POLY-SALICYLIC ACID MODIFIED GLASSY-CARBON ELECTRODE AND ITS APPLICATION

JINRUI XU and XIURUN ZHUANG

Department of Applied Chemistry, Huaqiao University, Quanzhou, Fujian, 362011,
People's Republic of China

(Received 3 January 1991. Revised 25 March 1991. Accepted 26 March 1991)

Summary—A poly-salicylic acid modified glassy-carbon electrode (PSAMGCE) was prepared by electropolymerisation. The behaviour of copper on this electrode was investigated by anodic stripping voltammetry. The electrode is about 40 times more sensitive than the unmodified glassy-carbon electrode. It was applied to the determination of trace copper(II) in water, and shows a 96–106% recovery and a relative standard deviation of ca. 3%.

The modification of electrode surfaces is currently an active area of research. A variety of methods for preparing modified electrodes have been reported.¹⁻⁸ In recent years electrodes modified by electropolymerisation have become of great interest.⁹⁻¹⁴ In the present work, salicylic acid was electrochemically polymerised on the surface of a glassy-carbon electrode in an aqueous solution containing salicylic acid, formaldehyde and sodium hydroxide. The electrochemical properties of the poly-salicylic acid modified glassy-carbon electrode (PSAMGCE) have been investigated by anodic stripping voltammetry. The modified electrode was applied to the determination of copper(II) in water, and its sensitivity for copper(II) is about 40 times higher than that of the unmodified glassy-carbon electrode.

EXPERIMENTAL

Apparatus

Current-potential curves were obtained by a Model 79-1 voltammetric analyzer (Jinan No. 4 Radio Factory, Shandong, China), and voltamperograms were recorded on an X-Y recorder (Shanghai Dahua Instrument Factory, China). A simple three-electrode electrochemical cell with a saturated calomel electrode (SCE, Model 232, Shanghai Tien Kuang Scientific Instruments Works, China) as reference electrode, a platinum wire as an auxiliary electrode and a PSAMGCE as working electrode were used for all the electrochemical experiments. Infra-red spectra were recorded with a Perkin-Elmer 983 IR Spectrometer (Perkin-Elmer Corp., U.S.A.).

Reagents

All reagents used were of analytical grade. All water used was doubly-distilled water from a quartz apparatus. The standard stock solution of copper(II) was 1 mg/ml and diluted as required. An aqueous solution containing 0.5 g of salicylic acid (Shanghai Wulian Chemical Factory, China), 0.5 g of formaldehyde (Shanghai Solvents Factory, China) and 0.5 g of sodium hydroxide (Beijing Chemical Factory, China) in 50 ml of water was used in the electropolymerisation.

Surface modification

The glassy-carbon disk electrode (Model AD-2, area = 0.1 cm², Jintan Analytical Instrument Factory, China) was first polished to a mirror finish with a paper tissue and then washed with ethanol and doubly-distilled water for 2 min with each, in an ultrasonic bath. The glassy-carbon working electrode was immersed in 50 ml of aqueous solution containing 0.5 g of salicylic acid, 0.5 g of formaldehyde and 0.5 g of sodium hydroxide, with the SCE and Pt wire as reference and auxiliary electrodes respectively. The electropolymerisation on the glassy-carbon electrode was carried out by sweeping the electrode potential between -0.1 and +1.3 V (*vs.* SCE), with a scan-rate of 100 mV/sec and a scan-time of 5 min, while stirring. Finally, the electrode prepared was rinsed thoroughly with doubly-distilled water, and a poly-salicylic acid modified glassy-carbon electrode (PSAMGCE) was made.

Procedure

Nitrogen gas was passed through the test solutions containing sodium acetate-acetic acid to remove dissolved oxygen before the measurements, and over the solutions during the measurements. On the PSAMGCE, the pre-electrolysis was conducted at -0.6 V (*vs.* SCE) for 2 min, while stirring. After a rest period of 30 sec, the 2nd order differential anodic stripping voltamperogram was recorded with a scan rate of 100 mV/sec. After each determination, the PSAMGCE potential was shifted at $+0.6$ V (*vs.* SCE) and the electrolysis was done for 5 min with strong stirring. The regenerated PSAMGCE is used in the next determination.

RESULTS AND DISCUSSION

Composition of the modified film

The modified film obtained from electropolymerisation of salicylic acid was insoluble in water, dilute acid and base solutions.

According to DeGeiso *et al.*,¹⁵ salicylic acid could be condensed with formaldehyde, and a poly-salicylic acid could be prepared by refluxing a mixture containing salicylic acid, formaldehyde and oxalic acid. The polymer could then be treated with dilute sodium hydroxide solution and dried. The infrared spectrum of the resulting polymer was about the same as that of the modified film and does not change on heating the polymer under reflux with rapid stirring. This indicates that the treatment with the electrochemical method indeed results in the formation of a salicylic acid-formaldehyde copolymer on the electrode surface which may be represented by the following formula:¹⁵

Voltammetric properties of Cu(II) on PSAMGCE

The voltammetric properties of PSAMGCE were studied by cyclic voltammetry in 0.05M sodium acetate-0.05M acetic acid containing copper(II). Figure 1 shows a cyclic voltamperogram of the redox reaction of copper on the PSAMGCE between -0.5 and $+0.5$ V (*vs.* SCE) at 100 mV/sec. The oxidation and reduction peaks of copper appear at -0.05 and

Fig. 1. Cyclic voltamperogram of copper on PSAMGCE (—) and unmodified glassy-carbon electrode (···). $[Cu^{2+}] = 100$ ng/ml, supporting electrolytes 0.05M sodium acetate-0.05M acetic acid, scan-rate 100 mV/sec.

-0.2 V (*vs.* SCE), respectively. The peak separation for the redox reaction of the copper is about 0.15 V. It shows that the redox process of the copper on the PSAMGCE is an irreversible redox reaction. When the PSAMGCE is placed in 0.05M sodium acetate-0.05M acetic acid that does not contain copper(II), no electrochemical peaks occur between -0.5 and $+0.5$ V (*vs.* SCE).

According to the procedure described in the experimental section, a 2nd differential anodic stripping voltamperogram for the solution containing 0.05M sodium acetate-0.05M acetic acid and 5 μ g/ml copper(II) was recorded (Fig. 2). The sensitivity of the PSAMGCE for copper(II) is about 40 times higher than that of the unmodified glassy-carbon electrode. This results from the formation of complexes be-

tween copper(II) and the salicylic acid polymer film which act as a linking agent on the electrode surface. In other words, the modified polymer film results in the transport of more copper(II) ions to the electrode surface during pre-electrolysis.

Electropolymerisation conditions

According to the modified method described in the experimental section, cyclic voltampero-

Second-differential anodic stripping voltamperogram of copper on unmodified glassy-carbon electrode (1) and PSAMGCE (2). $[Cu^{2+}] = 5 \text{ ng/ml}$, supporting electrolytes $0.05M$ sodium acetate- $0.05M$ acetic acid, pre-electrolysis for 2 min at -0.6 V (*vs.* SCE), scan-rate 100 mV/sec .

grams of successive potential sweeps in a solution containing salicylic acid, formaldehyde and sodium hydroxide were recorded (Fig. 3). It shows an oxidation peak at $+0.5 \text{ V}$ (*vs.* SCE)

for the solution containing the salicylic acid, formaldehyde and sodium hydroxide. In this work, a potential sweep between -0.1 and $+1.3 \text{ V}$ (*vs.* SCE) was selected for electropolymerisation of the salicylic acid. Sweeping potentials more positive than $+1.3 \text{ V}$ (*vs.* SCE) will lead to the formation of gas which will interfere with electrode modification.

Figure 3 also indicates that the oxidation peak decreases with scan time. The peak height stabilizes after about 5 min. Therefore an electropolymerisation time of about 5 min was used in the above experiments.

Effect of composition of the solution used for modification

The solution used for modification was composed of salicylic acid, formaldehyde and sodium hydroxide. The amount of salicylic acid was 0.5 g in 50 ml of aqueous solution and the effects of formaldehyde and sodium hydroxide on the peak height for copper(II) are summarized in Table 1. These results indicate that the highest peak was found with 0.5 g of formaldehyde (36%) and 0.5 g of sodium hydroxide.

Fig. 3. Cyclic voltamperogram of electrode modification in 50 ml of aqueous solution containing 0.5 g of salicylic acid, 0.5 g of formaldehyde and 0.5 g of sodium hydroxide (—), containing only 0.5 g of formaldehyde and 0.5 g of sodium hydroxide (···), scan-rate 100 mV/sec .

Fig. 4. Effect of the concentration of sodium acetate-acetic acid on stripping peak height of copper. $[Cu^{2+}] = 5 \text{ ng/ml}$, pre-electrolysis for 2 min at -0.6 V (*vs.* SCE), scan-rate 100 mV/sec .

Effect of supporting electrolytes

For comparison, the seven supporting electrolytes chosen were ammonium sulphate, ammonium acetate, sodium acetate, ammonium chloride, sodium acetate-acetic acid, potassium chloride and potassium nitrate. The effect of these supporting electrolytes on the anodic stripping peak height of copper at the modified electrode was examined by the procedure described in the experimental section. The results show that a well-formed peak appears at -0.05 V (*vs.* SCE) and its peak height is highest if sodium acetate-acetic acid is used as supporting electrolyte.

When the sodium acetate-acetic acid ratio is 1:1, the highest peak is obtained with $0.05M$ sodium acetate- $0.05M$ acetic acid as shown in Fig. 4.

Influence of pH, pre-electrolysis potential and pre-electrolysis time

When the pH is varied by addition of hydrochloric acid or sodium hydroxide to the solution

Fig. 5. Effect of pH on stripping peak height of copper. $[Cu^{2+}] = 5 \text{ ng/ml}$, supporting electrolytes $0.05M$ sodium acetate- $0.05M$ acetic acid, pre-electrolysis for 2 min at -0.6 V (*vs.* SCE), scan-rate 100 mV/sec .

Fig. 6. Effect of pre-electrolysis potential on stripping peak height of copper. $[Cu^{2+}] = 5 \text{ ng/ml}$, supporting electrolytes $0.05M$ sodium acetate- $0.05M$ acetic acid, pre-electrolysis for 2 min, scan-rate 100 mV/sec .

containing 5 ng/ml copper(II) and the $0.05M$ sodium acetate- $0.05M$ acetic acid supporting electrolyte, the higher peak is found near pH 4-6 (Fig. 5). At pH values lower than 4, the height of the peaks decreased very sharply. The explanation is probably that the formation and stability of copper(II)-salicylic acid chelates decreases at low pH. At $\text{pH} > 6$, the peak height also decreased, which is possibly due to hydrolysis of copper(II).

The peak height also depends on the pre-electrolysis potential. Figure 6 shows that the anodic stripping peak height of copper at the PSAMGCE is higher and more stable from -0.6 to -0.7 V (*vs.* SCE).

The peak height is linearly related to the pre-electrolysis time up to 4 min. In the present experiment adequate sensitivity for the determination of trace copper(II) in water can be obtained with a pre-electrolysis time of 2 min. The detection limit is 0.27 ng/ml .

Dependence of peak height on the Cu(II) concentration

The anodic stripping peak height measured by the preceding method was plotted against the copper(II) concentration. It shows that the peak height depends linearly on the copper(II) concentration up to 20 ng/ml . The quantitative detection limit with this electrode was 0.3 ng/ml .

Reproducibility and selectivity of the PSAMGCE for Cu(II)

The PSAMGCE shows excellent reproducibility. The anodic stripping peak height of copper measured with a 2-min pre-electrolysis time at -0.6 V (*vs.* SCE) in a solution containing 5 ng/ml of copper(II), resulted in a relative standard deviation of only 2.7% ($n = 10$).

Table 2. Determination of copper(II) in water samples

Sample	Dam water	Tap water	Lake water	Single distilled water*
Concentration found†, ng/ml	6.28	7.08	4.36	10.22
Concentration added, ng/ml	6.00	2.00	2.00	4.00
Total concentration found, ng/ml	12.40	9.04	6.48	14.08
Recovery, %	102	98.0	106	96.5

*Distilled with distiller No. 34-4 (Shanghai Medical Apparatus and Instruments Factory, China).

†Mean of five replicate measurements.

The stripping peak of copper can tolerate 50-fold amounts of Cd^{2+} , Mn^{2+} and Pb^{2+} ; 35-fold amounts of Ni^{2+} , Zn^{2+} , Co^{2+} and Ag^{+} ; 25-fold amounts of Sn^{2+} , Cr^{3+} and Sb^{3+} ; 10-fold amounts of Fe^{3+} and Hg^{2+} and any amount of Cl^{-} , NO_3^{-} , K^{+} and Na^{+} .

Application of the PSAMGCE

From the experimental results it can be concluded that traces of copper(II) in water samples can be determined at the PSAMGCE. The best experimental conditions are: a water sample containing 0.05M sodium acetate-0.05M acetic acid (pH = 4-6), a pre-electrolysis potential of -0.6 V (vs. SCE) and a pre-electrolysis time of 2 min.

Quantitative data obtained with the previous experimental procedures are presented in Table 2. The PSAMGCE can be used in the determination of trace copper(II) in water with a satisfactory recovery of 96-106%. The relative standard deviation for five parallel determinations of the tap water is lower than 3%.

DETERMINATION OF UREA IN SERUM BY A FIBER-OPTIC FLUORESCENCE BIOSENSOR

XIANGFANG XIE, AHMAD A. SULEIMAN and GEORGE G. GUILBAULT

Chemistry Department, University of New Orleans, New Orleans, LA 70148, U.S.A.

(Received 14 August 1990. Revised 12 December 1990. Accepted 10 January 1991)

Summary—A new fiber-optic biosensor for urea has been developed, based on immobilized urease coupled to a fluorescence ammonia sensor. The enzymatically generated ammonia diffuses through the membrane into a solution of the fluorescent pH indicator trisodium 8-hydroxypyrene-1,3,6-trisulfonate. The sensor has been successfully used for the determination of urea in serum samples, with results in good agreement with those reported by a local hospital. The proposed sensor is reversible and selective to urea. The ease of construction of the sensor tip offers the possibility of designing disposable tips for use in clinical applications.

There has been increasing interest in the development of fiber-optic biosensors. Of special importance are applications in clinical analysis (because of the possibility of miniaturizing the sensor), the safety factor (direct electrical connections with the body are not required), and the ability to be used in a remote mode. Different types of fiber-optic biosensors based on fluorescence or absorption measurements have been developed, for O₂, glucose, pH, CO₂ and ammonia.¹

Urea is the chief nitrogenous end-product of protein catabolism in humans and other mammals.² The determination of urea concentration in blood and urine is important in the diagnosis of liver and kidney diseases. There are several indirect methods for urea determination based on the use of urease, which hydrolyzes urea to ammonia and carbon dioxide. These methods differ only in the measurement of the generated ammonia. The oldest method used Nessler's reagent, K₂HgI₄, which gives an orange-red color when it reacts with ammonia in alkaline solution.³ Later the Berthelot reaction, where the ammonium ion reacts with phenol and hypochlorite in alkaline medium to form indophenol, was used.⁴ Absorbance of dissociated indophenol, a blue chromophore, is measured at 630 nm. The third method for the determination of ammonia is based on the following reaction catalyzed by glutamate dehydrogenase (GluDH):^{5,6}

where NAD(P)H and NAD(P)⁺ are the reduced and oxidized forms, respectively, of nicotinamide adenine dinucleotide (phosphate). The decrease in absorbance is monitored at 340 nm in either an end-point or kinetic mode. One direct method used in most clinical laboratories is the diacetyl monoxime method.² In an acidic solution, diacetyl monoxime is converted into diacetyl hydroxylamine which reacts with urea at high temperature to form diazine which absorbs strongly at 520 nm. Thiosemicarbazide and Fe(III) are usually added to the system to enhance and stabilize the color. All of the above-mentioned methods involve the use of unpleasant reagents, high temperature or stabilizers.

Since 1986, several urea fiber-optic sensors based on the use of urease and of different pH-indicator phases to measure ammonia have been reported. The urea sensor developed by Yerian *et al.*^{7,8} was based on commercial non-bleeding acid-base indicator papers situated in a flow stream in an integrated micro-conduit at the tip of a fiber-optic bundle. The urease was adsorbed on the indicator paper and the analyte solution was directly in contact with the pH indicator, hence the sensor suffered from interference by the serum sample. Rhines and Arnold⁹ developed a urea sensor based on the immobilization of urease at the sensing tip of an ammonia gas-sensing fiber-optic chemical sensor. The indicator solution used was a mixture of 2',7'-bis(carboxyethyl)-5(and 6)-carboxyfluorescein and 5(and 6)-carboxyfluorescein, held by a Teflon membrane. Luo and Walt¹⁰ used a new technique called Avidin-Biotin

coupling for the immobilization of both indicator and urease. The indicator was a pH-sensitive fluorescein isothiocyanate isomer. Although the response time was significantly decreased, the sensor was not very sensitive to urea and the immobilization process involved extensive chemical treatments. Therefore, it is very difficult to make replicate sensors.

In this paper, a fluorescence fiber-optic urea sensor based on the use of trisodium 8-hydroxypyrene-1,3,6-trisulfonate (HPTS) as indicator is described. The indicator solution was held at the fiber tip by a membrane permeable to ammonia, which formed the bottom of a Teflon cap. The urease was immobilized on the membrane. HPTS has a pK_a of 7.3 and is highly stable with respect to photodegradation.¹ It was previously used in an ammonia gas-fiber optic sensor.¹¹ Both excitation (470 nm) and emission (518 nm) wavelengths of the basic form of HPTS are in the visible region, facilitating measurement with a glass fiber. One limitation of HPTS is its high sensitivity to ionic strength. However, in the present study, the indicator phase is separated from the analyte solution by the ammonia membrane, which is only gas-permeable, so the ionic strength of the indicator solution will not change significantly when different urea test solutions or serum samples are measured. Several characteristics of this urea sensor have been investigated. The practical application for the determination of urea in human serum has been demonstrated.

EXPERIMENTAL

Apparatus

Fluorescence measurements were made with a Perkin-Elmer model 650-10s fluorescence spectrophotometer modified to accommodate a fiber-optic arrangement. The bifurcated fiber-optic bundle used was an Oriel model 77533. A recorder was used to record the fluorescence intensity, which was converted into an electrical potential by a photomultiplier. A research pH-meter (Radiometer, model PHM 84) was used for all the pH measurements. A Beckman model DB-G grating spectrophotometer was also employed to measure the urea concentration by the diacetyl monoxime method in the comparison study.

Reagents

The indicator, trisodium 8-hydroxypyrene-1,3,6-trisulfonate (HPTS), was purchased from

Molecular Probes (Eugene, OR). Urease (E.C. 3.5.1.5) (Sigma u-2125) containing 7.1×10^4 units/g, urea, glutaraldehyde solution (25%), bovine serum albumin (BSA), diacetyl monoxime and thiosemicarbazide were purchased from Sigma (St Louis, MO). The Orion gas-permeable Teflon ammonia membranes (cat. no. 951204) were obtained from VWR Scientific.

The indicator solution was composed of 0.01M sodium chloride, 0.01M ammonium chloride, and 2.5mM HPTS. The working buffer, either for testing urea solution or serum sample, was 0.1M Tris buffer at pH 7.5.

All other chemicals were of reagent grade and were used without further purification. All solutions were prepared with doubly distilled demineralized water.

Configuration of enzyme cap

A Teflon tube (i.d. 6 mm) with two open ends was used to construct the cap. It was 6 mm in length, with an internal diameter to give a tight fit on the common end of the fibers. The ammonia membrane was mounted on one end of the tube with an O-ring and a Teflon "TEEZE"-strip was used to seal the rest of the membrane around the O-ring. Enzyme solution (15 μ l, containing 64.8 units of urease and 0.45 mg of BSA) and 2.5 μ l of 2.5% glutaraldehyde solution were added on the outside of the ammonia membrane, mixed gently for a few seconds and allowed to dry for 4 hr in air. The membrane was washed by immersing it in 0.1M glycine phosphate buffer solution for 15 min and was stored in 0.1M Tris buffer at 4° overnight.

Configuration of urea sensor

The common end of the fiber bundle was held upward, and the indicator solution (usually 4 μ l) was added onto it. The solution was evenly spread to cover the whole surface of the fiber end, then the fiber was pushed slowly into the cap described above.

Measurement procedure

The excitation wavelength was set at 470 nm and the emission wavelength at 518 nm. Working buffer (900 μ l) was added to the glass reaction cell. The cell compartment was covered and the output, which is proportional to the fluorescence intensity, was monitored until a stable baseline was achieved. Then the compartment was opened, 100 μ l of standard urea solution or serum sample were added and the

cell compartment was covered again. An increase in potential, proportional to the urea concentration, was observed. After the measurement, the sensor tip was immersed in buffer solution, and recovery was usually achieved in 15 min for a steady-state mode and 6–10 min for a kinetic mode.

RESULTS AND DISCUSSION

Concentration of HPTS

A study of the effect of HPTS concentration on sensor response (Fig. 1), showed that the response increased with increasing HPTS concentration up to 3 mM, then decreased drastically at above about 5 mM. Since the basic form of HPTS can be excited at 470 nm and emits fluorescence at 518 nm, the fluorescence intensity is proportional to the concentration of deprotonated HPTS, which is related to the amount of ammonia that diffuses through the membrane. At high HPTS concentration, the decrease in signal is probably due to the self-absorption of the fluorescence by the indicator itself.

Response and recovery times

The response time of the proposed urea sensor depends on the rates of the following steps: (1) the urease enzyme reaction, which is affected by several factors, including urease activity, the ratio of urease, BSA and glutaraldehyde in the immobilized matrix, pH, composition of working buffer, and urea concentration; (2) diffusion rate of ammonia through the membrane, which is controlled by the thickness of the immobilized enzyme layer as well as the inside pressure of the cap (usually the looser the cap, the less the pressure inside it). Because there is a 0.5-mm distance between the fiber end and the membrane, where the indicator solution is held, this inside pressure does not change the volume of

indicator solution, it only affects the diffusion of ammonia. The recovery time depends on the diffusion rate of ammonia outside the cap and the reversibility of HPTS. In our study, we found the following optimum parameters for this urea sensor: about 60 units of urease, 0.45 mg of BSA and 2.5 μ l of 2.5% glutaraldehyde solution as immobilization matrix; 4 μ l of 2.5mM HPTS indicator solution containing 0.01M sodium chloride and 0.01M ammonium chloride; 0.1M Tris buffer, pH 7.5, as working buffer. The higher the urea concentration, the shorter the response time and the longer the recovery time. The average response time for a steady-state mode was about 15 min, with a complete baseline recovery in about 15 min. However, measurement after 6 min was found suitable in the kinetic mode analysis.

Calibration curve

A calibration curve for the urea fiber-optic sensor was constructed by measuring the change of fluorescence intensity 6 min after addition of urea solution to the cell. The calibration curve was sigmoidal and the useful response range for urea was from 1×10^{-4} to 5×10^{-3} M. A calibration curve obtained by the standard-addition method showed the same characteristics, except that the response range was only from 1×10^{-4} to 1×10^{-3} M.

Reproducibility and stability

The reproducibility of this urea sensor has been investigated by making 10 measurements of a 1×10^{-3} M urea solution within one day with the same sensor. The standard deviation was 2.2 mV and the coefficient of variation was 2.9%. The long-term stability of this sensor depends only on the activity of the immobilized urease. No significant activity loss was found after one month, but after two months the activity was 80% of its initial value. Approximately 200 assays were performed with the same sensor during those two months. The whole enzyme cap was stored at 4° when not in use. The reproducibility of different sensors was also studied. A coefficient of variation of 4.2% was obtained when 5 different sensors were used for measurement of a 1×10^{-3} M urea solution. The ease of sensor tip construction and the reproducibility between the different sensor tips suggest the possibility of designing disposable tips for use in clinical application. It is worth mentioning that such disposable tips would probably cost only about \$1.50 each.

Fig. 1. Effect of HPTS concentration on response. Urea concentration was 2.5mM; 4 μ l of indicator solution containing 0.01M NaCl and 0.01M NH_4Cl .

Interference study

The interference study was performed by testing the response of the sensor to several potential interferents, as reported in the literature.¹² Glucose, uric acid, creatinine, creatine, cholesterol, potassium, sodium and chloride are the major components (besides urea) in blood which may cause interference in blood urea determination. For the selectivity study, 100 μ l of 6.0mM glucose, 0.3mM uric acid, 0.18mM creatinine, 0.5mM creatine, 0.15M sodium chloride and 5.0mM cholesterol were added to 900 μ l of 0.5mM urea solution, separately. None of these gave significant changes from the response for 0.5mM urea, and it was concluded that no interference need be expected in the determination of urea in serum with the proposed sensor.

Comparison study

The urea fiber-optic biosensor was tested for the determination of urea concentration in human serum. The blood samples were obtained from the Chemistry Laboratory of Louisiana Charity Hospital two days after these samples were taken from patients. They were stored in a freezer and centrifuged and only the sera were used for the measurements. Serum samples (100 μ l) were added to 900 μ l of working buffer, except for serum samples with a high urea concentration, where 50- μ l samples were added to 950 μ l of buffer. The calibration curve was constructed by measurement of mixtures of 100 μ l of various standard urea solutions with 900 μ l of working buffer. The change in fluorescence intensity was measured 6 min after addition of the urea solution or serum sample to the cell. The urea concentrations of the samples were obtained from the regression equation of the calibration curve by a series of calculations. The direct diacetyl monoxime method was also applied. Table 1 shows the comparison of the urea-nitrogen concentrations measured with the present urea sensor, the values from a hospital report and the results of the diacetyl monoxime method, for some serum samples. There is good agreement, suggesting that this sensor can be successfully used for urea determination in serum. The performance of this urea sensor is similar to that of the sensor reported by Rhines

Table 1. Comparison study of urea-nitrogen concentration of present urea sensor, hospital values, and diacetyl monoxime method for serum samples

Test No.	Present fiber-optic urea sensor,* mg/100 ml (mM)	Hospital report, mg/100 ml	Diacetyl monoxime†, mg/100 ml
1	13.7 (4.89)	14	12.6
2	28.6 (10.2)	30	26.0
3	4.5 (1.6)	4	3.4
4	8.0 (2.9)	8	7.0
5	36.3 (13.0)	36	35.0
6	18.7 (6.68)	19	18.2
7	23.2 (8.28)	22	23.5
8	25.0 (8.93)	26	24.1
9	48.5 (17.3)	50	45.8
10	10.7 (3.82)	11	10.4
11	31.0 (11.1)	32	30.0
12	14.3 (5.11)	14	13.6

*The standard deviations for the present fiber optic urea sensor ranged from 0.3 to 1.2 mg/100 ml ($n = 3$).

†The standard deviations for the diacetyl monoxime method ranged from 0.4 to 1.5 mg/100 ml ($n = 3$).

and Arnold,⁹ but the dye HPTS (used in the present sensor) is highly stable with respect to photodegradation and the construction of the present sensor tip seems more suitable for designing disposable tips.

Acknowledgements—The financial assistance of the LEQSF (Grant RD-8-17) is gratefully acknowledged. Also we wish to thank Dr W. T. Wu of the Chemistry Laboratory of Louisiana Charity Hospital for providing the serum samples and Dr S. S. Kuan of Food and Drug Administration, New Orleans, for his helpful discussions.

BOOK REVIEWS

The Scientific Examination of Documents: Methods and Techniques: D. ELLEN, Ellis Horwood, Chichester, 1989. Pages 182. £42.95.

Questioned Document Examination is an area of forensic science providing evidence for courts of law on subjects such as handwriting, typewriting and printing. Much of this work depends on "the experience and ability of the analyst". Mr Ellen, with 35 years experience in forensic science and a founder member of the Metropolitan Police Documents Section is perhaps the best qualified to write a book on the subject.

This book is aimed primarily at those who may need to use documentary evidence during the investigation, prosecution or defence of a case. Handwriting is the most difficult area of this work and occupies four chapters. The author is keen to show the reasoning behind handwriting evidence and first describes those features that can be observed in the reader's own writing, such as natural variation and letter structure, before moving on to discuss the scientific principles on which a document examiner bases his or her conclusions.

The typewriting section deals in detail with conventional typewriters but is less informative about more modern methods. Other chapters include simple and easy to follow descriptions of printing processes, photocopying and the use of light to compare inks. In particular the chapter on incidental marks may provide investigators with fresh ideas for solving a problem, and explains the mysterious and much publicised FSDA machine.

The use of frequent headings and a comprehensive index makes this a valuable reference book for the investigator and a useful starting point for would-be document examiners.

S. P. DAY

Handbook of Thin-Layer Chromatography: J. SHERMA and B. FRIED (editors), Dekker, New York, 1991. Pages viii + 1047. \$165.00 (US and Canada), \$198.00 (elsewhere).

Volume 55 in the Chromatography Science Series by Dekker is a large work containing contributions from 43 different authors. It is not a collection of papers from a symposium but purports to be an organized work by recognized, international experts. The co-editor, Professor Sherma, is well known for his biennial reviews of progress in TLC and this practical, comprehensive handbook is to be welcomed.

The book is divided into two parts, with Chapters 1-13 covering the principles and practice of TLC and Chapters 14-31 dealing with some specific applications. There is some inevitable overlap between contributions but the references (totalling over 2700) at the ends of each of each chapter appear to be selective.

Part 1 includes details of the theory, apparatus and techniques used in the different variations of planar chromatography. There are chapters on optimization, sorbents and instrumental methods such as TLC coupled with mass spectrometry. Preparative TLC is covered as well as qualitative and quantitative analysis. Part 1 is of general interest for all those who dabble with TLC, whereas part 2 concentrates on the analysis of specific chemical substances. It is probable that users of the handbook will just select those chapters in part 2 which are of relevance to their own work. Here the compounds covered include amino-acids, antibiotics, carbohydrates, pesticides, steroids, vitamins, toxins and many others. An important chapter on enantiomer separations is included and this is a useful addition, owing to the increased awareness of the importance of enantiomeric purity in pharmaceutical compounds. Throughout part 2 numerous tables are presented that give details of separations performed with various solvent systems, *e.g.*, the chapter on TLC of inorganics and organometallics contains 69 Tables and 217 references. At the end of the book a glossary of terms is provided together with a directory of suppliers and a competent index.

The book is extremely useful for those who wish to discover how a TLC separation has been performed. If you can cope with the weight and price of this work then it is to be recommended to the beginner and the advanced user of TLC.

P. J. Cox

Methods of Biochemical Analysis, Volume 34—Biomedical Applications of Mass Spectrometry: C. H. SUELTER and J. T. WATSON (editors), Wiley Interscience, New York, 1990. Pages xiii + 396. £39.80.

This is the latest book in a series covering techniques of biochemical analysis, and this volume focuses specifically on mass spectrometry. The book is comprised of five chapters each covering different aspects of the application of mass spectrometry in biomedical research.

Chapter 1 gives a comprehensive introduction which would give anyone new to this field a broad knowledge of mass spectrometry. This ranges from the mechanics of the vacuum pumps, through the many techniques available on modern instruments, to the interpretation of the spectra produced.

Methods of Biochemical Analysis, Volume 34—Biomedical Applications of Mass Spectrometry: C. H. SUELTER and J. T. WATSON (editors), Wiley Interscience, New York, 1990. Pages xiii + 396. £39.80.

This is the latest book in a series covering techniques of biochemical analysis, and this volume focuses specifically on mass spectrometry. The book is comprised of five chapters each covering different aspects of the application of mass spectrometry in biomedical research.

Chapter 1 gives a comprehensive introduction which would give anyone new to this field a broad knowledge of mass spectrometry. This ranges from the mechanics of the vacuum pumps, through the many techniques available on modern instruments, to the interpretation of the spectra produced.

The bulk of the book focuses on specific applications: carbohydrates, peptide sequencing, nucleic acids, and the role of mass spectrometry in pharmacology. These four chapters explain in greater detail those particular techniques applicable to each study area. The bulk of these chapters is concerned with the practical details of performing the analysis. Very detailed information is given enabling the reader to repeat the analyses and interpret the results obtained. Each chapter also contains a large number of figures and references to back up the text.

I feel that the book has two faults, the introductory chapter covers too much of the "nut and bolts" of mass spectrometry, and that as each chapter is written by a different author, some details about ionisation techniques are repeated in several chapters.

M. E. HARRISON

Chromatographic Analysis of Alkaloids: M. POPL, J. FAHRICH and V. TATAR, Dekker, New York, 1990. Pages 664. \$150.00 (U.S. and Canada), \$180.00 (elsewhere).

For anyone wishing to enter the field of alkaloid chemistry, reading this book will be a great help. It will give the reader an insight into how alkaloids are grouped (Chapter 1) as well as describing the general properties of these natural products (Chapter 2). This latter section is particularly useful as the data on basicity, solubility, dissociation constants, main chromophoric groupings, and electrochemical properties help one to appreciate the general behaviour of alkaloids. These criteria are necessary for their chromatographic properties to be assessed for selection of the best chromatographic procedure. These procedures are summarized in Chapter 3.

The next three chapters outline the techniques of gas, liquid and thin-layer chromatography, respectively, with well chosen examples explaining each chromatographic method. Derivatization reactions such as acylation, alkylation and silylation, which are required to improve volatility and thermal stability, are well covered in the chapters on gas chromatography and thin-layer chromatography. However, derivatization as a means of allowing the utilization of specific methods of detection, such as fluorescence, is not discussed under liquid chromatography.

In the penultimate chapter—Applications,—is where the "meat" of this book is located. First there are details of simple preparation—for materials from biological, plant and pharmaceutical sources—with tables summarizing preparative procedures. Then follows a sixteen-section tabulation on alkaloidal families in groupings starting with the simple, e.g., phenylethylamines, through to the complex, e.g., *Strychnos*, *Vinca* types. The dominant position of liquid chromatography, particularly reversed-phase HPLC, in the analysis of alkaloids is well exemplified. This list is comprehensive enough to allow the reader to make a rapid assessment in a selected field.

The final chapter (3 pages) is very much a critique of existing methodology with some pointers as to the future, including supercritical fluid chromatography.

The main index is sufficiently detailed to give rapid access to individual alkaloids and to plant genera. I would have liked each chapter to be prefaced by its own index—this would have been particularly helpful in the seventh chapter for locating areas for general perusal.

Although the price is somewhat prohibitive for individual purchase, this book makes a useful contribution to natural product chemistry and is to be recommended as a work of reference on the application of chromatographic techniques.

JOHN R. LEWIS

The Analytical Chemistry of Silicones: A. L. SMITH (editor), Wiley-Interscience, New York, 1991. Pages xxii + 551. £97.35.

This book is a recent addition to the highly successful and authoritative Wiley Chemical Analysis series, updating *Analysis of Silicones* edited by A. L. Smith and published in 1974. Silicones have a wide variety of commercial uses, from adhesives and sealants to textile finishes. Not unexpectedly, all the authors included in this book are affiliated with Dow Corning, and in some ways the book may be seen as a tribute to the impressive, multidisciplinary approach to silicone analysis at the company. Like Gaul, the book is divided into three parts: a very brief introductory chapter by Smith, a series of chapters on problem-solving in silicone analysis, followed by chapters on the basic techniques: physical properties, chemical analysis, microscopy, chromatography spectroscopy (IR, UV-Vis, NMR, MS, atomic) and X-ray methods. Useful tables of physical properties of silicones are provided at the back of the book. While some chapters are illustrated by a disappointingly brief range of applications, others are extremely well-written (especially the chromatography, solution NMR and MS chapters). For the general reader, the microscopy chapter presents a fascinating series of images ranging from contact lenses to finger implant tissue. Essential reading for the specialist and newcomer, of course, but at nearly £100, the non-specialist would be wise to view the book carefully before making a purchase.

J. A. CRAYSTON

Mössbauer Spectroscopy of Frozen Solutions: A. VERTES and D. L. NAGY (editors). Akadémiai Kiadó, Budapest, 1990. Pages 303. £22.50

The book is concerned with the use of Mössbauer spectroscopy to investigate structures and coordination, mainly in solutions but also in glasses. If during rapid freezing of solutions no structural changes occur, then Mössbauer spectroscopy (a solid state technique) can indeed be an excellent probe of solution structures.

The bulk of the book focuses on specific applications: carbohydrates, peptide sequencing, nucleic acids, and the role of mass spectrometry in pharmacology. These four chapters explain in greater detail those particular techniques applicable to each study area. The bulk of these chapters is concerned with the practical details of performing the analysis. Very detailed information is given enabling the reader to repeat the analyses and interpret the results obtained. Each chapter also contains a large number of figures and references to back up the text.

J. A. CRAYSTON

Mössbauer Spectroscopy of Frozen Solutions: A. VERTES and D. L. NAGY (editors). Akadémiai Kiadó, Budapest, 1990. Pages 303. £22.50

The book is concerned with the use of Mössbauer spectroscopy to investigate structures and coordination, mainly in solutions but also in glasses. If during rapid freezing of solutions no structural changes occur, then Mössbauer spectroscopy (a solid state technique) can indeed be an excellent probe of solution structures.

The book of ca. 300 pages consists of seven chapters, all written by East European scientists. The English is generally very good, but rather formal in style. Individual chapters are concerned with (i) the physical and technical basis of Mössbauer spectroscopy, (ii) Mössbauer spectra in frozen solutions, (iii) relaxation phenomena in frozen solutions, (iv) short range order in frozen aqueous solutions of Fe(III) salts, (v) chemical structure of liquid solutions, (vi) after-effects of nuclear transformations in frozen solutions and (vii) Mössbauer effects as applied to investigations of glassy material. Adequate references are listed at the end of each chapter and a collected subject index appears at the end of the book. There are numerous figures and tables.

There is a strong mathematical presence in the book; experimental details also are featured. However, the bulk of the book is concerned with experimental results and their interpretation.

The book was published in 1990 and a cursory look through the reference lists reveals a few references dated in the 1980s and even one dated 1988. There are a few references to conference proceedings and lectures in the 1960s and 1970s; presumably such work has never been published in refereed journals.

The price of the book just has to be noted; at £22.50 it makes many books published in western Europe look very expensive.

Overall the book is a useful one, and has suggested several ideas to this reviewer.

J. L. WARDELL

Infrared Spectroscopy of Adsorbed Species on the Surface of Transition Metal Oxides: A. A. DAVYDOV, Wiley, Chichester, 1990. Pages xii + 243. £65.00.

Although a number of texts are currently available on the IR spectroscopy of adsorbed species on the surfaces of transition metals, there is a marked shortage of books discussing the equally important field of adsorption on transition metal *oxide* surfaces. This book, therefore, makes a welcome and long needed contribution in this area. Essentially, the book is a summary of the author's investigations of the surface chemistry of simple and complex oxide catalysts. Throughout, the emphasis is on elucidating the relationships between the structure and function of oxide catalysts.

Chapters 1 and 2 discuss the use of IR spectra of probe molecules such as ammonia, CO and NO to investigate the nature and adsorption properties of surface centres such as hydroxyl groups, electron-donating oxygen ions and electron-acceptor metal cations. Of particular use to a surface IR spectroscopist is the discussion of a scheme for interpretation of the adsorption site occupied, based on the frequency of the CO and NO stretching vibrations.

Chapter 3 progresses to the use of more complex probe molecules, such as alkenes, to demonstrate the role of the surface centre in determining the adsorption characteristics of a system. This is a particularly relevant system of study since many catalytic hydrocarbon conversions occur on oxide surfaces. This chapter is also valuable for its discussion of the problems that confront a researcher when interpreting IR spectra from complex adsorbates. The author has developed a range of strategies to overcome these problems, with notable success achieved by combining IR spectroscopy with thermal desorption and chromatographic analysis of the desorption products.

Finally, Chapter 4 discusses the use of IR spectroscopy in elucidating the mechanisms of heterogeneous catalytic processes on oxide surfaces. In particular, the mechanistic aspects of the CO oxidation reaction, the water-gas shift reaction, the CO + NO reaction, the oxidation reactions of acrolein and methanol and the reactions of alkenes are discussed in detail.

The book was first published in Russian in 1984 and has been widely researched up to that date, totalling some 400 references. This is the English translation, hence the lack of references after 1984. Despite this, the book makes a valuable and timely contribution to the literature in this area and will prove to be an invaluable guide to researchers in this field.

R. RAVAL

Determination of the Precious Metals: Selected Instrumental Methods: J. C. VAN LOON and R. R. BAREFOOT, Wiley, Chichester, 1991. Pages x + 276. £45.00.

The book basically consists of two parts, the first dealing (sometimes too briefly) with the physical and chemical properties of the precious metals, the principles of the instruments used, sampling, sample processing, equipment, safety, reference materials and so on. The second gives detailed procedures for the determination of the precious metals in various types of sample by different instrumental methods, and as it consists mainly of information reprinted from the literature, it will save the practising analyst a great amount of library work. Useful comments are made on the methods selected. Because the nature of the instrumental methods generally makes the oxidation state of the metal of little or no consequence, the discussion of the chemistry of the metals concerned is rather cursory, and it would have been useful to have had more complete information given, especially with regard to the kinetic behaviour of the metal ions, and their hydrolysis and polymerization. However, the information given is doubtless adequate for the purposes for which the book will be used, and it forms a welcome addition to the literature on analysis for the platinum metals and gold.

R. A. CHALMERS

The book of ca. 300 pages consists of seven chapters, all written by East European scientists. The English is generally very good, but rather formal in style. Individual chapters are concerned with (i) the physical and technical basis of Mössbauer spectroscopy, (ii) Mössbauer spectra in frozen solutions, (iii) relaxation phenomena in frozen solutions, (iv) short range order in frozen aqueous solutions of Fe(III) salts, (v) chemical structure of liquid solutions, (vi) after-effects of nuclear transformations in frozen solutions and (vii) Mössbauer effects as applied to investigations of glassy material. Adequate references are listed at the end of each chapter and a collected subject index appears at the end of the book. There are numerous figures and tables.

There is a strong mathematical presence in the book; experimental details also are featured. However, the bulk of the book is concerned with experimental results and their interpretation.

The book was published in 1990 and a cursory look through the reference lists reveals a few references dated in the 1980s and even one dated 1988. There are a few references to conference proceedings and lectures in the 1960s and 1970s; presumably such work has never been published in refereed journals.

The price of the book just has to be noted; at £22.50 it makes many books published in western Europe look very expensive.

Overall the book is a useful one, and has suggested several ideas to this reviewer.

J. L. WARDELL

Infrared Spectroscopy of Adsorbed Species on the Surface of Transition Metal Oxides: A. A. DAVYDOV, Wiley, Chichester, 1990. Pages xii + 243. £65.00.

Although a number of texts are currently available on the IR spectroscopy of adsorbed species on the surfaces of transition metals, there is a marked shortage of books discussing the equally important field of adsorption on transition metal *oxide* surfaces. This book, therefore, makes a welcome and long needed contribution in this area. Essentially, the book is a summary of the author's investigations of the surface chemistry of simple and complex oxide catalysts. Throughout, the emphasis is on elucidating the relationships between the structure and function of oxide catalysts.

Chapters 1 and 2 discuss the use of IR spectra of probe molecules such as ammonia, CO and NO to investigate the nature and adsorption properties of surface centres such as hydroxyl groups, electron-donating oxygen ions and electron-acceptor metal cations. Of particular use to a surface IR spectroscopist is the discussion of a scheme for interpretation of the adsorption site occupied, based on the frequency of the CO and NO stretching vibrations.

Chapter 3 progresses to the use of more complex probe molecules, such as alkenes, to demonstrate the role of the surface centre in determining the adsorption characteristics of a system. This is a particularly relevant system of study since many catalytic hydrocarbon conversions occur on oxide surfaces. This chapter is also valuable for its discussion of the problems that confront a researcher when interpreting IR spectra from complex adsorbates. The author has developed a range of strategies to overcome these problems, with notable success achieved by combining IR spectroscopy with thermal desorption and chromatographic analysis of the desorption products.

Finally, Chapter 4 discusses the use of IR spectroscopy in elucidating the mechanisms of heterogeneous catalytic processes on oxide surfaces. In particular, the mechanistic aspects of the CO oxidation reaction, the water-gas shift reaction, the CO + NO reaction, the oxidation reactions of acrolein and methanol and the reactions of alkenes are discussed in detail.

The book was first published in Russian in 1984 and has been widely researched up to that date, totalling some 400 references. This is the English translation, hence the lack of references after 1984. Despite this, the book makes a valuable and timely contribution to the literature in this area and will prove to be an invaluable guide to researchers in this field.

R. RAVAL

Determination of the Precious Metals: Selected Instrumental Methods: J. C. VAN LOON and R. R. BAREFOOT, Wiley, Chichester, 1991. Pages x + 276. £45.00.

The book basically consists of two parts, the first dealing (sometimes too briefly) with the physical and chemical properties of the precious metals, the principles of the instruments used, sampling, sample processing, equipment, safety, reference materials and so on. The second gives detailed procedures for the determination of the precious metals in various types of sample by different instrumental methods, and as it consists mainly of information reprinted from the literature, it will save the practising analyst a great amount of library work. Useful comments are made on the methods selected. Because the nature of the instrumental methods generally makes the oxidation state of the metal of little or no consequence, the discussion of the chemistry of the metals concerned is rather cursory, and it would have been useful to have had more complete information given, especially with regard to the kinetic behaviour of the metal ions, and their hydrolysis and polymerization. However, the information given is doubtless adequate for the purposes for which the book will be used, and it forms a welcome addition to the literature on analysis for the platinum metals and gold.

R. A. CHALMERS

Detection-Oriented Derivatization Techniques in Liquid Chromatography: H. LINGEMAN and W. J. M. UNDERBERG (editors), Dekker, 1990. Pages xvi + 389. \$99.75 (U.S. and Canada), \$119.50 (elsewhere).

This volume is an excellent addition to the Chromatographic Science Series. It reviews how derivatization can extend high performance liquid chromatography applications and gives general coverage of the various types of analyte derivatization for all major detection techniques.

The text is well organized and arranged, starting with basic ideas and advantages of derivatization followed by a survey of the physical and chemical effects pertinent to the kinetics of derivatization reactions. A chapter is included on sample pretreatment which, although a bit removed from the general content of the volume, provides an excellent overview of the common and not so common techniques used for preparing analytes for injection. There is an interesting chapter on the theory and practical aspects of homogeneous and solid state post-column reactors.

The remainder of the book consists of a series of chapters covering derivatization procedures used to augment various detection methods. Where appropriate, for example in electrochemical detection and in enzyme derivatization, the principles of the detection method are also outlined.

As a result of its very complete coverage of derivatization related topics this will prove a very useful text both for general reading and for use in solving specific chromatographic problems. The balance of principles, practical and examples has been well struck.

R. B. TAYLOR

Analytical Methods in Forensic Chemistry: M. H. Ho, Ellis Horwood, Chichester, 1990. Pages XVII + 440. £56.00.

This book attempts to bring together in its 29 chapters various analytical methods available. In doing so the bias is towards drug analyses at the expense of inorganic techniques. However, this is not altogether a shortcoming since the vast majority of forensic work involves analysis and comparison of drugs and related samples.

Modern instrumental techniques (GC-MS, capillary GC, HPLC, *etc.*) are covered along with some of the more exotic and less well used methods (chiroptical), with quotation of case examples and methodology where necessary. I found the chapters on drug profiling by gas chromatography particularly interesting, as well as the chapter on the use of GCMS in arson analysis.

With the increasing incidence of firearms-related offences in the United Kingdom and world wide terrorism it is perhaps one criticism that the detection of explosives residues and firearms residues is not given more exposure. A chapter on computerization or data handling would also have been useful.

The book has been attractively presented and all the chapters appear clear and concise. I strongly recommend the book to students of forensic science, toxicology, science in general, the legal profession and to the experienced forensic scientist and it should be regarded as good reference material.

R. M. STEWART

Analytical Instrumentation Handbook: G. W. EWING (editor), Dekker, New York, 1990. Pages xi + 1071. \$195.00 (U.S. and Canada). \$234.00 (All other countries).

This book describes the modern instrumentation required for a very wide range of currently used analytical techniques. The readily understandable introductory chapter is on the use of computers in the laboratory. The computing aspect, particularly with regard to the collection and processing of acquired data, is emphasised throughout the book. The book is divided into five sections, *viz.* the measurement of mass, spectrochemical instrumentation, electrochemical instrumentation, chromatographic instrumentation and miscellaneous methods (which include mass spectrometry, thermoanalytical instrumentation, automatic titration and continuous flow analysis). In general, theoretical considerations are minimised but adequately referenced. The text concentrates on the description of the particular instrumental components, and on the description and discussion of the complete instruments, their limitations, and the errors associated with their practical use. The presentation is of high standard throughout, but for content, quality and references the chapters on IR, EPR, NMR, molecular fluorescence and phosphorescence, and continuous flow analysis deserve special mention.

This book represents a valuable reference source which will aid analysts in their selection of the most appropriate instrumentation to solve a particular analytical problem.

R. R. MOODY

Chemometrics: Experimental Design: E. MORGAN, Wiley, Chichester, 1991. Pages xviii + 275. £25.00.

Near the beginning of this book, Ed Morgen writes: "Often we waste time and effort by rushing into experimental work, and, most important, we frequently do not have any idea of the significance of the results we have obtained". So his purpose is to lay a sound foundation of rational experimental design for beginners, and there is no doubt that he succeeds. The book is in the ACOL series (Analytical Chemistry by Open Learning) with all that that implies, but unlike previous volumes it carries an index, although it is only a little over two pages long.

There are a lot of good things here. The writing is clear, with few typographical errors; at the start of the book there is a reading list as well as a brief survey of some suitable statistics computer programs that are currently available. The use of spreadsheets for experimental design is also mentioned. Sometimes the author is inconsistent with significant figures in his worked examples—trailing zeros are often omitted—and this could confuse students who are learning in isolation.

Chemometrics: Experimental Design: E. MORGAN, Wiley, Chichester, 1991. Pages xviii + 275. £25.00.

Near the beginning of this book, Ed Morgen writes: "Often we waste time and effort by rushing into experimental work, and, most important, we frequently do not have any idea of the significance of the results we have obtained". So his purpose is to lay a sound foundation of rational experimental design for beginners, and there is no doubt that he succeeds. The book is in the ACOL series (Analytical Chemistry by Open Learning) with all that that implies, but unlike previous volumes it carries an index, although it is only a little over two pages long.

There are a lot of good things here. The writing is clear, with few typographical errors; at the start of the book there is a reading list as well as a brief survey of some suitable statistics computer programs that are currently available. The use of spreadsheets for experimental design is also mentioned. Sometimes the author is inconsistent with significant figures in his worked examples—trailing zeros are often omitted—and this could confuse students who are learning in isolation.

There are times also when I would have preferred a more detailed description of the underlying assumptions of a given technique, and more mathematical formulae, but these are relatively small matters.

The book begins with revision of *t*- and *F*-tests, which leads naturally to simple analysis of variance techniques. Experimental design methods are then described for systems of increasing complexity. Factorial design then follows, and then fractional factorial design. The book concludes with a chapter on response surfaces. This is the right subject matter, well handled, and I recommend this book as a good introduction to chemometrics.

C. J. GILMORE

High Performance Liquid Chromatography in Biotechnology: W. S. HANCOCK (editor), Wiley-Interscience, New York, 1990. Pages x + 564, £74.35.

Lavoisier's axiom that only pure substances would yield information of significance is as true today as it was in his day. We now possess the techniques to enable us to isolate well-defined compounds that satisfy the most stringent of purity. There can be no doubt that high performance liquid chromatography has proved to be one of the most important and rapidly advancing of these techniques. Since biotechnology is another branch of science which is making rapid strides and which offers considerable promise for the future, this book, which examines the various applications of HPLC to biotechnology is very timely indeed. It is worth noting that the majority of papers published recently which are concerned with HPLC have concentrated on biological applications.

The book nicely reflects the multifaceted nature of the subject and the important interplay between its analytical and preparative aspects. The range of applications stretches from the nanogram scale, for characterization studies of novel proteins, to the kilogram amounts required for a manufacturing process.

Chapter 1 by the Editor is a useful introduction which provides an overview of the role of HPLC in biotechnology and a guide to subsequent chapters. Chapter 2, which deals with the design and synthesis of silica-based bonded phases for reversed-phase, ion-exchange and hydrophobic interaction chromatography, includes details for the purification of lysozyme, ovalbumin and other proteins.

Chapter 3 deals with nature of the sorption forces and the thermodynamics of protein adsorption. The next chapter addresses the important question of how much denaturation of proteins by organic solvents and consequent loss of biological activity occurs as a result of reversed-phase HPLC (RP-HPLC). The success of the technique depends very much on the particular protein—for example it can be used successfully for the isolation of human insulin without damage to the molecule, whereas with many other proteins reduced bioactivity may occur. This links in with Chapter 8 which deals in some detail with the use of analytical RP-HPLC in biosynthetic insulin production.

Chapter 5 deals with the physical properties and applications of new synthetic hydrophilic vinyl polymer packing materials for industrial separation of biopolymers. Next follows a substantial chapter on the scale-up of protein chromatographic separation, which contains some introductory material on the basic principles of chromatography which would not have been out of place in the introductory chapter. The subject of Chapter 7 is the HPLC of antigenic proteins and vaccines. Chapter 9 deals very specifically with the application of RP-HPLC to the separation of human growth hormone, and a more general review of methods and mechanisms of high performance ion-exchange chromatography of proteins is the subject of the next chapter. In Chapter 11 the complementary nature of ion-exchange HPLC and reversed-phase HPLC for polypeptide purification is pointed out—complementary in the sense that their combined use can provide the optimal separation or purity assessment of a peptide.

Hydrophobic interaction HPLC is the subject of Chapter 12, and Chapter 13 deals with high performance affinity chromatography (HPAC) or high performance liquid affinity chromatography (HPLAC) whichever one prefers to call it.

The next chapter on the purification of synthetic oligonucleotides provides a change from other chapters, which seem to concentrate almost exclusively on peptides and proteins. At first glance, one might consider a single chapter on oligonucleotides to represent an imbalance in the book, but on closer inspection one quickly realizes that it is a very extensive and detailed chapter (100 pages, 248 references). The emphasis of most chapters on the application of HPLC to polypeptide purification reflects the enormous effort which goes into the production of polypeptides which are antigenically or physiologically active. The final chapter deals with the chemical synthesis of peptides and the contribution of mass spectrometry to their analysis.

There is such a bewildering number of terms used in this book that a glossary of terms would not have been out of place and indeed it would have been welcomed. It does not help when alternative names for the same technique (gel filtration and size exclusion chromatography) are used in different chapters—the latter term is much preferred.

All chapters of the book are well-referenced and are illustrated with clear line drawings and photographs. The book is very broad in coverage, both of techniques and applications.

This is not a book for the newcomer to HPLC but I am certain that it will prove to be a valuable source-book to meet the needs of all workers in the field, whether they be analytical chemists, biochemists or chemical engineers.

A. K. DAVIES

Pharmaceutical Chemicals in Perspective: B. G. REUBEN and H. A. WITTCOFF, Wiley, Chichester, 1989. Pages xviii + 518. £59.00.

The aim of this book is to provide an overview of the pharmaceutical industry and its more important products. This is a somewhat ambitious goal to achieve within a mere five hundred pages.

The book is divided into three parts. The first part includes as an introductory chapter a brief review of the chronological introduction of drugs, coupling this to statistical data on changing patterns of mortality. This is followed by a wide-ranging

There are times also when I would have preferred a more detailed description of the underlying assumptions of a given technique, and more mathematical formulae, but these are relatively small matters.

A. K. DAVIES

Pharmaceutical Chemicals in Perspective: B. G. REUBEN and H. A. WITTCOFF, Wiley, Chichester, 1989. Pages xviii + 518. £59.00.

The aim of this book is to provide an overview of the pharmaceutical industry and its more important products. This is a somewhat ambitious goal to achieve within a mere five hundred pages.

The book is divided into three parts. The first part includes as an introductory chapter a brief review of the chronological introduction of drugs, coupling this to statistical data on changing patterns of mortality. This is followed by a wide-ranging

outline of the characteristics of the pharmaceutical industry. A third chapter deals with the distribution chain through physician to patient and highlights some emergent trends in drug prescribing. The section concludes with a chapter on pharmacological concepts.

The second part details the top one hundred prescribed drugs in the United States, classifying them into therapeutic categories and discussing aspects of their modes of action and production. The third part deals with other important therapeutic groups of drugs which do not fall under the aegis of Part II. This section is concluded by a chapter on problems that confront the drug industry and likely future developments.

For the serious reader much of the treatment is superficial, with even the limited statistical data overwhelming in the context. The laborious details of drug syntheses would only be appreciated by a chemist with a considerable depth of training in synthetic methodology. It is difficult therefore to adequately identify the audience to whom the book is addressed.

However within these limitations, the book contains a wealth of information, is readable, and amply illustrated with clear diagrams and tables. A minor irritation is the "wrap around" layout presentation of some figures. Particularly useful are the bibliography and notes (Appendix 3) which act as a "launch pad" for more extended study. A useful addition to most library shelves for undergraduate chemists with an interest in the pharmaceutical industry.

D. G. DURHAM

NMR, NQR, EPR, and Mössbauer Spectroscopy in Inorganic Chemistry: R. V. PARISH, Ellis Horwood, Chichester, 1990. Pages 223. £29.95.

Spectroscopy is one of those branches of science that can be made as easy or as difficult as we like. Some extremists look on it as a beautiful intellectual exercise in which quantum mechanics is really put to work, whilst others, equally extreme, regard it as a tool to be used by chemists, whether it is understood or not. Extremists always run into problems of one kind or another, so most chemists tend to find their own optimized spectroscopic level somewhere in between these extreme points of view. It is not true to say that this book belongs to either of the extreme spectroscopy camps, but it certainly lies closer to the latter than to the former.

In his preface the author explains, "... what this book is *not*. It is not a spectroscopic textbook, nor is it written for those with a need for detailed theory. Such books and reviews exist in abundance already. Rather, being written by a simple-minded inorganic chemist, it is intended to give an introduction to the *interpretation* of some of the types of spectra often met with in the inorganic laboratory."

Chapter 1 forms an introduction to features that are common to most of the four branches of spectroscopy with which the book is concerned, and Chapters 2, 3, 4 and 5 are concerned with nuclear magnetic resonance, nuclear quadrupole resonance, Mössbauer spectroscopy and electron paramagnetic resonance spectroscopy, respectively. The introduction, and the treatment of some of the more theoretical aspects of the other chapters, tend to be superficial, sometimes inaccurate, and occasionally quite wrong. The treatment is also somewhat out-dated, but the book does come into its own when the author applies each of the four branches of spectroscopy to inorganic chemistry. The inorganic applications, the bibliographies at the end of each chapter and the problems, with detailed answers, at the end of Chapters 2-5 are well-chosen and are particularly clearly presented.

Most of my inorganic friends are slick high-powered chemists, who are anything but simple-minded and are more than able to keep up with these four parts of spectroscopy. They will all learn quite a lot from this book. Its subject matter is changing fast and I look forward to a second, unblemished, up-dated edition. It cannot be far away.

A. L. PORTE

outline of the characteristics of the pharmaceutical industry. A third chapter deals with the distribution chain through physician to patient and highlights some emergent trends in drug prescribing. The section concludes with a chapter on pharmacological concepts.

The second part details the top one hundred prescribed drugs in the United States, classifying them into therapeutic categories and discussing aspects of their modes of action and production. The third part deals with other important therapeutic groups of drugs which do not fall under the aegis of Part II. This section is concluded by a chapter on problems that confront the drug industry and likely future developments.

For the serious reader much of the treatment is superficial, with even the limited statistical data overwhelming in the context. The laborious details of drug syntheses would only be appreciated by a chemist with a considerable depth of training in synthetic methodology. It is difficult therefore to adequately identify the audience to whom the book is addressed.

However within these limitations, the book contains a wealth of information, is readable, and amply illustrated with clear diagrams and tables. A minor irritation is the "wrap around" layout presentation of some figures. Particularly useful are the bibliography and notes (Appendix 3) which act as a "launch pad" for more extended study. A useful addition to most library shelves for undergraduate chemists with an interest in the pharmaceutical industry.

D. G. DURHAM

NMR, NQR, EPR, and Mössbauer Spectroscopy in Inorganic Chemistry: R. V. PARISH, Ellis Horwood, Chichester, 1990. Pages 223. £29.95.

Spectroscopy is one of those branches of science that can be made as easy or as difficult as we like. Some extremists look on it as a beautiful intellectual exercise in which quantum mechanics is really put to work, whilst others, equally extreme, regard it as a tool to be used by chemists, whether it is understood or not. Extremists always run into problems of one kind or another, so most chemists tend to find their own optimized spectroscopic level somewhere in between these extreme points of view. It is not true to say that this book belongs to either of the extreme spectroscopy camps, but it certainly lies closer to the latter than to the former.

In his preface the author explains, "... what this book is *not*. It is not a spectroscopic textbook, nor is it written for those with a need for detailed theory. Such books and reviews exist in abundance already. Rather, being written by a simple-minded inorganic chemist, it is intended to give an introduction to the *interpretation* of some of the types of spectra often met with in the inorganic laboratory."

Chapter 1 forms an introduction to features that are common to most of the four branches of spectroscopy with which the book is concerned, and Chapters 2, 3, 4 and 5 are concerned with nuclear magnetic resonance, nuclear quadrupole resonance, Mössbauer spectroscopy and electron paramagnetic resonance spectroscopy, respectively. The introduction, and the treatment of some of the more theoretical aspects of the other chapters, tend to be superficial, sometimes inaccurate, and occasionally quite wrong. The treatment is also somewhat out-dated, but the book does come into its own when the author applies each of the four branches of spectroscopy to inorganic chemistry. The inorganic applications, the bibliographies at the end of each chapter and the problems, with detailed answers, at the end of Chapters 2-5 are well-chosen and are particularly clearly presented.

Most of my inorganic friends are slick high-powered chemists, who are anything but simple-minded and are more than able to keep up with these four parts of spectroscopy. They will all learn quite a lot from this book. Its subject matter is changing fast and I look forward to a second, unblemished, up-dated edition. It cannot be far away.

TALANTA MEDAL

PROFESSOR WILHELM SIMON

The Publisher and Editorial Board of *Talanta* take great pleasure in announcing that, with the approval of the Advisory Board, the Thirteenth Award of the Talanta Medal has been made to Professor Wilhelm Simon, of the Department of Chemistry, Eidgenössische Technische Hochschule, Zürich, in recognition of his outstanding contributions in the field of ion-selective electrodes, especially with regard to the use of neutral carriers.

The previous winners of the Talanta Medal are as follows:

1961	F. FEIGL	1974	B. V. L'VOV
1963	G. SCHWARZENBACH	1977	R. BELCHER
1965	I. P. ALIMARIN	1981	J. RŮŽIČKA
1967	E. STAHL	1983	T. FUJINAGA
1969	A. WALSH	1986	E. PUNGOR
1971	R. PŘIBIL	1988	H. A. LAITINEN

THE LOUIS GORDON MEMORIAL AWARD

The Louis Gordon Memorial Award for 1990 (for the paper judged to be the best written of those appearing in *Talanta* during the year) will be made to Mrs. Elsie M. Donaldson, of the Canada Centre for Mineral and Energy Technology, for her paper "Determination of antimony in ores and related materials by continuous hydride-generation atomic-absorption spectrometry after separation by xanthate extraction" (*Talanta*, 1990, 37, 955).

THE PHARMACIA PRIZE

The Pharmacia Prize for the paper published in *Talanta* and judged to be the best contributed from an industrial laboratory has been awarded to Dr. Jun'ichi Toei, of the Tosoh Corporation, Kanagawa, Japan, for his paper "Potential of the flow-gradient function in FIA with a multifunction pump delivery system" (*Talanta*, 1988, 36, 425).

SOLUTION INFRARED SPECTROELECTROCHEMISTRY: A REVIEW

KEVIN ASHLEY

Department of Chemistry, San Jose State University, San Jose, California 95192, U.S.A.

(Received 30 November 1990. Revised 20 February 1991. Accepted 13 March 1991)

Summary—Infrared (IR) spectroelectrochemical techniques have seen extensive use in studies of electrode surface processes. They have also been employed, albeit less frequently, to investigations of redox species dissolved in solution. The application of IR spectroscopy to electrochemical solution processes represents a special challenge, for absorption of IR radiation by the solvent is a significant interference to detection of vibrational modes of dissolved analytes. It is also difficult to maintain potentiostatic control of the system in specially designed thin-layer spectroelectrochemical cells. Solution IR spectroelectrochemical experiments are important for investigations of redox systems in which it is desired to spectroscopically monitor the structures of dissolved products, intermediates and reactants involved in electrode reactions. Such experiments have been conducted on biochemical, inorganic, organic, and other systems. In this paper some examples of applications of IR spectroelectrochemical studies of solution species in the above areas are presented, and experimental aspects are discussed.

In situ spectroscopic techniques for studying electrode processes were first introduced in the 1960's in an effort to provide a better means to elucidate electrode reaction mechanisms and kinetics. These first experiments employed UV-visible spectroscopy coupled with an electrochemical cell,¹ and were used to monitor solution concentrations of redox species dissolved in solution. By using a UV-visible probe, it became possible to follow the time- and potential-dependent spectra of reactants, intermediates, and products of electrode reactions. Species in the diffusion layer could be monitored spectroscopically, and therefore it was possible to elucidate electrode reaction mechanisms and kinetics; investigations of this kind were previously much more difficult without the advantage of an optical probe. A tremendous amount of activity in the area of UV-visible spectroelectrochemistry followed for the next several years,^{2,3} but the experimental emphasis later shifted to phenomena occurring at the electrode surface. Since UV-visible spectroelectrochemical methods are largely insensitive to surface species, other techniques were required for surface studies. This change in emphasis led to the development of surface infrared spectroelectrochemistry, as well as other surface-sensitive methods. Much less emphasis has been placed on infrared studies of solution species, but in the past five years or so a few examples of such investigations have appeared.

The past decade has seen numerous advances in the development of infrared (IR) spectroscopy as applied to electrochemical systems. Much of the progress in this field has been due to the development of the Fourier transform instrument, which was unavailable during the first UV-visible experiments in the mid-1960's. Most of the effort has focused on the characterization of electrode surfaces by IR techniques,^{4,5} since surface phenomena are supremely important in electrochemical systems. These surface infrared studies have the advantage of being conducted *in situ*, and have served to complement other *in situ* surface spectroscopic probes such as surface-enhanced Raman scattering (SERS),⁶ optical second-harmonic generation (SHG),⁷ and x-ray methods.⁸ These *in situ* techniques are seen as having an advantage over *ex situ* methods which require that the spectroscopy be performed in air, gas, or in ultra-high vacuum (*i.e.*, outside the electrochemical cell). The reason for this is that in an *ex situ* experiment the electrode environment might be different from its environment *in situ*. In addition to being an *in situ* technique, IR spectroelectrochemistry also has an advantage over other *in situ* spectroscopic techniques in that experiments can be performed on either smooth or rough electrodes, and a great deal of information concerning identities and orientation of species at electrode surfaces is obtainable. Thus IR spectroscopy, as applied to electrode sur-

faces, has emerged as a very powerful probe of electrochemical surface processes.

Applications of IR spectroscopy to electrochemical processes occurring in solution (*i.e.*, in the diffusion layer near the electrode surface) have been relatively few when compared to surface studies. The principal reason for this is that the strong absorption of IR radiation by the solvent can interfere with the absorption by the dissolved redox species. Studies of solution processes in electrochemical systems are extremely important in such fields as organic, inorganic, and biological chemistry. Other spectroscopic techniques to monitor solution electrochemical processes *in situ* have been limited to methods such as UV-visible spectroelectrochemistry (mentioned above),⁹ electron spin resonance (ESR),¹⁰ and Mossbauer spectroscopy.¹¹ IR spectroscopy offers an advantage over these and other spectroscopic methodologies in that much more detail regarding molecular structure of products, intermediates and reactants of electrode processes is attainable when IR radiation is employed as a spectroscopic probe. While ESR and Mossbauer techniques can give detailed structural information in many cases, it is generally difficult to conduct these types of experiments on electrochemical systems. UV-visible spectroelectrochemical methods are much more straightforward, but other spectroscopies (such as IR) are better suited for providing structural information regarding species involved in electrode-mediated reactions.

In this paper, some examples of applications of IR spectroelectrochemistry to studies of redox species dissolved in solution are presented. Also, considerations on the design of IR spectroelectrochemical cells for solution studies, as well as instrumental considerations, are presented. The systems chosen for discussion represent examples of solution IR spectroelectrochemical investigations in the areas of inorganic, organic and biological chemistry.

CELL DESIGN AND INSTRUMENTATION

Two principle IR spectroelectrochemical cell designs which have been employed for investigation of solution redox species in electrochemical systems are external reflectance and transmission cells. It is also possible to use internal reflectance, but this sampling technique is generally not feasible owing to the low electrical conductivities of available internal reflection elements. A special internal reflection IR spec-

troelectrochemical cell design has been demonstrated to be quite useful for surface studies,¹² but applications of this design to solution studies are not recommended due to the possibility of interference from surface adsorbed species. Prime considerations in the design of a useful cell for solution applications include high electrode conductivity and optimized throughput of the IR radiation through the solution chamber of the electrochemical cell.

External reflection cells

The external reflection IR spectroelectrochemical cell is amenable to investigations of solution redox species. This cell, which was first used about a decade ago,¹³ has seen a number of refinements and improvements.¹⁴⁻¹⁷ Figure 1 shows the design of a reflectance IR spectroelectrochemical cell.¹⁻⁴ An IR transparent window is mounted at one end of the cell; this window may be flat or bevelled (as shown) to minimize reflection losses.¹⁸ The working electrode, which is usually a flat metal disk polished to a mirror finish, is positioned close to the window. For surface IR applications the mirror electrode is pushed up against the window, and a thin solution layer several microns thick is trapped between the electrode surface and the back side of the window. However, for solution applications the electrode is pulled back so that a thicker "thin layer" of electrolyte solution, say 50 microns thick, exists between the metal surface and the IR window. Incident radiation passes through the window and the thin solution layer, strikes the electrode surface and is then reflected back out of the cell to be focussed on a detector. The external reflection geometry serves to minimize absorption of IR radiation

Fig. 1. Configuration of an external reflectance cell for IR spectroelectrochemistry. Reproduced from Ref. 4.

by the solvent, while maximizing the sampling efficiency of absorbing analyte species present within the diffusion layer near the electrode surface.

The IR window material chosen depends on the spectral region of interest and on the solvent. For mid-IR applications calcium fluoride, silicon, or zinc selenide windows are used most often, while polyethylene or Mylar window materials are used in the far-IR region.

The cell housing can be comprised of inert materials such as glass^{2,16,18,19}, Teflon^{17,20}, or Kel-F^{14,21}. It is important that the cell material be inert so that the solution does not become contaminated. The electrode is mounted onto the end of a metal rod which is generally sheathed in glass, Teflon, or Kel-F so that the connecting metal rod is insulated from solution. This rod is then inserted into the cell body so that the polished mirror electrode may be positioned as desired (Fig. 1). A Luggin capillary reference probe or microreference electrode is positioned near the edge ($\sim 1mM$) of the working (mirror) electrode. The secondary (counter) electrode is usually a platinum wire which is placed behind the working electrode in a configuration that minimizes the solution resistance. The geometry of the secondary electrode is circular (see Fig. 1); this gives a symmetric current distribution pattern to the working electrode. Inlets and outlets for de-gassing of the cell must also be provided.

Adaptations to the basic reflectance cell design described above have provided for control of temperature and maintenance of the cell within an evacuated sample chamber.²⁰ Another cell design enables the use of a carbon dioxide laser source.²² Flow cells have also been contrived so that one may control the flow of electrolyte through the thin layer,^{16,17} such cells have applications in both surface and solution studies.

Transmittance cells

Just as in the external reflectance cells described above, the design for a transmittance IR spectroelectrochemical cell is based on the requirement of a thin solution layer. Such cells are known as optically transparent thin-layer electrochemical (OTTLE) cells, and are based on a "sandwich" design in which an optically transparent electrode (OTE) is positioned between two IR-transparent windows.²³ Transmittance cells offer an advantage over external reflection cells in that the cell may be placed directly

within the sample chamber of most conventional IR spectrometers. External reflection cells usually require additional optics that allow for the infrared beam path to be directed onto the face of the working electrode, which is positioned outside the sample chamber or within a specially modified sample chamber. This has three disadvantages. First, throughput is decreased since the IR beam must be reflected off a minimum of at least two additional mirrors, and much light is lost due to reflection losses. Second, alignment of the IR beam is much more difficult if a reflection geometry rather than transmission cell is used. Third, there is added expense since additional optical components must be purchased.

Figures 2 and 3 show two recent designs for thin-layer transmittance cells for use in IR spectroelectrochemistry;^{24,25} these cells are similar in design to the transmittance cells originally used in UV-visible spectroelectrochemistry^{2,3} and in some of the first IR spectroelectrochemistry experiments.²³ Other similar designs for solution IR applications have also been reported²⁶⁻²⁹, some requiring the use of O-rings and spacers to sandwich the cell together. Both designs shown in Figs. 2 and 3 avoid the use of adhesives and O-rings, which can cause cell contamination and/or leakage. Besides these advantages, the cells are reusable and robust, and are relatively inexpensive to fabricate. In all cases it is essential to employ a three-electrode design, since it is crucial that solution resistance

in the thin layer be minimized. The reported percent transmittance attainable with these IR OTTLE cells is as high as 50%,³⁰ representing a very high throughput. The superiority of newer transmission cells partially results from the fact that the measurements were conducted on more favorable systems than those studied early on. For example, organometallic species dissolved in methylene chloride³⁰ are more easily studied by IR than is ninhydrin in water²³ is, especially when an FTIR instrument is made available.

Instrumental considerations

For the most studies Fourier transform instruments are employed for solution IR spectroelectrochemistry owing to the multiplex and throughput advantages of FTIR.³¹ Usually fast scans are required since thin-layer electrochemistry is fraught with inherent instabilities. In many cases electrode reactions within a thin-layer cell can be subject to poisoning by the window material; this is especially a problem with ZnSe, which can foul electrolyte solutions rather quickly. Polarization of the electrode at high applied potentials for long periods can also lead to the formation of undesired impurities and, in some instances, films on the electrode surface. Electrolyte depletion within the thin layer may also be a problem if electrodes are held at high potentials for long periods,^{32,33}

although this is less of a concern in solution applications than in surface studies where the thin layer is much thinner. For these reasons it is desirable to obtain IR spectroelectrochemical spectra as quickly as possible. Signal averaging of numerous scans is virtually always necessary in IR spectroelectrochemical experiments.

Both absolute transmission spectra and difference spectra can be obtained by solution IR spectroelectrochemical techniques. Transmittance spectra may be obtained at desired applied potentials, and difference spectra may be plotted which show the ratio of absolute spectra taken at different potentials. Difference spectra are often used so that spectral interferences from species whose concentrations do not change with potential (e.g., solvent, electrolyte, atmosphere, etc.) are effectively cancelled. It is also possible to obtain time-dependent spectra, conduct spectrocoulometric titrations, and perform other experiments as well. In surface IR applications, usually potential-dependent difference spectra are required, although it is possible to obtain absolute spectra of surface species at a single potential by the technique of polarization modulation.² For solution IR applications no light polarization is required. In surface IR spectroscopy of electrodes¹ [at least for potential-dependent IR spectroscopy (PDIRS)³⁴], the light must be p-polarized. The lack of the necessity for a polarizer is a decided advantage, since polarizers are rather expensive and also serve to attenuate the infrared beam. Solution species can be distinguished from surface species by employing s-polarized radiation.¹⁻⁴ However, since in most cases the signal from surface species is much weaker than that from solution species, polarization of the incident radiation is not typically necessary for solution IR applications. It should also be mentioned that in cases where semiconductor electrodes are employed, the field strengths of p- and s-polarized components near the surface are similar, so there is clearly no benefit in using polarized radiation in this situation to determine between surface and solution species.

APPLICATIONS

Solution IR spectroelectrochemistry has been used to study electrode reactions involving inorganic, organic, organometallic, and biological systems. Such investigations have also been done in conjunction with surface IR spectroelectrochemistry in efforts to elucidate the identities

of reactants, intermediates, and products of electrode reactions both on the electrode surface and within the diffusion layer. In this section a few examples of studies in which solution IR spectroelectrochemistry has been employed in the above areas are presented, and the utility of the technique is discussed.

Organic systems

The earliest applications of IR spectroelectrochemistry were in studies of the redox behavior of conjugated and aromatic organic molecules^{23,35,36}. Early solution studies employed IR-OTTLE cells,²³ but the electrochemical characteristics of the thin layer cell were poor and spectral quality was substandard due to a number of factors, not the least of which was the unavailability of FTIR instruments. More recent thinlayer cell designs demonstrate much better cell characteristics than were previously attainable. Thin-layer cells were originally subject to severe potential drop problems caused by high solution resistance, but newer thin-layer cells are designed to alleviate effects of solution resistance within the thin layer as much as possible. Furthermore the advent of FTIR instruments enabled spectra to be obtained much faster than was possible with dispersive IR spectrometers.

An OTTLE cell was employed to study the reduction of tetracyanoquinodimethane (TCNQ) to its radical anion and dianion in the aprotic solvent acetonitrile:²⁴

Both electron transfers are nearly reversible, and the radical anion and dianion are stable on the experimental timescale. Figure 4 shows the cyclic voltammetry of this system in the thin-layer transmittance cell illustrated in Fig. 2. The two cathodic waves are well separated and show rather large peak separations compared to the voltammetry that is obtainable in bulk solution³⁷. However, it is important to emphasize that the quality of the voltamperogram is excellent, considering that the thin-layer geometry results in increased solution resistance. The effects of solution resistance in this cell are minimized by careful placement of the working and auxiliary electrodes.

Figure 5 shows potential-difference IR spectra produced by stepping the Pt gauze OTE through the first and second reduction waves.

Fig. 4. Thin-layer cyclic voltamperogram of a solution of 5mM TCNQ in acetonitrile (0.1M tetraethylammonium perchlorate supporting electrolyte) obtained in the cell described in Fig. 2. Potentials are vs. SCE, and the sweep rate was 5 mV/sec. Reproduced with permission from the American Chemical Society from Ref. 24.

The upper spectra correspond to the first reduction wave (due to the formation of anion radical from neutral TCNQ), while the lower spectra correspond to the second reduction (dianion formation from the radical anion). Negative bands are due to the disappearance of species present at the base (reference) potential,

Fig. 5. Potential difference IR spectra obtained during reduction of TCNQ. Upper spectra (referenced to +0.5V): $E = 0.295, 0.255, 0.210,$ and 0.130 V vs. SCE. Lower spectra (referenced to -0.15 V): $E = -0.250, -0.315, -0.350, -0.400, -0.450$ V. Reproduced with permission from the American Chemical Society from Ref. 24.

while positive bands are due to species prevalent at the sample (pulsed) potential. The upper spectrum of Figure 5 shows the disappearance of a weak IR band due to neutral TCNQ, and the appearance of two strong bands due to TCNQ^- ; the spectral features are due to normal $\text{C}\equiv\text{N}$ stretching vibrations. The observation of significantly greater extinction coefficients for radical anions than for neutral reactant species has been made previously for aromatic and/or conjugated organic molecules such as anthracene and tetracyanoethylene (TCNE)^{38,39}. The lower spectra show the appearance of positive bands due to TCNQ^{2-} , concurrent with the disappearance of bands attributed to TCNQ^- . The quality of the different spectra are quite good, and are in agreement with previous studies⁴⁰. This work illustrates the benefits of the thin-layer IR spectroelectrochemical cell design shown in Fig. 2, which has also been employed in solution IR studies of redox reactions in molten salts⁴¹. This cell can therefore be used in severe solution environments. The novel application to molten salt electrochemical measurements is a demonstration of the applicability of solution infrared spectroelectrochemistry to a variety of diverse and previously unforeseen systems. Other applications of these techniques in materials science and engineering may also be forthcoming.

The external reflection technique has been used to study the ion pairing reactions of the dianions of TCNE and TCNQ mentioned above.⁴⁰ A polished mirror electrode was used, and the electrode surface was pulled back from the window to give a thin layer about 50 microns across. PDIRS experiments were then performed by pulsing between potentials at which different species involved in the reduction of TCNE or TCNQ were predominant. Spectra were collected at pulsed and reference potentials, and ratioed as described previously.

The IR bands due to TCNE^{2-} and TCNQ^{2-} ($\text{C}\equiv\text{N}$ stretching modes) were found to be dependent upon the supporting electrolyte. In acetonitrile the $\text{C}\equiv\text{N}$ stretching frequencies of the dianions were observed to shift to higher wavenumbers in the presence of alkali metal salts than in the presence of tetraalkylammonium salts. Figure 6 shows representative IR difference spectra (in the $\text{C}\equiv\text{N}$ stretching region) obtained during the electroreduction of TCNE to TCNE^- at a Pt mirror electrode. While there are differences in reflectance intensities for spectra obtained in lithium perchlorate

Fig. 6. Potential differential spectra in the C-N stretching region for the reduction of TCNE to TCNE^- at a Pt mirror electrode. Spectra were obtained with an external reflection cell similar to the cell described in Fig. 1. Solutions consisted of 5mM TCNE in CH_3CN with either 0.1M LiClO_4 (top spectrum) or 0.1M TBAF (bottom spectrum) as background electrolyte. The potential was modulated from $+0.5\text{ V}$ to -0.5 V vs. $\text{Ag}/0.01\text{M}$ Ag^+ reference. Reprinted with permission from Elsevier Science Publishers from Ref. 40.

vs. tetrabutylammonium tetrafluoroborate (TBAF) electrolyte, there are no differences in band frequencies for the two bands observed. Figure 7 shows IR difference spectra obtained during the reduction of neutral TCNE to its

Fig. 7. PDIRS results (obtained in the C-N stretching region) for the reduction of TCNE to TCNE^- at Pt; solution conditions and reference electrode are the same as in Fig. 6. Top spectrum: 0.1M LiClO_4 as supporting electrolyte; potential modulated from $+0.5$ to -1.2 V . Bottom spectrum: 0.1M TBAF as supporting electrolyte; potential modulated from $+0.5$ to -0.2 V . Reproduced with permission from Elsevier Science Publishers from Ref. 40.

dianion. In this case a clear shift in the frequencies of the C≡N stretching modes is observed, suggesting environmental differences in the two electrolytes. Similar effects were seen in PDIRS results for the TCNQ system.

The observed frequency shifts seen during the formation of the TCNE²⁻ species were attributed to ion pairing between the dianion and the alkali metal cation. No shifts of this kind were observed, however, for the radical anion species. The observed frequency shifts (or absence thereof) correlated well with observed voltammetric behaviour, *i.e.*, if ion pairing was observed, the voltammetry indicated shifts in the value of the half-wave potential for the radical anion < = > dianion redox couple. This work was one of the first applications of solution IR spectroelectrochemistry to studies of ion pairing interactions between solute anions and cations dissolved in solution.

Other studies of organic systems have dealt with features from both the solution within the thin layer as well as the electrode surface.^{42,43} Reflectance cells are necessary for such investigations, since surface features can only be elucidated from a bulk electrode surface and not from an OTE. In one study it was possible to use real-time FTIR spectroscopy to monitor the temporal behavior of electrode reactions on a voltammetric timescale.⁴³

Inorganics and organometallics

A number of solution IR studies have focussed on inorganic and organometallic redox systems. Several investigations have focused on the ferro–ferricyanide redox couple.^{17,44,45} This redox couple is used routinely in electroanalysis as an example of a well-behaved, ‘totally reversible’ couple in most solvent and electrolyte systems. Surface IR spectroelectrochemical studies of this system, however, have shown that adsorbed intermediates exist on the electrode surface, suggesting that the electron transfer reaction is not a simple process involving the formation of an activated transition state complex⁴⁴. These results confirmed radiotracer measurements which indicated the presence of irreversibly adsorbed hexacyanoferrate and cyanide ions at platinum electrode surfaces⁴⁶. Solution IR spectroelectrochemical studies (employing an external reflectance cell) of the ferro/ferricyanide system in aqueous electrolytes showed that the C≡N stretching frequency of the ferrocyanide anion (formed as a result of reduction of the ferricyanide species) was depen-

Table 1. C≡N stretching infrared frequencies for various hexacyanoferrate complexes⁴⁵

Complex	Wavenumbers, cm ⁻¹

K _n La _m Fe(II)(CN) ₆ ^{(4-n-3m)-}	2064

dent on the pH and on the identity of the supporting electrolyte cation. A mechanism was proposed for the overall redox process:

where M⁺ is an electrolyte cation, and the superscript * denotes an activated complex. Table 1 lists the various solution complexes that were detected in the IR spectroelectrochemical study, along with their observed C≡N stretching frequencies. This study shows how solution IR spectroelectrochemistry is useful for detecting dissolved redox species in the diffusion layer which are not otherwise detectable.

Other studies have been concerned with monitoring the redox chemistry of various rhodium organometallic complexes by solution IR spectroscopy.^{25,28} Transmittance spectroelectrochemical cells were used for this work. In one study²⁵ the cell shown in Fig. 3 was employed. The cyclic voltammetry of the ferro–ferricene redox couple was first studied in this cell. At slow sweep rates the peak separation between cathodic and anodic peaks was extremely narrow, indicating a small solution resistance across the thin layer. Subsequently, redox systems of interest were investigated in the cell. A case in particular is that of Rh₂(ap)₄(C≡CH) in CH₂Cl₂ system, where ap = 2-anilinopyridinate. The neutral compound can either be oxidized or reduced reversibly through one-electron transfers, and the product of the first oxidation can in turn be oxidized to a dication:⁴⁷

The cation and anion are stable on the experimental timescale, while the dication is unstable and rapidly forms decomposition products.

PDIRS data were obtained for the first oxidation and reduction waves of the neutral rhodium species in CH_2Cl_2 containing 0.1M tetrabutylammonium perchlorate (TBAP) (Fig. 8). The band at 1954 cm^{-1} is due to the $\text{C}\equiv\text{C}$ stretching mode of the neutral compound, as indicated by the transmission IR spectrum obtained at 0.0V *vs.* Ag/Ag⁺ [Figure 8(a)]. Difference spectra taken during reduction and oxidation [Figures 8(b) and (c), respectively] indicate a $\text{C}\equiv\text{C}$ band shift to 1922 cm^{-1} for the

Fig. 8. FTIR spectra of $[\text{Rh}_2(\text{ap})_4(\text{C}\equiv\text{CH})]^x$ (where $x = +1, 0,$ or -1) complexes in 0.1M TBAP/ CH_2Cl_2 . (a) Initial spectrum of the neutral complex; applied potential = 0.0 V *vs.* Ag/Ag⁺. (b) Difference IR spectrum of neutral and singly reduced species; applied (sample) potential = -0.8 V, reference voltage = 0.0 V. (c) Difference IR spectrum of neutral and single oxidized species; applied potential = $+0.7$ V, reference potential = 0.0 V. Reproduced with permission from the American Chemical Society from Ref. 25.

anion and a shift to 1972 cm^{-1} for the cation. While not stated in the original study,²⁵ the shift to lower wavenumber (of the anion) is probably due to higher occupancy of antibonding π^* orbitals of the $\text{C}\equiv\text{C}$ moiety, which causes an overall decrease in bond order and a corresponding decrease in frequency. For the cation, a shift to higher frequency (with respect to neutral species) is attributable to decreased σ -donation to the Rh metal center, which results in an increase in bond order of the $\text{C}\equiv\text{C}$ bond. This work demonstrated the utility of an inexpensive, easily fabricated, and reusable OTTLE cell for solution IR applications. It was determined, however, that use of a thin-layer transmittance cell is not reliable for quantitative purposes in spectral regions where solvent and/or electrolyte absorbance is strong.

Another study concerned the IR spectroelectrochemistry of the Creutz-Taube ion, $[\text{Ru}(\text{NH}_3)_5]_2\text{pyrazine}]^{5+}$, in aqueous solution.⁴⁸ Near- and mid-IR spectroelectrochemical studies of this ion revealed a low frequency electronic transition, which had been postulated previously based on results from other spectroscopic studies. It was shown that each ruthenium center of the Creutz-Taube ion bears a charge of $+2.5$, indicating that on the vibrational timescale the odd electron is fully delocalized between the two metal centers. This work represents the first application of spectroelectrochemical techniques to the study of low energy electronic transitions of mixed-valent compounds.

Several other investigations have been reported^{20,26,27,49} concerning the redox chemistry of organometallic compounds. Other work has focussed on potential-dependent dynamic processes within the thin layer.⁵⁰ It is clear that from the evidence of these few successes, solution IR spectroelectrochemical methods ought to be applicable to studies of many organometallic and inorganic redox systems.

Biological systems and 'model' biosystems

A few IR spectroelectrochemical studies have been concerned with systems of biological interest. In one investigation, an OTTLE cell was used to characterize the electro-oxidation of a series of selected metalloporphyrins.³⁰ Metalloporphyrins form the central redox sites in a number of biomolecules, including heme proteins, chlorophyll, and the cytochromes, to name a few. Analysis of the potential-dependent IR difference spectra of certain metallopor-

phyrins allowed the site of electrooxidation on the metalloporphyrin molecule to be deduced.³⁰ Furthermore, it was possible to determine the oxidation state of the electrogenerated species and the fate of any axially coordinated NO or CO group. Additionally, it was found that other axial ligands oriented *trans* to the electrooxidized metalloporphyrin could be spectrally monitored. Such a degree of spectral characterization had not previously been obtained (for electro-oxidized compounds in solution) prior to the advent of solution IR spectroelectrochemistry.

The redox behavior of (TPP)Co(NO) (where TPP is the dianion of tetraphenylporphyrin) has been studied by a number of electrochemical and spectroscopic techniques, including *in situ* FTIR spectroelectrochemistry in an OTTE cell.⁵⁰ This metalloporphyrin can undergo two one-electron oxidations and three one-electron reductions in CH₂Cl₂ solvent,⁵¹ but the third oxidation is observed only at very high potential scan rates or at low temperature. The voltammetry of the (TPP)Co(NO) system, presented in Fig. 9, clearly shows the first two oxidations and reductions, which are reversible at a microelectrode. IR spectroelectrochemistry was employed to study the first two oxidations of

Fig. 9. (a) Top: cyclic voltamperogram (scan rate = 10 V/sec); and bottom: steady-state voltamperogram (scan rate = 50 mV/sec) of (TPP)Co(NO) at a 25-micron diameter Pt microelectrode in 0.1M TBAP/CH₂Cl₂. (b) Conventional cyclic voltamperogram (scan rate = 100 mV/sec) of (TPP)Co(NO) in 0.1M TBAP/CH₂Cl₂. Potentials are vs. the Ag/AgCl reference. Reproduced with permission from the American Chemical Society from Ref. 50.

Fig. 10. Solution FTIR difference spectra of (TPP)Co(NO) species. (a) Spectrum of neutral species dissolved in 0.1M TBAP/CH₂Cl₂; reference spectrum is that due to blank electrolyte. (b) Spectrum obtained after controlled potential oxidation at +1.1 V; referenced potential = 0.0 V. (c) Spectrum obtained after controlled potential oxidation at +1.4 V. Reproduced with permission from the American Chemical Society from Ref. 50.

(TPP)Co(NO). Figure 10 shows the *in situ* IR difference spectra taken (in the N-O stretching region) as a result of pulsing to potentials positive enough to effect the first two oxidations. The spectra indicate that the NO moiety remains associated with the singly oxidized species, but dissociates from the dication at a long time scale. Evidence for this dissociation had not been determinable previously.

IR spectroelectrochemical studies of redox biosystems have appeared. A recent study was concerned with the redox chemistry of bacteriochlorophylls and bacteriopheophytins.⁵² IR spectroelectrochemical studies allowed detailed structural analyses of the redox states, and provided for implications concerning the binding of pigments with the reaction centers of photosynthetic bacteria.

