole) in acetone (100 ml). The mixture was cooled to 0–5° and aqueous sodium hydroxide solution (2*M*, 140 ml) was added slowly so that the temperature remained at 0–5°. After the addition was complete, the reaction mixture was stirred for 24 hr at ambient temperature, poured into water (75 ml), and extracted with diethyl

ether (3×50 ml). The combined ether extracts were washed with water (25 ml) and dried over anhydrous sodium sulfate. Removal of the ether under reduced pressure gave the triazine derivatives (**7a-c**) as sticky oils which were then converted into the picrates and characterized. Each picrate was then dissolved in dichloromethane and washed with aqueous sodium hydroxide solution to afford the pure product (see Tables 1 and 2).

RESULTS AND DISCUSSION

Derivatives of the 1,3,5-triazines, such as cyanuric acid (**1**), were discovered as early as 1776,¹⁸ although the parent compound 1,3,5-triazine was identified only much more recently by Grundmann and Kreutzberger.¹⁹

The most important precursor for the synthesis of 1,3,5-triazine derivatives is cyanuric chloride (**4**), the substituents in which can be displaced readily by nucleophiles to afford trisubstituted-1,3,5-triazines. Thus symmetrical tri(alkylthio)- and tri(arylthio)-triazines have

been prepared by the reaction of sodium mercaptides with (**4**).²⁰

We have now found that treatment of (**4**) with various dialkylaminoethanathiols at 0° in the presence of sodium hydroxide gives the trithioethers (**7**) in yields of 83–90%. The compounds were characterized by elemental analysis and their characteristic NMR spectra. In all three cases, the single aromatic carbon signal appeared between 178.7 and 179.4 ppm. The aliphatic $N-C_\alpha$ carbon atom in NCH_2CH_2S showed an upfield shift of about 6.7 ppm as the dialkylamino substituent was changed from methyl to ethyl to isopropyl. The $N-C_\beta$ carbon atom of the isopropyl substituent (**7c**) gave a shift 3 ppm downfield from the signal for the dimethyl (**7a**) and diethyl (**7b**) derivatives.

Previous workers found that the use of a weaker base such as collidine¹⁷ or pyridine²¹ and equimolar amounts of cyanuric chloride and a thiol or an alcohol, led to the displacement of a single chlorine atom to give monosubstituted adducts, which with other nucleophiles, formed unsymmetrical trisubstituted triazines.

As expected, reaction of cyanuric chloride with equimolar amounts of octanethiol or dodecylthiol in the presence of collidine afforded the monosubstituted thioethers (5) and (8) respectively. The remaining two chlorine atoms in (5) were readily displaced by octylamine in the presence of sodium hydroxide to give 4,6-di-(octylamino)-2-octylthiotriazine (2). Reaction of (5) and (8) with mercaptoacetic acid, with collidine as the base, formed (6) and (9) in yields of 89 and 79% respectively. With two equivalents of thiourea, (5) gave the dithione derivative (3).

Compounds 2, 3 and 5–9 were then tested as microsensors coatings by exposure to DMMP, CEES and water vapors (Table 3). The frequency shifts were calculated by subtracting the lowest frequency recorded during vapor exposure from the initial (baseline) frequency. Resistance changes were the ratios of the initial

resistance to the lowest resistance recorded over the same period (thus, a value close to unity denotes no change). The low signal to noise ratio in the SAW device enables small frequency changes to be detected quite readily. Typically, for an SAW delay line operating in the frequency range of 30–300 MHz, mass changes of the order of 10⁻⁹ g can be detected. However, for chemiresistor devices, a 100-fold change is required for a compound to be considered a good coating.

A large reversible resistance change (351-fold) on exposure to DMMP was observed with 2,4-dicarboxymethylthio-6-octylthio-1,3,5-triazine (6) as the coating. The dodecylthio analog (9) showed a comparable change (283-fold). This large resistance change is not surprising since the presence of two carboxylic acid groups would be expected to result in some interaction with an ester group. What is surprising though

*Frequency change equivalent to the mass.

is the fact that both these coatings showed a comparatively low response to water vapor (Fig. 1). Furthermore, both displayed good frequency responses to DMMP (27.2 and 17.4 kHz, respectively) indicating that there was a mass loading (absorption) effect. A large resistance change with a low frequency change would have implied a surface effect.

The largest resistance change (37.4-fold) for CEES vapor was observed with 2,4-dichloro-6-dodecylthio-1,3,5-triazine (8). The octylthio compound (5) also gave a high response (34.0-fold) to CEES and a similar response (37-fold) to DMMP vapor. Compound 8, however, did not show a comparable response to the DMMP vapor. The highest responses to water vapor were from the dicarboxylic acids (6) and (9), but these were still low, so these derivatives would make good chemiresistor coatings for the detection of DMMP vapors.

The greatest SAW frequency response was with the dithione (3), which displayed a frequency shift of 52.6 kHz for DMMP and

Fig. 1. Chemiresistor response of: a, compound 6 and; b, compound 9 vs. time, for exposure to DMMP and water vapor.

Fig. 2. Frequency response of 2-octylthio-1,3,5-triazine-4(3H),6(5H)-dithione (3) vs. time, for exposure to vapor.

had good discrimination, shown by its small response to CEES and water vapors (Fig. 2). Furthermore, it was 90% reversible. Consequently, this makes it a very good coating for an SAW device in the detection of DMMP in the presence of CEES and water vapors. A sharp change in frequency when the vapor is turned on and off is shown in Fig. 3. After purging of the

Fig. 3. Frequency response of 2-octylthio-1,3,5-triazine-4(3H),6(5H)-dithione (3) vs. time for periodic vapor exposure to DMMP (on/off time interval 5/2 min until $t = 48$ min, then 10/4 min until $t = 90$ min).

system with nitrogen for 5 min the vapor was repeatedly turned on for 5 min and then off for 2 min over a period of 40 min. The on/off times were then changed to 10 and 4 min respectively for a further 60 min. Analysis of the results shows that for both absorption and desorption the change in frequency is a quadratic function of time (with correlation factors of 0.992 and 0.997 respectively). The dicarboxylic acids (6) and (9) also showed good selectivity, displaying a large response only to DMMP vapor. For CEES vapor, the largest response was with the dichloro-octylthio compound (5) with low responses towards DMMP and water, thus displaying potential as a coating for the detection of CEES vapors. However, the dodecyl derivative (8) showed poor responses to all three vapors.

Previous work in our group¹³ has shown that within series of dimethyl-, diethyl- and di-isopropyl-amino derivatives, the frequency response to CEES decreases, indicating that steric hindrance around the amino group is an important factor for interaction with CEES vapor. Interestingly, in the present case, the tris(*N,N*-di-isopropylamino) analog (7c) showed the greatest response of the three. This further highlights the fact that there is still a lack of understanding of the precise interactions between coatings and vapors.

In all cases when a high response to DMMP or CEES vapor occurred, there was a low response to water vapor, indicating a low interference by humidity. The moderate to good solubility of these triazine derivatives in chloroform caused no difficulties in the spraying of these coatings. The relatively low volatility (as indicated by a baseline drift of *ca.* 1 kHz/hr, which is normal in a laboratory environment without temperature control), indicated a negligible tendency of the coating to vaporize when exposed to air, and hence the possibility of a reasonable lifetime, since the responses were reversible.

The coating thicknesses were much the same for all the triazines tested. Although a thicker coating would display a larger response, owing to the greater number of sorption sites, there are other factors such as shear modulus and film mass-density that come into play. The

vapor diffusion rate and device response times are closely related,³ and very close packing (high mass-density) of the coating would hinder easy diffusion of the analyte and the corresponding response time would be greater. It is for this reason that we have chosen not to study the relation between coating thickness and response times.

(Received 4 April 1990. Revised 19 July 1990. Accepted 26 July 1990)

Summary—Formaldehyde in air was detected and assayed with a piezoelectric quartz crystal coated with a 7,10-dioxa-3,4-diaza-1,5,12,16-hexadecatetrol/chromotropic acid solution. Water vapor and several gaseous interferences were removed by passing the sampling stream through a column of anhydrous magnesium perchlorate. The response curves were linear in the concentration ranges 0.4–4.5 and 0.4–3.6 ppm v/v CH₂O with and without the scrubber column, respectively. A single coating was used for 12 days (500 assays) without significant loss in sensitivity. With a single-point daily recalibration, the useful lifetime of the coating is about 2 months.

Formaldehyde is a major air contaminant in residential and industrial occupational environments.¹⁻³ Its effects on the health of humans^{1,4} and animals⁵⁻⁷ have generated great interest in developing techniques to control and monitor this compound.

OSHA and NIOSH have set the acceptable levels of formaldehyde exposures in the industrial atmosphere at 3 and 1 ppm v/v respectively,^{8,9} while AGCIH has recommended a voluntary standard of 0.1 ppm v/v in residential areas.¹⁰

Several methods have been developed for the determination of formaldehyde in air,^{2,11-20} but many are laborious or time-consuming.

Guilbault²¹ has developed an enzyme-coated piezoelectric crystal formaldehyde detector by immobilization of formaldehyde dehydrogenase together with both co-factors (reduced glutathione and nicotinamide adenine dinucleotide) on both sides of silver-plated metal electrodes, but this sensor has a lifetime of only 3 days.

In this paper, a new piezoelectric sensor for the detection and determination of formaldehyde in air is described, which can be portable, simple, of low cost and with fast response.

The theory and general application of the piezoelectric crystal sensors have been well reviewed²²⁻²⁴ and sensors for several atmospheric pollutants have been reported. The principle of

the sensor is that the frequency of vibration of an oscillating crystal is decreased by the selective adsorption of a target gaseous pollutant on the crystal surface. The linear relationship between the mass added onto the crystal surface and the change in its frequency can be derived from the Sauerbrey^{25,26} equation

$$\Delta F = -2.3 \times 10^6 F \Delta M / A$$

where ΔF is the frequency change (Hz), F is the basic frequency of the quartz crystal (MHz), ΔM is the mass of the deposited material (g), and A is the surface area of the quartz crystal (cm²).

Several compounds were evaluated as coating substrates for the detection of formaldehyde. Among these, a 2:1 v/v mixture of saturated solutions of 7,10-dioxa-3,4-diaza-1,5,12,16-hexadecatetrol and chromotropic acid in chloroform showed good sensitivity, response time, recovery time and stability. The effect of many potential interferences, flow-rate, temperature and amount of coating on the response of this sensor was also examined.

EXPERIMENTAL

Figure 1 shows a schematic diagram of the experimental manifold used, which is a modification of that used in previous work.²⁷ The 10-MHz piezoelectric crystals were AT-cut quartz crystals with gold-plated electrodes that were mounted in an HC6/U holder (Bliley, Erie, PA). The instrumentation utilized was a PZ 101 gas phase detector (Universal Sensors, New

Orleans, LA), which is equipped with oscillator circuitry, frequency counter and dual-crystal chamber and can be interfaced to a recorder or a computer. The response was determined by monitoring the difference in frequency changes between reference (uncoated) and sensor (coated) crystals and was read from either the counter or recorder. Temperature monitoring was done with a thermistor (Thermometrics, Edison, NJ) connected to a multimeter (Honeywell Digitest, Model 33R).

Air (Air Products and Chemicals, Inc., Allentown, PA) was passed through a water bubbler in the humidity study and the relative humidity was monitored with a digital hygrometer (model HI8064, Cole-Parmer Ind. Co., Chicago, IL). The various concentrations of formaldehyde were prepared by the permeation method. A certified formaldehyde permeation tube 5.0 cm long (type HE, VICI Metronics, Santa Clara, CA) with a permeation rate of $250 \text{ ng} \cdot \text{min}^{-1} \cdot \text{cm}^{-1}$, generating 10 ppm v/v formaldehyde at a flow-rate of 100 ml/min, and a calibration system (model 570, Kin-Tek Laboratories, Texas City, TX) were used. Different formaldehyde concentrations were generated by dilution with nitrogen.

The 7,10-dioxa-3,4-diaza-1,5,12,16-hexadecatetrol was synthesized as described by Jordan.²⁸ All other reagents used were of analytical grade.

Preparation of coating

The best coating material was prepared by mixing saturated solutions of 7,10-dioxa-3,4-diaza-1,5,12,16-hexadecatetrol and chromotropic acid (in chloroform), in 2:1 v/v ratio.

The crystals were coated onto both gold electrodes of the piezoelectric crystal by addition of known volumes of the mixed solution with a microsyringe and spreading the solution with a glass rod. The coated crystal was placed in an oven at 85° for 2 hr to evaporate the chloroform, leaving a thin film of coating on the surface. The amount of coating applied to the crystal was calculated from the Sauerbrey equation and by monitoring the frequency change due to the coating.

RESULTS AND DISCUSSION

Choice of coating material

Table 1 contains a list of some of the substances tested as coatings for adsorption of formaldehyde. The results indicate that 7,10-dioxa-3,4-diaza-1,5,12,16-hexadecatetrol/chromotropic acid (2:1 v/v) mixture gives the most sensitive and reproducible coating. The use of a mixture improved the sensor response and performance. None of the other mixtures tested gave a synergic effect, and this coating was therefore used for all subsequent work.

Table 1. Initial evaluation of possible coatings for detection of formaldehyde at 10 ppm v/v levels with 10 MHz crystals*

Coating	$\Delta F, \dagger$ Hz
7,10-Dioxa-3,4-diaza-1,5,12,16-hexadecatetrol/ chromotropic acid (2:1 v/v)	190
7,10-Dioxa-3,4-diaza-1,5,12,16-hexadecatetrol	100
7,10-Dioxa-3,4-diaza-1,5,12,16-hexadecatetrol/ Girard T reagent (2:1 v/v)	80
7,10-Dioxa-3,4-diaza-1,5,12,16-hexadecatetrol/ <i>N</i> -benzylethanolamine	65

*Flow-rate 100 ml/min; temperature 25°; sampling time 1 min.

†Average for $n = 5$.

Amount of coating

It is evident from Fig. 2 that the frequency change (ΔF) increases as the amount of coating applied to the crystal increases, and this is due either to a decrease in the rate of saturation of the coating or to an increased probability of interaction between the coating material and the CH₂O molecules. The response levels off at 30–35 μg ($\Delta F = 13000\text{--}16000$ Hz) of coating, indicating saturation of the surface contact area with formaldehyde. Higher coating levels overloaded the crystal and impaired vibration.

Fig. 2. Effect of coating on sensitivity: [CH₂O], 3.4 ppm v/v; temperature, 25°; flow-rate, 100 ml/min; sampling time, 2 min.

Fig. 3. Effect of flow-rate on (a) sensitivity and (b) recovery time: [CH₂O], 10.0 ppm v/v; temperature, 25°; amount of coating, 35 μg ; sampling time, 2 min.