CONCLUSION

It is apparent that while surface IR spectroscopy of electrode surfaces is presently a well-developed methodology, solution IR spec-

troelectrochemistry needs expansion. Comparatively few studies have been conducted in which solution IR spectroelectrochemistry was used as a tool. This is rather surprising, considering the wealth of detailed structural, dynamical, and other information that can be gleaned from IR studies of redox species which are dissolved in solution. Numerous advances in this area have been made recently owing to improvements in spectroelectrochemical cell design and instrumental sensitivity. In the next few years it is probable that many redox systems of interest will be investigated with solution IR spectroelectrochemical techniques, and much more elegant experiments than those described in this review are anticipated.

SPECTROPHOTOMETRIC DETERMINATION OF TETRACYCLINE AND OXYTETRACYCLINE IN PHARMACEUTICAL PREPARATIONS

KAMLA M. EMARA, HASSAN F. ASKAL and GAMAL A. SALEH

Department of Pharmaceutical Chemistry, Faculty of Pharmacy, University of Assiut, Assiut, Egypt

(Received 24 October 1990. Revised 12 May 1991. Accepted 27 May 1991)

Summary—A simple, rapid and sensitive spectrophotometric procedure for the assay of tetracycline hydrochloride and oxytetracycline hydrochloride has been developed. 2,2-Diphenyl-1-picrylhydrazyl (DPH), an intensely violet-coloured stable free radical, is changed in colour on reaction with the antibiotics investigated. The decrease in the intensity of the violet colour is used to measure the concentration of the drug. All measurements are made at 520 nm on methanolic solutions of the drug and reagent, buffered at pH 6. Beer's law is obeyed in the concentration ranges 2.5–15 and 2.5–20 $\mu\text{g/ml}$ for tetracycline and oxytetracycline respectively. The proposed method has been successfully applied to analysis of the bulk drugs and their pharmaceutical formulations.

The tetracyclines are broad-spectrum antibiotics that are effective against nearly all gram-positive and gram-negative organisms. However, tetracycline and oxytetracycline are unstable under certain conditions, yielding structurally related decomposition products which have no significant antibacterial activity,¹ and determination of the active drugs in the presence of their decomposition products is therefore of importance.

Various titrimetric,² colorimetric,^{3–10} spectrophotometric,^{11,12} spectrofluorimetric,^{13,14} polarographic,¹⁵ complexometric,^{16,17} voltammetric,¹⁸ radioimmunoassay,¹⁹ TLC²⁰ and HPLC²¹ methods have been reported. The official B.P.,²² and U.S.P.²³ methods are biological assays.

In this work, a simple, rapid and sensitive spectrophotometric method is adopted for the determination of tetracycline and oxytetracycline, in the pure forms and in pharmaceutical preparations, with 2,2-diphenyl-1-picrylhydrazyl (DHP).

EXPERIMENTAL

Reagents

Pharmaceutical grade tetracycline hydrochloride (TC) and oxytetracycline hydrochloride (OTC) (Cid, Cairo, Egypt) were used as working standards.

DPH (Sigma) was used as received. A $1 \times 10^{-3}M$ methanolic solution was used except in the solvent study, where a solution of the

reagent was prepared in the solvent in question. The solution is stable for one week when kept at 4° and protected from sunlight.

A 0.1M acetate buffer was prepared and adjusted to pH 6. A 0.2M calcium chloride solution and a 0.5M 5,5-diethylbarbituric acid solution were prepared, both in distilled water.

All solvents used were of spectroscopic grade (Merck) and analytical grade reagents (or equivalent) were used whenever possible.

Calibration procedure

Weigh 50 mg of TC or OTC into a separating funnel and dissolve the drug in 30 ml of water. Add 2.0 ml of 0.2M calcium chloride and 2.0 ml of 0.5M 5,5-diethylbarbituric acid, and extract the undecomposed drug (as its complex with calcium and the barbituric acid)²⁴ with three 10-ml portions of ethyl acetate. Filter the organic phase through anhydrous sodium sulphate, evaporate the ethyl acetate under reduced pressure, dissolve the residue in methanol and dilute the solution to volume in a 50-ml standard flask. Dilute this solution stepwise with methanol to obtain drug concentrations in the ranges 25–150 $\mu\text{g/ml}$ for tetracycline hydrochloride and 25–200 $\mu\text{g/ml}$ for oxytetracycline hydrochloride. For each solution accurately transfer 1.0 ml into a 10-ml standard flask, add 2 ml of the buffer solution followed by 2 ml of DPH solution, and mix well. Heat the mixture in a water-bath at $60 \pm 5^\circ$ for 12 min. Cool and complete to volume with methanol. Measure the

R = OTC, TC molecule residue

Scheme 1.

absorbance of the test solution and of a reagent blank against methanol at 520 nm. Plot the difference in absorbance (ΔA) against drug concentration to obtain the calibration graph.

Assay of tablets

Weigh and finely powder 20 tablets. Extract an accurately weighed portion of the powder, equivalent to about 50 mg of the drug, with three 10-ml portions of methanol and filter. Transfer the filtrate and washings to a separating funnel and proceed as above, beginning with the addition of 2.0 ml of 0.2M calcium chloride. Use an aliquot containing $\sim 100 \mu\text{g}$ of the drug.

Assay of capsules

Weigh an amount of the mixed contents of 20 capsules that will be equivalent to about 50 mg of the antibiotic drug, extract with two 15-ml portions of methanol, and extract the active drug with calcium *etc.*, as for assay of tablets.

RESULTS AND DISCUSSION

Diphenylpicrylhydrazyl (I) is used for the determination of phenols.²⁵ It is employed here to abstract a hydrogen atom from a phenol group on the tetracycline molecule (II), resulting in the formation of yellow diphenylpicrylhy-

drazine (III) and a phenoxy radical (IV) as shown in Scheme 1.

The decrease in the violet colour of the DPH is proportional to the amount of tetracycline that has reacted.

Optimization of variables

At room temperature, the reaction proceeds very slowly. When mixtures of the drug with DPH and buffer solutions were heated in a water-bath at 60°, the optimum reaction time was found to be 12 min for both tetracycline and oxytetracycline hydrochlorides (Fig. 1). Higher temperatures result in a decrease in ΔA , which may be due to decomposition of DPH and/or the drugs studied.

The most suitable range of pH for the reaction was found to be 5.5–6.5. A 0.1M acetate buffer (pH 6) was used throughout all further experiments. Highly acidic and highly alkaline media led to destruction of the reagent.

Different solvents (methanol, ethanol, 1-butanol, 1-propanol, 2-propanol and mixtures of these with water) were investigated. Methanol was found to be the best solvent and was used for dissolving both the drugs and the reagent.

Interferences. The commonly used tablet excipients, such as starch, talc and magnesium stearate, were found not to interfere with the proposed method.

Fig. 1.

Table 1. Spectral characteristics of the products from the reaction between DPH and the drugs studied

Compound	ϵ_{max} , $10^4 \text{ l. mole}^{-1}, \text{ cm}^{-1}$	Linear range, $\mu\text{g/ml}$	Quantitative parameters*		
			Intercept	Slope	Correlation coefficient
Tetracycline hydrochloride	1.92	2.5–15	0.0094	0.0458	0.9993
Oxytetracycline hydrochloride	1.44	2.5–20	0.0233	0.0466	0.9976

*From five determinations.

Table 2. Determination of tetracyclines by DPH and reported methods

Sample	DPH method		Reported method ²⁶		<i>t</i> ‡	<i>F</i> ‡
	Recovery,* %	SD, %	Recovery %	SD, %		
Micycline capsules	98.5	1.3	99.8	1.1	0.72	1.40
Hostacycline tablets	100.3	1.0	99.2	0.9	0.69	1.14
Oxytetracid capsules	99.9	1.6	98.6	1.1	1.55	2.15
Tetracid capsules	100.7	1.3	99.5	1.6	1.53	1.73

*Average of 5 determinations.

†Tabulated *t* for 4 degrees of freedom at *P* 0.05 is 2.776.

‡Tabulated *F* for (4,4) degrees of freedom at *P* 0.05 is 6.39.

Interference by the structurally related decomposition products, as reported, could be eliminated by the use of calcium chloride and 5,5-diethylbarbituric acid, which form a complex with the undecomposed biologically active antibiotics, the complex being extractable with ethyl acetate.²⁴ The decomposition products do not form such complexes.

In examination by thin-layer chromatography, the extracted antibiotics TC or OTC gave single spots corresponding to the undecomposed drugs, whereas several spots were obtained with the original aqueous solutions. These findings are in agreement with those reported by Kohn.²⁴ In addition, the reaction mixture in the proposed analytical method is buffered at pH 6, at which, as reported,¹ there is minimal decomposition of TC and OTC.

Quantification

A linear correlation was found between ΔA at 520 nm and concentration for each drug in the range given in Table 1. The slope of the linear Beer's plots can also be used for calculation of the concentration of the antibiotics.

The precision (coefficient of variation) of ten replicate determinations at the 10- μ g/ml level was 1.9% for tetracycline and 1.5% for oxytetracycline (both as the hydrochlorides).

Application to bulk drugs and dosage form

Table 2 shows the results obtained for determination of the antibiotics in the pure form and in some of their dosage forms by means of the proposed and reported methods. The average recoveries obtained by the proposed method ranged between 98.5 and 100.7% and the relative standard deviations were both 1.3%, indicating good accuracy and precision. In addition, the proposed method, when accompanied by the extraction method, enables the analyst to determine the undecomposed antibiotics in pharmaceutical formulations.

SUBSTITUTION COMPLEXOMETRIC DETERMINATION OF CADMIUM IN THE PRESENCE OF ZINC IN HOMOGENEOUS WATER-ORGANIC SOLVENT MEDIUM

ASSEN KAROLEV

Institute of Ferrous Metallurgy, Sofia 1870, Bulgaria

(Received 31 July 1989. Revised 16 May 1991. Accepted 29 May 1991)

Summary—A method for substitution complexometric determination of cadmium is based on the decomposition of the Cd-EDTA complex by the combined action of ethylxanthate and zinc. The reaction is performed in a slightly acid homogeneous water-organic solvent medium in which the cadmium ethylxanthate complex is stable and soluble.

In two earlier papers^{1,2} we have described the theoretical basis of some analytical procedures generalized by the equation

where MY is the complexonate of the metal (M) to be determined, N is the ion used for titrating the complexone (Y) released, and A (or L) is an auxiliary reagent used to form a slightly soluble compound (MA_i) or a soluble complex (ML_i).

The methods are applied in two steps.

1. Determination (direct or by back-titration) of the sum of the elements reacting with the complexone under the given conditions.

2. Selective displacement of the metal to be determined, by formation of a sparingly soluble compound or another complex of M. The Y released is titrated with N. The earliest example of this type of reaction was reported by Pfišil and Veselý.³

In an earlier paper we reported⁴ a complexometric method for determination of cadmium in the presence of zinc, in aqueous solution, by means of the reaction

where CdY²⁻ and ZnY²⁻ are the EDTA complexes of the two metals, Ex⁻ is the ethylxanthate ion and Cd(Ex)₂ is cadmium ethylxanthate.

The sum of cadmium and zinc is first determined by addition of excess of EDTA and back-titration with zinc in acetate-buffered medium at pH 5.1-5.7 with Xylenol Orange as indicator or at pH 5.7-6.2 with Methylthymol

Blue as indicator. Back-titration is preferred to direct titration with Methylthymol Blue as indicator, as the end-point is sharper. Addition of ethylxanthate then produces a precipitate of cadmium ethylxanthate during further titration with zinc. The quantity of zinc required to reach the second end-point is equivalent to the cadmium. By similar procedures Pb, Cu(II), Hg(II) and Bi can be determined.

This cadmium determination is based on the considerable difference between the solubility products of cadmium and zinc ethylxanthates (2.6×10^{-14} and 4.9×10^{-9} respectively⁵).

The equilibrium constant for the reaction in equation (2) is

$$K_{eq} = \frac{[ZnY]}{[CdY][Zn][Ex]^2} \quad (3)$$

Since the activity of a precipitate is conventionally taken as unity, multiplication of equation (3), top and bottom, by [Y][Cd] and substitution of the stability constants for the EDTA complexes and the solubility product of the precipitate will give

$$K_{eq} = \beta_{ZnY} / \beta_{CdY} K_{sp}[Cd(Ex)_2] \quad (4)$$

Because the reaction is done in 0.5M acetate buffer at pH 5, the side-reactions of zinc, cadmium and EDTA must be taken into account, and the conditional concentrations and constants⁶ must be used:

$$K'_{eq} = \beta'_{ZnY} / \beta'_{CdY} K'_{sp}[Cd(Ex)_2] \quad (5)$$

Under the conditions used, the values are $\beta'_{ZnY} = \beta_{ZnY} / \alpha_{Y(H)} \alpha_{Zn(Ac)}$, $\beta'_{CdY} = \beta_{CdY} / \alpha_{Y(H)} \alpha_{Cd(Ac)}$

and $K'_{sp} = K_{sp} \alpha_{Cd(Ac)} \alpha_{Ex(H)}^2$, and substitution into (5) gives

$$K'_{eq} = \beta_{ZnY} / \beta_{CdY} \alpha_{Zn(Ac)} K_{sp} \alpha_{Ex(H)}^2 \quad (6)$$

For 99.9% conversion of CdY into Cd(Ex)₂ and 99.9% conversion of the liberated Y into ZnY, the value of K'_{eq} must be not less than $K'_{99.9}$, given by

$$K'_{99.9} = \frac{[ZnY]}{[CdY][Zn'][Ex']^2} \\ = \frac{[ZnY]}{0.001 C_{Cd} \times 0.001 (C_{Zn} + C_{Cd}) [Ex']^2} \quad (7)$$

where $[Ex'] = (C_{Ex} - 1.998 C_{Cd})$, C_{Zn} , C_{Cd} , and C_{Ex} are the initial concentrations of zinc, cadmium and ethylxanthate respectively. Note that $[ZnY]$ must be the sum of the ZnY formed in the first titration and that formed in the second.

Under the conditions given in the procedure,

$$\alpha_{Zn(Ac)} = 1 + \beta_1 [Ac'] / \alpha_{Ac(H)} \\ + \beta_2 [Ac']^2 / \alpha_{Ac(H)}^2 \\ = 1 + 10^{1.3} \times 0.5 / 1.45 \\ + 10^2 \times 0.25 / 1.45^2 \approx 23$$

$$\alpha_{Ex(H)} = 1 + [H^+] / K_{a(HEX)} \\ = 1 + 10^{-5} / 10^{-3.5} \approx 1$$

Since $K_{sp[Cd(Ex)_2]} = 2.6 \times 10^{-14}$, $K'_{eq} = 1.7 \times 10^{12}$. For $C_{Zn} = C_{Cd} = 0.01M$, and $C_{Ex} = 0.1M$, $K'_{99.9} = 0.02/2 \times 10^{-10} \times 0.08^2 \approx 1.6 \times 10^{10} < K'_{eq}$

It is known that metal xanthate complexes are soluble in certain organic solvents⁷⁻¹¹ and the stability constants of some of them have been determined in aqueous methanol media.¹² It therefore seemed logical to extend the approach indicated by equation (2) by using a medium in which the cadmium ethylxanthate would be soluble.

The experiments showed that cadmium ethylxanthate is readily soluble in ethanol, dioxan, acetone and other organic solvents that are completely miscible with water. At $\leq 10^3M$ cadmium concentration, in the presence of $10^{-2}M$ ethylxanthate, no precipitate is formed in solutions containing not less than 25% v/v ethanol or 20% v/v acetone or dioxan.

EXPERIMENTAL

Apparatus

A Zeiss Specol 10 instrument for photometric titration with 30-ml cells (path-length 20 mm) was used.

Reagents

Analytical grade chemicals were used throughout, and 0.01M disodium EDTA, zinc acetate and cadmium acetate solutions and 10% ammonium acetate solution (adjusted to pH 5.5), were prepared. A 0.02% Xylenol Orange solution (XO) was used as indicator.

Procedure

To a slightly acid solution containing some mg of cadmium and zinc, add 4–5 ml of pH-5.5 ammonium acetate solution and a known and excessive volume of EDTA solution. Add a few drops of XO and back-titrate with zinc solution to a sharp rise in the absorbance measured at 570 nm. This gives the sum of the cadmium and zinc. Then add enough ethanol (or other organic solvent) to keep the cadmium ethylxanthate in solution, followed by ethylxanthate in 10–15-fold ratio to the expected cadmium content, and titrate again with zinc solution to a sharp and stable absorbance change. The zinc required is equivalent to the cadmium content.

RESULTS AND DISCUSSION

Figure 1 shows the back-titration curve and the substitution titration curve obtained with a water-ethanol medium.

The absorbance changes are very sharp at the equivalence points. This permits the very precise determination of the consumption of back-titrant and practically no construction is needed for interpretation of the titration curves (a fact of real importance in routine analysis).

The broken line on the first titration curve marks its shape in the absence of ethylxanthate. Addition of ethylxanthate, however, causes the absorbance to return to nearly its initial value, which is then maintained until just before the equivalence point in the back-titration (in practice, owing to the kinetics of the exchange reaction the absorbance momentarily rises and then falls as each drop of zinc solution is added in this region).

The difference between the titrant consumptions for the second and the first titration, which is equivalent to the cadmium content, is in practice the same whether it is determined by means of the equivalence points E_{eq}^2 and E_{eq}^1 or the end-points E_{ep}^2 and E_{ep}^1 , i.e., by means of $\Delta V = V_2 - V_1 \approx V_4 - V_3$.

The absorbance change in the first titration is smaller than that in the second because at the first titration end-point the indicator colour

Fig. 1. Photometric titration with $0.01M$ Zn^{2+} ; I, 2.00 ml of $Cd^{2+} + 2.00$ ml of $0.01M$ $Zn^{2+} + 5.00$ ml of $0.01M$ EDTA in the presence of 4.0 ml of 10% ammonium acetate solution and 1.0 ml of 0.02% Xylenol Orange solution; II, the back-titration of the EDTA liberated by addition of 6 ml of ethanol and 1 ml of $0.025M$ potassium ethylxanthate to the titrated solution I.

change will be due to formation of a mixture of the zinc and cadmium XO complexes (owing to the exchange reaction $CdY^{2-} + Zn^{2+} \rightleftharpoons ZnY^{2-} + Cd^{2+}$), and the molar absorptivity of the $Zn-XO$ complex is higher than that of the $Cd-XO$ complex, and only the $Zn-XO$ complex will be formed at the second end-point.

The proposed method can be applied for complexometric titration with photometric end-point detection, especially when a very high zinc concentration is present. The procedure has been used for analysis of "Weltz-oxides". These are intermediate products in zinc production technology, and contain $54-57\%$ Zn, $13-15\%$ Pb, $1.5-3.0\%$ Fe, $0.6-1.0\%$ Cd.

Lead reacts like cadmium and interferes, so should be removed as lead sulphate (a reaction which can be included to allow the complexometric determination of the lead as well). Iron is bound as a very stable EDTA complex, so will not interfere in the determination of cadmium. The Weltz-oxides generally contain $0.1-0.4\%$ copper as impurity. Copper interferes strongly, forming copper ethylxanthate, which has a low solubility even in the mixed solvents. Up to $10-12$ mg/l. concentration, the copper can be

Table 1. Average \pm standard deviation of six determinations of the Cd content (%) in two samples of "Weltz-oxides" ($Cu = 0.36\%$)

Sample	Complexometric method	Polarographic method
1	0.62 ± 0.018	0.61 ± 0.016
2	0.92 ± 0.025	1.05 ± 0.027

reduced to Cu(I) and bound as the thiourea complex, before the first EDTA titration. The thiourea concentration has to be at least $5-6$ g/l. to prevent copper from reacting with both EDTA and ethylxanthate, and the organic solvent concentration has to be increased by about 10% (absolute).

Table 1 gives the results obtained for cadmium in Weltz-oxides by the proposed method and by polarography.

The values obtained by the two methods show that the proposed method has good reproducibility and accuracy.

In conclusion, it has to be stressed that the substitution titration is successful because the stable soluble cadmium ethylxanthate complex is formed whereas the corresponding zinc complex is either not formed in the aqueous organic solution or is less stable than the zinc-Xylenol Orange complex, and hence does not affect correct end-point detection in the back-titration after the substitution reaction.

SIMULTANEOUS FLOW-INJECTION DETERMINATION OF CHLORPROMAZINE AND PROMETHAZINE BY PHOTOCHEMICAL REACTION

DANHUA CHEN,* A. RÍOS, M. D. LUQUE DE CASTRO† and M. VALCÁRCEL

Department of Analytical Chemistry, Faculty of Sciences, University of Córdoba, 14004 Córdoba, Spain

(Received 26 November 1990. Revised 1 May 1991. Accepted 15 May 1991)

Summary—Chlorpromazine and promethazine were simultaneously determined by irradiating flow-injection manifolds with ultraviolet light. The simultaneous determination was based on the difference in pH of the media where the photochemical conversion of each phenothiazine into a fluorescent product took place. The choice of the best flow-injection configuration and mathematical treatment for solving the mixtures are discussed. Chlorpromazine and promethazine can be simultaneously determined at the $\mu\text{g/ml}$ level with r.s.d. values between 2 and 4% and sampling frequencies in the range 30–40/hr.

Flow-injection analysis (FIA) has been applied for 16 years in over 2500 pieces of research work. However, little attention has so far been paid to photochemical reactions^{1–4} compared to complex formation, acid-base, redox, ion-pair formation and catalytic reactions. Photochemical reactions have many advantages over other chemical reactions that originate in the great purity, cleanliness, selectivity, availability and affordability of the reagent (UV or visible light).

Phenothiazine compounds are usually employed in medicine as psychotropic drugs in pharmaceutical preparations. Several analytical methods have been developed for their qualitative^{5–7} and quantitative determination.^{8–10} An interesting feature of these compounds is their photochemical instability,^{11,12} which we exploited in previous work for the individual determination of chlorpromazine and promethazine. Both compounds were exposed to UV irradiation and determined at the $\mu\text{g/ml}$ level by two different flow-injection methods. In the present work, chlorpromazine and promethazine were simultaneously determined by using different configurations for implementation of the photochemical reactions involved. The resulting products were sensed fluorimetrically.

EXPERIMENTAL

Reagents

Chlorpromazine and promethazine stock solutions of 1.000 mg/ml each were prepared in distilled water and kept in a refrigerator in the dark. Working solutions were prepared daily by direct dilution with distilled water and also kept in the dark. Both $1 \times 10^{-3}M$ hydrochloric acid and $1 \times 10^{-3}M$ sodium hydroxide were utilized as carriers.

Instruments and apparatus

Fluorescence measurements were made on a Kontron SM25 spectrofluorimeter equipped with a Knauer x-t recorder. UV irradiation on the PTFE reactor was performed by a Uvaton 70 lamp emitting at 50 Hz, 220 V and 254 nm. An external fan was fitted to cool the reactor to room temperature. The analytes were injected by means of a Rheodyne Teflon rotary valve (110- μl loop) and driven through the reactor to the fluorescence flow-cell (1.1 mm path length) by the $1 \times 10^{-3}M$ hydrochloric acid and $1 \times 10^{-3}M$ sodium hydroxide carriers, which were propelled by a Gilson Minipuls-2 peristaltic pump.

RESULTS AND DISCUSSION

Foundation of the simultaneous determination

Chlorpromazine and promethazine undergo photodecomposition to fluorescent products

*Permanent address: Department of Chemistry, Wuhan University, Wuhan, China.

†Author for correspondence.

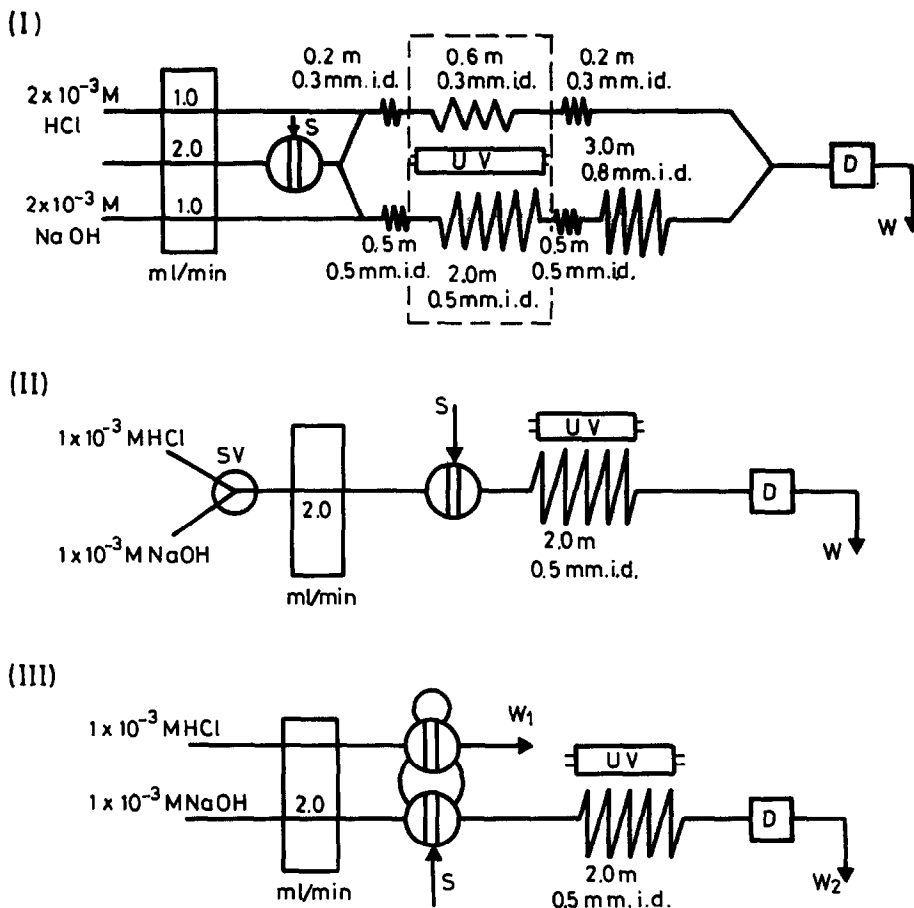

Fig. 1. Configurations for the simultaneous (I and III) and sequential (II) determination of chlorpromazine and promethazine. S denotes sample, SV selecting valve, UV ultraviolet source, D detector and W waste (for details see text).

under different working conditions. Thus, the reaction product of chlorpromazine was highly fluorescent in $1 \times 10^{-3} M$ hydrochloric acid, but scarcely fluorescent in basic medium (sodium hydroxide). On the other hand, promethazine was reactive in both solutions. This distinctive behaviour was the basis for the simultaneous determination of the two phenothiazine compounds.

Configuration designs

The aim of the configuration used for the simultaneous determination was to provide different reaction conditions for the photodecomposition of the two analytes present in the samples. Three configurations were tested for this purpose (Fig. 1).

In configuration I, the sample solution was injected via the valve into a distilled water carrier, then split into two streams, one of which was merged with $2 \times 10^{-3} M$ hydrochloric acid and the other with $2 \times 10^{-3} M$ sodium

hydroxide. Both streams were passed through PTFE reactors under UV irradiation. Arrival of the sub-plug in the sodium hydroxide carrier at the detector was delayed by using a 3-m PTFE tube of 0.8 mm i.d. to achieve complete resolution of the two peaks; *i.e.*, to allow the reaction products in the two reactors to reach the detector sequentially. The different i.d. of the reactors for the two sub-plugs was intended to balance the two channels to a similar pressure and hence to a similar volume. The shorter the reactor used for the acid stream, the smaller the diameter it should have to match its flow resistance to that of the longer reactor (basic stream), of also a larger diameter.

Configuration II included a selection valve for switching between the hydrochloric and sodium hydroxide carrier solutions, hence the sample solution had to be injected twice. Different peaks were obtained on the sample solution in different carriers sequentially passing through

Fig. 2. Influence of the reaction media by using configuration I. (A) 2 $\mu\text{g/ml}$ chlorpromazine, (B) 2 $\mu\text{g/ml}$ promethazine. (a) With $1 \times 10^{-3}M$ NaOH and, (I) $1 \times 10^{-3}M$ HCl, (II) $1 \times 10^{-4}M$ HCl, (III) $1 \times 10^{-3}M$ HCl, (IV) $1 \times 10^{-2}M$ HCl, (V) $0.1M$ HCl. (b) with $1 \times 10^{-3}M$ HCl and, (I) $1 \times 10^{-3}M$ NaOH, (II) $1 \times 10^{-4}M$ NaOH, (III) $1 \times 10^{-3}M$ NaOH, (IV) $1 \times 10^{-2}M$ NaOH, (V) $0.1M$ NaOH.

the reactor under UV irradiation and reaching the detector.

Two injection valves were internally coupled¹³ in configuration III and intended to create two basic medium-sample interfaces (head and tail of the overall injected plug) and two acid medium-sample interfaces in the centre of the injected plug. The sample and hydrochloric acid solutions were injected through the main and secondary valve, respectively, into a sodium hydroxide stream, so the sample volume was divided into two parts by the hydrochloric acid plug. A pH gradient was formed as the plugs passed through the reactor. Instead of the three peaks expected, only two overlapped peaks or a single one were actually obtained even if the injection volumes of the hydrochloric acid and sample solution and the concentrations of the acid and sodium hydroxide were adjusted. This was a result of the maximum concentration of the two gradients (sample and acid medium) lying in different positions and hence of the insufficient fluorescence difference in the middle portion of the plugs.

Configurations I and II were finally chosen for the simultaneous determination as they provided better defined recordings.

Influence of variables

The working irradiation wavelength was 254 nm. The results obtained with light of wavelengths in the range 230–320 nm were similar. Between 320 and 360 nm, the yield of the photochemical reaction clearly decreased. Above 360 nm the reaction does not take place at all. To obtain as high a sensitivity as possible, the reactors were stitched across a frame of steel net which was placed near the UV lamp. A fan was used to remove the heat generated by the light source from the reactor. The optimal reactor lengths (*i.e.*, those resulting in the best peak resolution) are given in Fig. 1. The influence of the hydrochloric acid and sodium hydroxide concentrations were studied from 0.1 to $1 \times 10^{-5}M$, the optimal value being $1 \times 10^{-3}M$ in both cases. The shape and behaviour of the recordings in this study are illustrated in Fig. 2. The energy of the detector was adjusted at 550 V. The photochemical products of both phenothiazines showed maximum emission at 373 nm and four excitation maxima at 253, 273, 295 and 333 nm. The excitation wavelengths at 253 and 333 nm were the most suitable for the formation of the photochemical product of

chlorpromazine, while the amount of product yielded by promethazine increased with an increase in the wavelength. As the signal provided by the product from chlorpromazine was smaller than that of the promethazine product (see Fig. 2) a wavelength of 253 nm was selected for the simultaneous determination; irradiation at 333 nm was applied to samples containing promethazine concentrations much smaller than those of chlorpromazine. The optimal sample volume was 100 μl for both configurations and the flow-rates of the streams were 2.0 ml/min in configuration II, and 2.0 and 1.0 ml/min for the top and bottom channels, respectively, in configuration I. Under the above working conditions, sampling frequencies of 30/hr (60 determinations) for configuration I and 40/hr (40 determinations) for configuration II were achieved.

Features of the simultaneous determination

As the mixture of chlorpromazine and promethazine reacts with a common "reagent" (UV light) to form highly fluorescent products in two different carrier solutions, the total fluorescence can be expressed as:

$$H_j = \sum_{i=1}^2 h_{ij} \quad (j = 1, 2) \quad (1)$$

where i denotes the component and j the carrier solution; h_{ij} stands for the fluorescence contributed by each component, where

$$h_{ij} = a_{ij}C_i + b_{ij} \quad (i = 1, 2 \quad \text{and} \quad j = 1, 2) \quad (2)$$

The values of a_{ij} and b_{ij} were obtained by experiments at known concentration of chlorpromazine and promethazine alone.

(a) *Configuration I.* For chlorpromazine, over the concentration range 0.4–10.0 $\mu\text{g/ml}$, in $10^{-3}M$ hydrochloric acid and $10^{-3}M$ sodium hydroxide,

$$h_{11} = 14.34 C_1 - 5.60 \quad (r^2 = 0.9984)$$

$$h_{12} = 2.61 C_1 - 0.43 \quad (r^2 = 0.9993)$$

For promethazine, over the concentration range of 0.4–10.0 $\mu\text{g/ml}$, in $10^{-3}M$ hydrochloric acid and $10^{-3}M$ sodium hydroxide,

$$h_{21} = 7.63 C_2 + 0.52 \quad (r^2 = 0.9992)$$

$$h_{22} = 14.43 C_2 - 0.16 \quad (r^2 = 0.9979)$$

(b) *Configuration II.* For chlorpromazine, from 0.5 to 4.0 $\mu\text{g/ml}$, in $10^{-3}M$ hydrochloric acid and $10^{-3}M$ sodium hydroxide,

$$h_{11} = 38.03 C_1 + 6.05 \quad (r^2 = 0.9995)$$

$$h_{12} = 2.70 C_1 - 0.60 \quad (r^2 = 0.9998)$$

For promethazine, from 0.5 to 6.0 $\mu\text{g/ml}$, in $10^{-3}M$ hydrochloric acid and $10^{-3}M$ sodium hydroxide.

$$h_{21} = 24.32 C_2 - 7.06 \quad (r^2 = 0.9998)$$

$$h_{22} = 18.40 C_2 + 0.54 \quad (r^2 = 0.9992)$$

Therefore, the concentrations of chlorpromazine (C_1) and promethazine (C_2) in the mixture can be obtained from the total fluorescence in $10^{-3}M$ hydrochloric acid (H_1) and $10^{-3}M$ sodium hydroxide (H_2), by solving equation (1),

$$C_1 = [(H_1 - b_{11} - b_{21}) a_{22} - (H_2 - b_{12} - b_{22}) a_{21}] / (a_{11} a_{22} - a_{12} a_{21}) \quad (3)$$

$$C_2 = [(H_2 - b_{12} - b_{22}) a_{11} - (H_1 - b_{11} - b_{21}) a_{12}] / (a_{11} a_{22} - a_{12} a_{21}) \quad (4)$$

Tables 1 and 2 list the results obtained in the determination of chlorpromazine and promethazine in synthetic samples by using

configurations I and II, respectively, and the above calibration curves. The errors made were generally larger than 10%, as a result of the interaction of the two phenothiazines, which reduced the reaction rate of each other, the effect being more significant on promethazine. Recoveries were usually low; thus, development of the photochemical reaction in isolated standards was more extensive than in the mixtures.

In order to solve the problem caused by the above-mentioned negative synergistic effect, calibration curves were run by using different combinations of known concentrations of the two phenothiazines in mixtures. As C_1 and C_2 were known, H_1 and H_2 were determined; a_{11} , a_{12} , B_1 and B_2 being calculated by multicomponent regression according to the following equations:

$$H_{1k} = a_{11}C_{1k} + a_{21}C_{2k} + B_1 \quad (k = 1, 2, \dots, n) \quad (5)$$

$$H_{2k} = a_{21}C_{1k} + a_{22}C_{2k} + B_2 \quad (k = 1, 2, \dots, n) \quad (6)$$

From the above expressions, the equations for the calibration curves obtained by multicomponent regression from the experimental data were as follows:

(a) Configuration I

For the different combinations of known concentrations of the two phenothiazines in mixtures from 1.0 to 8.0 $\mu\text{g/ml}$ in $10^{-3}M$ hydrochloric acid and $10^{-3}M$ sodium hydroxide for chlorpromazine and promethazine, respectively.

$$H_1 = 14.331C_1 + 7.296C_2 - 6.44 \quad (r = 0.996) \quad (10)$$

$$H_2 = 2.263C_1 + 13.532C_2 - 4.05 \quad (r = 0.996) \quad (11)$$

(b) Configuration II

For the different combinations of known concentrations of the two phenothiazines in

mixtures from 0.5 to 4.0 $\mu\text{g/ml}$ in $10^{-3}M$ hydrochloric acid and $10^{-3}M$ sodium hydroxide for chlorpromazine and promethazine, respectively.

$$H_1 = 39.510C_1 + 22.670C_2 - 5.27 \quad (r = 0.998) \quad (12)$$

$$H_2 = 2.137C_1 + 16.700C_2 - 0.00 \quad (r = 0.999) \quad (13)$$

Hence, the concentration of each component in the mixture (C_1 and C_2) can be obtained from the total fluorescence in $10^{-3}M$ hydrochloric acid (H_1) and $10^{-3}M$ sodium hydroxide (H_2) by solving the corresponding equations.

Tables 3 and 4 list the results obtained in the determination of the analytes in synthetic samples with configurations I and II, calculated from the multicomponent regression equations. The errors made were generally less than 5%; only a few were larger than 10% owing to the large concentration ratio of the two components. However, this was overcome by weighted regression calibration.

The relative standard deviations of configuration I were 3.77% and 2.11 for chlorpromazine and promethazine, respectively (5 $\mu\text{g/ml}$ of each analyte in 11 different samples injected in triplicate), while those of configuration II were 4.23% for chlorpromazine and 3.76% for promethazine (2 $\mu\text{g/ml}$ of each analyte under the same conditions used with configuration I).

The proposed method was also applied to the resolution of mixtures of pharmaceuticals including both phenothiazines. The results obtained (Table 5) are consistent with the certified values.

CONCLUSIONS

Photochemical reactions were used in two flow-injection manifolds to develop a simultaneous determination for two analytes.

From our experience,^{1,2,4} light-wavelength is more critical to photochemical reactions than the intensity and irradiation time, just like the features of the reagents are more influential than their concentrations and reactions times. As a rule photochemical reactions do not take place at wavelengths above 360 nm, and start immediately on "addition" of the "reagent" (UV light of a wavelength usually below 320 nm) and stop as this unique reagent is removed. As a result, methods based on this type of reaction (e.g., the proposed method) are quite selective and sensitive.

FLOW-INJECTION SUCCESSIVE DETERMINATION OF CYSTEINE AND CYSTINE IN PHARMACEUTICAL PREPARATIONS

TOMÁS PÉREZ-RUIZ, CARMEN MARTÍNEZ-LOZANO, VIRGINIA TOMÁS and GABRIEL LAMBERTOS
Department of Analytical Chemistry, University of Murcia, Murcia, Spain

(Received 1 October 1990. Revised 22 March 1991. Accepted 31 March 1991)

Summary—A flow-injection configuration is proposed for the individual determination of cysteine and cystine and for the mixtures of both analytes. The procedure is based on the inhibitory effect of cysteine on the oxidation of thiamine to thiochrome by mercury(II). Linear calibration graphs were obtained between 1.0×10^{-5} and $1.0 \times 10^{-4}M$, with a sampling rate of 22 samples/hr and relative standard deviation of 1.14%. The inclusion of a selecting valve in the configuration, to pump water or hydroxylamine, allows the successive determination of these two analytes. The applicability of the method to the determination of cysteine and cystine in pharmaceutical preparations was demonstrated by investigating the effect of potential interferences and by the analysis of commercial preparations.

The amino acids *L*-cystine and *L*-cysteine are substances of great biological importance. *L*-Cysteine participates in a number of biochemical processes that depend directly on the particular reactivity of thiols. The high nucleophilicity of thiols facilitates the role of cysteine as an active site, covalent catalyst (e.g., in papain¹ and glyceraldehyde-3-phosphate dehydrogenase²) and allows the cysteine residue of glutathione to scavenge and detoxify electrophiles during mercapturic acid biosynthesis^{3,4} and peroxide reduction.⁵ Oxidized derivatives of *L*-cysteine have additional metabolic roles. The disulphide bonds of *L*-cystine residues stabilize the tertiary structure of proteins, for example. As *L*-cystine is hydrolysed to *L*-cysteine in water, and *L*-cysteine is readily oxidized to *L*-cystine in air, they are often presented together (in hair, liver, horn, etc.). Several different methods have been developed for the determination of cysteine and/or cystine.⁶ However, the analysis of cysteine-cystine mixtures has rarely been performed by non-chromatographic techniques. Photometric,^{7,8} electrochemical,⁹ titrimetric,¹⁰ flow-injection¹¹ and catalytic¹² methods have been used with this aim.

Flow-injection analysis offers the chance to determine species in a mixture without prior separation, by several methods based on the different working conditions with the use of a very simple manifold and a flow cell in a single detector.^{13,14} The indicator reaction chosen for

the development of the determination method of cysteine and cystine in mixtures is the oxidation of thiamine to fluorescent thiochrome by mercury(II). Cysteine is an inhibitor of this reaction while cystine requires reduction to cysteine in order to do so. On this basis, a sequential method involving the use of a simple manifold with a diverting valve which provides carriers with water or hydroxylamine for the determination of cysteine or cystine plus cysteine has been applied. Hence, the method will involve the following reactions:

The technique chosen was the reversed FI mode because it enables a higher sensitivity to be reached and wider dynamic concentration range.¹⁴

EXPERIMENTAL

Apparatus

A Gilson Minipuls peristaltic pump was used and the components of the system were linked by polypropylene connectors and 0.5-mm i.d. PTFE tubing. An Omnifit selecting valve was used to select the carrier solution for the simultaneous determination. A Perkin-Elmer 3000

Fig. 1. Reversed FIA mode manifold for the individual determination of cysteine and cystine and for the simultaneous determination of both analytes (inclusion of selecting valve SV).

spectrofluorimeter connected to a Linseis 6512 recorder was used as a detector.

The manifold used is shown in Fig. 1. In the successive determination, valve SV allows switching between the distilled water stream (determination of cysteine) and that of hydroxylamine (joint determination of cysteine and cystine). This selection valve is cancelled for the individual determinations.

Reagents

All reagents were of analytical-reagent grade and solutions were always prepared with doubly-distilled water.

A $10^{-3}M$ stock cysteine solution was prepared daily by dissolving 0.0302 g of *L*-cysteine (Merck) in water and diluting to 250 ml in a calibrated flask. A $10^{-3}M$ stock cystine solution was prepared daily by dissolving 0.0600 g of *L*-cystine (Sigma) in 10 ml of 0.5M sodium hydroxide and diluting with water to 250 ml in a calibrated flask. Working solutions of both analytes were prepared from the stock solutions by appropriate dilution with water.

A $3.5 \times 10^{-3}M$ thiamine solution was prepared by dissolving 0.295 g of thiamine hydrochloride in water, adjusting to pH 4 with hydrochloric acid and diluting to 250 ml in a calibrated flask. This solution was stable for three months if kept refrigerated.

A $10^{-3}M$ mercury(II) solution was prepared from mercuric chloride and adjusted to pH 4 with hydrochloric acid. The working solution, $10^{-5}M$, was prepared daily by appropriate dilution with water.

Phosphate buffers were prepared from 0.2M disodium or dipotassium hydrogen phosphate and sufficient 5M potassium hydroxide to give the desired pH.

RESULTS AND DISCUSSION

Stationary system

Thiamine is oxidized to fluorescent thiochrome (TC) by mercury(II) in basic solutions.^{15,16} The order of addition of the reagents is critical. If the thiamine is mixed with the base first, a low yield of TC is obtained on the addition of Hg(II). The addition of a large excess of Hg(II) to the thiamine solution apparently stabilises the latter by the formation of a complex which can then be oxidised to TC when the base is added. The time taken to reach equilibrium decreases with increasing Hg(II) and HO^- concentrations; optimum values are obtained between pH 11 and 13. The phosphate buffer was selected because it provided a good buffering capacity at this pH range and good precision in the fluorescent measurements.

The formation of a precipitate in a spectrofluorimetric detection is unacceptable because of the lack of reproducibility of the measurements. Therefore, it was necessary to study the solubility of Hg(II) at alkaline pH. It was found that with $1.0 \times 10^{-3}M$ Hg(II) and 0.2M phosphate buffer, precipitation did not occur after 8 min in the pH range 10–13.

When cysteine is present in this system, the formation of TC is decreased because Hg(II) forms a complex with cysteine ($\log \beta = 14.21$),¹⁷ which thus acts as an inhibitor.

Flow system

The inhibitory effect of cysteine on the oxidation of thiamine to TC by Hg(II) was adapted for FIA to achieve a rapid and sensitive method for the determination of this amino acid. Of all the FIA tested, the best results were found with the reversed mode manifold shown in Fig. 1, because it resulted in an increase in sensitivity

Fig. 2. Influence of pH on the peak height. [Cysteine]: (1) 0; (2) $5 \times 10^{-5} M$.

and a decrease in the number and level of interferences.

Optimization of the chemical variables

To test different pH values, 0.2M phosphate buffers were used, and the optimum pH for measurement was found to be 12.0 (Fig. 2).

The influence of the concentration of thiamine was studied in the range 10^{-4} – $5.0 \times 10^{-3} M$. Maximum signals were obtained with $3.5 \times 10^{-3} M$ thiamine.

The effect of the concentration of Hg(II) is shown in Fig. 3; the optimum concentration of the Hg(II) stream was found to be $10^{-5} M$ because then the highest peaks and the largest concentration range for the determination of cysteine were obtained.

The reaction rate of the oxidation of thiamine by Hg(II) increases with increasing temperature. A temperature of $30 \pm 0.5^\circ$ was found to be suitable to obtain an appropriate peak height.

Optimization of the FIA variables

The reactor R_1 is where the complex formation reaction between Hg(II) and cysteine

Fig. 3. Influence of Hg(II) concentration on the peak height.

takes place. A length of 100 cm is sufficient for the chemical reaction to reach or come near to completion with a flow-rate between 1.7 and 3 ml/min. Changes in the volume of thiamine injected in the range 90–130 μl yields an almost constant signal, which decreases outside this range; a volume of 100 μl was always used. The peak height increased with increasing residence time because the oxidation of the thiamine to TC by Hg(II) is not fast. The best results were obtained if the pump was stopped when the plug was located in the reaction coil R_2 . After a given period of time the pump was triggered by a timer and the reaction zone was directed towards the detector. A coil length of 100 cm and a timer programmed to stop the flow after 30 sec for 1 min were chosen as a compromise between analytical signal and sampling rate.

Determination of cysteine

A series of standard solutions were pumped in triplicate to test the linearity of the calibration graph. The calibration graph is linear from 1.0×10^{-5} to $1.0 \times 10^{-4} M$ with a correlation coefficient of 0.9997. The sample rate is about 22 samples/hr. The statistical study performed on 11 samples of triplicate pumping of $2.0 \times 10^{-5} M$ concentration yielded a r.s.d. of 1.14%.

Determination of cystine

The determination of cystine involved the previous reduction to cysteine. In the manifold shown in Fig. 1 (with no selecting valve) the cystine stream and hydroxylamine stream merged, after the reduction step, with the mercury(II) solution.

A r.s.d. of 1.23% was obtained when 11 samples of $2.0 \times 10^{-5} M$ cystine were pumped in triplicate.

Interferences

An interference study, aimed at the determination of cysteine in pharmaceutical preparations, was performed. Samples containing a fixed concentration of cysteine ($5.0 \times 10^{-5} M$) and various concentrations of the foreign substance were injected into the FIA system. A substance was considered not to interfere if the variation in the peak height of cysteine was less than 3% in its presence. The results are shown in Table 1.

*Mean of four determinations.

Successive determination of cysteine and cystine

The resolution of the cysteine-cystine mixtures was based on the fact that cystine did not inhibit the oxidation of thiamine by Hg(II). The behaviour of both amino acids with reductants was the basis for their successive determination. The use of a selecting value to pump a distilled water stream or hydroxylamine stream merging with the sample stream in an alternate fashion (Fig. 1) makes possible the determination of the cysteine-cystine mixture to obtain analytical signals due to the contribution of cysteine or both analytes, respectively.

The results for the determination of cysteine and cystine in a series of synthetic mixtures are given in Table 2.

Analysis of pharmaceutical preparations

The method was applied to the determination of cysteine and cystine in pharmaceuticals. Commercially available formulations were analysed and the results obtained are summarized in Table 3. As can be seen for all the formulations the assay results were in good agreement with the declared content.

Table 3. Determination of cysteine and cystine in pharmaceuticals

Sample*	Source	Nominal value, mg		Found,† mg	
		Cysteine	Cystine	Cysteine	Cystine
Pil-Food	Pamies	80	25	79.2	24.6
Tulgrasum	Liade	0.356	—	0.349	—
Cistina	Quim.Med.	—	250	—	249.6
Freamine	Farmiberia	20	—	21.1	—

*Composition of samples—Pil-Food: methionine, 200 mg; cysteine, 80 mg; cystine, 25 mg; millet, 20 mg; calcium pantothenate, 25 mg; riboflavin, 1 mg; pyridoxin, 10 mg; biotin, 0.2 mg; α -tocopherol acetate, 3 mg. Tulgrasum: benzalconium chloride, 0.04 mg; bencil benzoate, 1.58 mg; threonine, 15.8 mg; cysteine, 0.356 mg; glycine, 0.216 mg. Cistina: cystine, 250 mg; excipient, 70 mg. Freamine: isoleucine, 300 mg; leucine, 770 mg; L-lysine acetate, 870 mg; methionine, 450 mg; phenylalanine, 480 mg; threonine, 340 mg; tryptophan, 130 mg; valine, 560 mg; alanine, 600 mg; arginine, 810 mg; histidine, 240 mg; proline, 950 mg; serine, 500 mg; glycine, 1190 mg; cysteine hydrochloride, 20 mg; sodium, 1 meq; acetate, 7.4 meq; phosphate, 2 meq; chloride, 0.2 meq; water and excipient up to 100 ml.

†Average of four determinations.

The accuracy of the proposed method was verified by carrying out recovery studies. When synthetic preparations that reproduced the compositions of the commercial formulations spiked with known amounts of these analytes were analysed, quantitative recoveries, 99.5–100.4% for cysteine and 99.8–100.3% for cystine, were obtained.

DETERMINATION OF BROMAZEPAM BY COUPLING A CONTINUOUS LIQUID-LIQUID EXTRACTOR TO AN ATOMIC-ABSORPTION SPECTROMETER

RICARDO E. SANTELLI,* MERCEDES GALLEGO and MIGUEL VALCARCEL

Department of Analytical Chemistry, Faculty of Sciences, University of Córdoba, Córdoba-14004, Spain

(Received 1 October 1990. Revised 6 May 1991. Accepted 13 May 1991)

Summary—Bromazepam, in the form of the ion-pair (bromazepam)₃Cu(ClO₄)₂, can be extracted into methyl isobutyl ketone, and determined indirectly by atomic-absorption spectrometry with a limit of detection of 0.1 µg/ml bromazepam at the 324.8 nm copper resonance line. The optimum conditions for determining this drug (0.4–4.0 µg/ml) are described. The relative standard deviation achieved is 1.7%. The method is selective and free from the interference of other 1,4-benzodiazepines. It was applied to the determination of bromazepam in pharmaceuticals and was also spiked in plasma samples.

The potential of the 1,4-benzodiazepines as medical drugs was first exploited by Zbinden and Randall in their studies on chlordiazepoxide.¹ Since then, many of these compounds have been synthesised and tested for pharmacological activity. Comprehensive reviews by different authors^{2,3} have compared the pharmacological actions of the therapeutically active members and the methods of analysis of this group. Bromazepam [7-bromo-1,3-dihydro 5-(2-pyridyl)-2H-1,4-benzodiazepin-2-one] is a major sedative-hypnotic drug widely employed in clinical as an anti-anxiety agent. Only the parent compound has been found to occur in blood after therapeutic administration. Both gas and liquid chromatographic methods with electron capture and ultraviolet detection, respectively, have been developed for the determination of bromazepam in plasma with a sensitivity of 5 ng/ml.⁴ Other techniques including spectrophotometry⁵ and voltammetry^{6,7} have been used for its determination.

The occurrence of the α - α' -dipyridyl moiety enables bromazepam to form cationic 3:1 complexes with divalent metal ions such as copper(II), cobalt(II), iron(II), nickel(II) and zinc(II).^{6, 8–10} These complexes have been employed for the indirect determination of bromazepam by spectroscopic techniques such as spectrophotometry and atomic-absorption spectrometry after manual solvent extraction

into methyl isobutyl ketone (MIBK) of the ion-pair formed with perchlorate.

The combination of flow-injection and atomic-absorption spectrometry (FI/AAS) has been shown to be of use in extending the performance of atomic spectrometers, increasing nebulization efficiency and diminishing physical manipulation of the samples by use of continuous separation systems.¹¹ We have conducted research into the use of FI/AAS in conjunction with liquid-liquid extraction for the indirect determination of perchlorate in human urine and serum samples,¹² nitrite and nitrate in meat¹³ and surfactants in waters.^{14,15}

This paper reports a simple and accurate method for the determination of bromazepam in plasma and pharmaceuticals involving the continuous liquid-liquid extraction of the ion-pair formed between the chelate, copper (bromazepam)₃²⁺, and perchlorate (as counter-ion), and the determination of copper in the extract by AAS.

EXPERIMENTAL

Instrumentation

A Perkin-Elmer 380 atomic-absorption spectrometer equipped with a copper hollow-cathode lamp (absorbance measured at 324.8 nm, spectral bandpass 0.7 nm) and an air-acetylene flame was employed with a multi-range Radiometer REC-80 recorder. The flow system comprised two peristaltic pumps (Gilson Minipuls-2), an injection valve (Rheodyne

*Permanent address: Chemistry Institute, University Federal Fluminense, Niterói-24020, Brazil.

5041), an A-10T solvent segmenter and a phase separator furnished with a Fluoropore membrane (1.0- μm pore size, FALP 02500, Millipore) described elsewhere,¹⁴ and displacement bottles for pumping methyl isobutyl ketone (MIBK). Poly(vinyl chloride) pumping tubes and Teflon tubing for the coils were also used.

Reagents

A stock solution of bromazepam (from Sigma) was prepared by dissolving 0.100 g in 100 ml of methanol and was stored at 0–4° in the dark. A 1000-mg/l. copper solution was prepared by dissolving 1.000 g of copper metal in a minimum volume of nitric acid (1 + 1 v/v) and diluting to 1 litre with 1% v/v nitric acid. A 5M perchlorate solution was made from sodium perchlorate.

The carrier solution was prepared by mixing 2.5 ml of 1000 mg/l. copper, 20 ml of 5M sodium perchlorate and 10 ml of 1M acetic acid/1M sodium acetate buffer (pH 4.75) and diluting to 100 ml with distilled water.

Sample preparation

Bromazepam standards with concentrations in the range 0.4–4.0 $\mu\text{g}/\text{ml}$ were made by pipetting appropriate volumes into 50-ml calibrated flasks and diluting to the mark with 1:4 (v/v) methanol–water.

The contents of 2–8 capsules of each Lexatin sample (from Roche, Spain) were placed in a 100-ml vessel, 25 ml of methanol were added, the mixture was shaken electromagnetically for 10 min, filtered, and the residue washed with water. The filtrate was then diluted to volume with water in a 100-ml standard flask. For continuous flow analyses, different aliquots of the sample solution (0.5–2.0 ml) were placed in 50-ml calibrated flasks and diluted to the mark with a 1:4 (v/v) methanol–water mixture.

Bromazepam spiked in plasma (5 ml) was extracted into 20 ml of chloroform, the solvent

was evaporated off at 50° on a water bath, and the residue was diluted to 25-ml with 1:4 (v/v) methanol–water.

Procedure

The manifold used for the extraction is illustrated in Fig. 1. The sample, containing 0.4–4.0 $\mu\text{g}/\text{ml}$ of bromazepam in methanol–water (1:4 v/v) at pH 3.8–9.8, was continuously pumped into the system and mixed with the carrier solution. The ion-pair formed was extracted into MIBK from a displacement bottle. A fraction of the extract, controlled through another displacement bottle, was separated in the membrane phase separator. The determination was effected by injecting 100 μl of the organic extract via injector I into a water stream that was directly aspirated by the nebuliser. The heights of the peaks were proportional to the bromazepam concentration in the sample. No blank extraction was required.

RESULTS AND DISCUSSION

Prior to selecting perchlorate as counter-ion, nitrate, chloride and chlorate were also tested. These anions, however, did not allow the $\text{Cu}(\text{bromazepam})_2^{3+}$ complex to be extracted. MIBK, ethyl acetate and 1,2 dichloroethane were tested as extractants. MIBK was chosen because it yielded a negligible blank absorbance and was neither viscous nor toxic. On the other hand, Fe(II), Zn(II), Co(II), Ni(II) and Cu(II) were also assayed as metal ions forming complexes with bromazepam. The copper ion provided the highest extraction efficiency in terms of sensitivity and reproducibility. Finally, a 1:4 v/v methanol–water medium resulted in a signal 50% greater than that provided by water alone. This was probably the result of the ethanol molecules competing with those of water, thereby hindering the formation of hydrated ions and hence favouring ion-pair formations.

Influence of chemical variables

This study was performed by introducing a standard solution containing 1 $\mu\text{g/ml}$ of bromazepam into the system. The effect of the carrier and sample pH was studied in the range 1–6 and 3–11, respectively. The pH was found to have no influence on the signals over the ranges 3.5–6.0 and 3.8–9.8 for the carrier and sample, respectively. Above pH 6, the carrier solution (copper) was precipitated. A 1M acetic acid/1M sodium acetate buffer (pH 4.75) was selected to adjust the pH (it was added to the carrier solution). The effect of changing the concentration of the buffer between 0.2–1M was negligible. The concentration of the perchlorate (ion pairing reagent) was varied between 0.1 and 5M in the carrier solution. To study the influence of the concentration of copper on the absorbance, several carrier solutions with concentrations in the range 1–200 $\mu\text{g/ml}$ were investigated. A 10 $\mu\text{g/ml}$ solution of copper was found to be sufficient for maximum response. The absorbance remained constant at higher concentrations (up to 200 $\mu\text{g/ml}$). The ionic strength (adjusted with potassium nitrate or ammonium chloride) had no effect, at least up to 1M.

A carrier solution containing 25 $\mu\text{g/ml}$ Cu^{2+} , 1M in perchlorate and 0.2M buffer was selected for routine analyses.

Influence of flow-injection variables

The flow-rates of the aqueous and organic phases were studied. For this study an extraction coil length of 300 cm (0.7 mm i.d.) and an injected volume of 100 μl were used. The carrier flow-rate was kept at 0.22 times the sample flow-rate in order to avoid excessive dilution of the continuously pumped sample (1.0 $\mu\text{g/ml}$ bromazepam).

First, the sample flow-rate was varied between 1.4 and 3.8 ml/min while keeping that of the organic phase constant at 0.5 ml/min. The absorbance did not increase with increasing sample flow-rate, as one would expect taking into account that it increased the preconcentration ratio. A similar effect was observed by decreasing the organic phase flow-rate (1.0–0.3 ml/min) at a sample flow-rate of 2.5 ml/min. These results were checked by carrying out six experiments at three aqueous/organic phase flow ratios (1, 5 and 10) and two bromazepam concentrations (0.4 and 4.0 $\mu\text{g/ml}$). The blank solutions yielded negligible signals in every

instance and the absorbance of the two samples assayed remained constant at the three flow-ratios used.

The influence of the residence time was also studied by changing the length of the extraction coil in the range 30–500 cm (0.7 mm i.d.) at an aqueous and organic phase flow-rate of 3.9 and 0.8 ml/min, respectively. The absorbance was not affected by extraction coil lengths longer than 200 cm (residence time 10 sec), which ensured the fast extraction of the ion-pair. The tube length between the mixing point for the sample and carrier stream and the segmenter did not affect the signal at values above 30 cm for an inner diameter of 0.7 mm.

The extracted sample volume injected into the water line had a significant effect on the absorbance. The peak height increased with increasing injected sample volume up to 90 μl , above which it remained constant up to 300 μl . The areas of the peaks recorded at a low chart rate increased with increasing injected volume (Fig. 2).

Determination of bromazepam

Under the optimum conditions, a linear calibration graph (absorbance vs. $\mu\text{g/ml}$) for 0.4–4.0 $\mu\text{g/ml}$ bromazepam was obtained. The equation of the graph was:

$$A = 0.004 + 0.052 (\text{bromazepam}) \quad (r = 0.997)$$

where A is the peak height absorbance and the concentration is expressed in $\mu\text{g/ml}$. The detection limit, 0.1 $\mu\text{g/ml}$, was calculated as 3 times the standard deviation of the peak height for 30 injections of the same sample. The precision of the method was checked on 11 samples containing 1.0 $\mu\text{g/ml}$ bromazepam. The relative

Fig. 2. FIA peaks obtained with different injected volumes at three chart rates. A, B and C: 2 min/cm, 10 sec/cm and 5 sec/cm.

Table 1. Determination of bromazepam in pharmaceutical preparations

Sample	Manufacturer*	Nominal amount	Found	Mean Recovery, † %
Lexatin 1.5	Roche	1.5 mg/capsule	1.51 ± 0.05	100.4
Lexatin 3	Roche	3 mg/capsule	3.03 ± 0.01	98.7
Lexatin 6	Roche	6 mg/capsule	5.8 ± 0.1	101.6

*Spanish; †Mean of 7 determinations.

standard deviation was 1.7% and the sampling frequency was 40/hr.

To test the specificity of the method for bromazepam, other narcotic-analgesics and hypnotic drugs were investigated. The benzodiazepines assayed were chlordiazepoxide (librium), nitrazepam, diazepam, oxazepam, flurazepam, medazepam and lorazepam. Codeine, metamphetamine and pentobarbital were also assayed. Foreign species were added at a maximum level of 1 mg/ml per 1.0 µg/ml of bromazepam. There was no interference from any of the substances studied. (Tolerated ratio 1000:1.)

Applications

The proposed method was applied to the determination of bromazepam in three commercial pharmaceuticals (lexatin) containing 1.5, 3 and 6 mg of bromazepam per capsule. The results found were consistent with the nominal contents, as can be shown in Table 1.

The procedure was also evaluated on the determination of bromazepam spiked in human plasma. A maximum volume of 1 ml of plasma was diluted to 25-ml with methanol-water (1:4 v/v); the recovery was about 99%. Higher volumes of plasma resulted in greater recoveries because of the interfering organic substances present in the fluid, and resulted in incomplete phase separation as a result of the formation of emulsions. Thus, plasma volumes larger than 1 ml must be treated as described in the Experimental section. Blanks of different human plasmas treated like the samples, yielded negligible absorbance values. Different amounts of bromazepam (25, 50 and 100 µg) were added to 5 ml of plasma and subsequently treated as described above. Application of the continuous mode of analysis yielded bromazepam recoveries of about 96% (average of five determinations on the whole amount added).

CONCLUSIONS

The proposed automatic method for the determination of bromazepam allows the direct

assay of formulations. Plasma samples require prior extraction into chloroform for volumes higher than 1 ml (diluted to 25-ml). The procedure yields acceptable results and is subject to no interference from other 1,4-benzodiazepines at concentrations 1000-fold higher than that of bromazepam.

The method compares favourably with its batch counterpart and has several advantages: small sample volume, low reagent consumption, and higher sampling frequency (inherent in the FIA techniques); wide pH range (3.8–9.8 and 4.0–5.4 for the continuous and manual extraction, respectively); higher sensitivity (0.052 and 0.031 ml/µg for the continuous and batch extraction, respectively) and higher precision thanks to the lesser sample manipulation involved.

In this paper it has been demonstrated that liquid-liquid extraction implemented in FIA manifolds is an excellent way for eliminating any influence due to the potential lability of the copper-bromazepam complex formed and the possible negative effects of acetate because of the reproducible and exact timing of this approach.

A FAST METHOD FOR THE DETERMINATION OF LEAD IN PAPRIKA BY ELECTROTHERMAL ATOMIC-ABSORPTION SPECTROMETRY WITH SLURRY SAMPLE INTRODUCTION

MANUEL HERNÁNDEZ CÓRDOBA* and IGNACIO LÓPEZ GARCÍA

Department of Analytical Chemistry, Faculty of Chemistry, University of Murcia, 30071 Murcia, Spain

(Received 15 November 1990. Revised 15 April 1991. Accepted 19 April 1991)

Summary—A rapid procedure for the determination of lead in commercial paprika samples is described. The samples are first calcined at 350°, then suspensions are prepared in water containing 0.1% v/v Triton X-100 and 0.1% w/v ammonium phosphate and injected into the electrothermal atomiser. The use of platform atomisation with a preatomisation cooling step allows for simple calibration with aqueous standards. When using 0.4% suspensions the detection limit is 0.2 µg/g. The results for seven paprika samples agree with those obtained by an alternative method involving calcination and dissolution in acid.

Paprika, the ground dried ripe fruit of *Capsicum annum*, is widely used as a garnish and flavorant in foods. The lead content in paprika is restricted by law to less than 10 µg/g and the products must be periodically analysed to verify this condition. Lead determination in these samples, as well as in other biological materials, involves time-consuming steps and is subject to error due to contamination from reagents and the lengthy processes involved.

On the other hand, the direct analysis of slurries by electrothermal atomisation atomic-absorption spectrometry (ETA-AAS) offers recognized advantages over the conventional methods involving dissolution of the samples, and appears to be a suitable alternative for the rapid determination of a number of elements in a wide range of products, including foods. Thus, this analytical approach has been extensively studied by several researchers to determine lead in a variety of biological materials.¹⁻¹⁰

As far as we know, lead determination in paprika has been carried out with emission spectroscopy,¹¹ voltammetry¹² and ETA-AAS¹³ after a mineralisation and acid digestion step, but no slurry-ETA-AAS procedure has been specifically developed for this purpose. Recently, we were asked for a reliable and fast procedure for the determination of lead in commercial paprika and the slurry-ETA-AAS approach appears to be the most suitable way to

develop such a simple procedure for routine purposes. This paper describes the results of our study and as a consequence, a simple, rapid method for the determination of lead in commercial paprika samples is reported.

EXPERIMENTAL

Apparatus

A Perkin-Elmer Model 1100B atomic-absorption spectrometer with deuterium-arc background correction and an HGA-400 graphite furnace were used. Measurements were performed at the 283.3-nm line of lead with a spectrometer bandpass of 0.7 nm and a hollow-cathode lamp (Perkin-Elmer) operated at 8 mA. Background-corrected absorbance peak areas were measured. Grooved pyrolytically coated graphite tubes were used with pyrolytically coated platforms, unless otherwise stated. The samples were weighed with an analytical balance (Mettler, Model AJ100, precision ± 0.01 mg). Slurries were injected into the graphite furnace with precision micropipettes (Eppendorf).

Reagents

All inorganic chemicals used were of analytical-reagent grade and were used without further purification. Doubly distilled water was used exclusively.

A stock solution of lead (1000 mg/l.) was prepared by dissolving lead nitrate (Fluka Chemie AG, Switzerland) in 1% v/v nitric acid.

*Author for correspondence.

The solution was stored in a polyethylene bottle and working solutions were prepared daily by appropriate dilution.

Triton X-100 (octyl phenoxy polyethoxy-ethanol) and concentrated nitric and sulphuric acids were obtained from Merck (Merck, Germany).

Ammonium dihydrogen phosphate was from Fluka Chemie AG.

Procedure for the determination of lead in paprika with slurries

Weigh 1 g of dried sample (110°) and ash at 350° in a porcelain crucible for 2 hr. Weigh the ash, grind it in an agate ball mill for 10 min and sieve with a 325-mesh sieve. Discard the small fraction containing larger size particles. Take an amount of sieved, ashed sample ranging 10–100 mg and add 25 ml of a solution containing 0.1% Triton X-100 and 0.1% ammonium phosphate. Stir magnetically for a minimum of 10 min. While the suspension is being stirred, take 20- μ l aliquots by means of a micropipette and inject into the furnace. Start the heating programme given in Table 1, where all temperatures quoted are values set on the HGA-400 power supply, and obtain the absorbance peak area values. Prepare a calibration graph up to 2 ng of lead with aqueous lead standard solutions containing 0.1% Triton X-100 and 0.1% ammonium phosphate. If the standard additions procedure is preferred, calibration graphs are easily obtained by adding aliquots of standard lead solution to the slurry.

Determination of lead by dissolution of the samples

For comparative purposes, paprika samples were analysed with the following procedure. The samples were dried, weighed (1 g) and placed in a porcelain crucible. Concentrated sulphuric acid (2.5 ml) was added and the mixture carefully heated to dryness with a sand-bath. The crucibles were then heated in a furnace at 400° for 2 hr. After cooling, 1 ml of concentrated nitric acid was added and the heating steps were repeated. The entire process, addition of nitric acid and heating, was performed three times. Finally, the ashes were dissolved in 1 ml of concentrated nitric acid and small amounts of a solution containing 0.5% ammonium phosphate and 0.5% nitric acid were added to a volume of 50 ml. Aliquots of this solution were taken and analysed for lead by ETA-AAS with the standard additions

procedure. A reagent blank was performed to correct the results.

RESULTS AND DISCUSSION

There have been several reports of slurry analytical results which depend on particle size. Thus, Fuller *et al.*¹⁴ noted particle size effects for solids with $\geq 25 \mu\text{m}$ diameter and Jackson and co-workers^{15,16} confirmed that successful ETA-AAS determinations required particle size diameters of less than $30 \mu\text{m}$ for slurry preparations of soil. On the other hand, Miller-Ihli⁸ in an elaborate study on slurry sample preparation with ETA-AAS purposes, suggested that very small particle sizes ($< 30 \mu\text{m}$) may not be essential for precise slurry analyses of biological or botanical materials. With this in mind, a number of experiments were performed on two previously analysed commercial paprika samples containing 6.6 and 2.2 $\mu\text{g/g}$ of lead, respectively. The samples were dried and sieved through 200, 100, 50 and 30- μm sieves. The particle size distribution was very similar for the two samples and, as can be seen in Fig. 1, only 2–3% of particles were less than $30 \mu\text{m}$ with the bulk of the particles in the 50–200 μm range. An attempt was made to decrease the particle size by grinding the commercial samples in an agate

Fig. 1. Particle size distribution for two commercial paprika samples.

ball mill for 15, 30 and 90-min periods. However, because of the physical characteristics of paprika, the particle size distribution was not significantly modified even after 90 min of grinding. Several suspensions were then prepared with the same percentage of the 100–200, 50–100, 30–50 and $<30\ \mu\text{m}$ sieved fractions. Aliquots of $20\ \mu\text{l}$ from these suspensions were injected into the electrothermal atomiser and the signal from lead was obtained in the presence of ammonium phosphate as a chemical modifier with wall atomisation and 1000° and 1900° as charring and atomisation temperatures respectively. The lead signals from the slurries prepared from the 100–200, 50–100 and 30–50 μm fractions were only 1.1, 2.4 and 10.5% of that obtained from the slurry prepared from less than $30\ \mu\text{m}$ fraction, suggesting that in this case a considerable particle size effect occurs. On the other hand, the reproducibility of the signals from the slurries prepared from the coarse fractions was worse than that of the finest (RSD was $\pm 15.6\%$ for the 50–100 fraction and $\pm 5.6\%$ for the less than $30\ \mu\text{m}$ fraction).

These problems appear to be direct consequences of the sampling error which occurs when the aliquots are taken with the micropipette and of an ineffective action of the chemical modifier on the larger particles, leading to premature determinant losses. The latter point was proved when the charring temperature was decreased to 500° and the signal from the slurries prepared from the coarse material (100–200 μm) increased, being 21% of that obtained for the $<30\ \mu\text{m}$ slurries under the same experimental conditions. Furthermore, the separated fractions were mineralised and lead determined as indicated in Experimental, very similar lead contents being obtained in the four fractions. There is no doubt that the determinant is homogeneously distributed throughout the samples and the above quoted problems of low signal and poor reproducibility are exclusively due to an excessive particle size.

Taking into account all the above, the samples were calcined and then ground in an agate ball-mill, as indicated in Experimental, in order to render the particle size diminution possible. Under the recommended conditions, more than 90% of the ground calcined samples was easily sieved through a 325-mesh size. Since the determinant is homogeneously distributed through the sample, the sieved fraction was considered as representative and the small frac-

tion (3–7%) containing larger particles was discarded. The sieved portions were then used for the preparation of the slurries.

When suspensions were prepared from calcined samples, the ashes tended to float on top of the liquid and dispersion was difficult. For this reason, several concentrations of Triton X-100 were tried in order to obtain a stable suspension more rapidly and a 0.1% concentration was found to be the most adequate. Although only partial stabilisation was achieved and the aliquots had to be taken while the suspension was being continuously stirred, it was proved that the presence of the surfactant improved the reproducibility.

In spite of the pre-treatment of the samples at 350° , which allows the decomposition of most of the organic matter, problems from spluttering and high values for the background were encountered. To overcome this, a number of experiments were performed on a 0.2% w/v slurry prepared from a sample containing $6.6\ \mu\text{g/g}$ of lead, using both wall and platform atomisation. The suspension was prepared in the presence of 0.1% w/v ammonium phosphate to avoid premature loss of lead, and a charring step at 1000° with atomisation at 1900° was used. Both maximum power heating and a 1-s ramp for the atomisation step were considered. The best results were found when using platform and maximum power heating. Under these experimental conditions, the background signal was the lowest (0.094 A.s for peak area) with a peak height nearly constant during the development of the signal from lead (0.030 A), which makes the correction by the deuterium device more reliable.

Figure 2 shows char curves for a 0.2% slurry, without addition of a chemical modifier and

Fig. 2. Effect of the charring temperature on the relative signal for (A) aqueous Pb solution, (B) slurry paprika sample, (C) and (D) as (A) and (B) in the presence of 0.1% w/v ammonium phosphate.

with the addition of 0.1% ammonium phosphate solution. For comparison, curves for aqueous solutions of lead are also included and absorbance peak areas have been normalised, *i.e.*, data on the ordinate are the ratios between the signal obtained when using the charring temperature given in abscissas and the maximum signal obtained. As can be seen, when a 0.2% slurry was used (curve *b*), the charring temperature could be raised to 700° without loss of determinant. It was proved that this matrix auto-stabilising effect depends on the slurry percentage and it is preferable to add 0.1% w/v ammonium phosphate. Under this condition, the maximum char temperatures for slurries and aqueous solutions (curves *d* and *c*) were virtually identical, the charring step could be raised to 1000° and a lower background signal in the atomisation step was obtained.

The atomisation temperature was studied in the range 1400–2300° and the maximum signal for lead was obtained for temperatures ranging between 1800 and 2000°. Only for temperatures higher than 2100° did the signal decrease. This is a similar result to that previously reported by Hoenig and Van Hoeyweghen,⁵ which showed that when using ammonium phosphate as a modifier it was possible to use an atomisation temperature of 2200°. On the other hand, Lynch and Littlejohn⁹ proved that the temperature must not be higher than 1300° for a 4% w/v fish slurry and 1600° for a 4% w/v bovine liver slurry. As indicated by these authors,⁹ the discrepancy may be due to the use of lower slurry concentrations, as is the case reported here.

Because it has been reported that, in some instances, the inclusion of a cooling step before the atomisation stage improves the performance of ETA–AAS procedures, this point was also studied. When this cooling step was included in the programme, the time differentiation between the analyte and background signals increased and the background signal remained very small at the maximum of the analyte, permitting a more reliable background correction by the deuterium device.

Calibration, reproducibility and accuracy

From a practical point of view, it is desirable for calibration to be performed with aqueous standards, avoiding the need for using suspensions from samples of known lead content. Under the above conditions, the background-corrected peak areas obtained from atomisation of aqueous standards and slurries were additive.

Table 2. Slopes of the standard addition graphs with a charring temperature of 1000° and ammonium phosphate as chemical modifier*

Slurry, w/v	Slope, † A · s/ng
0.05	0.1965 ± 0.0008
0.09	0.1970 ± 0.0006
0.16	0.1968 ± 0.0005
0.20	0.1952 ± 0.0010

*Slope for aqueous standard, 0.1960 A · s/ng.

†The slopes were calculated from four-point standard additions. Each addition point was measured three times.

To prove this point, several slurries in the 0.05–0.2% w/v range were prepared from a paprika sample containing $6.6 \pm 0.3 \mu\text{g/g}$ lead and standard addition calibrations graphs were obtained. The results shown in Table 2 demonstrated, as expected, that the slopes of these graphs and the slope from a calibration graph for aqueous standard solutions, obtained under the same experimental conditions, are virtually identical. Therefore, direct calibration against aqueous standards is valid.

A linear relationship between the peak area and the percentage of sample in the slurries in the 0.04–0.4% range was verified for a sample containing $2.2 \pm 0.1 \mu\text{g/g}$ of lead. The background signals were in the 0.04–0.188 A.s range with a peak height nearly constant during the development of the lead signal ranging from 0.006 to 0.039 A. More concentrated suspensions were not studied because the sensitivity is high enough for the routine purposes for which the procedure was designed. Taking into account that the thermal pre-treatment of the sample at 350° involves a weight loss of about 80%, a 0.4% slurry prepared from the calcined sample is equivalent to a 2% slurry from the

Fig. 3. Reproducibility of the procedure. (A) aqueous Pb solution, (B) paprika slurries. Numbers on the graph indicate the percentage of the slurry.

Table 3. Lead content in paprika samples

Sample	Value (\pm SD) obtained, $\mu\text{g/g}$		
	Proposed method		
	Standard additions	Aqueous calibration	Acid-digestion and ETAAS
1	6.5 \pm 0.2	6.4 \pm 0.2	6.6 \pm 0.3
2	2.3 \pm 0.1	2.4 \pm 0.1	2.2 \pm 0.1
3	7.5 \pm 0.3	7.5 \pm 0.2	7.7 \pm 0.3
4	5.2 \pm 0.2	5.5 \pm 0.2	5.4 \pm 0.3
5	9.6 \pm 0.4	9.5 \pm 0.3	9.7 \pm 0.4
6	3.9 \pm 0.1	3.8 \pm 0.1	4.0 \pm 0.2
7	1.5 \pm 0.1	1.5 \pm 0.1	1.6 \pm 0.2

original vegetal material, which allows a detection limit for lead in paprika of 0.2 $\mu\text{g/g}$, calculated on the basis of 2σ .

Reproducibility was studied with five slurries prepared from the above cited sample covering the 0.05 to 0.4% range. Ten aliquots were taken from each suspension and the signal from lead obtained following the recommended procedure. Figure 3 shows a plot of RSD against the mean value of the peak area. As can be seen in the Figure, the RSD is higher than that obtained for aqueous standards, which are included for comparison, but the reproducibility is adequate for routine purposes.

In order to check the reliability of the method, seven samples of commercial paprika were analysed with the acid dissolution procedure indicated in the Experimental section. Table 3 gives the results obtained for four replicate analyses of each sample. As can be seen from the Table, the results agree with

those obtained by the slurry method reported here, using both direct calibration with aqueous standards and the standard additions procedure.

POTENTIOMETRIC TITRATION OF PHENOTHIAZINE COMPOUNDS IN CHLOROFORM AND ITS USE IN PHARMACEUTICAL ANALYSIS

S. M. GOLABI* and M. SHOWKATI-SHISHEVAN

Electroanalytical Chemistry Laboratory, Faculty of Chemistry, University of Tabriz, Tabriz, Iran

(Received 23 June 1989. Revised 30 April 1991. Accepted 18 May 1991)

Summary—The potentiometric titration of some phenothiazine drugs in chloroform is described. A standard solution of bromine in chloroform was used as titrant and the end-points were detected with a small platinum indicator electrode, and an Ag/AgCl electrode in 0.01M Et₄NCl in chloroform as reference. A fast redox reaction occurs during the titrations and the phenothiazine ring is oxidized to the phenothiazonium free radical (P⁺). The low dielectric constant of the medium favours the formation of (P⁺Br⁻) ion-pairs or (P⁺Br₃⁻) ion-pairs on further addition of bromine, which has no influence on the position of the first end-point. The method was used for the determination of promethazine, chlorpromazine, trifluoperazine and thioridazine in pharmaceutical preparations after extraction into chloroform. The relative standard deviation for the determination of 5 mg of all these phenothiazines was about 1%.

Numerous electroanalytical methods for the determination of phenothiazines are available in the literature.¹⁻⁹ Potentiometry with ion-selective membrane electrodes has also been reported¹⁰ and is applicable to aqueous buffered solutions, but a specific electrode is needed for each phenothiazine compound.

The official method proposed for the assay of phenothiazines in pharmaceuticals involves their extraction into chloroform and subsequent determination by ultraviolet spectrophotometry.^{11,12} An investigation of the polarographic properties of phenothiazines has shown that they can be anodically oxidized in chloroform medium¹³ and this suggests that they might be determined oxidimetrically in this solvent.

In this work, the potentiometric characteristics of some phenothiazines in chloroform have been studied and the compounds in various pharmaceutical forms were determined by potentiometric titration with bromine.

EXPERIMENTAL

Apparatus

Potentials were measured with a Metrohm recording potentiograph, type E536, equipped with an E578 titration stand. A Metrohm EA201 platinum electrode was used as indicator and the reference electrode was Ag/AgCl in

0.01M tetraethylammonium chloride solution in chloroform.

Reagents

All chemicals were of analytical reagent grade. Chloroform (Merck) was used as solvent without further purification. Stock bromine solution (0.1M) was prepared by dissolving pure bromine in chloroform. Titrant solutions (0.01 or 0.005M) were prepared by dilution just before use. These solutions must be protected from light to avoid the disappearance of bromine. A 0.005M phenothiazine solution in chloroform was prepared from the pure substance (Aldrich). *N*-Substituted phenothiazine solutions were prepared by dissolving an accurately weighed amount of each phenothiazine (as its hydrochloride) in water and then extracting with chloroform. The extracted phase was diluted quantitatively with the same solvent to give a 0.005M solution. The extraction was implemented by the procedure described in the *U.S. Pharmacopeia*,¹¹ except that the ammonia was replaced by 10M sodium hydroxide.¹³ The solutions can be used as standards instead of the phenothiazine solution.

Pharmaceutical preparations were purchased from local sources in various forms (tablet, syrup, injection, drops) and were treated by the dissolution procedures in the *U.S. Pharmacopeia*¹¹ before the phenothiazines were extracted as above.

*Author for correspondence.

Procedure

Standardization of bromine. A 5 or 10 ml portion of standard phenothiazine solution in chloroform (0.005M) was pipetted into the reaction vessel. The bromine titrant (ca. 0.01 or 0.005M) was added at 1 ml/min. The potential ranges from 800 to 1300 mV vs. reference electrode. The variation of electrode potential as a function of the volume of titrant is shown in Fig. 1a and the corresponding differential plot in Fig. 1b.

Potentiometric titration of phenothiazines. The titration is carried out as above with 5 ml of solution obtained from extraction of pharmaceutical samples with chloroform. Quantitative determination of phenothiazine drugs in the extracted phase and therefore in pharmaceutical preparations is achieved in one of the following ways.

(i) Comparison with standard. Another titration is carried out with 5 ml of a standard solution of the *N*-substituted phenothiazine. The quantity of pharmaceutical ingredient is calculated by comparison of the volumes of bromine consumed in the two titrations.

(ii) Standard addition method. Another titration is carried out, with a second 5 ml aliquot of extracted phase and 1 or 2 ml of standard phenothiazine or *N*-substituted phenothiazine solution. The content of phenothiazine is calculated from the ratio of the volumes of bromine consumed in the two titrations, and the amount of standard added.

Fig. 1. Titration of 5 ml of 0.005M phenothiazine with 0.005M bromine in chloroform. (a) Plot of E as a function of V_{Br_2} . (b) Plot of $\Delta E/\Delta V_{Br_2}$ as a function of V_{Br_2} .

RESULTS AND DISCUSSION

Reaction stoichiometry

The electron-transfer reaction between phenothiazine (P) and bromine can proceed by the following schemes.

(i) The reaction product is the P^+Br^- ion-pair:

The potentiometric curve for such a reaction is expected to be the first part of curve a in Fig. 1.

(ii) Following the oxidation of phenothiazine to P^+Br^- , the complex $P^+Br_3^-$ is formed:¹⁴

In this case, a second potential jump is expected to appear at $V_2 = 3V_1$ (the second part of curve a in Fig. 1).

In both cases, the low dielectric constant of the solvent ($\epsilon = 6.2$) favours the formation of P^+Br^- and $P^+Br_3^-$ ion-pairs.

In practice, the potentiometric titration of phenothiazine with bromine, curve a in Fig. 1, shows the second end-point expected for formation of $P^+Br_3^-$ following P^+Br^- , when $V_2 = 3V_1$. Alternatively, this can be tested by analysis of the experimental curve. The electrode potentials on the two sides of the equivalence point can be expressed as follows (at 25°).

Before the equivalence point ($P^+Br^- + e \rightleftharpoons P + Br^-$):

$$E = E_1^0 + 0.0591 \log\left(\frac{[P^+Br^-]}{[P][Br^-]}\right) \quad (3)$$

After the equivalence point and assuming the formation of stable $P^+Br_3^-$, ($P^+Br_3^- + 2e \rightleftharpoons P^+Br^- + 2Br^-$):

$$E = E_2^0 + \frac{0.0591}{2} \log \frac{[P^+Br_3^-]}{[P^+Br^-][Br^-]^2} \quad (4)$$

If the $P^+Br_3^-$ ion-pair is not sufficiently stable, the potential after the equivalence point ($x > 0.5$) will be associated with ($Br_2 + 2e \rightleftharpoons 2Br^-$):

$$E = E_3^0 + (0.0591/2) \log\left(\frac{[Br_2]}{[Br^-]^2}\right) \quad (5)$$

For an initial concentration of phenothiazine equal to C_0 , we have the following concentration balance during the titration:

$$xC_0 = C_{Br_2} = \text{bromine added.}$$

$$2xC_0 = C_{P^+Br^-} = \text{ion-pair produced.}$$

$$C_0 - 2xC_0 = C_0(1-2x) = P = \text{concentration of unreacted phenothiazine.}$$

Table 1. Potentiometric determination of phenothiazines in pharmaceutical preparations

Product*	Nominal content	Found†	
		Potentiometric titration	U.S.P. method
Promethazine syrup	5 mg/5 ml	5.20 mg/5 ml	5.28 mg/5 ml
Promethazine ampoule	50 mg/2 ml	50.6 mg/2 ml	50.5 mg/2 ml
Promethazine tablet	25 mg/tab.	25.2 mg/tab.	25.3 mg/tab.
Chlorpromazine ampoule	50 mg/2 ml	51.4 mg/2 ml	50.8 mg/2 ml
Chlorpromazine drops	1 mg/drop	0.97 mg/drop	0.98 mg/drop
Chlorpromazine tablet	25 mg/tab.	25.8 mg/tab.	25.8 mg/tab.
Trifluoperazine ampoule	1 mg/ml	0.98 mg/ml	1.01 mg/ml
Thioridazine tablet	25 mg/tab.	27.3 mg/tab.	26.1 mg/tab.

*In each case, the active principle is the hydrochloride of the drug.

†All values are the average of 3–5 determinations by the standard addition or reference method.

$x C_0 - C_0/2 = C_0(2x - 1)/2 = P^+Br_3^-$ produced after the equivalence point, or the excess of added bromine, when the $P^+Br_3^-$ is supposed to be nearly dissociated.

The dissociation of P^+Br^- can be considered as follows:

Substituting $[Br^-]$ from equation (6) into equations (3), (4) and (5) and considering the concentration balance, we have:

(i) before the equivalence point ($0.5 > x > 0$):

$$E = A + (0.0591/2)\log[2x/(1 - 2x)^2] \quad (7)$$

with $A = E_1^0 - (0.0591/2)\log K_d C_0$.

(ii) after the equivalence point ($1.5 > x > 0.5$); according to equation (4):

$$E = B + (0.0591/2)\log[(4x - 2)/(3 - 2x)^2] \quad (8)$$

with $B = E_2^0 - (0.0591/2)\log K_d C_0$.

or according to equation (5):

$$E = C + (0.0591/2)\log[(2x - 1)/2] \quad (9)$$

with $C = E_3^0 - (0.0591/2)\log K_d$.

The plots of $\log[2x/(1 - 2x)^2]$ against E for $0.5 > x > 0$ and $\log[(2x - 1)/2]$ against E for $1.5 > x > 0.5$ gave straight lines with slopes of $0.0591/2$ V (see Fig. 1). This agrees with the proposed stoichiometry for the titration reaction and confirms the instability of the $P^+Br_3^-$ ion-pair.

Analysis of pharmaceutical preparations

Several preparations of phenothiazine drugs were analysed by potentiometric titration and

by the U.S.P. spectrophotometric method. The results are given in Table 1. Errors are typically 1–4%, except for thioridazine. Figure 2 illustrates the potentiometric titration curves of chlorpromazine and promethazine in chloroform. The relative standard deviations of five assays of samples containing 5 mg of phenothiazines were about 1%.

CONCLUSIONS

The use of bromine as a convenient titrant in the oxidimetric titration of phenothiazine derivatives in chloroform with potentiometric end-point detection has been demonstrated. The stoichiometry of the titration reaction is the

Fig. 2. Potentiometric titration of chlorpromazine (a_1 and a_2) and promethazine (b_1 and b_2) with $0.005M$ bromine in chloroform. The titrands were obtained from pharmaceutical preparations. a_1 and b_1 , E vs. V_{Br_2} ; a_2 and b_2 , $\Delta E/\Delta V_{Br_2}$ vs. V_{Br_2} .

same for all phenothiazines and the reaction product is always a coloured cationic free radical (P^+) which is stabilized by formation of P^+Br^- ion-pairs. The P^+Br^- ion-pairs can be partially transformed into $P^+Br_3^-$ ion-pairs in the presence of excess of bromine. The reaction is adequately rapid and shows a sufficiently large potential jump at the equivalence point to make detection of this easy. However, the use of derivative curves is recommended for precise detection of the end-point at the first equivalence point. The second equivalence point in the derivative method is not quite sharp because the $P^+Br_3^-$ formation reaction is not quantitative and cannot be used for the end-point detection. The method can be used for concentrations as low as 0.2 mg/ml phenothiazine and allows the accurate and precise determination of phenothiazines in pharmaceutical products after extraction into chloroform.

(Received 12 January 1990. Revised 3 April 1991. Accepted 5 April 1991)

Summary—High-performance liquid chromatography with electrochemical detection by means of a re-polishable graphite-epoxy resin composite electrode, modified with the electrocatalyst cobalt phthalocyanine, has been used for the determination of reduced glutathione (GSH) in 25- μ l samples of whole blood. The mobile phase was 0.05M phosphate buffer (pH 2.3) containing 1 mM EDTA, used in conjunction with a Waters μ Bondapak ODS chromatography column. The use of the electrocatalyst reduced the overpotential for the oxidation of GSH at a carbon electrode by \sim 750 mV, and the applied potential used was +0.5 V vs. Ag/AgCl. The mean recovery of GSH added during the sample pretreatment step was 95%; the assay imprecision was 1-2% for triplicate analyses of the whole blood samples.

Within the human circulation glutathione exists predominantly in the erythrocytes, where it is maintained primarily in the reduced form (GSH, L- γ -glutamyl-L-cysteinylglycine). It is an important factor in conferring protection against toxic effects of reactive oxygen compounds, such as hydrogen peroxide and superoxide, which are produced during normal metabolism and the detoxification of some drugs.¹⁻³

Determination of GSH in whole blood is important since depressed concentrations arising from some types of infection or treatment with oxidant drugs may lead to acute haemolytic anaemias in both neonates and adults.³ These deficiencies may arise from faults in a number of enzyme pathways; the most common involves a deficiency, or reduced activity, of glucose-6-phosphate dehydrogenase (G6PD).^{3,4}

In a previous study we gave some results demonstrating that trace concentrations of GSH in human plasma could be determined

accurately with a graphite-epoxy resin composite electrode modified with the electrocatalyst cobalt phthalocyanine (CoPC),⁵ which reduces the overpotential necessary for the oxidation of GSH at plain graphite electrodes by \sim 750 mV to only +0.45 V vs. SCE.⁶

In the present investigation, we tested this electrode for the determination of GSH in whole blood. In particular, for future clinical use, we required a method that would be applicable to very small volumes of whole blood, taken from neonates without venepuncture.

EXPERIMENTAL

Apparatus

High-performance liquid chromatography with electrochemical detection (HPLC-EC) was performed at room temperature with an LDC Constametric III twin-piston reciprocating pump (flow-rate, 1 ml/min). Samples were injected with a syringe-loading Rheodyne valve (model 7125) fitted with a 10- μ l sample loop, into a Waters μ Bondapak (10 μ m) ODS column (30 cm \times 3.9 mm i.d.). An Uptight guard

*Author for correspondence.

column containing 30–40 μm ODS pellicular packing (kit No. 1602, Upchurch Scientific) was positioned in series before the main column.

For electrochemical detection a three-electrode thin-layer flow-through cell (BAS TL-3) with a 0.05 mm thick gasket was employed; the Ag/AgCl reference electrode was in a separate compartment, and the auxiliary electrode was the stainless-steel outlet tube. The working electrode was incorporated in an acrylic base which fitted the top half of the TL-3 cell. The acrylic base and working electrode were made as described previously.⁶ The electrode surface was washed with a jet of demineralized water and dried with tissue paper at the start of a day's work; it could be used all day without further cleaning. When properly polished and cleaned, individual electrodes could be used for several months.⁶

An EDT LCA15 amperometric detector, in conjunction with a J.J. Instruments PN4 *x/t-y* plotter, was used to record the chromatograms.

Reagents

All chemicals were of analytical-reagent grade and were obtained from BDH unless stated otherwise. The GSH and sulphosalicylic acid (SSA), CoPC, graphite (Ultra "F" grade, UCP-1M) and epoxy resin (CY 1301 GB/HY 1300 GB) were obtained from Sigma, Kodak, Johnson-Matthey, and Ciba-Geigy Plastics, respectively.

The mobile phase used for all studies was 0.05M sodium phosphate buffer (pH 2.3) containing 1 mM Na₂EDTA, filtered through a glass micro-fibre membrane (Whatman GF/F) and deaerated with helium immediately before use.^{6,7} All solutions were prepared with demineralized water obtained from a Millipore Milli-Q system.

Standard solutions of GSH, perchloric acid and SSA were freshly prepared in deaerated mobile phase for each investigation, and protected from light during all studies.

Procedures

Calibration. Calibration graphs were prepared by injecting 10- μl aliquots of standard solutions containing 0.76, 1.52, 3.04, 4.56 and 6.08 $\mu\text{g/ml}$ GSH. Injections of standard GSH solutions and samples were alternated to provide a continual check of electrode response.

Sample collection and analysis. Whole blood samples were collected by finger prick from normal adult males and females. The hands

were thoroughly washed and dried. The index finger was wiped with isopropyl alcohol and allowed to dry, then was pricked with a disposable sterile lancet and a drop of blood was allowed to form; 25 μl of this was drawn into a sterile plastic micropipette and expelled into 2 ml of a 50-mg/ml solution of SSA. This solution was mixed on a vortex mixer and allowed to stand in the dark for 5 min to ensure protein precipitation was complete. It was then centrifuged at ~ 3000 rpm for 10 min. The supernatant was decanted and passed through a 25 mm diameter Metrical filter membrane (5 μm pore size) and an aliquot of the filtrate (10 μl) was loaded onto the HPLC column. Each sample was analysed immediately after pretreatment, to avoid loss of GSH by oxidation during storage.

RESULTS AND DISCUSSION

The optimization of the conditions for the quantification of GSH with the modified electrode has already been reported.⁶ The optimum applied potential was +0.45 V *vs.* Ag/AgCl when the mobile phase was a phosphate buffer at pH 3. However, since the electrocatalytic current was shown to be pH-dependent, and a 1-electron oxidation is involved, an applied potential of +0.5 V is required with the pH 2.3 buffer used in the present investigation.

Comparison of protein precipitating agents

Perchloric acid and SSA have both been used successfully to precipitate proteins and to inhibit oxidation of GSH by endogenous enzymes.^{8,9} However, perchloric acid proved unsuitable in the present method, since it resulted in chromatograms with a large number of anodic peaks at retention times between 2.7 and 4.4 min, followed by a very broad cathodic response lasting for about 4.5 min. In contrast, SSA did not give any interfering peaks, and a 50-mg/ml solution was selected for protein precipitation.

Calibration and recovery

The calibration graphs were linear over the range studied, in agreement with previous investigations;⁶ higher concentrations were not studied, as they were not needed for the proposed application. The limit of detection (3:1 signal to noise ratio) was 450 pg of GSH when a full-scale deflection of 1 nA was used.⁶

To assess the recovery, replicate samples of blood from the same volunteer were subjected to the analytical procedure, and spiked with small volumes of a GSH standard prepared in 50-mg/ml SSA solution. The mean recovery of GSH, calculated from the slope of a recovery graph of amount of GSH added *vs.* GSH recovered, over the range 0.38–3.02 $\mu\text{g/ml}$, was 95%.

Determination of GSH in normal human whole blood

Figure 1 shows chromatograms of (A) normal human blood, and (B) the same blood sample spiked to give a final concentration of 3.4 $\mu\text{g/ml}$ GSH in the SSA solution. The endogenous GSH concentrations were determined in the blood of five normal male and female volunteers (Table 1). The ranges are in agreement with earlier studies on healthy human subjects.^{10,11}

CONCLUSIONS

Other workers have determined GSH in various biological matrices, *e.g.*, animal tissues,^{12,13}

Fig. 1. Chromatograms obtained by HPLC-EC with the CoPC modified carbon-epoxy electrode for (A) a typical normal male human blood sample (GSH in the diluted solution, 2.03 $\mu\text{g/ml}$, equivalent to 0.66 mM in the original sample) and (B) the same blood spiked with GSH to give a final concentration of 3.4 $\mu\text{g/ml}$ in the solution injected onto the column.

by HPLC-EC with conventional carbon electrodes. In both cases^{12,13} a series dual electrode coulometric cell was used, operated in the screen mode¹⁴ to remove spurious peaks, which probably arise from the oxidation of other naturally occurring species at the high operating potentials necessary for detection of GSH at plain carbon electrodes. Oxidized glutathione (GSSG) was also determined.¹³

Other workers have attempted to improve selectivity by developing methods incorporating pre-column derivatization with electron mediators¹¹ or by including the mediator in carbon paste electrodes.¹⁰ Shimada *et al.*¹¹ studied the use of derivatization reagents containing the ferrocene moiety for pre-column reactions with several biological compounds containing thiol groups. For electrochemical detection these workers still used the coulometric cell, operated in the screen mode, but were able to obtain less complicated chromatograms than those reported later,^{12,13} owing to the lower applied potentials employed. The disadvantage of the procedure was the extra sample pretreatment step, involving incubation of the thiol with the derivatization reagent. Post-column derivatization with *o*-phthalaldehyde has been investigated by Buchberger and Winsauer,¹⁵ who applied the method to liver, eye lens and blood samples; however, no chromatograms or normal values were given for the latter samples.

A similar approach to ours was reported by Halbert and Baldwin¹⁰ who incorporated CoPC into carbon paste electrodes and successfully determined GSH in whole blood. Wang *et al.* have also described a graphite-epoxy resin electrode containing CoPC, which they used for some preliminary studies on standard solutions of hydrazine, cysteine, penicillamine and oxalic acid.¹⁶ We consider our method, using the modified carbon-epoxy resin composite electrode, to provide a significant advantage. The electrode can be used for several hours in a flowing stream without any significant deterioration in the measured current response,⁶ and

only 25 μ l of whole blood is needed for the analysis. The pretreatment with SSA to prevent blood proteins from being loaded into the chromatographic column leads to a significant reduction in extraneous chromatographic peaks and should extend the column's usable life. The simplicity of the procedure permits rapid sample handling, which should minimize losses of GSH prior to analysis.⁷

DETERMINATION OF SULPHAMETHIZOLE IN THE PRESENCE OF NITROFURANTOINE BY DERIVATIVE SPECTROPHOTOMETRY AND RATIO SPECTRA DERIVATIVE

J. J. BERZAS NEVADO, J. RODRIGUEZ FLORES and M. L. DE LA MORENA PARDO

Department of Analytical Chemistry and Foods Technology, University of Castilla-La Mancha, 13071 Ciudad Real, Spain

(Received 8 March 1991. Revised 23 May 1991. Accepted 27 May 1991)

Summary—Two methods for determining sulphamethizol in the presence of nitrofurantoin in mixtures by first-derivative spectrophotometry and by the first derivative of the ratio spectra are described. The procedures do not require any separation step. In the first method the measurements are obtained in the zero-crossing wavelengths and the calibration graphs were linear up to 32 $\mu\text{g/ml}$ of sulphamethizole at 251 and 278.5 nm. In the second method, the calibration graphs were linear up to 43 $\mu\text{g/ml}$ by measuring at the maximum (263 nm), at the minimum (244 nm) and peak to peak. The methods were applied for determining sulphamethizole in a pharmaceutical product containing nitrofurantoin.

Sulphonamides are widely used in medicine and veterinary practice as antibacterial drugs. Many sulphonamides are now available as pharmaceutical products and numerous methods have been developed for their determination. Different chromatographic techniques have been reported for the analysis of sulphonamide mixtures.¹⁻⁵ Methods for the determination of the total content of sulphonamides have also been reported. These methods involving spectrophotometric techniques based on the Bratton-Marshall procedure⁶ have been studied and have been automated by using an air-segmented continuous flow analyser⁷ and by using flow-injection analysis.⁸ Recently, derivative spectrophotometry has been used for determining the total content of sulphonamides in urine and honey without pretreatment of the samples.⁹

Derivative spectrophotometry can also be used to resolve mixtures with few chromophores without sample pretreatment. This is the case for some pharmaceutical products that contain one sulphonamide mixed with another drug. In this way derivative spectra have been used for resolving the mixture of sulphametoxazole and trimethoprim.¹⁰

Recently, Salinas *et al.*¹¹ developed a new method for resolving mixtures of chromophores with overlapped spectra. This method is based on the use of the first derivative of the ratio of the spectra. The absorption spectrum of the mixture is divided by the absorption spectrum

of a standard solution of one of the chromophores (amplitudes by amplitudes at each wavelength) and the first derivative of the ratio spectrum is obtained. The concentration of the other component is then determined from a calibration graph obtained previously.

In this work, the determination of sulphamethizole (SMT) in the presence of nitrofurantoin (NFT) is proposed by using first-derivative spectra and the first derivative of the ratio spectra for resolving a pharmaceutical product, with good results. The nitrofurantoin is an antibacterial agent that increases the effect of the sulphamethizole.

EXPERIMENTAL

Apparatus

A Beckman Instruments DU-70 spectrophotometer connected to an IBM PS/2 fitted with Beckman Data Leader Software¹² and an Epson FX-850 printer were used for all the measurements and treatment of data.

Solutions

All solvents and reagents were of analytical reagent grade. Sulphamethizole ethanol-water 1:1 solution and nitrofurantoin ethanolic solution were prepared from Sigma products at a concentration of 250 $\mu\text{g/ml}$. Ammonia/ammonium chloride buffer solution (0.5M,

pH = 10) was prepared from analytical reagent grade materials.

Procedures

First derivative spectrophotometry. Samples were prepared in 25-ml calibrated flasks containing up to 32 $\mu\text{g/ml}$ of sulphamethizole (in the presence of nitrofurantoin), 5 ml of buffer solution and were diluted with water and ethanol to the mark (the resulting final solution was 10% ethanol). The absorption spectra of the samples thus prepared were recorded against a reagent blank and stored in the IBM computer. The sulphamethizole content is determined from the first derivative spectrum (obtained with $\Delta\lambda = 6$ nm) by measuring the signal at 251 or 278.5 nm (zero-crossing points for nitrofurantoin) and by using an appropriate calibration graph.

First derivative of the ratio spectra. Samples were prepared and their absorption spectra were recorded and stored in the computer as described above. For determining sulphamethizole, the stored spectra were divided by a standard spectrum of nitrofurantoin of 5.0 $\mu\text{g/ml}$. From the ratio spectra thus obtained, first derivatives were calculated with $\Delta\lambda = 6$ nm. The concentration of sulphamethizole was proportional to the amplitude of the maximum at 263 nm, the minimum at 244 nm and the peak to peak (244–263 nm). The calibration graph can be extended up to 43 $\mu\text{g/ml}$ of sulphamethizole.

RESULTS AND DISCUSSION

Method development

The influence of pH on the absorption spectra of SMT and NFT was studied. The best results for analytical purposes were obtained at pH = 10 (ammonia/ammonium chloride buffer solution) because SMT absorption spectra were stable between pH 7 and 12 and NFT between pH 9 and 12.

The ethanol content slightly affects the absorption spectra of SMT and NFT, and as a result 10% was selected to be optimum. Under these conditions (pH = 10 and ethanol 10%), diluted solutions of SMT and NFT are stable for at least 4 hr.

Derivative spectrophotometry

The zero-order spectra of SMT and NFT in the 200–500 nm wavelength range are shown in Fig. 1. It can be seen that the absorption spectra of nitrofurantoin shows a prominent peak that

Fig. 1. (a) Absorption spectrum of 10.8 $\mu\text{g/ml}$ SMT, (b) absorption spectrum of 14.3 $\mu\text{g/ml}$ NFT.

can be used for reliable direct absorbance measurements. However, the absorption spectrum of sulphamethizole is completely overlapped with the spectrum of NFT and because of that the determination of SMT in the presence of NFT cannot be used for reliable direct absorbance measurements.

Derivative spectrophotometry can be suitable to obviate this problem. The commonest procedures for the preparation of analytical calibration graphs are "peak to peak" and "base line" measurements (generally called graphical measurements) and "zero-crossing" measurements. In practice, the measurement selected is that which exhibits the best linear response, gives a zero or near zero intercept on the ordinate of the calibration graph, and is less affected by the concentration of any other component. The shape of the first derivative spectra is adequate for determining SMT in the presence of NFT. Figure 2 shows the first derivative absorption spectra of a solution of SMT and other samples with different NFT concentrations.

It can be seen that due to the overlapping spectra of these compounds in a determined region, the zero-crossing method is the most appropriate for resolving mixtures of these compounds and it was used in this work with satisfactory results.

Preliminary experiments showed that the height, h_1 , of the first derivative at 251.0 and 278.5 nm (working zero-crossing wavelength of NFT) was proportional to the SMT concentration. The results obtained for the SMT in the presence of the nitrofurantoin were in accordance with the above calibration graph.

Fig. 2. (a) First derivative spectrum of 10.8 $\mu\text{g/ml}$ SMT, (b) first derivative spectrum of 6.7 $\mu\text{g/ml}$ NFT, (c) first derivative spectrum of 19.0 $\mu\text{g/ml}$ NFT.

Selection of optimal instrumental conditions.

The main instrumental parameters that affect the shape of the derivative spectra are the wavelength scanning speed, the wavelength increment over which the derivative is obtained ($\Delta\lambda$) and smoothing. These parameters need to be optimized to give a well-resolved, large peak *i.e.*, to give good selectivity and larger sensitivity in the determination. Generally, the noise level decreases with an increase in $\Delta\lambda$ thus decreasing the fluctuations in the derivative spectrum. However, if the value of $\Delta\lambda$ is too large, the spectral resolution is very poor.

Therefore, the optimum value of $\Delta\lambda$ should be determined by taking into account the noise level, the resolution of the spectrum and the sample concentration. Some values of $\Delta\lambda$ were tested and 6.0 nm was selected as the optimum in order to give a satisfactory signal to noise ratio. In this way, a smoothing function was not necessary.

Once the experimental conditions were established, the calibration graphs were tested between 2.16 and 32.4 $\mu\text{g/ml}$ SMT concentration at 251.0 and 278.5 nm. Good linearities were observed in both cases.

First derivative of the ratio spectra

When derivative spectrophotometry is used for resolving a mixture of chromophores with overlapped spectra it is often necessary to use zero-crossing, which causes a considerable loss of sensitivity. The name "ratio spectra derivative" permits the use of the wavelengths corresponding to a maximum or minimum and, also, the use of the peak to peak between consecutive maxima and minima.

Figure 3A shows the ratio spectra of different SMT standards (spectra divided by the spectrum of a 5.0 $\mu\text{g/ml}$ NFT solution) in basic medium and in Fig. 3B their first derivatives are calculated. The first derivative amplitudes at a given wavelength are proportional to the SMT concentration. As the noise levels were small a smoothing function was not needed.

The influence of the $\Delta\lambda$ for obtaining the first derivative was tested and $\Delta\lambda$ of 6 nm was considered suitable. The concentration of the NFT solution used as divisor can be modified and different calibration graphs are obtained. A standard spectrum of 5 $\mu\text{g/ml}$ of NFT was considered as suitable.

Calibration graphs were constructed at wavelengths of 263 and 244 nm corresponding to a maximum and minimum, and measuring the

peak to peak between this maximum and minimum. Straight lines were obtained up to 43 $\mu\text{g/ml}$.

Statistical comparative study. Tables 1 and 2 summarize the most characteristic statistical data obtained from the different calibration graphs and from the reproducibility of the reagent-blank and a standard by eight successive scans. In all cases good results were obtained. The best limit quantification was obtained from the first derivative at 251 nm. Nevertheless, in general the methods that used the first derivative of the ratio spectra show a bigger accuracy and comparable limit quantifications.

Applications

The proposed methods were applied for resolving the determination of SMT in the presence of NFT in artificial mixtures. The results corresponding to these determinations are summarized in Table 3. The obtained recoveries were in the range 90–110%. The recoveries by first-derivative spectrophotometry were in the order of 95% except when the ratio of NFT to SMT was 5:2. In this case the recovery was lower. Better results were obtained from the first derivative of the ratio spectra method as can be seen in Table 3. In conclusion, both methods

gave good results for the determination of SMT in the presence of NFT.

The proposed methods were applied to the determination of SMT in the pharmaceutical Micturol from Liade laboratory (Spain) with a content of 50 mg NFT and 100 mg SMT per tablet. The determination of SMT in the pharmaceutical Micturol gave recoveries around at 96%.

CHANGES IN PLASMA CHARACTERISTICS CAUSED BY EASILY IONISABLE ELEMENTS IN HOLLOW CATHODE DISCHARGE EMISSION SPECTROGRAPHY

Zs. SZILVÁSSY-VÁMOS, A. GYÖRFI-BUZÁSI and Zs. PÁSZTOR

Department of Radiochemistry and Physics, University of Veszprém, Veszprém, 158, Hungary

(Received 10 December 1990. Revised 22 April 1991. Accepted 21 May 1991)

Summary—The effect of several concomitant easily ionisable elements (EIE's), Li, Na, K, Rb and Cs on the line intensity of Sr II (first ionised state) and Al I and He I (atomic states) has been studied by atomic emission spectrometry (AES) hollow cathode (HCD) analysis. The spectral line intensities emitted by Sr II, Al I and He I have been measured while varying the volume of the EIE's concentrations, ranging from 0.1 mg ml to 10 mg ml. In the presence of EIE's at higher concentrations than 0.5% a considerable decrease of the line intensities of Sr II at 430.54 nm and 407.71 nm was observed, together with a gradual decrease in the line intensities of both Al I 494.40 nm and 396.15 nm, and He I 412.1 nm. It is demonstrated in the present experiments with a water-cooled HCD source that interference effects caused by EIE's are observed when the ratio of the number of gas atoms (n_g) and atoms with low ionisation energy (n_a)— n_g/n_a —is lower than 10^{12} .

The first publications on emission sources of atomic spectrometry such as various low pressure discharge tubes (*e.g.*, Grimm's lamp) and hollow cathode discharge tubes (HCD) indicated freedom from all sorts of interelement effects.^{1–5}

However, it has been proved in later studies that these spectrochemical emission sources do not offer complete freedom from interelement effects.^{6–7}

The interelement effect may exert its interfering actions in two ways: it may affect the evaporation, *i.e.*, the entrance of the element into the plasma or alternatively it may alter the conditions of excitation prevailing in the plasma.

The sample volatilization of copper-base alloys in hot-type HCD was investigated by Broekaert.⁸ His experiments proved that the sample volatilization is due to thermal evaporation processes and atomic sputtering. It has been pointed out that the volatile elements can only be evaporated quantitatively from a less volatile base when the sample is completely molten and when the cathode temperature is sufficiently high for allowing a quick thermal evaporation of the elements studied.

Broekaert also investigated matrix effects in hot HCD and observed that detection capability decreased in the presence of Mg which, at increasing concentrations, diminished the

number of useful collisions of analyte atoms with argon metastables because it possesses a low ionisation potential and decreases the excitation of the rare earths, except for Sc and Y, which have equal relative atomic masses to Mg and Ar.⁹ Maksimov and co-workers studied the effects of cadmium vapour introduced into the plasma by the HCD excitation processes and he reported that the addition of Cd resulted in increased intensity of some analyte elements.^{10–12} He observed that particular levels of Ca and Na are excited with higher intensity at the optimal Cd concentration of 6%. He assumes that the possible source of the enhancement of the intensity of some Ca and Na lines in the presence of Cd is the resonance transfer of the energy of the metastable levels of Cd atoms and ions.

Analysing biological samples, Caroli and Delle Femine performed a comparative study of matrix effects hollow cathode under conditions and concluded that slight matrix effects can also be observed in HCD, but the HCD emission source is affected by this type of interference to a lesser extent than with graphite furnace AAS and arc-emission spectrography.¹³

Its assay of Al tracers in various organs and brain tissues led to substantially identical considerations, *i.e.*, matrix effects were practically negligible.¹⁴

Typical interelement effects can be found in the excitation of gas mixtures. Thus, the emission

of helium excited in a Geissler-tube is suppressed by introduction of 1% argon, and only the small amount of argon present is excited to emission.¹⁵

The excitation energies of the metastable states of He 1¹S and 2³S are 20.55 and 19.77 eV, respectively. The first ionisation energy of He is 24.77 eV. The metastable state of Ar is 11.83 eV. The presence of Ar in the He discharge, even in an Ar concentration of 1%, quenches the excited and ionised states of He. This can be explained by the collision of Ar atoms with fast electrons, leaving so called slow electrons behind which do not allow high energy He levels to be produced.

All these experiments indicate that some interference effects also occur in the HCD during analyses of multi-component samples, such as the majority of biological and environmental samples, *etc.*

The interference effects can exert positive effects, *e.g.*, the increasing effects of Cd, Zn on line intensity, or negative effects, decreasing line intensities and worsening detection limits.

Similar phenomena can be found in other low pressure discharges such as HCD tubes, that is, elements with higher ionisation potentials are

not excited if the concentration level of EIE's present exceeds a specified value.

In this study, the minimum concentration values of EIE's present causing detectable interferences have been investigated. The effects of EIE's on elementary processes and plasma characteristics of HCD have been studied and changes of spectral line intensities of Sr II, Al I and He I in the presence of EIE's have been interpreted.

EXPERIMENTAL

Instrumentation

The experimental method used has been described by Szilvássy.¹⁶ A brief description is as follows.

The discharge tube applied in our experiments was made of steel. Both the anode and cathode units have double walls and can be cooled by water. The cylindrical cathode cups made of aluminium or spectroscopic grade carbon and having a cylindrical hole can be placed in the cathode unit (Fig. 1).

The secondary discharge is defined as a negative glow light occurring in the hot hollow cathode placed perpendicularly to the main axis

Fig. 1. Cross-section of the improved demountable hollow cathode lamp. Silicon rubber sealing [1], brass cathode block [2], brass anode block [3], quartz window [4], PVC clamping disc [5], cathode hole for negative glow discharge [6], pyrex glass tube [7], steel spring [8], PVC ring clamp [9], tungsten filament [10], auxiliary cathode block [11], carbon cathode cup [12], water cooling system [C, 1-4], gas inlet, outlet [C, 5, 6], connecting branch [C, 7].

of the discharge tube. This cathode consists of a carbon cathode cup on a tungsten wire.

The secondary cathode, which can also contain samples, can be switched on after an appropriate delay, once the main discharge has stabilised. It has been proved in earlier studies that in this case the standard deviation and the detection limits can be decreased.¹⁷

The secondary discharge can function without samples as a source of electrons, ions and metastable state gas atoms. Having no charge, the metastable state gas atoms can reach every part of the discharge tube by diffusion, so they also reach the excitation zone, thus increasing the number of excitation and ionisation processes.

In the present work, the discharge tube shown in Fig. 1 was applied with parameters listed in Table 1.

The discharge tube was mounted on the optical axis of a PGS-2 Zeiss plane-grating spectrograph and connected to a vacuum system, (as described previously)¹⁶ with a dual-rotating-vane pump. A 2 kW D.C. power supply (2000 V, 1 A) was connected to the discharge tube.

Sample preparation

A series of aqueous solutions were prepared containing the analytical element—Sr—at a concentration of 0.1 mg/ml, together with the easily ionisable elements (Li, Na, K, Rb and Cs) in a concentration range of 0.1–10 mg/ml.

A sample volume of 0.1 ml was placed in an aluminium cathode cup. The analytical solutions were dried in a cabinet drier at 40°.

Table 1. Experimental conditions

Excitation: D.C. power supply of 2 kW connected to the modified version of the water-cooled hollow cathode discharge tube
Hollow cathode: material of the cathode cups: at the primary and secondary discharges; aluminium and carbon, respectively
Diameter of cathode holes: 5.5 mm
Depth of the cathode holes: 10 mm
Carrier gas: gas mixture of 75% He and 25% Ne at a pressure of 666 Pa
Discharge current: 500 mA–700 mA
Voltage: 400–500 V
Exposure time: 5 min
Spectrograph: Zeiss/Jena/PGS 2 plane grating
Wavelength scale 1st order 200–780 nm
Dispersion 1st order, 651 lines/mm
Grating: 0.74 nm/mm
Illumination of spectrograph: intermediate focusing
Entrance slit: 0.02 mm
Step filter: 100/50/10% average light transmission
Photographic plate: ORWO WU 3
Developer: KODAK D 19
Developing temperature: 19°
Microdensitometer for spectroscopy: Zeiss G II

Evaluation of spectrograms

“ ℓ ”-Transformation¹⁸ was applied to transform blackening values measured with a Zeiss G-II microphotometer for spectroscopy; “ ℓ ” blackening transformation assigns a quantity to the blackening (s) which remains linearly proportional to the logarithm of intensity (Y), thereby to the logarithm of the concentration also.

The equation of “ ℓ ” transformation is:

$$\ell = s - (k - s)d$$

where: $s = S/\gamma$ (reduced blackening, $\gamma =$ gradation, the slope of the straight portion of the characteristic curve), $k =$ constant of “ ℓ ” transformation (the lowest blackening value on the straight part of the characteristic curve) and $d = s - 1 \text{ g}(10^s - 1)$ (Gaussian subtraction logarithm belonging to s). Therefore, the “ ℓ ” transformation relates only to the underexposed part of the characteristic curve. When $s \geq k$, $s \equiv \ell$, i.e., only in the case of $s < k$ is the transformation necessary.

For the determination of relative standard deviations (r.s.d.), 7 parallel measurements were carried out. This value was found to be less than 8%.

RESULTS AND DISCUSSION

Decrease of spectral line intensities

The effects of EIE's were investigated on the spectral line intensities of (i) rare gas atoms having high excitation energies, (ii) Sr⁺ ions having medium excitation energies and (iii) two Al atom lines having low excitation energies.

The excited and ionized states can be formed in the following processes:

Fig. 2. Background corrected Sr^+ curves as a function of EIE concentration. X_1 and X_2 values on axis Y show Sr^+ Y intensity values without EIE's present; $Y = \log I/I_0$ background corrected relative signal.

Where A is the atom of the sample, A^X is the excited state, A^+ is the ionized state, B is the atom of the rare gas, B_m is the metastable state, e_f is fast electron and e_s is slow electron.

The presence of EIE's in the plasma reduces the number of fast electrons [processes (1)–(9)] and hinders process (10) that is, less metastable rare gas atoms are produced. Process (14) describes a possible form of decay of metastable states of rare gas atoms, which is significant in view of high energy collision processes, because the fast electrons are reproduced in this process.

Decrease of line intensities of He I 412.10 nm (23.97 eV) and He I 447.15 nm (23.73 eV) lines

Figure 2 shows the changes in line intensities of He carrier gases for Li, Na, K, Rb and Cs concentration ranges from 0.01–1%. It can be observed that a decrease in intensity occurs at 0.01% concentration and the intensity of spectral lines further decreases gradually as the EIE's concentration is increased.

Processes (11) and (12) describe the generation of rare gas ions and excited rare gas atoms by collisions. The number of both processes decreases if there are less fast electrons in the discharge zone. Therefore the spectral line intensities of the carrier gas decrease under the effect of EIE's.

The ionization energies of the alkali metals are listed in Table 2.

The effects of EIE's on Sr II 407.71 nm (3.04 eV) and 430.54 nm (5.91 eV) spectral line intensities

For the present investigations two Sr^+ ion lines of the highest intensity were selected from the Sr spectrum. For both spectral lines the decrease of intensity was observed.

The presence of EIE's in the negative glow light results in the decrease of the number of fast electrons participating in processes (1), (2) and (3) thus reducing the number of higher energy

Table 2. First ionisation energies of the alkali metals

Element	Energy, eV
Li	5.390
Na	5.138
K	4.340
Rb	4.176
Cs	3.893

excited atoms and ions, as well as the number of single-step excited ions. [Penning ionisation, Process (3)].

The sum of ionization and excitation energies in the present measurements are higher than 8 eV, the probability of process (3) therefore occurring is less, which causes the intensity of Sr⁺ spectral lines to decrease.

Figure 3 shows the changes of two ion lines of Sr under the effect of EIE's. Detectable decreases in intensity can only be detected when the concentration of EIE's is higher than 0.5%.

Changes in Al I 396.15 nm (3.14 eV) and Al I 394.40 nm (3.14 eV) spectral line intensities due to EIE's

The excitation energy of the above two Al spectral lines is 3.14 eV. The atoms of the cathode cup made of Al are sputtered by the rare gas ions and metastable rare gas atoms into the plasma.

The decrease of Al line intensity in the presence of EIE's—as shown in Fig. 4—can be explained by the lower efficiency of sputtering. The presence of EIE's does not reduce the number of lower energy collisions, the decrease of intensity can be explained by the lower number of sputtered Al atoms.

The decreased sputtering yield indicates that a reduced number of rare gas ions and metastable state atoms with lower energies occur in the plasma due to the EIE's.

The increase of the conductivity does not contradict this phenomenon. Greater numbers of charged particles are present due to the easy ionisation of EIE's, however, the energy distribution of the charged particles changes to the detriment of higher energies.

Changes in current intensity under the effects of Li, Na, K, Rb and Cs

The entrance of EIE's in the plasma is indicated by an increased conductivity, and an increase in current between 10 and 150 mA was noted. Current intensities were measured at constant voltage.

Table 3 contains the changes of the absolute values of current in the presence of Li, Na, K, Rb and Cs at concentrations of 0.01 and 1% for the latter four, and 0.01 and 0.1% for Li. It is well illustrated that the maximum 25% increase of relative current intensity occurs at 1% Cs concentration.

CONCLUSIONS

From the results presented in this paper it is clear that the sputtering, excitation and

Fig. 3. Background corrected He I curves as a function of EIE concentration. X₁ values on axis Y represent He I Y values obtained using empty Al cathode cup. X₂ values represent He I intensity values in the presence of 0.1% Sr (dried from aqueous solution); Y = log I/I₀ background corrected relative signal.

Fig. 4. Background corrected Al I curves as a function of EIE concentration. X_1 values on axis Y represent Y values obtained with empty Al cathode cup. X_2 values represent Al intensities in the presence of 0.1% Sr (dried from aqueous solution); $Y = \log I/I_0$ background corrected relative signal.

ionisation processes in the HCD are not completely free from interelement effects.

The EIE's in the plasma cause ion and electron densities, and electron energies to change, and as a consequence the conditions for the ionization and excitation processes are also changed, a smaller number of metastable state excited gas atoms are produced; all these processes causing changes in the spectrum.

The interelement processes can be detected for Sr, He and Al spectral lines in the presence of concomitant EIE's.

A considerable decrease in Sr^+ ion line intensities measured in the presence of EIE's was observed at concentrations higher than 0.5% for Li, Na, K and over 1% for Rb and Cs.

Table 3. Changes in current intensity under the effect of Li, Na, K, Rb and Cs

	%	i/mA	^{87}Sr (560 mA)	
Li	0.01	570	1.02	
	0.1	580	1.04	
Na	0.01	610	1.09	
	1	630	1.13	
K	0.01	620	1.11	
	1	640	1.14	
Rb	0.01	650	1.16	
	1	670	1.20	
Cs	0.01	680	1.21	
	1	700	1.25	

This phenomenon can be explained by the decreased electron energies and the reduced number of metastable gas atoms. The decrease in the spectral line intensities of He carrier gas clearly indicates a decrease of energy in the plasma. The decrease in spectral line intensities of Al originating from the cathode cup in the presence of EIE's indicate the decrease of the sputtering yield, which may be explained by the decrease in the number and energy of gas ions and metastable gas atoms.

It has been observed that the effect of EIE's is considerable when the ratio between the number of gas atoms (n_g) and the number of atoms with low ionisation energy (n_a) — n_g/n_a — is lower than 10^{12} .

Although a relative standard deviation of less than 5% can generally be achieved with the HCD/AES method, in the present experiments the relative standard deviation obtained from 7 parallel measurements was found to be up to 8% due to the presence of EIE's in the plasma.

ENZYMATIC DETERMINATION OF N-METHYLCARBAMATE PESTICIDES AT THE NANOMOLAR LEVEL BY THE STOPPED-FLOW TECHNIQUE

M. C. QUINTERO, M. SILVA and D. PÉREZ-BENDITO

Department of Analytical Chemistry, Faculty of Sciences, University of Córdoba, 14004 Cordoba, Spain

(Received 15 October 1990. Revised 8 April 1991. Accepted 15 April 1991)

Summary—A sensitive and selective kinetic enzymatic method for the determination of N-methylcarbamate pesticides is presented. It is based on their inhibitory effect on electric eel acetylcholinesterase and the use of 5,5'-dithiobis(2-nitrobenzoic) acid (DTNB) as chromogenic reagent for the thiocholine released from the acetylthiocholine iodide substrate. The fast DTNB-thiocholine reaction is monitored photometrically by the stopped-flow technique. Carbaryl, propoxur and carbofuran can be determined at concentrations in the ranges 6.5–120, 2–15 and 0.1–5.0 ng/ml, respectively, by the proposed method. An interference study was also reported.

Pesticides of the carbamate family have become increasingly important in recent years because of their wide ranging biological activity. Among the analytical methods available for their determination, enzymatic methods based on cholinesterase (ChE) inhibition are widely used and can be combined with optical^{1,2} and chromatographic techniques^{3,4} for detection. On the other hand, the inhibitory effect of pesticides (including organophosphorous and chlorinated pesticides) on cholinesterase is known to depend on enzymes sources (human serum, rat liver, electric eel, *etc.*), which also affects the detection limit and sensitivity of determinations. In this context, some attempts have been made^{2,5} at establishing a relationship between the Michaelis-Menten constant (K_m), an index of enzyme-substrate affinity and I_{50} , the inhibitory concentration resulting in 50% inhibition. Kinetic studies of biochemical nature on the inhibition of ChE by carbamate pesticides⁶⁻⁸ or others⁹ have been developed with the aid of stopped-flow instrumentation. However, so far this technique has not been applied to these pesticides for analytical purposes.

This paper reports the use of a single modular stopped-flow system for the kinetic determination of carbaryl, propoxur and carbofuran on the basis of their inhibitory effect on electric eel acetylcholinesterase (AChE), using acetylthiocholine iodide (ATChI) as substrate and 5,5'-dithiobis(2-nitrobenzoic) acid (DTNB) as chromogenic reagent. The use of the above-

mentioned enzyme source, the optimized procedure for the incubation process and the stopped-flow technique to monitor the chromogenic reaction improved already existing methods in terms of sensitivity and selectivity, thereby providing a useful automated means of carrying out analyses for these pesticides.

EXPERIMENTAL

Reagents

All reagents used were analytical-reagent chemicals; solutions were prepared in distilled water and 1,4-dioxane. Carbaryl, propoxur and carbofuran (Chem. Service Inc.) solutions ($6.63 \times 10^{-6} M$) made by dilution of more concentrated stock solutions prepared by dissolving 100.0 mg of the corresponding chemical in 100 ml of 1,4-dioxane, were stored in PTFE bottles in a refrigerator. An acetylthiocholine iodide ($9.4 \times 10^{-3} M$) solution was prepared by dissolving 68 mg of this chemical (Sigma Chemical) in 25 ml of distilled water. A $1 \times 10^{-3} M$ DTNB solution was prepared by dissolving 100 mg in 250 ml of TRIS buffer of pH 7.4. A 0.05M TRIS buffer solution was prepared by dissolving 6.05 g of Tris and 6.64 g of sodium chloride in water and using hydrochloric acid or sodium hydroxide to adjust the pH to 7.4, 8.0 or 9.0 in a final volume of one litre. An electric eel acetylcholinesterase (Sigma Chemical) solution of 4.0 units/ml was prepared from the lyophilized powdered enzyme containing 5% ammonium

sulphate and featuring a protein activity of 200–400 units/mg.

Apparatus

A Perkin–Elmer Lambda 5 spectrophotometer coupled on-line with a stopped-flow module¹⁰ was used. The acquisition and treatment of kinetic data was performed by a Hewlett-Packard 98561AE computer and a 16-bit Hewlett-Packard 98640A analogue-to-digital converter. The software required for application of the kinetic method was written by the authors themselves.

Procedure for kinetic-enzymatic determination of *N*-methyl-carbamate pesticides

Two solutions were prepared and placed in the drive syringes. For solution A, an aliquot of the pesticide solution containing a few nanograms of the compound (32.5–600 ng of carbaryl, 10–75 ng of propoxur and 0.5–25 ng of carbofuran) and 0.5 ml of electric eel acetylcholinesterase solution of 4.0 units/ml were added to a 5-ml standard flask. The mixture was then diluted to the mark with 0.05M TRIS buffer of pH 8.0. This solution was incubated at 37° for 30 min. Solution B was prepared by mixing 0.8 ml of 9.4×10^{-3} M acetylthiocholine iodide solution and 2.5 ml of 10^{-3} M DTNB solution in a 10-ml standard flask and diluting to the mark with 0.05M TRIS buffer of pH 9.0. Equal volumes of both solutions were mixed in the stopped-flow system and the reaction was monitored at 400 nm. The temperature was kept constant at $35 \pm 0.1^\circ$ throughout. The kinetic curve, the initial rate (both in the presence of pesticide and in its absence) and the analyte concentration were automatically acquired by the computer.

RESULTS AND DISCUSSION

Carbamate insecticides, like other pesticides (organochlorine and organophosphorous) are known to inhibit the action of acetylcholinesterase, which acts on the hydrolysis of acetylthiocholine. The inhibitory effect involves the formation of a complex between the enzyme and the pesticide and the subsequent carbamoylation and de-carbamoylation of the enzyme. The overall inhibition process is rather slow and requires several minutes for the incubation step, depending on the specific activity of the inhibitor.

In the proposed method, the amount of the thiocholine released in the hydrolysis reaction of acetylthiocholine, which is a measure of the amount of pesticide-inhibitor present, is monitored photometrically by adding DTNB, which reacts with thiocholine yielding a sulphur derivative of 2-nitrobenzoic acid which is responsible for the colour observed. This compound shows maximum absorption at 400 nm. This reaction is completed in a few seconds, which calls for the use of the stopped-flow technique to make the kinetic measurements. Figure 1 shows the kinetic curves obtained, both for the enzymatic (curve 1) and for the inhibited (curve 2) reaction, which are the basis for the development of this automated kinetic method for *N*-methylcarbamate pesticides.

Three *N*-methylcarbamates, namely carbaryl, propoxur and carbofuran were selected to develop this enzymatic stopped-flow approach by using DTNB as chromogenic reagent. This reagent had previously been used for the kinetic determination of thiofanox with electric eel acetylcholinesterase on a CentrifChem 400 Analyser;¹ however, the sensitivity achieved was lower than that provided by the proposed method.

Influence of variables

The working conditions for application of the method were optimized by using carbaryl only as pesticide-inhibitor to examine the influence of variables on both the incubation and the chromogenic reaction (post-incubation) processes.

Fig. 1. Inhibitory effect of carbaryl on the enzymatic reaction: (1) enzymatic reaction; (2) reaction inhibited by 120 ng/ml of carbaryl. Reaction conditions as described in Procedure.

The optimal conditions found for carbaryl were applied to propoxur and carbofuran and appropriate corrections were introduced if required.

Incubation process. Variables were optimized so as to obtain the maximum inhibition of the enzymatic activity of the pesticide. The inhibition percentage I (%), the measurement parameter used, is given by:

$$I(\%) = [(V_E - V_I)/V_E] \times 100 \quad (1)$$

where V_E and V_I are the reaction rate in the absence and presence of inhibitor, respectively. There is a linear relationship between I (%) and the concentration of pesticide-inhibitor.

The pH, temperature and incubation time were the factors which most strongly influence the enzyme-pesticide reaction. However, as the pesticide was previously dissolved in an organic solvent (1,4-dioxane), it was necessary to examine the influence of the solvent on the enzyme action in the absence of pesticide. The results of the experiments carried out at 25° and pH 7.4 (with 0.05M TRIS buffer) showed high 1,4-dioxane contents inhibit the action of AChE; the maximum allowed content of this solvent without causing inhibition was 2.8% (14 μ l of 1,4-dioxane per 0.5 ml of electric eel acetylcholinesterase solution of 4.0 unit/ml).

Other variables were also studied at a physiological pH value of 7.4 adjusted with TRIS buffer. By using the procedure described under Experimental, the effect of the temperature on the incubation was examined between 30 and 40° for a constant, arbitrary incubation time of 5 min. The results showed I (%) to increase with the temperature up to about 34°, above which it kept constant up to 37°. At higher temperatures, I (%) decreased owing to the enzyme denaturation [Fig. 2(a)]. An incubation temperature of 37° was thus selected. The effect of the incubation time on I (%) at 37° is shown in Fig. 2(b). An incubation time of 30 min was finally chosen.

In order to check the suitability of the incubation procedure, we studied the stability of the incubated solution under the conditions described above. The inhibition percentage was found not to vary with time, at least up to 2 hours after the incubation step.

Post-incubation step. The working conditions for this step, which involves the fast coloured reaction by mixing the DTNB solution with the incubated solution, was aimed at obtaining the maximum possible rate of the chromogenic reaction. The slope of the initial portion of the

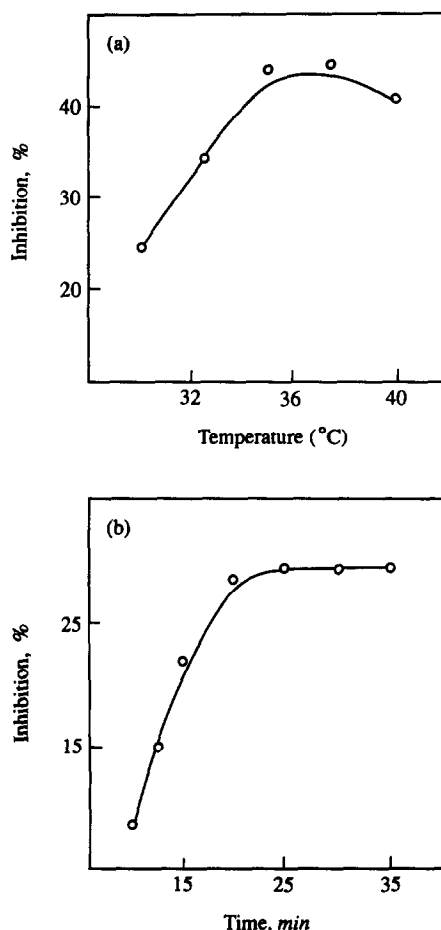

Fig. 2. Effect of (a) temperature and (b) time on the enzyme inhibition by carbaryl in the incubation process (conditions described in Experimental)

absorbance-time curves (initial-rate method) was monitored by the stopped-flow technique and used as a kinetic parameter.

The effect of temperature on the reaction rate was examined between 15 and 45°. The initial rate increased with the temperature up to 35°, above which it remained practically constant but decreased slightly above 40°. A temperature of 35° was chosen as optimal.

The influence of the ATChI substrate concentration was studied over the range 9.43×10^{-5} – $9.43 \times 10^{-4}M$; the reaction rate was found to increase with the ATChI concentration up to $6.5 \times 10^{-4}M$ above which it remained constant [see Fig. 3(a)]. An ATChI concentration of $7.5 \times 10^{-4}M$ (0.8 ml of the $9.4 \times 10^{-3}M$ solution) was selected. From the dependence shown in Fig. 3(a), the Michaelis-Menten constant was found to be $K_m = 2.54 \times 10^{-4}M$.

The effect of the concentration of the chromogenic reagent, DTNB, was studied in the

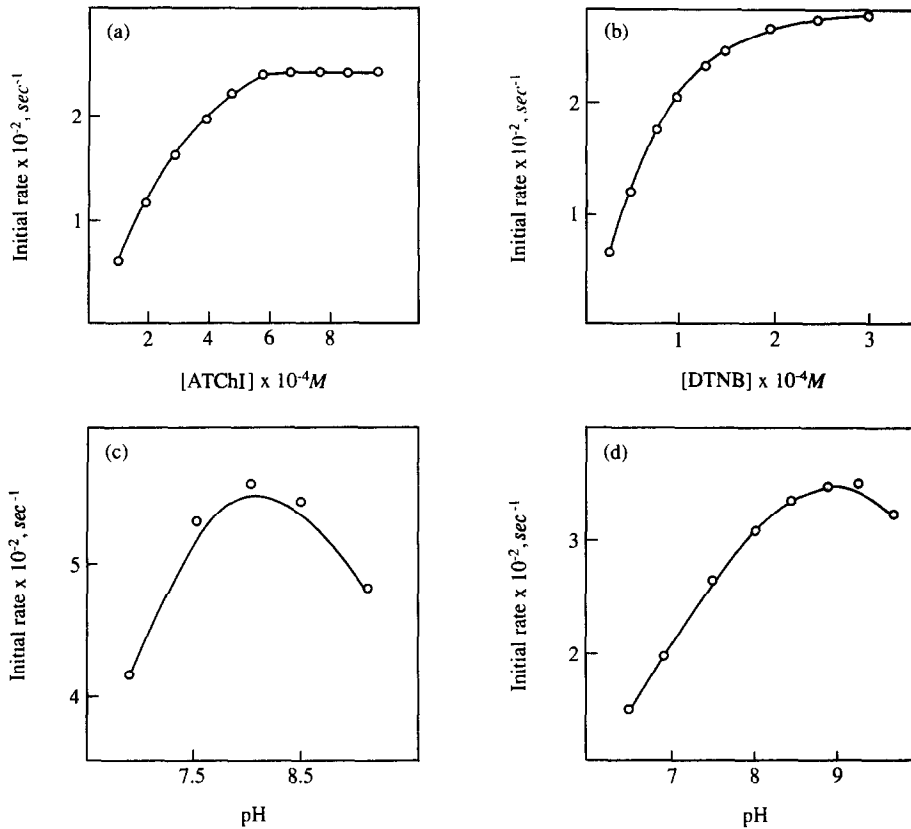

Fig. 3. Effect of (a) ATChI, (b) DTNB concentration, (c) pH of analyte solution and (d) pH of chromogenic reagent solution in the post-incubation step (conditions described in Experimental).

range $0.25\text{--}3.0 \times 10^{-4}M$ [Fig. 3(b)]. A DTNB concentration of $2.5 \times 10^{-4}M$ was selected (2.5 ml of $10^{-3}M$ DTNB solution), corresponding to zero-order zone of the dependence observed.

The study of the effect of pH on the reaction rate was made alternately on the analyte solution (from the incubation process) (solution A) and on the chromogenic reagent solution (solution B) by adjusting the pH between 6.2 and 10.3 with $0.05M$ TRIS buffer in both cases. The influence of the pH of solution A is shown in Fig. 3(c) and a pH of 8.0 was selected as optimum, whereas a pH value of 9.0 was chosen as optimum for solution B according to the results shown in Fig. 3(d). The decreasing of the initial rate at pH higher than 8 is due to hydrolysis of the substrate itself. The optimal concentration of the TRIS buffer was found to be $0.05M$ in both cases.

The influence of the enzyme on the sensitivity of the determination of N-methylcarbamate pesticides (using carbaryl) was studied at three concentrations, 2.4, 4.0 and 5.6 unit/ml under optimal conditions described under Experimental over the linear concentration range of the pesticide. The results obtained are shown in

Fig. 4. Although, with 5.6 unit/ml of the enzyme, the sensitivity was slightly higher, a concentration of 4.0 unit/ml was more than adequate and avoided unnecessary usage of the enzyme.

Analytical features

Under the optimal working conditions, carbaryl, propoxur and carbofuran were determined at the nanomolar level by the proposed

Fig. 4. Calibration graph for carbaryl at various AChE concentrations (conditions described in Experimental).

Table 1. Analytical figures of merit of the determination of N-methylcarbamate pesticides by the proposed kinetic enzymatic stopped-flow method

Feature	Carbaryl	Propoxur	Carbofuran
Dynamic linear range, ng/ml	6-150	2-15	0.1-5.0
Sensitivity, ng/ml	0.398	2.06	13.21
I_{50} , ng/ml	120	40	3.0
Detection limit, ng/ml	4.3	0.8	0.1
Precision (RSD), %	0.61	0.76	0.55

kinetic enzymatic method. The temperature and time used in the incubation of carbaryl also yielded good results for propoxur and carbofuran. Table 1 shows the analytical figures of merit of the determination of these pesticides. The linear range of the calibration graph varied with the pesticide, the concentration quoted being the actual concentration of the analyte in the mixing-observation chamber of the stopped-flow module. The comparative sensitivities, taken as the slope of the respective calibration graphs, and the I_{50} values (the inhibitor concentration for 50% inhibition), varied in the sequence:

Carbofuran > Propoxur > Carbaryl

The detection limit was calculated as the minimum pesticide concentration resulting in a statistically significant I (%) according to the expression:

$$C_{DL} = I_{DL}(\%)/m \quad (2)$$

where $I_{DL}(\%)$ is the minimum value statistically obtained by substituting $V_E - V_I$ in equation (1) by three times the standard deviation (3σ) of the initial rate of the enzyme, V_E , in the absence of pesticide; m is the slope of the calibration graph (analytical sensitivity). The detection limit was experimentally obtained by substituting $I_{DL}(\%)$ in the calibration graph of each pesticide. Taking into account the calculated value of V_E was $9.03 \times 10^{-2} \text{ sec}^{-1}$ and that its $3\sigma = 1.54 \times 10^{-3}$, the minimum detectable value of the inhibition percentage [$I_{DL}(\%)$] found was 1.7%. Substituting this value into equation (2) gave the C_{DL}

Table 2. Selectivity achieved in the kinetic enzymatic stopped-flow determination of 20 ng/ml of carbaryl

Compound assayed	Tolerance ratio
Malathion, methylparathion, aldrin, dieldrin	100†
α -HCH,* lindane, maneb, zineb, ziram	
Fenitrothion	25
Paraoxon, carbofuran, propoxur	< 1

* α -HCH = 1,2,3,4,5,6-hexachlorocyclohexane.

†Maximum ratio tested.

values listed in Table 1. The precision was determined from 11 samples containing 80, 10 and 12 ng/ml of carbaryl, propoxur and carbofuran each, respectively. These results show the method is highly sensitive for the determination of these pesticides, especially carbofuran.

Regarding the selectivity, it is well known that many pesticides, not only those of the carbamate family, inhibit the action of the enzyme ChE,¹¹ the selectivity being strongly dependent on the enzyme source.¹² Thus, it has been claimed² that by using electric eel cholinesterase only chlorinated pesticides inhibit the enzyme activity. However, studies on the influence of organochlorine pesticides on the determination of these N-methylcarbamates pesticides by the proposed method (using electric eel acetylcholinesterase) showed chlorinated pesticides do not interfere at the maximum level tested (see Table 2). This selectivity study also showed the proposed method to be selective against organophosphorous pesticides assayed, except for paraoxon, which interfered at the same concentration level as the pesticide tested.

Taking into account the good selectivity achieved by this method for the determination of these N-methylcarbamate pesticides and their relative reactivity, it is useful for the determination of carbofuran in water samples as well as for the analysis of these pesticides in formulations.

(Received 2 January 1991. Revised 17 April 1991. Accepted 22 April 1991)

Summary—The aim of this study was to separate and identify by chromatographic and spectrometric methods, the various allergenic vulcanization agents and antioxidants used in the manufacture of industrial rubber. Specimens of elastomers were manufactured specially for this study. The specificity of the gas chromatographic method developed allows separation of all the manufacturing additives in the selected rubber types after one injection only, even though they belong to extremely varied chemical categories. The GLC method was coupled with mass spectrometry, which permitted identification of the peaks obtained and the study of the fragmentation of the 4 reference products under various conditions. Separation by TLC was performed in parallel on the same extracts, allowing rapid identification of the products tested for, and showed new spots after vulcanization.

The allergenic potential of rubber items is well known and has been widely investigated in numerous publications. In particular, many cases of reaction to surgical gloves have been reported. It appears, from the literature data, that the allergenic potential of rubber would not be essentially due to the actual polymer, but to secondary constituents, in particular manufacturing agents such as antioxidants and vulcanization accelerators or retardants. The isolated agents have also been tested for potential allergenicity. Such investigations do not however take into account the changes induced by the heat process in vulcanization. Few authors envisaged this issue.^{1,2}

Manufacture of industrial rubber requires an elastomer, sulphur, one or more vulcanization accelerators, an antioxidant and filling material. We have taken an analytical approach to these investigations and carried out a study on specially manufactured experimental specimens containing two accelerators and an antioxidant with each elastomer. Various agents were added to obtain formulations which could be manufactured under normal industrial conditions in the following proportions: elastomer 100, zinc oxide 5, stearic acid 1, carbon black 25, sulfur 2, accelerators 1 + 0.5 and antioxidant 2.

Furthermore, we tested the composition of the mixtures before and after vulcanization, which does not seem to have been done in existing literature. Preparation of the initial mixtures takes place at a temperature of approximately 70°, and the vulcanization process itself around 200°, generally under pressure.

EXPERIMENTAL

Extraction

Extraction was performed on the rubber specimens in a Soxhlet extractor for six hours with a defined amount of acetone at the boiling temperature of the solvent. The samples obtained were stored in a refrigerator after evaporation to dryness in a vacuum, to be recovered extemporaneously with a small amount of acetone for analysis.

Separation

Gas-liquid chromatography. The following operating conditions were used:

Temperature graded from 50 to 230° in levels of 10°/1 min without an initial plateau.

Splitless injector.

Table 1. *R_f* values of the products by TLC with two solvents

Products	Solvent 1	Solvent 2
MBT	0.07	0.25
CBS	0.52	/
DPG	/	0.65
TMTM	0.35	0.88
IPPD	0.31	/
6PPD	0.49	/

Thin-layer chromatography. Two solvents were used:

System 1: Toluene/ethylacetate/ammonia (100/5/1)

System 2: Toluene/acetone/ammonia (45/65/1)

Separation was obtained with the *R_f* values shown in Table 1 for the following products:

solvent 1: CBS, MBT, IPPD, 6PPD, TMTM

solvent 2: DPG, MBT, TMTM.

Operating conditions

Materials. Specimens of elastomers were manufactured specifically for this study. Raw materials were therefore selected with particular regard to their allergenic potential. Two types of elastomers were used: isoprene rubber (IR) and styrene butadiene rubber (SBR).

The following vulcanization accelerators were selected to typify the various chemical categories, since it was observed that the allergic reactions to rubber items are most frequently related to groups of chemicals: cyclohexyl benzothiazyl sulphenamide (CBS), mercaptobenzothiazole (MBT), tetramethyl thiuram monosulphide (TMTM) and diphenylguanidine (DPG).

The two antioxidants used are *para*-phenylene diamine derivatives: *N*-isopropyl *p*-phenylene diamine (IPPD) and *N*-1,3-(dimethyl-butyl) *N'*-phenyl phenylene diamine (DMPPD or 6PPD). The specimens were manufactured with the additives in different formulas. In this way, the role of each of the additives could be derived from the comparison of results observed (Table 2). One half of each sample was vulcanized and the other half left raw to show the effects of vulcanization on the constituents of the mixtures.

Extraction. The method of extraction is derived from the exhaustive study of Vimalasiri

*et al.*³ The duration of the procedure was determined by successive extractions for one hour each and determination by gas chromatography of the amounts present in each extraction.

For a better assessment of possible losses, we also evaluated product degradation resulting from extraction by gas-chromatography in the presence of an internal standard. As a result of the disappearance of CBS, the study of this product was impossible with this extraction method.

Preservation of the obtained organic extracts was evaluated by thin-layer chromatography. In view of the results, it was decided to eliminate the solvent and to store the dried extracts in a refrigerator before analysis. The appearance of additional spots on TLC performed a few hours after storage in the solvent, evidenced degradation of the extracts in the liquid phase.

Separation. The difficulty in isolating each of the additives used and present in the rubber mixtures in one operation arises from their very different polarities.

(i) Gas-liquid chromatography. Separation of the vulcanization agents in rubber extracts was obtained by gas-liquid chromatography coupled with mass spectrometry for identification of the peaks observed. We verified that stearic acid does not interfere with the tested agents. To study the effect of vulcanization, we used chromatographs of raw elastomer extracts previously performed under the same conditions as blanks. Reference mixtures of additives corresponding to the manufactured specimens were also prepared under the same conditions. The addition of measured amounts served to confirm the presence or absence of the test agents. Reproducibility and repeatability of the method were tested before coupling with mass spectrometry.

(ii) Thin-layer chromatography. TLC was performed simultaneously to separate additives in the extracts. Results yielded by each method were found to be complementary. Separation of all test agents required the use of two solvents.

Analysis by mass spectrometry. The reference additives selected for the study were first injected alone under the same conditions as defined for the extracts to obtain reference

Table 2. Formulas of the samples

IR	SBR
IR ₁ = CBS + TMTM	SBR ₁ = MBT + TMTM + 6PPD
IR ₂ = CBS + TMTS + 6PPD	
IR ₃ = CBS + TMTM + IPPD	SBR ₃ = MBT + DPG + 6PPD

chromatograms and groups. The results obtained with a 70 eV electronic impact were for most agents in agreement with those reported by several authors.⁴⁻⁸

However, the mass spectrum of TMTM obtained under these conditions did not give a molecular peak, and therefore identification of the agent in a complex mixture was impossible. Furthermore tests were therefore carried out with a 20-eV impact, at which the molecular peak was obtained.

RESULTS

Thin-layer chromatography

The separation of the products in the extracts were possible, using the two solvents, as shown in Figs. 1 and 2.

Analysis by mass spectrometry of reference samples

The mass spectrum with 70 eV electronic impact and fragmentations of the 5 tested products can be found in the existing literature. To our knowledge, however, no data are available on 6PPD, which was therefore investigated in our study (Fig. 3).

As indicated previously, the conditions selected to obtain the mass spectrum of TMTM did not provide for the molecular peak. Further tests were therefore performed with 20 eV and the molecular peak obtained (Fig. 4). Some of the products were also studied under these

Fig. 2. TLC of the extracts using solvent 2. (⊙) yellow, fluorescent under UV. (⊗) yellow-brown, no fluorescent. (○) fluorescent under UV.

conditions and the new fragmentations give evidence of the preferential terminations; the fragmentation of DPG under 20 eV is given as an example in Fig. 5.

DISCUSSION

The specificity of the chromatographic method used is that it allows separation of all the manufacturing additives in the selected rubber types, although they belong to extremely varied chemical categories and contain inorganic parts which make chromatographic analysis difficult in the polymer compounds. The effects of vulcanization on the extracts could be seen after just one only.

The selected method gives the best extraction of the rubber for our chromatographic conditions while being least drastic in view of the stability of the tested products and of the treatments to which the specimens were submitted prior to analysis. Indeed, acetone reaches boiling point at 66°, a temperature lower than that used to mix the additives into the gum before vulcanization (approximately 70°); besides, exhaustion of the specimens under reflux was found to be the only efficient method of extraction.

Fig. 1. TLC of the extracts using solvent 1. (⊙) yellow, fluorescent under UV. (⊗) yellow, no fluorescence. (○) fluorescent under UV.

Fig. 3. 6PPD Mass fragmentation.

CBS cannot withstand such temperature conditions and is present in the extracts in a degraded form: degradation may take place during extraction, but it is thought that it occurred previously, since the mixture is prepared under heat.

Our chromatographic study was meant to be exclusively qualitative; the GLC study included

a reproducibility study of the retention time results obtained with the tested products individually and as a mixture. We also tested the peak height relationship in order to detect a possible adsorption of the products on the column or interactions between products, but such phenomena failed to be observed. TMTM, however, shows some particular features with

Fig. 4. TMTM Mass fragmentations under 20 eV.

Fig. 5. DPG Mass fragmentations under 20 eV.

chromatography. With TLC, its presence in the extracts before vulcanization is sometimes characterized by several spots, and in GLC by a group of peaks, one of which only has the molecular weight of the initial product as measured by mass spectrometry. The product therefore appears to have undergone partial transformation while being mixed into the rubber in hot air.

Separation by TLC performed in parallel on the same extracts rapidly allowed the products tested to be identified and showed new spots after vulcanisation. The additional advantage of this method is that it allows one to detect, from large deposits, products present in small amounts in the extracts after vulcanization (e.g. MBT).

Mass spectrometry permitted not only to identify the peaks obtained, but also to study the fragmentation of the 4 reference products by applying two different electronic energy levels.

Two examples are shown here of the preferential fragmentations which occur under 20 eV and of the new fragmentations which may occur under 70 eV, an impact too heavy in view of the stability of such fragmentation intermediates.

(Received 15 October 1990. Revised 15 April 1991. Accepted 18 April 1991)

Summary—The effects of a sodium dodecylsulphate micellar solution on the coupling rates of several diazotized arylamines with *N*-(1-naphthyl)-ethylenediamine and the shifts in the protonation constants of the corresponding azo dyes are quantitatively studied. Aniline, *o*-, *m*- and *p*-aminobenzoic acids, ethyl *p*-aminobenzoate and several sulphadriugs are used, and the relationships among the intensity of the effects and the molecular structure of the diazonium ions and the dyes are discussed. A single simplified procedure for the determination of all the substances at pH = 1.3 ± 0.3, where coupling is quickly completed to directly produce the protonated form of the dyes, is established and applied to the analysis of several pharmaceutical preparations.

Arylamines are frequently determined spectrophotometrically after diazotization and coupling with an adequate substrate such as *N*-(1-naphthyl)-ethylenediamine (NED).¹⁻⁴ The procedures are highly sensitive and widely applicable, but drawbacks are slow reactions, the limited solubility of many analytes or of their corresponding azo dyes, and finally, the necessary pH changes before and after coupling which are needed. Diazonium ions are formed at pH ≈ 1, whereas pH > 4 is necessary for coupling if the diazonium ion lacks a strong activating substituent, and an additional adjustment of pH is usually done to obtain the protonated form of the dye, which has a higher absorptivity and absorbs at longer wavelengths than its basic form.

In a previous paper⁵ we showed that in a sodium dodecylsulphate (SDS) micellar solution the rate of the coupling reactions greatly increases. Also, in this medium, the protonization of the azo dyes is inhibited. Both effects permit the rapid formation of the protonated dyes in an acetate buffer, thus making possible a simplification of the conventional procedures for the determination of arylamines. The possibility of directly analyzing hydrophobic samples, such as vegetable oils, in a microemulsion containing SDS has also been demonstrated.⁶

In this work, the effects of the SDS micellar medium on the coupling rates of several arylamines with NED and the shifts in the protonation constants of the corresponding azo dyes are quantitatively studied. The relationships among the magnitude of the effects and the molecular structure of the diazonium ions and the dyes are discussed, and consequences of analytical interest are drawn.

EXPERIMENTAL

Reagents and apparatus

Analytical-reagent grade aniline, sodium nitrite, sulphamic acid (Probus, Spain), NED dichloride (Scharlau, Spain), *o*- and *m*-aminobenzoic acids (Merck, Germany), SDS, *p*-aminobenzoic acid and ethyl *p*-aminobenzoate (Fluka, Switzerland) were used. Sulphonamides were obtained from several pharmaceutical laboratories. Solutions of the diazotizable substances were prepared in water, as well as in a medium containing 1.25% SDS and 0.15M hydrochloric acid. Distilled demineralized water was used throughout.

A Crison micropH 2001 pH-meter, a Shimadzu UV-240 and a Perkin-Elmer Lambda 9 spectrophotometer were used. All measurements were made at 25°.

Procedures

Acid-base titrations. A mixture of 200 ml of the diazotizable substance solution and 10 ml

*Author for correspondence.

of 1% sodium nitrite was allowed to react for 5 min in a 500-ml standard flask. The nitrite excess was removed by adding 10 ml of 3% sulphamic acid. After 10 min, 200 ml of 0.5M sodium acetate, 10 ml of 0.75% NED, 25 ml of 1.5M sodium hydroxide and water up to the mark were added.

The final 0.5% SDS concentration was above the critical micelle concentration (cmc) which, at low and moderate ionic strengths, is below 0.3%.^{7,8} In addition, it has been shown that, at this SDS concentration, all changes produced by the surfactant on the log *K* values of the azo dyes have been completed.⁹

Titration with 2M hydrochloric acid, in the absence and presence of 0.5% SDS, were done in triplicate with 150-ml aliquots. Simultaneous photometric and potentiometric monitoring was implemented. Protonation constants were evaluated by linear regression with points within the range $\text{pH} = \log K \pm 1$, the ionic strength being 0.3M. Other details have been reported previously.¹⁰

Kinetic studies. The procedure given above was modified as follows: 25-ml standard flasks were used and the volumes were proportionally reduced. After elimination of the nitrite excess, 4 ml of 0.5M sodium acetate, 0–5 ml of concentrated hydrochloric acid, and water were added. The mixture was kept at 25° in a thermostat. Coupling was started by adding 0.5 ml of 0.75% NED and the reaction was spectrophotometrically monitored for at least 20 min.

Analysis of pharmaceutical preparations. Tablets were pulverized and samples of 50–100 mg were taken. Five successive extractions were made by heating, stirring and centrifuging the powder with 5 ml of the 1.25% SDS–0.15M

hydrochloric acid mixture. The same mixture was used to conveniently dilute the extracts. Suspensions were treated similarly with 1 ml of sample. In all cases, a sixth extract was made and treated separately to assure quantitative extraction. Diazotization and coupling was made in 25-ml standard flasks with 10-ml aliquots of the sample, 0.5 ml of 1% sodium nitrate, 0.5 ml of 3% sulphamic acid, 0.5 ml of 0.75% NED, and water up to the mark. The absorbance was measured at 550 nm.

RESULTS AND DISCUSSION

Absorption spectra

The wavelengths and molar absorptivities of the maxima of the dyes, obtained in a hydrochloric acid medium of $\text{pH} = 1$ in the absence and presence of 0.5% SDS, are given in Table 1. Most sulphonamide dyes were not soluble in water but no precipitation was observed in the micellar medium. The micellar medium produces small bathochromic shifts and slightly enhances the sensitivity, indicating that the $\pi \rightarrow \pi^*$ transition must take place in a less polar environment than in water. The dye formed by *o*-aminobenzoic acid shows a significantly smaller sensitivity which decreases in the micellar medium. This particular behaviour can be due to the presence of an intramolecular hydrogen bond.

Protonation constants

The protonation constants of the dyes in water and in a 0.5% SDS micellar medium are also given in Table 1. It has been shown⁹ that in the latter medium, the apparent protonation constants of the dyes correspond to the

†The dye was not soluble in HCl at $\text{pH} \approx 1$ in the absence of surfactant.

protonation of the dye-surfactant aggregates, $\log K_c^H$, and that:

$$\log(K_c^{HA}/K_c^A) = \log K_c^H - \log K \quad (1)$$

where K is the protonation constant of the dye in the absence of surfactant, and K_c^{HA} and K_c^A are the binding constants of the protonated and unprotonated forms of the dye to the micelles. Equation (1) indicates that the difference between $\log K_c^H$ and $\log K$ is a measure of the selective ability of the surfactant to bind the protonated form of the dye with respect to the unprotonated form. In all instances, the data in Table 1 indicate that the former is more strongly bound than the latter.

This can be explained by assuming that hydrophobic interactions are of the same order of magnitude for both forms of the dye, but binding of the protonated form is strengthened by electrostatic attraction. Consequently, the value of $\log(K_c^{HA}/K_c^A)$ must increase as the basic character of the dye increases. Hydrophobic interactions are probably of similar strength for aniline and the series of aminobenzoic acids and therefore provide a means of checking this. The data in Table 1 show that the values of $\log K$ and $\log(K_c^{HA}/K_c^A)$ follow the same order, which is:

ortho \gg *para*

> non substituted (aniline) > *meta*

In addition, the value of $\log(K_c^{HA}/K_c^A)$ must decrease as the hydrophobicity of the substituents increases, which holds for the series:

aminobenzoic acids

> sulphanilamide > ethyl ester

It can be concluded that, with the exception of the *o*-aminobenzoic acid dye, the shifts in the protonation constants are small, approximately of one pH-unit, increasing with $\log K$ and decreasing as the hydrophobicity of the substituents increases.

Kinetic studies

The coupling reactions were found to be adequately described by the pseudo-first order model:

$$\ln \frac{A_\infty}{A_\infty - A_t} = k't \quad (2)$$

where k' is the rate constant, and A_t and A_∞ are the absorbances at a given time t and at the end of the experiment when a constant

Fig. 1. Plot of equation (2) for coupling of the *p*-aminobenzoic acid dye: (1) in the absence and (2) presence of 0.5% SDS. Hydrochloric acid concentration was 1.92M and 2.16M, respectively.

value has been reached. A plot of equation (2) for *p*-aminobenzoic acid in the absence and presence of 0.5% SDS is shown in Fig. 1.

Some selected values of k' at increasing hydrochloric acid concentrations are given in Table 2. Coupling rates follow the order of the activity of the diazonium ions which is:

sulphadrigs

> aminobenzoic acids > ethyl ester

Diazonium ions are activated by electron withdrawing substituents, such as sulphonic, carboxylate and ester groups, the former having a stronger effect than the others.¹¹ The intensity of the effect of micellar catalysis is also shown in Table 2 and is positive for all dyes with the exception again of the *o*-aminobenzoic acid dye. Micellar catalysis is particularly strong for ethyl *p*-aminobenzoate and *m*-aminobenzoic acid.

Coupling rates slow down when the acid concentration increases due to protonation of NED, which hinders electrophilic substitution. Since NED has two amino groups, the relationship between k' and $[H^+]$ is not simple. As a first approximation, it was assumed that:

$$k' = k/[H^+]^n \quad (3)$$

The values of n , within the hydrochloric acid concentration ranges of Table 2, were higher in the micellar medium than in water. As the hydrochloric acid concentration increased, the values of n decreased, between approximately 4 and 1 in the micellar medium, and 3 and 1 in water. Therefore, when the acid concentration increases, coupling is more rapidly inhibited in

†An optimum pH range does not exist or it is smaller than 0.5 pH-units.

the micellar medium than in water. However, micellar catalysis was always positive.

Optimum pH range

An optimum pH range for the determination of a diazotizable substance with NED can be deduced as follows. The upper limit can be taken as:

$$pH_{max} = \log K - 2 \quad (4)$$

which corresponds to a 99% protonation of the dye. A practical lower limit, pH_{min} , will be given by the time allowed for coupling to be completed to a satisfactory degree. Values of pH_{min} estimated to reach a 99% degree of coupling in about one min are also given in Table 2. These values were obtained by interpolating or extrapolating the points given in the Table, in some cases with the aid of a few additional measurements of k' .

Table 3. Analysis of pharmaceutical preparations

Compound	Pharmaceutical	Declared	Found*

*Average from triplicate measurements.

It may be observed that where these criteria are met, an optimum pH range does not exist or is very small in water, but ranges from 1 to 4 pH units in the micellar medium. Furthermore, all the optimum pH ranges overlap between the values $1.0 < \text{pH} < 1.6$, which permits the establishment of a single and simplified procedure for the determination of all the diazotizable substances studied here. Consequently, in the procedure given above, the hydrochloric acid concentration was adjusted to give a final pH of about 1.3 (final hydrochloric acid concentration, $0.06M$), thus avoiding the addition of sodium acetate before coupling and more hydrochloric acid after coupling, as in the conventional procedure.

Analysis of pharmaceutical preparations

Application of the simplified procedure to the analysis of several pharmaceutical preparations led to the results given in Table 3.

CONCLUSION

A simplified procedure which permits the determination of many diazotizable substances in an SDS micellar medium with an optimum pH range of 1.3 ± 0.3 has been developed. The

advantage of micellar catalysis of the coupling reaction particularly concerns analytes giving diazonium ions which lack strong activating substituents rather than sulphadruugs. However, the determination of the latter benefits from the advantage of higher solubility of azo dyes in the micellar medium.

THE EFFECT OF pH ON A MULTIPROTONATABLE QUINIDINE ION-SELECTIVE ELECTRODE

MA WAN-LI

Research Institute for Material Protection, Wuhan Institute of Technology, Wuhan 430070,
People's Republic of China

(Received 5 February 1991. Revised 11 April 1991. Accepted 17 April 1991)

Summary—The pH effect on the quinidine ion-selective electrode performance and its electroactive material composition were investigated. It was found that variation of the pH in the bulk solution can alter the ion-pair composition in the membrane phase, thus affecting the electrode behaviour. A capacitor model was suggested for the description of the electrode response.

Numerous drugs contain more than one nitrogen atom which can be protonated, e.g., nicotine, quinidine and cinchonine. The pK_{a1} and pK_{a2} values of their relevant protonated acids are different (nicotine $pK_{a1} = 3.15$, $pK_{a2} = 7.87$; quinidine $pK_{a1} = 4.0$, $pK_{a2} = 8.54$; cinchonine $pK_{a1} = 5.85$, $pK_{a2} = 9.92$).¹ Each drug has a pH range in which both its mono- and diprotonated pharmaceutical ions co-exist. The problem that arises here is whether the monoprotonated or the diprotonated ion will show the main response when a corresponding ion-selective electrode is employed. It is well known the more responsive ions are held by the carriers or sites in the ion-pair complex within the membrane; others are interferences. But if the composition of the complex in the electrode membrane varied due to the pH influence of the bulk solution, the electrode behaviour might be affected, Efstathiou *et al.*² reported that the monoprotonated nicotine ion-selective electrode became progressively sensitive to the diprotonated nicotine ions with a decrease in the pH of the sample solution.

The present paper reports a capacitor model built to describe the electrode performance, based on further investigation of the effect of pH on the quinidine electrode performance and on oil/water extraction models of different protonated quinidine ions.

EXPERIMENTAL

Reagents

Demineralized doubly distilled water and A.R. grade chemicals were used throughout unless otherwise stated. Quinidine hydrochlor-

ide was of Chinese Pharmacopoeia quality (>99%).

pH buffers

The method employed for the preparation of pH = 2.2, 2.6, . . . , 7.0 McIlvaine buffers was essentially the same as proposed by Elving *et al.*,³ except that sodium chloride was added instead of potassium chloride to keep the ionic strength constant at 0.1M. The mixture at pH 1.8 was prepared with hydrochloric acid and sodium chloride.

Ion-pair complexes

To investigate the pH effect on the ion-pair composition of the products synthesized in different pH buffers ion-pair complexes, under their corresponding pH conditions, were prepared by continuously adding 0.01M tetraphenylborate (TPB) sodium solution to $1.002 \times 10^{-2}M$ quinidine solution dropwise until no further precipitate appeared when more drops were added. The precipitates were filtered with a sintered glass crucible No. 4 and then washed with distilled water several times. The filtrates were dried at 50° for 10 hr in a vacuum chamber. Each product was carefully weighed. The mole fraction of monoprotonated quinidine-TPB complex (g_1) and the composition ratio of quinidine to TPB [$1:n$, $QH_n^+(TPB)_n^-$] under its corresponding pH condition were calculated.

Extraction

quinidine solution (pH varying from 1.8 to 7.0, in steps of 0.4) were employed to simulate the pH effect on the composition of the electroactive material in the electrode membrane. Originally, only the monoprotonated quinidine-TPB complex was dissolved in chloroform. After mixing with different pH buffered quinidine solutions for thirty minutes, each organic phase was separated and washed with its corresponding pH buffer. The absorbances of 20, 40, 60 and 80- μ l portions of the organic phase, diluted with 2.0 ml of chloroform (giving a concentration series), were determined with a Pye Unicam PU 8800 U/V spectrophotometer at $\lambda_{max} = 334.0$ nm. The slope of absorbance *vs.* carrier concentration was calculated and by dividing this value with the value of the slope obtained when only monoprotonated quinidine-TPB complex existed, the mole fraction of the monoprotonated quinidine-TPB complex (Table 1) under the given pH condition can be calculated (see appendix).

Concentration effect. To study whether the composition of the electroactive material in the electrode membrane remains constant when employed in a given pH series, the influence of concentration on the ion-pair composition was observed in the same simulation system, with the quinidine concentration in pH = 4.2 buffered aqueous phase varying from $1.0 \times 10^{-3}M$ to $1.0 \times 10^{-5}M$ (1×10^{-3} , 5×10^{-4} , 1×10^{-4} , 5×10^{-5} and $1 \times 10^{-5}M$). The mole

fractions of the monoprotonated quinidine-TPB complex in the organic phase under different concentration conditions were determined by the same method. The results are recorded in Table 2.

Electrode system and EMF measurement

Poly(vinylchloride) (PVC) quinidine ion-selective electrodes were prepared by a standard method.⁴ Contained in the membrane were 30% (m/m) PVC and 70% dibutyl-*o*-phthalate (DOP, in which about 5 mM electroactive material was dissolved). The electroactive materials used were either monoprotonated quinidine-TPB complex, diprotonated quinidine-TPB complex or any ratio of their mixtures prepared in the previous step. Cells of the type

Hg; Hg₂Cl₂, KCl(std.)|0.1M KCL|Sample solution

|| membrane || 0.01M KCl, AgCl; Ag

were employed. Potentiometric measurements were performed with an Orion 980 Digital Ion Analyser with the prepared electrode connected with a Model 217 double junction calomel reference electrode (Shanghai, China), with 0.1M potassium chloride in the outer compartment. The pH adjustment was conducted with a Model 231 glass electrode (Shanghai, China). Calibration graphs were obtained for different pH buffered solutions containing quinidine in concentrations ranging from 10^{-2} to $10^{-6}M$.

RESULTS AND DISCUSSION

Effect of pH on electrode performance.

No obvious differences were observed for the electrodes containing the monoprotonated quinidine-TPB complex, diprotonated quinidine-TPB complex or any ratio of their mixtures; only the absolute potential may have a slight variation within 10 mV. The behaviour of quinidine electrodes depends only on the bulk solution conditions. The response slopes obtained in various pH buffered series are summarized in Table 1. Three typical calibration curves for a monoprotonated quinidine-TPB electrode are drawn in Fig. 1. All are linear with regression coefficients higher than 0.996.

Table 2. Influence of quinidine concentration upon ion-pair composition, pH = 4.2

C, M	1.0×10^{-3}	5.0×10^{-4}	1.0×10^{-4}	5.0×10^{-5}	5.0×10^{-5}
h_1	0.62	0.59	0.62	0.60	0.61

Fig. 1. Calibration curves for a monoprotated quinidine-TPB electrode, (a) pH = 6.6, (b) pH = 4.2, (c) pH = 1.8.

Similar to an ideal univalent ion-selective electrode, the electrode still only responded to monoprotated quinidine ions in approximately neutral solution (pH = 6.6). But with decreasing pH the electrode gradually changed its behaviour to act in a completely different way. Its response slope was no longer a constant value or a step function *vs.* ionic charge (Z) as predicted by the Nernst equation.

$$S = \frac{RT}{F} \ln 10 \frac{1}{Z} \quad (1)$$

but became a continuous function *vs.* pH. It decreased synchronously with decreasing pH, demonstrating a transient process from responding to monoprotated quinidine ions to diprotonated ones. In strongly acidic solution, the electrode responded only to diprotonated quinidine ions (pH \leq 2.2), just like an ideal divalent ion-selective electrode. Also, the apparent charge calculated from the Nernst equation in the transient process was no longer a constant whole number.

When testing a given pH series following a change in pH, the measurements must be performed one or more times until a stable and linear response can be observed. The two dashed curves on Fig. 1 (curves 1 and 2) demonstrate the initial measurement at the 4.2 pH series following the measurement at the 6.6 pH series. The calibration curve gradually approaches linearity, first at the low concentration range and then over the whole range, implying that the electrode itself might have changed; increasing its sensitivity to diprotonated quinidine ions.

The effect of pH on the ion-pair composition of the synthesized products. In the products synthesized under different pH conditions, either the monoprotated quinidine-TPB complex (1:1), diprotonated quinidine-TPB complex (1:2) or their mixture is present. The mole fractions, g , of these two kinds of complexes in a certain product are approximately equal to the distribution fractions, f , of their corresponding quinidine ions under corresponding pH conditions.

$$g_1 = f_1; \quad g_2 = f_2 \quad (2)$$

$$f_1 = \frac{K_{a1}[\text{H}^+]}{[\text{H}^+]^2 + K_{a1}[\text{H}^+] + K_{a1}K_{a2}}; \quad (3)$$

$$f_2 = \frac{[\text{H}^+]^2}{[\text{H}^+]^2 + K_{a1}[\text{H}^+] + K_{a1}K_{a2}}$$

These kinds of ions can react with a given carrier to produce a precipitate, and the corresponding ion-selective electrode can be made with that carrier. So mono- and di-protonated quinidine ion-selective electrodes can be prepared with TPB carrier. Even an electrode which can respond to both mono- and di-protonated quinidine ions can be prepared, by using a mono- and di-protonated quinidine-TPB mixture as the electroactive material.

Existing state of the ion-pair complex in the organic phase

Following the pH variation in the aqueous phase from 7.0 to 1.8, the ion-pair composition in the organic phase varied synchronously. At first, only monoprotated quinidine-TPB complex existed, then the diprotonated quinidine-TPB complex appeared and its proportion increased gradually. Finally, under strong acidic conditions, only the diprotonated quinidine-TPB complex can be observed. Under the same pH conditions, the mole fractions, h , of mono- and di-protonated quinidine-TPB complexes in the organic phase almost equal the distribution fractions of mono- and di-protonated quinidine ions.

$$h_1 = f_1; \quad h_2 = f_2 \quad (4)$$

Three typical spectra are drawn in Fig. 2. The $n - \pi^*$ transition peak diminishes gradually with decreasing aqueous phase pH, directly indicating that the proportion of monoprotated quinidine-TPB complex in the organic phase has comparatively decreased. Since only monoprotated quinidine-TPB complex can generate this peak, an unprotonated nitrogen

Fig. 2. Three typical spectra. Total concentration of quinidine species = $2.0 \times 10^{-6}M$, (a) pH = 6.6, (b) pH = 4.2, (c) pH = 1.8.

atom on its molecular structure is the source for the $n - \pi^*$ transition.

However, in a series at given pH, the ion-pair composition in the organic phase is essentially constant. The concentration of quinidine in the aqueous phase hardly influences it.

The variation of the ion-pair composition in the organic phase is due to entering ions, and provides information about the states of extracted protonated quinidine ions. The experimental result is that the ratio of mono- and di-protonated quinidine ions "extracted" depend only on the bulk solution conditions. This result requires that the extraction ability of the given electroactive material is strong enough to instantly "extract" either the mono- or the di-protonated quinidine ions reaching the interface and that the extraction process is controlled by the partition diffusion step of protonated quinidine ions from the bulk solution to the interface. This is in agreement with the three-step model proposed by Buck⁵ and Thomas *et al.*⁶ for a single ion system.

Now, it may be concluded that the extraordinary behaviour of the quinidine electrode is due to the variation of the electroactive material composition as a function of the pH. The ions extracted into the electrode membrane depend only on the probability of different protonated quinidine ions reaching the membrane surface or their distributions in the bulk solution, for changes in the mobility of different protonated quinidine ions in the bulk solution phase are negligible due to their large sizes, especially under strong stirring conditions. The roles of mono- and di-protonated quinidine ions as host or guest ions can no longer be identified, since both of them contribute to the membrane potential.

Capacitor model

The electrode membrane separates two aqueous phases. Electroneutrality makes the ions on either side impossible to transfer over completely. But this tendency exists if the electrochemical potentials on the two sides are different. To make the process valid, the existence of electroactive material is crucial. The TPB carriers homogeneously distribute in the electrode membrane, serving as sites to construct a space lattice. The mole fraction of the sites occupied by mono- and di-protonated quinidine ions respectively equals

$$m_1 = \frac{h_1 Z_1}{h_1 Z_1 + h_2 Z_2}; \quad m_2 = \frac{h_2 Z_2}{h_1 Z_1 + h_2 Z_2} \quad (5)$$

The site group held by a certain kind of ion establishes a hopping pathway which only allows this kind of ion to pass. The mono- and di-protonated quinidine hopping pathways distribute on the electrode membrane (surface area, S) respectively at their element areas

$$S_1 = m_1 S; \quad S_2 = m_2 S \quad (6)$$

When the responding ions transport from the bulk solution into the internal reference solution selectively through the corresponding hopping pathways, their counterpart ions with opposite sign (Cl^- , *etc.*) are left in the bulk solution, thus generating a potential difference due to the enrichment of response ions at the internal reference solution side and their counterpart ions at the bulk solution side, much like recharging a parallel-plate capacitor (Fig. 3). When the potential rises to match the original electrochemical potential difference an equilibrium will be established. As a result, on the element capacitors occupied by mono- and di-protonated quinidine the hopping pathway is

$$C_1 = D \frac{S_1}{d}; \quad C_2 = D \frac{S_2}{d} \quad (7)$$

where D and d are the dielectric constant and thickness of the electrode membrane respect-

Fig. 3. An electrode membrane treated as two bridging capacitors.

ively, ideal Nernst potentials are generated independently for each element:

$$V_1 = \frac{RT}{Z_1 F} \ln \frac{a_1}{\bar{a}_1}; \quad V_2 = \frac{RT}{Z_2 F} \ln \frac{a_2}{\bar{a}_2} \quad (8)$$

Now the membrane body is separated into two parts, one responding to mono-protonated quinidine ions, the other to di-protonated ones. Actually, the mono- and di-protonated quinidine hopping pathways are alternately and uniformly distributed in the electrode membrane, and so are transported ionic charges. Then for the whole electrode membrane, the apparent potential can be calculated upon the principle of bridging capacitors.

$$CV = C_1 V_1 + C_2 V_2 \quad (9)$$

$$D \frac{S}{d} V = \frac{D}{d} \frac{h_1 Z_1}{h_1 Z_1 + h_2 Z_2} S \frac{RT}{Z_1 F} \ln \frac{a_1}{\bar{a}_1} + \frac{D}{d} \frac{h_2 Z_2}{h_1 Z_1 + h_2 Z_2} S \frac{RT}{Z_2 F} \ln \frac{a_2}{\bar{a}_2} \quad (10)$$

$$V = \frac{RT}{F(h_1 Z_1 + h_2 Z_2)} [(h_1 \ln f_1 + h_2 \ln f_2) - (\ln \bar{a}_1 + \ln \bar{a}_2)] + \frac{h_1 + h_2}{h_1 Z_1 + h_2 Z_2} \frac{RT}{F} \ln a \quad (11)$$

Introducing equation (4), and designating the first term as V_0 since it is constant in a given pH series, then

$$V = V_0 + \frac{RT}{F} \frac{f_1 + f_2}{f_1 Z_1 + f_2 Z_2} \ln a \quad (12)$$

The slope function is

$$s = \frac{\partial V}{\partial (\log a)} = \frac{RT}{F} \ln 10 \frac{f_1 + f_2}{f_1 Z_1 + f_2 Z_2} \quad (13)$$

To define the s -pH function for pH around pK_{a1} , equation (3) is introduced and the term K_{a1} , K_{a2} neglected, yielding

$$s = \frac{RT}{F} \ln 10 \frac{10^{pH - pK_{a1}} + 1}{Z_2 + Z_1 10^{pH - pK_{a1}}} \quad (14)$$

Solving

$$\frac{\partial^2 S}{\partial pH^2} = 0$$

$$pK_{a1} = pH \Big|_{\frac{\partial^2 S}{\partial pH^2} = 0} - \log(Z_2/Z_1) \quad (15)$$

Fig. 4. Comparison of tested and simulated slopes for nicotine (N), quinidine (Q) and cinchonine (C) electrodes.

Model verification

Figure 4 shows experimental and simulated slopes for different electrodes as a function of pH. The dots represent the experimental slope data, and the lines are the computer simulated graphs, using model equation (14). The experimental and simulated data fit quite well (slope data for nicotine and cinchonine were obtained with their corresponding TPB electrodes). McIlvaine pH buffers were not employed for the nicotine electrode due to its lack of selectivity. The pH of a series was controlled by adding 0.01M hydrochloric acid or sodium hydroxide, (pH = 2.0, 3.0, 3.5, 4.0, 5.0, 6.0, 7.0).

The pK_{a1} values obtained from experimental slope data by the numerical differentiation method through equation (15), (Table 3) are close to the literature values.¹ (Note it seems that the pK_{b1} rather than the pK_{a1} value for cinchonine had been mistakenly quoted in the 13th edition of "Lange's Handbook of Chemistry".)

CONCLUSION

Both the mono- and di-protonated quinidine ions can be extracted into the electrode membrane and contribute to the membrane potential. Their individual roles as host or guest ions are impossible to identify, but diprotonated quinidine is dominant in acid solution and the monoprotated form in the mid-pH range. The composition of the electroactive material in

Table 3. Comparison of tested pK_{a1} values with those from Ref. 1

	Nicotine	Quinidine	Cinchonine

*From 12th edition of "Lange's Handbook of Chemistry".

the electrode membrane is no longer a single kind of ion-pair complex, but a mixture of mono- and di-protonated quinidine-TPB complexes, varying synchronously with the bulk solution conditions. The electrode response is controlled by the partition diffusion process of different protonated quinidine ions from the bulk solution to the membrane surface via a kinetic mechanism. The proposed capacitor model can serve to describe the response.

APPENDIX

Calculation of the Fraction of Monoprotonated quinidine-TPB complex (h_1)

The TPB carriers can be assumed to be held in the organic phase in the simulation system, since both the mono- and di-protonated quinidine complexes are insoluble in water. The mole concentration was defined as T . The mole fraction of total TPB carriers occupied by mono- and di-protonated quinidine ions respectively equals

$$m_1 = \frac{h_1 Z_1}{h_1 Z_1 + h_2 Z_2}; \quad m_2 = \frac{h_2 Z_2}{h_1 Z_1 + h_2 Z_2} \quad (1)$$

The mole concentration of mono- and di-protonated quinidine-TPB complexes can be presented as a function of the TPB carrier concentration

$$t_1 = m_1 T / Z_1; \quad t_2 = m_2 T / Z_2 \quad (2)$$

After 20, 40, 60 and 80- μ l portions of the organic phase were diluted,

$$t'_1 = t_1 \frac{v}{V+v}; \quad t'_2 = t_2 \frac{v}{V+v} \quad (3)$$

($V = 2.0$ ml, the volume of the solvent for dilution, v was the volume of the sample taken from the organic phase.)

Only the mono-protonated quinidine-TPB complex can generate the $n - \pi^*$ transition absorption peak. According to Beer's law, the absorbance under given pH conditions is

$$A = \epsilon b t'_1 \quad (4)$$

$$= \epsilon b m_1 T \frac{v}{V+v} \quad (5)$$

$$= \epsilon b m_1 T' \quad (6)$$

$T' = Tv/(V+v)$ was the TPB concentration after dilution. It depends only on the volume of the sample, and its concentration in the series remains unvaried when the pH in the aqueous phase has varied, so it can serve as a reference to observe the existing state of the protonated quinidine ions associated with the carriers.