Therefore, 30–35 μg of coating is sufficient for good response and reproducibility.

Flow-rate and reversibility

The effect of flow-rate on the sensitivity and recovery time of the formaldehyde sensor is shown in Fig. 3. The results indicate that the highest response was obtained in the flow-rate range 95–120 ml/min. In subsequent studies, a flow-rate of 100 ml/min was used for convenience in dilution. The recovery time was longer when lower flow-rates were used. Complete reversibility was obtained in 4 min at a flow-rate of 100 ml/min with sampling times of 2 min for a 3.4 ppm v/v CH₂O sample, and varied from 3 to 6 min over the formaldehyde concentration range 0.4–4.5 ppm v/v.

Effect of cell temperature

Figure 4 shows the effect of temperature on the sensor response. The response decreased

Fig. 4. Effect of temperature on the response: [CH₂O], 3.4 ppm v/v; flow-rate, 100 ml/min; amount of coating, 35 μg ; sampling time, 2 min.

drastically as the temperature rose from 20 to 50°, indicating that the adsorption of CH₂O by the coating decreases with increase in temperature, which seriously affects the sensitivity of the sensor. Recovery times of 4 and 3 min were obtained for a sample of 3.4 ppm v/v CH₂O at 25 and 40°, respectively. Although shorter recovery times can be achieved at higher temperatures, this improvement is not worth the sacrifice in sensitivity, so 25° is chosen as the optimum temperature.

For practical applications it is recommended that the temperature is controlled or the sensor recalibrated to minimize effects of temperature variations.

Effect of interferences

Several potential inorganic and organic interferences which would be expected to exist in the atmosphere were tested at their TLV (threshold limit values). The effect of moisture was studied by a continuous process, while other gases, including NH₃, H₂S, CO, SO₂, NO₂, COCl₂, HCl, chloroform, carbon tetrachloride, methanol, acetone, ethanol, toluene, xylene, and propionaldehyde were studied by the syringe dilution method. This study showed that NH₃, chloroform, carbon tetrachloride, methanol, acetone, ethanol, toluene, xylene and water caused high frequency changes in comparison with a sample of 3.4 ppm v/v formaldehyde.

Several approaches to elimination of these interferences were tested, with use of several desiccants, hydrophobic membranes, and molecular sieves.

Table 2. Effect of other substances on the assay of formaldehyde at TLV concentrations

Interferent	Concentration, ppm v/v	Interference, † %
NH ₃	50	0

*The Mg(ClO₄)₂ scrubber was used.

†Average for *n* = 5.

‡Relative humidity levels of 8–80%.

Fig. 5. Response of the sensor to CH₂O under two different conditions: (a) without column, (b) with Mg(ClO₄)₂ column; temperature, 25°, flow-rate, 100 ml/min; amount of coating, 35 µg; sampling time, 2 min. The error bars represent the spread of five measurements.

All of these interferences, except those of high levels of chloroform and carbon tetrachloride, were completely eliminated by passing the sampling stream through a column of anhydrous magnesium perchlorate (Table 2). Although about 24% of the CH₂O was also absorbed by the column, a calibration curve with adequate sensitivity for the determination of CH₂O could be constructed.

Calibration curves, lifetime and precision

The effect of sampling times (0.5–4 min) on the response of the CH₂O sensor was initially studied in the concentration range 0.4–8.0 ppm v/v formaldehyde. Figure 5 shows representative calibration curves obtained with a sampling time of 2 min. Curve a was obtained for dry gas without use of the Mg(ClO₄)₂ scrubber, and curve b was obtained with use of the scrubber. Curves a and b were linear over the concentration ranges 0.4–3.6 and 0.4–4.5 ppm v/v CH₂O, respectively. The good linearities (*r* = 0.987 for a and 0.988 for b) and the sensitivities of 29.0 and 22.1 Hz/µg, respectively, show that use of the scrubber does not affect the determination of CH₂O.

A single coating was used for 12 days (500 assays) without significant loss in sensitivity. With a daily single-point recalibration, a coated crystal can be used for 2 months with good results, the response decreasing by only 15% during this time. The proposed sensor is more stable than that reported earlier,²¹ and has the advantage that real applications are possible.

The reproducibility of the coating preparation was checked for 5 crystals. The performance of each crystal was evaluated under the optimum

conditions found [sampling time 2 min, flow-rate 100 ml/min, concentration of CH₂O 3.4 ppm v/v, (Mg(ClO₄)₂) scrubber used, temperature 25°]. The average $\Delta F \pm$ standard deviation found was 81 ± 3 Hz.

CONCLUSIONS

The piezoelectric sensor coated with 7,10-dioxa-3,4-diaza-1,5,12,16-hexadecatrol/chromotropic acid mixture possesses good selectivity, sensitivity and reproducibility for the detection and determination of CH₂O in air. The sensor is useful in the ranges corresponding to the acceptable levels set by several regulatory agencies, portable, simple, of low cost and with fast response.

LIQUID CHROMATOGRAPHY AMPEROMETRIC DETECTION OF CARBOXYLIC ACIDS AND PHENOLIC ACIDS WITH A COPPER-BASED CHEMICALLY-MODIFIED ELECTRODE

JIANXUN ZHOU and ERKANG WANG*

Laboratory of Electroanalytical Chemistry, Changchun Institute of Applied Chemistry, Chinese Academy of Sciences, Changchun, Jilin 130022, People's Republic of China

(Received 15 October 1990. Accepted 20 November 1990)

Summary—A copper-based chemically-modified electrode has been constructed and characterized by various experimental parameters in flow-through amperometric detection of carboxylic acids and phenolic acids. Novel hydrodynamic voltamperograms were first obtained in flow-through amperometric detection with the Cu-based CME and subsequently negative and positive peaks were observed in a single chromatogram. This unique and flexible potential dependence could be of great benefit in chromatographic speciation and quantification. These observations suggest that the detector response was governed by the complexation reaction of copper ions with the solutes.

The development of detection methods for aliphatic compounds, including carbohydrates, amino-acids and organic acids in liquid chromatography (LC) has presented an analytical challenge of major proportions. The absence of a strongly absorbing chromophore in simple aliphatic compounds restricts the use of direct UV-visible detection to wavelengths in the range 180–250 nm and thereby makes the usual spectrophotometric techniques largely unsuitable or insensitive. Consequently, the approaches most commonly employed for these analytes, especially for carbohydrates, have relied on either refractive-index detection (with its characteristically poor sensitivity) or chemical derivatization to produce sense adducts with better spectral characteristics.¹

Simple and sensitive direct detection in LC will always be preferred, when available. Historically, however, researchers have agreed that aliphatic compounds are not amenable to direct amperometric detection.² This difficulty encountered in LC electrochemical detection (LCEC) for direct sensing of aliphatic compounds at trace levels has been solved by several approaches. The first was pulsed amperometric detection (PAD), developed by Johnson and LaCourse³ platinum⁴⁻⁶ or gold^{7,8} electrodes. In the most typical applications, the method provides quantification at 100–500 ng levels.

However, because of the surface cleaning and regeneration steps necessary to obtain stable and reproducible responses, triple-pulsed potential wave-forms are required for acceptable long-term use of these electrodes. PAD systems are more expensive than the usual constant-potential detectors, and less sensitive for flow-through analysis applications, because of the accompanying charging current.

In the second approach, catalytic electrodes with oxidizable metals such as nickel,⁹ copper¹⁰ and silver¹⁰ have been developed and characterized mainly for the catalytic oxidation of carbohydrates. Detectability of 1 ng for glucose has been found with the Ni electrode. Strongly alkaline conditions were essential for these catalytic electrodes, as well as for the PAD methods with Pt and Au electrodes in the first approach, and this largely restricted the selection of chromatographic separation systems.

For the third approach, copper electrodes were used as either potentiometric¹¹⁻¹³ or amperometric¹⁴⁻¹⁷ LCEC sensors, for the detection of aliphatic compounds, including amino-acids and aliphatic and aromatic carboxylic acids. The detector response was inferred to be governed by the complexation reaction between the solutes and the cupric ion in neutral or alkaline media.

Recently, copper-based chemically-modified electrodes (CMEs) have been developed and characterized¹⁸⁻²⁰ for the catalytic LCEC

*Author for correspondence.

detection of polyhydroxy compounds, including carbohydrates, amino sugars, alditols and sugar-acids. The lowest detection limit of 0.1 ng for ribitol by FIA with such a CME was obtained at a typical catalytic oxidation potential of +0.50 V *vs.* Ag/AgCl.

This paper describes a copper-based chemically-modified electrode constructed by a method similar to that of Prabhu and Baldwin¹⁹ and used in flow-through systems (FIA and HPLC) for the detection of carboxylic and phenolic acids. The dependence of the detector response for these analytes on various experimental conditions, such as the pH and flow-rate of the mobile phases and the working potential applied, was investigated. Novel hydrodynamic voltamperograms for the solutes of interest were first obtained with the modified electrode. Subsequently, both negative and positive peaks were observed for the first time in the same LCEC chromatogram. On the basis of all the observations, it is suggested that the detector response in flow-stream measurement resulted from the difference in solubility of the cupric or cuprous species formed by the components of the mobile phase and the analyte ligands at the electrode surface.

EXPERIMENTAL

Reagents

Cupric chloride (analytical reagent grade) was purchased from the Beijing Chemical Co.; analytical-grade carboxylic acids (oxalic, citric, malic, tartaric and glyceric) were from Merck; 3,4-dihydroxyphenylacetic acid was from Fluka; vanillic and benzoic acids were from Shanghai 1st Chemical Co. and gallic acid was from Zunyi 2nd Chemical Co. (Zunyi, China). All were used as received. Other chemicals were of analytical grade. Doubly-distilled water was used for the preparation of all solutions. Phenolic acid stock solutions were kept under purified nitrogen at 4° in the dark. The mobile phase was 0.025M phosphate buffer (pH 7.0), thoroughly degassed in an ultrasonic bath before use.

Electrode

The working electrode was modified by a procedure similar to that of Prabhu and Baldwin.¹⁹ A freshly polished thin-layer glassy-carbon electrode was immersed in 0.15M sodium hydroxide for about 10 min, then rinsed thoroughly with water and immersed face-up in an aqueous 0.05M solution of copper(II) chlor-

ide, together with a small slice of metallic copper, for about 20 min, whereupon a uniform white deposit appeared on the glassy-carbon surface. At this point, the electrode was removed from the chloride solution and rinsed with water, and was ready for use. A fresh glassy-carbon surface could be obtained, whenever necessary, by immersion of the Cu-based electrode surface in 1M hydrochloric acid for 1 min.

Apparatus

Cyclic voltammetry was performed with a home-made potentiostat employing a conventional three-electrode cell, with a 3-mm diameter glassy-carbon working electrode (modified or unmodified), an Ag/AgCl (saturated KCl) reference electrode and a platinum-wire counter-electrode. Flow-injection and chromatographic experiments were performed with a JASCO-350 pump, a home-made injection valve with a 10- μ l loop and a TL-5A electrochemical detector (Bioanalytical Systems). A laboratory-made bipotentiostat was used to control the detector. The column was 7 μ m Nucleosil C₁₈ (200 \times 4 mm i.d.). The chromatograms were obtained at room temperature (20 \pm 2°). In these experiments the reference electrode was of the saturated calomel type.

RESULTS AND DISCUSSION

Electrochemistry

Cyclic voltamperograms (CVs) for the Cu-coated electrode in 0.15M sodium hydroxide and pH 7.0 phosphate buffer, respectively, are shown in Fig. 1. In 0.15M sodium hydroxide, curve A(1), a broad oxidation wave and another small one at peak potentials of +0.55 and +0.70 V *vs.* Ag/AgCl, respectively, were observed on the initial scan. In subsequent scans, these two waves decreased in magnitude and rapidly disappeared, curve A(2). This behaviour was consistent with that in an earlier study.¹⁸ Several views on the electrode surface species and the electrode mechanism of the oxidation process described by Fig. 1A have been advanced,¹⁸⁻²⁰ but considerable uncertainty remains. However, such an inactive electrode surface did catalyse glucose oxidation, with a peak potential of +0.58 V *vs.* Ag/AgCl, curve A(2), as already reported.¹⁸ CVs obtained in neutral phosphate buffer (Fig. 1B) were quite different from those in 0.15M sodium hydroxide. A rather broad oxidation wave with a peak

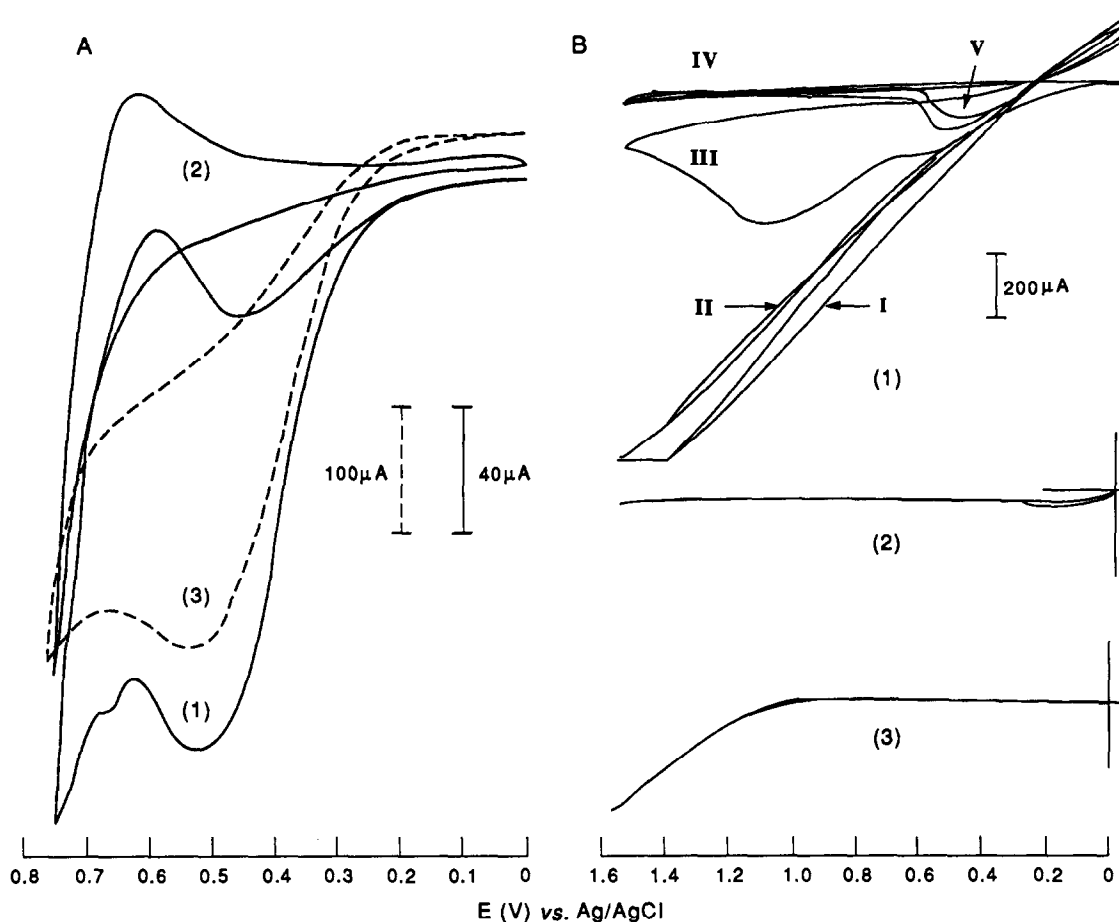

Fig. 1. Cyclic voltamperograms of the Cu-based CME in (A) 0.15M NaOH: (1), initial scan; (2), fourth scan; (3), (2) plus 10mM glucose; (B) pH 7.0 phosphate buffer: (1), initial to fifth scans; (2), tenth scan; (3), (2) plus 10mM tartaric acid. Scan-rate, 20 mV/sec.