The determined slope ratio (r) in the $A - T'$ coordinate system is

$$r = \frac{\epsilon b m_1}{\epsilon b_1} = m_1 \quad (7)$$

or

$$h_1 = \frac{r Z_2}{Z_1 + r(Z_2 - Z_1)} \quad (8)$$

ACID-BASE INDICATORS IN *N,N*-DIMETHYLFORMAMIDE: CHROMATIC PARAMETERS OF TRANSITION RANGES

JOSÉ BARBOSA and CARLES M. BOSCH

Department of Analytical Chemistry, University of Barcelona, 08028 Barcelona, Spain

(Received 30 October 1990. Revised 19 February 1991. Accepted 18 March 1991)

Summary—A series of commercial indicators in *N,N*-dimethylformamide has been established. Their chromaticity coordinates, transition pH ranges, pH of maximum colour change, optimum concentration for titration, quality of colour change and the effect of ionic strength have been determined. A variety of acids and their mixtures have been titrated to test the indicators.

N,N-Dimethylformamide is particularly useful in organic reaction chemistry due to its moderately high dielectric constant, 36.7 at 25^o, and its aprotic nature. It is also useful in electrochemical and coordination chemistry studies. In addition, DMF and to a lesser extent ethylenediamine (EDA) are very popular solvents for the titration of acids and mixtures of acid. The much greater basicity of EDA than DMF is an analytical disadvantage because of the levelling off effect. Also, EDA is toxic and unpleasant in use.

In addition, because of its greater hydrogen bond accepting basicity, with a solvatochromic parameter $\beta = 0.69^2$ the formation of homoconjugation and heteroconjugation complexes occurs to a lesser extent in DMF than in acetonitrile (AN)³ and hence often gives normal shaped titration curves in the buffer region.¹

In DMF indicators have been recommended for acid-base titrations⁴ because visual end-point detection is very precise and accurate for acids. As the neutralization curves for acids can be calculated, if the indicator dissociation constants are known, it is possible to predict which indicators will have a sharp colour change at the end-point.

In connection with our studies of acid-base equilibria and colour change quality of the indicators in several solvents,⁵⁻⁸ a series of commercially available indicators in DMF with pronounced colour change have been studied in this work. The colour changes were characterized by the chromatic parameters in both the CIE and complementary chromaticity systems.⁹⁻¹¹ The optimum concentrations for the

indicators were determined by the Vytras¹² and Kotrly and Vytras¹³ methods. In accordance with CIE recommendations, the CIELAB (L*, a*, b*) and CIELUV (L*, u*, v*) co-ordinates were used to calculate the index of colour change perceptibility. The sensitivity, sharpness of colour change, pH corresponding to maximum colour change, and the transition ranges of each indicator were determined.

In this paper we report the pH value at which an indicator would show a specific colour, at zero ionic strength, taking into account the activity coefficients, as reported earlier.⁶ Finally the behaviour of the indicators was tested by titration of different acids and mixtures of acids.

EXPERIMENTAL

Apparatus

For the determination of chromaticity coordinates a Beckman DU-7 spectrophotometer with cells of 1-cm path length and a Hewlett-Packard 9816 computer were used. For potentiometric titrations, a Crison Digilab 517 pH-meter equipped with a Radiometer G202B glass electrode and a 0.01M AgNO₃(DMF)/Ag reference electrode with 0.1M tetramethylammonium perchlorate in DMF serving as a double salt-bridge similar to that used by Kolthoff *et al.*¹⁶ were used (see Fig. 1). This system of electrodes and salt-bridge (kept at 25^o) gave the best combination of all those tested; stable and reproducible potentials were obtained in 15 min or less. The glass electrode was kept in DMF when not used, as recommended.¹⁶

Fig. 1. Potentiometric cell for titrations in DMF with the reference electrode and salt bridge. A, Silver electrode; B, AgNO_3 0.01M in DMF; C, tetramethylammonium perchlorate 0.1M in DMF; D, glass electrode; E, burette with titrant.

The DMF solutions with Ag^+ ions are colourless and clear when prepared, but in about ten days they became crimson and turbid, even though not exposed to light for more than one hour during that period.¹⁷ To minimize possible decomposition of the reference electrode solution, millimolar quantities of perchloric acid were added.¹⁷

Since DMF hydrolyses at a relatively fast rate in the presence of acid or bases, we have been particularly careful to avoid contamination of the solvent by atmospheric moisture. All the experiments have been carried out under a purified nitrogen atmosphere.

Reagents

Tetramethylammonium perchlorate. Carlo Erba, R.S. grade.

Tetrabutylammonium hydroxide (TBAH). A 0.1M solution in propan-2-ol (Carlo Erba, RPE grade).

Benzoic acid. (Carlo Erba, RPE grade).

Acetic acid. (Carlo Erba, RPE grade).

Phenol. (Panreac, AR grade).

Salicylic acid. (Panreac, AR grade)

Malonic acid. (Panreac, AR grade)

Hydrochloric acid gas solution in DMF.

The indicators studied in DMF were: thymol blue (TB), (Scharlau, AR grade); bromocresol green (BCG), (Scharlau, AR grade); bromothymol blue (BTB), (Merck, ACS grade); *m*-Cresol purple (MCP), (Merck, ACS grade); phenol red (PR), (Panreac, AR grade) and azo violet (AV), (Scharlau, AR grade).

Standard potential and DMF autoprotolysis constant

To calibrate the glass electrode in DMF, mixtures of benzoic acid and its tetrabutylammonium salts have been used. The $pK = 12.27$ value of benzoic acids in DMF¹⁶ was taken as a standard reference value.^{16,18-20} The pH values were calculated on the basis of simple dissociation of the acid and complete dissociation of the salts.¹⁶

The glass electrode was calibrated by titration of 0.005M benzoic acid in DMF with 0.1M tetrabutylammonium hydroxide.^{5,6,8} The small quantity of water and alcohols introduced with the titrant have a negligible influence on the chemical potential in DMF.²¹ A computer program, ACETERISO, written in BASIC, was used to calculate the standard potentials in acidic and basic media ($E_a^0 = -51.3$ and $E_b^0 = -1423.6$ mV). From here, the average autoprotolysis constant of the medium was $pK_{ap} = 23.2 \pm 0.3$.

Procedure

Indicator solutions (approximately $10^{-5}M$) were titrated with 0.1M tetrabutylammonium hydroxide solution, in the presence of an appropriate buffer. Hydrochloric and benzoic acid mixture for TB, salicylic acid for BCG, benzoic acid for BTB, a mixture of hydrochloric acid and phenol for MCP, acetic acid for PR and malonic acid for AV were used. Simultaneous potentiometric and spectrophotometric monitoring at 10 nm intervals between 380 and 770 nm was implemented.

The test solution, stirred with a stream of nitrogen, was continuously circulated between the titration vessel and the spectrophotometer cell by means of a peristaltic pump. The temperature was $25 \pm 0.2^\circ$.

Computation method

To calculate the chromaticity parameters, the weighted ordinate method ($\Delta\lambda = 10$ nm), with

the coefficients for the standard illuminant C and "2° standard observer" was used. To compute the optimum concentration of the indicator in the titrations, the chromaticity co-ordinates in a variety of colour spaces,⁶ and the *pK* value of the indicator, the program SUPER-COLOR,²² written in BASIC, was used.

RESULTS AND DISCUSSION

The criteria for selection of the indicators were commercial availability, widespread use, solubility in DMF and sharpness of visual transition. Involved equilibria were:

1. AV1

$$pK = \text{pH} - \log y_{\text{HI}^-} - \log([\text{HI}^-]/[\text{H}_2\text{I}])$$

2. BCG, AV2, BTB, MCP, PR, TB

$$pK = \text{pH} + \log(y_{\text{HI}^-}/y_{\text{I}^{2-}}) - \log([\text{I}^{2-}]/[\text{HI}^-])$$

Table 1 shows the effect of ionic strength (*I*) on activity coefficients in DMF. However, due to the high dielectric constant of DMF (36.7),¹ the activity coefficients have less influence than in other solvents, such as 2-methyl-2-propanol and propan-2-ol and similar influence to that in acetonitrile. Using the pH value at zero ionic strength (*pH*₀) to specify a reference indicator colour⁶ we have:

$$\text{pH}_0 = \text{pH} - \log y_{\text{HI}^-} \quad (1)$$

$$\text{pH}_0 = \text{pH} + \log(y_{\text{HI}^-}/y_{\text{I}^{2-}}) \quad (2)$$

These relationships allow chromaticity parameters to be referred to *pH*₀ values, and colour transitions at different ionic strengths for indicators of various types to be compared. The activity coefficients were calculated by means of the Debye-Hückel equation

$$\log \gamma = -A I^{1/2}/(1 + B a I^{1/2})$$

Table 1. Influence of ionic strength (*I*) on activity coefficients in DMF

were

$$A = 1.594, B = 0.480 \times 10^8 \text{ and } a = 5 \text{ \AA.}^{23}$$

The pH range of a given colour transition can be calculated from the *pH*₀ range and the ionic strength of the solution.

The CIELAB (see Fig. 2) and CIELUV systems can be used advantageously in calculations of chromaticity.

The complementary chromaticity co-ordinates (*Q*_x, *Q*_y), were used to describe the colour sequence of the indicators, Fig. 3. For all the indicators tested, straight lines denoting mixtures of two pure coloured forms were obtained. The fact that AV gives two linear segments shows the presence of two equilibria,

Fig. 3. Colour transitions in the complementary chromaticity diagram. Symbols as in Fig. 2.

Table 2. Colour changes of indicators

Indicator	C_{ref}, M	Optimum concentration M	pK	pK'	Transition pH range	pH_{mcc}	$\Delta pH_{1/2} \text{SCD}$	$pK - pH_{mcc}$

AV2	1.4×10^{-5}	6×10^{-5}	13.52 ± 0.06	16.02	13.0–13.6	13.50	0.30	0.02

each involving a particular colour change, the first from red to yellow and the second from red to blue.

Thymol blue and *M*-cresol purple show a second colour change at very low pH values, which has no analytical interest. We have, therefore, studied only the transition referring to the colour change from yellow to that of the strongly blue alkaline form.

The indicator dissociation constants were determined from the complementary chromaticity co-ordinates according to Reilley *et al.*²⁴ and by a procedure described by Albert and Serjeant.²⁵ The results of the two methods agree and are shown in Table 2. In the case of TB and MCP, the first protonation equilibria, perceptible as short lines in the complementary chromaticity diagram, Fig. 3, were taken into account in the respective pK computation. The colour point of the pure form HI^- can be found from the intersection of the two linear segments in Fig. 3.²⁶

One of the purposes of studies dealing with the influence of solvents on acid–base equilibria is to obtain a solvent-independent acidity scale. By referring the acid–base character of non-aqueous solvents to the same aqueous standard state, an “absolute” pH scale is obtained, which allows the acidity of aqueous solutions to be compared directly,²⁷

$$pH' = pH_s + p\gamma'_{w \rightarrow s}(H^+)$$

where pH_s is the pH in solvent, s , $p = -\log$ and $\gamma'_{w \rightarrow s}(H^+)$, is the proton transfer activity coefficient, which is closely related to $\Delta G'_{w \rightarrow s}(H^+)$, the standard free energy of transfer of 1 mole of protons from water to the solvent s .

$$\log \gamma'_{w \rightarrow s}(H^+) = [\Delta G'_{w \rightarrow s}(H^+)]/2.303 RT$$

The proton transfer activity coefficient, represents the acid end of the solvent independent pH' scale in each solvent s with ultimate reference to the familiar aqueous pH scale and with physical comparability with the latter. The basic

limit of the pH' scale in any solvent is conventionally defined from its autoprotolysis constant.²⁸

For a solvent s , like DMF, the dissociation constants of a series of indicators in this solvent, pK , were then translated to the absolute scale by the equation:

$$pK' = pK + p\gamma'_{w \rightarrow DMF}(H^+)$$

In recent reviews,²⁹ the various extrathermodynamic assumptions which have been made to find transfer activity coefficients have been discussed. Here, $\log \gamma'_{w \rightarrow DMF}(H^+) = -2.5$, was used, as reported by Kolthoff and Chantooni.³⁰ These data are based on the tetraphenylborate assumption, which with reference to water would appear to yield, γ' values closer to the true values than other assumptions do.²⁹

The pK' values obtained for the indicators studied are shown in Table 2. It must be emphasized that each pK value is valid only for the pH scale relevant to the specific pure solvent considered.²⁸ Values of pK pertaining to different solvents would become physically comparable on an “intersolvental” pH scale with ultimate reference to the familiar pH scale in water³¹ only by being first converted to pK' values.

From Fig. 3, and considering only segments with a similar orientation it can be deduced that the colour change qualities of BCG and BTB are similar. As the orientation of the other segments are different their transitions cannot be compared. Further, complementary data give no information about the ideal concentration for the use of the indicators.

In order to obtain the optimum concentrations of the indicators for the titration arrangement used, the method of Kotrlý and Vytřas¹³ was followed. In this method, the minimum of the plot of $\Delta pH/\Delta E$ (index of colour change perceptibility) *vs.* $\log(c/c_{\text{ref}})$ gives the optimum indicator concentration; c_{ref} is the reference experimental value of the indicator concentration, c is the indicator concentration and ΔE is the

Fig. 4. Changes of SCD values in CIELAB system, with pH at zero ionic strength (pH_0). A-TB, B-PR, C-MCP, D-BTB, E-BCG, F-AV1 and G-AV2.

total difference between two colours, calculated by using the CIELAB and CIELUV systems. The data obtained by the two systems agree and the results (for a 1-cm path-length) are given in Table 2.

To describe the quality of colour change of the indicators objectivity, a modification¹⁵ on the method of Bhuchar and Agrawal¹⁴ based on a plot of $\Delta E/\Delta \text{pH}$ [or the specific colour discrimination (SCD) values] vs. pH (Fig. 4), was used.

In this plot, the band-width, of each peak is the transition pH range, and the pH value at the maximum is the pH for the maximum change of colour (pH_{mcc}). The half band-width ($\Delta \text{pH}_{1/2\text{SCD}}$) is also related to the sharpness of the chromatic transition, and the maximum of each peak (in SCD units) is taken as the sensitivity of the colour change. Table 2 gives the average of the results obtained by the CIELAB and the CIELUV system, except for the SCD values, which are not comparable for different chromatic systems.

Fig. 5. Indicator transition ranges, at zero ionic strength, for the indicators in DMF. Diagonal hatching, before the pH of maximum colour change; no hatching, after the pH of maximum colour change.

From the SCD values (Fig. 4) it can be deduced that MCP and AV2 show very pronounced colour changes in DMF and the other indicators studied show similar quality of colour changes with adequate sensitivity. These conclusions all agree with visual observations.

Table 2 shows the difference between the $\text{p}K_a$ and pH_{mcc} values that do not agree, as a result of the varying sensitivity of the human eye to different colours. The pH_{mcc} values are displaced, relative to the $\text{p}K$ values, towards pH values at which the concentration of the less intensely coloured form is the higher. Thus the $\text{p}K$ values of all the sulphonephthaleins studied are higher than their pH_{mcc} values, because the blue or violet basic form is more intensely coloured than the yellow acidic form. Values of pH_{mcc} are important because they allow selection of the most suitable indicator for a specific titration.³²

Figure 5 gives the colour-change pH ranges of the indicators studied, the colours before and after the pH of maximum colour change, and the pH_{mcc} value. The series of indicators studied covers the necessary pH range, for acid-base titration of weak acids.

In order to test the proposed indicator scale, suitable amounts of acid were weighed and titrated in DMF with 0.1M tetrabutylammonium solution.

The acids tested were hydrochloric, 2,6-dihydroxybenzoic, salicylic, benzoic and acetic acids with $\text{p}K$ values of 3.2, 3.56, 8.24, 12.27 and 13.5,¹⁶ respectively, and phenol. All tested indicators gave very sharp end-points in titrations of acids with $\text{p}K$ values of about 14 or lower. The titration curve for phenol had no clear inflection at the equivalent point.⁴

Hence, taking into account the $\text{p}K$ values of the indicators, and the quality of the colour change, we suggest the use of MCP, TB and PR for titrations, all of the acids tested, BTB and AV2 for hydrogen chloride, 2,6-dihydroxybenzoic, salicylic and benzoic acids and BCG for strong acids, hydrogen chloride and 2,6-dihydroxybenzoic acid. A binary mixture of 2,6-dihydroxybenzoic and benzoic acids was titrated with AV, with an error smaller than 2%.

UTILIZATION OF *O*-PHTHALALDEHYDE–SULPHURIC ACID AS A SPRAY REAGENT IN THIN-LAYER CHROMATOGRAPHIC DETECTION OF SOME INDOLEALKYLAMINES AND APPLICATION TO CUTANEOUS SECRETION EXTRACTS OF TOAD SPECIES

(Received 11 February 1991. Accepted 8 April 1991)

Summary—An expansion of the utilisation of *o*-phthalaldehyde in sulphuric acid medium as spray reagent was carried out when tryptophan and some tryptophan-derived indole alkylamines such as tryptamine, serotonin, bufotenine, dehydrobufotenine and bufotenidine were examined by thin-layer chromatography. *R_f*-values and limits of detection ranging from 20 (serotonin) to 100 (dehydrobufotenine) ng per spot were found. Application of this reagent for the detection of some of these compounds was carried out, using either methanolic extracts or column chromatographic fractions of the skin secretion of the toads *Bufo ictericus* and *Odontophrynus cultripes*.

Paraformaldehyde gas,¹ van Urk's or Ehrlich's reagents (*p*-dimethylaminobenzaldehyde in HCl medium),^{2,3} Prochazka reagent (formaldehyde in HCl: ethanol solution)^{2,3} or *paraformaldehyde* in alkaline medium⁴ are the classical spray reagents for the chromogenic or fluorogenic identification of indolic compounds.

In spite of that, *o*-phthalaldehyde (OPA) has been developed and successfully used for the detection of indole compounds after thin-layer chromatography (TLC),^{5–20} generally in hydrochloric acid conditions. *o*-Phthalaldehyde in hydrochloric acid medium, as proposed by Maickel and Miller,²¹ but modified by the addition of cysteine, was employed by Narasimhachari and Plaut⁵ for the identification of 5-hydroxytryptamine (serotonin), *N*-methylserotonin, 5-hydroxy-*N,N*-dimethyltryptamine (bufotenine) and 5-methoxy-*N,N*-dimethyltryptamine. This technique was later used for the determination of *N*-methyltransferase activity present in human and animal tissues.⁶

5-Hydroxy-3-ylacetic acid was detected under similar conditions after separation by TLC by Korf and Valkenburgh-Sikkema.⁷ Recently, Arqué *et al.*⁸ searched for the optimum hydrochloric acid concentration for the identification and determination of several 5-hydroxy and 5-methoxy indoleamines, including serotonin, employing TLC of the reaction products of these and other compounds with OPA–hydrochloric acid. The limits of detection from the fluorescent intensities of the spots were determined with a chromatograph-spectrofluorometer.⁸ OPA was used in sulphuric acid medium by Szabó and Karacsony¹⁰ for the detection of ergolones and ergolines (indole alkaloids) in TLC conditions. Based on their previous work,²² Pastore and de Lima¹¹ examined the utilization of this spray reagent for the detection of a series of indol-3-ylacids including indol-3-ylacetic acid and 4-(indol-3-yl) butyric acid, both known as phytohormones. OPA has also been proposed as a spray reagent in the determination of tryptophan,^{9,12} histamine,^{9,13,14} histidine^{9,18} and other aminoacids and peptides,^{16–18} hydrazine and substituted hydrazines,¹⁹ amphetamines, mescaline and noradrenaline,²⁰ using TLC, paper chromatography

*Author for correspondence.

†Present address: Departamento de Bioquímica, Universidade Federal de Minas Gerais, Belo Horizonte, MG, Brazil.

or electrophoresis under different reaction conditions. A large number of compounds also react with OPA, depending on the reaction medium, either in chromatographic or solution fluorimetric conditions.⁹

In the present work we examined the possibility of detecting tryptophan and some indolealkylamines such as tryptamine, serotonin, bufotenine, bufotenidine and dehydrobufotenidine with OPA in sulphuric acid and TLC medium. Using OPA-HCl in an investigation with tryptophan or tryptamine, an extremely weak signal was observed.²¹ Similar results were also found by Aures *et al.*¹ after examining OPA as spray reagent in acid (acetic acid in acetone) or basic (potassium hydroxide) conditions. According to our previous work,²² both serotonin and tryptophan react with OPA-sulphuric acid in solution, with a λ_{\max} of emission at 478 and 463 nm, respectively; the latter being shifted to 470 nm after ultraviolet irradiation.

o-Phthalaldehyde, in alkaline medium and in the presence of 2-mercapthoethanol (Roth's reagent),²³ reacted with tryptamine,²⁴ although the reaction was carried out in solution. No reference was found in the literature to the reaction of bufotenidine or dehydrobufotenine with OPA.

Due to the interesting biological behaviour, derived principally from the hallucinogenic action of most of these compounds,²⁵ there is great interest in their detection and determination by TLC. We studied the feasibility of detection of these compounds in 'real' samples and then examined the application of the present method for the detection of some of these compounds, using samples of cutaneous secretion extracts of toad species, either raw or after column and TLC separation.

EXPERIMENTAL

Reagents and apparatus

All reagents used were analytical-grade. Ethanol 99% (Merck S. A., Rio de Janeiro, Brazil) was purified through reflux (12 hr) with Zn-KOH and distillation. Tryptamine (as hydrochloride), tryptophan, serotonin (as hydrochloride) and *o*-phthalaldehyde were purchased from Sigma Chemical Company (St. Louis, MO, USA) and used as received. Bufotenine and dehydrobufotenine were of laboratory origin having been isolated and purified,

using extraction, picrate formation, free base column chromatograph separation and TLC examination of the purity, from different natural sources, such as *Anadenanthera colubrina* (bufotenine), according to Stromberg²⁶ and from a sample (bufotenine) kindly provided by Dr. Nuno A. Pereira (Faculdade de Farmácia, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil), which was isolated from *Piptadenia peregrina* (monopicrate m.p. 176–178; literature 177.5).²⁷ Dehydrobufotenine was isolated from the secretion of a toad (*Bufo ictericus*) according to Slotta and Neisser.²⁸ Bufotenidine was obtained through methylation of bufotenine²⁷ with methyl iodide, in absolute ethanol at a temperature of 60° for 2 hr. Picrates of dehydrobufotenine and bufotenidine were obtained with melting points of 184–186° (literature 186°) and 197–198° (literature 198°),²⁷ respectively. Structural diagrams of bufotenine, dehydrobufotenine and bufotenidine are shown in Fig. 1.

Thin-layer glass plates (50 × 200 mm or 100 × 200 mm) were coated with silica-gel (G, type 60, Merck Darmstadt, FRD). Ascending, one dimension, thin-layer chromatography was carried out at room temperature (*ca.* 25°) in glass tanks, the plates having previously been eluted (washed) with ethyl acetate and air dried. As eluent a solvent mixture (ethyl acetate: propan-2-ol: conc. ammonium hydroxide; concentrations; 45:35:20 v/v) was used, a modification from a known solvent system which uses methyl acetate in place of ethyl acetate, as described by Randerath.²

The indole compound solutions (dissolved in 1 ml of absolute ethanol and diluted to 10 ml with water) were applied to the plates with a 10- μ l Hamilton microsyringe (Hamilton, Reno, NV, USA). For the visual observation of the fluorescent spots, determination of the *R_f*s and estimation of the limits of detection, an ultraviolet viewing box (Ultra Violet Products, San Gabriel, CA, USA) was employed.

Procedure

Classical procedures were used for the preparation of the plates, the chromatographic process and the detection.^{2,3} The volumes of analyte solutions, ranging from 1 to 5 μ l, were applied in the plates at 10 mm from the base. The spots were air dried. The plate was developed (ascending chromatography) 120–140 mm from the starting point with running times of *ca.* 60–80 min.

Fig. 1. Structural diagrams of some of the compounds studied: bufotenine (IV), dehydrobufotenine (V) and bufotenidine (VI).

After development, the plates were dried with an air blower. Hot air was avoided. After being dried, the plates were sprayed with an *o*-phthalaldehyde-sulphuric acid solution 0.15% (m/v). The OPA solution was prepared as follows: 0.15 g of OPA was dissolved in 10 ml of absolute ethanol in a standard flask. After dissolution, the volume was made up to the mark with 7.77*M* sulphuric acid, yielding an OPA hydroalcoholic solution of concentration 7*M* sulphuric acid. This solution can be used for 7 days if kept in darkness in a refrigerator.

RESULTS AND DISCUSSION

Solutions of the pure compounds with a known concentration (ranging from 20–350 µg/ml) were spotted on the plates and eluted for the determination of the *R_f*s, limits of detection and colour of the spots. Table 1 shows the results obtained. The *R_f*-values fluctuate as a

function of the distance run. Due to the volatile character of the components of the solvent mixture (principally ammonium hydroxide) a fresh eluent must be used. Otherwise, a much larger spread in the *R_f*-values is found.

Some colour intensities increased with time and ultraviolet exposure (such as the case of tryptophan and 5-OH-tryptamine) and the limits of detection were determined 15–60 min after spraying. The spots were usually stable even after 24 hr, although some bleaching was observed in some cases.

It is interesting to observe that the compounds with the 5-hydroxy substituent or the unprotonated (fenolic) group at the same position showed yellow or yellowish colours. In contrast, compounds in which the 5-hydroxy substituent is absent, such as tryptamine or tryptophan, yields products with blue or bluish colours. In the present case we also observed that when hot air is used in the drying step

Table 1. Analytical characteristics of the compounds studied with OPA-H₂SO₄ spray reagent

Compound	<i>R_f</i> *	Colour	Estimated limit of detection, ng per spot
I Tryptamine	0.68 ± 0.06 (0.77)	Blue	40
II Serotonin (5-Hydroxytryptamine)	0.59 ± 0.05 (0.65)	Whitish-yellow	20
III Thryptophan	0.38 ± 0.01 (0.23)	Bluish-white	50
IV Bufotenine† (5-Hydroxy- <i>N,N</i> -dimethyltryptamine)	0.76 ± 0.04	Yellow	25
V Dehydrobufotenine†	0.36 ± 0.02	Yellow	100
VI Bufotenidine† (5-Hydroxy- <i>N,N,N</i> -trimethyltryptamine)	0.13 ± 0.04	Yellow	50

*In parenthesis are the results described in the literature² with methyl acetate; propan-1-ol: ammonium hydroxide, 25% (45:35:20).

†See Fig. 1.

(after chromatography), the yellow colour may change to blue, possibly due to a thermal reaction. In our previous observation,^{11,22} 5-hydroxyindol-3-ylacetic acid was the sole compound to produce a colour which was different from blue (green) in comparison with some unsubstituted indol-3-ylacids. Even with 5-methoxy-indol-3-ylacetic acid a bluish spot was found. Similar results have also been found by Arqué *et al.*,⁸ when OPA-hydrochloric acid (Maickel and Miller's reagent)²¹ was examined: the 5-hydroxy indoleamines produced orange spots but with 5-methoxyindoleamines blue spots were observed. Using OPA-hydrochloric acid also (but in the presence of cysteine), Narasimhachari and Plaut⁵ found yellow spots with serotonin and bufotenine (which are 5-hydroxy substituted compounds) and blue spots with 5-methoxy-*N,N*-dimethyltryptamine. From these observations we can conclude that different products are obtained and this difference can be useful for the possible characterization of the analyte's chemical structure present in the spot.

The estimated limits of detection were in the range 25–100 ng. The limit of detection of serotonin was equal to that found by Narashimhachari and Plaut (20 ng)⁵ despite being much higher if compared with 0.6 ng, found by Arqué *et al.*⁸ with OPA-hydrochloric acid and a TLC-scanner-spectrofluorometer. The limit of detection found in the present work with tryptophan is higher if compared to the results found by Lindeberg (5–10 ng for each spot),¹⁵ using OPA-2-mercaptoethanol as proposed by Roth.²³ Our result is also higher when compared with 5 ng described by Stahl³ (using formaldehyde) or 1.6 ng found by Toneby⁴ (paraformaldehyde in alkalized ethanol as spray reagent).

With bufotenine a lower result was observed, in comparison with previous work (50 ng).⁵ Cowles *et al.*²⁹ obtained a weak fluorescence signal with bufotenine, using formaldehyde (from paraformaldehyde) as a spray reagent, although with tryptamine, serotonin and tryptophan strong fluorescence signals were present. These authors conclude that an amino terminal group is necessary for reaction completion when formaldehyde is employed.

On the other hand, the reaction with OPA can occur in the presence or absence of such a group. As previously observed by us, OPA either in solution or in thin-layer conditions can react in sulphuric acid medium with compounds

which lack a primary amino group or even with indole compounds without a 5-hydroxy or 5-methoxy substituent. This was demonstrated when indole—substituted at position 3 with an *n*-alkylcarboxylic acid group—reacted with OPA-sulphuric acid.^{11,22} OPA also has the advantage of substituting formaldehyde, a reagent which is suspected of having carcinogenic action.³⁰ Also, it is known that the reaction of formaldehyde with hydrochloric acid in the vapour phase can possibly occur, yielding bis(chloromethyl)ether, a potent carcinogenic compound.³¹

o-Phthalaldehyde in sulphuric acid medium was successfully applied to the detection of serotonin and dehydrobufotenine in fresh cutaneous secretion of the South American toads, *Odontophrynus cultripes* and *Bufo ictericus*,³² by TLC. The results were confirmed with either Ehrlich's reagent or Pauly reagent (sulphanilic acid in the presence of sodium nitrite) after TLC. Some chromatographic fractions of toad extracts—prepared with alumina as the stationary phase and methanol as the eluent followed by TLC separation—were also examined. In such conditions bufotenine and bufotenidine were identified besides serotonin. This spray seems to be extremely useful for the identification of indolealkylamines after chromatography.

EFFECTS OF SALTS ON THE STABILITY OF THE CATIONIC RADICAL OF PHENOTHIAZINE DERIVATIVES

I. JELÍNEK, I. NĚMCOVÁ and P. RYCHLOVSKÝ

Department of Analytical Chemistry, Charles University, Albertov 2030, 128 40 Prague 2, Czechoslovakia

(Received 11 February 1991. Accepted 6 March 1991)

Summary—Effects of cations and anions of various salts on the stability of the diethazine cation radical were studied in various mineral acids. It was found that stability is enhanced in the presence of salts that contain the same anion as that contained in the cation radical salt. Other anions decrease the stability. The influence of salt cations is negligible.

Many derivatives of phenothiazine (I) are used in analytical chemistry, especially those substituted in positions 3 and 7 (dyes of the methylene blue group) as well as those substituted in position 10 alone and positions 2 and 10. The latter substances are also utilized in medicine as antipsychotic pharmaceuticals.

Analytical use of phenothiazine derivatives with substituents in position 10 (A) is usually based on their reversible oxidation to intensely coloured cationic radicals (A^+), which makes it possible to employ them as redox indicators or spectrophotometric reagents.¹ However, this application is complicated by limited stability of these cationic radicals, the rate of their degradation being strongly dependent on the composition of the reaction mixture. The stability of the cationic radical is also considered as an important factor in pharmacological use, as these radicals are often assumed to be the actual pharmacologically active component.

It follows from published studies²⁻⁷ that cationic radicals of most phenothiazine derivatives decompose to yield an approximately equimolar mixture of the original derivative (A) and its sulphoxide (AO), according to the overall equation

However, the decomposition is more complex in some cases and products have not yet been unambiguously identified.

It has been demonstrated that the stability, or the rate of degradation, of cationic radicals strongly depends on the following factors:

(a) type and position of substituents on the phenothiazine skeleton.²⁻⁵

(b) acidity of the reaction medium³—the stability of the cationic radical A^+ increases with increasing acidity, given by the H_3O^+ ion activity rather than its concentration (as correlation with the Hammett acidity function); *i.e.*, the H_3O^+ ion exerts a thermodynamic stabilizing effect rather than a kinetic effect.

(c) in media with low acidities (pH 2–7) the rate of cationic radical decomposition depends on the type and concentration of buffer used.⁵⁻⁷

From the kinetics of decomposition of cationic radicals which are second-order with respect to A^+ , the following reaction mechanisms have been proposed:

(For anions B^- that do not contain acidic hydrogen, *e.g.*, acetate, CH_3COO^-)

(For anions HB^- that contain acidic hydrogen, *e.g.*, dihydrogenphosphate, $H_2PO_4^{2-}$)

Both reactions are specifically base catalysed, *i.e.*, the catalytic effect of a base depends on the chemical structure of the base.

The above kinetic studies employed buffered media (acetate, phosphate, citrate, glycine, *etc.*) and a constant ionic strength obtained with sodium chloride; however, the effect of sodium chloride on the reaction has not been studied. The effect of neutral salts on rate of decomposition of the cationic radical, A^{+} , is also very important from the point of view of practical application (especially in view of the observed specific catalysis of the decomposition) and thus this paper deals with this problem.

Diethazine (10-diethylaminoethylphenothiazine) was selected for the study; this substance is also used in clinical practice as an antiparkinson drug.

EXPERIMENTAL

Chemicals

Diethazine hydrochloride, used for the preparation of the diethazine radical cation, was obtained from Léčivae (Modřany, Czechoslovakia) and its purity was checked by TLC with a methanol-chloroform (1:1) mobile phase.

The diperchlorate salt of the diethazine cationic radical, $DE^{+}ClO_4^{-}HClO_4$ ($M_r = 498.4$), was prepared by oxidation of diethazine hydrochloride with hydrogen peroxide in perchloric acid, according to Levy *et al.*³ A stock solution of $1 \times 10^{-2}M$ $DE^{+}ClO_4^{-}HClO_4$ was prepared by dissolving this substance in concentrated perchloric acid. This solution, stored in the dark, is stable for several weeks.

The dichloride salt of the diethazine cationic radical, $DE^{+}Cl^{-}HCl$ ($M_r = 370.4$), was prepared by electrochemical oxidation of $1 \times 10^{-3}M$ diethazine chloride in concentrated hydrochloric acid. The oxidation was performed coulometrically at a potential of 750 mV *vs.* SCE, the potential was found from an experimental voltammetric curve and the end of the generation was determined from the measured electric charge. Ultra-violet absorption spectra indicated that the oxidation of DE to DE^{+} was quantitative. Bands corresponding to DE hydrochloride and to the higher oxidation state, *i.e.*, the DE sulphoxide, were absent.

Salt solutions were prepared by dissolving these salts, of analytical-grade purity, in distilled water.

Apparatus

Spectrophotometric measurements were performed with a PU 8800 instrument (Pye Unicam, Cambridge, England) in 1.00-cm cuvettes. Solutions were kept at $25 \pm 0.5^{\circ}$.

Procedure

Absorbance was recorded against time at a wavelength of 512 nm corresponding to the absorption maximum of the radical cation, over an interval of 60 min starting from the moment the compounds were mixed. Degradation half-times were found from these curves and these variables were linearized (assuming a second-order reaction, the equation $1/c = k_r t + 1/c_0$ is valid). Values of the rate constant, k_r , were obtained from the slope of a plot of $1/c$ *vs.* t .

The ϵ_{512} value for DE^{+} , which was used to calculate concentration from the measured absorbance, was found from the absorbance of $2 \times 10^{-4}M$ DE^{+} in concentrated (11.0M) perchloric acid where DE^{+} is stable.

RESULTS AND DISCUSSION

Initial time dependent changes of the diethazine cationic radical, DE^{+} were obtained from its UV and visible absorption spectra. It can be seen in Fig. 1 that the absorption maxima of the diethazine cationic radical⁸ ($\lambda = 212, 265$ and 272 nm) decrease with time while maxima of diethazine⁹ ($\lambda = 205, 250$ and 299 nm) and its sulphoxide⁹ ($\lambda = 2332.5, 268$ and 292.5 nm) increase indicating that the latter substances are the final products of DE^{+} , decomposition.

The effect of the non-oxidized diethazine hydrochloride on the rate constant of the DE^{+} decomposition was studied first. As assumed, an addition of diethazine hydrochloride leads to a decrease in the k_r value for decomposition of the diethazine cationic radical (measurements were performed in perchloric acid medium). Dependence of the rate constant on the diethazine hydrochloride concentration is linear. Measurements were performed up to a diethazine hydrochloride concentration of $1 \times 10^{-3}M$; at higher concentrations the solution becomes turbid.

In the study of the influence of ions on the rate of DE^{+} decomposition, phosphoric acid was first selected as the reaction medium, as it is often used in spectrophotometric determinations of metals with phenothiazine derivatives and its effect on the stability of the cationic radicals of phenothiazine derivatives has

Fig. 1. Time changes in the absorption spectrum of the diethazine radical cation in the UV region. Concentration of $\text{DE}^+ \cdot \text{ClO}_4^- \cdot \text{HClO}_4 = 5 \times 10^{-5} M$. Concentration of $\text{HClO}_4 = 0.23 M$. Curves 1 to 4 were obtained at times of 1, 30, 60 and 180 min, respectively after mixing.

already been studied.¹⁰ In order to interpret the results obtained, the behaviour of DE^+ perchlorate in perchloric acid and DE^+ chloride in hydrochloric acid had to be studied.

Stability of the perchlorate of the diethazine radical cation

Phosphoric acid media. The effect of the concentration of the sodium salts of ClO_4^- , Cl^- , SO_4^{2-} and NO_3^- on the rate constant of DE^+ degradation was studied. The DE^+ species was prepared as the perchlorate salt and dissolved in 3M phosphoric acid. It can be seen from Fig. 2 that the presence of the perchlorate anion increases the DE^+ stability; the rate constant is seen to decrease. On the other hand, Cl^- and SO_4^{2-} decrease the DE^+ stability. The degradation of DE^+ is greatly enhanced in the presence of nitrate; the effect of nitrate is apparently described by a more complex mechanism, as demonstrated by the time dependences of DE^+ degradation that do not correspond to a second-order reaction.

The effect of the salt cations on the resultant k_t value was also studied [LiCl, NaCl, KCl and NH_4Cl , curves 2(a)–(d)]. The cation exerts only a small influence on the resultant rate constant. The ratio increases in the order,

Fig. 2. Dependence on salt concentration of the rate of decay of the perchlorate salt of the diethazine radical cation. Concentration of $\text{DE}^+ \cdot \text{ClO}_4^- \cdot \text{HClO}_4 = 2 \times 10^{-4} M$; medium, 3M H_3PO_4 .

 Curve 3 Na_2SO_4

$\text{Li}^+ < \text{Na}^+ < \text{K}^+ < \text{NH}_4^+$, *i.e.*, with decreasing value of the mean activity coefficient for these salts (γ_{\pm} values for 0.5M solutions of these salts are 0.73, 0.68, 0.65 and 0.62, respectively). Moreover, hydrolysis of ammonium chloride probably also plays a role.

It follows from the above results that only sodium perchlorate, *i.e.*, a salt with the same anion as that of the diethazine cation radical, causes a decrease in the rate of the cation radical degradation. Therefore, a further study of the behaviour of the DE^+ perchlorate was conducted in a medium containing only the ClO_4^- anions.

Perchloric acid media. The effect of perchloric acid concentration, *i.e.*, the influence of H^+ and ClO_4^- ions, on the rate constant of the DE^+ perchlorate decomposition was studied first, from a maximal (11.0M) to a minimal (0.23M) perchloric acid concentration, obtained by dilution of the stock solution.

The dependence of the rate constant on the perchloric acid concentration is given in Fig. 3 (values are averages of five experimental values). It can be seen that the rate constant decreases with increasing perchloric acid concentration. There is a variance on the dependence around 4.0M perchloric acid. The decomposition of the

Fig. 3. Dependence of the HClO_4 concentration of the rate of decay of the perchlorate salt of the diethazine radical cation. Concentration of $\text{DE}^{+\cdot}\text{Cl}^- \text{HClO}_4 = 2 \times 10^{-4} M$.

diethazine radical cation probably obeys a more complex mechanism at perchloric acid concentrations higher than $4.0 M$, as the $1/c$ vs. t dependences do not correspond to 2nd order kinetics. The $\text{DE}^{+\cdot}$ perchlorate is stable at a perchloric acid concentration of $6 M$ or higher.

To verify the hypothesis that the perchlorate anion decelerates the decomposition of the perchlorate of the diethazine cationic radical, the effect of sodium perchlorate was studied over the concentration range 0.05 – $1.0 M$. The dependence of the rate constant on the sodium perchlorate concentration is given in Fig. 4, curve 1. The reaction rate is constant up to a

Curve 3 NaClO_4

sodium perchlorate concentration of $0.2 M$ and then decreases at higher concentrations.

The effect of chloride anion (sodium chloride) was also followed in a perchlorate medium (curve 2). It can be seen that sodium chloride increases the rate of the $\text{DE}^{+\cdot}$ decomposition, especially at lower concentrations.

To verify this finding, the effect of hydrochloric acid was also studied (curve 3). The decomposition rate increases from 0.01 – $2.0 M$ hydrochloric acid, *i.e.*, the effect of Cl^- predominates over the stabilizing effect of H^+ .

Sodium nitrate affects the $\text{DE}^{+\cdot}$ disproportionation in perchloric acid medium according to a mechanism that is more complex than a 2nd order reaction.

Stability of the chloride of the diethazine radical cation

As above, the effect of selected anions (ClO_4^- , SO_4^{2-} and Cl^-) was studied by following the rate of degradation of the diethazine radical cation

prepared by electrochemical oxidation of the hydrochloride salt. Dependences are given in Fig. 5. It is evident that chloride causes the rate constant for the decomposition of the $DE^{+\cdot}$ radical cation to decrease, *i.e.*, increases the stability of the radical cation. In contrast, sulphate and perchlorate cause an increase in the rate constant; sulphate a slight increase and perchlorate a large one.

The effects of Li^+ , Na^+ , K^+ and NH_4^+ on the resultant rate constant were also followed [curves 1(a)–(d)]. Here, the rate constant of $DE^{+\cdot}$ disproportionation decreases, *i.e.*, the $DE^{+\cdot}$ stability increases as follows: $NH_4^+ < K^+ < Na^+ < Li^+$.

It follows from the above results that the kind of salt present in solution significantly affects the stability of the cationic radicals of phenothiazine derivatives. The stability is strongly enhanced in the presence of salts with the same anion as that contained in the salt of the cation radical, while other salts decrease the stability. This finding can be utilized in analytical deter-

minations based on the formation of coloured cationic radicals of these substances.

CHROMOGENIC BENZO- AND MONOAZA-12-CROWN-4, 13-CROWN-4 AND 14-CROWN-4 LITHIUM-SELECTIVE CROWN ETHERS

K. WILCOX and G. E. PACEY

Department of Chemistry, Miami University, Oxford, Ohio 45056, U.S.A.

(Received 13 February 1990. Revised 19 March 1991. Accepted 29 March 1991)

Summary—Chromogenic benzo-12-crown-4, benzo-13-crown-4 and benzo-14-crown-4 ethers have been compared with monoaza-12-crown-4 and monoaza-13-crown-4 ethers. Of these compounds, monoaza-13-crown-4 exhibited the best analytical characteristics toward the selective determination of lithium. $K_{Li/Na}$ was 525 for the monoaza-crown-4 compound.

The search for a lithium selective ionophore has been continuous over the past two decades. Both open chained¹ and cyclic²⁻¹¹ compounds have been studied. From an analytical viewpoint, the primary difficulty was to develop a colorimetric ionophore that exhibits substantial selectivity for the lithium ion over the sodium ion.

The majority of these investigations have centered around the 12-crown-4 to 14-crown-4 substituted and unsubstituted ether compounds. For example dodecyl-14-crown-4 has exhibited the best selectivity.⁷ However, the addition of a chromogenic tag requires certain structural features which do not exist in some of the alkyl substituted crown ethers. Therefore, the best chromogenic crown ether for lithium has been the chromogenic monoaza-12-crown-4.²

There have been two approaches to color addition in crown ethers. The intermolecular approach uses an azo type dye attached to the crown ether. On complexation, the conformational changes in the crown ring affect the energy levels of the *pi* electron system, usually producing a bathochromic shift. Unfortunately, the majority of the compounds reported exhibit small 5–25 nm shifts upon complexation. The second approach is to synthesize intramolecular ion pair compounds which utilize a functional group that deprotonates upon complexation, to provide the required counter ion. The result is usually an extension of the conjugation of the dye portion of the chromogenic crown ether. This approach is the one used in this study. Some lithium chromogenic crown ethers that have been reported include those such as Misumi "crowned" dinitrophenylazophenols.¹²⁻¹⁵

This paper reports the systematic study of the chromogenic 12-crown-4 through 14-crown-4 unsubstituted and benzo substituted crown ethers versus the monoaza 12 and 13 crown ether substituted compounds (Fig. 1).

EXPERIMENTAL

Synthesis

Benzocrown ethers. Chromogenic and nonchromogenic benzo-14-crown-4 compounds have been reported.³ Benzo-12-crown-4 and benzo-13-crown-4 were synthesized by combining the appropriate dichlorodiethyl glycol with catechol in *n*-butanol. Catechol (8.6 g, 0.08 mole), lithium hydroxide (6.6 g, 0.16 mole) and lithium perchlorate (4 g, 0.04 mole) were placed in 500 ml of *n*-butanol and refluxed. The dichloride, 1,2-bis(2-chloroethoxy)ethane for benzo-12-crown-4 or 1,2-bis(2-chloroethoxy)propane for benzo-13-crown-4, (0.08 mole in *n*-butanol), was added dropwise and the reaction was continued for six days. The cooled mixture was rotary evaporated and the residue taken up in 5% potassium hydroxide (250 ml). The aqueous phase was extracted several times with chloroform. The organic layer was combined, washed with water, dried over magnesium sulfate and evaporated. For benzo-12-crown the thick residue was passed through a silica column. The yield was 30% with a melting point of 44–45°. For the benzo-13-crown-4 the residue was distilled under vacuum (95–100°, 0.05 mm Hg). A clear liquid was collected which solidified upon standing. Recrystallization from hexane provided a pure compound in 55% yield.

Fig. 1. Compounds developed and tested in this investigation.

The chromogenic tag was added to both of these compounds by the following procedure. The benzo-12-crown-4 or benzo-13-crown-4 compound (4.5 g or 4.8 respectively, 0.02 mole) was dissolved in 200 ml of chloroform/acetic acid (50:50 v/v). Concentrated nitric acid (20 ml) was dripped into the solution and the reaction mixture was stirred for 24 hr at room temperature. After neutralization with sodium bicarbonate, the separated aqueous layer was extracted with chloroform several times. The combined organic layers were dried over magnesium sulfate, filtered and evaporated to dryness. The pure product crystallized as a yellow solid. The 4'-nitrobenzo-12-crown-4 yield was 60%, mp 134–135°. The 4'-nitrobenzo-13-crown-4 yield was 86% with a mp of 144–145°.

The next step is the conversion of the nitro group to amine. The 4'-nitrobenzo crown ether (0.5 g, 2.0 mmole), 10% palladium on carbon (0.2 g) and freshly distilled ethanol were shaken in a hydrogen atmosphere at 33 psi. After 4 hr the mixture was filtered and the solvent was rotary evaporated. The dark residue was taken up into 40 ml of water and extracted with several portions of chloroform. The combined organic fractions were dried with anhydrous magnesium sulfate, filtered and evaporated to dryness. The product obtained was a dark

brown liquid. Yields were between 80–90%. This compound must be used immediately or kept under a nitrogen atmosphere.

The chromogenic tag was added by placing aminobenzo crown ethers (0.4 g, 1.6 mmole) into 250 ml of methanol and refluxing. Sodium bicarbonate (0.15 g, 1.8 mmole) and 2-chloro-3,5-dinitrobenzene trifluoride (0.48 g, 1.8 mmole) were added together. The stirred mixture was refluxed overnight. The cooled solution was neutralized with 1.0M hydrochloric acid, filtered and extracted with chloroform. The chloroform was dried over magnesium sulfate, filtered and rotary evaporated. The dark oily residue was dissolved in hot isopropanol followed by addition of petroleum ether until a slight cloudiness appeared. The solution was cooled overnight and the pure compound was collected as a darkened crystal. Yields range from 50–70%. Elemental analysis: chromogenic benzo-12-C-4; calc. 48.20% C, 3.81% H, 27.06% O, 8.62% N, 12.05% F; found 48.14% C, 3.14% H, 8.53% N, 11.96% F; chromogenic benzo-13-C-4; calc. 49.28% C, 4.11% H, 26.28% O, 8.62% N, 11.7% F; found 49.19% C, 4.01% H, 8.53% N, 11.43% F.

Monoazacrown ethers. The synthesis of the chromogenic monoazacrown ether has been significantly shortened by eliminating the need for protecting the amine group during the cyclization reaction. The first step is to prepare the two sections—the glycol and the amine—of the cyclic ring. The 1,2-bis(ethoxy)ethanes were synthesized and then tosylated. The tosylation reaction was performed in triethylamine (100 ml). The glycol (16.5 g, 0.1 mole) was cooled with an ice-water bath while *p*-toluenesulfonylchloride (38.4 g, 0.2 mole) was added in small portions. The heterogenous mixture was stirred overnight by an overhead stirrer while warming to room temperature. The resulting white slurry was poured over 100 g of ice, diluted with 75 ml of water and made acidic with dilute hydrochloric acid.

The precipitated ditosylate was filtered off, washed with water and recrystallized from ethanol. The pure product was obtained in 70% yield with a melting point of 89°.

The amines were prepared by using excess 2-aminoethanol (250 ml) with sodium carbonate (15 g, 0.19 mole). The mixture was heated to 150° under a nitrogen atmosphere. Then the appropriate chlorohydroxypropane was added dropwise to the stirred mixture. For monoaza-12-crown-4, 1-chloro-2-hydroxy ethane was

used; for monoaza-13-crown, the 1-chloro-2-hydroxy propane was used. After 30 hr the cooled solution was diluted with methanol (50 ml) and filtered. The precipitate was washed with a minimum amount of methanol and the combined washings and filtrates were concentrated under reduced pressure. The remaining oil was vacuum distilled to remove excess 2-aminoethanol leaving a reddish-gray, taffy-like residue. This was extracted several times with hot tetrahydrofuran. The combined tetrahydrofuran extracts were concentrated under reduced pressure to give a yellow oil which was vacuum distilled. The pure compound was obtained in 80% yields.

The cyclization of the dihydroxamine with the ditosylate was accomplished by dissolving the dihydroxyamine (0.3 mole) into t-butyl alcohol (200 ml) with sodium (0.6 mole). This mixture was heated to 40° under nitrogen pressure. Lithium bromide (0.03 mole) was added to the stirred mixture after the sodium was consumed. The ditosylated glycol (0.03 mole) was dissolved in 50 ml of 1,4-dioxane and dripped into the mixture. After 30 hr, the heterogenous mixture was cooled and filtered. The precipitate was washed with dichloromethane and the combined filtrate and washings were concentrated under reduced pressure. The residue was taken up in 20 ml of water and washed once with hexane and several times with dichloromethane. The combined dichloromethane extracts were concentrated under reduced pressure to give a yellow oil which was vacuum distilled. The final oil product was obtained in a 9% yield.

The chromogenic tag was added by dissolving the monoaza crown ether (0.012 mole) in THF and triethylamine (0.02 mole). This mixture was cooled in an ice water bath before the 2-hydroxy-5-nitrobenzyl bromide (0.012 mole), which was dissolved in THF, was added dropwise to the stirred mixture. The reaction was run under nitrogen at room temperature overnight. The resulting yellow solution was refluxed for 3 hr, cooled and filtered. The precipitate was washed with THF and the combined filtrate and washings concentrated under reduced pressure. The remaining yellow oil was dissolved in 25 ml of water and 2M hydrochloric acid was slowly added until the color turned pale yellow or colorless.

The acidic solution was extracted with chloroform while 2.5M potassium hydroxide was added dropwise until the color remained constant. The aqueous layer was extracted four

times with 30-ml portions of chloroform. All the organic extracts were combined, washed with three 20-ml portions of water, filtered and evaporated to dryness.

The residue was taken into water, filtered and concentrated. This residue was dissolved in chloroform and evaporated to dryness in a vacuum with gentle heating. Yellow crystals were recrystallized in hexane to give final product yields of 80–90% for monoaza-12-crown-4 and 85–87% for monoaza-13-crown-4. Elemental analysis: chromogenic monoaza-12-C-4; calc. 55.21% C, 6.75% H, 29.44% O, 8.59% N; found 55.14% C, 6.70% H, 8.53% N; chromogenic monoaza-13-C-4 calc 56.47% C, 7.06% H, 28.24% O, 8.24% N; found 56.39% C, 7.00% H, 8.13% N.

Extraction procedures for chromogenic benzocrown ethers

Determination of acid dissociation constant. The fact that the acid and base forms of the compound absorb in the ultraviolet and visible regions of the spectrum allows the acid dissociation constant to be determined spectrophotometrically. A weighed quantity of the reagent was dissolved in a 5% acetonitrile/water mixture. A 5-ml aliquot of the standard solution was pipetted into a 50-ml beaker and 2 ml of 1.0M rubidium chloride were added to control the ionic strength. The pH was adjusted with a dilute cesium hydroxide solution. The solution was transferred to a 25-ml standard flask and diluted to volume giving final concentrations of $1.89 \times 10^{-3}M$ crown ether and $8.0 \times 10^{-2}M$ rubidium chloride. The absorbance spectra at several pH values were obtained after which the pH was measured. From the absorbance values at the wavelengths of maximum absorption for the acid and base species the equilibrium concentrations could be calculated by solving simultaneous equations. The pK_a was readily determined from the Henderson-Hasselbach equation.

Determination of extraction constants. Attempts to obtain the extraction constants for the chromogenic reagent followed the experimental methods previously reported.³ Aliquots (4 ml) of the organic phase containing the reagent (6.6×10^{-5} – $2.0 \times 10^{-3}M$) and of the aqueous metal solutions (7.5×10^{-3} – $2.0 \times 10^{-1}M$) were placed in 50-ml flasks. The stoppered flasks were shaken for 15 min at a constant speed. Following phase separation, the absorbance of the organic layer was measured.

Instrumentation. All absorbance spectra were obtained on a Hewlett-Packard 8450A Diode Array spectrophotometer. A Fisher Accumet model 825 mp pH meter with an Orion model 91-05 combination electrode was used to measure the pH. All extractions were performed with a Lab-line multi-wrist shaker model 3587. The titrations of the reagents were done with a Metrohm Dosimet E-535 equipped with the potentiograph E-536.

Extraction procedures for chromogenic monoazacrown ethers

Determination of the acid dissociation constants. An aqueous solution (20–25 ml) containing the monoaza crown being studied ($3.36 \times 10^{-4} M$), hydrochloric acid ($3.6 \times 10^{-3} M$) and cesium chloride (0.1M), was titrated with potassium hydroxide (0.05M below pH 11; 0.9M above pH 11). The titration was stopped every 0.3–0.9 pH unit increase to measure the absorbance of the solution. A 3–4 ml portion was pipetted into a cuvette, and the spectrum recorded. The absorbances were corrected for dilution.

Determination of extraction constants. A 4-ml aliquot of the organic phase under study and a 4-ml aliquot of the aqueous phase containing the monoaza crown, potassium hydroxide, and varying concentration of lithium or sodium were placed in successive 50-ml round bottom flasks. The final concentrations of all species were (4.78–6.36) $10^{-4} M$ crown, 0.1M potassium hydroxide, $0-4.4 \times 10^{-3} M$ lithium, or 0–0.52M sodium. The stoppered flasks were shaken for 15 min at room temperature and left standing. After separation of the two layers, the absorbance of the organic and aqueous phases was recorded.

Interference study. To a series of 50-ml round bottom flasks was added 4 ml of dichloroethane and 4 ml of an aqueous phase containing $6.1 \times 10^{-4} M$ monoaza crown, 0.2M potassium hydroxide, $1.2 \times 10^{-4} M$ lithium bromide and $(0.004-4.0) \times 10^{-2} M$ sodium chloride. The stoppered flasks were shaken for 15 min, the layers were given time to separate and the organic phase absorbance was measured at 400 nm.

RESULTS AND DISCUSSION

Benzocrown ethers. The equations used for these experiments have been reported previously.⁴ Conclusions from the literature²⁻¹¹ would suggest that the best candidates for the

addition of chromophores would be the benzo-12-crown-4, benzo-13-crown-4 and benzo-14-crown-4 ethers. Using these compounds in picrate ion-pairing extraction studies,³ the data in Table 1 were generated. Using the chlorinated solvents, chloroform, methylene chloride and 1,2-dichloroethane as the organic phase, benzo-14-crown-4 exhibited the best selectivity toward the lithium ion. It should be pointed out that in the case of benzo-13-crown, the lithium-to-sodium selectivity was very dependent on the solvent used; chloroform being lithium-selective and methylene chloride and 1,2-dichloroethane sodium selective. This solvent dependence is not unusual.^{1,16} The usual conclusion is that the larger the solvent donor number the lower the formation or stability constant, particularly with the lithium cation because of its high-charge density. That is, the constants are dependent on how effectively the crown ether can desolvate the metal ion. Benzo-12-crown-4 did not extract lithium at all.

A linear response toward lithium was observed in the 3–140 meq/l. range with an equation $y = (5.00 \pm 0.03) \times 10^{-4} X + (7.6 \pm 0.5) \times 10^{-3}$ and a correlation coefficient of 0.999 where y denotes the absorbance and X is the lithium concentration in meq/l. However, as would be expected, sodium interferences began at about 1 meq/l. A linear response for lithium was observed in the 2–100 meq/l. range with an equation $y = (5.69 \pm 0.03) \times 10^{-4} X + (1.23 \pm 0.5) \times 10^{-5}$ and a correlation coefficient of 0.999. In the benzo-14-crown-4 case sodium interference began at 13 meq/l.

It has been shown that the selectivity of the benzocrown ethers is significantly increased by the physical attachment of a chromogenic compound.⁴ Therefore, both the 13- and 14-benzocrown ethers where tagged through an amine attachment to the benzene ring, using 1-chloro-, 4-dinitro-6-trifluoro-methylbenzene.

By tagging the crown ether, an intramolecular ion-pair which is inherently more stable, is formed during the extraction process. In the case of these chromogenic crown ethers, the protonated form exhibits one color while the deprotonated form exhibits another color. For 2'',4''-dinitro-6''-trifluoromethylphenyl-4'-aminobenzo-13-crown-4 the protonated form has a wavelength maximum at 375 nm ($\epsilon = 14,000 \text{ l. mole}^{-1} \cdot \text{cm}^{-1}$) and the deprotonated form has a wavelength maximum at 450 nm ($\epsilon = 18,000 \text{ l. mole}^{-1} \cdot \text{cm}^{-1}$). The 2'',4''-dinitro-6''-trifluoromethylphenyl-4'-aminobenzo-14-crown-4 exhibits a protonated wavelength maximum at 380 nm ($\epsilon = 12,000 \text{ l. mole}^{-1} \cdot \text{cm}^{-1}$) and deprotonated wavelength maximum at 462 nm ($\epsilon = 20,000 \text{ l. mole}^{-1} \cdot \text{cm}^{-1}$). The acid dissociation constants were 10.15 ± 0.02 and 9.99 ± 0.03 .

These acid base properties of both compounds behaved as expected; however, they exhibited very unexpected complexing abilities. The chromogenic benzo-13-crown-4 exhibited no extraction of any alkali metal ions. Single-crystal X-ray studies¹⁷ show that the lithium cation does not fit in the plane of the ring oxygens, but is positioned slightly out of the ring, forming a pyramidal shaped complex. Without the additional coordination from the picrate anion, as in the ion-pair extractions, the cation is exposed to coordination by other species such as water. The same certainly holds true for the rest of the alkali metal ions which are larger. The presence of the water makes the reagent too lipophobic to be extracted back into the organic phase. The fact that the aqueous phase took on the red color of the deprotonated reagent during the extraction process supports this argument.

For chromogenic benzo-14-crown-4, lithium extraction was quite good. The extraction constants for this compound are given in Table 2. A linear calibration curve was obtained for 2–80 meq/l. with a sensitivity of $1.69 \times 10^{-3} \pm 2.2 \times 10^{-5}$. Sodium did not interfere below a concentration of 130 meq/l.

Although this compound is lithium selective, it is not sensitive enough for the intended uses such as test strips and sensors for manic depressives. Previously, a report from this laboratory disclosed that monoaza-12-crown-4 exhibits very good lithium selectivity. It is now clear that the configuration of these monoazacrown ethers is superior to the benzocrown ethers. In other words, the chromogenic benzo-12-crown-4 and

benzo-13-crown-4 ethers do not compete favorably with the water for the coordination sites of the alkali metal where as the ring nitrogen and phenolic counter ion do compete effectively. Therefore, the chromogenic monoaza-13-crown-4 was investigated.

Nonchromogenic and chromogenic monoaza-crown ethers

Determination of acid dissociation constants.

To determine the K_{a1} and K_{a2} from the experimental data, it is first necessary to define the proton-dissociation process of the system. The equilibria for the chromogenic monoaza crown ethers are summarized in Fig. 2. The HL species can exist in the aqueous phase in two tautomeric forms, *i.e.*, nonionic and zwitterionic forms. Therefore, as reported by Katayama,¹⁸

Fig. 2. Schematic representation of the equilibria for the monoazacrown ethers.

coexistence of a small amount of one species or the other cannot be totally excluded, and Ka_1 may be considered as the sum of Ka'_1 and Ka''_1 .

The acidity constants can be described as follows:

$$Ka_1 = \frac{[HL][H^+]}{[HLH^+]} \quad (1)$$

and

$$Ka_2 = \frac{[L^-][H^+]}{[HL]}. \quad (2)$$

Figure 3 shows absorption spectra of the 13-crown-4 reagent in water at various hydrogen ion concentrations. From the spectra it is seen that the reagent exhibits two pH dependent isosbestic points at 343 nm and 402 nm.

Within certain pH regions, $[HL]^- \gg [L^-]$ for Ka_1 and $[HL]^- \gg [HLH^+]$ for Ka_2 , and $[L^-]$ or $[HLH^+]$ can be neglected when compared with $[HL]^-$. In terms of pH, $[HL]^-$ is much greater than $[L^-]$ at pH 6.9, and $[HL]^-$ is much greater than $[HLH^+]$ at pH 9.6.

Working with this knowledge, the acid dissociation constant, Ka_1 was determined by substituting the absorbance data below pH 6.9 in simultaneous equations to obtain the concentrations of, $[HLH^+]$ and $[HL]$. From these equilibrium concentrations and the pH, the first acid dissociation constant could be calculated. In a similar fashion, using the absorbance data above pH 9.6, the second acid dissociation constant was determined. The values obtained for the two chromogenic monoaza crown ethers are reported, along with the literature values of other monoaza crown ethers in Table 3. The values obtained in this study are comparable to the literature values.

Determination of the extraction constants. The metal extraction processes equilibria can be expressed mathematically as:

$$K_{ex} = \frac{[ML]_0 [H^+]_{aq}}{[HL]_0 [M^+]_{aq}} \quad (3)$$

The analytical concentrations of the reagent and metal ion can be expressed as:

$$[HL]_t = [HL]_{aq} + [HL]_0 + [ML]_{aq} + [ML]_0 + [L^-]_{aq} + [HLH^+]_{aq} \quad (4)$$

$$[M^+]_t = [ML]_{aq} + [ML]_0 + [M^+]_{aq} \quad (5)$$

and molar absorptivity at any wavelength can be expressed by:

$$E = A_0 / ([HL]_0 + [ML]_0) \quad (6)$$

By substituting $A_0 = (\epsilon_{HL}^0 [HL]_0 + \epsilon_{ML}^0 [ML]_0)$ we get

$$E = (\epsilon_{HL}^0 [HL]_0 + \epsilon_{ML}^0 [ML]_0) / ([HL]_0 + [ML]_0) \quad (7)$$

From the experimental conditions at pH 12 it is known that

$$[HL]_t \gg [HLH^+]_{aq} \text{ and } [L^-]_{aq} \gg [HL]_{aq} + [ML]_{aq}.$$

Fig. 3. Absorption spectra for monoaza-13-crown-4 pH = 1 (4.3), 2 (5.2), 3 (6.7), 4 (9.3), 5 (10.8), 6 (1.5).

Therefore, equation (4) simplifies to:

$$[\text{HL}]_t = [\text{HL}]_0 + [\text{ML}]_0 + [\text{L}^-]_{\text{aq}} \quad (8)$$

and the only absorbing species in the aqueous phase is L^- , so that:

$$[\text{L}^-]_{\text{aq}} = A_{\text{aq}}/\epsilon_{\text{L}^-} \quad (9)$$

Equation (7) can be transformed into a linear relationship, as indicated by Sasaki and Pacey,² which allows the extraction constants to be obtained graphically. First subtract the molar absorptivity of the blank, $E^0 = \epsilon_{\text{HL}}^0$, from both sides.

$$E - E^0 = \frac{\epsilon_{\text{ML}}^0 [\text{HL}]_0 + \epsilon_{\text{HL}}^0 [\text{ML}]_0}{[\text{HL}]_0 + [\text{ML}]_0} - \epsilon_{\text{HL}}^0 \quad (10)$$

By taking the reciprocal of both sides and multiplying ϵ_{HL}^0 by $([\text{HL}]_0/[\text{HL}]_0)$ to achieve a common denominator, equation (10) becomes:

$$\frac{1}{E - E^0} = \frac{1}{\left(\frac{\epsilon_{\text{ML}}^0 [\text{HL}]_0 + \epsilon_{\text{HL}}^0 [\text{ML}]_0}{[\text{HL}]_0 + [\text{ML}]_0} \right) - \left(\frac{\epsilon_{\text{HL}}^0 [\text{HL}]_0 + \epsilon_{\text{HL}}^0 [\text{ML}]_0}{[\text{HL}]_0 + [\text{ML}]_0} \right)} \quad (11)$$

If like terms are cancelled and combined over the common denominator, equation (11) becomes:

$$\begin{aligned} \frac{1}{E - E^0} &= \frac{1}{\left(\frac{\epsilon_{\text{ML}}^0 [\text{ML}]_0 - \epsilon_{\text{HL}}^0 [\text{ML}]_0}{[\text{HL}]_0 + [\text{ML}]_0} \right)} \\ &= \frac{[\text{HL}]_0 + [\text{ML}]_0}{\epsilon_{\text{ML}}^0 [\text{ML}]_0 + \epsilon_{\text{HL}}^0 [\text{ML}]_0} \quad (12) \end{aligned}$$

Separating the fraction into individual parts allows:

$$\begin{aligned} \frac{1}{E - E^0} &= \frac{[\text{HL}]_0}{\epsilon_{\text{ML}}^0 [\text{ML}]_0 - \epsilon_{\text{HL}}^0 [\text{ML}]_0} \\ &+ \frac{[\text{ML}]_0}{\epsilon_{\text{ML}}^0 [\text{ML}]_0 - \epsilon_{\text{HL}}^0 [\text{ML}]_0} \quad (13) \end{aligned}$$

By placing like terms outside parentheses we get:

$$\begin{aligned} \frac{1}{E - E^0} &= \frac{[\text{HL}]_0}{(\epsilon_{\text{ML}}^0 - \epsilon_{\text{HL}}^0) [\text{ML}]_0} \\ &+ \frac{[\text{ML}]_0}{(\epsilon_{\text{ML}}^0 - \epsilon_{\text{HL}}^0) [\text{ML}]_0} \quad (14) \end{aligned}$$

Cancelling like terms gives:

$$\frac{1}{E - E^0} = \frac{[\text{HL}]_0}{(\epsilon_{\text{ML}}^0 - \epsilon_{\text{HL}}^0) [\text{ML}]_0} + \frac{1}{(\epsilon_{\text{ML}}^0 - \epsilon_{\text{HL}}^0)} \quad (15)$$

Substituting $[\text{H}^+]_{\text{aq}}/(K_{\text{ex}}[\text{M}^+]_{\text{aq}}) = [\text{HL}]_0/[\text{ML}]_0$ and $\epsilon_{\text{ML}}^0 - \epsilon_{\text{HL}}^0 = \Delta\epsilon$ gives:

$$\frac{1}{E - E^0} = \frac{[\text{H}^+]_{\text{aq}}}{K_{\text{ex}}[\text{M}^+]_{\text{aq}} \Delta\epsilon} + \frac{1}{\Delta\epsilon} \quad (16)$$

For lithium, equation (17) shows that a plot of $1/(E - E^0)$ vs. $1/[\text{M}^+]_{\text{aq}}$ should be linear and K_{ex} can be calculated from the slope, intercept and the pH. By combining equations (6), (8) and (9), the values of E and E^0 (E^0 is determined from the blank absorbance value) can be obtained according to equation (17)

$$\begin{aligned} E &= \frac{A_0}{[\text{HL}]_0 + [\text{ML}]_0} + \frac{A_0}{[\text{HL}]_t - [\text{L}^-]_{\text{aq}}} \\ &= \frac{A_0}{[\text{HL}]_t - (A_{\text{aq}}/\epsilon_{\text{L}^-})_{\text{aq}}} \quad (17) \end{aligned}$$

where A_0 is the absorbance of the organic layer at 400 nm, A_{aq} is the absorbance of the aqueous layer at 412 nm, and ϵ_{L^-} is the molar absorptivity of the aqueous species at 412 nm.

The poor extraction, and the experimental conditions used, allow the assumption $[\text{M}^+]_{\text{aq}} = [\text{M}^+]_t$ for the sodium system, so that:

$$\frac{1}{E - E^0} = \frac{[\text{H}^+]_{\text{aq}}}{K_{\text{ex}}[\text{M}^+]_t \Delta\epsilon} + \frac{1}{\Delta\epsilon} \quad (18)$$

The K_{ex} for sodium can then be determined in a similar fashion by plotting $1/(E - E^0)$ vs. $1/[\text{M}^+]_t$. Typical plots of the data for the respective extraction systems were straight lines as shown in Fig. 4.

Table 2 shows the $-\log K_{\text{ex}}$ values for the monoaza crown ethers together with the $-\log K_{\text{ex}}$ values reported for other ionizable lithium selective reagents.

In comparison to the other reagents, the new reagent exhibits significantly greater selectivity for lithium over sodium. There are several factors which may contribute to this increased selectivity.

A CPK space-filling model shows that the attachment of the chromophore to the nitrogen atom in the ring allows the phenolate anion to

Fig. 4. Typical plots for extraction constant data.

be positioned directly over the cavity of the crown. In such a geometry the interaction of the anion with the metal cation is much greater than the interaction where the chromophore is attached to a carbon atom in the ring. When attached to a carbon atom the chromophore essentially has too short a "tether" to allow the phenolate anion to be positioned above the cavity. Rather, it is off to one side and does not interact as effectively with the cation.

Because of this favourable positioning, the interaction of the phenolate anion and the lithium cation ion should be very strong. In fact, the bond between the two may have considerable covalent character.¹⁹ Katayama¹⁸ has shown that the less basic, more charge-delocalized phenolate anions, such as the 2,4-dinitrophenol used by Kimura,⁷ prefer the extraction of the larger metal ions (lower surface-charge density). In contrast, the more basic, less charge-delocalized phenolate anions prefer the extraction of the use of 4-nitrophenol as the chromophore may enhance the metal:crown complex.

The presence of the nitrogen atom in the crown ether ring may also provide additional stability to the complex. The non-bonding electrons of the nitrogen may be polarized such that

the interaction between the metal ion and the nitrogen may have much covalent character.²⁰ In addition, models show the monoaza crown structure is such that formation of a six-membered chelate ring is possible, comprised of the nitrogen atom, a methylene carbon, two aromatic carbons, the phenolate oxygen, and metal cation, two aromatic carbons, the phenolate oxygen and metal cation within the crown ether cavity. In classical chelating compounds, six-membered rings are usually considered to be ideal in terms of their complex stability.²¹ Such an additional chelate ring should strengthen the initial complexation due to interaction of the metal ion with the ring heteroatoms. Those reagents which have the chromophore attached to a ring carbon cannot form true chelate rings. Thus, the extra stability is not present.

The excellent selectivity exhibited by these monoaza compounds is also illustrated in Fig. 5. This shows the results of competitive extractions performed with a constant lithium ion concentration while increasing the sodium ion concentration.

Analytical characteristics

The reagents were examined in two different solvent systems, chloroform and dichloromethane. Although both systems extracted the lithium cation effectively, the dichloromethane system exhibited better sensitivity as defined by the slope of the sample response curve (Fig. 4). It is interesting to note that Sasaki and Pacey tested several organic solvents and reported that chloroform gave the best results,² while Katayama *et al.* reports using 1,3-dichloroethane in their system.¹⁸

The observed selectivity may be dependent on how the particular organic phase solvates or interacts with the complex. In the monoaza 14-crown-4 the metal ion is probably not fully shielded from the organic phase. This may allow

Fig. 5. Selectivity plots for the monoaza crown ether.

Fig. 6. Sample response curves for monoaza crown ether in the two solvents.

the cation to interact with the solvent significantly, or possibly a water molecule is coordinated to the cation. The larger azacrowns may be more capable of shielding the cation from such interactions and thus the complex prefers different solvents. It is reasonable to assume the more lipophilic complex would extract more easily into the more lipophilic solvent. *i.e.* 1,2-dichloroethane.

The response observed for lithium ion extraction is shown in Figs. 6 and 7. The limited linear range does occur below the physiological concentration of lithium, therefore allowing dilution.

Good precision about triplicate determinations is shown by the error bars. The majority of the error is believed to arise from two areas. First, the method of extraction sometimes leads to incomplete extraction. Second, the absorbance of the organic phase was unstable. Sasaki reported the same difficulty with the absorbance and attempted to correct it but had little success.² No attempt was made, in this study, to eliminate this problem. However, adaptation of this extraction procedure to an automated system such as flow-injection analysis may reduce or remove both sources of error.

Fig. 7. Optimized sample response curve for monoaza-13-crown-4.

The detection limits for the individual reagents can be theoretically determined from equation (19).²²

$$\text{Detection limit} = KS_{\text{bk}}/M_{\text{rc}} \quad (19)$$

Here K equals some constant, typically 2 or 3, S_{bk} is the standard deviation of the blank and M_{rc} equals the slope of the response curve. The detection limit (K equals 3) calculated for the monoaza 13 was 0.06 ppm.

CONCLUSIONS

It is clear from this work that the chromogenic monoaza crown ethers do possess better selectivity toward lithium ion than the chromogenic benzocrown ethers. This work suggests that further extension of the monoaza-crown system will provide useful information. Compounds such as the isomers of chromogenic monoaza-14-crown-4 may well be even better reagents for the lithium ion.

THERMODYNAMIC STUDY OF SOLVENT EXTRACTION OF 15-CROWN-5- AND 18-CROWN-6-s-BLOCK METAL ION COMPLEXES AND TETRAALKYLAMMONIUM IONS WITH PICRATE ANIONS INTO CHLOROFORM

YASUYUKI TAKEDA,* NOBUYUKI IKEO and NORIKO SAKATA

Department of Chemistry, Faculty of Science, Chiba University, Yayoi-cho, Chiba 260, Japan

(Received 26 November 1990. Revised 22 February 1991. Accepted 26 February 1991)

Summary—Enthalpy and entropy changes for ion-pair extractions of tetraalkylammonium ions (R_4N^+) with picrate anions, overall extractions of s-block metal picrates with 15-crown-5 (15C5) and 18-crown-6 (18C6) and the partition of 15C5 itself were determined between chloroform and water. The distribution behaviour of crown ethers and the extraction process of s-block metal picrates with the crown ethers are discussed in detail on molecular grounds from the thermodynamic point of view. Moreover, enthalpy and entropy changes for ion-pair extractions of 1:1 15C5- and 18C6-s-block metal ion complexes with picrate anions are calculated from these experimental thermodynamic parameters and the literature values for complex-formation reactions of the crown ethers with the s-block metal ions in water. Enthalpy and entropy changes are negative for overall extractions of all the s-block metal picrates with 15C5 and 18C6. The extractions of the metal picrates with 15C5 and 18C6 at 25° are completely enthalpy driven. Plots of thermodynamic parameters for ion-pair extractions of R_4NA vs. the number of carbon atoms of R_4N^+ show a linear relationship. From these experimental data, contributions of a methylene group and an ether oxygen atom to the thermodynamic parameters of the ion-pair extraction of R_4NA and the partition of the crown ethers, respectively, between chloroform and water were obtained. Enthalpy and entropy changes for ion-pair extractions of 15C5- and 18C6-s-block metal picrate complexes were compared with those of R_4NA . A striking difference in the ion-pair extraction process was found between the crown ether complexes and R_4NA .

Since Pedersen conducted extractions of alkali metal picrates with crown ethers for the first time,¹ solvent extraction has been used as one of the least difficult methods for evaluating the complexing abilities of newly synthesized crown compounds with cations.² In general, a crown compound efficiently extracts a cation of suitable size into the cavity of the crown compound. The overall extraction consists of some fundamental processes.³ Thus, in order to elucidate the extraction efficiency and selectivity of a crown compound for a cation, it is necessary to analyse the overall extraction equilibrium in terms of the underlying equilibria; for example, distribution of the free crown compound, complex formation in the aqueous phase and ion-pair extraction of the crown compound complex. The distribution of an uncomplexed crown compound governs the extractability of the crown compound for cations. The stability in water and the ion-pair extractability of the crown compound complex govern both the

extractability and selectivity of the crown compound for cations. In addition, these basic equilibrium constants provide valuable information on solute-solvent interactions of crown compounds and their complexes. For further study of the role of crown compounds in the extraction process and of solvation properties of free crown compounds and their complexes, it is important to obtain thermodynamic parameters for the overall extraction process and the fundamental processes. Some enthalpy and entropy changes of overall extraction processes have been presented, but only a few thermodynamic quantities concerning the basic processes have been reported.⁴⁻⁶

In the present study, enthalpy and entropy changes for ion-pair extractions of tetraalkylammonium ions (R_4N^+) with picrate anions, overall extractions of s-block metal picrates with 15-crown-5 (15C5) and 18-crown-6 (18C6) and the partition of 15C5 itself were determined between chloroform and water. The distribution behaviour of crown ethers and the extraction process of s-block metal picrates with the crown

*Author for correspondence.

ethers are discussed in detail on molecular grounds from the thermodynamic point of view. Moreover, enthalpy and entropy changes for ion-pair extractions of 1:1 15C5- and 18C6-s-block metal ion complexes with picrate anions are calculated from these experimental thermodynamic parameters and the literature values for complex-formation reactions of the crown ethers with the s-block metal ions in water. The thermodynamic quantities for ion-pair extractions of 15C5- and 18C6-s-block metal picrate complexes are compared with those of R_4NA .

EXPERIMENTAL

Materials

Tetramethyl-, tetraethyl-, tetrapropyl-, and tetrabutylammonium hydroxides were purchased from Wako-Pure Chemicals Ltd. and used as received. 15-Crown-5 (Nisso Co., Ltd.) was purified by distillation under vacuum [b.p. 129.0–130.5°, 2.6 mmHg (1 mmHg \approx 133.322 Pa)]. 18-Crown-6 (Nisso Co., Ltd.) was recrystallized from acetonitrile and, prior to use, dried at 80° *in vacuo*. Chloroform, picric acid, lithium hydroxide ($LiOH \cdot H_2O$), sodium hydroxide, potassium hydroxide, strontium hydroxide [$Sr(OH)_2 \cdot 8H_2O$] and barium hydroxide [$Ba(OH)_2 \cdot 8H_2O$] were analytical grade reagents. Rubidium and cesium hydroxides were of reagent grade. Chloroform was purified by distillation and washed three times with distilled water.

Extraction procedure

Ion-pair extraction of tetraalkylammonium picrate. A $CHCl_3$ phase and an aqueous phase of R_4NOH (3.8×10^{-3} – $2.3 \times 10^{-2}M$; lithium hydroxide (0.01M), and picric acid (3.2×10^{-5} – $1.5 \times 10^{-2}M$) in stoppered glass tubes (30 ml) were shaken for 2 hr in a water bath kept at 15, 20, 25, 30 and $35 \pm 0.2^\circ$, and centrifuged. The initial volume of each phase was 10 ml in all cases. Extractions were conducted at pH 11.3–12.1. For the Bu_4NA system, the concentration of the picrate anion in the aqueous phase was determined spectrophotometrically at 356 nm ($\epsilon = 1.45 \times 10^4$ l. mole $^{-1}$. cm $^{-1}$). For Me_4NA , Et_4NA and Pr_4NA systems, an 8-ml portion of the $CHCl_3$ phase was transferred to a beaker and allowed to evaporate over several days. The residue was dissolved in 4 ml of 0.1M aqueous sodium hydroxide and the picrate concentration was determined spectrophotometrically (at 356 nm, $\epsilon = 1.45 \times 10^4$ l. mole $^{-1}$. cm $^{-1}$).

In blank experiments, there was no extraction of picrate anions in the absence of R_4N^+ .

Extraction of metal picrates with 15C5 and 18C6. A $CHCl_3$ phase of crown ether (1.1×10^{-5} – $3.6 \times 10^{-3}M$), and an aqueous phase of metal hydroxide (6.7×10^{-4} – $2.3 \times 10^{-2}M$) and picric acid (2.8×10^{-4} – $1.5 \times 10^{-3}M$) in a stoppered glass tube (30 ml) were agitated in a water bath kept at constant temperature for 2 hr and centrifuged. The initial volume of each phase was 12 ml in all cases. Extractions were performed at 15, 20, 25, 30 and $35 \pm 0.2^\circ$ for 15C5 systems, and at 15, 20, 25, 30 and $32 \pm 0.2^\circ$ for 18C6 systems; carried out at pH 11.2–12.2 for alkali metal ions and at pH 9.1–10.0 for alkaline earth metal ions. The picrate in the $CHCl_3$ phase was back-extracted twice into 0.01M sodium hydroxide aqueous solution, and the picrate concentration was determined by spectrophotometry (at 356 nm, $\epsilon = 1.45 \times 10^4$ l. mole $^{-1}$. cm $^{-1}$). In blank experiments, there was no extraction in the absence of the crown ethers.

Distribution coefficient of 15C5. A 10-ml $CHCl_3$ solution of 15C5 (3.0×10^{-4} – $2.2 \times 10^{-3}M$) and an equal volume of distilled water in a stoppered glass tube (30 ml) were shaken (in a water bath kept at constant temperature) for 2 hr and centrifuged. A 6-ml portion of the aqueous phase and an equal volume of an aqueous solution (pH 10.9–11.8) containing sodium hydroxide ($1.1 \times 10^{-1}M$) and picric acid ($1.0 \times 10^{-1}M$) were placed in a stoppered glass tube and 12 ml of $CHCl_3$ were added. The two phases were agitated for 1 hr at 2–30. After centrifuging, the picrate in the $CHCl_3$ phase was back-extracted into 0.01M sodium hydroxide aqueous solution, and the picrate concentration was determined spectrophotometrically (at 356 nm, $\epsilon = 1.45 \times 10^4$ l. mole $^{-1}$. cm $^{-1}$). Experiments were conducted at 15, 20, 25, 30 and $35 \pm 0.2^\circ$. The distribution coefficient [$K_D(L)$] values of 15C5 are shown in Table 1. Each $K_D(15C5)$ value is the average of about 30 measurements.

Table 1. Summary of $K_D(L)$ values of 15C5 between $CHCl_3$ and water

Temp, °C	$K_D(L)$
15	6.83 \pm 0.02
20	7.42 \pm 0.02
25	8.27 \pm 0.05
30	9.03 \pm 0.08
35	9.86 \pm 0.03

The uncertainties are the standard deviations.

RESULTS

Ion-pair extraction of R_4NA

In an equilibrium between $CHCl_3$ and an aqueous solution of R_4NA , the equilibrium constants are defined as

$$K_A(R_4NA) = [R_4NA]_o/[R_4N^+][A^-], \quad (1)$$

$$K_D(R_4NA) = [R_4NA]_o/[R_4NA], \quad (2)$$

$$K_{ex,ip}(R_4NA) = [R_4NA]_o/[R_4N^+][A^-] \\ = K_A(R_4NA)K_D(R_4NA). \quad (3)$$

The subscript "o" and the absence of a subscript denote the organic and aqueous phases, respectively. The distribution ratio of R_4N^+ is represented by

$$D = [R_4NA]_o/([R_4N^+] + [R_4NA]). \quad (4)$$

Combination of equations (1–4) leads to

$$D^{-1} = K_D(R_4NA)^{-1} \\ + (K_{ex,ip}(R_4NA)[A^-])^{-1}. \quad (5)$$

Plots of D^{-1} vs. $[A^-]^{-1}$ show a linear relationship in every case. Values of $K_{ex,ip}(R_4NA)$ were obtained from the slopes of the straight lines. Since the $K_D(R_4NA)$ value scarcely varied in the range 15–35° in all cases, enthalpy and entropy changes for this process could not be determined.

Plots of $R \ln K_{ex,ip}(R_4NA)$ vs. T^{-1} were found to be linear in every system. The enthalpy change $[\Delta H_{ex,ip}^\circ(R_4NA)]$ and entropy change $[\Delta S_{ex,ip}^\circ(R_4NA)]$ for equation (3) were calculated from these data. The thermodynamic parameters are compiled in Table 2.

Extraction of metal picrates with crown ethers

When an equilibrium occurs between an aqueous phase of a metal ion (M^{m+}) and picrate ion, and a $CHCl_3$ phase of a crown ether (L), the equilibrium constants are defined as

$$K_{ex} = [MLA_m]_o/[M^{m+}][L]_o[A^-]^m, \quad (6)$$

$$K_D(L) = [L]_o/[L], \quad (7)$$

$$K_{ML} = [ML^{m+}]/[M^{m+}][L], \quad (8)$$

$$K_{ex,ip}(MLA_m) = [MLA_m]_o/[ML^{m+}][A^-]^m \quad (9)$$

The overall extraction equilibrium constant, K_{ex} , can be written as

$$K_{ex} = K_{ML} \cdot K_{ex,ip}(MLA_m) \cdot K_D(L)^{-1} \quad (10)$$

The distribution ratio of the metal is represented by

$$D = [MLA_m]_o/([M^{m+}] + [ML^{m+}]) \quad (11)$$

In the case of $[M^{m+}] \gg [ML^{m+}]$, equation (11) is transformed into

$$D = K_{ex}[L]_o[A^-]^m \quad (12)$$

Plots of $\log(D/[A^-]^m)$ vs. $\log[L]_o$ give a straight line with a slope of 1 in every case. This indicates that the crown ether forms a 1:1 complex with the M^{m+} ion.

From the mass balances, $[L]_o$ and $[M^{m+}]$ are given by

$$[L]_o = ([L]_t - [MLA_m]_o)/(\alpha + \beta[M^{m+}]) \quad (13)$$

$$[M^{m+}] = ([M]_t - [MLA_m]_o)/(1 + \beta[L]_o) \quad (14)$$

where the subscript "t" denotes the total concentration, $\alpha = 1 + K_D(L)^{-1}$, and $\beta = K_{ML}K_D(L)^{-1}$. The K_{ex} value was determined by using the $[L]_o$ value of equation (13), the $[M^{m+}]$ value of equation (14), and the $[A^-]$ value of equation (15),

$$[A^-] = [HA]_t - m[MLA_m]_o \quad (15)$$

Equilibrium constants are summarized in Table 3.

$-R \ln K_D(L)$ vs. T^{-1} and $-R \ln K_{ex}$ vs. T^{-1} plots show a linear relationship in every system (Figs. 1, 2 and 3). Enthalpy and entropy change for equations (6) and (7) were calculated from the data in the same manner as that described above. The thermodynamic quantities are listed in Table 4.

DISCUSSION

Ion-pair extraction of R_4NA

The $\log K_A(Bu_4NA)$ value at 25° in this study is almost consistent with that (3.1₅) at 25° reported in a previous paper (benzene/water system).⁶ From Table 2, the $\log K_A(R_4NA)$ value sequences are $Me_4N^+ < Et_4N^+ \ll Pr_4N^+ \ll Bu_4N^+$; namely, the $\log K_A(R_4NA)$ value increases with an increase in the R_4N^+ size, which is not compatible with coulombic ionic association theories. In water saturated methylene chloride, however, the order of the $\log K_A(R_4NA)$ value is completely reversed ($Me_4N^+ > Et_4N^+ > Pr_4N^+$).⁷ The trend of the $\log K_A(R_4NA)$ values in water reflects the effect of increasing enforcement of a hydrogen-

bonded structure of water on the R_4N^+ ion ($Me_4N^+ \rightarrow Bu_4N^+$). The $\log K_A(R_4NA)$ value in water is very much smaller than the corresponding $\log K_A(R_4NA)$ value in water saturated methylene chloride [5.021(Me_4NA), 4.276(Et_4NA), 4.117(Pr_4NA)]⁷ ($\epsilon_r = 8.94$ at 25°) which is attributed to water having a very much higher dielectric constant.

The $\log K_D(R_4NA)$ order is $Me_4NA \ll Et_4NA < Pr_4NA < Bu_4NA$ (Table 2); the same tendency is found for benzene⁶ and methylene chloride;⁷ namely, the $\log K_D(R_4NA)$ value increases with an increase in the R_4N^+ size. This is attributable to the effect of increasing enforcement of the hydrogen-bonded structure of water on the R_4NA ($Me_4NA \rightarrow Bu_4NA$). The difference in the $\log K_D(R_4NA)$ values

Fig. 1. $-R \ln K_D(L)$ vs. T^{-1} plots for 15C5 between CHCl_3 and H_2O .

$[\Delta \log K_D(\text{R}_4\text{NA})]$ between Pr_4NA and Et_4NA is nearly equal to that between Bu_4NA and Pr_4NA ; but, the $\Delta \log K_D(\text{R}_4\text{NA})$ values are much smaller than the $\Delta \log K_D(\text{R}_4\text{NA})$ value between Et_4NA and Me_4NA . The same trend is also observed for the cases of C_6H_6 and CH_2Cl_2 .⁷ This indicates that the $\log K_D(\text{Me}_4\text{NA})$ value is much lower than that expected based on a contribution to the $\log K_D(\text{R}_4\text{NA})$ value of a methylene group calculated from $\log K_D(\text{R}_4\text{NA})$ values of Et_4NA , Pr_4NA and Bu_4NA . The unexpectedly low $\log K_D(\text{Me}_4\text{NA})$

value is probably due to the fact that the ratio of the number of carbon atoms of R_4N^+ to that of the neighbouring larger R_4N^+ is the smallest for the case of Me_4N^+ and Et_4N^+ (1:2).

It can be seen from the $\log K_{\text{ex,ip}}(\text{R}_4\text{NA})$ values in Table 2 that extractability of the R_4N^+ with a picrate ion into CHCl_3 increases with an increase in the R_4N^+ size. The order of increasing extractability of the R_4N^+ is consistent completely with those of increasing $K_A(\text{R}_4\text{NA})$ and $K_D(\text{R}_4\text{NA})$ values. This is also the case in C_6H_6 and CH_2Cl_2 systems.⁷ It can be concluded from the above discussion that the ion-pair extractability of R_4N^+ with a picrate ion is determined by the strength of enforcement of the hydrogen-bonded structure of water for the R_4N^+ ion. Plots of $\log K_{\text{ex,ip}}(\text{R}_4\text{NA})$ vs. the number of carbon atoms of R_4N^+ give a straight line with a slope of 0.582. This indicates that the contribution of a methylene group to the extraction constant of ion pairs (Π_{CH_2}) at 25° between chloroform and water is 0.582. The Π_{CH_2} value (0.58) determined in this study is consistent with the value of 0.59 reported by Motomizu *et al.*⁸ but is slightly larger than those reported by Modin and Schill⁹ (0.56), Matsunaga and Yotsuyanagi¹⁰ (0.54) and Eksborg and Schill¹¹ (0.52). The difference in $\log K_{\text{ex,ip}}$ values between Me_4N^+ and Et_4N^+ is nearly equal to that between Et_4N^+ and Pr_4N^+ and that between Pr_4N^+ and Bu_4N^+ . This is due to the fact that the unexpectedly large $\log K_A$

Fig. 2. $-R \ln K_{\text{ex}}$ vs. T^{-1} plots for 15C5-alkali metal picrate complexes between CHCl_3 and H_2O .

Fig. 3. $-R \ln K_{\text{ex}}$ vs. T^{-1} plots for 15C5- and 18C6-alkaline earth metal picrate complexes between CHCl_3 and H_2O .

and small $\log K_D$ values of Me_4N^+ compensate each other.

Plots of thermodynamic quantities for ion-pair extraction of R_4NA against the number of carbon atoms of R_4N^+ in Fig. 4 show a linear relationship. Contributions of a methylene group to ΔH° and ΔS° of ion-pair extraction [$\Delta H_{\text{ex,ip}}^\circ(\text{CH}_2)$ and $\Delta S_{\text{ex,ip}}^\circ(\text{CH}_2)$] between CHCl_3 and water were obtained from the slopes to be 0.93 kJ/mole and 14 J K^{-1} mole $^{-1}$, respectively. Positive values of $\Delta H_{\text{ex,ip}}^\circ(\text{CH}_2)$ and $\Delta S_{\text{ex,ip}}^\circ(\text{CH}_2)$ indicate that the methylene group undergoes hydrophobic hydration in water. The $T\Delta S_{\text{ex,ip}}^\circ(\text{CH}_2)$ value at 25° is 4.5 times larger than the $\Delta H_{\text{ex,ip}}^\circ(\text{CH}_2)$ value. Thus the larger the size of R_4N^+ , the more entropy- and the less enthalpy-driven the ion-pair extraction process of R_4NA is (Table 2).

Table 2 shows that for Me_2NA , a favourable enthalpy change is completely cancelled by an unfavourable entropy change, resulting in the negative $\log K_{\text{ex,ip}}$ value; for Bu_4NA , favourable enthalpy and more favourable entropy changes lead to the large $\log K_{\text{ex,ip}}$ value. Both $\Delta H_{\text{ex,ip}}^\circ(\text{R}_4\text{NA})$ and $\Delta S_{\text{ex,ip}}^\circ(\text{R}_4\text{NA})$ values increase with an increase in the size of R_4N^+ . This may result from the change from a structure-breaking effect of Me_4N^+ to a structure-making effect of Bu_4N^+ in water.¹²

A linear relationship is found for plots of $\Delta H_{\text{ex,ip}}^\circ$ and $\Delta S_{\text{ex,ip}}^\circ$ of R_4NA *vs.* the reciprocal of the radius of R_4N^+ (correlation coefficient $r = -0.980$ for $\Delta H_{\text{ex,ip}}^\circ$ and -0.986 for $\Delta S_{\text{ex,ip}}^\circ$). Both $\Delta H_{\text{ex,ip}}^\circ$ and $\Delta S_{\text{ex,ip}}^\circ$ of R_4NA are composed mostly of electrostatic interaction.

Distribution of crown ethers

From $\log K_D(\text{L})$ values of 15C5 and 18C6 obtained in our laboratory, the contribution (Π_0) of an ether oxygen atom to $\log K_D(\text{L})$ at 25° between CHCl_3 and water can be calculated by use of the Π_{CH_2} value determined in this study; namely $\Pi_0 = [\log K_D(\text{L}) - \Pi_{\text{CH}_2} \times a]/b$ (a and b denoting the number of methylene groups and ether oxygen atoms, respectively). The Π_0 values from 15C5 and 18C6 are nearly equal, -0.98_0 and -1.03_3 , respectively. The Π_0 value is -1.00 on the average. An ether oxygen atom is hydrophilic, whereas a methylene group is lipophilic. The $\log K_D(\text{L})$ values of 12-crown-4 (12C4), 15C5 and 18C6 can be estimated to be 0.66, 0.82 and 0.98, respectively. They are consistent with the respective experimental $\log K_D(\text{L})$ values [$\log K_D(12\text{C4}) = 0.90(\text{exptl})$]¹³. Contributions of benzo ($\Pi_{\text{C}_6\text{H}_4}$) and methyl

Fig. 4. Plots of thermodynamic quantities for ion-pair extraction of R_4NA *vs.* the number of carbon atoms of R_4N^+ .

(Π_{CH_3}) groups to $\log K_D(\text{L})$ at 25° between CHCl_3 and H_2O can be calculated to be 2.57 and 1.09 from $\log K_D(\text{L})$ values of benzo-18-crown-6 (B18C6) (2.569)¹⁴ and 1,2-bis[2-(2-methoxyethoxy)ethoxy]benzene (AC·B18C6) (3.40),¹⁵ that is, $\Pi_{\text{C}_6\text{H}_4} = 2.569 - 0.582 \times 10 - (-1.00) \times 6$ and $\Pi_{\text{CH}_3} = [3.40 - 0.582 \times 8 - (-1.00) \times 6 - 2.57]/2$. From these empirical parameters, the $\log K_D(\text{L})$ values of benzo-15-crown-5 (B15C5), B18C6, AC·B18C6, and dibenzo-18-crown-6 (DB18C6) can be estimated to be 2.23, 2.39, 3.41 and 3.80, respectively. They are in accord with the respective experimental $\log K_D(\text{L})$ values of B15C5 (2.4),¹⁶ B18C6, AC·B18C6 and DB18C6 (3.9).¹⁷ Using these empirical parameters, $\log K_D(\text{L})$ values of crown ethers at 25° between CHCl_3 and H_2O can be estimated regardless of their shapes.

By using the $\Delta H_{\text{ex,ip}}^\circ(\text{CH}_2)$ and $\Delta S_{\text{ex,ip}}^\circ(\text{CH}_2)$ values determined in this study, contributions of an ether oxygen atom to $\Delta H_D^\circ(\text{L})$ [$\Delta H_D^\circ(\text{o})$] and $\Delta S_D^\circ(\text{L})$ [$\Delta S_D^\circ(\text{o})$] between CHCl_3 and H_2O were calculated from $\Delta H_D^\circ(\text{L})$ and $\Delta S_D^\circ(\text{L})$ of 15C5 and 18C6 (Table 4); namely, $\Delta H_D^\circ(\text{o}) = [\Delta H_D^\circ(\text{L}) - \Delta H_{\text{ex,ip}}^\circ(\text{CH}_2) \times a]/b$ and $\Delta S_D^\circ(\text{o}) = [\Delta S_D^\circ(\text{L}) - \Delta S_{\text{ex,ip}}^\circ(\text{CH}_2) \times a]/b$. $\Delta H_D^\circ(\text{o})$ and $\Delta S_D^\circ(\text{o})$ are 0.8₈ kJ/mole and -15.0_6 J K^{-1} mole $^{-1}$ from 15C5, and 1.5 kJ/mole and -16.0_1 J K^{-1} mole $^{-1}$, respectively, from 18C6. They are almost the same. $\Delta H_D^\circ(\text{o})$ and $\Delta S_D^\circ(\text{o})$ are 0.9₆ kJ/mole and -15.8 J K^{-1} mole $^{-1}$, respectively, on the average. Strong interaction between an ether oxygen atom and water¹⁸ is responsible for the positive $\Delta H_D^\circ(\text{o})$ and negative $\Delta S_D^\circ(\text{o})$ values. The $\Delta H_D^\circ(\text{o})$ and $\Delta S_D^\circ(\text{o})$ values between benzene and water are 2.8 kJ/mole and -13 J K^{-1} mole $^{-1}$, respectively,⁶ and are larger than

those between CHCl_3 and water. This is attributable to the interaction between an ether oxygen atom and CHCl_3 via hydrogen bonding. $\Delta H_D^\circ(\text{L})$ and $\Delta S_D^\circ(\text{L})$ values of 15C5 and 18C6 between CHCl_3 and water can be estimated from these empirical parameters. They are as follows:

	15C5	18C6
$\Delta H_D^\circ(\text{L})/\text{kJ/mole}$	14	17
$\Delta S_D^\circ(\text{L})/\text{J K}^{-1} \text{mole}^{-1}$	61	73

They are consistent with the experimental $\Delta H_D^\circ(\text{L})$ and $\Delta S_D^\circ(\text{L})$ values (Table 4). $\Delta H_D^\circ(\text{L})$ and $\Delta S_D^\circ(\text{L})$ values of a 3m-crown-m ether between CHCl_3 and H_2O can be estimated, regardless of its shape, from the empirical thermodynamic parameters.

Partition of 15C5 and 18C6 from H_2O to CHCl_3 is entropy driven; favourable $T\Delta S_D^\circ(\text{L})$ values at 25° are largely cancelled by unfavourable $\Delta H_D^\circ(\text{L})$ values, resulting in small positive $\log K_D(\text{L})$ values of 15C5 and 18C6. Positive $\Delta H_D^\circ(\text{L})$ values of 15C5 and 18C6 are a result of a sum of the effect of interaction between ether oxygen atoms and water and the effect of hydrophobic hydration of methylene groups in water. The effect of hydrophobic hydration of methylene groups surpasses that of interaction between ether oxygen atoms and water, resulting in positive $\Delta S_D^\circ(\text{L})$ values of 15C5 and 18C6.

Extraction of metal picrates with crown ethers

From Table 3, extraction-selectivity sequences of 15C5 for the alkali metal ions are $\text{Na}^+ > \text{K}^+ > \text{Rb}^+ > \text{Cs}^+$ [ionic radius¹⁹: 1.02 Å (Na^+), 1.38 Å (K^+), 1.49 Å (Rb^+) and 1.70 Å (Cs^+)], indicating that the more closely the metal ion fits into the 15C5 cavity (cavity radius 0.85 Å,²⁰ the more extractable the 15C5-metal ion complex is (size-fit concept). $\log K_{\text{ML}}$ and $\log K_{\text{ex,ip}}$ sequences of 15C5 for the alkali metal ions are $\text{Cs}^+ > \text{K}^+ > \text{Na}^+ > \text{Rb}^+$ and $\text{Na}^+ > \text{K}^+ > \text{Rb}^+ > \text{Cs}^+$, respectively. The $\log K_{\text{ex}}$ sequences of 15C5 are not consistent with the $\log K_{\text{ML}}$ sequences, but are consistent with the $\log K_{\text{ex,ip}}$ sequences. The 15C5- Na^+ and K^+ complexes are more stable than the 15C5- Rb^+ complex in water. This enhances extraction selectivity of 15C5 for Na^+ and K^+ over that for Rb^+ . However, the extraction-selectivity sequences of 15C5 for the alkali metal ions are determined completely by the $\log K_{\text{ex,ip}}$ sequences (equation 10). Whereas extraction-selectivity sequences of 18C6 for the alkali metal ions are governed largely by the $\log K_{\text{ML}}$ sequences. Ion-pair extraction selectivity for

18C6-alkali metal ion complexes partly enhances the extraction selectivity of 18C6 for the alkali metal ions.

The size-fit concept holds for the selectivity of 15C5 and 18C6 (cavity radius 1.38 Å²⁰) for Sr^{2+} and Ba^{2+} (ionic radius¹⁹: 1.13 and 1.36 Å, respectively) in water, but does not hold for the extraction selectivity of 15C5 and 18C6 for Sr^{2+} and Ba^{2+} . The unexpected extraction selectivity is attributed to the higher ion-pair extractability of the 15C5- Ba^{2+} and 18C6- Sr^{2+} complexes compared with the 15C5- Sr^{2+} and 18C6- Ba^{2+} complexes, respectively.

Partition equilibrium between CHCl_3 and H_2O of free 15C5 and 18C6, which are less water-soluble, lowers the extractability for the metal ions of 15C5 and 18C6, respectively. For every crown ether-metal ion system in Table 3, the $\log K_{\text{ex,ip}}$ value is much greater than $\log K_D(\text{L})$ and $\log K_{\text{ML}}$ values. Thus, the magnitude of the $\log K_{\text{ex}}$ value depends largely on that of the $\log K_{\text{ex,ip}}$ value.

All $\Delta H_{\text{ex}}^\circ$ and $\Delta S_{\text{ex}}^\circ$ values in Table 4 are negative. The $T\Delta S_{\text{ex}}^\circ$ value at 25° is much larger than the corresponding $\Delta H_{\text{ex}}^\circ$ value. Thus, all the extractions of the metal picrates with 15C5 and 18C6 are completely enthalpy driven. For 15C5, the difference between $|\Delta H_{\text{ex}}^\circ|$ and $|T\Delta S_{\text{ex}}^\circ|$ is larger for the bivalent metal ion than for the univalent metal ion. The same is true for the case of 18C6. Extraction of the bivalent metal ion is more enthalpy driven than that of the univalent metal ion. For the 15C5- M^+ system, the most favourable $\Delta H_{\text{ex}}^\circ$ of Na^+ is balanced by the most unfavourable $T\Delta S_{\text{ex}}^\circ$, leading to the greatest $\log K_{\text{ex}}$ value.

Ion-pair extraction of crown ether-metal ion complexes with picrate anions.

The $\log K_{\text{ex,ip}}$ value of 15C5 varies with a cation of the same charge except for the cases of K^+ and Rb^+ ; those of the 15C5- K^+ and Rb^+ complexes are nearly equal (Table 3). The same tendency is found for 18C6. For alkali metal ions, the $\log K_{\text{ex,ip}}$ value of 15C5 decreases in the order, $\text{Na}^+ > \text{K}^+ \geq \text{Rb}^+ > \text{Cs}^+$; that is, the 15C5- M^+ complex, where the metal ion has a suitable size for the cavity, is more extractable as an ion pair with a picrate ion. However, this is not true for each case of 15C5- and 18C6-alkaline earth metal ion complex systems; the crown ether complex with a less size-fitting metal ion is more extractable. The higher ion-pair extractability of the less size-fitting alkaline earth metal ion is ascribed entirely to the more

favourable $\Delta H_{\text{ex,ip}}^\circ$ value. For 15C5, the most favourable $\Delta H_{\text{ex,ip}}^\circ$ value of Na^+ among the alkali metal ions is cancelled by the most unfavourable $T\Delta S_{\text{ex,ip}}^\circ$ value, resulting in the greatest $\log K_{\text{ex,ip}}$ value. Ion-pair extraction of $\text{K}(15\text{C5})\text{A}$ is completely entropy driven, whereas ion-pair extractions of $\text{M}(15\text{C5})\text{A}_m$ ($\text{M} = \text{Rb}, \text{Cs}, \text{Sr}, \text{Ba}$) and $\text{M}(18\text{C6})\text{A}_2$ ($\text{M} = \text{Sr}, \text{Ba}$) are enthalpy controlled.

From the structure of the 15C5 complex with the alkali metal ion held in the cavity, anion- and solvent-contact are possible in respective directions perpendicular to the plane of the 15C5 ring. Gibbs free energies of hydration ($\Delta G_{\text{h}}^\circ/\text{kJ/mole}$) of Na^+ , K^+ , Rb^+ and Cs^+ are -411.3 , -338 , -320 and -297 , respectively.²¹ The interaction of the alkali metal ion with water increases in the order, $\text{Cs}^+ < \text{Rb}^+ < \text{K}^+ \ll \text{Na}^+$. The order of the interaction with water of the alkali metal ion trapped in the 15C5 cavity is expected to be $\text{Cs}^+ < \text{Rb}^+ < \text{K}^+ < \text{Na}^+$. The association constant of the alkali metal ion with a picrate ion in water decreases in the order, $\text{Cs}^+ > \text{Rb}^+ > \text{K}^+ > \text{Na}^+$.²² The order of the association constant with a picrate ion of the alkali metal ion held in the 15C5 cavity is expected to be $\text{Cs}^+ > \text{Rb}^+ > \text{K}^+ > \text{Na}^+$. From the above discussion, the $\log K_{\text{ex,ip}}$ -value sequence of the 15C5 complex is expected to be $\text{Cs}^+ > \text{Rb}^+ > \text{K}^+ > \text{Na}^+$. But, the sequence of the experimental $\log K_{\text{ex,ip}}$ value of the 15C5 complex in Table 3 is the reverse. This unexpected result is attributed to a negligible effect of water on association of the alkali metal ion in the 15C5 complex with a picrate ion and/or weak interaction with water of the alkali metal ion in the 15C5 complex. Table 4 shows that, in the cases of the 15C5-alkali metal ion complexes, both $\Delta H_{\text{ex,ip}}^\circ$ and $\Delta S_{\text{ex,ip}}^\circ$ values vary considerably with the cation. This is probably attributed to large differences in interactions of the 15C5 complexes directly with picrate anions in an aqueous phase rather than those with water molecules. It has been reported that, when 15C5 extracts an alkali metal ion into nitrobenzene, the more closely the alkali metal ion fits into the 15C5 cavity, the more water molecules attached to the alkali metal ion are released; and that the number of water molecules coextracted with the uncomplexed alkali metal ion varies appreciably from Na^+ to Cs^+ but those coextracted with the 15C5 complex vary little with the alkali metal ion.²³ This strongly supports the above discussion.

The $\log K_{\text{ex,ip}}$ value of Na^+ is greater for 15C5 than for 18C6, but the reverse holds for the cases of the other metal ions (Table 3); a more favourable $\Delta H_{\text{ex,ip}}^\circ$ value is responsible for the higher ion-pair extractability of the M^{m+} complex with one crown ether compared with the corresponding M^{m+} complex with the other crown ether (Table 4). $K_{\text{ex,ip}}$ consists of two underlying equilibria, $K_{\text{ex,ip}} = K_{\text{MLA}_m} \cdot K_{\text{D}}(\text{MLA}_m)$, where $K_{\text{MLA}_m} = [\text{MLA}_m]/[\text{ML}^{m+}][\text{A}^-]^m$ and $K_{\text{D}}(\text{MLA}_m) = [\text{MLA}_m]_o/[\text{MLA}_m]$. Since $K_{\text{D}}(\text{MLA}_m)$ is a distribution constant of a neutral complex MLA_m between CHCl_3 and H_2O and hydrogen bonding to the ether oxygen atoms when the crown ethers are complexed is greatly decreased as a result of ionic M^{m+} -O bonding,²⁴ the effect of interaction of the MLA_m with water on the partition of the MLA_m is negligible as is stated above. Thus, the $K_{\text{D}}[\text{M}(18\text{C6})\text{A}_m]$ value is expected to be higher than the corresponding $K_{\text{D}}[\text{M}(15\text{C5})\text{A}_m]$ value because of the larger size of 18C6 than that of 15C5. This is one of the dominant factors in determining the larger $\log K_{\text{ex,ip}}$ value of the 15C6- M^{m+} complex compared with the corresponding 15C5- M^{m+} complex except for the case of $\text{M}^{m+} = \text{Na}^+$. It follows from this that the higher $K_{\text{ex,ip}}$ value of the 15C5- Na^+ complex compared with that for the 18C6- Na^+ complex is caused entirely by the larger K_{MLA} value of the 15C5- Na^+ complex. The number of water molecules attached to the 15C5- Na^+ complex (0.9) in nitrobenzene is smaller than that to the 18C6- Na^+ complex (1.2).²³ This supports the above discussion.

Both $\Delta H_{\text{ex,ip}}^\circ$ and $T\Delta S_{\text{ex,ip}}^\circ$ values of 15C5 vary with the cation more than do those of 18C6. This indicates that 15C5 less effectively shields the cation in the cavity from the access of picrate ions and solvents than does 18C6.

Sizes of 15C5- Na^+ and 18C6- K^+ complexes are nearly equal to those of Pr_4N^+ and Bu_4N^+ ions, respectively.²⁵ Since 15C5 and 18C6 have the most suitable cavity sizes for Na^+ and K^+ , respectively, among alkali metal ions, the cation held in the cavity is most effectively shielded by the crown ether. Four alkyl groups of a tetra-alkylammonium ion screen the central nitrogen atom well. The 15C5- Na^+ and 18C6- K^+ complexes are regarded as disks, whereas Pr_4N^+ and Bu_4N^+ are regarded as spheres. Therefore, it is interesting to compare the ion-pair extraction process of $\text{Na}(15\text{C5})\text{A}$ and $\text{K}(18\text{C6})\text{A}$ with that of Pr_4NA and Bu_4NA , respectively. From the standpoint of thermodynamics, a striking

difference in the ion-pair extraction process is observed between the crown ether complexes and the tetraalkylammonium picrates. $\Delta S_{\text{ex,ip}}^{\circ}$ values of Na(15C5)A and K(18C6)A complexes are negative; but, those of Pr₄NA and Bu₄NA are positive. $\Delta H_{\text{ex,ip}}^{\circ}$ and $T\Delta S_{\text{ex,ip}}^{\circ}$ values of Na(15C5)A and K(18C6)A complexes are much smaller than those of Pr₄NA and Bu₄NA, respectively. Ion-pair extraction of the crown ether complexes is completely enthalpy driven, whereas, that of Pr₄NA and Bu₄NA is both enthalpy and entropy driven; in particular, ion-pair extraction of Bu₄NA is dependent largely on the entropy contribution. The log $K_{\text{ex,ip}}$ value of Na(15C5)A is larger than that of Pr₄NA, and the reverse is true for the cases of K(18C6)A and Bu₄NA. This reflects the difference in the solute-solvent and solute-picrate anion interaction caused by the difference in the shape between the crown ether complex and the corresponding R₄N⁺ though they are nearly equal in size.

(Received 8 March 1991. Revised 15 April 1991. Accepted 30 April 1991)

Summary—The oxygen to uranium ratio in uranium oxides such as U_3O_8 , UO_{2+x} powders and UO_2 fuel pellets has been determined by a new spectrophotometric method. The method can be used for determination of O/U ratio in UO_2 pellets and powders on a routine basis. In the described method, uranium oxides in the powder form are dissolved in 2M sulphuric acid containing a few drops of HF. The concentrations of U(IV) and U(VI) are directly determined by means of the absorbances of these species at different wavelengths. For determination of the O/U ratio in U_3O_8 powder samples, 630 and 310 nm are the wavelengths chosen for U(IV) and U(VI), respectively. For UO_{2+x} powder, where the O/U ratio lies between 2.04 to 2.15, U(IV) and U(VI) are determined at 630 and 300 nm respectively, whereas for UO_2 fuel pellets, where the O/U ratio is less than 2.01, 535 and 285 nm are used. The molar absorptivity of U(IV) at 630 and 535 nm is 21.4 and 6.8 l.mole⁻¹.cm⁻¹ and that of U(VI) at 310, 300 and 285 nm is 178.1, 278.6 and 585 l.mole⁻¹.cm⁻¹, respectively. Standard deviations of ± 0.002 O/U ratio units for pellets and ± 0.004 O/U ratio units for powders have been achieved.

The uranium–oxygen system is one of the most complex systems known because of the multiplicity of stable oxidation states of uranium. Because of this, the exact stoichiometry of uranium dioxide is seldom attained, as it usually exists as a hyperstoichiometric oxide which includes excess oxygen in its cubic lattice. One of the most important parameters of nuclear grade uranium dioxide pellets is the O/U ratio, as it is important in the characterization of the sinterability of the powder and its performance as a fuel under reactor conditions. An oxygen-to-uranium ratio closely approaching 2.000 is a frequent requirement for nuclear fuel, so, as a quality control measure, it is essential to know the O/U ratio of the UO_2 powder.

There are many instrumental and chemical methods available for the determination of the O/U ratio. Both destructive and non-destructive methods have been reviewed by Florence.¹ Some of the instrumental methods are X-ray diffraction analysis,² electromotive force measurement of a Ni, NiO electrolyte– UO_{2+x} cell^{3–6} and X-ray photoemission spectrometry.^{7,8} A major disadvantage of these methods, is that they need reference materials having identical composition with that of the sample in order to calibrate the methods. Chemical methods include gravimetry,^{3,9} coulometry,^{10,11} titrimetry^{3,12} and polarography.^{13–15}

All the wet chemical methods for the determination of the O/U ratio are based on the determination of either U(IV) and/or U(VI), since the degree of hyperstoichiometry can be directly related to the concentration of U(VI).¹⁶ Thus, the estimation of U(VI) serves as a measure of the excess oxygen and, coupled with total uranium determination, enables one to determine the exact composition of the oxide. For near stoichiometric UO_2 pellets, where a minute quantity of U(VI) has to be determined in the presence of a large excess of U(IV), polarographic, coulometric and biamperometric methods are preferred.¹⁷ However, for UO_{2+x} powders, where U(VI) is also present in relatively higher concentration, titrimetric procedures^{1,18,19} using potentiometric and/or visual indicator techniques²⁰ are more convenient. However, these methods require that the sample is weighed accurately and dissolved completely.

Spectrophotometric methods for the determination of the O/U ratio do not require weighing and complete dissolution of the sample because both U(VI) and U(IV) are determined in the same aliquot. Our experiments demonstrate that uranium dissolves at the same rate in both oxidation states as evidenced by the same O/U ratio obtained irrespective of whether the sample is partially or completely dissolved. However, spectrophotometric methods which

use phosphoric acid²¹⁻²⁴ reported so far for the determination of O/U ratios of UO_2 pellets are not convenient on a routine basis because they suffer from many disadvantages such as high viscosity, long dissolution time, poor sensitivity and elaborate treatment procedures.²⁵ The present method is based on the dissolution of the sample in 2M sulphuric acid in the presence of a very small quantity of HF, followed by measurement of absorbances at specific wavelengths for U(IV) and U(VI).

Earlier, Takeuchi *et al.*²⁶ have reported the dissolution of uranium oxide in 1M sulphuric acid containing a few drops of HF and subsequent determination of the U(VI) coulometrically by titrating with electrogenerated Ti(III). Stronhill¹⁹ determined uranium(IV) titrimetrically with Fe^{2+} or Ti^{3+} based on sulphuric acid dissolution.

EXPERIMENTAL

Reagents

Uranium dioxide pellets, UO_2 powders and U_3O_8 powders produced at the Nuclear Fuel Complex, Hyderabad, India were used as samples. All dissolution reagents were prepared with reagent grade materials and distilled water.

Instrumentation

Absorbance measurements were carried out on a Shimadzu Model UV-240, Graphicord UV-visible Recording Spectrophotometer. Matched quartz cells of 1-cm path length were used. The base line and digital absorbance readings were adjusted to 0.000 for a reagent blank (2M sulphuric acid) before each set of measurements.

Procedure

In order to obtain a reliable value of the O/U ratio in UO_{2+x} , it is essential that the oxidation states of uranium in the solid be kept unchanged throughout procedures such as the grinding of the UO_{2+x} pellet and the dissolution of the powder obtained. Keeping this in view, the following strategy was adopted for grinding the pellets and dissolution of the powder.

UO_2 pellets. The UO_{2+x} pellet was placed in a cylindrical container and the air was displaced with a jet of argon. After sufficient flushing the lid was tightened, and the sample was ground for about 10–15 sec in a Spex Mixer Mill to provide a mesh size no smaller than 150. If the particles are very fine some oxidation may

occur. Nearly 10–15 g of the ground powder was then dissolved under argon atmosphere in 100–110 ml of 2M sulphuric acid containing 1–2 drops of HF, on a water bath. The dissolution was carried out for about one and half hours. The absorbances for U(IV) and U(VI) were measured at 535 and 285 nm, respectively.

UO_2/U_3O_8 powders. About 80–100 mg of powder was dissolved in 40–50 ml of 2M sulphuric acid containing one drop of HF. Dissolution was carried out on a water bath in ambient air for about half an hour. For UO_2 powders, the absorbances of U(IV) and U(VI) were measured at 630 and 310 nm, respectively, while for U_3O_8 powders they were measured at 630 and 300 nm.

Determination of molar absorptivity of U(IV) at 630 and 535 nm. Nuclear grade uranium metal turnings were degreased with carbon tetrachloride, pickled with 1:1 nitric acid, washed with 1:3 hydrochloric acid followed by distilled water and finally acetone.

A weighed quantity (300–350 mg) of the cleaned and dried uranium metal turnings was dissolved under argon atmosphere in 2M sulphuric acid containing a few drops of HF on a water bath. After complete dissolution of the turnings, the solution was cooled to room temperature under inert atmosphere and transferred to a 100-ml standard flask and diluted to volume with 2M sulphuric acid. The absorbances were recorded immediately.

Determination of molar absorptivity of U(VI) at 310, 300 and 285 nm. An accurately weighed amount of cleaned uranium metal turnings was dissolved in concentrated nitric acid and evaporated to dryness. A few milliliters of concentrated sulphuric acid were added and the solution was heated to dense white fumes. This residue was then dissolved in 2M sulphuric acid and diluted to 100 ml. This solution was used as a stock solution and absorbances were recorded after appropriate dilution of this solution.

RESULTS AND DISCUSSION

From the absorption spectra of U(IV) and U(VI) in 2M sulphuric acid medium (Fig. 1), it is seen that U(IV) has maxima at 535 and 630 nm with no absorption by U(VI) at these wavelengths. U(IV) does not absorb at all in the wavelength region 280–380 nm. Below 275 nm, however, there is a continuous absorption by U(IV) as well as U(VI). U(VI) absorbs in the wavelength region 360–480 nm. Below 340 nm,

Fig. 1. Absorption spectra of U(IV) and U(VI) in 2M sulphuric acid medium. (a) U(IV), 14.6 mg/ml (b) U(VI) 0.32 mg/ml.

there is no wavelength of maximum absorption for U(VI), but rather is a continuous absorption. However, the Beer-Lambert law is obeyed for solutions of U(VI) at 310, 300 and 285 nm from 0.06–1.2 absorbance units. The molar absorptivities of U(VI) at 310, 300 and 285 nm are 178.1, 278.6 and 585 l.mole⁻¹.cm⁻¹, respectively, whereas the molar absorptivities of U(IV) at 630 and 535 nm are 21.4 and 6.8 l.mole⁻¹.cm⁻¹, respectively. The higher molar absorptivity value of U(VI) at 285 nm and lower molar absorptivity value of U(IV) at 535 nm enables one to determine the O/U ratio in UO₂ pellets close to 2.001, a measurement which is difficult in phosphoric acid medium.

The extent of oxidation of U(IV) in 2M sulphuric acid by air at ~100° within half an hour is 0.1–0.2%, an amount which contributes to a positive bias of 0.001–0.002 O/U ratio units (well within the required precision). Secondly, since stringent O/U specifications are not required in the case of powder samples, purging of

Fig. 2. Absorption spectra of U(IV) and U(VI) in 13M phosphoric acid medium. (a) U(IV), 9.53 mg/ml (b) U(VI), 1.53 mg/ml.

inert gas during dissolution of uranium oxide powders is not necessary. However, in the case of uranium dioxide pellets, the O/U ratio is an important parameter and a precise O/U ratio determination is required. (The O/U ratio specification for powders is normally in the range 2.05–2.15 compared with 2.000–2.015 for pellets. The powder ratio is important for characterizing sinterability of the pellets.) The rate of dissolution in the case of pellet powders is slow compared to uranium oxide powders and therefore a dissolution period of about 1.5 hours is required to dissolve sufficient U(VI). During such extended dissolution periods, oxidation of U(IV) by air becomes significant (1–1.5%) and would result in an increase in the O/U ratio of 0.015 O/U ratio units. Hence, an inert atmosphere is essential during dissolution of the pellet samples. The volume of 2M sulphuric acid to be used for the dissolution purpose should be 100–110 ml with 0.3–0.5% (v/v) HF so that precipitation of uranium(IV) sulphate does not take place, even after slight evaporation during dissolution. This precipitation would cause a higher O/U ratio because of the preferential precipitation of the uranium(IV) sulphate by virtue of its limited solubility in sulphuric acid.

At room temperature, oxidation of U(IV) by air in 2M sulphuric acid medium is not significant within 5–6 hr. However, this rate of oxidation of U(IV) at elevated temperatures (~100°) decreases with an increase in sulphuric acid concentration because of the increased stability of U(IV) in a higher concentration of sulphuric acid. The effect of air oxidation in various concentrations of sulphuric acid at ~100° are shown in Fig. 3. At a sulphuric acid concentration greater than 5M, the oxidation may not be significant and at this acidity an inert atmosphere may not be needed during dissolution of pellet powders also, thus making the procedure still convenient. The drawback of dissolving the uranium dioxide powders in such high concentrated sulphuric acid is the limited solubility of uranium(IV) sulphate. Hence, 2M sulphuric acid is taken as the medium of dissolution, using inert gas purging during dissolution.

It is observed that gadolinium in 2M sulphuric acid medium does not have significant absorbance in the wavelength range 700–250 nm. Hence, the present method is well suited even for determining the O/U ratio of uranium dioxide pellets containing gadolinium as a burnable poison.

Fig. 3. Effect of concentration of sulphuric acid on air oxidation of U(IV). $\Delta(O/U)$ indicates the difference of O/U ratio values with and without inert atmosphere during dissolution.

Absorption spectra in 2M sulphuric acid. The absorption spectra of U(IV) and U(VI) in 2M sulphuric acid and strong (13M) phosphoric acid (SPA) are shown in Fig. 1 and Fig. 2, respectively. It is clear from the spectra of U(IV) and U(VI) in 2M sulphuric acid and SPA for expected concentrations of U(IV) and U(VI), that the spectral pattern in both media is essentially similar, indicating the similarity between the molecular structure of U(IV) and U(VI) and the nature of transitions involved²⁴ in these two media. In both cases there is a shift towards lower wavelengths and significant difference in

Fig. 4. Absorbances of a mixture of 14.6 mg/ml U(IV) and 0.32 mg/ml U(VI) at varying concentrations of sulphuric acid. U(VI) at (a) 310 nm, (b) 300 nm, (c) 285 nm. U(IV) at (d) 630 nm, (e) 535 nm.

the molar absorptivity, causing better sensitivity in sulphuric acid medium when compared to phosphoric acid medium. The absorbances of U(IV) and U(VI) at the wavelengths considered are independent of the concentration of sulphuric acid between 1 and 5M, which is clear from Fig. 4.

The reported molar absorptivity of U(IV) at 544 nm is 11.66 l.mole⁻¹.cm⁻¹ and that of U(VI) at 290 nm is 215.9 l.mole⁻¹.cm⁻¹ in SPA.²³ Whereas in the present 2M sulphuric acid medium, the molar absorptivity of U(IV) at 535 nm is 6.8 l.mole⁻¹.cm⁻¹ and that of U(VI) at 285 nm is 585 l.mole⁻¹.cm⁻¹. Hence, in the present medium there is an almost five-fold increase in sensitivity with respect to O/U ratio units. This has enabled the work to be extended to the determination of O/U ratio in UO₂ pellets closer to 2.001 O/U units with good accuracy.

The rate of dissolution of UO_{2+x} is greater in 2M sulphuric acid containing a few drops of HF compared to SPA, which makes the present method of analysis more rapid. HF seems to act as a catalyst in the dissolution, as is the case with PuO₂ and ThO₂ dissolution in HNO₃-HF mixture²⁷ where the nature of the intermediate complex is assumed to be MF₂⁺. Most of the HF vaporizes out of solution with the argon stream by the end of the dissolution period. Therefore, the concentration of the residual HF, if any, is too low to attack quartz cells at room temperature during the absorbance measurements. It has been observed that a small quantity of free HF in 2M sulphuric acid does not alter the absorbance values of U(IV) and U(VI) at their respective wavelengths.

The data tabulated in Table 1 shows the precision of the method for UO₂ fuel pellets and UO_{2+x} powders. It is clear from Table 2 that the O/U ratios obtained by the spectrophotometric method are in close agreement with those

obtained by the volumetric method. This indicates the stability of tetravalent uranium in 2M sulphuric acid medium. The O/U ratios calculated with possible combinations of wavelengths for U(IV) and U(VI) give the same value of O/U ratio for a given sample (Table 3). It is concluded that the combination 535 and 285 nm for U(IV) and U(VI), respectively, is well suited to the determination of the O/U ratio in UO_2 pellets where the O/U ratio lies between 2.001 and 2.010 units.

Comparison of O/U ratios of uranium dioxide pellets obtained by the spectrophotometric method based on dissolution in SPA and 2M sulphuric acid are shown in Table 4. The fair agreement between these results emphasize that the stability of U(IV) towards oxidation in both media is of the same order. The values of O/U

ratios of UO_2 pellets obtained by polarography and the present spectrophotometric method have been compared and the results are shown in Table 5. This table shows the good agreement between the two methods. The fact that the O/U ratio values obtained by the two independent methods are in good agreement confirms the non-oxidising nature of the present medium, *i.e.*, 2M sulphuric acid, and also the accuracy of the present spectrophotometric method.

CALCULATIONS

Let the absorbances of U(IV) at λ_1 nm be a units and that of U(VI) at λ_2 nm be b units and the corresponding molar absorptivities be ϵ_1 and ϵ_2 respectively. Then, the O/U ratio of the

Table 4. O/U ratios in UO_2 pellets

S. No.	Oxygen to Uranium ratio	
	13M phosphoric acid medium [544 nm and 290 nm are used for U(IV) and U(VI)]	2M sulphuric acid medium [535 nm and 285 nm are used for U(IV) and U(VI)]
1	2.010	2.009
2	2.007	2.008
3	2.006	2.005
4	2.008	2.006
5	2.008	2.007

various kinds of uranium oxides can be calculated as follows:

$$\begin{aligned} \text{OU} &= 2 + \frac{C_{\text{u(VI)}}}{C_{\text{u(VI)}} + C_{\text{u(IV)}}} \\ &= 2 + \frac{1}{1 + \frac{(\epsilon_2)(a)}{(\epsilon_1)(b)}} \end{aligned}$$

However, in the case of pellets where $C_{\text{u(VI)}} \ll C_{\text{u(IV)}}$, the above expression reduces to

$$\text{O/U} = 2 + \frac{(\epsilon_1)(b)}{(\epsilon_2)(a)}$$

If the observed absorbance for U(IV) at 535 nm is a units and that of U(VI) at 285 nm is b units, then the O/U ratio is given by $\text{O/U} = 2 + 0.0116 b/a$.

(Received 15 December 1990. Revised 18 April 1991. Accepted 25 April 1991)

Summary—A multicomponent analysis method is proposed for the determination of chlorophenols by diode array derivative spectrophotometry. The method is based on formation of ion-pairs with tetrabutylammonium as counterion and extraction in chloroform at pH 9.1. Quantitative determinations (within the 2–20 mg/l. concentration range) of two-, three- and four-component mixtures were possible, using the first derivative spectra and a least-squares computer programme.

Chlorophenols are widely used in pesticide production. The presence of chlorophenols in water, soil, food and animal foodstuffs presents a potential hazard due to their high toxicity. Spectrophotometric determination of these phenols is of limited use because their absorption bands overlap.¹ The need for reliable determination of these chemicals has led to the development of many analytical methods,^{2–7} mainly using chromatographic techniques (HPLC and GC).

A review of papers published on the spectrophotometric analysis of multicomponent mixtures shows that the quantification of compounds continues to be a difficult problem when there is high spectral overlapping and components have unequal concentration, but also shows that the application of derivative spectroscopy offers a powerful approach to the problem of resolution of mixtures.^{7,8} O'Haver and Green⁹ have evaluated the utility of the derivative spectrometry in multicomponent analysis in reducing band-overlap error of the type often encountered in quantitative spectrometry. This method is useful for reduction of band-overlap errors if the systematic error caused by the overlap is large compared to the random error and the interfering band is either known and constant or is broader than the analyte band. In general, the derivative technique reduces the total error by a factor of at least 3, and usually by much more.

This paper describes the development of a method for the multicomponent determination of chlorophenols by diode array derivative spectrophotometry. The method is based on ion-pair formation with tetrabutylammonium as counterion and extraction in chloroform at pH 9.1. Quantitative determination of two-, three- and four-component mixtures were possible, using the first derivative spectra and a least-squares computer programme.

THEORY

The background and theory of multicomponent analysis have been discussed before.¹⁰ Therefore, only key equations are presented here.

The Beer's Law model can be generalized for multicomponent systems and expressed in matrix notation as:

$$A = C\epsilon \quad (1)$$

where ϵ is the matrix of linear response constants whose elements represent the sensitivity of each wavelength to each analyte. To find a solution for the system expressed in equation (1), the number of wavelengths must be at least equal to the number of analytes. Once the ϵ matrix is calculated, its inverse can be used to determine the concentrations of unknowns from measured absorbances as:

$$C = A\epsilon^{-1} \quad (2)$$

If the number of wavelengths is greater than the number of analytes, ϵ is not a square matrix. C

*Author for correspondence.

is solved by using the generalised inverse of ϵ where according to:

$$C = A\epsilon^T(\epsilon\epsilon^T)^{-1} \quad (3)$$

where

$A = m \times n$ matrix of calibration spectra
 $C = m \times 1$ matrix of component concentrations
 $\epsilon = 1 \times n$ matrix of absorptivity-path length products

The utility of a spectrophotometric method for multicomponent analysis is determined by its selectivity and by all errors inherent in the calibration and prediction procedure. Several statistics may be used to describe the accuracy and precision of a multiple linear least squares regression.

In our research, the spectra of synthetic mixtures of known composition were compared with absorbances calculated from the spectra of the individual components and the composition of the solution to establish the additivity of the absorbances of the pure components. This comparison was made at 2 nm intervals in several wavelength ranges and a standard deviation,¹¹ S.D., was calculated for each synthetic mixture at different wavelength ranges, based on the following relationship:

$$\text{S.D.} = \left[\sum_{h=1}^k (Ah - \hat{A}h)^2/k \right]^{1/2} \quad (4)$$

We used this S.D. to verify the additivity of absorbances of components in a mixture within the limits of experimental error. A more complete statistic also used¹² to quantify the analytical precision in each mixture is the prediction error:

Prediction error (%)

$$= 100 \left[\sum_{i=1}^N (ci - \hat{c}i)^2 / \sum_{i=1}^N Ci^2 \right]^{1/2} \quad (5)$$

S.D. and prediction error can be expressed¹³ for all mixtures and components as follows:

$$\text{S.D.} = \left[\frac{\sum_{i=1}^N \sum_{j=1}^M (cij - \hat{c}ij)^2}{N(M-1)} \right]^{1/2} \quad (6)$$

Prediction error (%)

$$= 100 \left[\frac{\sum_{i=1}^N \sum_{j=1}^M (cij - \hat{c}ij)^2}{\sum \sum c^2ij} \right]^{1/2} \quad (7)$$

Ah = the mixture absorbance at each wavelength

$\hat{A}h$ = the calculated absorbance

k = the number of wavelengths

N = the number of components

M = the number of mixtures

c = the "true" concentration

\hat{c} = the estimated concentration

S.D. and prediction error for one component can be calculated from equations (6) and (7) making $N = 1$.

EXPERIMENTAL

Equipment

A detection system consisting of a diode array HP 8452A spectrophotometer equipped with a 1-cm path length silica cell was used. The spectrophotometer was interfaced to an HP Vectra AT computer and an HP Think Jet printer.

Reagents

All chemicals were of analytical reagent grade and purified water was obtained with a Milli-Q apparatus.

Pentachlorophenol (99% pure, Carlo Erba), 2-chlorophenol (99% pure, Carlo Erba), 2,4-dichlorophenol (99% pure, Aldrich Chemie) and 4-chloro-3-methylphenol (99% pure, Aldrich Chemie) were used for preparing 150.0 and 50.0 mg/l. stock solutions in $10^{-3}M$ sodium hydroxide. Standard working solutions of the chlorophenols were prepared by suitable dilution of the stock solutions with water. A 5000 mg/l. stock solution of tetrabutylammonium nitrate (98% pure, Fluka Chemie AG) was also used. The pH was adjusted with a 0.1M borate buffer (pH 9.1).

Spectrophotometric grade chloroform (Carlo Erba) was used in extraction.

Procedure

To a 100-ml extraction funnel add, in the following order, 3.0 ml of 0.1M $\text{Na}_2\text{B}_4\text{O}_7 \cdot 10\text{H}_2\text{O}$ buffer (pH 9.1), 1.0 ml of 5000 mg/l. tetrabutylammonium nitrate solution, chlorophenol stock solution within the 2–20 mg/l. range in the final volume and the purified water necessary for a 10-ml final volume. Equilibrate with three 3.0-ml portions of chloroform, shaking for 1 min each time. The total organic extract is transferred into a 10-ml standard flask and made up to volume with chloroform. In order to obtain a standard spectrum of pure

components, 40 replicate solutions were prepared for each component. The absorbance spectra of chlorophenols and/or chlorophenol ion-pairs were obtained and normalized to 1.0 mg/l. The Q Dixon or t Student tests were used to exclude the spectra which are outside the 95% confidence interval around the mean. Several mixtures with different ratios of two, three and four components with 5 replicates per composition were prepared from the stock solutions. A home-made multicomponent programme allows the determination of different chlorophenol mixtures with the first derivative normalized standard spectra in the 250–380 nm wavelength range. This programme fits a combination of standard spectra to the spectrum of the mixture by means of the least-squares method.

RESULTS AND DISCUSSION

Optimization of working conditions

The effects of varying chemical conditions in the chlorophenol determination were examined

Variable	Range studied	Value selected
pH	2–10	9.1
Counterion	CTAB Hyamine 3500 TBA TPA TMA	TBA
TBA, mg/l.	0–1500	500
Organic solvent	1,2-Dichloroethane Chloroform Carbon tetrachloride	Chloroform

and the parameter values selected for use are listed in Table 1.

The effect of pH within the range 2–10 and the nature of the counterion was investigated. Several 1500-mg/l. quaternary ammonium salts solutions were studied, *viz.* cetyltrimethylammonium bromide (CTAB), benzyldiisobutylphenoxyethoxydimethylammonium bromide (Hyamine 3500), tetrabutylammonium nitrate (TBA), tetrapropylammonium bromide (TPA) and tetramethylammonium nitrate (TMA).

20	15.0	9.0	3.0	3.0

The effect of counterions on formation and/or extraction of ion-pairs was studied keeping the chlorophenol concentration constant. It was found that the presence of quaternary ammonium salts is necessary to extract chlorophenols at pH values above their respective pK_a values. In the absence of these ammonium salts, the extraction does not take place. The ion-pair formation is more effective in the presence of the bigger counterions and at high pH, but CTAB and Hyamine 3500 produce strong emulsions and hence irreproducible results. Thus, tetrabutylammonium (TBA) was selected for further studies.

The effect of pH on the formation of ion-pairs and on the extraction of chlorophenols and/or chlorophenol ion-pairs was examined with the following buffers in the 2–10 pH range: hydrochloric acid, sodium acetate/acetic acid, Na_2HPO_4/NaH_2PO_4 , borax and sodium hydrox-

ide. It was observed that only pentachlorophenol forms ion-pairs with all counterions studied at pH values higher than 4.7. On the other hand, a small amount of 2,4-dichlorophenol forms ion-pairs only at pH 10, while monochlorophenols do not form ion-pairs at any pH. Figure 1 shows the pentachlorophenol ion-pairs and chlorophenol absorbances, and first derivative spectra at pH 9.1 with TBA as counterion.

The effect of different TBA concentrations on chlorophenol extraction was investigated within

the 0–1500 mg/l. range. It was found that chlorophenols and/or chlorophenol ion-pair extraction was not significantly increased by using TBA concentrations higher than 500 mg/l.

The effect of organic solvents on the extraction of chlorophenols and/or chlorophenol ion-pairs was examined. Several organic solvents, *viz.* 1,2-dichloroethane, chloroform and carbon tetrachloride, were tested. The pentachlorophenol ion-pair was not extracted with carbon tetrachloride. In 1,2-dichloroethane, an absorption band was observed between 226–230 nm; this band is not characteristic of chlorophenols and is not reproducible. Thus, chloroform was selected for further studies.

Determination of chlorophenols in binary, ternary and quaternary mixtures

The accuracy of results obtained in the multicomponent analysis of overlapping spectra depends on the wavelength range. Several wavelength ranges were studied and the optimum conditions were selected based on standard deviation and prediction error. The study was made on 20 quaternary mixtures (Table 2) containing different concentrations within the 3–15 mg/l. concentration range and the results

in the spiked water in the 250–380 nm wavelength range with relative errors below 4.4% for binary and ternary mixtures and in the 1–10% range for quaternary ones.

When matrix effects are encountered, the prediction error reaches values higher than 50%. The method can be applied to the determination of chlorophenols in the absence of nitrophenols because when the presence of nitrophenols is suspected in the same sample, the calibration method described above is not suitable. We are using the generalized standard addition method, or GSAM, to prevent this problem, but this will be described in a future paper.

CONCLUSIONS

It can be concluded that a photodiode array multi-wavelength detector, together with multi-component analysis, is a very efficient tool for the analysis of multicomponent samples. The overlapping of spectra in the simultaneous determination of a substance can be overcome.

The accuracy of the results depends on the wavelength ranges used.

STATISTICAL OPTIMISATION APPLIED TO THE SPECTROPHOTOMETRIC STUDY OF THE TOLMETIN-Fe(III) COMPLEX

S. AGATONVIĆ-KUŠTRIN, LJ. ŽIVANOVIĆ, D. RADULOVIĆ and M. VASILJEVIĆ

Institute of Pharmaceutical Chemistry, Faculty of Pharmacy, Dr. Subotica 8,
11000 Belgrade, Yugoslavia

Summary—Tolmetin sodium has been examined and determined from dosage forms as its Fe(III) complex and the method has been optimized by statistical optimization.

Tolmetin [(1-methyl-5-*p*-toluoylpyrrol-2-yl)-acetic acid] is a non-steroidal anti-inflammatory agent with analgesic and antipyretic activities. As the sodium salt dihydrate it is formulated in tablet and capsule forms, both of which are used for the treatment of rheumatoid arthritis and osteoarthritis.

Tolmetin has been determined by a variety of analytical techniques, the most common ones being colorimetry,¹ UV spectrophotometry² and gas and liquid chromatography.³⁻⁷ Other methods include thin-layer chromatography,⁸⁻⁹ fluorimetry¹⁰ and polarography.¹¹ The compendial assay for tablets and capsules entailed lengthy spectrophotometric procedures.¹² Because spectrophotometric techniques offer significant economic advantages over gas and liquid chromatography, the aim of the present work was to establish a new, highly sensitive spectrophotometric method for the determination of tolmetin sodium in bulk drug form and in tablets.

Colorogenic reaction with iron(III) chloride in the presence of ammonium thiocyanate was used to modify the spectrum of tolmetin and enable its detection in the visible spectral region. The method involves the formation of a tolmetin-iron(III) complex which is soluble in chloroform and is stable, but does not absorb in the visible region. The complex can be converted to a red coloured ion-pair, by the addition of ammonium thiocyanate. The ion-pair is extractable with chloroform and can be detected colorimetrically.

The assay was developed with two mathematical statistical models: factorial design and response surface mapping.¹³ The decision to apply experimental design techniques to the development of the method was made after a

series of screening experiments revealed that the complex formation and extraction are maximized as a function of supporting electrolyte concentration, concentration of colour reagents and pH of reaction mixture. One set of two-level four variable factorial experiments were carried out in order to evaluate the main effect, as well as the interaction among factors. The final step was to optimize the values of four variables with response surface design. The best set of conditions was selected for further investigation.

EXPERIMENTAL

Reagents

Tolmetin sodium bulk drug and Tolectin® tablets (200 mg) were obtained by courtesy of McNail Inc. (New York, USA). Iron(III) chloride, potassium chloride, acetic acid and sodium hydroxide were obtained from Merck A. G. (Darmstadt, FRG). Doubly-distilled water was used throughout.

Solutions

For analytical purposes a freshly prepared (1.6 mg/ml; $5.07 \times 10^{-3} M$) aqueous solution of tolmetin sodium bulk drug was used as the standard solution. The calibration curve was prepared with ten standard solutions having concentration in the range 0.2–2.0 mg/ml (6.34×10^{-4} – $6.34 \times 10^{-3} M$). A sample solution containing 1.0 mg/ml ($3.17 \times 10^{-3} M$) tolmetin sodium was prepared by extracting tolmetin sodium from tablets.

Iron(III) chloride solution (27.03 mg/ml; $1 \times 10^{-1} M$) was prepared by dissolving 1.3515 g of iron(III) chloride in 40 ml of water, adding 1 ml of 1M hydrochloric acid and diluting the solution to 50 ml with water.

Ammonium thiocyanate solution (76.12 mg/ml; 1M) was prepared by dissolving 3.806 g of ammonium thiocyanate in 50 ml of water.

The ionic strength of the final solution was kept constant at 0.2M by addition of 2M potassium chloride. Acetate buffer solutions covering the pH range 4.0–6.5 were made by mixing appropriate volumes of 1M sodium hydroxide and 1M acetic acid.

Apparatus

A Specord M 40 Carl Zeiss Jena spectrophotometer, provided with matched 10-mm quartz cells and a Radiometer 22 pH-meter calibrated with appropriate standard buffer solutions were used.

Procedure

To 2 ml of tolmetin sodium solution placed in an Erlenmeyer flask fitted with a ground glass stopper, 2 ml of iron(III) chloride, 2 ml of ammonium thiocyanate, 1 ml of 2M potassium chloride and 3 ml of acetate buffer were added, followed by 5 ml of chloroform. The Erlenmeyer is stoppered and after shaking the reaction mixture for 10 min the red-coloured chloroformic layer is separated with a separating funnel and the absorbance measured at 486 nm, against a reagent blank. This procedure was employed for measuring the absorption spectrum and for determination of tolmetin sodium from bulk drug and tablets.

RESULTS AND DISCUSSION

Absorption spectrum of the tolmetin–iron(III) complex

Tolmetin sodium reacts with iron(III) chloride in the presence of ammonium thiocyanate at pH 4.6–6.8 to form a red, chloroform extractable complex. The absorption spectrum of the extracted complex was measured in the spectrum region from 400–600 nm. The complex shows maximum absorbance at 486 nm (Fig. 1), which can therefore be used as the wavelength for the determinations. Under the same conditions, the chloroformic extract of iron(III) chloride, ammonium thiocyanate, potassium chloride and acetate buffer solution does not absorb in this spectral region. The maximal production and extraction of the complex was reached after 5 min and the colour was stable for 24 hr.

Iron(III) chloride and ammonium thiocyanate were added in excess. Investigation

Fig. 1. Absorption spectra of the tolmetin–Fe(III) complex in chloroform. [Tolmetin] = $5.07 \times 10^{-3}M$; [Fe(III)] = $10^{-1}M$; $[NH_4SCN] = 1M$; pH 5.8; $\mu = 0.2M$.

showed that the absorbance increases up to a molar ratio of 20:1 for iron(III)–tolmetin and 9:1 for ammonium thiocyanate–iron(III) chloride.

Effect of pH and ionic strength on complex formation

The complex is only produced at pH values above 4.6. The general trend observed was a gradual increase in absorbance to pH 5.6, followed by a steady decrease in absorbance after pH 5.8 (Fig. 2); therefore, the optimum conditions for complex formation were found to be in the pH range 5.6–5.8.

As the shape of the absorption curves and positions of the absorption maximum do not vary with pH, we assumed that in this pH range only one type of complex is formed (Fig. 3).

The ionic strength also plays a significant role by its influence on the shape and intensity of the

Fig. 2. The effect of pH on complex absorption at 486 nm. [Tolmetin] = $5.07 \times 10^{-3}M$; [Fe(III)] = $10^{-1}M$; $[NH_4SCN] = 1M$; $\mu = 0.2M$.

recorded peaks. The effect of ionic strength and complex formation was followed in the range 0.1–0.4M. At an ionic strength of 0.2M, spectra with optimum shape were recorded.

Optimum conditions for complex formation

Optimization of this spectrophotometric procedure was especially difficult because the absorbance and reproducibility response depend on several variables that interact with each other. In order to investigate the effect of each factor and their interaction, a four variable, two level factorial design was chosen. The variables were: ionic strength (*A*), pH (*B*), iron(III) chloride concentration (*C*) and concentration of ammonium thiocyanate (*D*) in the reaction mixture. Different levels of these variables were selected in order to maximize the information that could be extracted from experimental data. The design matrix (Table 1) shows the 16 treatment combinations of low (–) and high (+) level factors.

From the estimate of factors effect (Table 2) it can be seen that the pH of reaction mixture is the most significant effect. The interaction of the concentration of iron(III) chloride and concentration of ammonium thiocyanate was greater than the other combined effects which indicates that the amount of the formed complex influenced by the concentration of iron(III) chloride is dependent on the concentration of ammonium thiocyanate.

In order to increase the sensitivity of the method response, a surface diagram was chosen to identify the optimum experimental conditions. Response surface can simultaneously

Fig. 3. The effect of pH on complex formation and extraction. [Tolmetin] = $5.07 \times 10^{-3}M$; [Fe(III)] = $10^{-1}M$; $[NH_4SCN] = 1M$; $\mu = 0.2M$.

CD	= -0.10209
ACD	= -0.01416
BCD	= -0.02011
ABCD	= -0.00339

Maximum absorbance of the extracted complex can be obtained with $2 \times 10^{-2} M$ iron(III) chloride and $2 \times 10^{-1} M$ ammonium thiocyanate in the reaction mixture as can be seen from the assumed response surface and contours of constant response for the response surface given in Fig. 4.

For the relationship between pH, ionic strength and absorbance, while holding the concentration of colour reagents constant at optimal concentrations, ten solutions were examined (pH 5.2, 5.8, 6.4 and $\mu = 0.1, 0.2, 0.3 M$, with a replicate at the mid-point pH 5.8, $\mu = 0.2 M$) and model fitting methods give the equation:

$$A = -13.971 + 5.1904\mu + 4.9756 \text{ pH} \\ - 14.0995 \mu^2 - 0.4379 \text{ pH}^2 \\ + 0.1043 \rho \text{ pH}$$

Fig. 4. The absorption response of the tolmetin-Fe(III) complex in chloroform and contours of constant response for the response surface as a function of the concentration of colour reagents. [Tolmetin] = $5.07 \times 10^{-3} M$; pH 5.7; $\mu = 0.2 M$.

Fig. 5. The absorption response of the tolmetin-Fe(III) complex in chloroform with respect to the pH and ionic strength. [Tolmetin] = $5.07 \times 10^{-3} M$; [Fe(III)] = $10^{-1} M$; $[\text{NH}_4\text{SCN}] = 1 M$.

The equation maximum is obtained with pH 5.7 and $\mu = 0.2 M$. The assumed response surface is shown in Fig. 5. All further measurements were carried out at pH 5.7, ionic strength 0.2 M and a ten-fold excess of ammonium thiocyanate concentration to iron(III) chloride concentration.

Stoichiometry of the complex

The composition of the tolmetin-iron(III) complex was determined by applying Job's method of continuous variation. The concentration of aqueous tolmetin sodium and iron(III) chloride solutions was $5 \times 10^{-3} M$. Nine solutions were prepared containing tolmetin sodium and ferric chloride in various molar ratios so that their volume always amounted to 5 ml with addition of 2 ml of

Fig. 6. Job's curve of equimolar solutions for the tolmetin-Fe(III) complex in chloroform. [Tolmetin] = [Fe(III)] = $5 \times 10^{-3} M$; pH = 5.7; $\mu = 0.2 M$.

Fig. 7. Job's curve of non-equimolar solution at 486 nm. [Tolmetin] = $2.5 \times 10^{-3} M$; pH 5.7; $\mu = 0.2 M$.

ammonium thiocyanate solution, 1 ml of potassium chloride and 2 ml of acetate buffer solution. The extraction was performed with 5 ml of chloroform and the absorbance measured at 486 nm. The plot reaches maximum value at a mole fraction $X_{\max} = 0.5$ (Fig. 6), which indicates the formation of a 1:1 complex. The composition of the complex was confirmed by the molar ratio method. The curve obtained shows a break point at the iron(III)-tolmetin molar ratio of 1:1.

Relative stability of the complex

The relative stability constant of the complex has been determined by applying the method of Sommer *et al.*¹⁶ on the basis of results obtained by Job's method for the composition of the complex and also by the application of Job's method of non-equimolar solutions¹⁵ (Table 3). By Job's method of non-equimolar solutions the curves for a five- and ten-fold excess of reagent were obtained (Fig. 7).

The conditional stability constant was then calculated in the following way:

$$K' = \frac{(p-1)(1-2X_{\max})}{(C_{\text{tolmetin}})[(1+p)X_{\max}-1]^2}$$

Table 3. Conditional stability constant of the tolmetin-Fe(III) complex*

Job's method of non-equimolar solutions*			
[Fe(III)]	p	X_{\max}	$\log K'$
1.25×10^{-2}	5	0.208	4.18
2.50×10^{-2}	10	0.166	3.78
Mean: 3.98			
Sommer's method*			
$\log K'$	$\log K'_{\min}$	$\log K'_{\max}$	SD RSD, %
3.84	3.71	4.01	0.11 2.37

*Conditions: pH 5.7; $\mu = 0.2$; Temperature = $25 \pm 0.5^\circ$

where $p = 5$ or 10, X_{\max} is projection of the peak maximum divided by the total volume of chloroform used for extraction in each case (12 ml). The values obtained by the two different methods are in good agreement.

Validation

The method was tested for linearity, precision and reproducibility. The Beer-Lambert law was obeyed over the tolmetin sodium concentration range 0.04–0.04 mg/ml; $A_{486} = a + bC$, where C is the concentration of tolmetin sodium in mg/ml (calculated in the final solution for extraction), $a = -0.0172$ and $b = 2.326$; the regression coefficient being $R = 0.999$ ($n = 10$) indicates excellent linearity.

The precision of the method was checked at three different concentrations. The relative standard deviation varied from 1.31–2.33% for concentration of tolmetin sodium from 0.4–1.6 mg/ml.

The applicability of the method for the assay of simple dosage forms was examined by analysing Tolectine[®] tablets. The recovery was 98.6% ($n = 10$) relative to the labelled strength of those preparations and relative standard deviation of 1.62%.

The statistical analysis of the results obtained in the determination of tolmetin as a pure compound and from dosage forms is shown in Table 4.

The colorimetric procedure, based on selective reaction of tolmetin sodium with iron(III) chloride in the presence of ammonium thiocyanate and extraction of the formed complex is

A POTENTIOMETRIC TECHNIQUE FOR KINETIC DETERMINATION OF CITRATE, BASED ON INHIBITION OF CRYSTALLINE GROWTH OF LEAD CARBONATE SEED CRYSTALS

F. GRASES and C. GENESTAR

Department of Chemistry, University of Balearic Islands, 07071 Palma de Mallorca, Spain

(Received 22 April 1991. Revised 6 June 1991. Accepted 25 June 1991)

Summary—The growth of lead carbonate seed crystals is strongly inhibited by the presence of citric acid. The kinetics of crystal growth were followed potentiometrically with a lead ion-selective electrode. The study of different variables on such a process was carried out with the aim of developing kinetic procedures to determine citrate (0.5–2.0 $\mu\text{g/ml}$). The selectivity and sensitivity of these processes allow the application of his crystallization reaction to direct determination of citrate in drinks and in a pharmaceutical product.

Citric acid has aroused notable interest as an additive in food, mainly as an acidifying agent in drinks. Citrate is also widely used in pharmaceutical preparations. It is biologically involved in the well-known Krebs cycle of glucid metabolism¹ and plays an important role in preventing calcium oxalate urolithiasis due to its effective inhibitory effects.²

Determination of citric acid can be accomplished through gravimetric and volumetric methods,³ photometric procedures,⁴ enzymatic analyses⁵ and chromatographic determinations, mainly HPLC.⁶ Recently, an indirect potentiometric method was also presented.⁷ In this paper we propose a kinetic potentiometric technique for kinetic determination of citrate based on its inhibitory effects on the growth of lead carbonate seed crystals. The determination was applied to the direct determination of citrate in drinks. We have demonstrated previously the usefulness of inhibitory processes of crystalline growth with analytical purposes, due to the sensibility and selectivity of such processes. Thus, procedures for phytic acid determination with seed crystals of calcium oxalate monohydrate⁸ and determination of phosphate with calcite (calcium carbonate) seed crystals⁹ were developed.

EXPERIMENTAL

Reagents and apparatus

Solutions of sodium bicarbonate, sodium citrate (both from Panreac) and sodium per-

chlorate (Carlo Erba) were prepared with analytical-reagent grade chemicals. A standard solution of 0.1M lead perchlorate (Orion) was used. Lead carbonate seed crystals of analytical reagent grade (Panreac) were characterized by termogravimetry (with a Perkin-Elmer TGS 2 Electromicroanalytical balance) and scanning electron microscopy (with a Hitachi S-530 SEM). Potentiometric measurements were taken by means of a Crison pH/mV-meter digit 501 with a lead electrode (Orion Model 94-82) coupled with a silver/silver chloride electrode, separated from the cell solution by an intermediate junction containing potassium chloride. The temperature was controlled by a sensor immersed in the working solution.

Procedure

In a 250-ml beaker were placed 2 ml of 5M sodium perchlorate, 0.4 ml of 0.1M lead perchlorate, the volume of citrate solution necessary for a final concentration between 0.5 and 2 ppm of citrate, and water to a final volume of 200 ml (initial pH = 5.8). The solution was immersed in a constant-temperature waterbath and was always magnetically stirred. After the temperature of the working solution was stabilized ($25.0 \pm 0.2^\circ$), 1 ml of a perfectly homogeneous suspension, obtained by mixing 5 g of lead carbonate seed crystals and 20 g of water, was added. Finally, when the potentiometer gave a constant reading (± 0.5 mV), 1 ml of 0.2M sodium bicarbonate solution was added.

Fig. 1. Lead crystallization runs in the absence and presence of citrate. $[Pb^{2+}]_0 = 2 \times 10^{-4}M$, $[HCO_3^-]_0 = 1 \times 10^{-3}M$, $[NaClO_4] = 0.05M$, initial pH = 5.8; 0.25 g of lead carbonate seed crystals, temperature = 25°. (1) without citrate; (2) [citrate] = $2.5 \times 10^{-6}M$; (3) [citrate] = $3.4 \times 10^{-6}M$; (4) [citrate] = $5.0 \times 10^{-6}M$; (5) [citrate] = $6.8 \times 10^{-6}M$.

Potential-time curves were obtained whether the induction period method or the fixed-time method of rate measurement was applied (Fig. 1). The duration of each measurement was *ca.* 10 min.

RESULTS AND DISCUSSION

Study of crystalline growth of lead carbonate seed crystals

The crystalline growth of lead carbonate seed crystals was potentiometrically studied with a lead ion-selective electrode in order to obtain optimum conditions to observe inhibitory processes of crystal growth. Thus, the influence of pH, supersaturation, ionic strength, temperature and seed morphology on the reaction rate were studied.

Figure 2 shows the influence of initial pH on the reaction rate. As can be seen the rate of lead carbonate crystal growth increases when initial pH increases. This is directly related to the displacement of the following equilibrium.

giving a higher initial free carbonate concentration at higher pH values and consequently increasing the initial crystallization rate of the lead carbonate. Considering the pH range of the optimum response for the lead ion-selective electrode, a pH of *ca.* 5.8 was chosen as optimum. When the lead carbonate crystallization process took place with working solutions containing lead, hydrogen carbonate and carbonate (without pH buffer), using the above conditions, a continuous increase in the pH of the solution was observed (one unit of pH, approx.) and this

Fig. 2. Influence of the initial pH on the initial rate ($tg \alpha$) of lead carbonate crystallization. $[Pb^{2+}]_0 = 2 \times 10^{-4}M$, $[HCO_3^-]_0 = 5 \times 10^{-4}M$, $[NaClO_4] = 0.05M$; 0.25 g of lead carbonate seed crystals, temperature = 25°.

is explained by considering the existence of basic lead forms at 5.8 initial pH value.

Figure 3 shows the rate of crystallization corresponding to different selected supersaturation values. As can be appreciated for a total initial lead concentration of $2 \times 10^{-4}M$ and bicarbonate concentration of $1 \times 10^{-3}M$, the electrode potential remained constant before seed addition, and after bicarbonate addition the rate of crystalline growth provoked a rapid decrease in the potential with time. These are two essential conditions for exploiting this methodology for analytical purposes. For those reasons the above-mentioned lead and bicarbonate concentrations were chosen as optimum. As can be seen in Fig. 3, it can be assumed that no nucleation processes took place and consequently only crystalline growth on seed crystals was produced.

The study of the ionic strength influence demonstrated that in the studied interval

Fig. 3. Lead carbonate crystallization runs at different supersaturation. $[Pb^{2+}]_0 = 2 \times 10^{-4}M$, $[NaClO_4] = 0.05M$, initial pH = 5.8; 0.25 g of lead carbonate seed crystals, temperature = 25°. (1) $[HCO_3^-]_0 = 3 \times 10^{-4}M$; (2) $[HCO_3^-]_0 = 4 \times 10^{-4}M$; (3) $[HCO_3^-]_0 = 5 \times 10^{-4}M$; (4) $[HCO_3^-]_0 = 1 \times 10^{-3}M$; (5) $[HCO_3^-]_0 = 2 \times 10^{-3}M$; (4') and (5') experiments without seed.

Fig. 4. Effects of several substances in lead carbonate crystal growth. $[Pb^{2+}]_0 = 2 \times 10^{-4}M$, $[HCO_3^-]_0 = 1 \times 10^{-3}M$, $[NaClO_4] = 0.05M$, initial pH = 5.8; 0.25 g of lead carbonate seed crystals, temperature = 25°. (1) Reference, thiamine ($5 \times 10^{-6}M$), threonine ($1.7 \times 10^{-6}M$), sulphate ($2 \times 10^{-5}M$), phosphate ($2 \times 10^{-5}M$), EDTA ($1 \times 10^{-5}M$), fumaric acid ($1.7 \times 10^{-5}M$); (2) ascorbic acid ($1.1 \times 10^{-5}M$); (3) oxalate ($2.3 \times 10^{-5}M$); (4) pyrophosphate ($1.4 \times 10^{-5}M$); (5) citrate ($6.8 \times 10^{-6}M$).

(0.025–0.15M sodium perchlorate) the crystalline growth is only slightly affected. An ionic strength of 0.05M sodium perchlorate was chosen as optimum after consideration of the most appropriate electrode response. Studies of the temperature influence on lead carbonate crystal growth demonstrated that between 25 and 30°, the crystallization runs were practically unmodified.

The size and morphology of seed crystals can in some cases affect the rates of crystal growth.¹⁰ Thus to evaluate the influence of size and morphology of the lead carbonate seed on crystallization runs, experiments were made with seeds of two different surface characteristics (aged and non-aged seed crystals). No significant

Fig. 5. Influence of the initial pH on the inhibition of citrate in the crystalline growth of lead carbonate. $[Pb^{2+}]_0 = 2 \times 10^{-4}M$, $[HCO_3^-]_0 = 1 \times 10^{-3}M$, $[NaClO_4] = 0.05M$, $[citrate] = 3.4 \times 10^{-6}M$; 0.25 g of lead carbonate seed crystals, temperature = 25°. (1) pH = 6.3; (2) pH = 5.8; (3) pH = 5.3; (4) pH = 5.0.

variations were observed when using the two distinct seeds, in spite of their different morphology, demonstrating that in this case the type of seed used had little influence on the process. The quantity of seed crystals used in each experience was also studied and it was found that 0.25 g of lead carbonate seed crystals caused a rapid and easily measurable decrease in the potential with time.

Finally, the crystalline growth of lead carbonate seed crystals was studied in the presence of several additives. As is shown in Fig. 4, the growth of lead carbonate crystals was notably delayed by the presence of citrate and pyrophosphate, in such a manner that the citrate exhibited the highest effect and ascorbic and oxalic acids the lowest one, whereas, fumaric acid, thiamine, threonine, sulphate, phosphate and EDTA manifested no significant effects in the experimental conditions used. These results demonstrate that the structure of the citric acid

permits a very effective adaptation of the substance on the crystal surface. The adsorption of the polyhydroxycarboxylic acid to the active growth sites would be responsible for the reduction in the crystalline growth rates.

Effects of citrate on lead carbonate crystallization

Study of experimental conditions. For the purpose of finding the optimum conditions to develop a kinetic procedure for the determination of citric acid based on its inhibition on lead carbonate crystal growth, the influence of pH and ionic strength on the reaction rate was investigated. Figure 5 shows the study of the pH influence. As can be appreciated when pH increased the citrate inhibitory capacity did not increase. This indicates that deprotonation of the citrate molecule does not affect its inhibitory capacity. On the other hand, when considering the influence of the ionic strength (Fig. 6), the citrate inhibition increases when ionic strength also increases. These findings seem to indicate that the citrate-lead carbonate interaction is not a simple electrostatic interaction. Thus, an initial pH value of 5.8 and an ionic strength of 0.05M were chosen to prepare the calibration graph.

Characteristics of the analytical methods. The fixed-time (5 min) and the induction period methods were applied to the potential (mV)–time curves, recorded in the presence of different amounts of citrate under selected conditions in order to obtain the calibration graph. The

Wine	2.80 ± 0.06	2.24 ± 0.04

*Average of 5 determinations.

results obtained are shown in Table 1. As can be seen the induction period method exhibited the best analytical characteristics. The selectivity was tested by obtaining the rate curves in the presence of several species that could potentially act as inhibitors of lead carbonate crystal growth. The results in Table 2 show few interferences, thus only pyrophosphate caused some important disturbance at concentrations similar to that of citrate. The proposed method exhibited a good calcium tolerance, even though this species forms precipitates with carbonate. It is evident that large amounts of species that could precipitate with lead ions must be avoided.

Applications

The proposed method was applied to citrate determination in drinks and in a pharmaceutical product. It was noteworthy that no matrix effects were observed when analysing such real samples. This permitted the methods to be applied without any previous treatment of the samples (except appropriate dilutions). Nevertheless, with the aim of confirming the reliability of the procedure, the standard addition method was applied and the results (Table 3) were compared with those obtained by a spectrophotometric procedure based on the formation of an Fe(III) yellow complex.⁴ As can be seen, there was fair agreement between the present and Fe(III) procedures, confirming the applicability of the method.

EXPLOITING THE HYDRODYNAMIC ASPECTS OF CONTINUOUS-FLOW SYSTEMS

ANGEL RÍOS and MIGUEL VALCÁRCCEL

Department of Analytical Chemistry, Faculty of Sciences, University of Córdoba, Córdoba, Spain

(Received 20 April 1991. Revised 27 June 1991. Accepted 28 June 1991)

Summary—An overview of the analytical potential of the hydrodynamic aspects of unsegmented flow systems is presented. Different approaches involving flow manipulation are described: stopped-flow methodologies, intermittent pumping, selecting-diverting carrier (reagent) streams, open-closed flow systems, flow reversal and flow gradient.

The flow-rate (q) is one of the major variables in flow manifolds. Every method developed is optimized for a characteristic flow rate, which is kept constant throughout analyses through the different available propulsion elements (usually peristaltic pumps). Few methods use variable flow-rates; the best known are probably those based on stopping a pump of the system. The stopped-flow and intermittent pumping techniques are the most representative in this respect.^{1,2} However, other methods based on manipulation of the flow-rate during the analysis step also offer major analytical possibilities as shown below.

The manipulation of hydrodynamic aspects in flow systems allows interesting analytical applications to be developed and a high degree of automation to be accomplished. Several of such applications were recently reported and could strongly influence the future of unsegmented flow analysers. This paper offers a systematic overview of the different modes involving manipulation of hydrodynamic features of flow systems, their applications and analytical potential.

The flow is usually manipulated in its pattern, direction or intensity; thus, pumps and valves are the two key devices allowing the hydrodynamic conditions of flow systems to be suited to one's requirements. Methodologies developed in this way involve stopping the flow, altering the flow pattern without changing the flow-rate, reversing the flow direction or establishing flow rate-gradients (Fig. 1).

Thus, to date, constant flow-rates have dominated the applications of continuous flow systems [Fig. 1(a)]:

$$q_{t_0}^n = \text{constant}$$

where t_0 is the time in which the analysis starts and t_n is the time in which the analysis finishes. Time stopped-flow modes have been used, alternating go/stop steps [Fig. 1(b)]:

$$q_{t_0}^1, q_{t_2}^2, \dots, q_{t_i}^i = q = \text{constant}$$

but

$$q_{t_1}^1, q_{t_3}^3, \dots, q_{t_{i-1}}^{i-1} = 0$$

Flow reversal methodology are based on an analogue flow pattern, but in this case [Fig. 1(c)]:

$$q_{t_0}^1, q_{t_2}^2, \dots, q_{t_i}^i = q$$

and

$$q_{t_1}^1, q_{t_3}^3, \dots, q_{t_{i-1}}^{i-1} = -q$$

Flow rate-gradients [Fig. 1(d)] are characterized by the continuous change of the flow-rate according to a linear function:

$$q = a*t + b \quad (t = \text{time}; a = \text{slope}; b = \text{intercept})$$

or a non-linear function:

$$q = F(t) \quad (\text{polynomic, exponential, etc.})$$

This variability is associated with constant flow gradients for the linear functions:

Flow-gradient = $Q = dq/dt = a = \text{constant}$ and non-constant flow-gradients for the other function, in general:

$$Q = d[F(t)]/dt$$

It is also possible to combine two or more of these methodologies by using different mathematical functions [Fig. 1(e)]. All these alternatives are discussed below.

Stopped-flow modes

The flow can be stopped either in the entire system or only in part of it. These two possibilities are related to stopped-flow methods and intermittent pumping, respectively.

Stopped-flow methods¹ involve an abrupt change in the flow-rate (q) from a $q \neq 0$ to zero. During the period over which $q \neq 0$ the sample plug is mixed with the reagent and transported to the detector [Fig. 2(a)]. When the flow is stopped, the chemical reaction on which the determination is based develops and the detector continuously monitors the signal-time curve. The slopes of the curves obtained are proportional to the analyte concentration. Experimentally, stopped-flow methods can be implemented by synchronizing injection with the pump operation, or by using a three-way valve between the injection unit and the detector. In both cases a timer or microcomputer is used to control and synchronize the operation of the valves and the pump. One of the most outstanding practical advantages of stopped-flow methods is the elimination of background signals from the blank or matrix as they are based on measurements of the signal change during the stop period. In this way, Růžicka and Hansen have developed interesting applications for the determination of sulphur dioxide in wine,³ alcohol in blood or serum without sample pretreatment,⁴ and glucose in serum.⁵ The reduction in the number and level of interfering species is another asset of the stopped-flow methods,⁶ as shown by Lázaro *et al.* with their catalytic-fluorimetric determination of trace copper.⁷

An alternative conception of the stopped-flow technique involves stopping the flow not as the sample reaches the detector, but in the tubing zone (reactor) [Fig. 2(b)], in order to increase the residence time and avoid the dispersion of the injected plug. A significant increase in sensitivity is obtained as a result of the longer reaction time without the dilution of the plug that would ensue with ordinary FIA systems. Several methods have been developed by using this methodology.⁸⁻¹⁰ The term "parallel analysis" used by Růžicka and Hansen¹ also allows the reaction time to be increased by using two or more reaction coils in parallel, but decreasing the dispersion of the sample; the sample is sequentially stored in parallel coils before reaching the detector. The same authors explained a parallel FIA analyser with eight 80- μ l storage

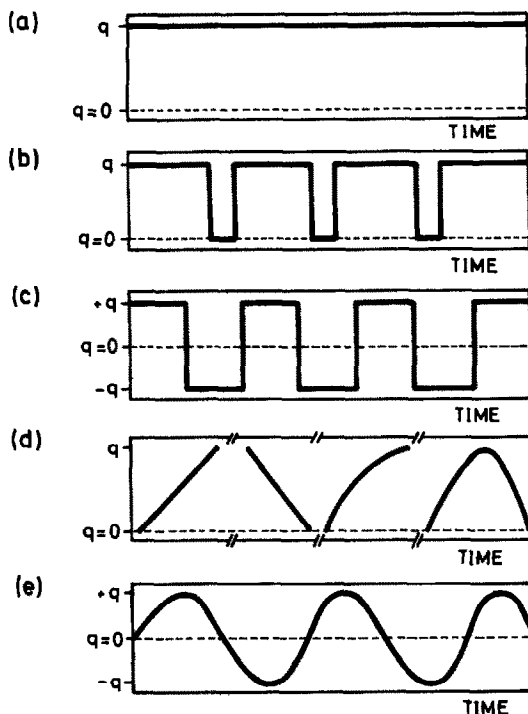

Fig. 1. Characteristic flow rate-time profiles for different methodologies: (a) constant flow-rate modes; (b) stopped-flow; (c) flow reversal; (d) flow-gradient and (e) flow-gradient/flow reversal coupling.

tubes in which several sample zones are stored in parallel (in a rotating drum) for a desired period of time.

An interesting assembly for simultaneous multideterminations by the stopped-flow technique was recently applied to the determination of free and bound sulphur dioxide in wines.¹¹ It uses a doubly stopped-flow manifold and can be considered to be a combination of the two above approaches [Fig. 2(c)]. Free sulphur dioxide directly reacts with formaldehyde and *para*-rosaniline to form a coloured compound which is monitored photometrically, whereas bound sulphur dioxide requires a prior hydrolytic release. Two sample plugs are injected simultaneously. Plug-1 merges with the *para*-rosaniline/formaldehyde mixture. The resulting merging stream is stopped when it reaches the detector, where the indicator reaction is monitored (determination of free sulphur dioxide). Simultaneously, plug-2 is stopped in a previous reactor coil, where its alkaline hydrolysis takes place. Then, on starting the pump, plug-1 is flushed out of the system and plug-2 is driven to the detector after merging with the reacting mixture. The second halting is effected as plug-2 reaches the detector and is followed by the

monitoring of the signal change with time, which is now made up of the contribution of free and bound sulphur dioxide. On starting the pump again, plug-2 is driven to waste.

Intermittent pumping involves stopping and starting one or several pumps from injection and the consequent temporary halting of one or several streams in the course of a determination. According to Růžička and Hansen,¹² two pumps can be incorporated into a manifold in a variety of combinations, especially if one considers different timings of their stop-go intervals, but, to date, little work has been done in this respect. The simplest application of a two-pump FIA system is to increase the sampling frequency by increasing the washout speed from the coils and from the flow-cell. Thus, the Brazilian FIA group, using commutation units, developed an improved procedure for the determination of nitrite in waters,¹³ and the turbidimetric determination of sulphate in natural waters and plant digests.¹⁴

Constant flow rate methodologies

FIA modes involving a constant flow-rate allow one to manipulate hydrodynamic aspects through selecting/diverting valves. These valves are of great interest to unsegmented flow methods.¹⁵

The six-way rotary valves usually employed in injection systems, converted to selecting-diverting valves by an alternative connection of different channels, probably represent the most useful alternative in this context. Olsen *et al.*¹⁶ employed a flow system incorporating three of these valves to preconcentrate heavy metals in a Chelex-100 minicolumn in a first step, followed by an elution step (in a reverse direction) to bring the eluted metal to a flame atomic-absorption detector. These readapted valves can also be used to co-ordinate two FIA subsystems by selecting the stream coming from one of them from a location prior to the detector¹⁷ [Fig. 3(a)]. In other applications, they perform selecting-diverting operations on flow streams.

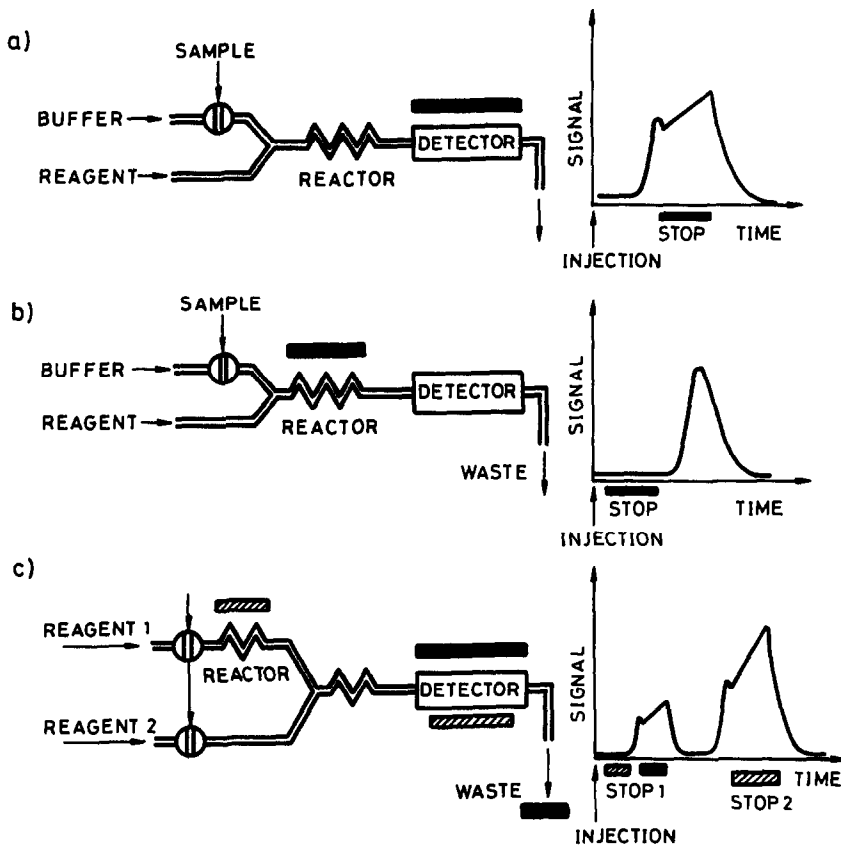

Fig. 2. Different approaches to the implementation of the stopped-flow technique: (a) Stopping the flow as the reacting plug reaches the detector. (b) Stopping the flow while the reacting plug is in the tubing zone (reactor). (c) Doubly stopped flow: first stop when plug-1 (■) reaches the detector and plug-2 (▨) is stopped in the reactor; second stop when plug-2 reaches the detector. [■ and ▨ indicate the position of the plug at the stop times].

One of the streams reaching the valve is selected at its exit; the other is driven to waste or allowed to reach a given point in the FIA configuration [Fig. 3(b)]. One such assembly was employed in speciation studies of chromium.¹⁸ The main channel, which contains sulphuric acid as carrier and into which the sample is injected, is merged with channel C from the selecting-diverting valve. The valve allows the selected stream [1,5-diphenylcarbazide (DPC) or oxidant] to reach the merging point. Initially, the oxidant stream (2) is fed to waste by the valve, whilst DPC (1) flows through channel C, so that the indicator reaction [DPC selectively reacts with Cr(VI)] can take place in the subsequent reactors. When valve selects the oxidant stream, DPC is driven to the second reactor. Thus, Cr(III) is oxidized to Cr(VI) in the first reactor, the indicator reaction takes place in the last reactor and total chromium is determined as a result.

Figure 3(c) shows an alternative possibility recently proposed for simultaneous kinetic determinations.¹⁹ Fe(III) and Co(II) form colourless

complexes with EGTA [reagent 1 in Figure 3(c)], which react at a different rate with PAR (reagent 2) in ligand-displacement reactions, to yield coloured complexes that are monitored photometrically at the same wavelength. In one position, the valve [Figure 3(c)], selects the sample-EGTA mixture and leads the PAR stream to point B (in this case the reaction only occurs along the last reactor). In the other position, the valve selects the PAR stream and leads the sample-EGTA mixture to point A. The reaction occurs now along the two reactors before detection. The two continuous signals obtained correspond to different reaction times and allow one to determine the Fe(III) and Co(II) present in the sample.

Six-way rotary valves adapted as selecting-diverting valves are a key to designing open-closed systems,²⁰ in which multidetection is carried out by repeatedly passing the reacting plug through a single detector. In this case, one of the streams reaching the valve is the carrier solution and the other is that coming from the detector (Fig. 4). In the open position [Fig. 4(a)],

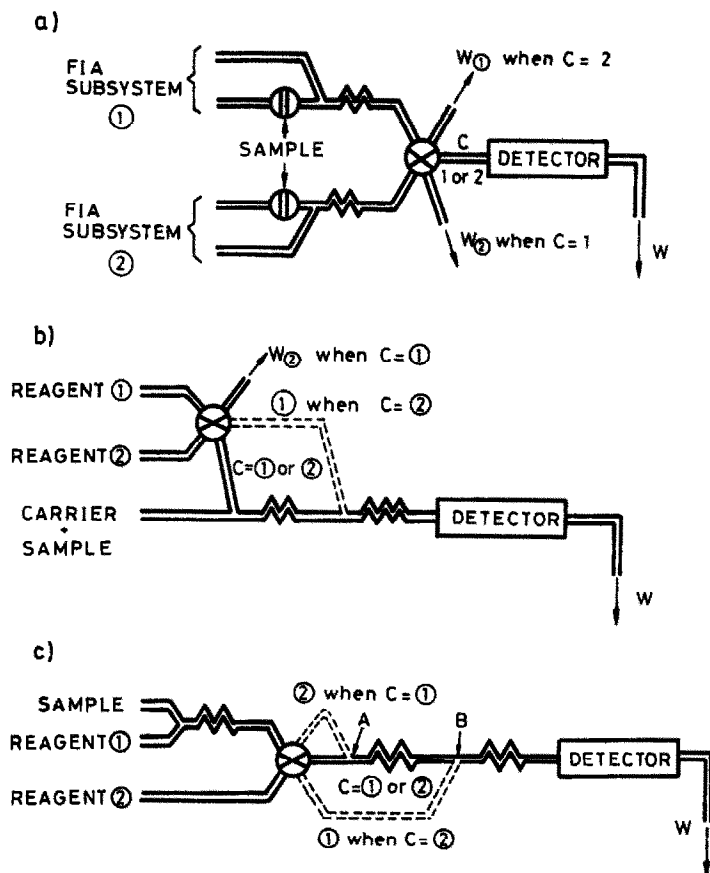

Fig. 3. Different uses of selecting-diverting valves to control the direction of one or two flow streams (see text). C = selected stream; W = waste. ⊗ selecting-diverting valve. ⊕ injection valve.

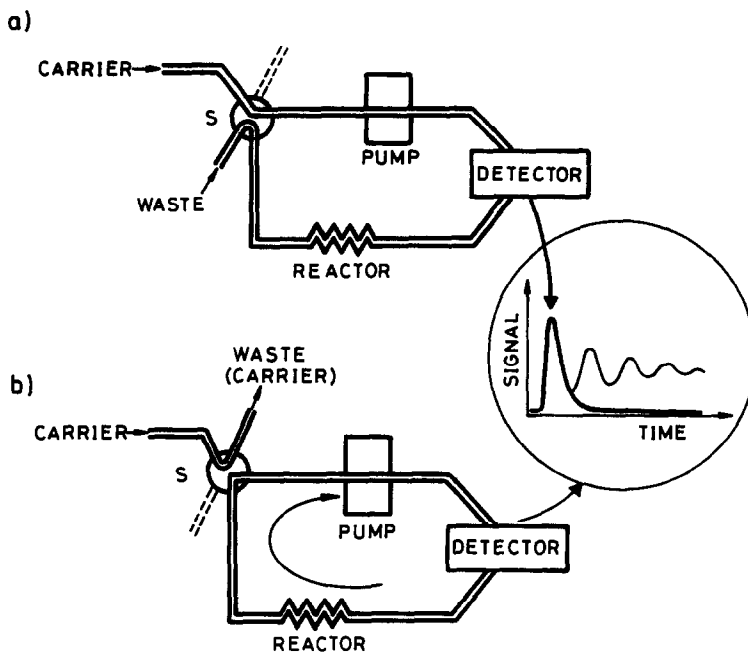

Fig. 4. Role of the selecting-diverting valve (S) in establishing open-closed flow systems. (a) Open-system position; (b) Closed-system position. The signal-time graph shows the response obtained by the detector in the open position configuration (■) (single FIA peak) and in the closed-system configuration (—) (multipeak recording), assuming no chemical reaction takes place (injection of a dye).

the valve selects the carrier solution and drives it to the detector, after which it goes to waste. In the closed-system position [Fig. 4(b)], a closed circuit is established as a result of the selecting-diverting valve selecting the channel coming from the detector. In this latter position the physical and chemical evolution of a sample injected into the flow can be monitored.

The analytical potential of open-closed flow systems has been clearly shown in the last few years. Their most remarkable applications are amplification methods,^{20,21} kinetic^{20,22} and speciation²³ studies, determination of reaction stoichiometries²⁴ and viscosity,²⁵ simultaneous kinetic determinations,²⁶ and determinations of enzymatic activities.^{27,28}

Flow reversal methodology

This methodology is based on the change of flow direction from $+q$ to $-q$, which establishes constant or non-constant time cycles. As pointed out by Betteridge *et al.*,²⁹ flow reversals can be implemented in three different ways (Fig. 5). One involves using two pumps [Fig. 5(a), pump A propels the carrier stream, pump B is unused. Then, the sample is injected and allowed to travel downstream into the reaction coil for a set time. Pump A is then stopped and pump B is started at the same

flow-rate to pull the sample plug back and through the detector and a second coil, and then out to waste. Therefore, this procedure requires two pumps.