potential of +1.10 V *vs.* Ag/AgCl was clearly observed only on the third scan, but it then decreased in magnitude and rapidly disappeared, curve B(2); a reduction wave on the reverse scan, as observed in alkaline solution, curve A(2), could no longer be observed. Furthermore, such an inactive electrode surface did not catalyse the oxidation of tartaric acid in neutral buffer solution, curve B(3), although this exhibited a catalytic oxidation wave with an E_p of +0.60 V *vs.* Ag/AgCl at such a Cu-based CME in strongly alkaline media.¹⁹

The white deposit, as suggested previously,^{19,20} is most probably crystalline CuCl resulting from the interaction of the Cu(II) solution with metallic copper to form the Cu(I) salt, the subsequent reactions of which account well for the colour of the Cu-based CME at various stages in its usage: light-coloured initially and then green on exposure to air, CuCl; yellow after exposure to neutral buffer, Cu₂O; black after exposure to oxidizing potentials,

CuO. Accordingly, the broad oxidation waves in Fig. 1 should correspond to the Cu(I)/Cu(II) oxidation process.

Once the modification was accomplished and the electrode reassembled into the thin-layer cell, the initial background current (lasting about 20 sec) on exposure to oxidizing potentials (0.0–0.15 V *vs.* SCE) in a flowing stream with pH 7.0 phosphate buffer as the mobile phase was so large that it could not be compensated instrumentally. After about 40 sec, this large background current gradually decreased until, after about 10 min, it reached a steady level which could easily be compensated instrumentally. The larger the initial oxidizing potential applied, the longer the time necessary to stabilize the background current. The function of this step for passivation of the electrode surface is similar to that for metallic copper electrodes by polarization with negative and positive potentials applied alternately.^{15,17}

Flow-through system detection

Applied potential. It seemed unclear whether or not the facile amperometric detection of carboxylic and phenolic acids in a flow-through system could be done with the copper-based electrode at modest positive potentials in neutral media, in view of the fact that no significant oxidation current was observed in the CVs of tartaric and other carboxylic acids, as shown in curve B(3) of Fig. 1. This doubt, however, was removed by making serial injections of 1mM oxalic acid and applying FIA-EC at +0.15 V *vs.* SCE (Fig. 2). Reproducible current responses were obtained, as illustrated in Fig. 2. After 40 injections, the peak response was still nearly 97% of its initial value, with a relative standard deviation of only 2.4%.

Novel hydrodynamic voltamperograms (HDVs) for carboxylic and phenolic acids were obtained with the Cu-based CME and are shown in Figs 3 and 4, respectively. These responses were different from both the *S*-shaped ones obtained on metallic copper electrodes for amino-acids in neutral buffer solution^{15,17} and the peaks obtained on a similar Cu-CME for glucose catalysis in strongly alkaline media.¹⁸

Fig. 2. FIA response obtained at the Cu-CME for a series of injections of 1mM oxalic acid: potential, +0.15 V *vs.* SCE; mobile phase, pH 7.0, 0.025M phosphate buffer; flow-rate, 0.5 ml/min. The serial number is given at the top of the peak, and recording was stopped during the other injections.

Fig. 3. Hydrodynamic voltamperograms for 1mM citric acid (■), oxalic acid (▲), tartaric acid (●), malic acid (×), glyceric acid (∇), at the Cu-CME. Flow conditions as for Fig. 2.

Figure 3 shows HDVs for some carboxylic acids. In the potential range more negative than -0.10 V *vs.* SCE, glyceric acid exhibited an anodic current that decreased as the potential became more positive; when the potential was more positive than -0.05 V, a cathodic current appeared, which gradually decreased with more positive potentials. Oxalic and malic acids behaved oppositely to glyceric acid. In the potential range more negative than -0.10 V, they exhibited cathodic currents, which decreased sharply at more positive potentials, and anodic currents appeared at potentials more positive than -0.10 V, slightly decreasing with more positive potentials. Citric and tartaric acids possessed similar HDV behaviour, always giving sharply decreasing anodic currents in the potential range investigated (from -0.20 to 0.50 V *vs.* SCE), then a peak-shaped curve up to $+0.30$ V; after that the response increased with more positive potentials. All these carboxylic acids, except glyceric acid, produced similar HDVs in the potential range from -0.50 to 0.40

Fig. 4. Hydrodynamic voltamperograms for 0.24mM gallic acid (▲), 50mM 3,4-dihydroxyphenylacetic acid (▲), 10mM vanillic acid (●), 50mM benzoic acid (×). Experimental conditions as for Fig. 2.

V vs. SCE, exhibiting curves with identical peak potentials of +0.20 V.

Among the phenolic acids (Fig. 4), vanillic acid exhibited HDV behaviour similar to that of glyceric acid, giving anodic currents at poten-

tials more negative than -0.10 V vs. SCE, which decreased very rapidly as potentials became more positive, and then reached a nearly steady level in the potential range from -0.05 to 0.15 V. Gallic acid and 3,4-dihydroxyphenylacetic acid had similar HDV behaviour, exhibiting identical peak potentials -0.10 V, whereas benzoic acid had a peak potential of 0.0 V. The anodic currents of gallic, 3,4-dihydroxyphenylacetic and benzoic acids increased again (at different rates) in the potential range 0.05 – 0.15 V.

Negative peaks would be expected for either a single analyte at different applied potentials or a mixture of analytes at one fixed potential properly selected for flow-through LC detection according to the observed HDVs of the carboxylic and phenolic acids. This unique feature was obtained with the Cu-CME and is shown in Figs. 5–8.

The identification of the actual mechanism for the appearance of negative peaks in flow-through amperometric detection still proved difficult, however. There is no possibility of a catalytic electrode mechanism such as was reported for the detection of polyhydroxy compounds with a Cu-CME in strongly alkaline media,¹⁹ as has been proved by CV experiments [Fig. 1, curve B(3)]. It is worth noting that similar negative peaks were obtained in LC potentiometric detection for organic acids with a metallic copper electrode and neutral phosphate

buffer as mobile phase.¹¹ That response was explained as resulting from the difference in complexation strength between compounds in the mobile phase and the analytes injected. Eluted species may form stronger or weaker copper complexes than do the ligands in the mobile phase, resulting in either an increase or a decrease in the observed electrode potential, hence both positive and negative peaks could be expected. The explanation was based theoretically on the Nernstian relationship between the copper electrode potential and the total ligand concentration under conditions where formation of a single complex species of copper with the analyte ligand predominated. Any explanation based on the Nernstian relationship is not applicable to the detector response in flow-through amperometric detection. Alternatively, there is a possibility that the response of a Cu-CME in flow-through amperometric detection resulted from the difference in the solubility

of compounds formed between the components in the mobile phase or the analyte ligands present in the injected sample with Cu(I) or Cu(II) (depending on the applied potential) produced at the electrode surface. Eluted species may form more or less water-soluble copper complexes than do the components of the eluent, increasing or decreasing the copper concentration at the electrode surface and, thereby, the current observed for copper oxidation, resulting in amperometrically negative or positive peaks.

The flexible dependence of the detector response on the operating potential could be a unique and critical characteristic of the Cu-based CME in flow-through amperometric detection for carboxylic and phenolic acids and, if properly utilized, could be of great benefit in LCEC detection both qualitatively and quantitatively. In the case where a single compound is concerned, oxalic acid for example, different working potentials can serve different purposes

(Fig. 5A): $+0.20$ V *vs.* SCE is obviously the proper selection for conventional LCEC detection of the carboxylic acids, with high sensitivity. If oxalic acid is the compound of interest, the selection of -0.20 V, at which there is a distinct negative peak, would enable it to be distinguished from other eluted species (Fig. 6A), making chromatographic speciation and quantification easier. If oxalic acid is regarded as an interfering species, however, it is advantageous to operate the LCEC detection at -0.15 V *vs.* SCE if possible. For mixtures of the five analytes, operating at -0.10 V *vs.* SCE results in conventional chromatograms with amperometric detection. When glyceric acid is the species of interest, it could be clearly recognized at a working potential of $+0.20$ V (Fig. 6C).

It is worth noting that the higher applied potential did not necessarily increase the current response with a Cu-CME for LCEC detection of organic acids, unlike the case for amino-acids with metallic copper electrodes.^{15,17} In some cases, for example, the LCEC detection of carboxylic acids at modest positive potentials, $+0.40$ V (Fig. 6B), resulted only in a decrease in detector response, except for citric acid, compared with that obtained at -0.10 V (Fig. 6D), as well as an increased background current.

This flexible dependence, on electrode potential, of the detector response for phenolic acids,

Fig. 7. Chromatograms of 10mM vanillic acid at the Cu-CME with applied potential of -0.15 (A), -0.10 (B), 0.0 (C) V *vs.* SCE. Chromatographic conditions as for Fig. 6.

Fig. 8. Chromatograms of 0.24mM gallic acid (1), 50mM 3,4-dihydroxyphenyl acetic acid (2), 10mM vanillic acid (3), 50mM benzilic acid (4) at the Cu-CME with applied potentials of -0.15 (A) and 0.0 (B) V *vs.* SCE. Flow conditions as for Fig. 6.

which are conventionally electroactive at oxidation potentials above 0.60 V *vs.* SCE in neutral media and electro-inactive in the potential range investigated (from -0.15 to $+0.15$ V *vs.* SCE) on a bare glassy-carbon electrode, could be used in different ways for various requirements. As can be seen from Fig. 8, selective detection of 3,4-dihydroxyphenylacetic and vanillic acids in the presence of gallic and benzilic acids could be realized by employing a working potential of -0.15 V *vs.* SCE (Fig. 8A); the selection of 0.0 V enables vanillic acid to be distinguished from the others, making the facile chromatographic speciation and quantification of vanillic acid practical. It should be noted that this unique feature would never be observed in conventional LCEC sensing of phenolic acids with a bare glassy-carbon electrode.

Flow-rate dependence. The dependence of the detector response on the flow-rate of the mobile phase was studied for oxalic and other organic acids and is shown in Fig. 9 (for oxalic acid at $+0.15$ V *vs.* SCE). It is clear that the response always decreased with increasing flow-rate, contrasting sharply with conventional LCEC detection with unmodified electrodes.^{21,22} This suggests that the detector response is controlled entirely by the kinetics of the reaction with copper ions. In conventional LC systems, the choice of flow-rate involves a compromise between the detector sensitivity and the sample throughput. In this work, for example, a typical flow-rate of 0.5 ml/min was used throughout. This flow-rate dependence is especially

advantageous for compatibility with microbore HPLC, high sensitivity being attained at rather low flow-rates of the mobile phase.

Dependence on pH. It was found that the Cu-based CME could perform effectively in neutral and alkaline media (pH 7.0–11) for LCEC detection of carboxylic and phenolic acids. Lowering the pH of the mobile phase made the detector less efficient. As shown in Fig. 10, the detector gave smaller and broader current responses at pH 6.0 (except for glyceric acid) than those obtained at pH 7.0.

This pH-dependence, similar to that of metallic copper electrodes for organic acids,^{14–17} turned out to be somewhat less limiting than that previously observed with Pt and Au electrodes in PAD mode^{4–8} and Cu-based CMEs for the catalytic detection of polyhydroxy compounds,^{18,19} which functioned well only down to 0.001 M hydroxide concentration. The ability of the Cu-based CME constructed in this work to function at much lower pH values was important because it allowed greater freedom for the selection of an effective chromatographic system.

Difference between pH values for separation and detection. Although the pH-dependence of the Cu-based CME was found less limiting there was still a difference between the pH values for optimal reversed-phase chromatographic separation and amperometric detection of the organic acids studied: the former required low pH values (typically 2.0–3.0) and the latter pH > 6.0. With a pH 7.0 mobile phase in reversed-phase LC systems with ODS columns carboxylic acids were eluted with nearly identical retention times of *ca.* 1.5 min and the phenolic acids were eluted close together in the range 2–2.5 min. A possible means of resolution might be the use of ion-pairing to suppress the ionization of the

Fig. 9. Effect of the mobile-phase flow-rate on the FIA response for 1mM oxalic acid at the Cu-CME. Experimental conditions as for Fig. 2.

analytes in neutral media. The first pairing ion tested was TBA⁺ (as tetrabutylammonium perchlorate), which had little effect on the retention of these organic acids under the chromatographic conditions employed throughout this work, with the mobile phase pH > 7.0. Other, more hydrophobic, pairing ions, such as HTA⁺ (as hexadecyltrimethylammonium bromide), increased the retention of these analytes, under the conditions above, but the detector performance was much poorer, which might have resulted from poisoning of the electrode by bromide, as has been reported for a metallic copper electrode.¹⁴

CONCLUSIONS

A copper-based CME has been constructed and used in flow-through amperometric detection of carboxylic and phenolic acids. The dependence of the detector response on the operating potential, the pH and flow-rate of the mobile phase was systematically investigated. A unique potential-peak current relationship in flowing streams was obtained and its potential for analytical applications has been demonstrated. On the basis of all the observations, it is suggested that the detector response is

governed by the reaction of copper ions with the solutes. There is still a difference between the pH values required for optimum separation and detection of these organic acids in reversed phase LC with amperometric detection employing Cu-based CMEs.