The second procedure [Fig. 5(b)] uses a single pump and two valves, one for injecting the sample and the other as a selecting-diverting valve, which is the key to this procedure. First, the sample is injected into a carrier stream flowing at $+q$. After the entire plug has passed through the detector, the flow is reversed (at flow-rate $-q$) by switching the selecting-diverting valve. The peak is passed back through the detector, thereby establishing a cycle reversal.

The simplest procedure to perform flow reversal FIA involves using a single pump and changing the direction of the drum rotation [Fig. 5(c)]. This requires electronic³⁰ or computer³¹ control.

The reversal of the flow direction in continuous automatic analysers was first achieved by the air-segmented mode proposed by Technicon. In the last few years this approach has been used in unsegmented continuous flow analysis (*e.g.*, to control the dispersion and automatic variation of reaction coil length).²⁹ The reaction coil length plays a major role in determining the characteristics of any FIA system and significantly interacts with other factors. Other FIA variables (flow-rate, inner tubing diameter, *etc.*)

play their part in determining the amount of dispersion that a sample plug undergoes as it traverses a flow-injection manifold. Flow reversal may be used in conjunction with choice of flow-rate and sample size to determine the amount of dispersion that a sample undergoes. The flow can be reversed not only by allowing the entire plug to pass through the detector but also by "sampling" a preset zone of the plug, so that the reversal cycles all take place within one FIA peak.³⁰ In a way, this mode can be considered a peculiar variant of the sampling zone mode proposed by Krug *et al.*,³² but intended to obtain a multiplex recording that defines kinetic profiles (Fig. 6) that one can readily manipulate through the flow-rate, sample zone and cycle time.

Toei used flow reversal FIA for the determination of glucose in clinical samples with a

single-³³ and double-pump system.³⁴ The specific enzymatic reaction of glucose oxidase with β -D-glucose was exploited, but straight calibration graphs could not be obtained when the reaction time was short or when using a stopped-flow FIA procedure. A long period (5 min) was needed for the reaction with end-point rate assay. However, in a conventional single-line manifold with sufficiently long tubing to obtain the required delay, the peak analysis time was rather long because of the large dispersion of the samples in the long reaction tubing. The kinetic FIA procedure in which two peaks are obtained by flow reversal offers better results, probably as a consequence of more efficient mixing that in turn results in a higher reaction rate. Moreover, by measuring the difference between the two peaks for a sample, the blank signal of the samples can also be eliminated. Recently, Wang

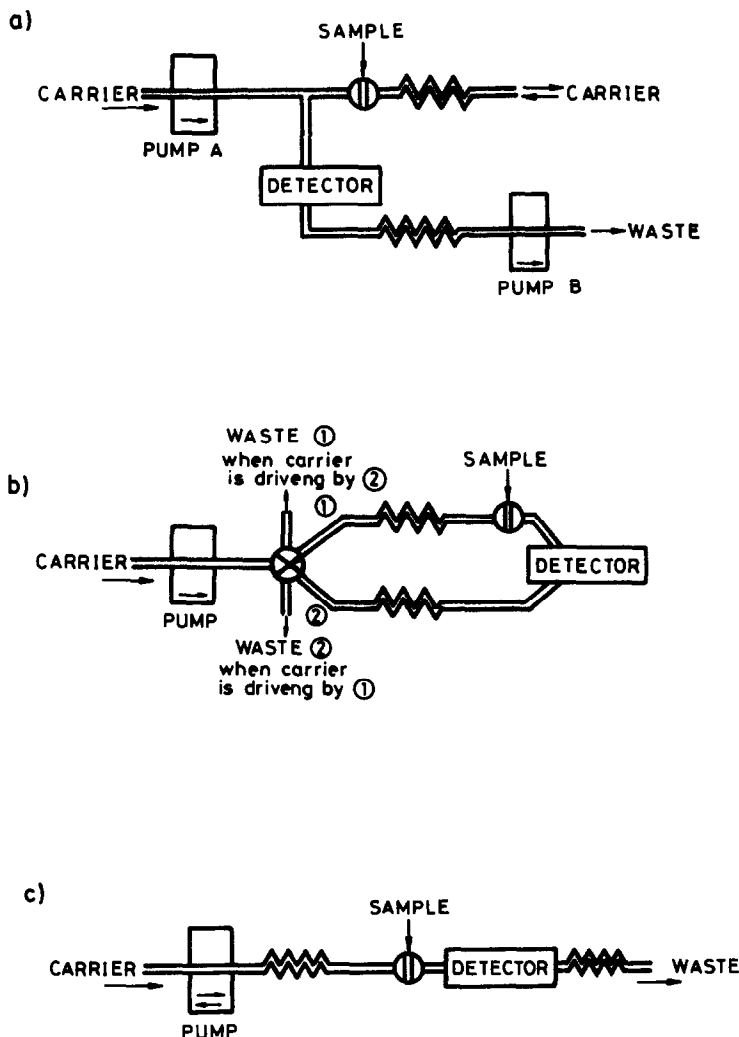

Fig. 5. Different procedures for applying the flow-reversal methodology: (a) by means of two pumps, (b) a selecting-diverting valve or (c) a single pump reversing the direction of the drum.

et al. also showed the use of repeated reversals of the flow direction to significantly improve the sensitivity of flow-injection stripping voltammetric measurements.³⁵ The plating efficiency and the resulting stripping peak currents were greatly enhanced thanks to the repeated passage of the same sample plug over the working electrode, which addressed the time restriction of conventional flow-injection stripping measurements.

The direct analysis of gas samples by flow injection is another interesting approach afforded by flow reversal methods implemented without a debubbler.³⁶ The sample is injected into a liquid carrier-reagent stream and the repeated passage of the liquid zone close to the gas-liquid interface nearest to the detector is monitored to obtain a signal-time multipeak recording. The method lends itself readily to automation and speeds up the analytical process as no prior collection in an absorbent solution or on a filter is required.

Flow reversal is also the foundation of a new methodology for performing liquid-liquid extraction processes in automatic unsegmented flow systems based on simplified configurations with no segmenter or separation units.³⁷ The key to this methodology is the placement of the detector in the loop of an injection valve, which is filled with the organic phase, whereas the aqueous phase containing the analyte makes the carrier. The process (reversal cycles as the two liquid-liquid interfaces are created by switching

the injection valve) is repeated as many times as required to achieve a suitable solute transfer between the two liquid-liquid interfaces; and is favoured by the formation of a thin layer of organic phase on the Teflon coil. The phases are never segmented or separated, and the organic phase plug is continuously monitored. Therefore, the solute transfer between the two phases, and the dispersion of the solute into the organic phase, can be continuously monitored. Some kinetic aspects of extraction in continuous flow systems and the behaviour of different ion pairs have been studied.³⁸ Simultaneous kinetic determinations by flow reversal/liquid-liquid extraction have also been reported.^{31,38}

Clark *et al.* have recently used flow-reversal flow-injection analysis for FIA titrations.³⁹ They employed a single-line manifold for the titration of strong acids (HCl, H₂SO₄ and H₃PO₄). The main advantages were the flexibility in operation and the increase in sensitivity.

Recently, Růžička and Marshall used the movement of the piston of a syringe-type pump coupled with an eight-port valve to generate flow reversal steps and allowing sequential injections in the flow system.⁴⁰ The synchronization between the movement of the piston and the valve allowed sample zone injection, reagent addition, mixing, measurement, and ejection of the reacted mixture took place by a combination of forward and reversed flow steps. The concept of sequential injection analysis, based on the mixing of the sample with a reagent in order to

Fig. 6. Multipeak recordings obtained by the flow reversal methodology showing the kinetic profiles defined by their maxima and minima: (a) without chemical reaction; (b) with chemical reaction, by monitoring the formation of a product, or (c) the disappearance of a reactant.

produce a measurable response, was explained through the random walk model, being defined as a new concept for chemical sensors, process analysis and laboratory assays by the authors.

Flow-gradient technique

A flow rate-gradient (flow-gradient) can be defined as the variation of the flow-rate over a given period of time. It has been scantily used in FIA,^{41,42} but is well-known and widely employed in HPLC to increase resolution. Two FIA references describe the effect of flow-gradients on the more characteristic FIA parameters. In one, the flow-gradient was created by means of a hydrostatic head in a single channel.⁴¹ The flow-rate range obtained was limited to 0.7–2.4 ml/min. In later work, a multifunction pump delivery system was used to establish several flow patterns.⁴² The effects of these flow patterns on systems with and without chemical reaction were evaluated. One of the most important applications in this context is the washout effect (Fig. 7), whereby a higher sampling frequency is obtained. Thus, if a positive linear flow-gradient is established as the sample is injected, the peak-width can be dramatically decreased, the baseline restoration time shortened, the time lapse between consecutive injections minimized and the peak-height increased. Agudo *et al.* recently obtained similar results by using some non-constant flow rate-gradients.⁴³ Similar results can be obtained by operating with intermittent pumping, as was reported by Růžička and Hansen¹² and then reviewed by Krug *et al.*,⁴⁴ but in this mode it is necessary to use

two peristaltic pumps (one to propel the reagent stream and another to flush the system with the wash solution).

Different types of gradients were obtained by using a microcomputer which controlled (through an interface) the motion of the peristaltic pump drum.⁴⁵ These flow-gradients can be used to establish concentration-gradients in an easy, fast and accurate way (*e.g.*, to create pH-gradients allowing the photometric determination of acidity constants of compounds active in the UV-visible spectral region with no pH measurements,⁴⁵ and carry out acid–base titrations⁴⁶). Other linear concentration gradients can be created in flow systems for several analytical purposes. The stoichiometries of coloured complexes can be determined and complexometric titrations carried out by establishing ligand concentration gradients.⁴³

An interesting flow pattern combining variable flow-rates and flow reversal modes has been proposed by Růžička *et al.*⁴⁷ establishing sinusoidal flow functions by a cam-driven computer-controlled piston pump. This system controls two syringes (one for the sample and the other for the reagent) and an eight-port valve, generating alternate load and measurement cycles. The authors give an important number of advantages of the sinusoidal flow pump, its main disadvantages are low sampling frequency and the device being less flexible than a peristaltic pump. The establishment of this and other similar flow patterns through a conventional peristaltic pump controlled by a computer may provide higher flexibility, avoiding the refilling reservoir requirements.

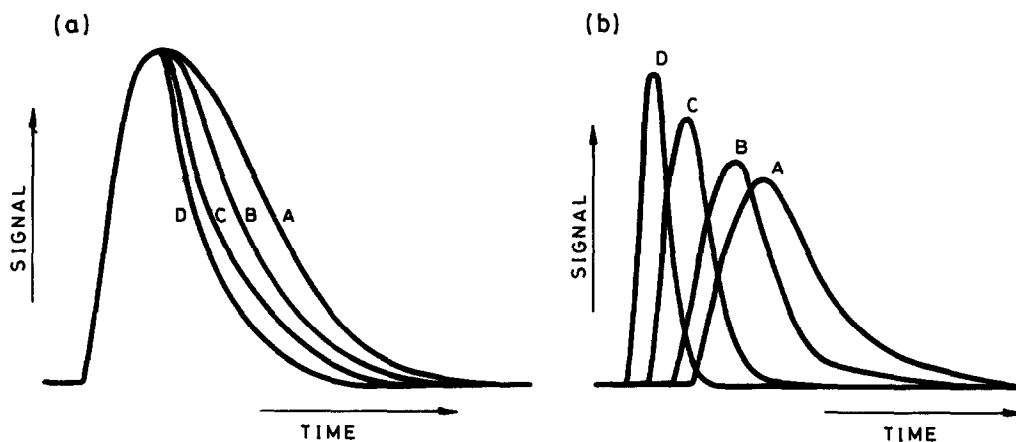

Fig. 7. Washing effect obtained by using positive linear flow-gradients applied at the residence time of FIA peak (a), and starting simultaneously with the injection of the sample (b). The flow-gradient increases from A to D in both cases.

Table 1. Analytical applications of methodologies based on hydrodynamic aspects of unsegmented flow systems

Methodology	Key element to perform the methodology	Analytical applications
Stopped-flow	Peristaltic pump (valves)	Kinetic studies Blank correction Reduction of interferences Increase of sensitivity Simultaneous determinations
Intermittent pumping	Peristaltic pump	Increase of sample frequency
Open-closed flow systems	Selecting-diverting valve	Improvement of sensitivity Kinetic studies Determination of viscosity Determination of stoichiometries Simultaneous determinations Speciation studies Enzymatic activities
Flow reversal	Peristaltic pump Selecting-diverting valve	Dispersion manipulation Improvement of sensitivity Kinetic studies Simultaneous determinations Direct gaseous sample analysis Liquid-liquid extraction
Flow-gradients	Peristaltic pump	Increase of sample frequency Establishment of concentration-gradients Determination of acidity constants Determination of stoichiometries

Another interesting and useful application of non-constant flow patterns was proposed by Růžička and Flossdorf by using variable forward flow with immobilized enzymes.⁴⁸ They employed designs with stopped flow, flow reversals and variable flow for the spectrophotometric determination of glucose with glucose oxidase and peroxidase immobilized on controlled-pore glass in the same reactor. The variable flow pattern was fast/slow/fast cycles to increase both the contact time and contact volume between the sample zone and the immobilized enzymes without increasing the zone dispersion or flow resistance.

CONCLUSIONS

The analytical potential of methodologies based on hydrodynamic features of flow systems offers interesting possibilities briefly discussed in this paper and summarized in Table 1. Pumps and valves are the key elements to these methodologies; they can be controlled by electronic timers or microcomputers (through active interfaces) in order to accomplish the maximum possible degree of automation. In addition to the dynamic foundation of these methodologies, most of them involve kinetic aspects that can be exploited for analytical purposes. Other interesting possibilities are the manipulation of dis-

persion (flow reversal) and sampling frequency (intermittent pumping and flow-gradient techniques). The flow reversal mode has introduced a new conception in flow manipulation with major repercussions on the automation of analytical processes. Thus, direct gas sample analyses and liquid-liquid extraction with no segmenter or separation units are two recent examples in this context. The flow-reversal/flow-gradient coupling is another potentially interesting approach that will offer important applications.

(Received 16 May 1991. Revised 26 June 1991. Accepted 26 June 1991)

Summary—Biosynthetic human Growth Hormone (B-hGH) is a protein comprising 191 amino acids. The molecular weight is 22,125 and the isoelectric point is close to pH 5. Due to the ready availability of closely related analogues B-hGH was used as a model protein thus allowing for the demonstration and evaluation of the high resolution capability of high performance capillary electrophoresis (HPCE). The same apparatus was used throughout the experiments and an optimum signal-to-noise ratio was found at 200 nm. Linearity was observed between peak area, retention time and the hGH concentration or sample introduction time. Baseline separation of hGH, desamido hGH and didesamido hGH was obtained. Examples showing analysis with 1 million theoretical plates per meter, high speed separation, simultaneous analysis of multiple samples, sample stacking, hGH tryptic digest, and hGH lysate are reported. The use of electrophoretic velocities instead of apparent velocities for peak identification is illustrated.

High performance capillary electrophoresis (HPCE) is an analytical technique which permits rapid and efficient charge and/or size based separations of various substances in an automated format. HPCE descends from various electrophoretic and chromatographic techniques, but in its present form it is most often dated back to the 1981–1983 papers by Jorgenson and coworkers.^{1–3}

Since then there has been a growing interest in the technique as judged from the exponentially increasing number of annual publications. At present more than 1000 papers have been published, and the third international meeting on HPCE was held in February 1991 with great success. Reviews of the technique have been presented by Karger *et al.*,⁴ Wallingford and Ewing⁵ and Kuhr,⁶ among others.

Analysis of biomolecules is among the most promising application areas^{7–17} of HPCE (*e.g.*, purity control and identification of byproducts) as high efficiency separations of proteins, peptides, nucleic acid fragments and poly-

saccharides may be obtained. Hence, in the years to come, HPCE is expected to become a major supplement to already existing analytical methods in the biotechnological industries.

Biosynthetic human Growth Hormone (B-hGH) comprises 191 amino acids (Fig. 1), the molecular weight is 22,125 and the isoelectric point is close to pH 5. The hGH is concerned with somatic growth and is produced in the anterior pituitary by the eosinophil or α -cells.¹⁸ As a pharmaceutical, hGH has so far been used primarily in the treatment of retarded growth and dwarfism caused by underproduction of hGH in the growth period.

In this paper B-hGH will be used as a model protein in order to illustrate some of the characteristics of HPCE. By choosing hGH as the model protein the ready availability of closely related analogues allows for the demonstration and evaluation of the high resolution capability of HPCE.

EXPERIMENTAL

Reagents

Biosynthetic human Growth Hormone (B-hGH) was from Novo Nordisk A/S

*Author for correspondence.

(Gentofte, Denmark). The B-hGH samples contained various preservatives. Tricine (N-[Tris-(hydroxymethyl)methyl]glycine) and sodium chloride were purchased from Fluka Chemie AG (Buchs, Switzerland). Citrate and CAPS [3-(Cyclohexylamino)-1-propanesulphonic acid] buffers were from Applied Biosystems (Foster City, CA, USA). Fused-silica capillaries were obtained from Polymicro Technologies (Phoenix, AZ, USA). Peak areas were integrated on a Shimadzu C-R5A integrator (Kyoto, Japan).

Procedures

All the experiments were performed on an Applied Biosystems (ABI) Model 270A CE instrument (Foster City, CA, USA). The fused-silica capillaries had an internal diameter of 50 μm and an outer diameter of 192 μm . Most of the capillary from the introduction end to the detector (termed the effective capillary length) was surrounded by an airbath kept at a constant temperature. Samples were introduced by means of a 4.95-in Hg (16.8 kPa) vacuum. The x-axis values of each electropherogram are

Fig. 1. Primary sequence of human Growth Hormone (hGH). The protein comprises 191 amino acids, the molecular weight is 22,125 and the isoelectric point is close to pH 5.

in minutes. Other experimental conditions are given in the figure legends.

RESULTS AND DISCUSSION

Basically, carrying out HPCE analysis is very simple. A typical sequence comprises four cycles:

- (1) The capillary is flushed with *e.g.*, 0.1M sodium hydroxide, thus ionizing the silanol groups of the fused-silica capillary inner surface.
- (2) The capillary is filled with running buffer.
- (3) Sample is introduced by siphoning or by applying a pressure or voltage gradient between the two capillary ends.
- (4) HPCE analysis/electrophoretic separation of the analytes is initiated by applying a voltage (typically 50–500 V/cm) between the two capillary ends, which are immersed in vials containing the running buffer.

Fig. 2. High speed separation of hGH and deamidated hGH. The total analysis time is less than 3 min. Peak EO marks the electroosmotic flow (flow of neutrals). The x-axis scale is in minutes, while the y-axis scale is in arbitrary absorbance units. Experimental conditions: Buffer; pH 8.0, 10mM tricine, 20mM NaCl. Sample; 0.2 mg/ml B-hGH in distilled water and allowed to degrade several weeks at ambient temperature, introduced for 0.5 sec by 16.8 kPa vacuum. Detection at 200 nm, 0.5 sec risetime. Capillary length 55 cm (total), 30 cm (effective). 20 kV applied. Temperature; 30°.

Fig. 3. Baseline separation of hGH, desamido and didesamido hGH. Peak EO marks the neutrals (electroosmotic flow). The x-axis scale is in minutes, while the y-axis scale is in arbitrary absorbance units. Experimental conditions: Buffer; pH 8.0, 10mM tricine. Sample; 0.1 mg/ml B-hGH in distilled water and allowed to degrade several weeks at ambient temperature, introduced for 1.0 sec by 16.8 kPa vacuum. Detection at 200 nm, 0.5 sec risetime. Capillary length 100 cm (total), 75 cm (effective). 20 kV applied. Temperature; 27°.

Detection is most often accomplished on-line by means of UV light,^{19–22} though other detection means have been applied (*e.g.*, fluorescence,^{23–29} mass spectrometry,^{30–36} amperometry,³⁷ conductivity).^{20, 38–39} The detector signal *vs.* analysis time takes the form of an electropherogram. Figure 2 shows the separation of hGH and desamido hGH in pH 8.0 tricine buffer. During deamidation hGH acquires an additional negative charge. This makes separation of hGH and its deamidated form very suitable for capillary electrophoresis. The figure illustrates that high speed separations can be performed in HPCE. However, while total analysis time is less than 3 min, the resolution of hGH and desamido hGH is poor. If more time is allowed for the two peaks to separate, baseline resolution is obtained. This is shown in Fig. 3 for another partly degraded hGH sample. Didesamido hGH elutes shortly after and is baseline resolved from the desamido hGH peak. With a typical analysis time of 5–15 min HPCE can be used on-line to monitor reactions with time constants in the minutes to hours range.

In the free solution capillary electrophoresis (FSCE) mode,⁷ analytes migrate by the combined action of electrophoresis and electroosmosis. Electroosmosis is usually explained

by the Gouy–Chapman–Stern model.⁴⁰ At pH values above *ca.* 2 the silanol groups of the fused-silica capillary inner surface are partly ionized when in contact with the buffer solution. Electroneutrality is attained by hydronium cations in the bulk solution. This results in a bulk flow towards the cathode when voltage is applied. The electroosmotic flow increases with increasing pH and decreasing buffer ionic strength.⁴⁰ At neutral pH values the electroosmotic flow is much stronger than most peptide/protein electrophoretic velocities. Hence, positively as well as negatively charged peptides/proteins can be analysed in the same run as they are both swept towards the detector end (cathodic end) of the capillary. Peak EO in Figs. 2–3 marks the electroosmotic flow. The numerical v_{EO}/v_{EP} ratio (v_{EO} = electroosmotic velocity, v_{EP} = electrophoretic velocity) was *ca.* 5. In Fig. 2 the electroosmotic flow was *ca.* 15 cm/min or *ca.* 0.3 μ l/min, which equals 155 ml/year!

Mostly due to viscosity changes,^{41,42} the electroosmotic velocity increases by 2–3% per °C. The electrophoretic velocity also increases at increasing temperatures. A linear v_{EO} -T and v_{EP} -T relationship was found in the range 25–55°.

When a new running buffer is introduced, an “equilibrium” between the new buffer and the capillary surface must be established. During the equilibrium period (which can last for minutes, hours or even days) the buffer affects

Fig. 4. Electroosmotic (v_{EO} , cm/sec), electrophoretic (v_{EP} , cm/sec), and apparent ($v_R = v_{EO} + v_{EP}$, cm/sec) velocity *vs.* the run number after the capillary had been thoroughly flushed with 0.1M NaOH. The velocity is given relative to the anode. As the negatively charged hGH molecules migrate towards the anode (opposite the electroosmotic flow), negative velocity values are obtained. Experimental conditions: Buffer; pH 8.0, 50mM tricine. Sample; 0.5 mg/ml B-hGH in distilled water, introduced for 0.5 sec by 16.8 kPa vacuum. Detection at 200 nm. Capillary length 50 cm (total), 25 cm (effective). 5 kV applied. Temperature; 30°.

Fig. 5. Signal (S, Peak area/ t_R , arbitrary units), noise level (N, arbitrary units) and S/N ratio on the ABI Model 270A detector *vs.* wavelength. An optimum hGH signal-to-noise (S/N) ratio was obtained at 200 nm. Experimental conditions: Buffer; pH 8.0, 10mM tricine. Sample; 0.1 mg/ml B-hGH in distilled water, introduced for 1.0 sec by 16.8 kPa vacuum. Variable wavelength 190–280 nm, 0.2 sec risetime. Capillary length 70 cm (total), 50 cm (effective). 20 kV applied. Temperature; 30°.

the charge density of the capillary wall and thereby the electroosmotic flow. An example of this is shown in Fig. 4. A 50- μ m inner diameter capillary was rinsed thoroughly with 0.1M sodium hydroxide. First manually by means of a syringe, followed by a 20.35-in Hg (68.9 kPa) vacuum for *ca.* 30 min after the capillary had been aligned in the CE instrument. Immediately following this rinsing procedure 6 identical runs were carried out in a pH 8.0 tricine buffer. Prior to each run the capillary was flushed with 0.1M sodium hydroxide for 2 min by the 20.35-in Hg vacuum. (This results in *ca.* 3 μ l of the sodium hydroxide solution being sucked through the capillary. The internal volume of the capillary was *ca.* 1 μ l). Figure 4 depicts the measured v_{EP} , v_{EO} and v_R ($v_R = v_{EO} + v_{EP}$, the apparent velocity) values. The negatively charged hGH molecules migrate towards the anode while the electroosmotic flow is towards the cathode. As the velocity is written relative to the anode the hGH v_{EP} values are negative. While the v_{EO} value is not constant in the initial runs, v_{EP} is almost constant already from the first or second run. Hence, if absolute v_{EP} values are used instead of the v_R values, velocity based peak identification can be performed already from the first runs. As the residuals are not randomly distributed around the mean v_R value there is no point in comparing v_{EP} and v_R relative standard deviations (RSDs) of the six runs.

The ratio of hGH to total hGH and desamido hGH peak area per retention time was, however, randomly distributed around the mean with a RSD equal to 0.6% for the six runs.

The peptide bond shows a maximum absorbance at 193 nm. However, if the detector wavelength is set below 200 nm the noise level increases dramatically with an optimum signal-to-noise (S/N) level being governed by the quality of the UV absorbance detector. A series of experiments was performed on the ABI Model 270A CE instrument at 190, 195, 200, 205, 214, 225, 254 and 280 nm. The hGH concentration was 0.1 mg/ml. An optimum S/N ratio of 76 was obtained at 200 nm (Fig. 5). Changing the wavelength from 214 nm to 200 nm improved the S/N ratio by more than 50% with this specific detector.

In order to examine whether peak area per retention time (t_R) or peak height should be used for quantitative HPCE analysis two sets of experiments were performed. (Peak area is inversely proportional to the velocity of the analyte zone when it passes the detector. Division of peak area by the analyte zone retention time accounts for this difference.)

In the first set of experiments, sample was introduced for 5 sec (~ 12 nl) while the hGH concentration was varied in the range 7.8–1000 $\mu\text{g/ml}$. Peak area/ t_R and peak height were plotted *vs.* hGH concentration (Fig. 6). Linearity between hGH concentration and peak area/ t_R was observed in the range 16–1000 $\mu\text{g/ml}$. At the lowest hGH concentration, 7.8 $\mu\text{g/ml}$, there was a positive deviation from linearity, which may be ascribed to the integration of hGH and monodesamido hGH as one peak. When plotting peak height *vs.* hGH concentration linearity was only observed in the

Fig. 6. Peak area/ t_R (arbitrary units) and peak height (arbitrary units) *vs.* the hGH concentration. Linear regression of the area/ t_R points in the range 16–1000 $\mu\text{g/ml}$ gave a correlation coefficient equal to $r = 0.998$. Experimental conditions: Buffer; pH 8.0, 10mM tricine, 20mM NaCl. Sample; 7.8–1000 $\mu\text{g/ml}$ B-hGH in distilled water, introduced for 5.0 sec by 16.8 kPa vacuum. Wavelength; 200 nm, 1.0 sec risetime. Capillary length 109 cm (total), 90 cm (effective). 30 kV applied. Temperature; 30°.

Fig. 7. Peak area/ t_R (arbitrary units) and peak height (arbitrary units) *vs.* sample introduction time (sec.). Linear regression on all peak area/ t_R data points gave a correlation coefficients equal to $r = 1.000$. Experimental conditions: Buffer; pH 8.0, 10mM tricine. Sample; 0.1 mg/ml B-hGH in distilled water, introduced for 0.2–15.0 sec by 16.8 kPa vacuum. Wavelength; 200 nm, 1.0 sec risetime. Capillary length 100 cm (total), 75 cm (effective). 15 kV applied. Temperature; 30°.

range 16–250 $\mu\text{g/ml}$. The reason for the negative deviation from linearity above 250 $\mu\text{g/ml}$ hGH is interpreted to be an effect of sample overload, which causes increased dispersion. Sample overload, which is explained by the use of the Kohlrausch regulation function,^{43,44} occurs when the analyte ion (hGH) concentration cannot be neglected relative to the background electrolyte concentration. Increasing the hGH concentration decreased the number of theoretical plates (the theoretical plate number was higher by a factor of *ca.* 7 at 7.8 $\mu\text{g/ml}$ compared to 1000 $\mu\text{g/ml}$ hGH).

In the second set of experiments the hGH concentration was kept constant at 0.1 mg/ml while the introduction time, t_{inj} , varied in the range 0.2–15.0 sec (~ 0.5 –35.6 ml). Linearity was observed between peak area/ t_R and t_{inj} in the entire t_{inj} range (Fig. 7). When peak height was plotted *vs.* t_{inj} , linearity was only observed in the range 0.2–1.0 sec (Fig. 7). In this set of runs the deviation from linearity is caused by the sample plug originally introduced being a major contributor to the total analyte zone peak width.⁴⁵ Hence, at long introduction times the analyte peak changes appearance from gaussian towards plug shape. The analyte zone length can be compressed by the use of stacking conditions. This is exemplified in a subsequent paragraph.

Based on the analysis of a 0.02 mg/ml hGH sample solution and a detector risetime of 1.0 sec the detection limit was calculated to be 19 pg of hGH (~ 850 attomole). While the mass sensitivity of UV detection in general is higher in HPCE than HPLC, the concentration

sensitivity is poorer as the analyte in HPCE is detected in a very small sample volume (typically 1–10 nl).

One of the attractive features of HPCE is the possibility of obtaining high efficiencies with theoretical plate numbers in the order of 10^5 – 10^7 per meter,¹ *e.g.*, for proteins and peptides. In Fig. 8 one million theoretical plates per meter was obtained for the hGH peak. Sample was introduced for 0.2 sec thus introducing a volume of *ca.* 0.5 nl. One of the reasons for the high number of theoretical plates is that the electroosmotic bulk flow profile is much closer to plug flow than to laminar flow.^{45–47}

The dispersive factors in HPCE can be grouped into six additive variance terms,⁴⁵ axial and radial diffusion, sample zone length, detector size, chromatographic effects and sample overload. All six terms are effected by temperature changes.

Dispersion due to chromatographic effects is caused by electrostatic attractions between the analyte molecule and the negatively charged fused-silica capillary surface. In general proteins and peptides have a strong tendency for adsorption to the capillary wall, thus resulting in severe peak tailing or even total adsorption. The protein-capillary wall coulombic inter-

Fig. 8. 1,000,000 theoretical plates (N) per meter was obtained for hGH at 0.2 sec introduction. *Ca.* 0.5 nl was introduced. N was calculated as $5.54 \cdot (t_R/\omega_{1/2})^2$, where t_R is the hGH retention time, while $\omega_{1/2}$ is the peak width at half hGH peak height. The x-axis scale is in minutes and the y-axis scale is in arbitrary absorbance units. Experimental conditions are as for Fig. 7 except that sample was introduced for 0.2 sec.

Fig. 9. The number of theoretical plates (N) decreases exponentially with increasing sample introduction time (t_{inj} , sec). Experimental conditions are given in Fig. 7.

actions can be minimized in several ways. If analysis is performed at a pH value above the isoelectric point of the protein, it is negatively charged thus being repelled from the capillary wall. That approach has been used in most of the experiments reported here as the hGH isoelectric point is *ca.* pH 5, while analysis was performed at pH 8.0. Lowering the pH of the running buffer to a value where most of the negative charges are titrated off the capillary wall eliminates most of the electrostatic interactions even though the protein is positively charged.^{9,10} Another approach is to coat the capillary surface either through covalent bonding of chemical agents to the capillary wall^{9,48} or dynamically.^{12,49–52} Dynamic coating of the capillary is performed by the addition of ionic species to the buffer solution. This results in a competition between the cationic ions and the analyte molecules for the adsorption sites on the capillary surface.

Huang *et al.*⁵³ discussed that the introduction term of the total variance could only be neglected at very small sample plug lengths. This is demonstrated in Fig. 9. The introduction time of a 0.1 mg/ml hGH sample was varied in the range 0.2–15.0 sec (\sim 0.5–35.6 nl). The number of theoretical plates decreases exponentially as a function of increasing introduction time. At a 0.2-sec introduction time the introduction term was calculated to contribute *ca.* 7% of the total variance, while at a 15.0-sec introduction time the contribution was *ca.* 99%.⁴⁵

One way of improving the number of theoretical plates is to stack the originally introduced sample zone. Sample stacking (concentration of the analyte zone) is the process occurring when voltage is applied along the capillary tube containing a sample plug with a lower specific

conductivity than the surrounding running buffer. As the electric field strength is inversely proportional to the specific conductivity of the liquid, the field strength is higher along the sample plug than to the running buffer. In this way the electrophoretic velocity, which is proportional to the field strength, increases and the ionic analyte zone is narrowed. This "reversed dispersion" is termed stacking.⁴⁵ An example of stacking is shown in Fig. 10. A hGH sample was either diluted in distilled water (stacking conditions) or in the running buffer (non-stacking conditions) to a concentration of 0.1 mg/ml. At stacking conditions the ratio of the specific conductivity of the running buffer to that of the sample zone was *ca.* 16. Inherently, at non-stacking conditions the corresponding ratio was 1. Identical runs were carried out only differing by the two samples. Figures 10(a) and (b) show part of the two electropherograms with identical co-ordinate scalings. Turning from non-stacking to stacking conditions the number of theoretical plates was improved from 113,000 to 345,000 per meter.

Due to the low dispersion during HPCE analysis the voltage can be shut off for short periods of time with no significant loss of peak efficiency. In Fig. 11(a) the sample was introduced and normal HPCE analysis was carried out with a retention time of *ca.* 8.8 min. In Fig. 11(b) the applied voltage was shut off every 5 min and a new sample introduced. This means that there were always several hGH sample zones in the capillary. No significant peak broadening caused by the power shut-off period was observed. Hence, multiple samples can be run simultaneously in the capillary (provided the sample components elute closely) thus reducing the average analysis time.

At Novo Nordisk A/S recombinant hGH is produced intracellularly by *E. coli* cells. During the fermentation period the microorganisms produce hGH extended with 4 amino acids (4aa-hGH). During down-stream processing the 4 amino acids are removed thus yielding a molecule having an amino acid sequence, which is identical to that produced in humans. Figure 12 is an electropherogram showing baseline resolution of B-hGH and 4aa-hGH. Furthermore, monodeamidated forms of hGH and 4aa-hGH are also seen in the electropherograms.

During the down-stream processing after the hGH fermentation period the cells are lysed and

filtrated. Figure 13 shows an electropherogram of a fermentation broth sample after 4aa-hGH had been "extracted" with acetic acid and filtrated. 4aa-hGH was spiked to the sample. The running buffer was a pH-11.0 CAPS solution. The retention time of the 4aa-hGH peak was *ca.* 14 min but no baseline separation of 4aa-hGH and the other sample components was obtained. In order to use this method for reliable quantitative calculations further improvements in resolution should be made. The figure illustrates that HPCE can be used (on-line) to monitor, *e.g.*, products and metabolites

Fig. 10. A lower specific conductivity of the sample solution relative to the running buffer results in sample stacking when voltage is applied. The analyte zone is reduced in length and a higher number of theoretical plates is obtainable. (a) Stacking and (b) non-stacking conditions. The x-axis scale is in minutes, while the y-axis scale is in arbitrary absorbance units. Experimental conditions: Buffer; pH 8.0, 10mM tricine, 25mM NaCl. Sample; 0.1 mg/ml B-hGH in (a) distilled water (stacking) or (b) running buffer (no stacking), introduced for 3.0 sec by 16.8 kPa vacuum. Detection at 200 nm, 1.0 sec risetime. Capillary length 100 cm (total), 75 cm (effective). 5 kV applied. Temperature; 27°.

in fermentation broths. In general, only filtration or centrifugation is required as sample pretreatment.

Trypsin splits peptide bonds on the carboxyl side of lysine and arginine residues.⁵⁴ Trypsin digested hGH contains 21 fragments, two of which are crosslinked by disulphide bridges.⁵⁵ The fragments range in size from 147 to 3763D. Reversed phase HPLC (RP-HPLC) is often used to make a chromatographic fingerprint of

the tryptic digest peptide mixture thus yielding, *e.g.*, purity information on the hGH molecule. Fingerprints can also be obtained by FSCE. As analytes are separated according to fundamentally different principles in RP-HPLC and FSCE the two methods are orthogonal,^{14,15} and analytes which are not separated by RP-HPLC might be separated by FSCE and vice versa. If no differences are found it increases the confidence level of the first result. If differences

(b)

Fig. 11. Multiple sample analysis. Due to low dispersion in FSCE the voltage can be shut off for short periods of time with no significant loss of peak efficiency. The x-axis scale is in minutes, while the y-axis scale is in arbitrary absorbance units. In (a) the sample was introduced and analysis was carried out with a retention time of *ca.* 8.8 min. In (b) the applied potential was shut off every 5 min and a new sample introduced. Hence, multiple samples were run simultaneously in the capillary. Experimental conditions: Buffer; pH 8.0, 10mM tricine. Sample; 0.1 mg/ml B-hGH in distilled water, introduced for 1.0 sec by 16.8 kPa vacuum. Detection at 200 nm, 0.5 sec risetime. Capillary length 100 cm (total), 75 cm (effective). 20 kV applied. Temperature; 27°.

Fig. 12. Separation of hGH (peak A), desamido hGH (peak B), hGH extended with 4 amino acids (4aa-hGH, peak C) and desamido 4aa-hGH (peak D). Peak EO marks the neutrals. The x-axis scale is in minutes, while the y-axis scale is in arbitrary absorbance units. Experimental conditions: Buffer; pH 8.0, 10mM tricine, 20mM NaCl. Sample; 0.1 mg/ml B-hGH and 0.2 mg/ml 4aa-hGH in distilled water, introduced for 1.0 sec by 16.8 kPa vacuum. Detection at 200 nm, 1.0 sec risetime. Capillary length 105 cm (total), 80 cm (effective). 20 kV applied. Temperature; 27°.

Fig. 13. 4aa-hGH fermentation broth. 4aa-hGH was "extracted" by the addition of acetic acid and filtrated before being subjected to HPCE analysis. The x-axis scale is in minutes, while the y-axis scale is in arbitrary absorbance units. Experimental conditions: Buffer; pH 11.0, 10mM CAPS. Sample; 4aa-hGH lysate after filtration. 4aa-hGH was spiked to the sample, introduced for 1.0 sec by 16.8 kPa vacuum. Detection at 200 nm, 1.0 sec risetime. Capillary length 109 cm (total), 90 cm (effective). 30 kV applied. Temperature; 27°.

Fig. 14. Tryptic digest of hGH. Nothing was done in order to identify the individual peaks in the electropherogram. The x-axis scale is in minutes, while the y-axis scale is in arbitrary absorbance units. Experimental conditions: Buffer; pH 2.5, 20mM citrate. Sample; tryptic digest of B-hGH in pH 7.8 50mM tris, 2mM CaCl₂, introduced for 1.0 sec by 16.8 kPa vacuum. Detection at 200 nm, 1.0 sec risetime. Capillary length 109 cm (total), 90 cm (effective). 25 kV applied. Temperature; 30°.

are discovered it suggests further action maybe needed subject to the circumstance.

A 1-ml volume of 1 mg/ml hGH sample was digested with 10 μ l of 1 mg/ml trypsin for 6 hr at 37° and subjected to FSCE analysis. Figure 14 is an electropherogram of the trypsin digested hGH sample obtained in a pH 2.5 buffer. Nothing was done to identify the individual peaks of the electropherograms (*e.g.*, by spiking analysis) or to improve separations.

CONCLUSIONS

We have looked at some of the characteristics of HPCE by illustrative example electropherograms of "pure" as well as fermentation broth samples. The characteristics include:

(i) Low sample and reagent consumption. Typically: 1–10 nl sample for introduction; 50–150 ml reagent per year.

(ii) High speed separations. Typically: 1–15 min analysis time.

(iii) High separation efficiencies. Typically: 10^4 – 10^6 theoretical plates per meter.

(iv) High mass (but poor concentration) sensitivity. hGH: 20 pg (1 fmole).

(v) Non-toxic chemicals are usually employed.

(vi) Experimental conditions are changed by changing the running buffer rather than changing the column.

(vii) The presence of a strong electroosmotic flow towards the cathode in untreated fused silica capillaries.

Furthermore the following parameters were examined:

(i) Linearity between hGH concentration/introduction time and the peak area per retention time/peak height.

(ii) Absorbance at various wavelengths.

(iii) Stacking as a means to increase the number of theoretical plates.

(iv) Equilibrium period when introducing a new buffer.

We found that one of the major advantages of HPCE is the possibility of obtaining high efficiency separations (of *e.g.*, large molecules, fermentation broth) at high speed, which makes it an obvious on-line analytical technique.

PERMEATION-SOLID ADSORBENT SAMPLING AND GC ANALYSIS OF FORMALDEHYDE

CHANSA MUNTUTA-KINYANTA and JAMES K. HARDY*

Department of Chemistry, The University of Akron, Akron, Ohio 44325-3601, U.S.A.

(Received 9 April 1991. Revised 25 June 1991. Accepted 26 June 1991)

Summary—A passive method with membrane permeation sampling for the determination of time-weighted-average (TWA) concentration of formaldehyde in air is described. The sampling device was constructed by affixing an unbacked dimethyl silicone membrane to the base of a glass tube and by sealing the top with a rubber stopper. Formaldehyde permeates the membrane and reacts with 2-(hydroxymethyl)piperidine (2-HMP) coated on the surface of XAD-2. Sampling times from 15 min to 8 hr have been used. The formaldehyde-oxazolidine produced is thermally desorbed and determined by a packed column gas chromatograph equipped with a flame ionization detector (FID). The response of the monitor is directly proportional to the external concentration of formaldehyde over the concentration range 0.050–100 ppm. The permeation constant (the slope of the permeation curve) of the membrane is $0.333 \mu\text{g ppm}^{-1} \cdot \text{hr}$, and the detection limit of the method is 0.03 ppm for an 8-hr sampling period. Relative humidity (RH) (35–94%), temperature (0–82°) and storage period (0–25 days) do not affect the permeation process for sample collection. Moreover, potential chemical interferences, 10 ppm acetone or acrolein, respectively, have no detectable effect on the process. The method gives TWA concentration directly from the measurements, and the equipment is economical and convenient for personal or multi-location sample collections.

Exposure to formaldehyde in air results from a number of commercial and non-commercial users.¹⁻⁸ Due to the toxic, carcinogenic and mutagenic effects of formaldehyde,^{2-4, 6-9} the Occupational Safety and Health Administration (OSHA) has established new limits: (a) an 8-hr time-weighted-average (TWA) action level of 0.5 ppm; (b) a permissible exposure limit (PEL) of 1 ppm and (c) a 2 ppm 15-min short term exposure limit (STEL).¹⁰ These changes have led to increased interest in determining formaldehyde.

One particular difficulty is the sampling method. Although methods using real-time area monitors, impingers, and active adsorbents are currently used for the collection of formaldehyde, they are not convenient for personal monitoring.¹¹⁻¹³ The major drawbacks of the recommended active sampling method¹⁰ are the use of a toxic solvent desorption, CS₂ in benzene,¹⁴ and the lack of the sensitivity needed for the determination of nanogram levels of formaldehyde.^{12,15-18}

Permeation sampling has been used for sampling vinyl chloride,¹⁹ hydrogen sulfide,²⁰ and ethylene oxide in air,²¹ as well as phenols²²

and six volatile priority pollutants from aqueous solutions.²³ The technique relies on the selective permeability of materials through a polymeric membrane, where the rate of permeation is directly proportional to the external concentration of the permeating gas, or:

$$M_t = KC_{\text{ef}}t \quad (1)$$

where M_t is the mass of formaldehyde (μg) collected at any time; C_{ef} is the external concentration of formaldehyde in ppm; t is sampling time in hr and K is the permeation constant which is characteristic of the membrane. Moreover, the magnitude of the response (M_t) depends on interferences, the reactivity of the analyte with the reagent used, the stability and the detectability of the product as well. By exposing calibrated samplers for known sampling periods, it is possible to determine the TWA of formaldehyde, or:

$$C_{\text{TWA}} = M_t/Kt \quad (2)$$

The conversion of carbonyl compounds to oxazolidines^{24,25} with 2-HMP has been used for quantification of acrolein²⁶ and acetaldehyde;²⁷ the gas chromatographic determination detected no evidence of formaldehyde interferences.^{26,27} Other conversion reagents suffer

*Author for correspondence.

interferences and/or the instability of the products.²⁹⁻³¹ This paper reports a (2-HMP)-coated solid sorbent/permeation sampling method followed by gas chromatography determination of formaldehyde in air. The effects of relative humidity, temperature, storage period and interferences on the sampling technique are also reported. The method is simple, sensitive, efficient and allows a TWA level to be directly obtained from the measurements of formaldehyde. The sampling device, which responds within 3 min, is economical, lightweight and lends itself to repeated uses for personal or area monitoring.

EXPERIMENTAL

Apparatus

The investigation used a previously described^{21,22} sampling chamber and sampling device. The membrane affixed to the sampling device (Fig. 1) was a 0.025-mm thick unbacked polymeric dimethylsilicone membrane (General Electric Company, Schenectady, New York). The sorbent throughout the study was Amberlite XAD-2, a nonionic polymeric porous resin, 80/100 mesh size (Supelco, Inc., Supelco Park, Bellefonte, PA, U.S.A.), coated with 2-(hydroxymethyl)piperidine (2-HMP) (Aldrich Chemical Company, Inc., Milwaukee, Wisconsin USA). A Supelco thermal desorption unit, thermal tube desorber (TTD) Model 850, and desorption sample tubes (DST), 6 mm o.d. \times 4 mm

i.d. \times 11.50 cm, were used for the introduction of samples into the GC. A Hewlett-Packard gas chromatograph Model 5890A equipped with a flame ionization detector (FID) and a Supelco stainless steel packed column, 10% UCON 50-HB-5100/2% KOH on 80/100 chromosorb W-AW, 15 m \times 2 mm i.d., were used for the determination of formaldehyde in the collected sample. A water bath, a 300-ml round-bottomed flask with three \$24/40 ground glass joints, a 20-cm glass tube, and gas dispersion tubes were used to produce formaldehyde from paraformaldehyde. An Airguide Instrument Company humidity indicator Model 605 was required for monitoring the humidity of the system. A 4 cm \times 30 cm glass tube, a rotary evaporator and a Thermolyne Sybron Corporation furnace, TEMCOMETER Model CP-12915, were necessary for drying the adsorbent.

Reagents

Adsorbent preparation. Dry acetone (100 ppm) and dry acrolein (100 ppm) lecture size cylinders were purchased from the Akron Gas Specialities, in Akron, Ohio. All other chemicals were American Chemical Society (ACS) certified to be more than 95% pure, and used without purification. Paraformaldehyde was purchased from the Aldrich Chemical Company. About 250 g of XAD-2 were placed in a 300-ml round-bottomed evaporating flask to which 25% (w/w) of 2-HMP and 200 ml of methanol were added. The solution was vigorously shaken for several minutes to mix well and let sit for 8 hr at ambient temperature. A rotary evaporator was used to remove the solvent. The adsorbent was then transferred to a 30-cm glass tube and was continuously purged with a 20 ml/min helium flow at 80°, to remove residual formaldehyde and impurities. The sorbent was routinely analyzed for the detection of residual formaldehyde and/or contaminants, which were not specifically identified, from the chemical treatment of the adsorbent.

Procedure

Standard formaldehyde atmosphere. A temperature controlled depolymerization of paraformaldehyde was used to produce standards of formaldehyde. The components of the apparatus were: (1) a standard 300-ml round-bottomed flask with three \$24/40 ground glass joints as the mixing chamber; (2) a glass tube containing paraformaldehyde, 20 cm long, fitted to the middle joint of the flask as the diffusion

Fig. 1. Apparatus for sampling. Top, sampling device: (1) rubber stopper (2) glass tubing (3) adsorbent, (4) single backed dimethylsilicone membrane. Bottom, exposure chamber: (5) holes to support sampling devices (6) aluminum box.

tube; (3) two Fisher scientific dispersion tubes, extra course frit, 12 mm × 22 mm frit × 8 mm o.d., were used as the inlet and outlet, respectively, and prevented the carrier gas from disturbing the paraformaldehyde in the diffusion tube. A range of concentrations of formaldehyde up to several ppm was produced by immersing the diffusion tube in a water bath at a known temperature (30–60°). By passing a metered flow of dry air over the diffusion tube, 20–500 ml/min, a series of formaldehyde standards was produced. The flow rate of the dilution air was calibrated with both a flow sensor of the gas chromatograph and a bubbler flowmeter, and was routinely sampled with a syringe for the determination of the produced formaldehyde.

Sampling and analysis. The calibration of sampling devices was conducted at 22° and 27% RH. Two hundred milligrams of the treated Amberlite XAD-2 were transferred to a sampling device and exposed to a standard of formaldehyde in the sampling chamber for a sampling period ranging from 0.25–8 hr. Formaldehyde was trapped on the XAD-2 via a reaction between 2-HMP and formaldehyde forming a stable, slightly volatile product, which was readily detected by an FID. After sampling, the sample was spiked with formamide as an internal standard, transferred to a thermal desorption tube and analyzed for formaldehyde. The parameters of the instrument were as follows: sample desorption set at 300° for 2 min; the gas chromatograph initial temperature was 140° for 2 min, which was then increased to 200° at 16°/min. The flow-rate of the helium carrier gas was 20 ml/min. Figure 2 shows a typical chromatogram resulting from the above settings.

Fig. 2. A representative chromatogram: the parameters of the instrument are described in the text. The peaks are the oxazolidines of: (1) formaldehyde (2) acrolein (3) acetone and (4) formamide; and (5) 2-(hydroxymethyl)piperidine.

Table 1. Membranes investigated; the concentration of formaldehyde was 10 ppm, temperature 21° and RH = 35%

Membrane	Relative response (%) at steady state*	Response time, min
Unbacked dimethylsilicone	100	2.67
Single backed dimethylsilicone	87	33
Silicone Polycarbonate	65	57
Polyethylene	53	64
Polyvinylfluoride	9	83
Mylar	ND	$t > 120$
Teddlar	ND	$t > 120$
Polystyrene	ND	$t > 120$
Polyethylene terephthylate	ND	$t > 120$

*The highest response made was 100%.

ND = not detected.

t = time

RESULTS AND DISCUSSION

Permeation through membrane.

Initial permeation evaluation involved membrane screening and the calibration of sampling devices. A constant flow of formaldehyde was produced by a thermal decomposition of paraformaldehyde. By using a flow-through permeation cell,^{22,23} it was possible to determine the steady state permeation time. Results of membrane screening (Table 1) and the study of the breakthrough time (Fig. 3) indicate that the unbacked dimethylsilicone membrane has high formaldehyde permeability, with the lag time equal to 2.67 ± 0.08 min. The rapid transport is attributed to the flexibility of the silicon-oxygen-silicon chain and the absence of crystallinity in this membrane material.³²⁻³⁴ Additional advantages of the membrane are high thermal stability, high separation factors for many gases, inertness, the lack of pin holes and hydrophobicity.³²

Figure 4 shows a representative calibration plot of the sampling devices for the methods, which covers the concentration range from 0.050–100 ppm, for sampling periods over

Fig. 3. Breakthrough time.

Fig. 4. The detection or calibration curve.

0.25–8 hr. The result indicates that the rate of permeation of formaldehyde through the unbacked dimethylsilicone membrane is directly proportional to the external concentration of the toxin and sampling time. The calibration constant for the method, K , determined as the slope of the calibration curve, has been calculated to be $0.333 \mu\text{g ppm}^{-1} \cdot \text{hr}$, with the correlation coefficient being 0.99998. Representative results for TWA and K values are shown in Table 2.

Factors affecting sampling. Figure 5 is a representative result of environmental including stability studies, which indicated there were no detectable losses or response variations for the factors and the ranges covered. Temperature and RH variations, the presence of other chemi-

cals in air, and the storage period can be expected to alter device performance. To determine the effects of temperature, the mixing and sampling chambers were placed in a temperature controlled bath, and the exposure study was performed with a 1.89-ppm standard for 4 hr over the range 0–82°. The analysis was conducted as stated above. The result showed no detectable variations for the temperature range covered.

Fig. 5. A typical result of environmental factors and stability studies.

Studying the influence of RH, from 30–95%, on the permeation of formaldehyde involved adding moisture to the above dry standard of formaldehyde, and sampling for 4 hr. The relative humidity of the system was continuously monitored with the humidity indicator placed at the outlet of the sampling chamber. The determination was conducted as measured earlier, after 30 min of equilibration. Again, no change in the relative humidity was observed (Fig. 5).

Any chemical capable of reacting with formaldehyde and/or 2-HMP, thereby depleting the derivatizing reagent or degrading the membrane, is a possible interference. Similarly, any compound having the same retention time as formaldehyde and giving a detector response is a potential analytical interference. Analytical interference can usually be overcome by adjusting the gas chromatographic parameters to resolve component peaks. As acetone and acrolein contain a functional group (carbonyl) present in formaldehyde, sampling devices were exposed to a flow containing 20 ppm formaldehyde and up to 10 ppm acetone or acrolein, respectively. After 30 min of equilibration, sample collection and determination were performed as described above. Spiked samples showed a recovery above 99%, indicating there were no detectable losses of formaldehyde due to interferences (Fig. 5), which supports other researchers' findings.^{26,27}

To examine sample stability, samples were collected with the above standard and sampling period, and stored at ambient temperature in sealed thermal desorption sample tubes for a period of 0–25 days. At daily intervals, the determination was performed on a sample set (3 samples) as described above. The results showed samples can be stored up to 25 days without any deterioration (Fig. 5).

CONCLUSION

A permeation sampler for formaldehyde with Amberlite XAD-2 coated with 2-HMP has been found to be an effective sampling device. The calculated permeation constant (the slope) for a prototype monitor was $0.333 \mu\text{g ppm}^{-1}\text{hr}$, within the concentration range 0.050 ppm–100 ppm. The detection limit for an 8-hr sampling period was determined to be $0.039 \mu\text{g}$. Storage time and environmental variables have no detectable effects on the sampling rate or on the collected sample, *i.e.*, recovery was better than 99% at the 95% confidence limit. The lag

time of the sampling device and the minimum sampling time tested are about 3 and 15 min, respectively, which indicate the rapid response of the sampler. TWA concentration can be obtained directly from the calibration curve. The sampling method and the monitor can be an alternative technique for the determination of exposure to organic vapors in air.

(Received 19 March 1991. Revised 31 May 1991. Accepted 17 June 1991)

Summary—A new, sensitive and rapid spectrofluorimetric flow-injection method, is presented for the determination of trace levels of aluminium based on the formation of a fluorescent complex between aluminium and 5,7-dibromo-8-quinolinol (DBQ) and its extraction into diethylether ($\lambda_{exc} = 400$ nm, $\lambda_{em} = 525$ nm). Experimental conditions such as pH, reagent concentration, flow-rates, sample volume, extraction coil length, *etc.*, have been optimized for on-line and batch procedures. The detection limits are 1 ppb and 0.3 ppb for batch and on-line systems respectively. The coefficient of variation is 3.0% at the 4 ppb level for the FIA system. To remove interferences and to preconcentrate aluminium, a chelating resin microcolumn which was able to selectively complex Al(III) and was obtained by immobilizing Chromotrope 2B on AG1-X8 ion-exchange resin, was incorporated into the FIA system. The proposed method was successfully applied to determine aluminium in tap water, food samples and dialysis solutions.

Aluminium has been proven to be toxic to certain "at-risk humans",¹ including patients with chronic renal failure. The main sources of aluminium for the human organism are foods and drinking water as well as dialysis fluids for people undergoing renal treatment; therefore, monitoring of this element in such materials is necessary. Since aluminium is toxic at very low concentrations for the above-mentioned group of humans, the availability of sensitive analytical methods for this element is essential.

Several methods are available to determine aluminium in biological materials and dialysis fluids; none being fully satisfactory. In particular, atomic-absorption spectrometry with electrothermal atomization (ETAAS) is widely used²⁻⁴ for sample solutions with concentrations below 30 ppb. However, large discrepancies still exist in the results obtained² most probably due to contamination problems. Furthermore, the high salt content in dialysis concentrates interferes with the determination of Al by this technique.⁵ Other alternatives are the ICP-AES and FAAS techniques, which are less sensitive and need a preconcentration of the analyte.^{5,6}

Fluorimetric methods are very sensitive and require readily available instrumentation. Particularly sensitive are those based on the complexation with Morin⁷ and with 8-hydroxyquinoline-5-sulphonic acid (HQS) in the presence of surfactants,⁸ although both lack adequate selectivity. In the Morin method better selectivity is achieved by using a previous extraction with isobutyl methyl ketone. However, the reaction between Morin and aluminium is slow and does not allow the automatization of the process.

The method based on complexing with HQS in micellar medium does not require extraction which is an important advantage, but to overcome selectivity problems, the use of a complex high pressure liquid chromatography system is needed.⁹

As already mentioned, both selectivity and sensitivity problems need to be considered to satisfactorily determine aluminium in the required biological samples and dialysis concentrates. We thought that passing the sample through a chelating resin that could selectively retain the aluminium could simultaneously solve the two mentioned problems and therefore allow the analysis of the samples under study. It has been reported that aluminium is in fact strongly complexed by sulphonated azo dyes

*Author for correspondence.

Fig. 1. Scheme of the FIA system for removing interferences with a chelating microcolumn

Fig. 1. Scheme of the FIA system for removing interferences with a chelating microcolumn

possessing dihydroxylic groups.¹⁰ In particular, 1,8-dihydroxy-2-(*p*-nitro-phenylazo)-naphthalene-3,6-disulphonic acid (Chromotrope 2B) forms an extremely strong complex with Al(III) allowing its separation from the rest of the matrix¹¹ and simultaneously preconcentrating it.

If a microcolumn of chelating resin were prepared, it could be inserted in a flow-injection system with the known advantages of increased speed of analysis and decreased risk of sample contamination thus improving reproducibility of the results.

This paper describes a new, rapid, selective and sensitive method that allows the determination of aluminium in biological samples and dialysis concentrates. The method is based on the separation of the element in a chelating microcolumn followed by a spectrofluorimetric determination of the complex Al(III)-5,7-dibromo-8-quinolinol extracted into diethylether. In addition the conditions for automatization of the process by FIA have been established and samples of food, drinking water and dialysis concentrates analysed.

EXPERIMENTAL

Apparatus

A Perkin-Elmer Model MPF-44A Spectrofluorimeter equipped with a Hellma flow-cell (optical path 1 cm; inner volume 18 μ l) was used connected to a Perkin-Elmer 56 recorder.

Two Omnifit injection valves (six-way) were employed. Teflon tubes (i.d. 0.5 mm) and connectors were employed to build the reaction coils and transmission lines. A displacement flask (Omnifit), a laboratory-made phase separator and a teflon column of 35-mm length and 5-mm i.d. were also used.

Reagents

Aluminium standard solution (1000 μ g/ml). Prepared by dissolving aluminium metal (Merck) in 2% hydrochloric acid.

5,7-Dibromo-8-quinolinol (DBQ) (Flucka) solution, 0.05% (w/v) in diethylether (Carlo Erba).

2-Methyl-8-quinolinol (Scharlau) solution, 0.05% (w/v) in diethylether (Carlo Erba).

5-Sulphonic-8-quinolinol acid (Merck) solution, 0.05% (w/v) in demineralized water.

AG1-X8 anion-exchange resin, 100-200 Mesh (Bio-Rad).

Chromotrope 2B (Aldrich).

Acetate buffer carrier solution 0.05M (pH = 3.5-5.5).

Buffer 0.5M hexamethylenetetramine (HMTA) (Merck). Acidified with perchloric or hydrochloric acid (Merck) to pH = 5.5-7.5. All chemicals were of analytical reagent grade and demineralized water (Milli-Q) was used throughout.

Procedures

Batch method. A volume of solution containing up to 100 ng of aluminium was placed in a polypropylene test tube. DBQ solution (0.5 ml

of 0.5% (w/v) DBQ in acetone) and 1 ml of $\text{H}_2\text{MTA}^+/\text{HMTA}$ buffer (pH = 6.0) were added, and the final volume of the aqueous phase was made up to 2.5 ml with water. After adding 2.5 ml of diethylether, the mixture was shaken for 2 min and the fluorescence intensity of the organic extract was measured ($\lambda_{\text{exc}} = 400$ nm, $\lambda_{\text{em}} = 525$ nm) against a blank prepared in parallel.

Flow-injection method. The system for on-line preconcentration with a microcolumn is shown in Fig. 1.

The procedure is as follows: A 185- μl volume of the sample solution containing less than 100 ng/ml was injected from the first injection valve (B_1) into the acetate buffer carrier solution, pH = 5.5, at 0.6 ml/min.

This solution passed through a microcolumn (C) filled with immobilized Chromotrope 2B, in which the aluminium was retained. To remove the immobilized aluminium, 100 μl of 0.1M hydrochloric acid was injected from the second injection valve (B_2). The carrier solution was mixed with the organic phase [0.05% DBQ in diethylether from the displacement flask (G)] in segmenter (D), whose flow-rate was 0.36 ml/min. The alternative aqueous and organic phase segments were separated in the membrane separator (F) after passing through the reaction coil (E). The organic phase passed through the flow-cell (H) and the fluorescence peaks were recorded.

Full-column preparation. Chromotrope 2B was immobilized on the anionic AG1-X8 resin by soaking 1 g of wet resin in 25 ml of a solution containing about 6.6×10^{-3} millimoles of Chromotrope 2B. The suspension was shaken until the aqueous phase became colourless (30 min).

The chelating resin was placed in a microcolumn made of a teflon tube 35 mm long and 5 mm i.d. The column end-caps were teflon screws; a fibre glass membrane of 3- μm pore size to prevent loss of resin particles was used.

RESULTS AND DISCUSSION

Batch method

The properties to complex Al shown by three different derivatives of 8-hydroxyquinoline (5,7-dibromo, 2-methyl and 5-sulphonic acid) were studied in order to select the one showing the best analytical characteristics. Different organic media (n-butanol, chloroform and diethylether) were tested for extraction of the complex. The last, in spite of its notoriously inconvenient

Fig. 2. Uncorrected excitation and emission spectra of Al(III)-DBQ complex (I, III) and DBQ blank (II, IV). Conditions: [Al(III)] = 0.1 ppm; [DBQ] = 0.5% (w/v) in acetone; $\text{H}_2\text{MTA}^+/\text{HMTA}$ (pH = 6.0) medium.

handling, was chosen because it appreciably increased fluorescence intensity. The complex showing the best sensitivity was Al(III)-5,7-dibromo-8-quinolinol (DBQ) extracted into diethylether.

The Al(III)-5,7-dibromo-8-quinolinol complex in diethyl ether showed maximum fluorescence intensity at 525 nm when excited at 400 nm. Uncorrected excitation and emission spectra are given in Fig. 2.

To determine the optimum extraction pH, several regulatory media were tested: HCl (pH = 1), HAc/Ac⁻ (pH = 3.5-5.5), $\text{H}_2\text{MTA}^+/\text{HMTA}$ (pH = 5.5-7.5), $\text{NH}_4\text{Cl}/\text{NH}_3$ (pH = 8.0-9.0) and NaOH (pH > 10). The results given in Fig. 3 show that the optimum pH range is 5.5-7.5. It was noted that the presence of HMTA significantly increased the sensitivity compared to that obtained with HAc/Ac⁻ and therefore $\text{H}_2\text{MTA}^+/\text{HMTA}$ was chosen as optimum medium.

The effect of ionic strength was studied by adding increasing amounts of ammonium nitrate and sodium chloride as strong electrolytes to a solution containing 0.02 ppm aluminium. It was found that up to an ionic strength of 0.25M, the fluorescence intensity of the complex remained constant, and that above this value it decreased.

Changes in temperature over the range 0-25° had no effect on the fluorescence complex.

The analytical characteristics are as follows. The calibration graph is linear from 1 to 75 ppb.

Fig. 3. Effect of pH on fluorescence intensity for: (I) DBQ blank and (II) Al(III)-DBQ complex. pH was adjusted with (□) HCl, (●) HAc/Ac⁻, (○) H₂MTA⁺/HMTA, (■) NH₄⁺/NH₃ and (△) NaOH. Conditions: [Al(III)] = 50 ppb; [DBQ] = 0.05% (w/v) in diethylether.

The coefficient of variation, evaluated from ten independent determinations, was 6% at the 30 ppb level. The limit of detection was 1 ppb. A study of several potential interfering species showed that elements usually present at relatively high concentrations, such as Zn, Ca, Mg and Fe, seriously interfere. Thus, in spite of the fact that the proposed (batch) method is very sensitive, its selectivity is very low.

Flow-injection method

Both chemical and physical experimental conditions, affecting Al-DBQ formation and extraction into the FIA system were optimized.

Fig. 4. Fluorescence emission of Al(III)-DBQ complex with different volumes and concentrations of HCl eluant (■) 0.01M, (○) 0.05M, (●) 0.1M, (□) 0.5M. Conditions: [Al(III)] = 50 ppb; [DBQ] = 0.05% (w/v) in diethylether; HAc/Ac⁻ 5.10⁻³M (pH = 5.9) medium.

Table 1. Optimum values of FIA system physical and chemical variables. Liquid-liquid extraction followed by fluorimetric determination of Al(III) with DBQ

Variable	Optimum value
pH	6.5*
Regulating medium	0.5M H ₂ MTA ⁺ /HMTA*
DBQ concentration in diethylether	0.05% (w/v)
Aqueous flow-rate	0.62 ml/min
Organic flow-rate	0.36 ml/min
Injection volume	185 μl
Reactor length	300 cm
Coil shape	82 knots
Reactor inner diameter	0.5 mm
Segmenter angle	45°
Phase separator	Membrane

*Acetate buffer 0.05M pH = 5.5 was used when a chelating microcolumn was inserted into the FIA systems.

The optimum medium was, as in the batch method, HMTA buffer solution at pH 5.5–7.5. The optimum DBQ concentration in diethylether was 0.05%.

To choose the optimum organic and aqueous flow-rates, the range 0.3–2.1 ml/min was tested and 0.62 ml/min and 0.36 ml/min were chosen for aqueous and organic flow-rates respectively, using 185 μl as optimum sample injection volume. The effect of different lengths of extraction coil, inner diameter and shape were also tested, the optimum extraction coil having a 300-cm length, 0.5-mm inner diameter and 82 knots. It was found that knots in the extraction coil increased the yield of extraction by 300%. Optimum values for physical and chemical variables are summarized in Table 1.

The selectivity of the FIA method is substantially higher than that batch method, but not so high that it can be applied to determine Al(III) in complicated matrices such as food and dialysis fluids.

To increase the selectivity of the method, a chelating resin microcolumn was inserted in the FIA system (Fig. 1). Chromotrope 2B immobilized on the AG1-X8 anion exchange resin was used. This reagent is able to retain the aluminium present in the sample as a chelate. Previous studies¹¹ showed that this chelating resin completely separates aluminium from lead, nickel, cadmium, calcium and magnesium, although copper and iron were in part retained on the resin.

This microcolumn makes it necessary to use HAc/Ac⁻ carrier because the H₂MTA⁺/HMTA carrier acidified with both, perchloric acid or hydrochloric acid significantly increased blank fluorescence emission intensity due to its reaction with eluated Chromotrope 2B. The lower

fluorescence intensity with a HAc/Ac⁻ carrier was compensated by the aluminium preconcentration obtained with the chelating micro-column.

Optimum Al(III) retention in the micro-column and Al-DBQ fluorescence development were obtained at pH 5.5 with $5 \times 10^{-2} M$ HAc/Ac⁻.

Varying concentrations and volumes of hydrochloric acid eluant were studied. The results (Fig. 4) show that maximum fluorescence intensity is reached between 75 and 100 µl of $10^{-1} M$ hydrochloric acid. A volume of 100 µl was selected as optimum for further experiments.

The effect of varying the amount of Chromotrope 2B immobilized in the column from 1.3×10^{-4} to 1.6 mmoles was studied. For amounts higher than 6.6×10^{-3} mmoles, the retained aluminium could not be completely removed. For complete removal, it was necessary to raise the hydrochloric acid concentration above 0.5M which made it more difficult to reach the optimum pH for Al-DBQ complex formation. As a compromise, 6.6×10^{-3} mmoles of Chromotrope 2B per gram of AG1-X8 dry resin was used. The results of the preconcentration study showed that the fluorescence intensity of the signal increased proportionally with increasing volume of injected sample up to the maximum volume assayed of 1000 µl. Thus, using the optimum eluant volume of 100 µl it was possible to achieve a 10-fold sample preconcentration.

The calibration graph was linear from 1 to 50 ng/ml aluminium. The limit of detection for the sample solution is 0.3 ppb aluminium and the coefficient of variation at the 4 ppb level is about 3%.

Sample analysis

Various dialysis fluids, foods and tap water were analysed. Tap water was analysed without any sample pretreatment and dialysis fluid with a 1:25 sample:water dilution. Freeze dried fresh tomato was mineralized by the following dry ashing procedure: About 0.25 g of sample was placed in a porcelain crucible and held at 500° for 2 hr. The residue was dissolved in 0.5 ml of 65% (w/v) nitric acid and the final volume was made up to 25 ml.¹²

In all cases, the slope of the standard additions line was parallel to the slope obtained from the Al(III) standard solutions. It was concluded that the analysed samples did not show matrix effects.

The results obtained for tap water and fresh tomato with the proposed method agreed with those obtained by the ETAAS method; the differences were not significant at the 5% level. For dialysis fluids the mean value of recovery, obtained by adding different known amounts of aluminium to the samples, was 104%. The results obtained for six replicate determinations are summarized in Table 2.

CONCLUSIONS

The new spectrofluorimetric FIA method proposed for the determination of aluminium is very sensitive and selective, because interfering ions are removed by passage through a chelating resin microcolumn incorporated into the FIA system. Furthermore, samples can be preconcentrated at least 10-fold by retaining the Al(III) contained in 1000 µl of sample solution and eluting it with 100 µl of 0.1M hydrochloric acid. It is therefore a

valid alternative method to determine traces of aluminium in biological materials. It has been successfully applied to determine aluminium in tap water, food samples and dialysis fluids.

Summary—A simple, large-volume wall-jet cell was designed for unsegmented flow analysis. The working electrode is immersed in a solution that reactivates the electrode surface. During the sample measurement, the working electrode is screened from the reactivation solution by the streaming sample solution; between the individual samples, air is pumped through the jet and agitates the reactivating solution at the electrode surface. The properties of the cell were investigated with the fluoride and chloride ion-selective electrodes and the method was applied to determination of fluoride and chloride in steel corrosion products and in a reference sample of the fly dust from electric-arc furnaces. The method permits about 90 measurements per hour, the results are reproducible and the limits of determination (6.3×10^{-8} and $2.3 \times 10^{-7} M$ for fluoride and chloride, respectively) are substantially lower than the values commonly obtained in batch experiments. At least 150 measurements can be carried out without significant changes in the reliability of determination and the reactivation solution can then be replaced.

Various techniques of flow analysis have rapidly gained importance, as they exhibit many advantages that are thoroughly discussed in the literature.^{1,2} In addition to the most common spectrophotometric detection, some electrochemical methods are being progressively used more (primarily potentiometry, amperometry and coulometry), in view of their high sensitivity and selectivity that can, to a certain extent, be varied by judicious control of the experimental conditions.³ Potentiometry with ion-selective electrodes (ISE's) is very popular because it is highly selective and simple. However, problems may arise in flow detection due to rather sluggish response of many ISE's which, to make it worse, is dependent on the analyte activity (the response time generally increases with decreasing activity).³⁻⁵ Another difficulty, common to all the electrochemical methods except for high-frequency impedance measurements, stems from the interactions between the electrode surface and the test solution and leads to electrode passivation, memory effects and enhanced noise.^{3,6}

On the other hand, an advantage of flow measurements with ISE's lies in the fact that the measuring sensitivity is often somewhat higher than in batch experiments⁶ and that many operations required for the sample pretreatment and electrode reactivation are easy to carry out.

The cells for flow potentiometry are mostly low-volume thin-layer, wall-jet and tubular cells or open wall-jet systems with the working electrode placed above a solution containing a reference electrode.³ All these cells often suffer from noise and random interruptions to the electric circuit, due to air bubbles trapped in small cells or breakage of the thin film of liquid connecting the working electrode with the solution containing the reference electrode in the open systems. Moreover, if the working electrode is to be reactivated, it must either be taken out of the cell, or a different solution must be pumped through the cell, which is awkward and time consuming.

A large-volume wall-jet cell, in which the test solution is fed from a jet onto the working electrode surface and the whole system is placed

in a large vessel containing a suitable solution, was first described by Horvai *et al.*⁷ and later studied in detail by Gunasingham *et al.*⁸⁻¹⁰ The detector has primarily been used for amperometric detection in HPLC⁸⁻¹¹ and recently also for flow-injection potentiometric stripping analysis,¹² flow-injection potentiometry¹³⁻¹⁵ and potentiometric detection in ion chromatography.^{16,17}

It has been shown⁸⁻¹¹ that the liquid beam coming from the jet remains intact even at 10-mm distances of the jet orifice to the electrode surface, that the effective working volume of the cell is small (less than the volume of the hydrodynamic boundary layer at the electrode surface) and that the impinging test solution shields the electrode from the effects of the liquid in the cell, so that it is, *e.g.*, possible to perform amperometric reductive measurements without removal of oxygen from the solution in the cell.

The present paper describes a large-volume wall-jet cell of a very simple design and its application to unsegmented flow ISE potentiometry. The favourable properties of the cell are utilized for continuous reactivation of the working electrode surface and the method is applied to determination of fluoride and chloride in the products of steel corrosion and in a reference sample of fly dust from electric-arc furnaces.

EXPERIMENTAL

Apparatus

The potentiometric measurements were performed with an ION-85 instrument and a REC-80 chart recorder with a REA-120 module (all from Radiometer, Copenhagen, Denmark). The fluoride and Chloride ISE's and the saturated silver/silver chloride reference electrode were Crytur types 09-27, 17-27 and RAE-112, respectively, obtained from Monokrystaly, Turnov, Czechoslovakia. In order to suppress the noise caused by the high impedance of the chloride ISE, an impedance convertor based on a WSH-220 operational amplifier (Tesla, Lanškroun, Czechoslovakia) was placed inside the electrode body.¹⁸

The test solutions were propelled by a Type 315 peristaltic pump (Zalimp, Warsaw, Poland). In the measurement of the detector time constant dependence on the solution flow-rate, an ABU-80 autoburette (Radiometer, Copenhagen, Denmark) was used for pumping.

The sample solutions were aspirated from polypropylene beakers and the sample size was controlled by controlling the aspiration time. The solutions were aspirated through a PTFE tubing (1 mm in internal diameter) and led to the detection cell by silicone rubber tubing (40 cm long and 2 mm in internal diameter). Unless stated otherwise, the flow-rate was 3 ml/min.

The detection cell is schematically depicted in Fig. 1. The cell consists of a cylindrical glass vessel (1) with an opening for the working electrode (2) and reference (3) electrode and for the jet (4) which are fixed in place by polyethylene O-rings. The horizontal position of the ISE and the jet prevents gas bubbles from adhering to the ISE surface. The polyethylene jet is 0.3 mm in internal diameter and its distance from the ISE can be varied. The vessel is provided with a solution outlet stop-cock (5) and is placed in the neck of a waste bottle (7). Tube (6) maintains a constant solution level (a solution volume of 50 ml).

Reagents

Analytical-grade chemicals were employed as received from Lachema, Brno, Czechoslovakia.

Stock solutions of the analytes, 0.1M, were prepared by dissolving solid sodium fluoride and sodium chloride in water, and used as primary standards.

Buffer solution A [0.5M in sodium nitrate, acetic acid and sodium acetate and 0.1M in diaminocyclohexanetetraacetic acid (DCTA)], pH 4.3, was prepared as follows. A 36-g amount of DCTA was dissolved in *ca.* 500 ml of an aqueous solution of 15 g of sodium hydroxide,

Fig. 1. The large-volume wall-jet cell (for description see text).

then 43 g of sodium nitrate and 30 ml of acetic acid ($\rho = 1.060$) were added and the mixture was made up with water to 1000 ml.

Buffer solution B (pH 4.3) was 0.5M in sodium nitrate, acetic acid and sodium acetate, and was prepared by dissolving 6.0 g of sodium hydroxide in water, adding 30 ml of acetic acid ($\rho = 1.060$) and 43 g of sodium nitrate, and diluting with water to 1000 ml. Solutions A and B were filtered before use. Buffer solutions A and B were mixed with the sample solutions at a volume ratio of 1:5.

A reactivation solution, 0.1M in Al^{3+} and nitric acid, was prepared by dissolving 3.3 g of $\text{Al}_2(\text{SO}_4)_3 \cdot 18\text{H}_2\text{O}$ in 100 ml of 0.1M nitric acid.

General measuring procedure

The detection cell is prepared for measurement by directing the jet to the centre of the working electrode and adjusting its distance from the electrode. The jet is placed excentrically in a plastic stopper, so that its proper position is attained by turning the stopper, while pumping water onto the electrode surface through the jet in the empty vessel. The vessel is then filled with 50 ml of an appropriate reactivation solution and the ISE potential is allowed to stabilize.

The test solution is pumped for 5–10 sec, thus obtaining sample solution volumes from 0.25 to 0.5 ml at a flow-rate of 3 ml/min. When a sample is not aspirated, air is pumped through the jet and the reactivation solution is thus stirred at the electrode, hastening the reactivation process.

Procedure for determination of fluoride and chloride in the steel corrosion products and in the fly dust from electric-arc furnaces

A sample of 10–25 mg is fused in a platinum crucible with 0.5 g of sodium carbonate; 20 mg of silica may be added to assist the sample decomposition. The melt is extracted with 5 ml of cold water in an ultrasonic bath, the extract acidified with 2 ml of 5M nitric acid, degassed in an ultrasonic bath and diluted with water to 10 ml. A part of this solution is measured in a polyethylene beaker and diluted with water to 20 ml. A volume of 5 ml of buffer A (determination of fluoride) or buffer B (determination of chloride) is added to the beaker, the mixture is stirred and the determination is carried out according to the above measuring procedure. The vessel contains the appropriate

reactivation solution, *i.e.*, 0.1M Al^{3+} + 0.1M HNO_3 (fluoride) or 0.1M NaNO_3 + 0.1M CH_3COOH + 0.1M CH_3COONa + 0.02M DCTA, pH 4.3 (chloride). The samples are pumped for 10 sec at a flow-rate of 3 ml/min; the reactivation interval is 30 sec.

RESULTS AND DISCUSSION

So far, when the activity of a measuring ISE in a flow cell changed, the electrode was either removed from the cell and reactivated by a suitable mechanical or chemical procedure, or a chemical reactivation was carried out directly in the cell, by passage of a reactivating solution. In both cases, the sequence of analytical measurements had to be interrupted. However, the favourable properties of the large-volume wall-jet cell, primarily the fact that the solution impinging on the electrode efficiently separates the electrode surface from the bulk solution in the cell, make it possible to continuously reactivate the electrode by placing the reactivating solution in the cell. During passage of a sample solution, the reactivating solution has no access to the electrode surface; between samples, air is pumped through the jet and stirs the reactivating solution at the electrode.

The most efficient way of reactivating solid-membrane ISE's is removal of a very thin layer of the electrode surface, either by mechanical polishing or chemical etching. In this work, complexation reactions are used for the purpose—an acidic solution of aluminium ions for the fluoride ISE and a weakly acidic solution of DCTA for the chloride ISE. The action of these solutions is efficient but gentle and no mechanical damage is done to the electrode surface.

Basic properties of the cell

The results are in agreement with those published earlier.⁸⁻¹¹ The optimal distance of the jet orifice from the electrode surfaces lies within an interval of 2–12 mm. The higher the flow-rate, the greater is the optimal distance. At distances shorter than 2 mm, the noise sharply increases; at distances longer than *ca.* 12 mm, the beam of the liquid coming from the jet ceases to be intact. For the flow-rate used in further experiments, 3 ml/min, a distance of 3–6 mm was found optimal and was maintained within this interval throughout. At this or greater distance, there was also no danger of air bubbles being trapped between the jet and the electrode.

Table 1. Dependence of the time constant, T_k , of the detector with the chloride ISE on the flow-rate of the test solution

Flow rate, ml/min	T_k , sec
1	4.60
2	1.93
3	1.14
4	0.73
6	0.55
8	0.40

The T_k value is the time required for the signal to increase to 63.2% of the maximum value on a step change in the chloride concentration; the test solution, $0.1M HNO_3 + 2.5 \times 10^{-5}$ or $2.5 \times 10^{-4}M Cl^-$; the cell solution, $0.1M HNO_3$.

As can be expected, the response time decreases with increasing flow-rate (for the dependence with the chloride ISE see Table 1). From the points of view of electrode response and sample consumption, a flow-rate of 3 ml/min is a useful compromise.

Determination of fluoride and chloride

Whereas the response rate of the chloride ISE is independent of the solution pH from 1.1 to 4.6 and of the chloride concentration within the range of 2.5×10^{-4} – $2.5 \times 10^{-5}M Cl^-$, the response rate of the fluoride ISE increases with increasing concentration of fluoride and decreasing pH (see Table 2). Moreover, the linear dynamic range increases with decreasing pH (see Fig. 2). However, measurement in strongly acidic solutions is inconvenient because the potential stabilization is slow and the selectivity of measurement is poorer. Therefore, it is better to work at a pH between 4 and 5 (we further used

Table 2. Dependence of the time constant, T_k , of the detector with the fluoride ISE on the fluoride concentration and the solution pH

pH	c_{F^-} , $\mu g/25 ml$	T_k , sec
6.7	1.9	4.8
6.7	19	1.5
4.6	1.9	2.7
4.6	19	0.6
1.1	1.9	1.3
1.1	19	0.6

For the definition of T_k see Table 1; the test and the cell solutions were identical, either $0.1M HCl$ (pH 1.1), or $0.1M NaCl + 0.08M CH_3COOH$ with the pH adjusted between 4.6 and 6.7 by additions of NaOH.

Fig. 2. The effect of the test solution pH on the fluoride calibration plot. The test and the cell solution were identical: $0.1M$ sulphosalicylic acid + $0.02M$ EDTA with the pH adjusted with an NaOH solution, or a $0.1M HCl$ (pH 1.1).

a pH of 4.3), and add aluminium(III) ions to the cell solution to enhance the electrode reactivation ($0.1M HNO_3 + 0.1M Al^{3+}$). We further added DCTA to the sample solution, to improve the measuring selectivity.⁶

The calibration dependences obtained under these conditions are given in Fig. 3. It can be seen that the slope of the dependence is higher for the flow measurement (68 mV per concentration decade) than for the batch measurements under identical conditions (60 mV per concentration decade). The reason for this phenomenon is not only a somewhat higher sensitivity of measurement attained under flow conditions, but also the fact that a nonsteady-

Fig. 3. The calibration plots for fluoride obtained in flow (1, 2) and batch (3) experiments. Buffer solution A; reactivation solution of $0.1M Al^{3+}$ and HNO_3 .

state signal is measured in the flow system and that the electrode response is slower at low analyte concentrations. Therefore, the values obtained at low fluoride concentrations are further removed from the respective steady-state values than those obtained at higher analyte concentrations. The hysteresis region in the flow measurements is wider at low analyte concentrations (*ca.* 6 mV) and it only occurs in the presence of DCTA (this confirms the earlier observations that DCTA makes the response of the fluoride ISE slower⁶).

Typical recordings of repeated flow determinations of fluoride are given in Fig. 4. It can be seen that the baseline is usually subject to a drift and thus it is more convenient to measure the difference between the peaks corresponding to the highest and the actual analyte concentration. Hence the signal for the highest analyte concentration defines the working baseline, which is stable for several hours.

The limit of determination was determined as follows: A regression straight line was constructed for a narrow range of the lowest concentrations ($0-4 \times 10^{-7}$ and $0-4 \times 10^{-6}$ for fluoride and chloride, respectively), and the value was found on this line that corresponded to triple the standard deviation of the intercept divided by the straight line slope. The limit of determination for fluoride under the above flow conditions is $1.2 \mu\text{g/l.}$ ($6.3 \times 10^{-8} M$), which is a value about 30 times lower than that obtained in common batch measurements.¹⁹ An

Fig. 4. A recording of a series of flow determinations of fluoride. Measurements were always made in triplicate (for conditions see Fig. 3 and text). c_F ($\mu\text{g}/25 \text{ ml}$): 0 (1), 0.095 (2), 0.19 (3), 0.38 (4), 0.95 (5), 1.9 (6), 3.8 (7), 9.5 (8) and 19 (9).

Fig. 5. The calibration plots for chloride. Flow measurement with (1) and without (2) DCTA (for conditions see text).

analogous situation is with the determination of chloride, where the limit of determination equals $8 \mu\text{g/l.}$ (2.3×10^{-7}), about 14 times lower than in common batch measurements.¹⁹

In measurements with the chloride ISE, the optimal pH range lies between 2.5 and 4.5, as expected and thus a solution of buffer B was selected for the measurement. The electrode can be reactivated in the blank sample solution, but somewhat better results are obtained when this solution is made $0.02 M$ in DCTA. The slope of the calibration plot (Fig. 5) then slightly increases (from 61.4 mV per concentration decade in the absence of DCTA to 62.7 mV in its presence) and the linear correlation coefficient is somewhat improved (from 0.9996 to 0.9999). The cleaning effect of DCTA probably depends on the complexation reaction with the Ag^+ ions on the surface of the membrane. Moreover, DCTA improves the selectivity of determination, similar to the determination of fluoride.

Rather high concentrations of the reactivation solutions were used to prevent rapid loss of their function on dilution with the samples. Under the given experimental conditions, at least 150 measurements could be carried out without significant deterioration in the measuring reliability. The reactivation solution was then replaced.

The results of the application of the flow-through method to determination of fluoride and chloride in steel corrosion products and in a reference sample of an electric-arc furnace fly

Table 3. Determination of fluoride and chloride in the steel corrosion products and in a reference sample of the electric-arc furnace fly dust (for procedures see Experimental)

Sample	Decomposition procedure	Fluoride content	n	Chloride content	n	Turbidimetry
		(%) Confidence interval		(%) Confidence interval		
Corrosion products I	without SiO ₂	0.017 ± 0.003	3	0.21 ± 0.04	3	0.28 ± 0.05
Corrosion products II	without SiO ₂	0.053 ± 0.005	3	1.29 ± 0.04	4	1.3 ± 0.03
Fly dust	without SiO ₂	0.26 ± 0.04	4	1.35 ± 0.17	3	1.5 ± 0.08
	with SiO ₂	0.24 ± 0.04	4	1.39 ± 0.17	3	0.43 ± 0.10

dust are given in Table 3 (for the procedures see Experimental). The determination of chloride was compared with the results obtained by a turbidimetric method²⁰ employing a surfactant for stabilization of the turbidity and the agreement was satisfactory (see Table 3), except for the procedure in which SiO₂ was added to the fusion mixture. The turbidimetric determination is, of course, much more sensitive to colouration of the test solution and to cloudiness, which is caused in this case by a high content of hydrated silicon dioxide. The results indicate that the method yields good results and permits about 90 individual measurements per hour. There was no suitable reference method available for the determination of fluoride.

(Received 30 December 1990. Revised 13 May 1991. Accepted 18 June 1991)

Summary—Three main types of PVC solvent polymeric membrane ion-selective electrodes for chloroquine are described. They are based on three ion-pairing agents namely dipicrylamine (DPA), tetraphenylborate (TPB) or tetrakis(4-chlorophenyl)borate (TCPB) with either dioctylphenyl phosphonate (DOPP) or trioctyl phosphate (TOP) solvent mediator. All electrodes exhibit Nernstian responses, fast dynamic response times and a wide useful pH range. The best all-round electrode is based on TPB and TOP plasticizing solvent mediators with a limit of detection of $7.1 \times 10^{-6}M$ and was utilized for the assay of chloroquine in tablets. Direct potentiometric determinations with either the analyte addition method or the normal calibration method gave results comparable to the official method.

Malaria is a mosquito-borne disease and one of the major killers of the world, currently causing an estimated one million deaths annually.¹ In 1983, a report estimated the number of new malaria infections annually throughout the world was 210–230 million,² most of these (85%) being malignant malaria caused by the most dangerous of all the malaria parasites, *Plasmodium falciparum*.

Anti-malaria drugs are usually classified in terms of the action against the different stages of the life-cycle of the parasite. Chloroquine [7-chloro-4-(4-diethylamine-1-methylbutylamino)-quinoline] the most widely used anti-malarial drug is an example of a schizonticidal agent which is effective against the erythrocytic forms of the plasmodial organism and is used to cure the clinical attack of malaria.³ Chloroquine is effective against the erythrocytic forms of all types of malaria parasites with the exception of resistant strains of *Plasmodium falciparum* in South America and South-East Asia. With the exception of this resistant strain, they completely cure falciparum malaria.

Chloroquine in pharmaceutical preparations may be determined by two rather laborious methods: the U.S. Pharmacopoeia⁴ which involves extraction with chloroform followed by spectrophotometry at 343 nm; or the British

Pharmacopoeia⁵ which involves extraction of the chloroquine in sodium hydroxide with ether and back titration of excess base with hydrochloric acid, using bromocresol green as indicator.

Ion-selective electrodes have been advocated as simple, fast responding and sensitive devices for the monitoring of various biochemical and pharmaceutical species.^{6–8} In this context, a PVC membrane chloroquine selective electrode containing chloroquine–dinonylnaphthalene sulphonate (DNNS) as the electroactive material and 2-nitrophenyl octyl ether (NPOE) solvent mediator has been proposed.⁹ Here we report the development of chloroquine solvent polymeric membrane electrodes based on three other ion-pairing agents namely DPA, TCPB and TPB.

EXPERIMENTAL

Reagents

Sodium tetraphenylborate, potassium tetrakis(4-chlorophenyl)borate and high molecular mass poly(vinyl chloride) were obtained from Aldrich. The other reagents were obtained from the following sources: dioctylphenyl phosphonate (Lanchester Synthesis); chloroquine diphosphate, glucose, starch (Sigma); hydrochlorides of berberine and cinchonine, dipicrylamine (Tokyo Kogyo Kasei); trioctyl phosphate (Pfaltz and Bauer). Chloroquine tablets were

*Author for correspondence.

purchased from a local drug store. AnalaR-grade chlorides of calcium, magnesium, sodium, potassium and copper(II) were used.

Electrode preparation and use

Chloroquine-TPB ion-pair was formed by precipitation of an aqueous solution of sodium tetraphenylborate (0.1M) and chloroquine diphosphate (0.1M). The white precipitate was isolated by filtration, thoroughly washed with demineralized water and dried overnight at 30°. The dried salt (40 mg) was added to PVC (170 mg) and plasticizing solvent mediator (360 mg) dissolved in tetrahydrofuran (6.0 cm³). The homogeneous cocktail was next cast with a glass plate and glass ring (30 mm i.d.) as described elsewhere.¹⁰

For potassium tetrakis(4-chlorophenyl)borate and dipicrylamine which are both insoluble in water, it was necessary to prepare their master membranes by entrapping the ion-pairing agent without chloroquine (30 mg) plus plasticizing solvent in PVC, in an equal amount as for the TPB membrane. The TCPB- and DPA-chloroquine ion-pair was generated *in situ* by conditioning the assembled electrode¹⁰ in 10⁻²M chloroquine diphosphate (pH 4.70, ionic strength 0.03M) overnight. Similar chloroquine diphosphate concentration was used as the internal filling solution for all the electrodes. After overnight storage, the DPA-based membrane turned from orange to dark brown, indicating the formation of a DPA-chloroquine ion-pair.

Electrochemical measurements were made with an Orion digital ionanalyser (Model 701A). A double junction reference electrode (Orion model 90-02) was used. Electrode calibrations were effected by spiking with successive aliquots of a known concentration of sample into doubly demineralized water (20 cm³). All samples were prepared in doubly demineralized water. The chloroquine standard solution was prepared fresh and protected from light by wrapping the standard flasks with aluminium foil.