A GLASSY-CARBON ELECTRODE MODIFIED BY DISPERSED α -ALUMINA AS AN ENHANCED ELECTROCHEMICAL DETECTOR IN LIQUID CHROMATOGRAPHY FOR CYSTEINE AND GLUTATHIONE

WEIYING HOU and ERKANG WANG*

Laboratory of Electroanalytical Chemistry, Changchun Institute of Applied Chemistry, Chinese Academy
of Sciences, Changchun, Jilin 130022, People's Republic of China

(Received 15 October 1990. Accepted 17 November 1990)

Summary—The dispersion of alumina particles on a glassy-carbon surface serving as a modified electrode significantly enhances the amperometric detection of cysteine and glutathione following liquid chromatography. With an applied potential of 0.8 V *vs.* SCE, the detection limits were 1.2 ng for cysteine and 8 ng for glutathione and the electrode response was linear up to 600 ng for cysteine and 1.8 μ g for glutathione. The modified electrode displayed high sensitivity and stability and was easy and inexpensive to prepare.

Since Zak and Kuwana¹ found that dispersions of alumina particles on glassy-carbon surfaces had electrocatalytic properties for the oxidation of ascorbic acid, catechol, hydroquinone and oxalic acid, few papers²⁻⁶ have dealt with the α -alumina modified electrode. Wang and Freiha⁶ have detected ascorbic acid, epinephrine and oxalic acid at the α -alumina-modified glassy-carbon electrode (α -Al₂O₃/GC) following liquid chromatography and obtained high sensitivity, selectivity and stability.

At most conventional electrodes, cysteine (Cys) and glutathione (GSH) exhibit irreversible oxidation, at extreme positive potentials. Consequently, electrochemical detection of these species following liquid chromatography (LC) is usually performed at mercury⁷⁻¹⁰ or metal amalgam^{11,12} electrodes at which the mercury sulfide species formed can be oxidized at comparatively low applied potentials. Use of mercury electrodes may be undesirable because of their possible toxicity and instability. Carbon electrodes require undesirably large working potentials of the order of 1.0 V *vs.* Ag/AgCl (or higher).¹³ Halbert and Baldwin^{14,15} have developed carbon-paste electrodes containing cobalt phthalocyanine for the determination of Cys and GSH in LC with electrochemical detection (LCEC) at 0.75 V *vs.* Ag/AgCl. Recently, Wring *et al.*^{16,17} have developed a carbon-epoxy resin

composite electrode chemically modified with cobalt phthalocyanine for determination of GSH with LCEC at 0.45 V *vs.* Ag/AgCl.

In this paper we report that the α -Al₂O₃/GC electrode enhances the oxidation of Cys and GSH, giving responses of high sensitivity and stability. The principal advantages of the electrode are its ease of preparation and its stability. The electrode can be used as an inexpensive enhanced LCEC detector.

EXPERIMENTAL

Apparatus

A laboratory-built cyclic voltammetric analyser was used. A three-electrode cell system with either a glassy-carbon (GC) or an α -Al₂O₃/GC working electrode, a silver chloride (saturated potassium chloride) reference electrode and a platinum auxiliary electrode was employed in the conventional electrochemical arrangement.

The LC system consisted of a model 510 pump and a U6K injection valve from Waters Associates. The injection volume was 20 μ l. A Nucleosil C₁₈ (20 cm \times 4 mm i.d.; 7 μ m) column (packed by the Dalian Institute of Chemical Physics, Dalian, China) was used, together with a Model TL-5A thin-layer electrochemical cell (Bioanalytical Systems Inc.). A laboratory-built bipotentiostat was used for the amperometric detection.¹⁸ A saturated calomel reference electrode (SCE) was used.

*Author for correspondence.

Reagents

All chemicals were of analytical-reagent grade, except the following, which were biochemical-reagent grade. Glutathione (reduced form) was from the Shanghai Institute of Biochemistry, Chinese Academy of Sciences. DL-Cysteine was obtained from the Chemical Factory of Caoyang Second Middle School (Shanghai).

Procedure

All solutions were prepared in doubly distilled water, unless stated otherwise. Immediately before LCEC analysis, DL-cysteine and glutathione were dissolved separately in potassium hydroxide solution, and these solutions were diluted to 5 mg/ml with water and protected from light. Portions of these solutions were diluted to the appropriate concentrations with the mobile phase, 0.2M potassium dihydrogen phosphate (containing 50 μ M EDTA) adjusted to pH 3.0 with phosphoric acid. The flow-rate was 1.0 ml/min.

Electrodes

The α -Al₂O₃/GC electrode was prepared by polishing the GC surface with an aqueous slurry of 0.3- μ M α -alumina on a polishing cloth. The electrode was then rinsed several times with doubly distilled water and used immediately. An ordinary bare GC electrode was obtained by cleaning the polished surface in an ultrasonic bath for 30 min, with frequent changes of doubly distilled water in the bath.

RESULTS AND DISCUSSION

Electrochemical behaviour of Cys and GSH

The electrochemical behaviour of Cys and GSH was studied at GC and α -Al₂O₃/GC working electrodes. The cyclic voltamperograms for the oxidation of Cys and GSH on the GC and α -Al₂O₃/GC electrodes in a conventional electrochemical cell are shown in Figs. 1 and 2, respectively. Each yields irreversible oxidation waves. It is apparent that the response was enhanced, with a slight increase of background current, by use of the α -Al₂O₃/GC electrode. The oxidation waves of Cys and GSH on the α -Al₂O₃/GC electrode showed no obvious peaks.

Liquid chromatography with electrochemical detection (LCEC)

Good separation of the Cys and GSH was achieved with a mobile phase of 0.2M potass-

Fig. 1. Cyclic voltamperograms of cysteine at GC (A) and α -Al₂O₃/GC (B) electrodes. Electrolyte solution, 0.2M KH₂PO₄ (pH 3.0); scan rate, 50 mV/sec; broken line, blank solution; solid line, 1mM cysteine.

ium dihydrogen phosphate (containing 50 μ M EDTA) at pH 3.0 with a flow-rate of 1 ml/min (Fig. 3).

Hydrodynamic voltamperograms (HDVs) were obtained for Cys and GSH at both the GC and α -Al₂O₃/GC electrodes by injecting fixed volumes of the standard solutions and varying the potential between 0.5 and 1.0 V in the electrochemical detection (Fig. 4). At the GC electrode, no response to Cys or GSH was obtained at applied potentials less than 0.7 V. Significant responses were obtained only in high potential regions, and were subject to considerably larger background currents and a greater likelihood of interference. At the α -Al₂O₃/GC electrode, enhanced responses to Cys and GSH were obtained compared with those at the GC electrode. When the applied potential exceeded 0.5 V the oxidation currents of Cys and GSH

Fig. 2. Cyclic voltamperograms of glutathione at GC (A) and α -Al₂O₃/GC (B) electrodes. Electrolyte solution, 0.2M KH₂PO₄ (pH 3.0); scan rate, 50 mV/sec; broken line, blank solution; solid line, 6mM glutathione.

Fig. 3. Chromatograms for 40 $\mu\text{g/ml}$ cysteine (1) and 200 $\mu\text{g/ml}$ glutathione (2), with GC (A) and $\alpha\text{-Al}_2\text{O}_3/\text{GC}$ (B) electrodes as detectors, $E = 0.80\text{ V}$; same mobile phase and flow-rate as for Fig. 4.

were produced. However, the HDVs obtained do not show plateau currents, which is consistent with their cyclic voltamperograms not showing peaks. Operation at high potentials would be disadvantageous for LCEC, because of the higher background current, so a potential of 0.8 V was selected for the detection of Cys and GSH at the $\alpha\text{-Al}_2\text{O}_3/\text{GC}$ electrode. Figure 3 compares chromatograms for a mixture of 40 $\mu\text{g/ml}$ Cys (1) and 200 $\mu\text{g/ml}$ GSH (2) obtained with GC (A) and $\alpha\text{-Al}_2\text{O}_3/\text{GC}$ (B) detectors. It can be seen that the response peaks obtained at the $\alpha\text{-Al}_2\text{O}_3/\text{GC}$ electrode were 14 and 11 times larger for Cys and GSH, respectively, than at the GC electrode at the same potential. At the same time, equal noise levels (peak-to-trough amplitude of about 80 pA) were obtained at the GC and $\alpha\text{-Al}_2\text{O}_3/\text{GC}$ electrodes (not shown).

Fig. 4. Hydrodynamic voltamperograms of 40 $\mu\text{g/ml}$ cysteine (a) and 200 $\mu\text{g/ml}$ glutathione (b) at GC (---) and $\alpha\text{-Al}_2\text{O}_3/\text{GC}$ (—) electrodes. Mobile phase, 0.2M KH_2PO_4 (containing 50 μM EDTA) at pH 3.0; flow-rate, 1 ml/min.

The stability of the $\alpha\text{-Al}_2\text{O}_3/\text{GC}$ electrode was examined by comparing peak currents over a period of operation. The results indicate that the peak currents decreased substantially in the very early stages of the experiment, perhaps because some "loose" particles were washed off by the mobile phase.¹⁶ After about four injections, however, the peak currents became stable. The electrode was washed with doubly-distilled water each day after the LCEC experiments and then stored in water overnight. The peak current was 45% greater than the last on the previous day for Cys and 67% larger for GSH when the electrode was used again, and the peak currents again decreased substantially over four successive injections. We therefore think that the non-oxidizable products of the Cys and GSH oxidations may be adsorbed on the surface of the electrode and poison it. Poisoning was more obvious in the very early stages of each day's experiments and resulted in substantial decrease of the peak currents. The first four injections each day were therefore routinely disregarded. Eight replicate injections of the standard solution containing 10 $\mu\text{g/ml}$ Cys and 50 $\mu\text{g/ml}$ GSH were made over 50 min; the coefficients of variation for the peak currents were 1.6% for Cys and 2.1% for GSH. The stability of the response for eight measurements of 10 $\mu\text{g/ml}$ Cys and 50 $\mu\text{g/ml}$ GSH during an unbroken period of 3 hr at a flow-rate of 1 ml/min was examined: the coefficients of variation for the peak currents were 4% for Cys and 6.1% for GSH. When the $\alpha\text{-Al}_2\text{O}_3/\text{GC}$ electrode was used for three days, the LCEC system being washed with water after each day's experiments, no obvious decrease of activity was observed. These results indicate that the alumina particles remaining at the electrode surface maintain their activity over long periods of time, despite the vigorous hydrodynamic conditions prevailing in the narrow channel.

Calibration graphs were linear for injected amounts of Cys from 600 ng down to 1.2 ng (9.9 pmole) and of GSH from 1.8 μg down to 8 ng (26 pmole). The lowest amounts cited yielded S/N ratios of approximately 3 and thus represented the detection limits. The correlation coefficients were 0.9999 for Cys and 0.9994 for GSH and the slopes of the calibration graphs were 172 pA/ng for Cys and 28 pA/ng for GSH.

In conclusion, the experiments described above clearly indicate that the α -alumina-modified glassy-carbon electrode is very promising for use in LCEC of Cys and GSH and

performs with high sensitivity and selectivity. The main advantage of the alumina-modified electrode over the usual CMEs formed by adsorption, covalent attachment, polymer coating *etc.* is that it is easy to prepare, inexpensive, and very stable. In addition, it is apparent that the use of CMEs offers the possibility of extending LCEC techniques to Cys and GSH, which otherwise are poorly suited to electroanalysis.

NITRON TETRACHLOROAUROATE(III) ELECTRODES WITH POLY(VINYL CHLORIDE) AND LIQUID MEMBRANES FOR THE SELECTIVE DETERMINATION OF GOLD

SAAD S. M. HASSAN*

Department of Chemistry, Faculty of Science, Ain Shams University, Cairo, Egypt

EMAN M. ELNEMMA and MARAWAN A. HAMADA

Department of Chemistry, Faculty of Science, Qatar University, Doha, Qatar

(Received 14 November 1989. Revised 9 July 1990. Accepted 26 October 1990)

Summary—PVC matrix and liquid membrane electrodes have been developed for direct potentiometric determination of gold(III). The membranes incorporate nitron tetrachloroaurate(III) as electroactive material. Fast response for gold(III) over the concentration range 10^{-5} – $0.1M$, with response slopes of 52.8–55.2 mV/decade is obtained. The electrodes show good selectivity for gold(III) at pH 2–5 in the presence of many anions and cations. The PVC membrane electrode offers the advantages of greater selectivity (except for Cr^{3+} , Mn^{2+} and ClO_4^-) and higher thermal stability. The liquid membrane electrode gives a higher response slope and faster time of response than the PVC membrane electrode. Determination of $AuCl_4^-$ over the range 2 $\mu g/ml$ –2 mg/ml shows an average recovery of 98.5% and a mean standard deviation of 1.0%. Determination of gold in some gold alloys (58.3–99.9% Au) and pharmaceutical preparations gave an average recovery of 99.4% and a mean standard deviation of 0.7%, which are comparable with the performance obtained with the spectrophotometric Malachite Green and gravimetric U.S. Pharmacopeia methods.

Membrane electrodes responsive to gold(III) have been based on the ion-association complexes of dicyanoaurate(I),^{1,5} and tetrachloroaurate(III)^{3,5-13} with trinonyloctadecylammonium,^{1,2} Methylene Blue,⁵ Malachite Green,⁵ Butylrhodamine B,^{6,7} tetradecylphosphonium,³ tetraphenylarsonium,^{3,4,8,9} hexadecylpyridinium,¹⁰ tetraphenylpyridinium,¹¹ benzyldimethyloctadecylammonium,¹² and hexadecyltrioctylammonium¹³ cations, as electroactive materials dispersed in lipophilic solvents^{1,2,4,5} and polymeric matrices.^{3,6-13} All but one of these reports, however, were originally published in Russian and Chinese, which makes it difficult to obtain detailed information about the performance characteristics of these sensors. It appears, however, that some of these electrodes have long response time, or are inapplicable for monitoring gold(III) concentrations below $10^{-4}M$,^{3,5} or suffer from serious interference by Ag^+ , Bi^{3+} , Tl^{3+} , ClO_4^- , I^- and PO_4^{3-} ions.^{1,2,5,11,12}

Membrane electrodes for SCN^- ,¹⁴ ReO_4^- ,¹⁵ ClO_4^- ,¹⁶ and BF_4^- ,¹⁷ based on the use of nitron as a counter-cation in the electroactive materials, have some significant advantages for the determination of these ions in terms of fast response, and high stability and selectivity.

In the present investigation the nitron-tetrachloroaurate(III) ion-pair complex was prepared and characterized. The high stability of this complex and its extractability into lipophilic solvents, as well as its good selectivity, suggested its use as an electroactive material in liquid and poly(vinyl chloride) matrix membrane electrodes. The performance characteristics of these electrode systems have been evaluated according to IUPAC recommendations¹⁸ and compared. Both electrodes display fast linear response for 10^{-5} – $0.1M$ gold(III) over the pH range 2–5 without interference by many anions and cations. The membranes of these electrodes show remarkable stability towards high temperatures and γ -radiation. Determination of gold in some pharmaceuticals and alloys by the electrodes gave results in fairly good agreement with those obtained by the standard methods.

EXPERIMENTAL

Apparatus

Potentials were measured with an Orion pH/mV meter (Model SA 720) and a nitron tetrachloroaurate(III) liquid or poly(vinyl chloride) membrane electrode in conjunction with an Orion Ag/AgCl double-junction reference

*Author for correspondence.

electrode (Model 90-02) with its outer chamber filled with 100-mg/ml potassium nitrate solution. All measurements were made at $25 \pm 1^\circ$ unless otherwise specified. All pH adjustments were monitored with an Orion combination pH electrode (Model 91-02). The conductivity of nitron tetrachloroaurate(III) solution in nitrobenzene was measured with a Tacussel conductivity cell (Type CM 0.05/G) and Prolabo conductivity meter (Type CD 6N). A gamma cell 220 (Atomic Energy of Canada Ltd.) was used for irradiation of the PVC membranes. The infrared spectra were taken with a Pye Unicam SP 3-100 infrared spectrometer.

Reagents

Wherever possible, analytical-reagent grade chemicals and doubly distilled demineralized water were used. Nitrobenzene, tetrahydrofuran, dioctyl phthalate, chloroauric acid and poly(vinyl chloride) were obtained from B.D.H. Chemicals Ltd. (Poole, England). Nitron was purchased from Pfaltz and Bauer (Waterbury, CT, U.S.A.). A 0.1M gold(III) solution was prepared from chloroauric acid in $10^{-3}M$ hydrochloric acid and standardized iodometrically by the standard method.¹⁹ Dilute solutions (10^{-6} – $10^{-2}M$) were prepared by appropriate dilutions with $10^{-3}M$ hydrochloric acid. *Aqua regia* was prepared by mixing concentrated nitric and hydrochloric acids in 1:3 ratio, and diluted with an equal volume of demineralized water. Certified gold alloys were used.

Nitron-tetrachloroaurate(III) ion-pair complex

Twenty ml of $10^{-2}M$ nitron solution in 20% acetic acid and 10 ml of $10^{-2}M$ chloroauric acid were mixed and stirred for 15 min. The brown precipitate was filtered off with a porosity-3 sintered-glass crucible, washed with demineralized distilled water, dried at room temperature and ground (melting point 153°). The elemental analysis agreed with the composition $[C_{20}H_{17}N_4^+][AuCl_4^-]$.

Nitron tetrachloroaurate(III) PVC membrane electrode

PVC (0.35 g), 0.86 g of dioctyl phthalate and 0.023 g of nitron tetrachloroaurate(III) were dissolved in about 7 ml of tetrahydrofuran. The mixture was poured into a Petri-dish (~ 7.5 cm diameter), covered with a filter paper and allowed to stand overnight. Sections of the resulting membrane were cut out with a cork borer and used as described by others.^{20,21} A platinum

wire (~ 0.5 mm diameter) soldered on to a shielded cable was used as an internal reference electrode. A solution (pH 3–4) containing chloroauric acid and sodium chloride, each at a concentration of $10^{-3}M$, was used as an internal reference solution.

Nitron tetrachloroaurate(III) liquid membrane electrode

An Orion liquid membrane electrode body (Model 92) was used in conjunction with an Orion porous membrane (92-81-04). The internal Ag/AgCl reference electrode was replaced by a platinum wire (~ 0.5 mm diameter) soldered on to a shielded cable. The internal reference solution was a mixture of equal volumes of $2 \times 10^{-3}M$ sodium chloride and $2 \times 10^{-3}M$ $AuCl_4^-$, at pH 3–4. The liquid membrane was $10^{-2}M$ nitron tetrachloroaurate(III) solution in nitrobenzene.

Performance of the electrode systems

The electrodes were conditioned by soaking for 24 hr in approximately $10^{-3}M$ $AuCl_4^-$ and stored in the same solution when not in use. They were washed thoroughly with doubly distilled demineralized water between measurements. Calibration was done by measuring the potential yielded by 10^{-6} – $0.1M$ $AuCl_4^-$ solutions (pH 3–4) when the readings were stable within ± 1 mV.

The selectivity coefficients ($k_{Au, B}^{pot}$) were evaluated by the separate solution method^{18–20} with $10^{-2}M$ solutions of the interferent and $AuCl_4^-$ at pH 3–4. For cationic interference studies the metal chlorides were used (except for silver and lead, used as their nitrates). For anionic interference studies, sodium or potassium salts were used. All potential measurements for response curves and selectivity coefficients were made in triplicate.

The response times were taken as the times required for the electrodes to reach values within 1 mV of the final equilibrium potential when transferred from one tetrachloroaurate(III) solution to another differing from it in concentration by a factor of 10.

The detection limit was evaluated as the concentration giving an emf differing by 18 mV from the extrapolation of the linear section of the calibration graph.

Determination of gold in alloys

A 0.1–0.2 g sample was heated with ~ 3 ml of *aqua regia* in a 50-ml beaker, covered with a

watch-glass, until the evolution of nitrogen oxides ceased. The solution was evaporated almost to dryness. The residue was dissolved with ~25 ml of $10^{-3}M$ hydrochloric acid. The solution was adjusted to pH 3–4, transferred to a 50-ml standard flask and made up to the mark with $10^{-3}M$ hydrochloric acid, and 5 ml of this solution was diluted to volume with $10^{-3}M$ hydrochloric acid in another 50-ml standard flask (alternatively the original residue solution could be diluted directly to 500 ml). The potential given by the solution was measured with the nitron tetrachloroaurate(III) PVC matrix membrane electrode in conjunction with the double-junction Ag/AgCl electrode and the gold concentration was read from a calibration graph covering the range 10^{-4} – $10^{-2}M$. The spiking technique²¹ was used, the potential of the gold test solution being measured before and after addition of 0.50 ml of standard $0.1M$ $AuCl_4^-$ solution.

Determination of gold in pharmaceutical preparations

The contents of three ampoules of gold-containing pharmaceutical preparations were diluted to 10.0 ml with doubly distilled water and filtered. A 2-ml aliquot of the filtrate was transferred to a 50-ml Kjeldahl flask and treated with ~5 ml of concentrated nitric acid, followed by slow addition of 5 ml of concentrated sulphuric acid. The solution was gently heated on a hot plate until evolution of sulphur trioxide fumes. The flask was allowed to cool to room temperature, and the residue was dissolved in ~5 ml of *aqua regia* and heated again almost to dryness. The residue was dissolved in ~25 ml of $10^{-3}M$ hydrochloric acid and adjusted to pH 3–4. The solution was then transferred to a 50-ml standard flask and diluted to the mark with $10^{-3}M$ hydrochloric acid. The potential of the solution was measured with the PVC membrane electrode as described above.

RESULTS AND DISCUSSION

Response characteristics of the electrodes

The liquid membrane had electrical resistance of $7 \times 10^3 \Omega$ and an equivalent conductivity (Λ) of $1.95 \text{ ohm}^{-1} \cdot \text{mole}^{-1} \cdot \text{cm}^2$. The PVC membrane was prepared by using a casting solution of the composition 28:2:70 w/w PVC, nitron-tetrachloroaurate(III) complex and dioctyl phthalate plasticizer, respectively. Table 1 summarizes the response characteristics of both

Table 1. General performance characteristics of nitron tetrachloroaurate(III) liquid and PVC membrane electrodes

Parameter	Liquid membrane	PVC membrane

Response time for $10^{-3}M$, <i>sec</i>	20	30
Working acidity range, <i>pH</i>	1.5–5	1.5–5

electrode systems, from data collected over a period of 2 months for 4 different electrode assemblies. Similar results, but with the potential values 5 mV less negative were obtained with standard $AuCl_4^-$ solutions prepared in hydrochloric acid (pH 3–4) containing $0.1M$ sodium chloride.

Response time and stability

The response times of both electrodes were 10–30 sec for $\geq 10^{-3}M$ $AuCl_4^-$ and 20–60 sec for $\leq 10^{-4}M$. The steady-state potentials were attained 10–20 sec more quickly with the liquid membrane electrode than the PVC matrix membrane. For both electrodes the average change in potential for five consecutive measurements of standard 10^{-5} – $10^{-1}M$ $AuCl_4^-$ solutions during 2 hr was not more than 1.8 mV. Changes in the calibration slopes did not exceed ± 0.5 mV/decade. The long term reproducibility and stability of the potentials were evaluated by preparing 10 calibration graphs for both electrodes over a period of 2 weeks. During this period, the electrodes were stored and conditioned in $10^{-3}M$ $AuCl_4^-$ solution and washed with doubly distilled demineralized water between measurements. Although the absolute potentials of the electrodes became more positive by 4–8 mV, the slopes of the calibration graphs remained practically constant within ± 1 mV/decade over this period. No significant changes in the detection limit, selectivity coefficients and response time were observed.

Effect of pH

Standard 10^{-3} and $10^{-4}M$ $AuCl_4^-$ aqueous solutions were prepared and adjusted to various pH values in the range 0–10 with dilute hydrochloric acid and sodium hydroxide solution. Figure 1 revealed that within the working pH range 2–5, the potential given by both electrodes did not vary by more than ± 1 mV. The negative shift of the potential at pH below 1.5 is due to a change in the boundary phase of

Fig. 1. Effect of pH on the potential response of nitron tetrachloroaurate(III) electrodes: ●, PVC membrane; ○, liquid membrane.

the membrane caused by the increased acid concentration at the membrane surface. The sharp increase of potential at pH above 5 is due to the decrease in AuCl_4^- concentration and formation of AuCl_3 followed by $\text{Au}(\text{OH})_3$.²² These species are not sensed by the anionic membrane sensors. At pH above 8, the membrane behaviour is influenced by the hydroxide concentration, a phenomenon observed with all membranes containing nitron as counter-cation.¹⁴⁻¹⁷ It is therefore necessary to adjust the gold test solution to pH 3-4 with hydrochloric acid before measurement of the potential.

Effect of foreign ions

The responses of the electrodes to 21 different cations and anions were studied by measuring the selectivity coefficients ($k_{\text{Au}, \text{B}}^{\text{pot}}$) by the separate solutions method,^{20,21} with fixed concentration of the interferent (10^{-2}M), at pH 3-4. The selectivity coefficients are shown in Table 2. The selectivity of the liquid membrane electrode for AuCl_4^- is generally lower than that of the PVC matrix membrane electrode, but it shows better selectivity than the PVC membrane electrode in the presence of Cr^{3+} , Mn^{2+} and ClO_4^- ions.

The selectivity coefficient data for most of the previously described electrode systems have not been reported, so it is difficult to make quanti-

Table 2. Potentiometric selectivity coefficients for nitron tetrachloroaurate(III) liquid and PVC membrane electrodes

ClO_4^-	1.0×10^{-2}	5.5×10^{-3}

tative comparisons with the present data. It should be noted, however, that Fe^{3+} , Hg^{2+} , Cu^{2+} , Ni^{2+} , Cr^{3+} , Ag^+ , Ti^{3+} and ClO_4^- ions which are major and serious interferences even at low concentrations in many of the standard spectrophotometric,²³ potentiometric,^{1,2,5,11,12} and anodic stripping voltammetric²⁴ procedures, have little influence on the response of the present electrode systems. The concentrations of these ions must be at least 100 times that of the gold before significant interference is observed. Separate studies for determination of 10^{-2}M AuCl_4^- in the presence of up to 100-fold concentrations of some cations of alloying elements commonly associated with gold, such as Ag^+ ,

21 carat	87.5	87.0 ± 0.6	99.4	86.8 ± 1.1	99.2
18 carat	75.0	74.6 ± 0.9	99.5	74.3 ± 1.2	99.1
14 carat	58.3	57.6 ± 0.9	98.8	57.4 ± 1.3	98.5

*Average ± standard deviation of 5 measurements.

Cu²⁺ and Cd²⁺, showed minimal interferences. The average recovery of gold ranged from 96 to 102% with a standard deviation of 2% ($n = 5$).

Effect of temperature and γ -radiation

A gradual increase in the potential values was observed as the temperature was increased from 20 to 50°, but there was no significant variation in the limit of detection, response time, and slope of the calibration graph. The temperature coefficients of the potential were 0.25 and 0.5 mV/deg for the PVC and liquid membranes, respectively.

Electrodes incorporating PVC matrix membranes that had been exposed to 10³, 10⁵ and 10⁷ rad doses of cobalt-60 γ -rays gave essentially the same slope and linear response range as those made with the non-irradiated membranes, but gave faster response times. A shift of the response curve by +5 mV was observed for membranes irradiated with a dose of 10⁷ rad. The infrared spectrum of a pure sample of solid nitron-tetrachloroaurate(III) complex was almost the same before and after irradiation with up to 10⁸ rad, indicating high stability of the electroactive material.

Determination of gold in alloys

The accuracy and reliability of the results obtained with the electrodes were tested by measuring the concentrations of 2–2000 $\mu\text{g/ml}$ standard AuCl₄⁻ solutions by the standard-

addition (spiking) technique.²¹ The average recovery (Table 3) was 98.5% and the mean standard deviation 1.0%. The method was also applied to determination of gold in some certified gold-base alloys. Table 4 presents the results.

The average recovery was 99.4% of the certified value and the mean standard deviation was 0.7% ($n = 5$). For the same alloys the spectrophotometric Malachite Green method gave an average recovery of 99.1% and a mean standard deviation of 1.1% ($n = 5$) which agreed fairly well with the results obtained by the electrode method.

Determination of gold in pharmaceutical preparations

Gold in some pharmaceuticals commonly used in the treatment of rheumatoid arthritis was determined as described above. The results obtained (Table 5) show an average recovery of 99.8% of the nominal gold content and a mean standard deviation of 0.6%, in agreement with results obtained by the gravimetric method recommended by the U.S. Pharmacopeia²⁵ (average recovery 99.7%, mean standard deviation 0.6%).

In conclusion, the present electrode systems offer at least three main advantages over many of those previously reported, which suffered from a higher limit of detection,^{3,5} or slower response time and lower selectivity,^{1,2,5,11,12} Of

Table 5. Determination of gold in some pharmaceutical preparations by potentiometry with the PVC membrane electrode and gravimetrically by the U.S. Pharmacopeia method

Sample, trade name and source	Nominal content, mg/ampoule	Recovery,* %	
		Electrode method	USP method
Sodium aurothiomalate	10	99.5 ± 0.6	99.8 ± 0.5

Sodium aurothiosulphate	50	99.8 ± 0.7	99.5 ± 0.8
Sanocrysin (Ferrosan, Denmark)	100	100.1 ± 0.6	99.9 ± 0.7

*Average ± standard deviation of 5 measurements.

the present electrodes, the liquid membrane electrode has the advantages of higher calibration slope and shorter response time, but the PVC membrane electrode displays higher selectivity (except in the presence of Cr^{3+} , Mn^{2+} and ClO_4^-) and higher thermal stability.