Selectivity coefficients, $k_{i,j}^{\text{pot}}$ were measured with the separate solution method at a cation concentration of 10⁻²M, unless otherwise stated, using the equation;

$$\log k_{i,j}^{\text{pot}} = (E_2 - E_1)/S$$

where E_1 and E_2 are the measurements on separate solutions of the primary ion (i) and interferent ion (j), respectively, at the same

concentration, and S is the slope of the chloroquine calibration curve.

Tablet analysis

All analysis was done in 0.10M acetate buffer; pH adjusted to 5 with sodium hydroxide. Ten chloroquine tablets were finely ground and thoroughly mixed. A mean mass of each tablet of 0.4131 g was dissolved in acetate buffer in a standard flask (100 cm³) up to the mark. The analyte addition method was based on:

$$C_o = C_s [10^{\Delta E/S} (1 + V_s/V_o) - V_s/V_o]$$

where ΔE is the emf difference after spiking the tablet solution of volume V_o (150 μ l) of unknown concentration C_o into a chloroquine solution in buffer of volume V_s (15 cm³) and concentration C_s (10⁻⁴M).

RESULTS AND DISCUSSION

All electrodes prepared with TPB, TCPB and DPA as ion-pairing agents in a plasticized PVC liquid membrane gave functional chloroquine electrodes with almost Nernstian responses (Table 1) and a long linear range. Even though these electrodes possessed slightly inferior detection limits as compared to the reported chloroquine electrode based on dinonylnaphthalene sulphonate, this is sufficiently low for many analytical applications. These electrodes exhibit fast dynamic response times (= 10 sec), although at lower concentrations (< 10⁻⁶M), the response time is expectedly sluggish (30–60 sec). The electrode responses were found to be pH-independent in the pH range of about 3.5–8.0 (Fig. 1). This was studied by varying the pH of 10⁻³M chloroquine by addition of minute amounts of concentrated hydrochloric acid and/or sodium hydroxide. At higher pH values, the potential decreased due to the gradual increase in the concentration of unprotonated chloroquine resulting in the precipitation of chloroquine base, while at low pH, a triprotonated chloroquine species [ChlH_3^{3+}] is probably formed. The chloroquine base and the triprotonated chloroquine are presumably not detected by the electrode. Such pH-mV profiles are also observed for electrodes based on other ion-pairing agents.¹¹

When tested for possible interferents that might be present in pharmaceutical preparations, the electrodes were essentially interferent-free from the alkali and alkaline earth metal ions tested (Table 2). The electrode

responses were also not affected by glucose or binders such as starch. Indeed, the electrode response was unaffected even up to 500 ppm starch. However, alkaloids such as cinchonine and berberine cause serious interferences. This

is expected of electrodes based on ion-pairing agents where larger lipophilic species will also be efficiently extracted into the membranes,¹² hence the interference phenomena. Interference from lipophilic amines were also observed for the DNNS-based chloroquine electrode.⁹ However, this is of no deterrent to the use of these electrodes in the analysis of pharmaceutical preparations as these alkaloids are not present together with chloroquine.

The use of trioctyl phosphate plasticizing solvent also yields a good quality electrode (Table 1) with Nernstian response and fast response times. The use of TOP yields electrodes of slightly improved selectivity characteristics, especially for the TPB-based membrane (Table 2). Hence this electrode (electrode 2) was studied further.

Potentiometric determination of standard chloroquine solutions utilizing this electrode yields an average recovery of 103.0 and 100.9% with the normal calibration and the analyte addition methods, respectively (Table 3). When used for the analysis of chloroquine in tablets, the potentiometric normal calibration and analyte addition methods yield 252.0 and 250.0 mg per tablet of the base, respectively, as

compared to the British pharmacopoeia method of 246.0 mg.

CONCLUSIONS

The electrodes developed showed good prospects for the analysis of chloroquine in pharmaceutical preparations. Although the detection limit ($7.1 \times 10^{-6}M$) is slightly inferior as compared to the DNNS-based electrode ($2 \times 10^{-7}M$), good agreement was found between both the calibration and analyte

addition potentiometric methods and the official method, using the proposed electrode. The proposed electrode method has the advantage of being much simpler than the official method.

EXTRACTION AND COMPLEX FORMATION OF NIOBIUM(V) WITH 3-HYDROXY-2-METHYL-1-(4-TOLYL)-4-PYRIDONE

A. GOJMERAC IVŠIĆ and B. TAMHINA

Laboratory of Analytical Chemistry, Faculty of Science, University of Zagreb, Strossmayerov trg 14,

(Received 1 October 1990. Revised 4 June 1991. Accepted 4 June 1991)

Summary—The extraction of niobium(V) from aqueous hydrochloric and sulphuric acid solutions with 3-hydroxy-2-methyl-1-(4-tolyl)-4-pyridone (HY) dissolved in chloroform is described. Niobium(V) can be quantitatively extracted with HY in the form of two different complexes depending on the chloride ion concentration in the aqueous phase. At a low chloride concentration or without chloride in the aqueous phase niobium(V) is extracted with HY in the form of $\text{Nb}(\text{OH})_3\text{Y}_2$ and at a high chloride concentration as a mixed $\text{Nb}(\text{OH})_3\text{ClY}$ complex. Niobium extraction with HY enables the separation of niobium(V) from zirconium(IV) and hafnium(IV). The formation of a mixed chloro-4-pyridone complex is also applicable for the spectrophotometric determination of niobium in the organic phase at the maximum absorption at 350 nm.

In continuation of our investigations of metal extraction with 4-pyridone derivatives: 3-hydroxy-2-methyl-1-phenyl-4-pyridone (HX) and 3-hydroxy-2-methyl-1-(4-tolyl)-4-pyridone (HY)¹⁻⁵ the present experiments were undertaken to study the extraction of niobium(V) with HY from different aqueous solutions. The results described here show that the extraction of niobium(V) with HY is preferable to that with HX¹ because it is feasible from solutions without the presence of large amounts of chloride or thiocyanate ions. Niobium(V) can be quantitatively extracted with HX only in the presence of an excess of chloride or thiocyanate ions in the form of a mixed $\text{Nb}(\text{OH})_3\text{ClX}$ [$\text{Nb}(\text{OH})_3\text{NCSX}$] complex.¹ However, niobium(V) can be quantitatively extracted with HY in the form of two different complexes depending on the chloride ion concentration in the aqueous phase. At a low chloride concentration or without chloride in the aqueous phase niobium is extracted with HY in the form of $\text{Nb}(\text{OH})_3\text{Y}_2$ and at a high chloride concentration as a mixed $\text{Nb}(\text{OH})_3\text{ClY}$ complex. For some other metal ions, as for niobium(V), HY is a more effective extractant than HX.²⁻⁵ With some metal ions the tolyl analogue (HY) reacts at higher acid concentration than the phenyl analogue (HX), quantitatively extracted with less excess of extractant, and sometimes causes a change in the composition of extracted complexes.

Based on conditions of niobium(V) extraction with HY described here and those of zirconium(IV) and hafnium(IV) extraction with HY dealt with earlier,⁵ a simple and fast separation of niobium(V) from zirconium(IV) and hafnium(IV) is feasible by extraction with HY from 1M hydrochloric acid.

EXPERIMENTAL

Reagents and radioactive tracer

A standard solution of niobium(V) (about $2 \times 10^{-2}M$) was prepared in hydrochloric and sulphuric acid solutions as described earlier.¹ The ⁹⁵Nb isotope supplied from the Radiochemical Centre, Amersham, England, in the form of an oxalato complex in a 0.5% solution of oxalic acid was used as tracer. ⁹⁵Nb in the form of chloride and sulphate was prepared as described earlier.¹ HY was synthesized as described previously⁶ and used in a chloroform solution. All other chemicals used were of analytical reagent grade.

Apparatus and procedures

Radioactivity measurements were performed with a well-type gamma scintillation counter (NaI/Tl) from Ecko Electronic. Gamma-ray spectrophotometry was carried out with a computerized multichannel analyzer, Model 8100, Canberra. For extraction, a Griffin flask shaker with a time switch was used. Absorption spectra

Fig. 1. The dependence of the percentage of extraction (a) and the distribution ratio (b) of niobium on initial hydrogen ion concentration. Concentration: $6 \times 10^{-5} M$ Nb(V); \blacklozenge , sulphuric acid solution, without addition of Cl^- ; \circ , \triangle , hydrochloric acid solution, $(\text{H}, \text{Li})\text{Cl} = 10M$; \circ , $1.5 \times 10^{-3} M$ HY; \triangle , $3 \times 10^{-3} M$ HY.

and absorbance measurements of solutions were made with a Perkin-Elmer Hitachi-200 spectrophotometer.

Determination of the distribution ratio and spectrophotometric determination of niobium in the organic phase were performed by the same procedure as used for the HX method.¹

The testing of the separation of niobium(V) from zirconium(IV) and hafnium(IV) has been described earlier.⁵

RESULTS AND DISCUSSION

Optimum conditions for extraction

The extraction of niobium(V) from aqueous hydrochloric and sulphuric acid with HY dissolved in chloroform was examined at different acidities and ionic strengths. Niobium(V) can be quantitatively extracted with HY from aqueous

hydrochloric or sulphuric acid solution in the range 0.8–1.2M hydrogen ion concentration [Fig. 1(a)] if chloride concentration is less than 3M (Table 1). With an increase in chloride ion concentration in the range 3–6M the percentage of extracted niobium gradually decreases, but with an increase in chloride concentration above 6M it increases again and at a chloride ion concentration higher than 8M, niobium(V) is quantitatively extracted from hydrochloric acid solutions. From sulphuric acid solution and at a chloride ion concentration above 8M, the maximum niobium concentration is about 83%. The optimal hydrochloric acid concentration for quantitative extraction of niobium(V) at a chloride concentration higher than 8M is also 0.8–1.2M, and is the same for extraction of niobium(V) at a low chloride concentration or without chloride in the aqueous phase

Aqueous phase: $6 \times 10^{-5}M$ Nb(V), $1M$ H⁺.

[Fig. 1(a)]. These results suggest that niobium(V) can be extracted with HY in the form of two different complexes depending on the chloride ion concentration in the aqueous phase and also suggest that hydrochloric acid solutions are more suitable for extraction of niobium than sulphuric acid solutions. In order to extract niobium(V) quantitatively from an optimal hydrochloric acid concentration the HY concentration must be at least 17 times higher than that of niobium if extraction takes place from solution at a chloride concentration higher than $8M$ and 40 times higher if extraction is from solution without chloride or at a chloride concentration less than $3M$ (Table 2).

The niobium(V) extracted in the presence of an excess of chloride or at low chloride concentration, or without the presence of chloride can be quantitatively stripped with $10M$ hydrochloric or sulphuric acid. At optimum extracting conditions only citrate, tartrate, fluoride and oxalate minimize niobium extraction. These anions mask niobium(V) but do not interfere if present in moderate quantities. Citrate and tartrate may not exceed a 100-fold amount and fluoride and oxalate a 10-fold amount with respect to niobium(V).

Absorption spectra of the extracted complexes

The absorption maximum of the extracted complexes depends on chloride concentration and lies between 310 and 350 nm (Fig. 2). With an increase in chloride concentration it is shifted towards higher wavelengths. With chloride concentrations less than $3M$ the absorption maximum of the extracted complex is in the range 310–320 nm. With a chloride concentration between 3 and $5M$ the absorbance at

310–320 nm gradually decreases and, simultaneously, another absorption maximum appears at 350 nm. At a chloride concentration higher than $6M$ the absorption maximum of the organic phase is at 350 nm. At this wavelength there is no shift of either the absorption maximum or the absorbance values with an increase in chloride concentration. The absorbance of the organic phase obtained with an excess of chloride in the aqueous phase is stable for about 30 min. With prolonged standing the absorption maximum appears at 310–320 nm and the absorbance values at 310–320 nm increase with time. After 120 min, the maximum at 350 nm is still visible and after one day, the spectrum shows a maximum at 320 nm only (Fig. 3).

Identification of extractable niobium(V) complexes

The compositions of the extracted niobium(V) complexes have been studied by radiometric and spectrophotometric methods. Distribution studies (Fig. 4) show that at a low chloride concentration or without the presence of chloride in the aqueous phase niobium(V) can be extracted as a complex with two HY molecules bonded to a single niobium atom and at a high chloride concentration as a mixed chloro-HY complex with one HY molecule bonded to a single niobium atom. The ratio of niobium to HY was also determined on the basis of the dependence of niobium extraction on its initial concentration in the aqueous phase and spectrophotometrically by Job's method.

The results also indicate that niobium can be extracted as a complex with two HY molecules bonded to a single niobium atom or as a mixed chloro complex with one HY molecule bonded to a single niobium atom. Distribution studies also show that four protons are released in the formation of the mixed Nb-Cl-HY complex and five protons in the formation of the Nb-HY complex [Fig. 1(b)]. It was not possible to determine the ratio of niobium to chloride in the mixed chloro-HY complex, but the ratio was determined at extraction of niobium with HX as a mixed chloro-HX complex.¹ Comparison of those results and the results described here shows the compositions of the mixed Nb-Cl-HX and Nb-Cl-HY complexes to be identical. On the basis of all the results obtained and the fact that niobium(V) in an acidic solution can exist in the form of various hydroxo and oxo ions whose composition depends on the acidity as well as on the kind and concentration of anion present⁷⁻⁹ we suggest that complexes having the stoichiometries $Nb(OH)_3Y_2$ and $Nb(OH)_3ClY$ can be quantitatively extracted. The formation of these complexes may be shown as:

The formation of the complex at low chloride concentration or without chloride in the aqueous phase shown in equation (1) is fundamentally different from the extraction of niobium with HX. With HX, niobium is

Fig. 4. The dependence of the distribution ratio of niobium(V) on initial HY concentration; \blacklozenge , \circ , \blacktriangle , without addition of Cl^- ; \diamond , \triangle , \bullet , $10 M$ Cl^- ; \blacklozenge , $1 M$ H^+ ; \circ , $3.2 M$ H^+ ; \blacktriangle , $3.5 M$ H^+ ; \diamond , $4.5 M$ H^+ ; \triangle , $6 M$ H^+ ; \bullet , $6.5 M$ H^+ .

quantitatively extracted only as a mixed ligand complex.¹ Based on the absorption spectra of the extracted complexes (Figs. 2 and 3) it is also suggested that the mixed ligand complex produced from a high chloride concentration in the aqueous phase shown in equation (2) with maximum absorption at 350 nm by prolonged standing reacts with the excess of undissociated HY molecules in the organic phase giving $\text{Nb}(\text{OH})_3\text{Y}_2$ with maximum absorption at 310–320 nm as shown in equation (3):

Spectrophotometric determination of niobium in the organic phase

The formation of a mixed ligand Nb–Cl–HY complex is applicable to the spectrophotometric determination of niobium in the organic phase at the maximum absorption of 350 nm. Optimum conditions for extraction and spectrophotometric determination are: 0.8–1.2M hydrogen ion concentration and 10M chloride concentration ($\text{HCl} + \text{LiCl} = 10M$) in the aqueous phase and $3 \times 10^{-3}M$ HY in the organic phase. The optimum concentration range for niobium is 1–20 $\mu\text{g}/\text{ml}$. Beer's law is obeyed over this range. The effective molar absorptivity is $8.7 \times 10^3 \text{ l. mole}^{-1} \cdot \text{cm}^{-1}$. The absorbance of the organic phase is stable for 30 min (Fig. 3). The reproducibility of the method, expressed as a relative standard deviation, is 1–5% depending on niobium concentration. The influence of foreign ions on the absorbance at 350 nm was studied. A large concentration of ions can be present in the aqueous solution of niobium. Acetate, bromide, sulphate, nitrate, perchlorate, ammonium, sodium, potassium, magnesium, cadmium, manganese(II), nickel, barium, strontium, chromium(III), lead and zinc ions do not interfere in amounts exceeding 1000-fold those of niobium. Thorium, uranyl, tin(II), europium, mercury(II), copper, citrate and tartrate are tolerated in 100-fold and molybdenum(VI), titanium, fluoride and oxalate in a 10-fold molar ratio to niobium. Uranyl, zirconium, thorium, copper and molybdenum can be found in large amounts if a higher HY concentration is present in the organic phase, because these metals con-

sume HY for their own extraction and decrease the extraction of niobium.

Separation of niobium(V) from zirconium(IV) and hafnium(IV)

The varying behaviours of niobium(V), zirconium(IV) and hafnium(IV), in extraction with HY can be utilized for their separation. From 1M hydrochloric acid, niobium is quantitatively extracted (Fig. 1) while zirconium and hafnium remain in the aqueous phase.⁵ The separation of zirconium and niobium is of large practical importance because of the radiochemical equilibrium $^{95}\text{Zr}/^{95}\text{Nb}$. The separation of zirconium and niobium was tested with $^{95}\text{Zr}/^{95}\text{Nb}$ and that of hafnium and niobium with a mixture of ^{181}Hf and ^{95}Nb . A 0.1-ml volume of $^{95}\text{Zr}/^{95}\text{Nb}$ in 5M hydrochloric acid or 0.1 ml of a mixture of ^{95}Nb and ^{181}Hf in 5M hydrochloric acid, 0.9 ml of 5M hydrochloric acid and 4 ml of water were shaken mechanically for 20 min with 5 ml of $5 \times 10^{-3}M$ HY in chloroform. For quantitative separation the HY concentration in the organic phase must be at least 40 times higher than that of niobium (Table 2). After centrifugation the phases were separated. The results show that the radiochemical purity of niobium in the organic phase was 98% and in the aqueous phase 98% for zirconium and hafnium. The radiochemical purity of the separated ^{95}Zr and ^{181}Hf in the aqueous phase and of ^{95}Nb in the organic phase was verified by a gamma counting system consisting of a 40-cm³ Ge(Li) semiconductor crystal attached to a multichannel (4096) analyser (Canberra). The precision of this measurement was $\pm 2\%$.

JESS, A JOINT EXPERT SPECIATION SYSTEM—I. RAISON D'ÊTRE

PETER M. MAY

School of Mathematical and Physical Sciences, Murdoch University, Murdoch, Western Australia 6150

KEVIN MURRAY

Division of Water Technology, CSIR, P.O. Box 395, Pretoria, South Africa 0001

(Received 19 March 1991. Revised 10 June 1991. Accepted 14 June 1991)

Summary—JESS is a new computer package for modelling chemical systems in solution and performing numerical analyses on associated experimental data. It was developed to solve problems requiring specialist knowledge of chemical speciation. It currently comprises over 150 programs, 1200 subroutines and 120,000 lines of Fortran code. The main reasons for the development of JESS, and the principles which underpin it, are described. Subsequent papers detail the major facilities which JESS now provides.

This paper introduces a large computer package, written in Fortran 77, called JESS (for "Joint Expert Speciation System"). The package has been designed to minimize the expertise needed to carry out various calculations concerned with chemical species in solution. In particular, the aims have been to make JESS as "user-friendly" as possible and to embody in it a more comprehensive knowledge of solution chemistry than has hitherto characterized speciation computer programs. Whilst one purpose of this is to help inexperienced users, it is also intended for accomplished researchers who wish to perform their calculations more easily and/or with fewer errors. Such assistance can be of benefit to many scientists.¹

The specific reasons why speciation calculations can cause difficulties, even for those with a good basic training in chemistry, are numerous and inter-dependent. In essence, however, most of them boil down to a single problem: to use existing computer programs successfully requires considerable judgement guided by experience.² Reaching the overall goal may be simple enough in principle but, in practice, it always entails many sub-tasks, each of which demands some detailed knowledge. Often the information to be supplied to the program is peripheral to the chemical issue but, nevertheless, it is used to make decisions that can substantially influence the program's chemical predictions. Attempts to perform speciation calculations without sufficient expertise may accordingly yield deceptive or overtly incorrect results. All too frequently these are accepted at face value because it is

virtually impossible to identify and check all the assumptions upon which the calculations depend.

It is worth listing briefly the main difficulties that are encountered. First, there are significant technical obstacles in preparing input data. All existing programs have an implicit way of formulating the description of chemical systems which is computationally convenient but far from what might be termed "a natural chemical approach". Rarely are the program's requirements well documented and particular idiosyncrasies abound to trap the unwary or the uninitiated. Secondly, many applications of speciation modelling inherently require sophisticated chemical expertise. This includes the need to know about definition of components, methods of expressing equilibria, effects of background electrolytes, choice of standard state, changes of temperature and pressure, *etc.* Whilst each of these specific issues may be well enough understood individually, dealing with all of them simultaneously in complicated systems is not so easy.³ There are also subtle conceptual questions like how best to handle metastable chemical systems or the redox potential of solutions.¹ Thirdly, obtaining reliable thermodynamic data from the literature can be a formidable undertaking; considerable insight is required to discriminate properly between the large number of inconsistent equilibrium constants that have been published. All too often there is a paucity of critically-evaluated data for a particular system of interest.

Worrying evidence of the consequences of the above difficulties is provided by the recent CHEMVAL/MIRAGE report on the verification of speciation models used to describe the chemistry of radionuclides in the geosphere.⁴ CHEMVAL is an international project concerned with predictive simulations of radioactive waste disposal; it involves fourteen organizations from the European Community, Finland, Sweden and Switzerland. The verification exercise was "essentially a test that the mathematical models accurately perform the calculations for which they were written" (Reference 4, p. 11); in this comparison between organizations, no experimental measurements were performed, just simulations. Despite this, and despite the fact that the participants were all very well-experienced practitioners in the area of research, striking discrepancies in results were often obtained. For example, consider the data for species of Fe(II) and Fe(III) in the "straight-forward" case of a groundwater assuming no equilibration with solid phases, as shown in Fig. 1. Differences in database compilations, followed by individual decisions about data input, were found by the authors of the report to be the most frequent source of variation in the modelling results. There are also grounds for thinking some blame rests with dependence on computational procedures that demand too much from users: an intimate control over the calculations combined with the need for a good

grasp of all the relevant chemistry is a recipe for making mistakes.

In the area of solution chemistry, few computer programs to date can justifiably be called "user-friendly". This is illustrated in the complexities of program input requirements documented in Reference 5. Neither has a single standard program or approach emerged. This is surprising because computational methods have been utilized for equilibrium calculations and the determination of equilibrium constants since their introduction by Sillén and co-workers in the early 1960's.⁶⁻⁹ However, the codes and techniques in standard use today offer little improvement over the originals. Although new programs are regularly reported in the literature, the majority of these can, at best, be considered refinements.¹ Apart from a few notable exceptions,^{2,10-12} applications of novel numerical methods and/or artificial intelligence are conspicuous by their absence. Moreover, scant advantage has been taken of the modern, interactive computing environments which have become available over the last decade.

This is in stark contrast to other areas of chemistry where it has been evident for a long while that computer technology is making an impact in many ways other than by just performing traditional calculations more rapidly.^{13,14} For example, the emergence of "chemometrics" as a major activity in contemporary analytical research^{15,16} is based on the

Fig. 1. Example of result from CHEMVAL/MIRAGE verification exercises for groundwater speciation. Test case B. 1.—concentration of iron species—redrawn from Ref. 4.

additional information which can be obtained from experimental data with modern numerical techniques. So-called "expert systems"^{17,18} provide another example where chemistry has been expanded by new computing methods: these are decision-making computer programs which can assist the inexperienced in areas requiring specialist knowledge. Expert systems such as SYNCHEM¹⁹ and DENDRAL²⁰ have demonstrated unequivocally that, in certain limited contexts, computers can interpret chemical phenomena as well as, and often even better than, a competent person. It seems clear that, as performance-to-cost ratios continue to improve, so will the scope and effectiveness of this kind of computer application.

When work on JESS commenced in 1985, we decided to tackle the above difficulties with speciation calculations by exploiting developments in computing that, at that time, had either just occurred or could be foreseen. The newly-available computing power permitted an entirely novel approach. We wanted to generalize the way the calculations were performed, permitting the widest possible variety of simulations and avoiding dependence on particular numerical methods. As already mentioned, we sought to integrate chemical knowledge more intimately into the calculations. We also made a commitment to pay more attention than was conventional in scientific programming to the methodology of computer science.

CHEMICAL OBJECTIVES

This section outlines how our broad general vision translates into a variety of specific chemical goals.

A unified thermodynamic data depository

To perform speciation simulations successfully, inexperienced users must obviously have a source of equilibrium constants that is reliable, comprehensive and can be accessed automatically *i.e.*, without direct user-intervention.

A number of thermodynamic solution-chemistry databases in machine-readable form already exist. To our knowledge, all of these are associated with particular speciation programs, examples being GEOCHEM,^{21,22} MINEQL,²³ PHREEQE,²⁴ EQ3/6,³ SOLMINEQ.88²⁵ and ECCLES.²⁶ Unfortunately, these databases all exhibit serious weaknesses, as will be discussed in Part II of this series. Hence, a supremely important objective of JESS is to develop a large

on-line database of thermodynamic parameters which, by design, will evolve progressively to satisfy the majority of users regarding the data it ought to contain.

The accumulation over an extended period of time of critically-selected data into a unified primary source for speciation calculations is, unquestionably, an ambitious goal but, in our opinion, it is nevertheless feasible. Part II describes in detail how it has been tackled in the development of the JESS Thermodynamic Database. It is sufficient here to say that, clearly, success will depend on the extent to which the new database:

- (i) proves convenient to use;
- (ii) respects conflicts in expert opinion;
- (iii) encourages informed feedback.

Estimating unmeasured equilibrium constants

Large numbers of chemical reactions remain without measured equilibrium constants. At the same time there are a variety of methods which make it possible to estimate values for a significant proportion of these reactions. For example, "mixed-ligand" or "ternary" metal-ion complexes are formed in such plentiful combinations that to investigate them all would be a Herculean labour; however, it is often possible to calculate their formation constants quite precisely from a knowledge of the reactions forming their "binary" parent species.^{27,28} Estimating equilibrium constants from certain established chemical trends is another common way to obtain values when they have not yet been experimentally determined.²⁹

It is pertinent to note that if such estimates are to be used satisfactorily in speciation calculations, the method by which they are obtained must be visible, well-defined and reproducible. However, these ideals have seldom, if ever, been achieved. The large volume of the information that has to be recorded has been one pitfall and the temptation to resort to subjective judgments has been another.

Accordingly, the automation of procedures for estimating equilibrium constants that are not available in the thermodynamic database is another high priority of JESS. In some instances, this should be accomplished fairly readily. The calculation of formation constants for mixed-ligand complexes following the approach adopted for the model of low-molecular-weight equilibria in blood plasma²⁶ is the obvious example. It will not be as easy in other

cases. Our intention, therefore, is to introduce these facilities as soon as possible, just as long as there is some sound chemical basis for making the predictions.

Automatic generation of speciation models

Setting up the input for a speciation calculation has been identified in the introduction as being a major obstacle for the inexperienced and a significant cause of errors, even for more knowledgeable users. Thus, for the goals of JESS to be accomplished, automating these procedures is essential.

One difficulty here is to span the varying requirements users have, depending on their level of expertise.³⁰ Simplicity is the key to helping some users whereas speed and convenience are more important to others. Beginners should be able to specify a chemical system in very general terms, just by naming the substances present in the solution of interest. However, once they have the knowledge to do so, users must be able to exert a greater degree of control over the calculation. This goes beyond simply determining the model's parameters. Recasting the entire simulation to address various "what if" questions is a routine requirement. Resolving this conflict between the needs of novices and of experts has been a dominant theme of JESS development.

A second difficulty in setting up speciation calculations is associated with the choice of component set and the formulation of reaction equilibria. Although widely regarded as straightforward once understood, these tasks involve manipulations which are generally tedious and prone to careless mistakes. A good illustration of this is the interconversion of reactions and equilibrium constants made necessary by different assignments for the "number of dissociable protons" on ligands such as citric acid. Similar interconversions are also required when reactions reported in the literature are not expressed in the way demanded by the speciation computer program, *e.g.*, most programs only accept formation reactions, with a single species on the right-hand side of the chemical equation. As described in subsequent parts of this series, in JESS there are no program restrictions placed on the form which reactions can take or on which species can be regarded as components when data are entered into the database. Procedures have been developed to carry out all interconversions of reactions and equilibrium constants as required.

It is therefore possible to store all experimental data in the exact representation of its measurement but, nevertheless, to perform speciation calculations for any mathematically-feasible formulation of the reactions.

Correcting for changes in ionic strength and temperature

How to deal with changes in ionic strength and temperature is, in principle, well understood. Nevertheless these corrections cause profound difficulties in practice. First of all, there are well-known deficiencies in the theoretical expressions describing how the equilibrium constants change. Functions for ionic strength, especially, are rarely valid over an extended range. Resulting errors can be significant because many existing databases use "infinite dilution" as their reference ionic strength and no single alternative having presented itself as a better standard condition. Secondly, there isn't any uniformity regarding the best type of Debye-Hückel function to use. The Davies equation is widely employed despite almost universal reservations.³¹ This is because the theoretically superior Pitzer equations³²⁻³⁴ and other specific ion interaction models³⁵⁻³⁸ are frequently impractical due to a lack of data. Thus, an inadequate theoretical base is worsened by a widespread inconsistency of approach. Thirdly, the exact ionic strength of the solution only becomes known when the speciation has been calculated; this therefore requires an iterative approach which, in turn, implies slowness. Fourthly, in those computer programs which attempt such corrections simultaneously, *e.g.*, ESTA,³⁹ the chosen correction functions have to be imbedded very deeply into the equation-solving code. Modifying the functions, even in minor ways, can consequently be a big undertaking which tends not to get done, regardless of any deficiencies that might emerge. A new approach towards these problems has been developed and is now fully incorporated into JESS. Details will be given in Part III.

Improving model verification

In an effort to address some of the problems mentioned in the introduction concerning verification of results, special output should be produced automatically at each major stage of the modelling procedure to summarize the important assumptions made and, where any options are available, the particular methods used. The combined output from each stage would thus

provide a full description of all the relevant information, from start to finish, that may have affected the predictions of the model. It is envisaged that such information would be published routinely along with the results of the model, making detailed inter-model comparisons feasible. An important characteristic of expert systems is that they should be able to show how they arrived at their results.⁴⁰

Comprehensive modelling capability

The industrial, physiological or environmental applications for which many speciation calculations are performed cannot be adequately addressed by simulations limited to simple equilibria. Whilst it has been possible to include a broad variety of physico-chemical phenomena such as adsorption, transport and diffusion with equilibrium calculations for some time,^{41,42} models of such processes are still relatively imperfect and uncommon. Moreover, other much-needed capabilities are not yet available. The coupling of general speciation models with a variety of kinetic calculations and the ability to deal generally with metal ion binding by macromolecules fall into this category. Ways must still be found to link the different parts of such computations together intimately and efficiently. An inability to evaluate rigorously the sensitivity of speciation models to errors is another serious current weakness.¹

Although it is too soon to know how all these necessary features will eventually be provided, a large effort has been made to ensure that JESS is highly amenable to change and to extension. This should enable it to evolve into a comprehensive modelling package for simulating all kinds of systems in a far less restricted manner than is possible with the older program codes.

COMPUTATIONAL DESIGN

In any substantial software project, there are always a number of design decisions which have to be made at an early stage. Such decisions cannot later be reversed because this would generally mean rewriting too large an amount of code. This section describes the basis for the main computational design decisions on which JESS was based.

Modular program units

Since our main objectives could obviously only be accomplished by a large and complex

computer system, one of our first decisions was to implement JESS as a collection of many computer programs rather than as a single one. Certain benefits of tackling the project piecemeal are obvious: problems can be digested in whatever order and at whatever rate are most convenient; it is not necessary for the whole system to be operational before parts of it can be useful; solutions to intricate questions can be developed gradually. Moreover, even with the virtual memory capabilities of some modern computer operating systems, huge multi-purpose programs are still far from being a practical proposition. Inordinately long "link" times during the development cycle are a particular problem.

On the other hand, segmentation of the system into many units implies that all but the most simple of tasks need to be accomplished by sequential execution of programs. This has to be co-ordinated at a higher level, by involving the computer operating system. It also requires that knowledge of both the chemical and the computational goals be encoded and subsequently applied by some kind of artificial intelligence. For this reason, amongst others, we concluded that an expert-system capability was essential. To distinguish it from the user-interface provided by individual programs, we call the level controlling program execution and intended to supply expert-system guidance, the command interface.

Segmentation of the system into many programs also raises the need for effective inter-program communication. Substantial quantities of data must be transferred, as must information used to control, assist and check on progress towards current goals and subgoals. Putting all this into a conventional sequential formatted computer file would be highly inappropriate. Accordingly, a special mechanism has had to be developed which allows various data types (integers, reals, arrays, strings, files and so on) to be stored as nodes in a hierarchical tree structure. We have called this assembly of information "Resident Data".

User interface

The need to be helpful implies at least three things: the system must be consistent, it has to be tolerant of but not permissive towards errors and, where necessary, it should suggest how to proceed. We decided this could only be effectively achieved if it were tackled differently at command and program levels.

For various reasons including user-simplicity and system-portability (as discussed below), the command interface needs to be as basic as possible. Little more than a facility to select and execute sequences of programs is necessary; all the sophisticated capabilities of the system can then be embodied in specialized programs which are summoned up at the appropriate time. From the user's viewpoint however, the system at this level should appear to be driven by a small set of commands. These permit the user to exercise overall control but, at the same time, novices need only be aware of a few of the broader choices available. A comprehensive "help facility" ought to be apparent at this level. Likewise, expert system guidance regarding what goals can be reached and how best to reach them must be provided here. In reality, however, all these functions can be achieved by executing appropriate independent programs.

At program level, much more detailed interaction with users is required. In particular, this is where the convenience of the system is either accomplished or it is not. Consistency of messages/prompts issued, of input expected, of consequent program behaviour and of output displayed is one of the most important keys to helping new users. Thorough checking of user responses, as immediately as possible, is another. Using menus to indicate options available and supplying sensible defaults on prompts, are further aids that should be routinely implemented.

The conflicting priorities of experts and novices mentioned earlier is another of the challenges at design stage. Experts want speed and convenience; knowing where to go and what to do are not their main concern. Novices want help and do not mind if this means proceeding more slowly. In principle, we believe the solution to this lies in developing a "black box" system, but one which is sufficiently modular to permit intervention at appropriate stages by more knowledgeable users. Initially, such a system can produce results with a minimum of user involvement. Then, if and when the need to modify calculations or to change assumptions becomes apparent, the beginner is motivated to learn more about driving the system. This is made easier because the focus of attention falls on an individual aspect of the calculation—thus making it unnecessary to master the whole system in advance.

Computer portability

It is difficult to overstate our concern to ensure that JESS software is independent of the computers on which it will operate. The reasons are twofold:

- (i) with such a long term endeavour, it seems imperative to produce code that will work far into the future, well after the hardware on which it was developed has become obsolete;
- (ii) to succeed, JESS must become widely available.

The latter goal will not be achieved if JESS only runs under one or two computer operating systems. In our experience, most individuals interested in speciation calculations are as yet unable to acquire computers specifically for this purpose, even though this will probably change in time as microcomputers grow powerful enough to support larger software packages.

Writing portable software is difficult, much more difficult than is commonly supposed. Moreover, in the present context, the problem is intensified because the catholic requirements of JESS make it far more demanding than simple number-crunching programs.

Fortran 77 is the only scientific computer language which offers any realistic prospect of achieving the degree of hardware independence that we desire. It is fundamentally more efficient than the large majority of more recent computer languages, in particular Pascal. As well as being superior for numerical processing, it is far more portable than C. Fortran 77 therefore represents the language of choice for our purpose. However, it nonetheless suffers from a number of serious disadvantages. Perhaps the worst of these is that it is inherently very poorly structured, so that without great care, large amounts of code may easily become unmanageable. In particular, if programming gets too complicated, errors are impossible to eradicate and the system is impractical to maintain (*i.e.*, to modify and/or extend). Furthermore, compared with some languages that are now available, standard Fortran is technically deficient in many areas. For instance, there is no indexed file capability—something which is essential for our database applications. Limitations with the way Fortran handles character string manipulations is another profound weakness. Much of the early construction of JESS consequently had to be devoted to producing code which rectifies

these deficiencies in a rigorously portable manner. We had, for example, at the very earliest stage to define our own JESS collating sequence as a subset of printable ASCII and EBCDIC characters, to guarantee the compatibility of ordered data at all JESS sites.

IMPLEMENTATION

Although it may still be many years before the ambitions of JESS are all addressed, let alone fully realized, development has now reached the stage where the package can be used effectively for its essential purposes. To be specific, it is now possible to perform speciation calculations from a primary database of over 12,000 reactions in aqueous solution. There are no program-imposed constraints regarding the kinds of equations to be solved, the presence of other phases, the form in which reactions are represented, the choice of electrolyte medium or changes to ionic strength and temperature. Limits to the number of chemical species and number of reactions do exist but are probably in excess of 100,000. The entire procedure is automated so that it can be carried out with a minimum of user intervention; at the same time, each stage can be isolated and its input modified if greater control or flexibility is desired.

The JESS package presently comprises over 150 programs, most of these being interactive. Only relatively few are actually used for speciation modelling. Some exist specifically for thermodynamic database management. Yet others provide a range of facilities to help with everyday tasks. These include a portable general-purpose editor, a spelling-checker and a suite of programs to manage large numbers of literature references. The remainder are for general JESS development purposes.

This gamut of programs is made possible by extensive sharing of lower-level code. In total there are now over 1200 subroutines and 120,000 lines of Fortran code. The present computer storage requirement is generally about 25MB. The thermodynamic data, other data, Fortran code, object libraries and executable images each need about 5MB. It should be noted, however, that some computer systems require considerably more than this.

So far, the amount of experience we have had with JESS is necessarily patchy. Most of the common subroutines, and certain facilities like the JESS Literature databases, have been operational for several years but we have only

recently completed the software for equilibrium modelling. The thermodynamic database programs fall between these two extremes, having been initiated about 18 months ago but exercised intensively since then. The system seems to be evolving as planned, although at present it remains difficult to judge whether or not it will prove as helpful to inexperienced users as we hope. This is because the development of the final tiers of the system, especially at the command level, has only just commenced.

At program level, the user interface is well advanced. A substantial degree of consistency has been achieved. For example, simple commands like "View", "Insert", "Modify" and "Delete" operate in the same way everywhere, regardless of the program or the kind of database. The use of menus to present other choices is ubiquitous. Control is always implemented in a hierarchical way so that, for instance, entering "Back" generally causes the previous prompt to be re-issued. Likewise, entering "Quit" terminates the current context whatever it may be, first returning the program to its highest level of command and then exiting the program. Identical methods of editing data operate universally throughout the system. Similar methods of abbreviation are also widely implemented, although we have found it desirable to permit a few context-dependent differences. Low-level error detection (*e.g.*, if entered data are of the wrong type or happen to be outside present limits) is diagnosed and handled in the same way by all programs. The input stream can be redirected to accept data from a named sequential file at all interactive prompts. Database house-keeping mechanisms are completely independent of the kind of database. None of these features depend on the capabilities of the computer operating system external to the JESS programs themselves.

We have attempted to display sensible default responses on prompts for input wherever possible; however, this is not a trivial matter and it is already clear that improvements will have to be made as experience dictates. We are also conscious that until the command level is fully developed, users will need a knowledge of their computer operating system and an understanding of the relationships between JESS programs beyond our stated objectives.

From a computational viewpoint, the JESS code now available is highly structured. A hierarchy of interfaces has been constructed which deals with the various levels of processing in a

Table 1. Basic JESS interfaces

Name	Purpose
CHR	universal collating sequence
FIL	file manipulation
GEQ	general equation solving
JAR	storage and retrieval of large arrays of numbers
JED	editing
JIF	storage and retrieval of strings by key
JLR	storage and retrieval of literature references

TYM	time and date facilities
VDU	interaction with visual display units

strictly modular way. The common routines, providing standard facilities such as checking user responses, sorting data, list processing, generating random numbers have already been briefly described.⁴³ Table 1 shows how the system is subdivided and gives the purposes of the different sections of code. Two of the more notable features in this respect are:

- (i) the JIF (JESS Indexed File) subsystem, on which depends all database activity;
- (ii) the RSD (Resident Data) mechanism by which information is generally transferred between sequentially-executed programs.

The effort that has been put into producing portable Fortran has enabled us to implement

*Interested readers can obtain details of how to acquire the latest version of JESS (currently V3.0) by writing to either of the authors. Email inquiries can be sent to "may@murdoch.edu.au".

JESS on a wide variety of computer systems. These are listed in Table 2 to indicate the kind of facility required to support JESS. We have established that there are no compatibility problems associated with character sets (particularly control characters) when JESS data are transferred between different types of machine, or when interactive JESS programs are operated across computer networks.

Documentation is fairly extensive (>500 pages) and comes in two main parts. The User's manual describes how to operate the system and gives a certain amount of background chemical theory. The developer's manual contains specific information about the Fortran code and the algorithms applied therein. The developer's manual also contains a detailed statement of the Fortran coding conventions we have adopted and a specification of the minimum computer facilities required to implement JESS. Both manuals are extensively indexed and cross-referenced.*

CONCLUSIONS

For the future, completion of the command level interface is our highest priority, but this should become operational shortly. Work will also soon commence on the programs for automatic estimation of equilibrium constants and checking of the thermodynamic database for internal consistency. We have already written a prototype code for modelling systems in which compartmentalization and/or reaction kinetics are involved⁴⁴ and this is now ready to be integrated with the equilibrium modelling programs. Methods of dealing properly with macromolecular interactions are presently under investigation and will also be incorporated into JESS in due course.

†Compiled but not fully tested.

Thus far we have given little attention to the benefits which can be derived from the application of JESS to the analysis of experimental data, especially from potentiometric titrations. We have previously noted that an entirely new approach to the computation of solution equilibria is needed to extract the maximum information available from such data.¹² JESS has been designed as a foundation for this. Given other demands, however, there seems a while to go before we can embark in earnest on such an undertaking. In the meantime, we are distributing ESTA as part of the JESS package even though it does not conform to the JESS program specifications (many of which were formulated directly as a result of problems we experienced with ESTA portability).

Acknowledgements—We are grateful for the many suggestions regarding JESS development that have been made by colleagues in discussions over the past five years. Thanks go especially to Ria Jooste, Ruth May, Julius Pretorius, Marita Roos, Grahame Strong and Peter Verhoeven for their particular contributions to the overall project. The advice of Dr Sid Wright (Murdoch University) on computational matters is appreciated.

JESS, A JOINT EXPERT SPECIATION SYSTEM—II. THE THERMODYNAMIC DATABASE

PETER M. MAY

School of Mathematical and Physical Sciences, Murdoch University, Murdoch, Western Australia 6150

KEVIN MURRAY

Division of Water Technology, CSIR, P.O. Box 395, Pretoria, South Africa 0001

(Received 19 March 1991. Revised 10 June 1991. Accepted 14 June 1991)

Summary—The thermodynamic database of the JESS (Joint Expert Speciation System) software package is described. It overcomes many existing problems associated with solution-chemistry databases. The system is fully interactive. Reactions can be expressed in any form. Any number of equilibrium constants, enthalpy, entropy and Gibbs-free energy values can be associated with a reaction. Supplementary data such as background electrolyte, temperature, ionic strength, method of determination and original literature reference are also stored. Data can be readily transferred between databases. Currently, the thermodynamic database that is being distributed with JESS contains over 12,000 reactions and over 20,000 equilibrium constants. These data span interactions in aqueous solution of some 100 metal ions with more than 650 ligands.

As is well recognized, one of the most serious weaknesses with equilibrium calculations is the reliability of thermodynamic data.^{1,2} The preparation and handling of such data are major contributors to this unreliability. The process tends to be time-consuming and prone to human error. Accordingly, one of the most important objectives of JESS is to produce programs that will facilitate the development of a large, on-line database of reliable thermodynamic parameters.³

Many existing equilibrium calculation programs⁴⁻⁹ do supply some sort of thermodynamic data set. However, these systems were mostly written many years ago, when there was much less computer power than is now available. As a result, they suffer from a variety of limitations which tend to contribute to the problem of unreliable data rather than help to alleviate it. Common weaknesses include a lack of versatility in the calculations they can perform (increasing the need for manual intervention), technical difficulties with preparing their input, poor or non-existent error detection and an inherent tendency to divergence of their data sets across various sites running the same program. The last of these is especially troublesome and difficult to correct. Differing priorities and opinions make it inevitable that modifications to databases will vary from one location to another. Since none of the existing computer

systems offers a mechanism to resolve such differences, it has become prohibitively time-consuming to re-establish any kind of uniformity, and therefore authority, using currently-available speciation software.

Moreover, the data associated with these programs are themselves inherently limited. The sets are all relatively small, none possessing more than a few thousand reactions. Nearly always, only a single equilibrium constant can be stored for each reaction, *i.e.*, the value applies to a particular temperature and ionic strength (usually 25° and zero, respectively). Reactions are invariably expressed in a fixed form. The “components” or basis species are pre-defined and all “complexes” must be expressed in terms of these components. Changing the component set is tedious, necessarily requiring constants to be re-evaluated manually.

Some programs⁹ supply enthalpy data and others⁷ permit the storage of functions describing how enthalpy changes with temperature. However, these functions usually have to be determined prior to their insertion in the database. If new primary data become available the appropriate function needs to be re-determined manually and re-entered. A better approach is to preprocess the data, replacing the equilibrium constants with equivalent interpolating polynomials,¹⁰ but this is not yet widely done.

Another common limitation is the lack of information on what methods and/or publications were used to obtain a constant. This makes it difficult, and sometimes impossible, to assess the correctness of a value. Given the many problems that can be encountered in critically assessing the literature, or estimating constants for conditions under which no measurements are available, omission of such information does little to enhance confidence in the database and hence in the results of any calculations based on it. Inconsistencies between various results reported in the literature are a largely unsolved problem for those currently building thermodynamic databases.¹⁰

Finally, there are at present no convenient mechanisms by which data in solution-chemistry computer systems can readily be transferred from one database to another. This has led to a divergence of equilibrium constant values (and hence of results of equilibrium calculations) that has surely damaged the credibility in general of speciation modelling.³ There has also been much wasteful duplication of effort since the same primary data are often entered in more than one location. As a corollary, the databases tend to remain restricted in size, with only a small fraction of all the equilibrium constants that could usefully be included. An important reason for these problems is that the identity of every chemical entity is not unambiguously established within the database itself. In other words, the abbreviated symbols used to represent chemical species are not definitive. Consequently, it is impossible to automate the transfer process securely.

This paper describes how these various issues have been addressed in the development of the JESS thermodynamic database.

USER INTERFACE

Data definition

Every attempt has been made to ensure the interface of the database with the user is as clear as possible. One of the main ways this has been done is by using symbols directly recognizable in terms of the chemistry they represent. To achieve this, we have classified the data into four fundamental types.

The first is the unique symbol used to represent a chemical species in any input or output, referred to hereafter as an I/O symbol. Two types of I/O symbol exist, primitive and composite. The latter are comprised of two or more

primitive symbols in any order separated by underscore characters. Typical primitive symbols might be as follows:

The following are some examples of composite symbols:

These combinations of symbols permit a large number of chemical species to be represented, using relatively few primitives. However, users entering new data always have the choice. Any species, even complexes, can be represented by a single primitive symbol if this is deemed appropriate. For example, the above composite species could equally well be expressed as the following primitives:

This is particularly useful when a composite symbol would contain so many primitives that it might not clearly convey the identity of the species. In some cases a primitive symbol may be the only option because the species cannot be written in terms of any combination of existing primitives.

The second data type is "species". This term is used to describe both the I/O symbol (primitive or composite) and various data characteristics of the associated chemical entity. The molecular formula and the charge of each species are always determined for this purpose (although they only need to be entered specifically for primitive species). The CAS registry number and any number of names (common, IUPAC, Chemical Abstracts, *etc.*) can also be associated with species, as can certain other species-specific data, *e.g.*, regarding ionic strength corrections.

Since I/O symbols can be readily modified to suit any individual need, they cannot be used as unique identifiers, *e.g.*, when data are being transferred from one database to another. To overcome this problem, the CAS registry number serves as the primary means of unambiguous identification. Indeed, we carefully maintain the distinction between I/O symbols and species to emphasize that species are the real chemical entities whereas I/O symbols are just arbitrarily-formulated tokens.

The third data type is the reaction. This is expressed in terms of interacting species. The species are delimited within a reaction by plus or minus signs (surrounded by blanks) with reactants and products being separated by an equals sign. Species preceded by a stoichiometric coefficient are enclosed in angle brackets. The following are some examples:

Reactions may be entered with any number of reactants and products. Stoichiometric coefficients may be integers or real numbers. These conventions permit the insertion of all reactions in the exact form in which they are published, irrespective of what might be required for subsequent equilibrium calculations. A check is made to ensure that each reaction is balanced with respect to charge and mass when it is being inserted.

Two other, abbreviated, methods for expressing reactions are available which greatly simplify the specification of certain reactions and speed up their insertion. First, the conventional "beta formulation" is permitted, *i.e.*, overall formation reactions of simple binary and ternary complexes can be expressed as follows:

where the identity of M, L and X is given only once, prior to specifying the reaction or, more usually, sequences of related reactions. The second option permits specification of diverse reactions with the letters M, L, X, H and the pair OH. Thus, having once established the identity of each letter, the three reactions above could also be entered as follows:

The advantage of this second abbreviated method is that it also encompasses many step-wise reactions, for example:

ML2X/ML2.X meaning

LH3/LH2.H meaning

It is worth noting how easily ternary complexes (MLX, ML2X, *etc.*) are handled since these are somewhat inconvenient to classify in printed compilations of formation constants.

The fourth and final data type is the thermodynamic data itself. Such data may include equilibrium constants, standard enthalpy, entropy and Gibbs free energy values.

Any number of constants can be associated with a reaction although to help establish internal consistency only one value may exist for a given combination of medium, temperature and ionic strength. For the same reason, a constant is considered to exist if it can be determined from other existing data, using the following thermodynamic relationships:

$$\Delta G = -RT \ln K = \Delta H - T\Delta S$$

Each thermodynamic constant is characterized by certain supplementary data.

- (i) Each is associated with a medium (background electrolyte), a temperature and an ionic strength. The temperature and the ionic strength can both be represented as ranges if necessary. In addition to conventional mediums, *e.g.*, NaCl or KNO₃, we also often use this item to indicate particular groupings of equilibrium constants. For instance, all the values estimated for the simulation of metal-ligand equilibria in human blood plasma⁸ have been inserted in the database under the medium "Blood Plasma". The procedures for automatic extraction of the data, to be described in a subsequent paper, select constants according to an order of priority which is assigned to the various mediums as appropriate for each application. This mechanism also permits different sets of equilibrium constants to be held simultaneously in the database where there are irreconcilable differences in expert opinion regarding which ought to be used, *e.g.*, one might establish two mediums, NaCl (Toulouse) and NaCl (Cardiff), so that by specifying different medium-priority orders each centre could preferentially determine the data to be selected for their

simulations, *even though both centres were using the same database.*

- (ii) A three-character code is also associated with each constant indicating the method by which it was obtained. This distinguishes between experimentally measured, estimated and critically assessed (*e.g.*, averaged) constants. It also indicates the actual experimental technique used; for example, two such codes are MGL "Measured, Glass Electrode" and MSP "Measured, Spectrophotometry".
- (iii) An error is associated with each constant. It can be expressed as a standard deviation, maximum error or in terms of the number of significant figures. A three-character code can also be associated with the error describing how it was obtained.
- (iv) The literature publications from which the data are obtained are entered into a corresponding literature reference database (with cross-references between publications, if required). The unique number of the publication in this database is then stored in the thermodynamic database alongside each of its corresponding thermodynamic constants. In this way, the publications on which every constant in the database depends can always be ascertained.

Data display and modification

Data can be displayed on the VDU with a program that opens the database for read-only access. No modification of data is then possible; this serves as a useful protection mechanism (allowing for write-access to be restricted to certain users and minimizing the occasions when the database is open to corruption). Species (with any associated data) and reactions (with their thermodynamic data) can be displayed. Various facilities are available which permit rapid searching of the database. For example, all reactions containing specified species (or combinations thereof) can be displayed; species with a given name, CAS registry number or molecular formula can be located and so on.

Updating is done by a separate program which permits new species, reactions or data to be inserted, as well as allowing existing data to be modified or deleted.

Various miscellaneous facilities like producing lists of reactions whose data have been modified since a specified date and obtaining printed lists of specific species and reactions with their data are also provided by individual programs.

Database housekeeping

Physically, the database consists of eight JIFs (JESS Indexed Files [Part I]³). Each JIF contains a particular data type and/or certain links between the data items. Some of these links, called inverted lists, make it possible to provide those capabilities requiring rapid searching of the database.

Unfortunately, links such as these inherently make the database open to corruption. For example, if the computer's power supply happens to be interrupted while internal links are being updated, the database may be left in a badly-defined state. Although all programs operating on the database have built-in mechanisms that aim to minimize the chance of such corruption, a special set of programs has been developed to provide a convenient means of keeping backups of the database, from which it may be restored if necessary.

Such backups consist of all the data written out sequentially, with individual items existing more-or-less independently of other items, yet from which the whole original database can be reconstructed automatically. Indeed, regular reconstruction in this way is recommended as part of the routine housekeeping required to maintain a high level of efficiency in accessing databases that are frequently modified. Another advantage of this backup system is that the storage required to make a direct sequential copy of all the information is always considerably less than to make a copy of the database JIFs themselves.

Data transfer between databases

Although the process of inserting data from original publications into a JESS thermodynamic database is made as easy as possible, it nonetheless remains a time-consuming business. For this reason, at least, it is highly desirable that entry of data into local databases is not duplicated at different sites. One way to minimize this is to transfer data directly from one JESS database to another, making use of an intermediate set of sequential files. A set of programs exists to facilitate this.

The program that produces the set of “transfer files” processes *all* reactions and their data in the source database. The reactions, thermodynamic data, species, species data, literature references, *etc.*, are handled *en bloc*. If only a subset of the reactions in a database needs to be transferred, another program is available by which a sub-database, containing only the required reactions, can first be produced.

Usually, the owner of the “target database” checks the incoming data before they are inserted. In particular, synchronization may be necessary to ensure that the same data item is not being referred to by two different names or descriptions in the two databases. This also permits the deletion of any reactions or data that ought not to be transferred into the target database. The program which loads transferred data into the target database checks for such errors but overall control resides with the database owner.

Database management and responsibility

Within JESS, a thermodynamic database represents the starting point in the automation of equilibrium calculations leading to the final display of results. From this perspective, both the entry of data and the management of the database are different from subsequent steps in that there is no need for any involvement by completely inexperienced users. It nevertheless remains important that the knowledge required to perform these tasks should relate mainly to chemical rather than computational issues. Sooner or later many users will want either to insert new data or to modify copies of the database distributed with JESS. In practice we have found that chemical expertise is mostly required to define and enter new primitive species; entering composite species and reactions is relatively straightforward because the program can deduce most of its essential requirements. Regarding the input of primitive species, the user must at least be able to determine both the molecular formula and the appropriate charge. This is simple enough if the source publication is well-written but, unfortunately, all too frequently the details supplied are not as clear as they could be.

It is important to realize that control over the contents of a database cannot therefore be divorced from the possibility of introducing errors, no matter how expert the user. Accordingly, we envisage that wherever there are multiple users of a single JESS system, a variety of databases may be established. This will provide the flexibility required to deal with applications that are inevitably more diverse than can be accommodated by a single database. On the other hand, convenient exchanges between databases can and should be made whenever there are data which can usefully be shared.

The proliferation of JESS databases, locally and globally, makes it essential that the responsibility for each is clearly demarcated to the person mainly making changes to it. It also seems likely that, at each location there ought to be a single person in charge of the database distributed with JESS. In itself this will require little expertise, for housekeeping is only necessary if a database is extended or modified. However, where different research projects generate many individual databases, some co-ordination may become desirable to maintain local coherence.

IMPLEMENTATION

Although we expect many users to build JESS thermodynamic databases for their own specific needs, we have ourselves constructed a master set, pertaining to aqueous solutions, which we intend to distribute widely as part of the JESS package. This has two purposes:

- (i) to serve as a source of thermodynamic parameters for those who do not have the time or expertise to provide their own; and
- (ii) to provide a substantial amount of common data as a nucleus for those who wish to contribute their data and opinions to a unified primary source for speciation models.³

At the time of writing (Feb. 1991), the master database* contains over 12,000 reactions and over 20,000 equilibrium constants. Table 1 lists the metal ions for which more than 10 reactions exist. More than 25 inorganic ligands and over 600 organic ligands are involved. Data for about 250 solid species have so far also been included.

In an effort to achieve a practical database, best suited to the needs of speciation modelling, we have decided not to be overly restrictive concerning the reactions and constants which

*Interested readers can obtain details of how to acquire copies of this database by writing to either of the authors. Email inquiries can be sent to “may@murdoch.edu.au”.

Table 1. Number of reactions for various metal ions in the JESS master database

Ag ⁺ 209	Fe ³⁺ 299	Pu ⁴⁺ 124
Al ³⁺ 265	Ga ³⁺ 49	Rh ³⁺ 29
Au ⁺ 10	Gd ³⁺ 24	Ru ²⁺ 21

Eu ³⁺ 29	Pd ²⁺ 40	Zr ⁴⁺ 15
Fe ²⁺ 227	Pt ²⁺ 23	

we include. Our aim is to construct the best possible representation of reactions occurring in solution, regardless of experimental or other practical constraints. There are three aspects to this:

(a) *Methods of determining constants.* A constant may be inserted into the database if: (i) it has been experimentally measured; (ii) it is an average of values determined experimentally by more than one worker; or (iii) it has been estimated empirically, based on "expert" knowledge in this field (*e.g.*, using graphical methods, linear free energy relationships, Irving-Williams series, *etc.*). The use of method codes (*vide supra*) ensures that the distinction between measured and estimated values is always apparent. Of course, critical assessments which cast sufficient doubt on published values to justify them being excluded, override all of these selection criteria. Moreover, as mentioned above, only one constant is permitted under a single set of conditions (medium, ionic strength and temperature). Constants are not inserted into the database if they can be calculated automatically from data already existing in the database with a simple mathematical formula (like the van't Hoff equation).

(b) *Dealing with inadequacies of data in the literature.* Given the seriousness of the errors which pervade the formation-constant literature,¹¹ it is obviously important to establish a strategy for dealing with discrepancies in published values. The two most commonly-used sources of thermodynamic constants adopt different approaches, neither of them ideal. On

the one hand, the Chemical Society and certain IUPAC compilations¹²⁻¹⁵ strive to be comprehensive, leaving all assessment to the user. This makes things very difficult for everyone but the highly-specialized expert. On the other hand, the critical volumes of Smith and Martell¹⁶ are selective—they average values and omit outliers, for example. The problem with this is that the data available in the literature are often insufficient to make definitive judgements. One of the most common difficulties is to reconcile different sets of species reported by various investigators. Sometimes it is reasonable to pick the results of the work appearing to be of the highest standard but, all too frequently, objective criteria for judging this are inadequate. Another difficulty lies in distinguishing between the effects of electrolyte medium and differences due solely to the investigators' experimental errors. Consequently, the Smith and Martell tabulations largely disregard the effects of an electrolyte medium.

We are attempting to find a compromise between these two approaches, in which much of the evident experimental noise is filtered out but without arbitrarily selecting between sets of constants or neglecting the systematic effects of electrolyte mediums. We thus hope to compile an unbiased collection of constants, accurate and practical enough for automatic utilization by non-experts yet comprehensive enough to satisfy the needs of the more specialized researcher.

The principal means whereby we deal with unresolvable differences in the literature is to categorize each species in the database with respect to its likelihood of existence. Users can later select which reactions are extracted automatically from the database in a way similar to that for handling constants from different research groups, using the medium classification [see User Interface section 1(i)]. In this instance, we employ terms like "assured" (meaning found by every investigation of good standing), "probable" (found by most), "controversial" (no clear-cut agreement) and "improbable" (found by a minority, often only one investigation, but with otherwise insufficient reason for exclusion). In addition, where significant grounds exist regarding poor analytical techniques or in adequate computational methods, anomalous species can simply be omitted. However, when there is doubt, we prefer to include species in the database (as "improbable") rather than omit them. This is because (i) omission is tantamount

to an estimate for the formation constant of zero—it is generally possible to be more accurate than that; and (ii) omission is likely to mean a possible species is subsequently overlooked—it is better instead to exclude uncertain species later, during the equilibrium modelling process.

At present it is not feasible to employ the error estimates associated with each thermodynamic constant for automatic assessment and selection purposes. Errors are sometimes not reported and, even when they are, they tend neither to be reliable nor comparable from one system to another. For example, so-called “internal standard deviations” of formation constants (as computed by least squares programs) are invariably underestimates since they take no account of systematic errors in the titration parameters.¹⁷ This is not to say that the error estimate data are without value: they have been included in the database because (i) realistic values are occasionally available, *e.g.*, from various IUPAC critical reviews,^{18–23} (ii) reported errors may be indicative of the relative internal consistency of constants determined by a single investigator, and (iii) large estimated errors can be used to flag constants which can only be very roughly estimated.

(c) *Correcting errors introduced during the compilation of data.* Given that a reliable thermodynamic database is the cornerstone of all JESS procedures to help inexperienced users, a strategy for detecting and eliminating errors is essential. Many programmed checks are carried out when the data are being entered, particularly with the aim of preventing duplication of a species. However, these checks clearly cannot entirely prevent the entry of mistaken information or careless errors. We intend to pursue this problem in two ways, over and above being as systematic and as careful as we can be.

The first of these ways is to develop programs that predict equilibrium constants automatically; these will be used to search for internal inconsistencies, as foreshadowed in Part I of this series.³ Intra-reaction checking would confirm that the data for a particular reaction obey various established relationships, such as govern the effect of electrolyte mediums and changes in ionic strength or temperature. Inter-reaction checking would involve two approaches:

- (i) different linear combinations of reactions giving a particular reaction of interest, should give rise to constants in agreement with those of that reaction; and

- (ii) a given series of reactions, *e.g.*, with a common ligand or metal ion, can be expected to show characterizable trends in their equilibrium constants.

Of course, none of these approaches can be perfect; their usefulness will very much depend on quantifying the tolerance within which differences between observed and calculated values are considered acceptable. However, it seems likely that any gross discrepancies introduced by errors made whilst the data are being compiled or entered will thus be detectable.

Our second way of dealing with such errors in the master database is to invite input and feedback from all users of it. One of the great advantages of a computerized source of data compared with a printed compilation, is that it readily affords modification. Our hope is that users will see the benefits not only of sending us new data but also of notifying us of errors. Convenient mechanisms for transferring data make this feasible. There is also a strong incentive for anyone receiving regular updates of the system: they can avoid repeatedly having to modify each new copy of the enlarged database by having their improvements made centrally just once. Of course, all such suggestions will be assessed by us to preserve the integrity of the data distributed with JESS but this scheme should considerably reduce the workload involved in keeping the JESS master database up-to-date, comprehensive and as error-free as possible.

CONCLUSIONS

The various classifications and cross-linking of data in a JESS thermodynamic database make it potentially far more useful than either a printed compilation or a computerized list of equilibrium constants. The main purpose for which the system has been designed is to facilitate the automatic extraction of data for equilibrium speciation calculations following pre-determined selection criteria. This is essential for JESS to meet its primary objectives.³ However, it is clear, even as the system is currently developing, that the thermodynamic database will also serve in other ways. In a stand-alone capacity, it can provide solution-chemistry researchers with the means of accessing the formation-constant literature in a convenient and powerful manner. The whole master database can now readily be installed on certain commonly-available workstations (*e.g.*,

on a 386 desktop microcomputer). This only requires about 10 MB of hard disk, including space for the appropriate programs. At the same time, at the other end of the spectrum of potential applications, it is now possible to search through a large and growing body of integrated thermodynamic data, using special-purpose computer programs. Interesting new chemical relationships might well be revealed as such programs systematically quantify the collective properties of metals and ligands interacting in solution.

ASSAY OF SULPHUR COMPOUNDS WITH 1-CHLOROBENZOTRIAZOLE

C. CHANNE GOWDA and S. M. MAYANNA*

Department of Chemistry, Central College, Bangalore University, Bangalore-560 001, India

(Received 20 March 1991. Revised 29 May 1991. Accepted 13 June 1991)

Summary—A simple but accurate potentiometric method for the estimation of certain sulphur containing organic compounds has been developed, based on their oxidation with 1-chlorobenzotriazole. A back-titration procedure can also be used. The nature of oxidation in different media is discussed and the oxidation products have been identified.

Thioureas find extensive application in rubber vulcanization, electrodeposition and corrosion inhibition of metals, photography, polymers, textiles and agriculture. Dithiocarbamates and thioamides are well known analytical reagents. Methionine is one of the essential amino acids present in a large number of biological systems. A review of the literature reveals the use of a few procedures for the assay of thioureas,¹ dithiocarbamates,² thioamides³ and methionine.⁴ However, these methods have limitations due to time consumption, narrow range of developed experimental conditions and in some cases over oxidation of reductants.

Recently, 1-chlorobenzotriazole (1-CBT), an *N*-halogeno compound, has attracted the attention of organic chemists as a novel organic reagent in organic synthesis because of its reactivity towards a number of functional groups.⁵ However, its analytical application is scarce. As part of our investigations of potential oxidative reagents, we have studied its utility as an analytical reagent for the assay of a few industrially important organic compounds.^{6,7} In this communication we report titrimetric procedures for the assay of thiourea (TU), allylthiourea (ATU), phenylthiourea (PTU), tolythiourea (TTU), thioacetamide (TA), thiobenzamide (TB), diethyldithiocarbamate (DDC), ethylphenyldithiocarbamate (EPDC), diisopropylthiocarbamate (DIDC) and methionine (Met) with CBT.

EXPERIMENTAL

CBT was prepared by the method of Johnson *et al.*⁸ and recrystallized (m.p. 105.0–106.0 ±

0.1°) from dichloromethane. Its purity was checked (>99%) by the iodometric method. The sulphur compounds (Sigma or Aldrich, U.S.A.) were used after purification with suitable solvents. Comparative assay of these compounds showed acceptable purity (>99%). Solutions were prepared from analytical reagent grade chemicals and distilled water. The experiments were repeated to check reproducibility. The detailed procedures for preliminary studies, back titration and potentiometric titration are similar to those described earlier.⁶

The rate of oxidation at different temperatures and pH values prior to back titration are depicted in Fig. 1. Oxidation reactions are reproducible in 0.1M sodium hydroxide with stoichiometries of 1:4 for thioureas and thioamides, and 1:6 and 1:8 for methionine and dithiocarbamates, respectively (Table 1). Hence, 0.1M sodium hydroxide is used for the analysis.

Back-titration. Prepare accurately a solution containing about 1 mg/ml of the sulphur compound. Add an aliquot of this solution to 50.00 ml of $2 \times 10^{-3}M$ CBT solution in an iodine flask. Add enough sodium hydroxide to obtain the required concentration (0.1M). Set the reaction mixture aside at 30° for 15–20 min (40 min for PTU) and shake at intervals. Add 25.0 ml of 1.0M sulphuric acid and 5.00 ml of 2% (w/v) KI solution and titrate with standard thiosulphate solution ($1 \times 10^{-3}M$) to a starch end-point. Run a blank under the same conditions. The amount of sulphur compound in the solution (% mg) is given by the equation,

$$x = \frac{MY(V_2 - V_1)}{E}$$

*Author for correspondence.

Fig. 1. Rate of oxidation of phenylthiourea under different conditions. $[CBT] = 2 \times 10^{-3}M$, $[PTU] = 1 \times 10^{-4}M$.

where M is the molecular weight of the sulphur compound, Y the molarity of the sodium thio-sulphate solution, E is the number of electrons per mole of sulphur compound, V_2 ml is the blank titre and V_1 ml is the sample titre, respectively.

Potentiometric titration

During potentiometric titration the change in potential at the end-point on addition of 0.1 ml of $2.0 \times 10^{-3}M$ CBT was appreciable (50–120 mV) and reproducible in the pH range 1–5 (Fig. 2). The number of electrons involved in the stoichiometric reactions depends on the nature of the reductant and the medium (Table 2). In buffer solution of pH 5.0, it is 6 for TU and ATU, 4 for PTU and TTU, 5 for TA and TB, and 2 for Met.

RESULTS AND DISCUSSION

Some of the results obtained during back-titration and potentiometric titration are given

in Table 3. The present method (especially the potentiometric method) seems to be superior to the back-titration method.

The four-electron stoichiometry obtained for oxidation of Met in 0.1M perchloric acid can be represented by equation 1.

The respective 1:1, 1:2, 1:3, 2:5 stoichiometries for the oxidation of Met, arylthioureas, alkylthioureas and thioamides with CBT in pH 5 buffer can be represented by equations (2) to (5).

*Mean ± standard deviation of 10 determinations.

From the detailed investigations of the above compounds, it was found that Mg^{2+} , Ba^{2+} , Zn^{2+} , Cu^{2+} , K^+ , Na^+ , PO_4^{3-} , ClO_4^- and SO_4^{2-} had no effect on the rate of oxidation. [Chloride (>0.35 mg/ml) particularly in appreciably acidic media interferes in the estimation.] In the case of the back-titration procedure, the stoichiometry was unaffected by the reversal of the order of addition of CBT and reductant. 1-CBT showed stoichiometric reactivity towards the reductants and also in many occasions behaved as a powerful oxidizing agent when compared to other similar *N*-halogeno compounds like chloramine-T and chloramine-B.

ADSORBING COLLOID FLOTATION SEPARATION AND POLAROGRAPHIC DETERMINATION OF Mo(VI) IN WATER

BHARATHIBAI J. BASU, D. K. PADMA* and S. R. RAJAGOPALAN†

Materials Science Division, National Aeronautical Laboratory, Bangalore-560017, India

(Received 1 February 1991. Revised 19 June 1991. Accepted 19 June 1991)

Summary—A method is described for the flotation and determination of Mo(VI) in water at ng/ml levels. Mo(VI) is preconcentrated and separated by adsorbing colloid flotation employing aluminium(III) hydroxide as collector and sodium lauryl sulphate as surfactant at pH 5.3 ± 0.1 . The molybdenum content in the froth is estimated by using the catalytic wave of Mo(VI) in the presence of nitrate by charging current compensated d.c. polarography (CCDCP) or differential pulse polarography (DPP). The effect of variables such as pH, ionic strength, concentration of collector and surfactant, time of stirring and gas flow-rate on the recovery of Mo by flotation is reported. The effects of various cations and anions on the flotation and determination of Mo are studied. This method is employed for the determination of molybdenum in natural fresh water samples.

Adsorbing colloid flotation (ACF) has been applied to the separation and preconcentration of trace elements in many aqueous systems during the past two decades.¹⁻¹³ Analytical applications of flotation have been reviewed recently.¹⁴ Adsorbing colloid flotation has some advantages over ion flotation (IF) such as (i) surfactant needed in ACF is smaller compared to the stoichiometric or greater amount required in IF and (ii) the flotation is achieved in a few seconds in ACF whereas gas has to be bubbled for a longer duration in IF.

Kim and Zeitlin¹ have separated Mo by ACF with ferric hydroxide as collector and sodium lauryl sulphate (SLS) as surfactant and estimated Mo by spectrophotometry. Recently Hidalgo *et al.*² have preconcentrated Mo in sea water by flotation with iron(III) hydroxide and hexadecyl trimethyl ammonium bromide. They estimated Mo in the floated layer (after removing iron by ion exchange) by differential pulse polarography employing the catalytic wave in nitrate medium. In all the ACF separations of Mo reported so far, iron(III) hydroxide has been used as the collector.^{1,2} Iron interferes with the polarographic estimation of Mo when the Fe:Mo ratio is greater than 100. Hence iron has to be separated by ion-exchange or any other suitable method. This additional separation step

can be avoided if iron(III) hydroxide is replaced by aluminium(III) hydroxide. But previous efforts to use aluminium(III) hydroxide as collector were not successful.² The present study is aimed at finding out a method of preconcentrating Mo by ACF with aluminium(III) hydroxide as collector.

EXPERIMENTAL

Apparatus

Polarographic measurements were made with a model CL-90 Pulse Polarograph of Elico (P) Ltd., Hyderabad. A Metrohm polarographic cell with mercury pool as counter electrode and SCE as reference electrode was used with a Sargeant capillary having a 3-sec natural droptime as DME. The rate of flow of mercury was found to be 2.30 mg/sec. For DPP measurements, the pulse duration was 0.04 sec and the pulse amplitude was 50 mV. The droptime was mechanically controlled.

The flotation apparatus was similar to that described by Nakashima.⁶ The flotation cell was a tall glass cylinder with a 500-ml capacity fitted with a G-4 porosity sintered glass disc to generate small gas bubbles. A side arm was provided near the bottom of the cell to drain the mother liquor rapidly after flotation.

Purified nitrogen (free from oxygen) was used for deaeration of the solution prior to polarographic measurements as well as for bubbling through the flotation cell.

*Department of Inorganic and Physical Chemistry, Indian Institute of Science, Bangalore-560003, India.

†Author for correspondence.

Hitachi UV-Visible spectrophotometer (model 139) was used for spectrophotometric determination of some of the added ions present in the froth.

Reagents

All reagents used were of analytical grade. A Mo(VI) (1 mg Mo/ml) stock solution was prepared from ammonium molybdate, Al(III) (10 mg Al/ml) solution from aluminium nitrate and Fe(III) (2 mg Fe/ml) solution by dissolving pure iron powder in diluted hydrochloric acid. Standard solutions of other metals were prepared either by dissolving the pure metal in nitric acid or by dissolving the nitrate salt in water. Eighty per cent (v/v) ethanolic solutions of sodium lauryl sulphate (SLS) (1 mg/ml), sodium oleate (SO) (4 mg/ml) and cetyl trimethyl ammonium bromide (CTAB) (1 mg/ml) were employed. Sodium chloride, sodium nitrate and sodium sulphate were used to study the effect of ionic strength. For the study of anionic interferences, standard solutions of Na_2CO_3 , sodium carbonate, sodium hydrogen carbonate and sodium phosphate were used. A standard silicate solution is prepared by dissolving pure silica in sodium hydroxide solution and diluting to volume.

Procedures

Flotation step. Place 400 ml of water containing trace amounts of Mo(VI) in a beaker and add 2 ml of Al(III) solution. Adjust the pH to 5.3 ± 0.1 with aqueous ammonia solution while stirring with a magnetic stirrer. Continue stirring for 10 min. Add 2 ml of SLS solution to the beaker and then transfer the contents to the flotation cell, quantitatively. Pass nitrogen at a moderate rate for 1 min. Allow the froth to settle for 2 min. Drain most of the mother liquor through the side arm. The remaining mother liquor is sucked off through the sintered disc. Dissolve the froth in the cell with 10 ml of 2M nitric acid and collect it quantitatively in a beaker. Heat this solution to boiling and simmer until the volume is reduced to 1 ml. Make up to 10 ml with water. For the separation of Mo from natural water samples, the above procedure is modified by increasing the solution volume to 1000 ml and Al^{3+} and SLS concentrations to 100 mg and 5 mg respectively.

Polarographic measurement. Transfer a suitable aliquot of the preconcentrated Mo(VI)

solution to a polarographic cell. Add 10 ml of a solution containing 2M sodium nitrate and 0.5M sulphuric acid and dilute to 20 ml so that the solution is 1M in sodium nitrate and 0.25M in sulphuric acid. After deaeration, record the polarogram from 0.0 to -0.40 V vs. SCE at 25° . Determine the concentration of Mo(VI) by making standard additions of comparable amounts of Mo(VI).

RESULTS AND DISCUSSION

Effect of pH on the flotation behaviour of collectors with surfactants

The flotation behaviour of iron(III) hydroxide and aluminium(III) hydroxide with SLS, SO and CTAB was studied. This was done by adjusting the pH of solutions containing Al(III) and Fe(III) by means of dilute ammonia and nitric acid and floating with an ethanolic solution of surfactant. After flotation, a visual evaluation of the completeness of flotation was made by observing the residual solution and the froth. A clear residual solution, which is free from the collector as shown by quantitative testing, and a stable froth indicate complete flotation. If the flotation is incomplete, the precipitate remains dispersed in the solution. It was found that SLS was able to float ferric hydroxide completely in the pH range 4.5–8.0. Aluminium(III) hydroxide was completely floated in the pH range 5.0–7.5. The flotation was incomplete above pH 7.5 for aluminium(III) hydroxide and above pH 8.0 for iron(III) hydroxide. This was expected, because the isoelectric points (IEP) of the hydroxides of Al(III) and Fe(III) are 7.5 and 8.0, respectively.¹⁵ Flotation of these colloids with other surfactants like SO and CTAB was also dependent on pH. SO floats both aluminium(III) and iron(III) hydroxides completely above pH 7. CTAB floats iron(III) hydroxide partially at low pH values and completely at pH 9–10. With aluminium(III) hydroxide and CTAB, no flotation occurs in the pH range 4–10 and the precipitate remains dispersed in solution.

The results obtained for ferric hydroxide are in agreement with the results of Grieves and Bhattacharya.¹⁶ Matsuzaki and Zeitlin⁹ had studied the effect of pH on the ability of various surfactants to float the collectors from artificial sea water. Their results showed that ferric hydroxide could easily be floated with a number of surfactants while the flotation efficiency was

poor for aluminium hydroxide. The negative results for aluminium hydroxide were probably due to the effect of high ionic strength as found in sea water. No work has been reported on the flotation behaviour of collectors with surfactants from fresh water or water with low ionic strength. We have found that aluminium(III) hydroxide can be completely floated from fresh water samples by SLS in the pH range of 5–7.5 and by SO in the pH range 7–10. When the ionic strength is increased, complete flotation can be achieved by increasing the amount of surfactant to some extent. Above a particular limit, flotation remains incomplete. Further experiments on the flotation of Mo(VI) with aluminium(III) and iron(III) hydroxides were carried out with SLS as surfactant.

Effect of pH on the recovery of Mo(VI) by ACF

Figure 1 shows the effect of pH on the recovery of Mo(VI) using aluminium and ferric hydroxides as collectors and SLS as surfactant. A 100% recovery of Mo(VI) is achieved with aluminium(III) hydroxide in the pH range 5.2–5.5. As the pH is increased, the recovery of Mo(VI) decreases even though the flotation is complete. At higher pH values, the colloid becomes negatively charged and the recovery of molybdate decreases to zero. With iron(III) hydroxide as collector, 100% recovery is obtained in the pH range 4.5–6.0.

In ACF, the mechanism of collection of the analyte on the colloidal precipitate is either adsorption or coprecipitation. In the case of Mo(VI), the pH range for maximum recovery is quite narrow and in this pH range, the colloidal precipitate has a charge opposite to that of the analyte. Hence, it appears that the mechanism governing the separation of Mo(VI) from solution is adsorption. Since Mo(VI) is present as an anion at $\text{pH} > 1.0$, adsorption of this species can be expected to occur at a positively charged colloid. Fe(III) hydroxide and Al(III) hydroxide have positive charges at pH values lower than their IEP's. Above the IEP, there is no electrostatic attraction as both molybdate and the colloidal precipitates are negatively charged. Therefore the adsorption of Mo(VI) decreases almost to zero as the pH is increased to a value above the IEP of the colloidal precipitates (Fig. 1).

Kim and Zeitlin¹⁷ found that Mo(VI) could be completely coprecipitated with colloidal ferric and thorium hydroxides but the recovery of

Mo(VI) by coprecipitation on aluminium(III) hydroxide was very poor. They attributed this to the relatively higher solubility of aluminium molybdate compared to ferric and thorium molybdates. The Paneth–Fajans–Hahn rule for the coprecipitation mechanism requires that the collector must contain an ion which forms a compound of low solubility with the counter ion adsorbed. In the light of the above discussion, it may be concluded that the nearly complete recovery of molybdate on aluminium(III) hydroxide by flotation at pH 5.2–5.5 should be due to adsorption.

Effect of ionic strength

The effect of nitrate, chloride and sulphate ions on the recovery of Mo(VI) by ACF with aluminium(III) hydroxide as collector was investigated. The concentrations used for this study were 0.1 ppm Mo(VI), 50 ppm aluminium(III) and 5 ppm SLS. The inert ion concentrations were varied from 0.01 to 0.20M. The pH was adjusted to 5.3 ± 0.1 in all these experiments (Fig. 2). It was found that the doubly charged sulphate ions decreased the percentage recovery of Mo(VI) to a greater extent than singly charged nitrate or chloride ions. When the ionic strength was increased, the recovery of Mo(VI) decreased and the flotation was incomplete at concentrations higher than 0.1M for chloride and nitrate and 0.03M for sulphate. The flotation efficiency was very poor above 0.06M sulphate and 0.2M nitrate or chloride. In the presence of 0.1M chloride or nitrate, 64% of molybdate was recovered by flotation as seen from Fig. 2. The precipitate

Fig. 1. Effect of pH on the recovery of Mo(IV) with SLS as surfactant and aluminium(III) hydroxide (○) and iron(III) hydroxide (△) as collectors. [Mo(IV)] = 0.20 ppm; [Al(III)] = 50 ppm; [Fe(III)] = 50 ppm; [SLS] = 5 ppm; solution volume = 200 ml.

Fig. 2. Effect of ionic strength on the recovery of Mo(VI) with SLS as surfactant and aluminium(III) hydroxide as collector; (Δ) NaNO_3 , (\circ) NaCl and (\bullet) Na_2SO_4 . $[\text{Mo(VI)}] = 0.20$ ppm; $[\text{Al(III)}] = 50$ ppm; $[\text{SLS}] = 5$ ppm; $\text{pH} = 5.3 \pm 0.1$.

of aluminium(III) hydroxide remaining in the residual solution after flotation was separated by filtration and Mo(VI) in this residue was estimated. It was found that about 30% molybdate could be recovered from this precipitate showing that Mo(VI) is adsorbed by aluminium(III) hydroxide in the presence of 0.1M chloride or nitrate but the flotation of the collector by the surfactant is affected. The presence of sulphate seriously affected both the adsorption of Mo(VI) and the flotation of aluminium(III) hydroxide.

Effect of the concentrations of surfactant and collector

The effect of SLS on the ACF of Mo(VI) with Al(III) and Fe(III) hydroxides was studied by varying the SLS concentration from 0.2–10 mg. Concentrations of 0.1 ppm Mo(VI) and 50 ppm Al(III) or Fe(III) were used. The pH was maintained at 5.3 ± 0.1 . It was found that 1 mg of SLS was sufficient to float precipitates containing up to 40 mg of Fe(III) or Al(III) in a solution volume of 400 ml (when the ionic strength was less than 0.02M). Recovery of Mo(VI) was maximum when the SLS concentration was in the range 1–4 mg. Higher amounts of surfactant result in the formation of an excess of foam which is not beneficial. If the surfactant concentration exceeds the critical micelle concentration (cmc), the flotation tends to become incomplete. At very low concentrations of surfactant, the foam layer was thin and unstable and could not support the precipitate. Hence a surfactant concentration of 2 mg for a solution volume of 400 ml was used in this work.

The concentrations of Al(III) and Fe(III) were varied from 2–100 mg in a solution volume of 400 ml. SLS concentration was 5 ppm and the pH was adjusted to 5.3 ± 0.1 . When the Mo(VI) concentration was 1–40 μg , an optimum concentration of 10–20 mg Al(III) or Fe(III) was enough to bring about complete recovery of Mo(VI).

Effect of stirring time

The relation between stirring time and recovery of Mo(VI) was investigated. The concentrations of Mo(VI), Al(III) and SLS used were 0.2, 50 and 5 ppm, respectively. The pH was maintained at 5.3 ± 0.1 . It was found that at very low concentrations of colligend (less than 50 μg of Mo), the adsorption of Mo(VI) on the colloidal precipitate was rapid whereas at higher concentrations of Mo(VI), stirring time had an effect on the recovery of Mo(VI). The results obtained are shown in Fig. 3. It is seen that a stirring time of 15 min was needed to get 100% recovery for floating 500 μg of Mo(VI) with 10 mg of aluminium(III) hydroxide. Mo(VI) concentrations of 4, 10 and 40 μg could be collected almost instantaneously. This can be readily explained in terms of the adsorption since it is well known that the rate of adsorption increases when the ratio of adsorbent to adsorbate is large.

The other parameters like gas flow-rate, duration of gas flow and volume of solution had little effect on the recovery of Mo(VI). Gas was bubbled at a moderate rate for 1 min. The solution volume was changed from 100 to 1000 ml. A quantitative recovery of Mo(VI) was obtained.

Fig. 3. Effect of stirring time on the recovery of Mo(VI) with SLS as surfactant and aluminium(III) hydroxide as collector; $[\text{Mo(VI)}] = 500$ μg ; $[\text{Al(III)}] = 10$ mg; $[\text{SLS}] = 1$ mg; solution volume = 200 ml.

Catalytic wave of Mo(VI) in the presence of surfactants

Following Kannan and Rajagopalan,¹⁸ a supporting electrolyte of 1M sodium nitrate and 0.25M sulphuric acid was chosen for the catalytic wave polarographic determination of Mo(VI). The catalytic current is sensitive to temperature and hence all the polarograms were recorded at 25°. Hidalgo *et al.*² studied the effect of various surfactants on the catalytic wave of Mo(VI) and found that many of them suppress the peak current. Their report did not include the effect of SLS. In this work, the effect of 5–50 ppm surfactant on the catalytic current (both dc and DPP) of 1 ppm Mo(VI) was investigated (Fig. 4). It was found that in the presence of 30 ppm SLS, the catalytic current of Mo(VI) was suppressed to about half its original value. But at SLS concentrations less than 10 ppm, the reduction of catalytic current was <20%. However, it was noticed that the catalytic current was virtually unaffected after treatment of the froth with nitric acid. This might be due to the oxidative degradation of SLS into products that are not surface active. The catalytic current of Mo(VI) is affected to a lesser extent by the addition of SO and CTAB as seen from Fig. 4.

Comparison of DPP and CCCDCP for the determination of Mo(VI)

In order to arrive at the best technique from the point of view of improved sensitivity for the estimation of Mo(VI) by the catalytic wave, CCCDCP and DPP were compared both experimentally and theoretically. Typical polarograms (both CCCDCP and DPP) are shown in Fig. 5. Our experiments show that the dc catalytic current is 2.75 times more sensitive than the DPP catalytic current for a droptime of 0.5 sec. When the droptime is increased to 2.0 sec, the ratio of $i(\text{CCCDCP})$ to $i(\text{DPP})$ is increased to 3.4. The pulse duration was 0.04 sec in all the experiments. The ratio of dc catalytic current to DPP catalytic current was calculated with the expression derived by Rodriguez-Monge *et al.*¹⁹ for EC processes and the values were 2.77 and 3.76 for droptimes of 0.5 and 2.0 sec respectively. Thus it can be seen that the experimental values are in good agreement with the theoretical values. Therefore it may be concluded that the catalytic reduction of Mo(VI) by nitrate is more sensitive by CCCDCP than by DPP. This conclusion contradicts that stated

Fig. 4. Effect of variation of surfactant concentration on the catalytic current of Mo(VI); [Mo] = 1 ppm, time = 0.5 sec (a) dc catalytic current (b) DPP catalytic current; (Δ) SO, (\circ) CTAB and (\bullet) SLS.

by Lanza *et al.*²⁰ They found DPP to be 4.7 times more sensitive than DCP. This result is difficult to understand since it is contrary to theoretical expectations.

Effects of diverse cations and anions on the flotation and determination of Mo(VI)

The flotation of Mo(VI) was carried out in the presence of various cations and anions. This was done by adding known amounts of these ions to a synthetic solution before flotation.

Fig. 5. Typical polarograms of Mo(VI) in a supporting electrolyte of 1M NaNO₃ and 0.25M H₂SO₄. [Mo] = 0.1 ppm; $m = 2.30$ mg/sec; time = 2 sec (a) CCCDCP and (b) DPP, $\Delta E = 50$ mV.

The results are summarized in Tables 1 and 2. The amounts of added ions in the froth after flotation at $\text{pH } 5.3 \pm 0.1$ were determined either by polarography or by spectrophotometry. Cu(II), Pb(II), Ni(II), Co(II), Bi(III), Sb(III), Zn(II) and Cd(II) in the froth were estimated by polarography. Fe(III), Ti(IV), Zr(IV) and Cr(III) in the froth after flotation were determined by conventional spectrophotometric methods. Fe(III), Bi(III), Ti(IV), Cr(III) and Zr(IV) were floated completely along with Mo(VI). These elements with the exception of Fe(III) do not interfere with the polarographic determination of Mo. The recoveries of Cu(II) and Pb(II) were 75–80%. Co(II), Ni(II), Zn(II), Cd(II) and Sb(II) were partially floated.

Table 2 gives the results obtained on studying the effect of anions on the flotation of Mo. The flotation efficiency of Mo was affected by the presence of phosphate and silicate. Thus the recovery of Mo is reduced to 56 and 61% by 50 ppm levels of silicate and phosphate respectively. The interference was found to be negligible at or below 5 ppm silicate and phosphate. At higher concentrations, these multivalent anions compete with molybdate in the process of adsorption on the collector and thus cause a lower recovery for Mo(VI). Anions like carbonate and bicarbonate could be tolerated to a level of 1000 ppm in the solution.

The effect of various cations and anions on the catalytic wave of Mo(VI) was investigated.

Table 1. Effect of the addition of other metallic ions on the flotation of Mo with Al(OH)_3 as collector and SLS as surfactant. $[\text{Mo(VI)}] = 40 \mu\text{g}$; $[\text{Al(III)}] = 20 \text{mg}$; $[\text{SLS}] = 1 \text{mg}$; $\text{pH} = 5.3 \pm 0.1$; solution volume = 200 ml

Ion	Ratio of Mo(VI) to the added ion	% Recovery

	4.0	35.0	87.5
	10.0	24.4	61.0
CO_3^{2-}	10.0	39.2	98.0
	50.0	39.1	97.8
	100.0	38.0	95.0
	200.0	38.4	96.0
HCO_3^-	100.0	39.0	97.5
	200.0	38.0	95.0

The concentration of Mo(VI) in the supporting electrolyte was 0.2 ppm. The results are given in Table 3. The catalytic current of Mo(VI) is not affected by the presence of a 100-fold excess of silicate and phosphate. A 100-fold excess of metallic ions such as Pb(II), Cd(II), Zn(II), Ni(II) and Co(II) do not interfere as their reduction potentials are more negative than that of Mo(VI). A 1000-fold excess of Al(III) and 100-fold excess of Ti(IV) and Zr(IV) also do not interfere. Cu(II) and Bi(III) peaks occur at a more positive potential than that of Mo(VI). But since the peaks are separated by more than 150 mV and the sensitivities of copper and bismuth are much less than that of Mo(VI)

Table 3. Interferences due to foreign species in the polarographic determination of Mo. $[\text{Mo(VI)}] = 0.2 \text{ppm}$; time = 0.5 sec; $\Delta E = 50 \text{mV}$

PO_4^{3-}	100:1	nil

in nitrate medium, it is possible to determine Mo(VI) in the presence of a 25-fold excess of Cu(II) and Bi(III). In such cases, DPP offers better resolution than CCCDCP. Hence in the presence of an excess of Cu(II) and Bi(III), it is preferable to use DPP for the determination of Mo. A 10-fold excess of Cr(III), Cr(VI), Tl(I) and Sn(IV) does not interfere. Fe(III) does not interfere if present in small amounts but a 100-fold excess of Fe(III) causes a decrease in the Mo catalytic current by 10%. When the Fe:Mo ratio is 400, there is a significant reduction in the catalytic current of Mo(VI) as seen from Table 3. Sb(III) interferes as its reduction peak coincides with that of Mo(VI). It is seen that Sb(III) gets partially floated with Mo(VI). The interference was overcome by oxidizing Sb(III) to the electroinactive Sb(V) by adding a few drops of potassium permanganate solution to the solution of froth.