BOOK REVIEWS

Multielement Detection Systems for Spectrochemical Analysis: K. W. BUSCH and M. A. BUSCH, Wiley, New York, 1990. Pages xxi + 688. £70.00

This book should be of interest to analytical scientists involved with the design, development or operation of multi-channel spectrometers. Most texts on spectrochemical analysis concentrate on applications of the techniques and give little coverage to the fundamental design of the instruments. With this in mind, Ken and Marianna Busch have endeavoured to produce a textbook which considers, in some detail, the principles of the optical systems and detectors employed in a variety of multi-channel instruments operated primarily in the UV-visible wavelength region. The book is intended for graduate students in analytical spectroscopy and researchers in other disciplines who use optical spectroscopy for chemical analysis. The authors have tried to simplify the mathematical explanation of fundamental optical principles (*e.g.*, in Chapters 2 and 3), but I think that they are being somewhat optimistic when they suggest that the mathematical level "should be comprehensible to readers with an undergraduate background in chemistry or related science". Perhaps chemistry graduates in the USA are required to know more mathematics than students taking equivalent courses in some UK and European universities!

The book has essentially three parts. Chapters 1-7 deal with optical principles, Chapters 8-11 cover various types of detection systems and Chapters 12-15 discuss how optical systems and detectors can be combined to produce multi-channel spectrometers for chemical analysis. I believe that Chapters 2-11 will prove most useful to the majority of readers. Chapter 3 provides a rigorous treatment of the principles of diffraction. Important mathematical derivations and relationships are clearly explained and comprehension is assisted through liberal use of helpful diagrams and optical figures. Anyone who has struggled with the basic principles of transform spectroscopy will find Chapters 5-7 extremely useful. Chapter 5 includes sections on multiplexing and Hadamard transform spectroscopy, Chapter 6 is devoted to the principles of interference and Chapter 7 provides an overview of Fourier transform spectroscopy. Introductions to photoelectronic detection (Chapter 9) and image detectors (Chapter 10) are followed by a discussion of the attributes of solid-state detectors, such as the photodiode array and charge transfer devices, in Chapter 11. This is an area of rapid change, so it is not too surprising that some of the more recent advances in solid-state detectors have not been included in the authors' literature survey, which covers publication up to 1987.

The book has very few weaknesses. Although Chapter 13 provides only a superficial introduction to analytical atomic spectrometry, it contains excellent sections on the role of noise in spectroscopic systems, and the benefits of modulation. In the latter part of the book, some of the tables of analytical data do not indicate the techniques used to obtain the information and this might be considered a minor irritation by some readers. As might be expected, the literature quoted is heavily biased towards US publications or the work of US authors reported in European journals. There is no doubt that many important developments in multi-channel systems have emanated from the USA, but scientists from other locations have also made important contributions and might have expected recognition in such a text. For example, in Chapter 14, devoted to a survey of transform spectrometric systems, the work of Canadian and American scientists in FT-UV spectrometry is discussed in some detail, but there is no mention of equally important research performed by Thorne and colleagues at Imperial College, London.

In general, the authors have been reasonably successful in their attempts to produce a textbook which covers fundamental physical principles and the philosophy of instrument design in multi-element detection systems. For this reason, the book should be a valuable addition to the libraries of analytical chemists, physicists, engineers and anyone concerned with the use of optical spectroscopy in spectrochemical analysis.

D. LITTLEJOHN

Bioluminescence and Chemiluminescence—Studies and Applications in Biology and Medicine: M. PAZZAGLI, E. CADENAS, L. J. KRICKA, A. RODA and P. E. STANLEY (eds.), Wiley, Chichester, 1989. Pages 646. £92.00.

This book represents the Proceedings of the Fifth International Symposium on Bioluminescence and Chemiluminescence held in Bologna, 25-29 September 1988, and is a reprint from Volume 4, 1989, of the Journal of Bioluminescence and Chemiluminescence. The contents of the book are organized into nine main sections covering such topics as bioluminescence in biosystems: detection of low-level chemiluminescence; chemiluminescence associated with phagocytosing leucocytes; instrumentation, biosensors and natural bioluminescence; luminescence assays, including immunoassays, used in measurements of enzyme activity, and their use in the fields of genetic engineering and nucleic acid hybridization. The sections devoted to the use of luminescence assays in the detection and quantification of biomolecules is very topical and coincides with the advent of luminescent procedures which are gradually replacing radiometric methods, particularly in automated assays. The final section of the book is devoted to the proceedings of a variety of workshops on the diverse clinical applications of chemiluminescence techniques.

BOOK REVIEWS

Multielement Detection Systems for Spectrochemical Analysis: K. W. BUSCH and M. A. BUSCH, Wiley, New York, 1990. Pages xxi + 688. £70.00

This book should be of interest to analytical scientists involved with the design, development or operation of multi-channel spectrometers. Most texts on spectrochemical analysis concentrate on applications of the techniques and give little coverage to the fundamental design of the instruments. With this in mind, Ken and Marianna Busch have endeavoured to produce a textbook which considers, in some detail, the principles of the optical systems and detectors employed in a variety of multi-channel instruments operated primarily in the UV-visible wavelength region. The book is intended for graduate students in analytical spectroscopy and researchers in other disciplines who use optical spectroscopy for chemical analysis. The authors have tried to simplify the mathematical explanation of fundamental optical principles (*e.g.*, in Chapters 2 and 3), but I think that they are being somewhat optimistic when they suggest that the mathematical level "should be comprehensible to readers with an undergraduate background in chemistry or related science". Perhaps chemistry graduates in the USA are required to know more mathematics than students taking equivalent courses in some UK and European universities!

The book has essentially three parts. Chapters 1-7 deal with optical principles, Chapters 8-11 cover various types of detection systems and Chapters 12-15 discuss how optical systems and detectors can be combined to produce multi-channel spectrometers for chemical analysis. I believe that Chapters 2-11 will prove most useful to the majority of readers. Chapter 3 provides a rigorous treatment of the principles of diffraction. Important mathematical derivations and relationships are clearly explained and comprehension is assisted through liberal use of helpful diagrams and optical figures. Anyone who has struggled with the basic principles of transform spectroscopy will find Chapters 5-7 extremely useful. Chapter 5 includes sections on multiplexing and Hadamard transform spectroscopy, Chapter 6 is devoted to the principles of interference and Chapter 7 provides an overview of Fourier transform spectroscopy. Introductions to photoelectronic detection (Chapter 9) and image detectors (Chapter 10) are followed by a discussion of the attributes of solid-state detectors, such as the photodiode array and charge transfer devices, in Chapter 11. This is an area of rapid change, so it is not too surprising that some of the more recent advances in solid-state detectors have not been included in the authors' literature survey, which covers publication up to 1987.

The book has very few weaknesses. Although Chapter 13 provides only a superficial introduction to analytical atomic spectrometry, it contains excellent sections on the role of noise in spectroscopic systems, and the benefits of modulation. In the latter part of the book, some of the tables of analytical data do not indicate the techniques used to obtain the information and this might be considered a minor irritation by some readers. As might be expected, the literature quoted is heavily biased towards US publications or the work of US authors reported in European journals. There is no doubt that many important developments in multi-channel systems have emanated from the USA, but scientists from other locations have also made important contributions and might have expected recognition in such a text. For example, in Chapter 14, devoted to a survey of transform spectrometric systems, the work of Canadian and American scientists in FT-UV spectrometry is discussed in some detail, but there is no mention of equally important research performed by Thorne and colleagues at Imperial College, London.

In general, the authors have been reasonably successful in their attempts to produce a textbook which covers fundamental physical principles and the philosophy of instrument design in multi-element detection systems. For this reason, the book should be a valuable addition to the libraries of analytical chemists, physicists, engineers and anyone concerned with the use of optical spectroscopy in spectrochemical analysis.

Bioluminescence and Chemiluminescence—Studies and Applications in Biology and Medicine: M. PAZZAGLI, E. CADENAS, L. J. KRICKA, A. RODA and P. E. STANLEY (eds.), Wiley, Chichester, 1989. Pages 646. £92.00.

This book represents the Proceedings of the Fifth International Symposium on Bioluminescence and Chemiluminescence held in Bologna, 25-29 September 1988, and is a reprint from Volume 4, 1989, of the Journal of Bioluminescence and Chemiluminescence. The contents of the book are organized into nine main sections covering such topics as bioluminescence in biosystems: detection of low-level chemiluminescence; chemiluminescence associated with phagocytosing leucocytes; instrumentation, biosensors and natural bioluminescence; luminescence assays, including immunoassays, used in measurements of enzyme activity, and their use in the fields of genetic engineering and nucleic acid hybridization. The sections devoted to the use of luminescence assays in the detection and quantification of biomolecules is very topical and coincides with the advent of luminescent procedures which are gradually replacing radiometric methods, particularly in automated assays. The final section of the book is devoted to the proceedings of a variety of workshops on the diverse clinical applications of chemiluminescence techniques.

This book is a very timely overview of the mechanisms of chemiluminescence and their use in bioassays, and there is more than ample material within the numerous papers to satisfy the appetites of chemists and biologists alike who have common research interest in this exciting field. As a leucocyte biologist, who monitors the activities of these cells in normal and pathological situations by using luminescent assays, I found this book very stimulating, not only for the section on leucocyte bioluminescence, but also for the extremely interesting papers on the mechanisms of chemiluminescence and the instrumentation and assays used in measurement, all of which are very lucidly written.

The editors are to be congratulated for their endeavours in assembling the Proceedings into this handsome volume which serves not only to honour Professor William McElroy, whom many consider to be the father of bioluminescence, but also as a very fitting dedication to the memory of Marlene DeLuca who, along with Professor McElroy, has been an important contributor to our understanding of the biochemistry of bioluminescence reactions. I am confident this book will enjoy wide readership among senior undergraduates, postgraduates and active scientific and clinical researchers in the field of bioluminescence and chemiluminescence. Only the price will limit the number of purchasers, but all good scientific and clinical libraries should stock this book.

R. G. P. PUGH-HUMPHREYS

HPLC of Biological Macromolecules—Methods and Applications: K. M. GOODING and F. E. REGNIER (eds.), Dekker, New York, 1990. Pages xiii + 676. \$150.00 (U.S. and Canada), \$180.00 (elsewhere).

Before I opened this book I had expected from the title a balance between sections on experimental methods and the applications of HPLC to proteins, polynucleotides and carbohydrates. However, on examining the contents pages I was struck immediately by the fact that it is heavily biased towards proteins. I suppose it is a reflection of both the variety and importance of this particular class of macromolecule that proteins take first place in this book.

The book is divided into three parts. Part 1 (nine chapters) deals with the technique of HPLC, Part 2 (thirteen chapters) with polypeptides and Part 3 (1 chapter) with polynucleotides. I should add that carbohydrates are not completely left out in the cold, because Chapter 21 deals with glycoproteins, *i.e.*, proteins with covalently bound sugars.

In Chapter 1 various properties of silica as a support are examined. Chapter 2 is a description of various forms of organic supports while Chapter 3, which deals with size exclusion chromatography (SEC) begins by considering the confusion which has arisen in the literature by the use of the alternative terms "gel filtration" and "gel permeation chromatography." A useful chapter on ion-exchange chromatography—mainly for protein separation—is followed by one on hydrophobic interaction chromatography (HIC) with a nice balance of theoretical and practical aspects. Chapter 6, a well referenced chapter, deals with reverse-phase chromatography with a section on tryptic maps.

Metal interaction chromatography is the subject of Chapter 7. In this technique retention and separation of sample components are achieved largely by interaction with chelated metal ions. Sample preparation is the topic of the next chapter, and Chapter 9 rounds off Part 1 by dealing with the principles of gradient elution separations. Chapter 10 looks at the application of HPLC to amino-acid analysis and protein-sequence analysis.

Because enzyme purification is of immense importance to biochemists it is fitting to find a chapter on preparative enzyme purification by HPLC. Judging by the number of publications in this field in recent years the method promises to be of central importance in the near future.

In a chapter describing ribosomal protein separation, computer simulation is detailed, which allows separation patterns in complex chromatograms to be predicted, thus enabling the design of multistep gradients to maintain high resolution.

When it is realized that HPLC can cut down the time required for antibody purification from several weeks to a few hours it is not surprising that there is growing interest in this particular application. This is reflected in a chapter on the HPLC of antibodies, which is well referenced. Another chapter focuses on the application of size exclusion chromatography to the study of molecular interactions; methods for both ligand-protein and protein-protein binding are considered.

Part 2 concludes with a chapter on the application of HPLC to the assay of enzymatic activities; to date nearly one hundred enzymatic activities have been assayed by this method. Part 3 is concerned with the resolution of oligonucleotides and transfer RNAs where the advantages of speed and resolution, compared with those of the still widely used conventional methods, are amply demonstrated. Topics covered by other chapters include the HPLC of peptides, isoenzymes, membrane proteins, human haemoglobin variants, cereal endosperm storage proteins, histone and glycoproteins.

The book has well over a thousand references, about forty tables and is well illustrated with over two hundred figures. The chapters complement each other admirably. It is a source of up-to-date information on techniques and applications which will serve as an invaluable practical guide to anyone who is engaged in the HPLC of biological macromolecules.

dictionaries). Though the main purpose is obviously the provision of accurate German equivalents of English terms, a minor benefit may be the opportunity afforded for checking translation of German neologisms or author-constructed terms into English, by back-translation into German with the aid of this dictionary, and consequent avoidance of translation errors such as the legendary English–Swahili dictionary rendering of “out of sight, out of mind” as “invisible idiot”. It is to be hoped that a new edition of the corresponding German–English Dictionary of Chemistry and Chemical Technology will soon be available.

R. A. CHALMERS

Pore Size Engineering in Zeolites: E. F. VANSANT, Wiley, Chichester, 1990. Pages xi + 145. £24.95.

Separation science has benefited greatly from the application of zeolites. Zeolites are crystalline aluminosilicates, the open architecture of which gives rise to regularly repeated internal spaces or pores which serve as molecular sieves. The diffusion pathways giving access to these pores normally increase in size in steps. However, chemists have learned to fine-tune the entry size by a variety of methods, and these are the subject of the title of the book. Amongst the methods described are modification of the framework itself, by silanation, boronation, ion-exchange, implantation, and pre-adsorption of polar molecules.

The author is well-qualified to write this book; he and his group have been leaders in the field. However, it is necessary to express some reservations about the content, level and physical production of the book. The contents read like a collection of research papers strung together; specialists might as well read the originals and beginners will gain little appreciation of the subject. The references are inadequate; excluding the historical and standard reference books, they number less than 30. The book production is sub-standard; the text seems not to have been properly edited or proofread. Although the type face is legible, it is difficult to read because the spacing between words varies widely: indeed it is often non-existent.

ANALYTICAL APPLICATIONS OF 1,10-ANTHRAQUINONES: A REVIEW

AURORA NAVAS DIAZ

Department of Analytical Chemistry, Faculty of Sciences, University of Málaga, 29071-Málaga, Spain

(Received 7 March 1988 Revised 19 November 1990 Accepted 24 January 1991)

Summary—Analytical aspects of the chemistry in solution of 1,10-anthraquinone (AQ) derivatives is reviewed. The information about photometric and fluorimetric determination of inorganic species has been condensed and presented in tabular form.

Although technological advances in instrumentation have shifted the emphasis of analytical research towards improvement of methods by means of new and more powerful instruments or by modification of the instrumental configuration, the principle of chemical analysis still remains chemical reaction between the substance to be determined and an auxiliary substance to be added, the reagent. The extensive but widely dispersed amount of information on reaction chemistry makes a comprehensive and sufficiently critical review of great value for choosing a reagent for a particular application.

This review deals with anthraquinone (AQ) derivatives, a group of reagents widely used in analytical chemistry, but not hitherto surveyed.

The chemistry of anthraquinones has received much attention¹⁻⁵ because of its relevance to some important technological processes. Anthraquinone derivatives have also been widely used in analytical chemistry, mainly as strong chelating agents and chromophores. The major focus of this paper is on their optical properties, which are extensively used in analytical practice, mainly photometry and fluorimetry, and in the study of acid-base, redox, complexation and photochemical reactions. These compounds also display interesting electrochemical behaviour but its analytical use is more limited.

The basic chemical structure of anthraquinones is shown in Fig 1, with the position and nomenclature of the substituents. The trade names used by the dyestuff manufacturers can be obtained from the Colour Index⁶ and the chemical structures and properties can be found in the book by Venkataraman.¹

In dyes obtained by chemical synthesis, only substances which have formed during manufac-

ture, together with small amounts of electrolytes obtained during neutralization, will appear. In the commercial dyes different types of impurities may be present.⁷ Separation of anthraquinone dyes has been discussed¹ and various chromatographic procedures are available for analytical⁷⁻¹² and preparative scale^{13,14} separations.

The properties of anthraquinone and its derivatives that are of main interest in analytical chemistry are related to their spectral features. Theoretical and experimental studies of the absorption¹⁵⁻²⁵ and emission²⁵⁻³⁰ electronic spectra have been reported. The spectral characteristics of AQ compounds are related to the molecular structure and to the nature and relative positions of the electronic states. AQ is characterized by the electronic states S_0 , T_{n,π^*} , T_{π,π^*} , S_{n,π^*} , S_{π,π^*} . The weak long-wavelength absorption is due to the S_{n,π^*} transition. Phosphorescence occurs from the T_{π,π^*} transition. Both transitions are mainly due to the carbonyl group, which ensures minimum energy difference between the lowest excited and ground (S_0) electronic levels.³¹ S_{π,π^*} transitions are responsible for the intense short-wavelength absorptions.^{22,31}

The optical properties of AQ derivatives are modified by various factors: the nature and positions of the substituents, the formation of hydrogen bonds, and other intermolecular and intramolecular interactions. The spectral, photochemical and photophysical properties of the AQs have recently been reviewed.³²

ACID-BASE PROPERTIES

Studies have been made of the effect of pH on the spectra of AQ derivatives, in terms of the acid-base equilibria,³³⁻³⁶ which depend on the nature, number and position of the substituents.

Fig 1 Basic chemical structure of 1,10-anthraquinone

Although the agreement between the various reports of pK_a values is generally quite good, there are some discrepancies, which may be attributed to differences in the solvent system and the method of calculation.

In strong acid media, the nitrogen atom of 1- and 2-aminoanthraquinone is protonated³⁷ and in sufficiently acidic media so are the sulphonic groups in 1,5- and 1,8-dihydroxyanthraquinone-disulphonic acid ($pK_{A_r(SO_3H)H^+} = -6.03$ and -3.90 respectively).³⁸ At $pH < 4-6$ the imino-nitrogen atom in arylaminoanthraquinones is protonated³³

The acidity of a derivative depends on the electron-donor or acceptor nature of the substituent and on the conjugation effects involved

Generally, the pK value for the amino group is higher for the non-sulphonated compounds than the corresponding sulphonated derivatives^{33,34,39-41} This is usually attributed to the inductive effect of the sulphonate group leading to easier ionization of the amino group.

1,4-Diaminoanthraquinone and 1,4-dihydroxyanthraquinone have higher pK_a values than those for the imine groups of Quinizarin Green and its non-sulphonated derivative. For the diaminoanthraquinone this is attributed to the greater electron-donor power of the aryl-amino substituents in the latter compounds, and for the dihydroxyanthraquinones to the effect of intramolecular hydrogen bonding³³ The effect of different substituents can be observed in the pK value of the amino group for some 1-aminoanthraquinone derivatives: for 1-aminoanthraquinone-2-sulphonic acid $pK_a = 3.79$, for 1-aminoanthraquinone-2-carboxylic acid $pK_a = 5.74$, for 1-amino-4-hydroxyanthraquinone $pK_a = 9.10$, and for 1-amino-2-bromo-4-hydroxyanthraquinone $pK_a = 9.93$ ²³

Changes in the position of substitution can affect the pK values. For example, the values for 1-hydroxyanthraquinone are about two units greater than those for the 2-hydroxy compound,³⁵ but the dissociation constants of 1,2-dihydroxyanthraquinone are similar to those of the 2,3-dihydroxy derivative⁴²

Intramolecular hydrogen bonding also affects the acidity of AQ derivatives The markedly higher pK values of the 2- than the 1-derivatives have been attributed to intramolecular hydrogen bonding.¹⁷ Taking as examples alizarin (1,2-dihydroxyanthraquinone) and quinalizarin (1,2,5,8-tetrahydroxyanthraquinone), the hydrogen bond of the 8-hydroxyl group with the carbonyl group should affect the stability of the hydrogen bond of the 1-hydroxyl group with the same carbonyl group, this reduces the basicity of the 1-hydroxyl group.⁴³

In methanol, the amino- and *N*-substituted 2-aminoanthraquinones are markedly more basic than the corresponding 1-amino derivatives. Hydroxyanthraquinones show a similar effect.¹⁷ The basic strength of 1-dimethylaminoanthraquinone is higher than that of either amino- or methylaminoanthraquinone, because in the former the amino group is out of the plane of the aromatic nucleus, so the conjugation is reduced and the group tends to exert its normal basicity.¹⁷

The pK values measured in pure aqueous solutions are mostly higher than those obtained in mixed solvents ($< 40\%$ v/v water/organic solvent), the latter leading to increased ionization,^{33,34,37,44} but pK values have been reported for 1,4-dihydroxyanthraquinone,⁴² 1,8-dihydroxyanthraquinone⁴⁵ and 1,2,7-trihydroxyanthraquinone⁴⁶ in water which are greater than those obtained in mixed solvents ($> 30\%$ v/v water/ethanol).

The ionization of AQ derivatives is influenced by the nature and concentration of the solvent system. The changes in pK_a with organic solvent concentration, though mainly governed by the dielectric constant, are also affected by the solvent basicities^{33,34}

The pK of AQ derivatives increases as the dielectric constant of the medium decreases, e.g., in the presence of high proportions of alcohols,^{33,34,46} acetone^{33,34} or dioxan^{33,47} but decreases with increase in amount of ethylene glycol or glycerol. This is explained on the basis that the latter solvents act as proton-acceptors rather than donors, leading to easier dissociation.^{33,34}

The acidity constants of hydroxy- and aminoanthraquinones in 1.2 v/v dioxan-water are always higher for the excited singlet^{37,48} and triplet⁴⁹ states than for the ground state, but the triplet state constant lies much closer to the ground state value than does that for the singlet state

Some AQ derivatives, mainly the hydroxy-anthraquinones, change colour with pH and have been used as acid–base indicators. For analytical purposes the most suitable transition of HAQs is that between yellow and red. Quinizarin (1,4-dihydroxyanthraquinone) and Alizarin S (1,2-dihydroxyanthraquinone sulphonate) are very good indicators with a colour change quality similar to that of Bromocresol Green; alizarin is also a good indicator but with slightly lower colour change quality, and the colour change of quinizarin (1,2,5,8-tetrahydroxyanthraquinone) is still poorer.⁵⁰

Diaminoanthraquinones, which do not show such marked colour changes with pH as do various aminohydroxyanthraquinones in aqueous medium, have been used as indicators in the titration of weak bases such as urea and sodium acetate, benzoate or salicylate with perchloric acid in glacial acetic acid alone^{51–55} and mixed with other solvents,^{56,57} but are not applicable in the titration of weaker bases with perchloric acid.⁵²

COMPLEXATION REACTIONS

Anthraquinones have long been used as analytical reagents and particularly as chromogenic and fluorogenic ligands for various metal ions.

The co-ordination reactions of AQ derivatives characteristically display moderate selectivity and large absorbance changes.⁵⁸ The absorption and emission properties of these compounds and their complexes give great fluorimetric potential, but the relatively high blank signal and the comparatively small spectral shifts due to complexation impair the analytical performance.⁵⁸

The optical characteristics of the anthraquinone co-ordination compounds are due to intraligand transitions, so the complexation results in modification of only the position of the absorption and emission maxima, and non-fluorescent derivatives do not generate fluorescent complexes. It has been shown that, depending on the acidity, the solvent and the metal ion, the same reagent may give either excellent or poor analytical response.⁵⁹

When a more highly acidic reagent, such as Quinizarin Green in comparison with 1,4-dihydroxyanthraquinone,⁶⁰ is used, the stability of the complexes of the more acidic reagent will be lower than that of the complexes of the less acidic compound, and also the formation of its

complexes should be affected less by the pH of the solution.⁶⁰

When the colour contrast is due to differences in the positions of the absorption band maxima of the various acid–base forms, to make full use⁶¹ of the contrast it is essential to adjust the acidity or choose a solvent so that the free reagent will be in its molecular form, but the anionic form will be present in the metal complex.

As regards the influence of the solvent in the complexation, it has been shown⁴⁶ that it is necessary to consider the influence of the dielectric constant of the medium. An increase in the dielectric constant causes⁶² a decrease in the relative fluorescence intensity in both reagent and complex. The absorption maxima of both the reagent and the complex are shifted to longer wavelengths with increasing solvent polarity. The pH for maximum difference in absorbance between 1,2,7-trihydroxyanthraquinone and its Cu(II) complex as a function of the dielectric constant of the medium, shifts in parallel to the corresponding pK value for the reagent.⁴⁶

The nature of the metal, its position in the Periodic Table, the ionic charge, radius and potential, cation-field energies *etc.*, all affect the properties of the complexes.

It has been shown⁴³ that the molar absorptivity and luminescence intensity of alizarin and its complexes with group IIIa and IIIb elements are inversely related to the cation-field energy. The higher the field energy of the cation introduced into the complex, the higher the degree of localization of the n -electrons of the heteroatom, and the greater the electron-density deficiency in the ring. This affects the optical properties of the molecules. Hence reagents such as alizarin have been recommended⁴³ for determination of elements with cations which have a lower cation-field energy or ionic potential, *i.e.*, cations with large radius and small charge.

Mixed-ligand complexes of elements of subgroup IIIb with hydroxyanthraquinones and auxiliary ligands have been widely studied. The auxiliary ligands include 8-hydroxyquinoline,^{63,64} ethylenediamine,^{64,65} phenazone,^{66,67} benzoic acid,⁶⁸ *N*-phenylbenzohydroxamic acid⁶⁹ and sulphosalicylic acid.⁷⁰ It has been shown that auxiliary ligands containing nitrogen donor atoms form the most stable ternary complexes.⁷⁰ The order of stability of the ternary Th(IV) complexes of 3-amino-1,2-dihydroxyanthraquinone is as follows, for the auxiliary ligands

named: 1,10-phenanthroline > 2,2'-bipyridyl > salicylic acid > 5-sulphosalicylic acid = 5-nitrosalicylic acid. This order is explained⁷⁰ as due to interaction between the π -systems of the two ligands bound to Th(IV). These ternary complexes are more stable than the binary complex.

For the mixed-ligand complexes of the rare-earth metals with 1,2,5,8,-tetrahydroxyanthraquinone and 8-hydroxyquinoline the molar absorptivity depends directly on the ionic potential (cation-field energy)⁴³. Addition of boric acid to the system increases the linear range.⁶³

The reported complexation reactions of AQ derivatives generally show moderate sensitivity and selectivity, but in some cases the variables were not optimized for modern instrumentation. Also, recent approaches^{62,71-73} have improved the general performance of the analytical methods, especially sensitivity and selectivity. For example, a significant improvement in sensitivity and selectivity in the determination of Be(II) is achieved by use of its inclusion complex in cyclodextrins.⁵⁸ Again, developments in the treatment of spectral signals allow analysis of mixtures of lanthanides at trace levels, which is otherwise difficult because of interelement interferences.^{71,73}

The most important information on the use of anthraquinones in determination of elements by complexation reactions is given in Table 1 at the end of the paper. The most widely used reagents and their types of co-ordination are summarized below.

Hydroxy-, polyhydroxy- and carboxyanthraquinones have two oxygen donor-atoms, some typical configurations are shown in Fig. 2. Thus chelation by the quinonoid oxygen atom and the hydroxy group occurs in the Alizarin S complexes with Th(IV), Hf(IV) and Cr(III), and chelation by the two hydroxyl groups of the same reagent occurs with Pb(II), V(V), W(VI), UO₂(II)⁷⁴ and with Zr(IV).⁷⁵

It has been reported that with 1-hydroxyanthraquinone an ML₂ chelate is formed with Mg(II) whereas with 1,4-dihydroxyanthra-

Fig. 2 Configurations of (a) hydroxy-, (b) polyhydroxy- and (c) carboxyanthraquinones

quinone a 1:1 complex is formed.⁷⁶ The latter was reported to be polymeric.

Some complexes are polymers. For example, the fluorescent product formed between 1,2,4-trihydroxyanthraquinone-3-carboxylic acid and Cu(II) is said to have a polymeric complex structure.⁷⁷ Polymeric characteristics have also been assigned⁷⁸ to the lakes that are often formed by AQ derivatives and metal ions (Fig. 3).

The alizarin-Co(II)-Co(III) complex shows a similar structure, with participation of the 2-hydroxy group in the polymerization.⁷⁹ It has been reported that chain co-ordination polymers of 1,4-dihydroxyanthraquinone and bivalent metal ions with co-ordination number 4 can be formed from the metal acetylacetonates.⁷⁶ Alcohol solutions of *o*-hydroxyanthraquinones form internal complex salts when treated with magnesium acetate.⁸⁰ Because of its polarity, *N,N*-dimethylformamide is very often used as the medium for obtaining polymers.^{77,81}

The formation of insoluble hydroxyanthraquinone complexes of ion metals has long been used in qualitative analysis. Thus, Al(III) is identified by means of the red lake formed with alizarin in basic medium. Quinalizarin is used for the identification of magnesium and various bi-, ter- and quadrivalent cations by means of lake formation.

Amino-, polyamino- and aminohydroxyanthraquinones are compounds with *N,N* or *O,N* donor-atom configurations, as shown in Fig. 4

Fig. 3 Schematic formula of the lakes in which M₂ⁿ⁺ is a trivalent metal and M₂ is hydrogen, or a univalent, bivalent or quadrivalent metal

Fig 4 Configurations of (a) amino-, (b) polyamino- and (c) aminohydroxyanthraquinones

The co-ordination sites of the complexes of these AQ derivatives may be the carbonyl and amino groups, but the structure of the chelates may be due not only to the donor character of the carbonyl group and the displacement of a proton from the amino group by a metal but also to the donor character of the amino nitrogen atom. Furthermore, several of the reactions with metal ions may be attributed to redox processes.

Aminoanthraquinones, in contrast to the "broad spectrum" reactivity of the hydroxyanthraquinones, exhibit selectivity in their reactions, particularly in ethanolic medium.⁸² This selectivity is decreased in sulphuric acid medium, however.^{83,84} Thus in ethanolic media aminoanthraquinones react with the transition metal ions Pd(II), Cu(II) and Co(II), which tend to prefer nitrogen donor atoms. The Cu(II) complex with 1,2-diaminoanthraquinone has been used as a metallochromic indicator in the complexometric titration of calcium and strontium.⁸⁵

In contrast, in concentrated sulphuric acid medium, aminoanthraquinones co-ordinate with Se(IV), boric acid, calcium, strontium and barium. Selenium(IV) reacts with aromatic compounds containing amino and carbonyl groups. Of the monoamino anthraquinones only the 1-isomer reacts to form the dimer (Se)₂(1-AAQ)₂.⁸⁶ Similarly, 4,5-diamino-1,8-dihydroxyanthraquinone has an amino group adjacent to the quinone oxygen and reacts with Se(IV) to give both an SeL and an SeL₂ complex.⁸⁷

Aminohydroxyanthraquinones form metal co-ordination compounds which have the characteristics of both the amino- and hydroxyanthraquinone complexes. With metals such as Be, Th and the lanthanides they react in a similar manner to the hydroxyanthraquinones, and with Pd and Cu similarly to aminoanthraquinones. The stability constant of the 1:1 complexes of some rare-earth metals with 1-amino-4-hydroxyanthraquinone are very similar, increasing as the size of the cation decreases.⁸⁸

The anthraquinone-complexan reagents are derivatives which possess an iminodiacetic group, and have been applied for the photometric determination of several ions and as complexometric indicators.^{89,90} Alizarin Complexan (Alizarin Fluorine Blue) forms red complexes with Ce(III), La(III) and Pr(III). When fluoride is present it replaces a molecule of water in the co-ordination sphere of the metal ion and a blue ternary complex is formed (Fig. 5).⁸⁹⁻⁹²

Other anthraquinone derivatives used in complexation reactions are nitroanthraquinones and arylaminoanthraquinones. It has been reported⁵⁹ that the reaction between Ti(IV) and nitroalizarin gives a colour contrast comparable with that of the reaction of Al(III) and alizarin. 1,4-Diamino-5-nitroanthraquinone is not itself fluorescent, but gives an orange fluorescence with ions such as Au(III) and V(V).⁹³ The complexation equilibria of La(III)⁹⁴ and Y(III)⁶⁰ with 1,4-bis(4'-methylamino)anthraquinone (Quinizarin Green) have been studied spectrophotometrically.

Among the coloured chelates of anthraquinone derivatives and transition metal ions, the most widely studied and used is that of Zr with Alizarin Red S in strong acid medium. This reaction has been applied in the photometric determination of Zr in various materials, such as plutonium-uranium fission alloys^{95,96} and other alloys^{97,98} and minerals.^{99,100}

The most widely studied of the reactions of Aqs with subgroup IIIa elements are those of aluminium with Alizarin Red S, which is suitable for determination of aluminium in various materials,¹⁰¹⁻¹⁰³ and those of boron with carminic acid¹⁰⁴⁻¹¹⁰ and quinalizarin.^{104,111-114}

The reaction between fluoride and Alizarin Complexan⁸⁹⁻⁹² is one of the few colour reactions of the fluoride ion. It has been widely studied and applied.¹¹⁴⁻¹²⁰

Fig 6 Oxidation reaction of *p*-aminohydroxyanthraquinone

REDOX REACTIONS

Chemical oxidation

Anthraquinone derivatives readily undergo reduction-oxidation reactions under proper conditions of acidity. Amino-, hydroxy- and aminohydroxyanthraquinones are capable of further oxidation to a variety of anion radicals, quinones and quinone-imines. Oxidation of *o*- or *p*-amino- and aminohydroxyanthraquinone results in the corresponding *o*- or *p*-quinone through the intermediate imino- or di-iminoquinone^{121,122} (e.g., Fig 6)

The colour or fluorescence change accompanying their oxidation facilitates the use of a number of these AQ derivatives as redox indicators in titration of reducing agents such as ascorbic acid,^{121,123-127} phenazone,¹²¹ arsenic(III),^{121,123-127} hydrazine sulphate,¹²⁵ Fe(II),¹²⁷ but the reagents decompose in the presence of an excess of oxidizing agent and hence cannot be used¹²⁸ in titrations of oxidants.

There appear to be two stages of oxidation,¹²⁸ the first (perhaps a one-electron oxidation to an anion radical) producing a hypsochromic shift, and the second (perhaps a further one-electron oxidation to give the quinone) producing a bathochromic shift to restore the original colour

The redox reactions of AQ derivatives have been used for kinetic determination of the oxidant, the reductant or a catalyst. Catalytic methods give very high sensitivity¹²⁹⁻¹³³. Their mechanisms have been reviewed by Bontchev.¹³⁴

AQ derivatives provide good indicator reactions for kinetic photometric and fluorimetric methods of analysis, because they give pronounced colour^{129,134} and fluorescence^{122,134-137} changes in their redox transformation, and extremely low concentrations of the species involved can be determined.

Kinetic determinations based on the redox reactions of AQ derivatives show a greater selectivity^{122,130-132,134,136,137} than those based on the complexation reactions.

Various AQ derivatives have been used in indicator reactions. Thus, *o*-dihydroxyanthraquinones are oxidized by hydrogen peroxide in the presence of traces of cobalt,^{133,138-140} in borate buffer. The alizarin-hydrogen peroxide indicator reaction¹⁴⁰ permits the determination of cobalt in a range of about 1-7 ng/ml, Zn, Cd and Ni interfere.

The quinalizarin-H₂O₂ (or sodium perborate) reaction is quoted as an indicator reaction with which the sensitivity for Co at 100° is 20 and 0.2 pg/ml with H₂O₂ and NaBO₃ respectively as oxidizing agents.¹³⁸ After a detailed optimization study¹³³ the same reaction has been used at 25° to determine Co (sensitivity 0.5 ng/ml). A mechanism similar to that for enzymatic reactions was postulated to explain the optimal conditions found. Tartrate, citrate and oxalate have an inhibiting effect.

The reaction between 1-amino-4-hydroxyanthraquinone and V(V)¹³⁶ to yield an oxidation product of the reagent allows a sensitive (100-530 ng/ml) and selective [only Ce(IV) interferes seriously] kinetic fluorimetric determination of V(V).

Fluorimetric¹⁴¹ and kinetic-fluorimetric¹³⁷ methods have been proposed for the determination of Fe(II) and Ti(III), based on the intense green fluorescence that appears when these cations react with 1,4-diamino-2,3-dihydroanthraquinone. The fluorescence is due to the oxidative transformation of the reagent in the presence of these cations.

The blue non-fluorescent reagent 4,8-diamino-1,5-dihydroxyanthraquinone-2,6-disulphonic acid is transformed into a pink, highly fluorescent, product by oxidation in acid medium. This reaction is slow, but in the presence of certain inorganic oxidants it is accelerated and completed in about 30 min. This allows the kinetic determination of V(V),¹²² Fe(III),¹⁴² Ce(IV),¹⁴³ Au(III)¹³² and Mn(II).¹³⁵ The combined action of Fe(III) and V(V) notably increases the sensitivity of either or both determinations, and concentrations as low as

1 ng/ml V(V)¹³⁰ and 2 ng/ml Fe(III)¹³¹ can be determined

Oxidation of 1,2,4-trihydroxyanthraquinone-3-carboxylic acid by bromate¹⁴⁴ or iodate¹⁴⁵ in hydrochloric acid medium has served as the basis for their spectrophotometric determination and for a fluorimetric method for iodate¹³⁴ which is more selective and 10 times more sensitive than the spectrophotometric method.

Electrochemical reduction

Polarographic studies of analytically important anthraquinones have been made, to investigate their redox characteristics.³⁹ Because of their quinonoid structure, anthraquinones display interesting electrochemical behaviour.³⁹ When reduced¹⁴⁶ by taking up a single electron, they form semiquinones, and the uptake of a further electron results in the formation of hydroquinones. In all the redox processes of AQs these three oxidation states are expected to be involved. Whether under given experimental circumstances a single two-electron polarographic wave or two one-electron waves will be observed, depends on the stability of the semiquinone. Additionally, each oxidation state can involve different degrees of protonation.³⁹

The polarographic behaviour of anthraquinones depends as much on the nature of the derivative^{39,146-158} as on the pH,^{39,146,147,150,152,157,158} the solvent^{39,148,149,153} and the supporting electrolyte solution

For the complexes of Alizarin Red S with Be and Al information has been obtained on the structure of the complexes by polarographic reduction of the ligand.¹⁵⁹ Similarly, from voltametric and spectrophotometric studies it has been deduced that the two adjacent hydroxyl groups are involved in formation of the highly stable Zr-Alizarin Red S complex.⁷⁵

It has also been established¹⁶⁰ that the half-wave potential for the polarographic reduction of some AAQs is correlated with the wavelength of maximum absorption in the visible region and also with the polarizability of the carbonyl groups. Each AAQ can be determined in the range 0.1–0.5 mg/ml.

Redox photochemical properties

The excited states of some AQ derivatives are very reactive chemical species. The photochemical reactions involving these species can compete with luminescence for deactivation of the excited electronic states. The photo-

chemistry of AQs has been useful in analytical chemistry, from the point of view of photo-reaction and of deactivation of excited states. The absorption and fluorescence spectra of some AQs have been studied in relation to the photochemical properties.^{2,161,162}

The photochemical oxidation of anthraquinones is confined to oxidation of the side-chain, which is characteristic of *p*-quinones.³

Photochemical reduction is the simplest photochemical reaction of anthraquinones. It involves^{3,4,31} the addition of an electron or a hydrogen atom to the oxygen atom of the carbonyl group under conditions where the analogous dark reactions are impossible. The facile reduction of AQs to anthrahydroquinones under the influence of light has long been recognized⁴ as one of the major causes of the photoinstability and photoreactivity of these dyes.

The photochemical reactivity of an AQ derivative depends critically upon the nature of the lowest excited electronic state. Anthraquinones in which this lowest state is n,π^* are associated^{3,4,31,163} with high photochemical activity, because in that state the oxygen atom of the carbonyl group is electron-deficient, which renders it⁴ extremely reactive towards the hydrogen atom or electron abstraction. In the case of π,π^* states, and more particularly charge-transfer (C-T) states, photoexcitation causes an electron shift towards the oxygen atom, which lessens its affinity for the hydrogen atom and electron abstraction. Anthraquinones which possess low-lying π,π^* or C-T states are therefore comparatively unreactive.

Anthraquinone derivatives vary widely in their photochemical reactivity. They are divided into "strong" and "weak" sensitizers^{2,163,164} in the oxidation of the environment. The former give phosphorescence emission and semiquinone radical formation, while the latter give only fluorescence emission.¹⁶⁴

AQ and its derivatives with electron-accepting substituents ($-\text{HSO}_3$, $-\text{NO}_2$, halogens) are very photochemically reactive, but the position of the substituents can have a profound effect on their photochemical behaviour.^{4,163} Sodium anthraquinone-2-sulphonate, and 2,6- and 2,7-disulphonates are more active sensitizers than the 1- and 1,5-sulphonates, and the 1,8-disulphonate is inactive.^{163,165}

Powerful electron-donating groups ($-\text{OH}$, $-\text{NH}_2$, $-\text{NRR}'$) diminish the sensitizing power of AQs in the photochemical process,^{1,3,163} a substituent in the 1-position gener-

ally having a much more pronounced effect than one in the 2-position.^{1,4}

In the absence of a hydrogen donor, photoexcited AQs can undergo photoreduction by the abstraction of an electron. Aminoanthraquinones that are relatively unreactive towards hydrogen-atom abstraction, because of the C-T character of the lowest excited state, can undergo photoreduction by electron transfer¹⁶² from hydroxide ions in solutions of high pH.

The photochemistry of anthraquinone-2-sulphonate and anthraquinone-2,6-disulphonate has received much attention,²⁻⁵ and various reaction mechanisms have been proposed. These photoreactions have been used in liquid chromatography to detect compounds¹⁶⁶⁻¹⁶⁸ that do not absorb ultraviolet-visible radiation at all. An anthraquinone-sensitized photo-oxygenation reaction produces hydrogen peroxide during the oxidation of the analytes (alcohols, aldehydes, ethers and saccharides) by hydrogen-atom abstraction. Once formed, the hydrogen peroxide is measured by a chemiluminescence reaction. The photoreduction of anthraquinone-2,6-disulphonate to dihydroxyanthracene-2,6-disulphonate has been used for the determination of several herbicides.¹⁷⁰

Anthraquinone-2-sulphonates which have been reduced photochemically can serve as electron donors, and thus can behave as sensitizers of the reduction of electron acceptors.¹³

Another aspect of the photochemistry of anthraquinones is concerned with the generation of singlet oxygen. Energy transfer between the triplet state of a dye and molecular oxygen occurs as follows

Anthraquinones which possess relatively long-lived triplet states are likely candidates as sensitizers for the formation of singlet oxygen. 1-Amino-4-hydroxyanthraquinone and its 2-methoxy derivative are extremely efficient sensitizers of singlet oxygen production. Seven of the components of the dye C.I. Disperse Blue 35 are efficient producers of singlet oxygen under the influence of light, the most photoactive component being 1,8-diamino-4,5-dihydroxyanthraquinone.⁴

CONCLUSION

The anthraquinones are very versatile reagents. A summary of their principal analytical applications is given in Table 1.