Recovery of Mo(VI) from synthetic solutions

Initial experiments were carried out with 1 ppm Mo(VI), 10 mg Al(III) and 1 mg SLS in a solution volume of 400 ml to standardize the experimental conditions. Then under the standardized conditions, the flotation was done at lower Mo(VI) concentrations and the results are given in Table 4. Thus it was seen that 1 μg of Mo in 400 ml of water could be preconcentrated by this method.

The detection limit (at a signal-to-noise ratio of 3) is 5.0 $\mu\text{g/l}$. for CCCDCP and DPP at a droptime of 2 sec. When the initial volume of water for flotation was increased to 1000 ml, the concentration factor was 50. Thus it was possible to achieve a detection limit of 0.1 $\mu\text{g/l}$. for Mo(VI) in water by this flotation-polarographic method. This value is comparable to the detection limit obtained by adsorption voltammetry.²¹ The relative standard deviation for 8 replicate analyses of a solution containing 2 $\mu\text{g/l}$. Mo was found to be 3.0%.

Recovery of Mo from natural fresh water samples

It was noticed that the recovery of Mo from natural fresh water by ACF under the experimental conditions standardized for synthetic solutions [50 ppm Al(III), 5 ppm SLS and pH 5.3 ± 0.1] was about 50%. Fresh water samples often contain anions like carbonate, bicarbonate, chloride, silicate and phosphate in addition to some metal ions. The approximate ranges and typical values for some metals and ligands in fresh waters have been reported elsewhere.²²

Table 4. Results for the analysis of synthetic water samples*

No.	Mo(IV) added, μg	Mo(IV) found, μg	Recovery %
1	1.0	1.0	100
2	1.6	1.56	97.5
3	8.0	7.84	98.0
4	40.0	39.0	97.5
5	500.0	495.0	99.0

*Solution volume = 400 ml.

The results of the study of anionic interference on the flotation of Mo(VI) are already given in Table 2. The concentrations of Mo(VI), Al(III) and SLS used for this study were 0.2 ppm, 100 ppm and 5 ppm. It can be seen from Table 2 that up to 1000 ppm of carbonate and bicarbonate do not interfere with the flotation of Mo whereas the recovery of Mo is affected by silicate and phosphate at concentrations higher than 10 ppm. But the typical concentrations of phosphate and silicate in fresh water are of the order of 1 and 5 ppm respectively. We found that the recovery of Mo from natural water samples could be improved by increasing the collector concentration to 100 ppm. The alternative method is to repeat the flotation until all the Mo was recovered. The recovery of Mo was about 90% in a single flotation by employing 100 ppm Al(III). Two consecutive flotations with 50 ppm Al(III) also enabled us to recover 90% Mo but a single flotation with increased amount of collector and surfactant was less time consuming than double flotations.

Iron and copper present in natural water were also floated along with molybdenum. Copper does not interfere in the determination of Mo. The iron to molybdenum ratio was often higher than 100 in the froth and this decreased the sensitivity of molybdenum determination by catalytic wave polarography. By examining water samples from different sources like wells, lakes and borewells, we found that the Fe(III) to Mo(VI) ratio in the froth often exceeded 500. This suppresses the polarographic signal considerably and results in lower values for Mo. Hence it is essential to remove iron which is done by incorporating an additional flotation step prior to the flotation for the preconcentration of Mo.

Since the recovery of Mo(VI) falls to zero at pH values above 8.0, it is possible to separate Fe(III) from Mo(VI) by employing a flotation step. Therefore, for the determination of Mo in natural water samples containing considerable amounts of Fe(III), the procedure is modified

Table 5. Results for the determination of Mo(VI) in fresh water samples

No.	Sample*	Mo(VI) found† ($\mu\text{g/l}$)
1	A	0.42 ± 0.04
2	B	0.50 ± 0.04
3	C	0.64 ± 0.05
4	D	0.31 ± 0.03

*A = laboratory tap water; B = well water;

C = bore-well water; D = lake water.

†Mean \pm standard deviation ($n = 4$).

as follows: add 20 mg of Al(III) to 1000 ml of the sample solution, adjust the pH to 8.5 with dilute ammonia, add an ethanolic solution containing 5 mg of sodium oleate and float by bubbling nitrogen through the solution for 2 min. Fe(III) and other cations like Cu(II) and Pb(II) if present are separated in the froth. To the residual solution, add 100 mg of Al(III), adjust the pH to 5.3 ± 0.1 , add 5 mg of SLS and continue as described earlier in the experimental section. Mo(VI) in four natural water samples from different sources was estimated with this procedure and the results obtained are shown in Table 5. The reproducibility was good. Thus the method is found to have great potential in determining nanogram levels of Mo(VI) in natural fresh water samples.

ANALYTICAL DATA

MICROSCOPIC ACID–BASE EQUILIBRIA OF ARGININE

BÉLA NOSZÁL and RÓZSA KASSAI-TÁNCZOS

Department of Inorganic and Analytical Chemistry, L. Eötvös University, H-1518 Budapest 112, Pf. 32,
 Hungary

(Received 25 April 1991. Accepted 30 May 1991)

Summary—Three and two protonation macroconstants as well as twelve and four microconstants have been determined for arginine and citrulline, respectively. These data include microscopic basicity values of the arginine guanidino group, for which no reliable constants have been reported earlier. The determinations were carried out by a combination of potentiometric and deductive methods. The guanidino basicity proved to be extremely high, and can be characterized by microconstants between 14.7 and 15.0 log k units. The interactivity parameters could also be determined from the microscopic protonation constants. These values for the guanidino–amino and the guanidino–carboxylate interactions are 0.2 and 0.1 log k units, respectively. The pH-dependent distribution of all eight arginine microspecies is made visual by a microspeciation diagram. The microspeciation diagram is the most useful tool to predict bidentate binding isomerism in metal complex formation and site-specific bioligand–bioligand associations.

Arginine is a semi-essential amino acid, which plays an important role as a binding moiety in proteins¹ and also as a metal–complexing agent.²

Of the twenty “classical” amino acids, however, arginine is the only one for which no microscopic protonation constants (microconstants) have been published.³ Microconstants are submolecular thermodynamic parameters, quantitating the proton-binding capability of basic groups, when the protonation states of all other basic sites are definite in the molecule. Thus, microconstants are the proper terms for the thorough and exact characterization of the basicity of multidentate (bio)ligands^{4–6} and also the tools for the analytical determination of all protonation forms in the solution (microspeciation).^{7,8}

Concerning proton-binding sites, arginine is a tridentate ligand, which contains guanidino (G), amino (A) and carboxylate (C) groups. The protonation scheme can be seen in Fig. 1. The relationships between the arginine macro- and microconstants are as follows:

$$K_1 = k^G + k^A + k^C \quad (1)$$

$$\begin{aligned} K_1 K_2 &= k^G k_G^A + k^G k_G^C + k^A k_A^C \\ &= k^A k_A^G + k^C k_C^G + k^C k_C^A \end{aligned} \quad (2)$$

$$\begin{aligned} K_1 K_2 K_3 &= k^G k_G^A k_{GA}^C = k^G k_G^C k_{GC}^A \\ &= k^A k_A^G k_{GA}^C = \dots \end{aligned} \quad (3)$$

where K_1 , K_2 and K_3 are the stepwise macroconstants, k^G , k^A , k^C , k_G^A , k_{GA}^C , etc., are the microconstants. Superscripts of microconstants indicate the group protonating in the given microequilibrium protonation process, whereas subscript(s) (if any) stand for the group(s) already attached to the proton. Arg[−], HArg, H₂Arg⁺ and H₃Arg²⁺ are macrospecies, of which HArg and H₂Arg⁺ are composites of three protonation isomers each:

$$[\text{HArg}] = [\text{HArg}_G] + [\text{HArg}_A] + [\text{HArg}_C] \quad (4)$$

$$\begin{aligned} [\text{H}_2\text{Arg}^+] &= [\text{H}_2\text{Arg}_{G,A}^+] + [\text{H}_2\text{Arg}_{G,C}^+] \\ &\quad + [\text{H}_2\text{Arg}_{A,C}^+] \end{aligned} \quad (5)$$

where entries on the right-hand sides are protonation isomer microspecies. The subscripts G, A and C indicate the site(s) of protonation.

The protonation at one basic site modifies the basicity of the other site. The measure of this basicity-modifying (mostly decreasing) effect can be quantitated in terms of interactivity parameters. For example, the interactivity parameter for the guanidino and amino groups can be written as:

$$\Delta \log k_{G-A} = \log k^G - \log k_A^G = \log k^A - \log k_G^A \quad (6)$$

For arginine, it has long been recognized that the group-basicity gradually and significantly

Fig. 1. Microscopic protonation scheme of arginine.

decreases in the order guanidino, amino, carboxylate. Accordingly, the predominating protonations proceed along the k^G , k_G^A and k_{GA}^C microconstants. Nevertheless, it is important to determine all the microconstants and the microspecies concentrations, because the predominant species are not necessarily the reactive ones.⁹

Due to its biological significance, the acid-base properties of arginine have been studied in several cases.¹⁰⁻³¹ In the vast majority of papers, however, two stepwise macroconstants have been determined only, which essentially refer to the amino and carboxylate protonations (see Table 1). All three stepwise equilibria

(including the one for the guanidino group) have been studied only rarely.^{10,11,16,27,29-31} Unfortunately, the critical survey of equilibrium constants³² has accepted none of these data and the recent values also contain several controversies.²⁹⁻³¹ Owing to lack of basicity data and interactivity parameters for the guanidino group, the arginine microequilibria could not previously be characterized.

We therefore aimed at determining all the macro- and microconstants of arginine. The two major difficulties of the determinations were (i) the extremely high guanidino basicity and (ii) the concomitant need for a model compound which mimics those minor protonation isomers

*Data at several temperatures are reported, from which we took the 25° values.

of arginine where the guanidino group is not protonated.

The extremely high basicity of the guanidino group allows only partial deprotonation even at the upper limit of the pH-scale. To provide sufficiently high hydroxide ion concentration, we performed potentiometric titrations at several ionic strengths, including 5.0 and 2.0*M*. The hydroxide ion concentrations were calculated from acid-base titration data rather than from emf values. The latter always bear a considerable alkali and matrix error at high pH. The degree of guanidinium deprotonation was also calculated as Δ ml volume difference of titrant added to solutions with and without arginine. The emf values were only used to identify the corresponding potential values in the blank and the arginine-containing acid-base titrations.

Due to the very high guanidino basicity, the concentration of those microspecies is very low where the guanidino group bears no positive charge. Consequently, the combination of pH-metry and NMR or UV spectrometry (the most widely used methods for the determination of microconstants) can not be applied here. The only available means is a deductive method which needs a model compound of the minor protonation isomer. Our model compound was citrulline, a very close analogue of arginine. The carbamoyl locus of citrulline is isoelectronic and isosteric with the guanidyl group of arginine. The rest of the molecules are the same. An important difference between the carbamoyl and guanidyl moieties is that the carbamoyl group remains unprotonated throughout the entire pH-range. It has recently been shown that the isoelectronic, isosteric $-\text{COOH}$ and $-\text{CONH}_2$ residues⁶ have the same effect on the NMR parameters, rotamer populations and the basicity. In general, such analogous moieties in the same state of protonation influence equally the rest of the molecule. We applied the above principle to the guanidyl and carbamoyl groups and treated the citrulline protonation constants as constants for the corresponding minor microspecies of arginine.

In this paper we report the 3 and 2 macroscopic as well as the 12 and 4 microscopic protonation constants for arginine and citrulline, respectively, determined by potentiometry and using the principles described above. From microconstants of the same group the guanidino-amino and the guanidino-carboxylate interactivity parameters could be calculated. A microspeciation diagram is also presented here.

EXPERIMENTAL

Arginine and citrulline were products of Reanal and used as received. All chemicals were of analytical reagent grade. A microtitration technique was developed for the determination of equilibrium constants,³² with a combined microelectrode suitable in an initial volume of 0.6–1.0 ml. Potentiometric titrations were carried out with an ABU 12 Radiometer automatic buret, Ingold combined microelectrode and a Radiometer pHM 64 pH-mV meter. Arginine and citrulline were dissolved in 0.8 ml of hydrochloric acid, and potassium hydroxide solution was used as titrant. Both the initial and the titrant potassium hydroxide solutions contained potassium chloride as auxiliary electrolyte to provide constant ionic strength. All measurements were made at $25.0 \pm 0.1^\circ$. A n-pentane layer separated the solutions from the atmospheric carbon dioxide. The potentiometric measurements were made under various conditions, varying the arginine concentration at constant ionic strength and varying the ionic strength at constant arginine concentration (Table 2). The wide variety of ionic strengths and arginine concentrations were used to make sure that no significant intermolecular association occurs and also to provide sufficiently high OH^- concentration for the guanidinium group deprotonation. Prior to the pH-metric measurements the emf cells were calibrated by the following standard solutions: 0.01*M* HCl, 0.09*M* KCl (declared pH at $25^\circ = 2.075$); 0.05*M* KHphtalate ($\text{pH}_{25^\circ} = 4.008$); 0.01*M*

$\text{Na}_2\text{B}_4\text{O}_7 \cdot 10\text{H}_2\text{O}$ ($\text{pH}_{25^\circ} = 9.180$); $0.025M$ NaHCO_3 , $0.025M$ Na_2CO_3 ($\text{pH}_{25^\circ} = 10.012$). The pH-meter readings were used in the 1.0–12.0 pH range. Above pH 12 the hydroxide and hydrogen ion concentrations were calculated from acid–base titration data.

RESULTS AND DISCUSSION

The protonation macroconstants of arginine and citrulline as well as the conditions of determination are reported in Table 2. The estimated ambiguity of the data is 0.02–0.06 log K units (based upon standard deviations) except for the log K_1 value of arginine which equals 15 at $I = 2.0M$, where the ambiguity is 0.1–0.2 log K units. The same value was obtained at $5.0M$ (potassium chloride) ionic strength. The log K_1 values of arginine at 2.0 and $5.0M$ ionic strengths are concentration constants. All others are activity constants, based upon pH calibration by standard buffer solutions. The arginine total concentration was always approximately one third of the titrant potassium hydroxide concentration. Data in Table 2 show no differences in the function of ionic strength or potassium hydroxide concentrations, thus no intermolecular associations had to be hypothesized.

Table 3 contains the microconstants of arginine and citrulline. From the view-point of protonation, citrulline is a bifunctional ligand (containing amino and carboxylate groups), since the carbamoyl moiety does not associate with protons. The microscopic protonation scheme of citrulline is essentially the same as the bottom-left cyclic section of Fig. 1, which involves four microspecies and the k^A , k^C , k^A_C and k^C_A microconstants. In this thermodynamic sys-

tem the following relationships are valid between the macro- and microconstants:

$$K_1 = k^A + k^C \quad (7)$$

$$K_1 K_2 = k^A k^C_A = k^C k^A_C \quad (8)$$

To calculate all four microconstants, one more independent item of information in addition to the values of the two macroconstants is required. The most appropriate additional information is the interactivity parameter for the amino and carboxylate groups, which was basically determined for glycine,³³ but it proved to be valid for other amino acids as well.^{3,8} Introducing this $\Delta \log k_{A-C} = 2.18$ value into equations (7) and (8), all citrulline microconstants could be calculated.

All arginine microconstants could be calculated once the citrulline microconstants, the amino–carboxylate interactivity parameter and the relationships between the macro- and microconstants [equations (1)–(3)], were known.

Owing to the significantly different inherent basicities of the arginine guanidino, amino and carboxylate protonation sites, the k^G , k^A_G and k^C_{GA} microconstants indicate the major protonation pathway and are essentially equal to the K_1 , K_2 and K_3 macroconstants, respectively. For the k^A , k^C_A , k^C and k^A_C values, the corresponding citrulline constants were taken as described above. The k^G_{AC} microconstant then could be calculated as $k^G_{AC} = K_1 K_2 K_3 (k^A k^C_A)^{-1} = K_1 K_2 K_3 (k^C k^A_C)^{-1}$. The k^G_A value was obtained from the cyclic system as $k^G_A = k^G k^A_G (k^A)^{-1}$. A comparison of k^G_A and k^G_{AC} as well as k^C_A and k^C_{GA} values yielded the guanidino–carboxylate interactivity parameter ($\Delta \log k_{G-C} = \log k^G_A - \log k^G_{AC} = \log k^C_A - \log k^C_{GA}$) which could then be used to calculate k^C_G and k^G_C from k^C and k^G , respectively. Finally, k^A_{GC} was obtained as $k^A_{GC} = K_1 K_2 K_3 (k^G k^C_G)^{-1} = K_1 K_2 K_3 (k^C k^G_C)^{-1}$. Due to the inevitable proliferation of the errors, the estimated ambiguity of the microconstants varies between 0.04 and 0.3 log k units. The greatest ambiguities obviously belong to microconstants of the guanidino group. The amino–guanidino interactivity parameter can be calculated as 0.21 log k units, thus the more realistic rounded value is 0.2. The analogous guanidino–carboxylate value is equal to 0.1 ~ 0.13 log k units.

Data in Table 3 show that the guanidino microconstants (including the smallest k^G_{AC}) are extremely large values. This is in full agreement with the qualitative observation that even in

Table 3. Microscopic protonation constants of arginine and citrulline

Arginine	Citrulline
Microconstants	
log $k^G = 15.0$	log $k^A = 9.51$
log $k^A = 9.51$	log $k^C = 4.48$
log $k^C = 4.48$	log $k^A_C = 7.33$
log $k^A_G = 14.8$	log $k^C_A = 2.30$
log $k^G_{AC} = 14.9$	
log $k^G_A = 9.30$	
log $k^A_C = 7.33$	
log $k^C_G = 4.35$	
log $k^C_A = 2.30$	
log $k^G_{AC} = 14.7$	
log $k^A_{GC} = 7.12$	
log $k^C_{GA} = 2.17$	

1.0M strong base solutions no more than 10% guanidinium deprotonation can be reached.

The apparent reason why the guanidino basicity was underestimated in earlier works is methodical. On one hand, there are no standard buffer solutions to provide reliable calibration pH values at the upper extreme of the pH scale. Consequently, concentration constants are adequate to quantitate basicity here. On the other hand, the previous values were measured by glass electrode pH-metry, which produces distorted pH-meter readings at high concentration, high ionic strength alkali solutions, due to alkali, matrix and diffusion potential errors.

The occurrence probability (p) of arginine microspecies can be expressed by means of microspecies concentrations or by micro- and macroconstants and hydrogen ion concentrations. For example, the occurrence probability (relative concentration) for the non-protonated (Arg^-) and one of the three diprotonated ($\text{H}_2\text{Arg}_{\text{G,C}}^+$) microspecies can be expressed as follows in equations (9) and (10), respectively:

$$p_{\text{Arg}^-} = \frac{[\text{Arg}^-]}{([\text{Arg}^-] + [\text{HArg}] + [\text{H}_2\text{Arg}^+] + [\text{H}_3\text{Arg}^{2+}])^{-1}} \quad (9)$$

$$p_{\text{H}_2\text{Arg}_{\text{G,C}}^+} = \frac{[\text{H}_2\text{Arg}_{\text{G,C}}^+]}{([\text{Arg}^-] + [\text{HArg}] + [\text{H}_2\text{Arg}^+] + [\text{H}_3\text{Arg}^{2+}])^{-1}} \quad (10)$$

All macro- and microspecies can be expressed in terms of macro- and microconstants, Arg^- and H^+ concentrations. After reduction by $[\text{Arg}^-]$, (9) and (10) take the following forms:

$$p_{\text{Arg}^-} = (1 + K_1[\text{H}^+] + K_1K_2[\text{H}^+]^2 + K_1K_2K_3[\text{H}^+]^3)^{-1} \quad (11)$$

$$p_{\text{H}_2\text{Arg}_{\text{G,C}}^+} = k^{\text{G}} k_{\text{G}}^{\text{C}} [\text{H}^+]^2 (1 + K_1[\text{H}^+] + K_1K_2[\text{H}^+]^2 + K_1K_2K_3[\text{H}^+]^3)^{-1} \quad (12)$$

Relative concentrations for any other microspecies can be expressed in an analogous way. The relative concentrations can be converted into real solution concentrations if we multiply them by the total (analytical concentration of arginine).

A more visual representation of the microspecies distribution can be seen in Fig. 2, where the parallel running curves stand for the protonation isomers. This microspeciation diagram is a useful tool to predict binding isomerism in

Fig. 2. The pH-dependent distribution of the 8 arginine microspecies.

metal complex formation, where arginine can act as a mono-, bi- or tridentate Lewis-acid and in site-specific interactions with other biomolecules, where arginine can take part as mono-, di- or trivalent proton-donor or acceptor.

(Received 1 December 1990. Revised 24 May 1991. Accepted 27 May 1991)

Summary—The HPLC separation of heavy metal cations was studied with a column packed with Separon SGX silica gel. The retention of the cations is controlled by an ion-exchange mechanism. The ion-exchange capacity is primarily dependent on the mobile phase pH. The analyte retention is further affected by the type and concentration of the complexing agent present and of the counterion. The effect of acetate, tartrate and α -hydroxyisobutyrate as complexing agents and that of methanol as the organic modifier were studied in detail and the results were compared with the theoretical model of ion-exchange separation. Simple mixtures of metals can be rapidly separated on a short column (30×3.3 mm i.d.), e.g., with a mobile phase containing $10^{-2}M$ tartrate at pH 6.0. The metals separated can be detected by dc amperometry at a hanging mercury drop electrode. The limits of detection at an electrode potential of -0.95 V (Ag/AgCl) are in the units-tens of ng range with $20\text{-}\mu\text{l}$ samples with satisfactory precision (RSD values of 2-6%). The main advantages of the method are rapidly and simplicity because derivatization of the analytes is not required.

Silica gel is one of the oldest and most common chromatographic sorbents.¹ It has been extensively used for separations of substances of medium polarity in normal-phase chromatography and even more so as an ion exchanger²⁻⁵ in gravity-feed separations of inorganic cations.⁶⁻¹² The ion-exchange properties of silica gel are rather rarely utilized in HPLC, because of the complicated behaviour of silica gel and gaps in the theoretical model.

Iwachido and co-workers^{13,14} used a silica gel column for separation of the alkali and alkaline earth metal cations and determination of Na^+ , K^+ , NH_4^+ , Ca^{2+} and Mg^{2+} ions in river and rain waters with a mobile phase containing lithium acetate or oxalate. Smith and Pietrzyk¹⁵ studied the separation of the alkali metals, the alkaline earths and the rare earth metals. A mixed column containing silica gel as cation exchanger and alumina as the anion exchanger was used¹⁶ for separation of monovalent cations and anions with a lithium acetate mobile phase of pH 6.65. Conductometric detection was employed in all these cases.

In addition to almost universal conductometric detection, potentiometry with a copper elec-

trode¹⁷ and measurement of fluorescence¹⁸ have been employed in HPLC of metal cations. The transition and heavy metal cations have most often been detected photometrically, after post-column derivatization (e.g., with PAR¹⁹⁻²¹).

In view of the favourable polarographic characteristics,²² Cu^{2+} , Cd^{2+} , Pb^{2+} and Tl^{+} can be detected by amperometry at mercury electrodes. There is the problem of interference by oxygen dissolved in the mobile phase and/or the sample injected.²³ Many procedures and devices have been proposed for removal of dissolved oxygen, but they complicate the chromatographic procedure. Therefore, reversed-pulse voltammetry²³⁻²⁵ is preferable, as it discriminates between the reversible reduction of the test metals and the irreversible reduction of oxygen. However, with a suitable arrangement of the polarographic detector it is also possible to attain a sufficient low limit of detection in d.c. amperometric measurements.²⁶

The present paper studies HPLC separation of heavy metals on silica gel. On the basis of previous works,⁶⁻¹² possible main components of the mobile phases were selected, i.e., acetic acid which has also been successfully applied to

TLC separation of metal ions on silica gel,²⁷ tartrate that has been used in ion chromatography^{28,29} and micelle exclusion chromatography³⁰ and α -hydroxyisobutyric acid (HIB) that is often employed in HPLC of the rare earth metals.³⁰⁻³³ The effects on analyte retention of the mobile phase ionic strength, the pH, the type of counterion and the organic modifier were studied and the results compared with theoretical assumptions. The measurements were carried out on a short column (30×3.3 mm i.d.) which permits rapid analysis and a low pressure drop, thus improving the baseline stability and suppressing peak broadening of strongly retained analytes. The metal cations were detected amperometrically at a hanging mercury drop electrode.

EXPERIMENTAL

Apparatus

The liquid chromatograph consisted of a HPP 5001 high-pressure pump, an LCI 30-sample injection valve with $20\text{-}\mu\text{l}$ loop, an EDLC electrochemical detector and a TZ 4261 chart recorder (all from Laboratorní Přístroje, Prague, Czechoslovakia). The detection cell with a hanging mercury drop working electrode, a saturated silver/silver chloride reference electrode and a platinum counter electrode is described in detail elsewhere.³⁴ The glass analytical column, 30×3.3 mm i.d., was packed with silica gel Separon SGX ($5\ \mu\text{m}$) and placed between the pump and the sample injection valve to presaturate the mobile phase with dissolved silica. The columns were products of Tessek, Prague.

Reagents

Stock solutions ($0.1M$) of sodium acetate (NaAc), sodium tartrate (Na_2Tart) and sodium α -hydroxyisobutyrate (NaHIB) were prepared by neutralization of the acids with sodium hydroxide to a pH of 7.0. The mobile phases were obtained by diluting these stock solutions, mixing them with $0.1M$ stock solutions of sodium perchlorate and cerous nitrate, and with methanol and then adjusting the pH by addition of dilute perchloric acid.

Stock solutions of the test metal cations, $0.1M$, were prepared from the appropriate chlorides, nitrates or sulphates and were diluted to a concentration of $10^{-4}M$ unless stated otherwise.

All the chemicals were analytical grade (Lachema, Brno, Czechoslovakia): α -hydroxy-

isobutyric acid, *puriss.*, was obtained from Fluka, Switzerland.

The mobile phases were degassed in an ultrasonic bath. The flow-rate was $0.3\ \text{ml/min}$. All the electrode potentials refer to the saturated aqueous Ag/AgCl electrode. The measurements were performed at laboratory temperature ($20 \pm 2^\circ$).

RESULTS AND DISCUSSION

Separation

In the separation of the metal cations, silica gel acts as a weak cation exchanger whose properties depend on the degree of dissociation of the exchange sites (the silanol groups $-\text{SiOH}$). These groups make the silica gel surface acidic, with a $\text{p}K_a$ value³⁵ of 7.1. Therefore, dissociation of protons from the silanol groups occurs above a pH of *ca.* 4 and silica gel is then able to bind cations.³⁶ The corresponding ion-exchange equilibrium is described by

where M^{y+} is the cation to be separated and E^{z+} is the cation of the eluting agent. Analogous to the equation derived by Haddad and Foley,³⁷ equation (1) yields a relationship for the capacity factor in the form,

$$\log k = \frac{y}{z} \log(\text{cap}/z) + \frac{1}{z} \log K_M^E + \log(w/V_m) - \frac{y}{z} \log[\text{E}^{z+}] \quad (2)$$

where cap is the exchange capacity, K_M^E is the selectivity coefficient and w/V_m is the ratio of the stationary phase weight, w , to the mobile phase volume, V_m .

If cation M^{y+} participates in a complexation equilibrium, equation (2) assumes the form,³⁷

$$\log k = \log \alpha_M + \frac{y}{z} \log(\text{cap}/z) + \frac{1}{z} \log K_m^E + \log(w/V_m) - \frac{y}{z} \log[\text{E}^{z+}] \quad (3)$$

where α_M is the ratio of the concentration of the free cation and the overall cation concentration in the solution. Therefore, for the complexation equilibrium,

the α_M value is given by

$$\alpha_M = 1/(1 + \beta[L]^n), \quad (5)$$

provided that the $[L]$ value is sufficiently large, so that the concentrations of the lower complexes, ML , $\text{ML}_2, \dots, \text{ML}_{n-1}$, are negligible.

The exchange capacity of silica gel depends primarily on the pH.¹⁵ If the capacity is assumed to be constant at a given pH, then combination of equations (3) and (5) yields

$$\log k = \text{constant}$$

$$-\frac{y}{z} \log \{[E^{z+}] \cdot (1 + \beta[L]^n)^{z/y}\} \quad (6)$$

where all the constants are summarized in a single term.

It should be pointed out that the above relationships assume a negligible concentration of the positively charged (cationic) complexes.³⁷ This assumption should be satisfied in the Na_2Tart medium, but not necessarily in NaAc and NaHIB .

When the pH is not constant, then the variations in the dissociation of the $-\text{SiOH}$ groups must be considered; the relationship for the capacity factor has been derived for univalent cations by Smith and Pietrzyk.¹⁵

$$1/k = \frac{1}{qK_0} \left\{ \frac{[\text{H}^+](1 + K_{\text{app}})}{K\text{H}^M} + [\text{M}^+] + \frac{[\text{E}^+]}{K\text{E}^M} \right\} \quad (7)$$

where q is the ratio of the volumes of the stationary and mobile phases, K_0 is the exchange

capacity available, K_{app} is the apparent ionization constant of the $-\text{SiOH}$ group and K_{H^M} and K_{E^M} are the selectivity coefficients for exchange of the analyte with proton and the eluent cation, respectively.

It clearly follows from this simple theoretical model that the retention of metal cations on silica gel is primarily influenced by the type and concentration of the eluent cation (counterion), the type and concentration of the complexing agent and the mobile phase pH. Equation (7) also predicts a dependence of the capacity factor on the analyte concentration; however, the dependence is insignificant at analyte concentrations common in HPLC, as confirmed experimentally,¹⁵ and thus we did not study it here.

If the mobile phase contains a complexing agent, then the analyte retention depends on the two effects: The eluent cation (counterion) competes for the exchange sites with the analyte cation (the pushing effect of the E^{z+} ion). The ligand anion enhances the analyte affinity to the mobile phase (the pulling effect of ligand L^-). Both the two effects cause a decrease in the analyte retention. It follows from equation (6) that, at a constant ligand concentration and a constant pH, there is a linear relationship between the logarithm of the analyte capacity factor and the eluent cation concentration.

This experimental dependence is shown in Fig. 1. The concentration of the counterion (Na^+) was varied by adding sodium perchlorate

Fig. 1. Log-log dependence of the capacity factors on the Na^+ concentration in the mobile phase. (a) $5 \times 10^{-4} \text{M}$ NaAc , pH 5.0; (b) $2.5 \times 10^{-4} \text{M}$ Na_2Tart , pH 5.0; (c) $5 \times 10^{-4} \text{M}$ NaHIB , pH 6.0, -0.95V (Ag/AgCl), flow-rate, 0.3 ml/min. 1— Cd^{2+} ; 2— Tl^+ ; 3— Pb^{2+} ; 4— Cu^{2+} .

Table 1. Slopes of the experimental $\log k$ vs. $\log c_{\text{Na}^+}$ dependences

Cation	Slope		
	NaAc [Fig. 1(a)]	Na ₂ Tart [Fig. 1(b)]	NaHIB [Fig. 1(c)]
Cu ²⁺	-1.11	-0.06	-0.92
Cd ²⁺	-0.92	-0.80	-0.62
Pb ²⁺	-0.05	-0.16	-0.42
Tl ⁺	-0.59	-0.26	-0.63

to the mobile phases of a constant pH, containing constant concentrations of NaAc [Fig. 1(a)], Na₂Tart [Fig. 1(b)] or NaHIB [Fig. 1(c)], assuming that the complexation ability of perchlorate is negligible. It can be seen that the dependences are linear, but the experimental slopes are substantially smaller than the predicted value of -2.0 for divalent analyte cations and a monovalent eluent cation or -1.0 for monovalent analyte cations (see Table 1). The most probable reasons for this deviation are a substantial decrease in the effective charge on the analyte cation in real systems due to non-negligible content of lower complexes, *e.g.*, $M(\text{Ac})^+$, and the effect of the ionic strength, a contribution from interactions other than ion exchange, *e.g.*, non-specific interactions with the siloxane groups, molecular adsorption and hydrogen bonding and variations in the silica gel ion-exchange capacity with changing experimental conditions.

In some cases (Pb²⁺ with the NaAc mobile phase or Cu²⁺ with the Na₂Tart mobile phase),

the slope of the $\log k$ vs. $\log c_{\text{Na}^+}$ plot approaches zero: apparently, ion exchange does not control the retention in these systems and the cations are retained in the form of neutral or negatively charged complexes through a combination of various interactions.

It can be seen from Fig. 2 that the sodium perchlorate concentration affects not only the analyte retention time but also the peak shape. With low perchlorate concentrations the retention times are large and the peaks exhibit strong tailing. According to Giddings,³⁸ peak tailing most often stems from the presence of active sites of several different types on the surface of the stationary phase. This really is the case with silica gel;¹ the increase in the ionic strength with increasing concentration of perchlorate suppresses dissociation of minority exchange sites and enhances the complex formation in the mobile phase, thus suppressing the tailing and decreasing the retention time.

As can be expected, the replacement of the univalent counterion by a cation of a higher valence leads to a pronounced decrease in the retention (see Table 2), as the affinity toward an ion exchanger increases with increasing charge of the ion.

The capacity factor dependence on the concentration of the complexing agent also follows from equation (6): if the pH is maintained constant and the complexing agent is a salt of a weak acid, E_xL_x , where E is the counterion

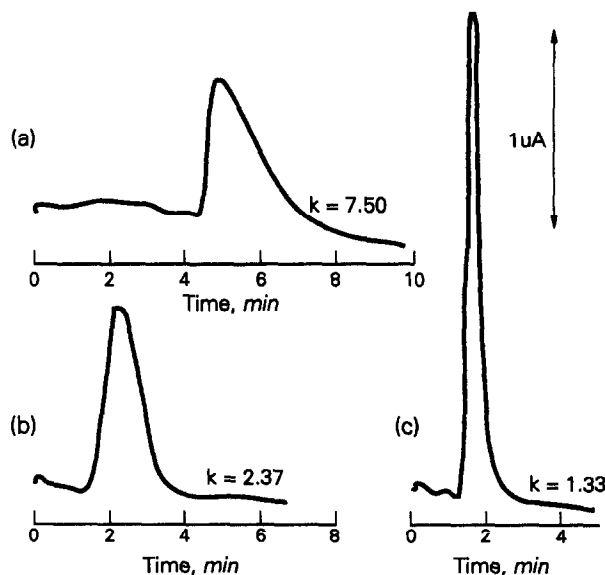

Fig. 2. The effect of the NaClO_4 concentration in the mobile phase on the shape of the Cd^{2+} peak. Mobile phase: $2.5 \times 10^{-4} \text{M}$ Na₂Tart + $x \text{M}$ NaClO₄. (a) $x = 10^{-3}$; (b) 5×10^{-3} ; (c) 10^{-2} . Other conditions as for Fig. 1.

Table 2. The effect of NaClO_4 and $\text{Ce}(\text{NO}_3)_3$ on the test cation retention

Cation	k	
	$2.5 \times 10^{-4}M \text{ Na}_2\text{Tart}$, $\text{pH } 5.0 + 10^{-3}M \text{ NaClO}_4$	$2.5 \times 10^{-4}M \text{ Na}_2\text{Tart}$, $\text{pH } 5.0 + 10^{-3}M \text{ Ce}(\text{NO}_3)_3$
Cd^{2+}	7.50	1.00
Cu^{2+}	1.00	1.00
Pb^{2+}	3.15	1.50
Tl^+	4.69	1.25

and L is the ligand in equation (4), then equation (6) can be rewritten as

$$\log k = \text{constant}$$

$$-\frac{y}{z} \log \left\{ \frac{z}{x} [L] \cdot (1 + \beta [L]^n)^{z/y} \right\} \quad (8)$$

where the charge of the ligand is omitted for simplicity. Equation (8) is simplified when the numeral 1 in the term $(1 + \beta [L]^n)$ can be neglected with respect to the product $\beta [L]^n$, i.e., when the ligand concentration is sufficiently high and/or the β value is large, obtaining

$$\log k = \text{constant} - \frac{y}{z} \left(n \frac{z}{y} + 1 \right) \log [L] \quad (9)$$

Hence there should be a linear relationship between the logarithm of the capacity factor and the ligand concentration. The stability constants for the complexes studied (except for those of thallium) are typically³¹⁻⁴¹ in the range of 10^2 – 10^3 and thus the above simplified equation should be valid for ligand concentrations greater than *ca.* $10^{-3}M$.

The experimental dependences are given in Fig. 3. It can be seen that the condition of linearity is satisfied, while the experimental slopes (Table 3) are again much smaller than expected: the probable reasons are the same as with the $\log k$ vs. $\log c_E$ plots.

The dependence of capacity ratio on the buffer concentration is most pronounced in the Na_2Tart medium. The slopes of the $\log k$ vs. $\log c_L$ dependences are greater in this system than those of the $\log k$ vs. $\log c_{\text{Na}^+}$ plots (Table 1), which is in agreement with equation (9). Hence the retention of the test cations is most effectively controlled by varying the tartrate concentration in the mobile phase. Equation (9) suggests that the retention of monovalent cations is more strongly affected by the presence of a ligand than that of divalent cations (relative increase in the slope is greater), as demonstrated by the $\log k$ vs. $\log c_L$ plot for Tl^+ in Fig. 3(b). It can also be seen from this figure that a change in the buffer concentration may also lead to changes in the eluting order. The slopes of the $\log k$ vs. $\log c_L$ dependences

Fig. 3. Log-log dependence of the capacity factors on the ligand concentration in the mobile phase. (a) NaAc , $\text{pH } 5.0$; (b) Na_2Tart , $\text{pH } 5.0$; (c) NaHIB , $\text{pH } 6.0$. 1— Cd^{2+} ; 2— Tl^+ ; 3— Cu^{2+} ; 4— Pb^{2+} . Other conditions as for Fig. 1.

Table 3. The slopes of the experimental $\log k$ vs. $\log c_L$ dependences

Cation	Slope		
	NaAc [Fig. 3(a)]	Na ₂ Tart [Fig. 3(b)]	NaHIB [Fig. 3(c)]
Cu ²⁺	-0.38	-1.04	-0.09
Cd ²⁺	-0.55	-0.84	-0.54
Pb ²⁺	-0.30	-0.77	-0.54
Tl ⁺	-0.37	-1.18	-0.54

Table 4. Dependence of the capacity factors on the presence of methanol in the mobile phase

Cation	k	
	$5 \times 10^{-4}M$ NaAc (pH 5.0)	$5 \times 10^{-4}M$ NaAc (pH 5.0) + 5% (v/v) methanol
Cd ²⁺	1.44	0.75
Cu ²⁺	3.11	1.15
Pb ²⁺	3.61	1.00
Tl ⁺	2.04	1.00

cannot be calculated rigorously, in view of the above simplifications and the lack of data on the composition and stability of the complexes involved in real systems. Deviations from the theory are greater in the NaAc and NaHIB media, mainly because of the presence of lower cationic complexes; other possible factors are discussed with the $\log k$ vs. $\log c_E$ dependence.

The theory predicts a strong dependence of the capacity factors on the mobile phase pH, through the effects of the pH on the dissociation of the mobile phase components and of the silanol groups. Equation (7) predicts an exponential relationship between the capacity factor and the hydrogen ion concentration. Figure 4 demonstrates that the experimental dependences correspond to equation (7) with NaAc [Fig. 4(a)] and Na₂Tart [Fig. 4(b)]. The dependences with NaHIB [Fig. 4(c)] are more complicated, indicating that the separation mechanism is more complex. (Similar plots were obtained in separations of the rare earths on silica gel.¹⁵)

It is clear from Fig. 4 that analyte retention becomes negligible under a pH of *ca.* 4. At pH values greater than *ca.* 7, the retention rapidly

increases and the peaks exhibit tailing, due to dissociation of minority exchange sites (see above). Above a pH of *ca.* 7.5, the silica gel matrix is damaged and the column efficiency decreases.

Addition of methanol to the mobile phase causes a decrease in the column efficiency²⁸ and enhanced complexation in the mobile phase, resulting in a shortening of the retention times, peak broadening and a poorer resolution, even with low methanol contents (5% vol.). Older magnetochemical measurements³ also demonstrate suppression of ion exchange on silica gel when the relative permittivity of the solvent decreases. The capacity factors in the presence and absence of methanol are compared in Table 4.

The dependences indicate that separation of metal cations on silica gel is affected by many factors and thus optimization of the separation conditions is difficult. Moreover, separations of complex mixtures are complicated by the fact that the elution curves exhibit tailing, especially with strongly retained components.

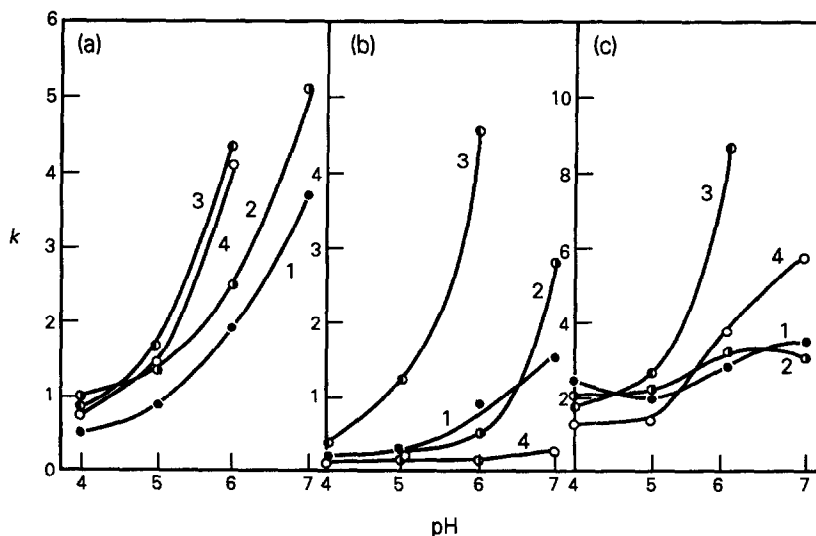

Fig. 4. Capacity factor dependence on the mobile phase pH. (a) $10^{-2}M$ NaAc; (b) $10^{-2}M$ Na₂Tart; (c) $10^{-2}M$ NaHIB. 1—Cd²⁺; 2—Tl⁺; 3—Pb²⁺; 4—Cu²⁺. Other conditions as for Fig. 1.

Fig. 5. Separation of Cu^{2+} (1), Cd^{2+} (2) and Pb^{2+} (3). Mobile phase: $10^{-2}M$ Na_2Tart , pH 6.0. Flow-rate, 0.3 ml/min; -0.95 V (Ag/AgCl).

For example, divalent cations, Cu^{2+} , Cd^{2+} and Pb^{2+} , can be successfully separated with a mobile phase of $10^{-2}M$ Na_2Tart , pH 6 (Fig. 5). However, Tl^{+} is co-eluted with Cd^{2+} under these conditions.

Detection

The dc hydrodynamic polarograms of Cd^{2+} , Cu^{2+} , Pb^{2+} and Tl^{+} are given in Fig. 6 for the three mobile phases used. In these experiments the analytical column was replaced by a capillary 50 cm long and 0.2 mm in internal diameter. The limits of detection were determined at a potential of -0.95 V and are summarized in Table 5. These values are comparable with the results obtained by using reversed-pulse polarography.²⁵

In real chromatographic systems, the limits of detection are somewhat higher, owing to poorer baseline stability and peak broadening, e.g., 5.4, 8.8, 53.1 and 36.6 ng for Cd^{2+} , Cu^{2+} , Pb^{2+} and Tl^{+} , respectively, in a mobile phase of $10^{-2}M$

Fig. 6. Hydrodynamic polarograms of Cu^{2+} (1), Pb^{2+} (2), Tl^{+} (3) and Cd^{2+} (4). Mobile phase: (a) $10^{-2}M$ NaAc , pH 5.0; (b) $10^{-2}M$ Na_2Tart , pH 5.0; (c) $10^{-2}M$ NaHIB , pH 5.0. Sample concentration, $1.5 \times 10^{-4}M$; injected amounts, $20 \mu\text{l}$; flow rate, 0.3 ml/min.

Na_2Tart , pH 6.0 and with $20\text{-}\mu\text{l}$ samples. The reproducibility of measurement is satisfactory: at concentrations equal to about 10 times the limit of detection, the relative standard deviations are 2.2, 3.1, 6.4 and 2.9% for $\text{Cu}(\text{II})$, $\text{Tl}(\text{I})$, $\text{Pb}(\text{II})$ and $\text{Cd}(\text{II})$, respectively, for six parallel measurements. Typical calibration plot parameters are given in Table 6.

CONCLUSION

Heavy metal cations are retained on silica gel by a mechanism in which ion exchange

Table 5. Polarographic limits of detection for some cations

Cation	Limit of detection, ng		
	$10^{-2}M$ NaAc (pH 5.0)	$10^{-2}M$ Na_2Tart (pH 5.0)	$10^{-2}M$ NaHIB (pH 5.0)
Cd^{2+}	3.2	2.8	4.5
Cu^{2+}	3.3	4.3	2.9
Pb^{2+}	2.5	16.5	31.1
Tl^{+}	3.8	9.5	17.2

Flow-rate, 0.3 ml/min; $20\text{-}\mu\text{l}$ samples; -0.95 V (Ag/AgCl); without analytical column. The limit of detection is the absolute amount of the analyte that produces a signal equal to three times the baseline noise.

Table 6. Calibration plot parameters for determination of Cd²⁺, Cu²⁺, Pb²⁺ and Tl⁺

Cation	Slope, nA/ng	Intercept, nA	Coefficient of correlation
Cd ²⁺	0.950	0.234	0.9996
Cu ²⁺	0.220	0.116	0.9987
Pb ²⁺	0.121	-0.008	0.9990
Tl ⁺	0.212	0.096	0.9895

Mobile phase: 10⁻²M Na₂Tart, pH 5.0; 0.3 ml/min; -0.95 V (Ag/AgCl)

predominates, although other interactions, *e.g.*, molecular adsorption,⁶⁻¹² may also play a role. The retention can be described by relationships that are analogous to those derived for classical ion exchangers.^{28,37} The heterogeneity of the silica gel surface and the presence of several types of ion-exchange site cause peak tailing which can be suppressed by increasing the mobile phase ionic strength and decreasing its pH, which also leads to reduced retention times. Methanol substantially decreases the efficiency of separation and the resolution and thus purely aqueous mobile phases are preferable. The separation is improved by complexing agents: tartrate seems to be most suitable.

The main advantages of the method, using polarographic detection that is sufficiently sensitive, are the rapidity and simplicity of determination, as very short columns can be used and there is no need for derivatization. Another advantage is the very small amount of sample required for analysis, compared with polarographic and stripping voltammetric methods of analysis.

EFFECT OF STRUCTURAL VARIATION WITHIN SYM-(R)DIBENZO-16-CROWN-5-OXYACETIC ACID RESINS UPON THE SELECTIVITY AND EFFICIENCY OF ALKALI-METAL CATION SORPTION

TAKASHI HAYASHITA, MI-JA GOO, JONG SEUNG KIM and RICHARD A. BARTSCH*

Department of Chemistry and Biochemistry, Texas Tech University, Lubbock, Texas 79409-1061, U.S.A.

(Received 31 May 1991. Accepted 17 June 1991)

Summary—Five new crown ether carboxylic acid resins have been prepared by condensation polymerization of *sym*-(R)dibenzo-16-crown-5-oxyacetic acids with formaldehyde. Competitive alkali-metal cation sorption by these novel resins, which contain both ion-exchange and crown ether binding sites for metal ions, has been investigated. As the R-group was varied (methyl, ethyl, propyl, butyl, hexyl and decyl) both the alkali-metal cation sorption selectivity and efficiency were affected. The highest efficiency (loading) and Na⁺ sorption selectivity were obtained when R = methyl, ethyl and propyl. The longer alkyl groups were found to be detrimental to both sorption efficiency and selectivity.

The development of chelating resins for separation of selected metal cations from aqueous solutions has received considerable attention. In general, these resins are prepared by immobilization of a chelating reagent which has an affinity for the desired metal ion into a polymeric matrix.¹ In the design of such resins, several factors must be taken into account. Interactions of the metal cation with the resin matrix as well as the chelating reagent may affect sorption behavior. The geometry and microenvironments of chelating resins are important factors for metal separation processes.²

In a recent study, we synthesized carboxylic acid resins **1**, **2** and **5** (Scheme 1) which contain integral acyclic or cyclic polyether units and evaluated their alkali-metal cation sorption behavior.³ These novel resins possess both ion-exchange and polyether binding sites for metal ions. It was found that the sorption selectivity for the cyclic polyether (crown ether) carboxylic acid resins was controlled by the relationship between the crown ether cavity and metal ion diameters. Thus the Li⁺ sorption selectivity observed for the acyclic polyether carboxylic acid resin **1** changed to Na⁺ selectivity for the *sym*-dibenzo-16-crown-5-oxyacetic acid resins **2** and **5**. The Na⁺ selectivity for resin **5** in which there is a propyl group attached to the same crown ether ring carbon as the side arm was much higher than that of resin **2**. It was postu-

lated that in resin **5** the lipophilic propyl group is directed away from the polar polyether ring.³ This orients the side arm over the crown ether cavity and enhances selectivity by pre-organization of the binding site.⁴ In an analytical application, crown ether carboxylic acid resin **5** has been utilized for the column concentration of alkali metal-cations from dilute aqueous solutions.^{3,5}

Since the introduction of an alkyl group into crown ether carboxylic acid resin **2** could affect not only the positioning of the carboxylic acid group but also the microenvironment of the resin, a study of the influence of alkyl group variation was undertaken. A series of *sym*-(R)dibenzo-16-crown-5-oxyacetic acid resins **3**, **4** and **6-8** in which the alkyl group is systematically varied (methyl, ethyl, butyl, hexyl, decyl, respectively) has been prepared and their alkali-metal cation sorption behavior evaluated and compared with that reported for resins **1**, **2** and **5**.

EXPERIMENTAL

Apparatus

The apparatus was the same as that in the previous study.³

Reagents

Unless specified otherwise, reagent grade reactants and solvents were obtained from chemical suppliers and used as received. Aqueous

*Author for correspondence.

stock solutions of 0.50M alkali-metal chlorides (NaCl, KCl, RbCl and CsCl, 0.50M in each), 0.50M LiCl and 0.50M LiOH were stored in polyethylene bottles. Sample solutions were prepared by mixing and diluting these stock solutions. Purified water for sample solutions was prepared by passing distilled water through three Barnsted D8922 combination cartridges in series. *sym*-Ketodibenzo-16-crown-5, *sym*-(butyl)dibenzo-16-crown-5-oxyacetic acid, and *sym*-(decyl)-dibenzo-16-crown-5-oxyacetic acid were prepared by the reported methods.^{6,7}

Preparation of *sym*-(hydroxy)(methyl)dibenzo-16-crown-5

To 0.84 g (34.5 mmoles) of magnesium turnings in 150 ml of anhydrous Et₂O under nitrogen was added dropwise 4.90 g (34.5 mmoles) of methyl iodide. The reaction mixture was refluxed until the magnesium disappeared. A solution of *sym*-ketodibenzo-16-crown-5 (4.00 g, 11.6 mmoles) in 300 ml of THF was added dropwise and refluxing was continued for 24 hr. The reaction mixture was cooled in an ice-bath, 90 ml of 5% aqueous ammonium chloride solution was added, and the mixture was stirred for 2 hr. The solvent was evaporated in vacuo and extracted with CH₂Cl₂ (2 × 100 ml). The CH₂Cl₂ solution was dried over magnesium sulfate and evaporated *in vacuo*. The crude product was recrystallized from pentane and

then subjected to column chromatography on silica gel with CH₂Cl₂ as eluent to give 1.73 g (41%) of the title compound as a white solid with mp. 110–111°, lit. mp. 109–110°.⁸

Preparation of *sym*-(hydroxy)(ethyl)- and *sym*-(hydroxy)(hexyl)-dibenzo-16-crown-5

By the procedure reported for the preparation of *sym*-(hydroxy)(propyl)-dibenzo-16-crown-5³ but replacing 1-bromopropane with 1-bromoethane and 1-bromohexane, the title compounds were prepared.

sym-(Hydroxy)(ethyl)dibenzo-16-crown-5, mp. 101–102°, 91% yield. IR (deposit) 3461 (OH), 1257, 1122 (CO) cm⁻¹. ¹H NMR (CDCl₃) δ 1.05 (t, 3), 1.90 (q, 2), 3.11 (s, 1), 3.89–4.27 (m, 12), 6.83–7.26 (m, 8). Analysis calculated for C₂₁H₂₆O₆: C 67.36; H, 7.00. Found: C, 67.55; H, 7.01.

sym-(Hydroxy)(hexyl)dibenzo-16-crown-5, mp. 126–127°, 85% yield. IR (deposit) 3395 (OH), 1122, 1039 (CO) cm⁻¹. ¹H NMR (CDCl₃) δ 0.88 (t, 3), 1.15–1.55 (m, 8), 1.80–1.92 (m, 2); 3.45 (br s, 1), 3.90–4.30 (m, 12), 6.84–7.02 (m, 8). Analysis calculated for C₂₅H₃₄O₆: C, 69.74; H, 7.96. Found: C, 69.63; H, 7.61.

Preparation of *sym*-(methyl)-, *sym*-(ethyl)-, and *sym*-(hexyl)-dibenzo-16-crown-5-oxyacetic acids

By the procedure reported for the preparation of *sym*-(propyl)dibenzo-16-crown-5-oxyacetic acid from *sym*-(hydroxyl)(propyl)dibenzo-16-crown-5,³ the appropriate crown ether alcohols were converted into the title compounds.

sym-(Methyl)dibenzo-16-crown-5-oxyacetic acid, mp. 100–102°, 80% yield. IR (deposit) 3400–3000 (COOH), 1766, 1736 (C=O), 1122, 1053 (CO) cm⁻¹. ¹H NMR (CDCl₃) δ 1.50 (s, 3), 3.80–4.15 (m, 10), 4.60 (d, 2), 4.85 (s, 2), 6.84–7.02 (m, 8), 8.88 (br s, 1). Analysis calculated for C₂₂H₂₆O₈: C, 63.15; H, 6.26. Found: C, 62.81; H, 6.34.

sym-(Ethyl)dibenzo-16-crown-5-oxyacetic acid, mp. 112–113°, 69% yield. IR (deposit) 3363 (COOH), 1738 (C=O), 1255, 1128 (CO) cm⁻¹. ¹H NMR (CDCl₃) δ 1.09 (t, 3), 2.00 (q, 2), 3.79–4.22 (m, 10), 4.57 (d, 2), 4.85 (s, 2), 6.70–7.01 (m, 8). Analysis calculated for C₂₃H₂₈O₈: C 63.88; H, 6.53. Found: C, 64.28; H, 6.62.

sym-(Hexyl)dibenzo-16-crown-5-oxyacetic acid, mp 139–141°, 85% yield. IR (deposit) 3400–3000 (COOH), 1735, 1699 (C=O), 1122, 1053 (CO) cm⁻¹. ¹H NMR (CDCl₃) δ 0.93 (t, 3), 1.25–1.50 (m, 8), 1.93–1.97 (m, 2), 3.80–4.15 (m,

10), 4.60 (d, 2), 4.85 (s, 2), 6.84–7.02 (m, 8), 9.90 (br s, 1). Analysis calculated for $C_{27}H_{36}O_8$: C, 66.38; H, 7.43. Found: C, 66.46; H, 7.87.

Preparation of crown ether carboxylic acid resins 3, 4 and 6–8

The crown ether carboxylic acid resins were synthesized by condensation polymerization of the *sym*-(R)dibenzo-16-crown-5-oxyacetic acid monomers with formaldehyde in formic acid as described in detail previously.^{3,9} The resins were ground and used in powder form (finer than 100 mesh).

Resin 3, 65% yield. IR (KBr) 3448 (COOH), 1719 (C=O), 1282, 1105 (CO) cm^{-1} . Analysis calculated for 9–1.5 H_2O : C, 63.68; H, 6.11. Found: C, 63.44; H, 5.80.

Resin 4, 65% yield. IR (KBr) 3448 (COOH), 1735 (C=O), 1282, 1102 (CO) cm^{-1} . Analysis calculated for 9–0.5 H_2O : C, 64.83; H, 6.29. Found: C, 64.57; H, 5.85.

Resin 6, 67% yield. IR (KBr) 3442 (COOH), 1720 (C=O), 1278, 1108 (CO) cm^{-1} . Analysis calculated for 9–3 H_2O : C, 64.80; H, 6.89. Found: C, 64.72; H, 6.64.

Resin 7, 65% yield. IR (KBr) 3448 (COOH), 1735 (C=O), 1274, 1132 (CO) cm^{-1} . Analysis calculated for 9: C, 67.31; H, 7.22. Found: C, 67.21; H, 7.02.

Resin 8, 83% yield. IR (KBr) 3448 (COOH), 1735 (C=O), 1277, 1120 (CO) cm^{-1} . Analysis calculated for 9: C, 69.15; H, 7.94. Found: C, 69.69; H, 7.84.

Procedure

The procedure was the same as that utilized in the earlier study.³ A resin (0.050 g) and 5.0 ml of an aqueous solution containing the alkali-metal chlorides with hydroxides for pH adjustment (0.10M in each) were shaken for 3 hr in a 30-ml separating funnel at room temperature (23–24°) with a Burrell wrist-action shaker. The aqueous phase was filtered with a sintered glass filter funnel (15 ml, medium porosity) and the equilibrium pH of the aqueous phase was measured. The resin was washed with 100 ml of distilled, demineralized water and dried. Of the dried resin, a 0.020-g sample was shaken with 5.0 ml of a 0.10M hydrochloric acid solution to strip the alkali-metal cations from the resin into an aqueous solution for analysis by ion chromatography.

RESULTS AND DISCUSSION

Preparation of crown ether carboxylic acid resins

Crown ether carboxylic acid resins 3, 4 and 6–8 were prepared by condensation of the appropriate *sym*-(R)dibenzo-16-crown-5-oxyacetic acid monomer with formaldehyde in formic acid. Previously it was shown for the synthesis of resin 5 by this method that the IR spectra of the crown ether carboxylic acid monomer and resin were nearly the same.³ Also it was demonstrated that the alkali-metal cation sorption behavior of two different independent preparations of resin 5 was very similar. As expected, the IR spectra for resins 3, 4 and 6–8 (see Experimental) showed very little change from those of the crown ether carboxylic acid monomers.

The structural representations for crown ether carboxylic acid resins 3, 4 and 6–8 imply polymers with no cross-linking. This is most certainly an oversimplification since some level of cross-linking is anticipated.¹⁰ A possible structure for the partially cross-linked resins is given by 9 in which A is the polyether carboxylic acid unit in the resin. Elemental analysis results for resins 7 and 8 agree with the formulation. For resins 3, 4 and 6, the elemental analysis results are consistent with that of 9 as 1.5, 0.5 and 3.0 hydrates, respectively. [Resin 5 which was prepared in the previous study analyzed as a dihydrate.³]

Alkali metal cation sorption by crown ether carboxylic acids

To provide more relevance to actual metal separation systems, competitive, rather than single species, alkali-metal cation sorption behavior of crown ether carboxylic acid resins 3, 4 and 6–8 was investigated.

An aqueous solution of the five alkali-metal cations (0.10M in each) as the chlorides and hydroxides was shaken with the crown ether carboxylic acid resin for 3 hr [even though sorption may be complete in a matter of minutes³]. The resin was filtered, washed with water, and dried. Of the dried resin a weighed portion was shaken with 0.10M hydrochloric acid to strip the alkali-metal cations from the resin into aqueous solution for analysis by ion chromatography. For a resin, sorption of a given alkali-metal cation at a given pH was found to be reproducible within 5 percent of the stated value.

Fig. 1. Sorption of alkali-metal cations by the polyether carboxylic acid *vs.* the equilibrium pH of the aqueous phase for (a) 1, (b) 2, (c) 3, (d) 4, (e) 5, (f) 6, (g) 7, (h) 8: (Δ) Li⁺, (○) Na⁺, (□) K⁺, (▲) Rb⁺, (●) Cs⁺.

The influence of the equilibrium pH of the aqueous phase upon the competitive sorption of alkali-metal cations for crown ether carboxylic acid resins 3, 4 and 6–8 is shown in Figs. 1(c), (d), (f)–(h), respectively. For comparison, data reported³ for acyclic polyether carboxylic acid resin 1 and crown ether carboxylic acid resins 2 and 5 are included as Figs. 1(a), (b), (e), respectively. The curve shapes for alkali-metal cation sorption by the resins *vs.* the equilibrium pH are typical for metal sorption by a weak acid resin.¹¹ Thus the negligible alkali-metal cation sorption observed when the aqueous solution is quite acidic (pH ≤ 3) increases markedly as the pH is enhanced.

As noted earlier,³ the Li⁺ sorption selectivity exhibited by acyclic polyether carboxylic acid resin 1 changes to modest Na⁺ selectivity for the *sym*-dibenzo-16-crown-5-oxyacetic acid resin 2.

Complexation selectivity for Na⁺ is anticipated for the dibenzo-16-crown-5 ring system.¹² Attachment of a methyl group to the crown ether ring carbon which bears the side arm causes a marked change in Na⁺ selectivity for resin 3 [Fig. 1(c)] compared with resin 2 [Fig. 1(b)]. Thus the introduction of the smallest alkyl group is sufficient to produce a major change in sorption selectivity. This enhanced Na⁺ selectivity remains virtually unchanged as the alkyl group is varied from methyl to ethyl [Fig. 1(d)] to propyl [Fig. 1(e)]. Further elongation of the alkyl group to butyl [Fig. 1(f)] produces a noticeable decrease in Na⁺ sorption selectivity. When the alkyl group is changed to hexyl a further decrease in selectivity is noted [Fig. 1(g)]

Table 1. Alkali-metal cation sorption efficiency of polyether carboxylic acid resins 1–8.

Resin	Alkyl chain	Ion-exchange capacity,* mmole/g	Sorption, mmole/g	Percent loading, %
1	none†	2.66	2.22	83
2	none	2.39	1.85	77
3	methyl	2.31	1.49	65
4	ethyl	2.23	1.43	64
5	propyl	2.17	1.40	65
6	butyl	2.11	1.27	60
7	hexyl	1.93	0.49	25
8	decyl	1.79	0.21	12

*Calculated from elemental analysis data.

†Acyclic polyether carboxylic acid resin.

Fig. 2. Effect of alkyl group chain length upon alkali-metal cation sorption by *sym*-(R)dibenzo-16-crown-5-oxyacetic acid resins at equilibrium pH = 12.5.

and for a decyl group only slight Na^+ selectivity is observed [Fig. 1(h)].

The total alkali-metal cation sorptions and loadings for polyether resins 1–8 at equilibrium $\text{pH} = 12.5$ are presented in Table 1. The loading is defined as the total alkali-metal cation sorption by the resin divided by the ion-exchange capacity calculated from the elemental analysis data. The loading decreases from 77% for crown ether carboxylic acid resin 2 to 65% when a methyl group is attached to the crown ether ring which bears the side arm. The efficiency then remains constant as the alkyl group is varied from methyl to ethyl to propyl. The loading shows a slight decrease for the butyl group then plummets to 25% for the hexyl group and only 12% for the decyl group.

The low alkali-metal cation loadings observed for resins 7 and 8 may be attributed to enhanced hydrophobicity which hinders penetration of the aqueous solution into the resin and diminishes effective interactions between the metal cations and the ion exchange sites. In agreement, when the solvent for the alkali-metal cations was changed from water to methanol-water (4:1), the percent loading for resin 8 changed from 12 to 44% with no variation in the sorption selectivity.¹³ This enhanced loading is consistent with better penetration of the alkali-metal cation solution into the resin with the mixed aqueous-organic solvent.

Figure 2 compares the influence of alkyl group variation upon the sorption of each alkali-metal cation by resins 2–8 at equilibrium $\text{pH} = 12.5$. The curve for Na^+ sorption is markedly different than those for sorptions for the other alkali-metal cations. Thus the sorption of Li^+ , K^+ , Rb^+ and Cs^+ shows a sharp decrease when the methyl group is introduced into the crown ether carboxylic acid unit and then remains nearly constant as the alkyl group is varied from methyl to ethyl to propyl to butyl. Elongation of the alkyl group from butyl to hexyl causes an abrupt diminution of sorption with a further decrease when the alkyl group is changed to decyl. In contrast, the Na^+ sorption is strongly enhanced when the methyl group is introduced. The Na^+ sorption then remains virtually the same as the alkyl group is varied from methyl to ethyl to propyl. However the change to a butyl group produces a substantial

decrease in Na^+ sorption and the decline continues for the hexyl and decyl groups. It should be noted that even though the sorption efficiency for crown ether carboxylic acid resin 8 which has a decyl alkyl group is very low its Na^+ selectivity is higher than that of resin 2 which has no alkyl group. Thus the predominant influence of the longer alkyl groups is to decrease sorption efficiency by making the resins more hydrophobic.

CONCLUSIONS

This study of structural variation within *sym*-(R)dibenzo-16-crown-5-oxyacetic acid resins reveals that the highest alkali-metal cation sorption efficiency and Na^+ selectivity is obtained when the alkyl group is methyl, ethyl or propyl. The incorporation of longer alkyl groups diminishes sorption efficiency by increasing the hydrophobicity of the resins.

INFRARED EMISSION SPECTROSCOPY OF LIQUID SAMPLES WITH MULTIVARIATE CALIBRATION AS A MODEL FOR PROCESS ANALYTICAL APPLICATIONS

BRICE C. ERICKSON*, RANDY J. PELL† and BRUCE R. KOWALSKI‡

Department of Chemistry, University of Washington, Laboratory for Chemometrics, Seattle, Wa. 98195

(Received 9 November 1990. Revised 17 May 1991. Accepted 21 May 1991)

Summary—Infrared emission spectroscopy and multivariate calibration are used to provide a method for the quantitative analysis of liquid samples. Differing forms of the data including second derivative and interferogram representation are used for prediction of sample composition, thickness and temperature. Comparisons are made with transmission measurements of the same samples. In some situations emission measurements may be the preferred method of analysis.

Many products made by the chemical industry are above ambient temperatures at some or all points in the manufacturing process. Some of these products are considerably higher in temperature as they are produced, *e.g.*, glass, metal, synthetic fibers, polymers and coatings. A non-invasive, remote method of monitoring the composition or quality of the product would be desirable,¹ but conditions and hazards in the plant environment may make spectroscopic absorption or reflectance measurements difficult to obtain. Any sample which absorbs IR radiation emits at the same wavelengths when heated, implying that the information in an absorption or transmission spectrum used for chemical analysis should also be present in the emission spectrum. Infrared emission spectroscopy (IES), therefore, may have several advantages over transmission spectroscopy in some situations, especially where remote monitoring is desirable such as process analysis applications.¹ However, its use has been limited due to lack of suitable instrumentation of the required sensitivity and ruggedness, and the difficulty in interpreting the complex spectra obtained. Emission spectra are much more complex than transmission spectra since they are affected not only by sample composition, but by several other effects as well such as background blackbody radiation, in-

ternal reflection and self-reabsorption, refractive index, sample thickness and geometry, and most importantly temperature and temperature gradients.² The recent innovations in process qualified Fourier transform infrared spectrophotometers have provided great progress on the limitations of instrumentation, but spectral interpretation—especially for quantitation—has remained a problem. Griffiths³ and Hirschfeld⁴ have both pointed out that IES could be a powerful quantitative tool if a general method or algorithm could be developed to aid in data interpretation.

Some potential advantages of IES over the more traditional spectroscopies include the fact that there is no need to use an external source of radiation since the hot sample acts as its own source; requirements for optical alignment are minimized; there is less sensitivity to effects such as reflections or diffractions which may occur at the surface of the sample; measurement can be made remotely, measurement is non-invasive and non-destructive; and information about sample temperature is contained in the spectrum.

Limitations of IES include the lower radiation levels available for detection, especially at shorter wavelengths, resulting in the need for cooled detectors; the requirement that the sample must be at a temperature different than the detector and its surroundings; and a decrease in spectral information as the sample becomes more opaque.

Infrared emission spectroscopy has been used in a number of different applications in the past. Most of these applications relate to temperature

measurements by optical pyrometry, or to qualitative analysis of optically thin samples, although there have been attempts to use IES quantitatively. Quantitative applications of IES in the chemistry literature generally involve optically thin samples under carefully controlled laboratory conditions, usually with known temperature. Some examples of samples types on which IES has been used are thin films of oils⁵ and lubricants,⁶ molten salts^{7,8} and oxide coatings on metals.^{9,10} A number of reviews or general papers are available of applications of IES in the chemistry literature.^{11,12}

Multivariate calibration methods, and specifically the Partial Least Squares (PLS) method, have been found useful for quantitative analysis in a number of spectroscopic techniques.¹³ For example, these methods have been applied to absorption or reflectance spectroscopy in the mid- and near-IR regions.^{14,15} In an earlier paper,¹⁶ the applicability of multivariate calibration methods, specifically partial least squares (PLS) calibration, was demonstrated for quantitation from infrared emission spectra of polymer film samples in spite of these non-linearities. The results of that work demonstrate the ability of multivariate calibration to extract not only information concerning the composition of the sample, but thickness and temperature as well, from emission data. This work is a further study on use of PLS for the analysis of IES data from liquid samples. The study was conducted to better understand the limitation for determining thickness, temperature and composition since these parameters can be better controlled with liquid samples.

EXPERIMENTAL

A Perkin-Elmer model 1720 FTIR spectrometer was modified to allow use of the instrument for either emission or transmission studies. For emission studies, the focal plane of the optical system is changed from the normal instrument source to an external sample mount by changing one reflector. With the instrument source turned off, the sample then becomes the source of radiation which eventually reaches the detector. No sample is placed in the normal sample compartment. A medium band MCT (Hg-Cd-Te) detector was used to provide the required sensitivity.

A model system was desired for IES studies which would allow more precise control of the parameters of sample composition, thickness

and temperature to further evaluate the effectiveness of the method. The samples studied are binary mixtures squalene and di(2-ethylhexyl)sebacate. These compounds were chosen for their low vapor pressures and thermal stability over a wide range of temperatures. Since they are complex organic molecules, they have a large number of strongly absorbing bands in the infrared. They may also serve as a model of organic systems that might be encountered in process situations.

For emission studies, mixtures containing 60, 70, 80 and 90% squalene were prepared by weight. Samples were placed in a variable pathlength liquid cell. Cell windows were potassium bromide, and no reflecting backplate was used. The cell pathlength was adjustable from 50 micrometers to 5 mm, and pathlengths of 0.1, 0.2, 0.4, 0.6, 1, 3 and 5 mm were used. The circumference of the cell was wrapped with a heating tape with temperature controlled by a variable voltage power supply. Sample temperature was accurately measured by an RTD temperature sensor placed against the back window of the cell. For longer pathlength samples, a thermocouple was also placed inside the cell to verify the measurements, and temperatures were in agreement within 1°. The single beam infrared emission spectrum, second derivative of the single beam emission spectrum and raw interferogram from the instrument were recorded for each concentration and thickness at 4 random temperatures in the range 45–80°. A 500-point spectrum was used for the PLS analysis from 3000–500 cm⁻¹ at 5 cm⁻¹ intervals for emission and derivative spectra; the 200 point interferogram was used for interferogram predictions.

For transmission and absorption spectra, squalene/di(2-ethylhexyl) sebacate mixture samples were prepared as above with concentrations of 60, 65, 70, 75, 80, 85 and 90% squalene; the three additional concentrations were added to assure a sufficiently large calibration data set. Temperature was not varied or predicted for transmission or absorption spectra, since it has minimal effect on the spectra obtained. Transmission spectra were obtained for the samples in the variable pathlength cell for the thicknesses used earlier from 0.1 to 5.0 mm on the same instrument, using the instrument source and the DTGS detector with the sample placed in the usual sample compartment. Spectra were saved in both transmission and absorbance units. The Perkin-Elmer data system does not record absorbance values

greater than 5 so these data points were given the value 5. The PLS method was applied for data analysis, using 500-point spectra from 3000–500 cm^{-1} at 5 cm^{-1} intervals.

The intention of this work was to investigate the use of multivariate calibration for quantitation using infrared emission data. Although the application of certain *a priori* information in the form of wavelength selection/deletion may have helped to optimize the data analysis, this approach was not taken. Minimal preprocessing of the data was performed to provide an approach that could easily be automated with little expert interaction. This approach provides a worst case scenario and any intelligent application of wavelength selection may only serve to further refine the method and improve the results.

RESULTS AND DISCUSSION

The PLS regression method and algorithm are described in the literature.¹³ A calibration set is used to develop the multivariate model, which can then be used to predict properties such as concentration for similar samples not included in the calibration. A method must be chosen to determine the number of latent variables or factors to be retained for the model. Since our main concern was the ability of the model to predict unknown samples, predictive ability was determined with a cross-validation procedure.¹⁷

In order to evaluate the effectiveness of the model in predicting the unknown, the SEP (standard error prediction, or average prediction error) is calculated to give a meaningful expression of how well the method is able to predict relative to the true values.

$$\text{SEP} = \left(\sum_{i=1}^N (y_i - \hat{y}_i)^2 / N \right)^{1/2}$$

where y_i 's are the reference values obtained by an independent method of analysis and the \hat{y}_i 's are the values predicted by PLS. The number of factors retained is the lowest number of factors with a SEP within the uncertainties of the lowest SEP obtained, that is, the lowest number of factors with a prediction which is not significantly worse than the best SEP obtained. The SEP then gives an indication of how well the model will predict a sample not contained in the calibration set. A number of diagnostics were used with the algorithm to detect samples which are outliers relative to the calibration (not to be discussed here).

Figure 1 shows typical spectra obtained on our instrument. The low intensities above 2000 cm^{-1} are due to the relatively low temperature of the samples related to Planck's equation. The sharp drop in intensity from 550 to 450 cm^{-1} and some of the additional apparent "structure" in the spectrum are actually due to variable instrument responses over the wavelength range. Some of the observable fine structure, especially between 1350 and 1800 and between 2300 and 2400 cm^{-1} , is due to absorption by atmosphere H_2O and CO_2 in the radiation path between the sample and instrument. No attempt is made to correct for these various response factors; they are assumed to be constant so that they will not affect the calibration from PLS. Figures 1(a), (b) and (c) show typical spectral changes due to changing sample composition, temperature and thickness respectively. Of the three sample properties studied, temperature has the greatest effect on the intensities in the spectra.

Table 1 summarizes the predictive ability of the method for certain subsets of the data, along with the number of latent variables (factors) found to be significant in the calibration. When samples with thicknesses in the 0.6–5 mm range are used, the SEP for concentration predictions is 3.4% absolute over the 60–90% range. Prediction of the thickness of these samples gives a SEP of 0.43 mm over the 0.6–5 mm range. Temperature in this case is predicted quite well, with a SEP of 0.7° over the 45–80° range. This verifies that temperature prediction is possible from emission spectra, using PLS, when temperature values are known to sufficient precision in the calibration set; this point was unclear in the earlier study.¹⁶

For thinner samples in the 0.1–0.6 mm range, of the 64 possible spectra (4 concentrations at 4 thicknesses and 4 temperatures), 3 were removed due to known experimental problems. An additional 3 were found statistically to be spectral outliers. These six samples were removed from the calibration set. Concentration predictions showed a SEP of 1.6% absolute over the 60–90% range. Sample thickness had a SEP of 0.03 over the 0.1–0.6 mm range. Temperature was predicted with a SEP of 0.9°. While a large number of factors were used for this prediction, it should be noted that a single factor predicted temperature with a SEP of 1.6, so it appears that the main temperature effect is easily modeled while additional factors make slight corrections for the non-linearities.

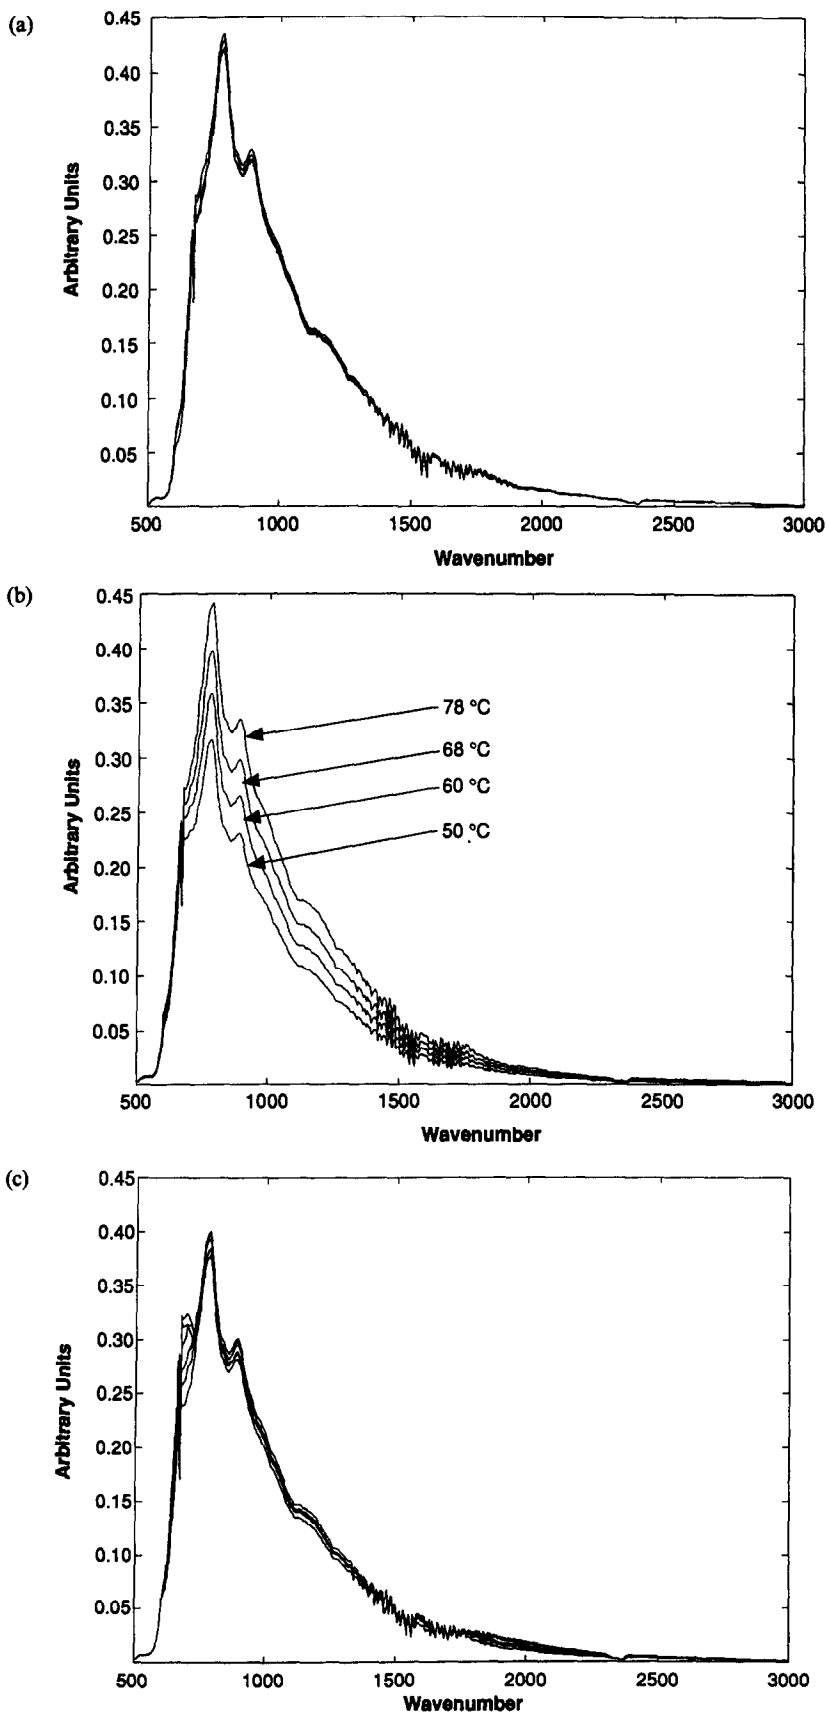

Fig. 1. Emission spectra. (a) Concentration variation: samples 0.4 mm thick at about 77° with concentrations of 60%, 70%, 80% and 90% squalene. (b) Temperature variation: samples 80% squalene and 0.2 mm thick at 50, 60, 68 and 78°. (c) Thickness variation: samples 80% squalene at about 67° and 0.1, 0.2, 0.4, 0.6, 1.0, 3.0 and 5.0 mm thickness.

Table 1. Summary of prediction results for emission spectra of liquids

Data type	Standard error of prediction					
	Conc., (%)	Factors	Thickness, mm	Factors	Temp., °C	Factors
Thick (0.6–5 mm) samples emission spectra	3.4	10	0.43	11	0.7	14
Thin (0.1–0.6 mm) samples emission spectra	1.6	16	0.03	15	0.9	13
Thin (0.1–0.6 mm) samples 2nd deriv. spectra	3.0	11	0.05	10	1.0	9
Thin (0.1–0.6 mm) samples interferograms	2.8	10	0.05	14	0.7	12

Table 1 also shows that the use of second derivative spectra for the prediction resulted in roughly the same prediction results for thickness and temperature but somewhat poorer results for composition, although 4 or 5 fewer latent variables were used for optimal prediction. It is interesting to note that the prediction can also be made directly from the interferogram,

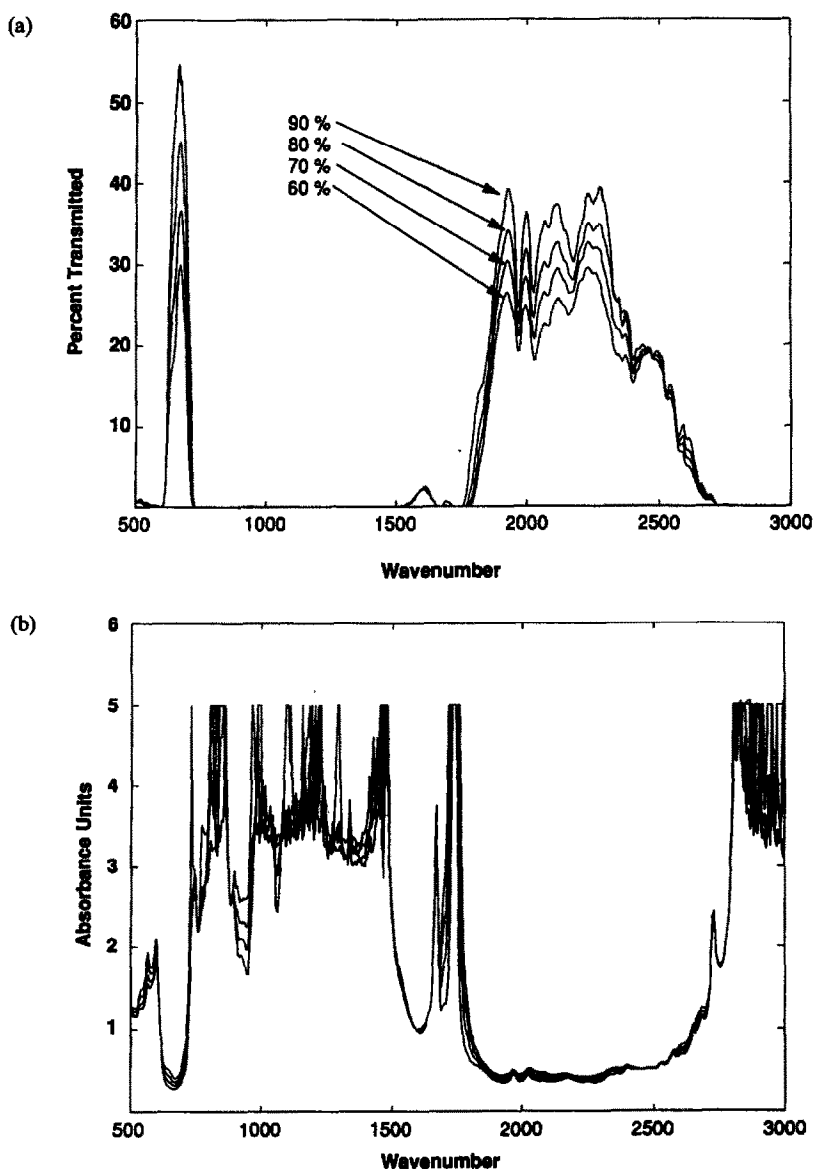

Fig. 2. Concentration variations. Transmission (a) and absorbance (b) spectra of 0.4-mm samples containing 60%, 70%, 80% and 90% squalene.

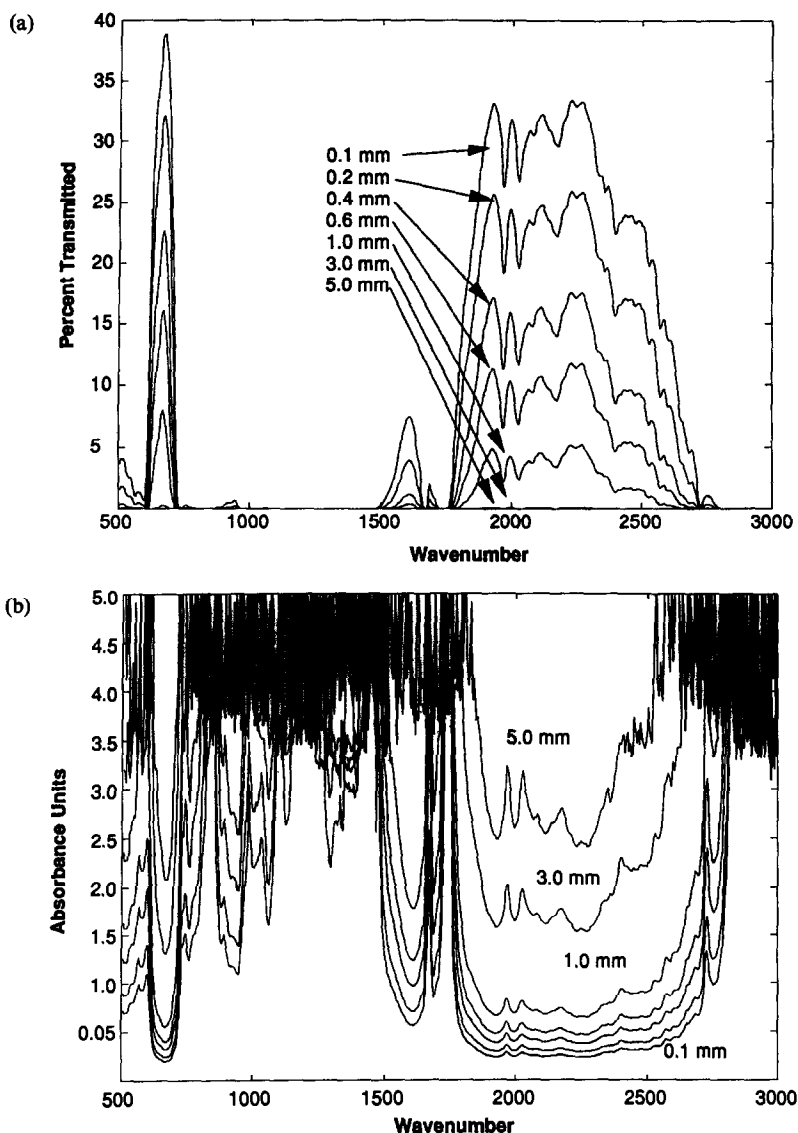

Fig. 3. Thickness variations. Transmission (a) and absorbance (b) spectra of 80% squalene sample with thicknesses of 0.1, 0.2, 0.4, 0.6, 1.0, 3.0 and 5.0 mm.

without transforming to the spectral domain. The concentration and thickness predictions are slightly worse than the prediction from the emission spectra, but still as good or better than the second derivative prediction.

The success of the PLS method in predicting composition, sample thickness and sample temperature with these liquid samples verifies the validity of the results of the earlier polymer studies that IR emission shows great promise as an analytical tool for certain process situation.

In the more typical transmission experiments, response is linearized for concentration and thickness effects by converting data to absorbance units. Spectra of the liquid samples were taken in the transmission mode and a

comparison is made in the number of factors retained and predictive ability for transmission, absorption and emission spectra of these samples.

Typical transmission and absorption spectra of samples with changing concentration are shown in Figs. 2(a) and (b). Figures 3(a) and (b) show spectra with changing thickness at constant composition. Results from the PLS analysis are summarized in Table 2, along with the earlier results from the emission experiments. For samples in the 0.6–5 mm thickness range, the emission spectra showed the best prediction of sample concentration with a SEP of 3.4 *vs.* 6.6 for absorption and 4.0 for transmission. Thickness, however, was predicted

Table 2. Summary of prediction results for emission, transmission and absorbance spectra of liquid samples

Data type	Standard error of prediction			
	Conc., %	Factors	Thickness mm	Factors
Thick (0.6–5 mm) samples emission spectra	3.4	10	0.43	11
Thick (0.6–5 mm) samples transmission spectra	4.0	10	0.1	11
Thick (0.6–5 mm) samples absorbance spectra	6.6	3	0.21	2
Thin (0.1–0.6 mm) samples emission spectra	1.6	16	0.03	15
Thin (0.1–0.6 mm) samples transmission spectra	0.1	13	0.002	12
Thin (0.1–0.6 mm) samples absorbance spectra	2.5	5	0.02	4
Thin (0.1–0.6 mm) samples absorbance trunc. at 3	0.77	9	0.003	11
Thin (0.1–0.6 mm) samples absorbance trunc. at 2	0.51	10	0.002	13

better by absorption (SEP of 0.21) than emission (SEP of 0.43), and better yet by transmission (SEP of 0.1). The absorption spectra, which are expected to be more linear with respect to concentration and thickness, require fewer latent variables to make the predictions, requiring only 3 for concentration and 2 for thickness. Emission and transmission both require 10 for concentration and 11 for thickness for their optimal predictions. This implies that the number of factors retained for prediction for emission spectra are reasonable, using about the same number as the less complex transmission spectra.

Figure 4(a) shows the SEP *vs.* number of factors used in prediction for the three types of spectra. The optimal prediction is reached quickly by absorbance calibration, and predictive ability is not significantly improved as additional factors are added. Emission and transmission predictions continue to improve until they reach their optimal predictions between 10 and 15 factors. A similar trend is seen in Fig. 4(b) for thickness predictions.

For the thinner set of samples in the 0.1–0.6 mm range, the emission spectra (SEP = 1.6) still have an advantage over absorption spectra (SEP = 2.5) in predicting concentration, but surprisingly the transmission calibration (SEP = 0.1) is an order of magnitude better than both. For thickness prediction, absorption (SEP = 0.02) is slightly better than emission (SEP = 0.03), but again transmission (SEP = 0.002) is an order of magnitude better than both. Again, absorption calibrations use far fewer factors for prediction.

Apparently the transformation of the data from transmittance to absorbance values expands the noise in the high absorption regions, due to the logarithmic relationship. To check this assumption, values in the absorption data set were truncated at 3 absorbance units; that is, all values greater than 3 were reassigned the value 3. The prediction for concentration was improved from a SEP of 2.5 to about 0.8, and thickness from 0.02 to 0.003. Thus removing those values suspected of being in a “noisy” portion of the spectrum greatly improves the predictive ability of the calibration. Truncating the data at 2 absorbance units results in slightly better prediction. In addition, over 98% of the spectral variance is now explained by the model for data with absorbances truncated at 3, and over 99% for data truncated at 2. Figure 4(c) shows the trends in the SEP for emission, transmission, absorption and truncated (at 3) absorption data over number of factors retained in the model for thin samples.

This result is significant for multivariate calibration in that it implies great care must be taken in preprocessing of data to be sure that the transformation used does not scale the noise level of the data up to intolerable levels.

While transmission and absorption spectra do predict better than emission for thin samples, this does not imply that emission will not be useful. The reasons cited earlier for using IES methods in process situations have more to do with other considerations which make emission methods more attractive than transmission methods. As long as predictive ability is sufficient for the application, IES should remain

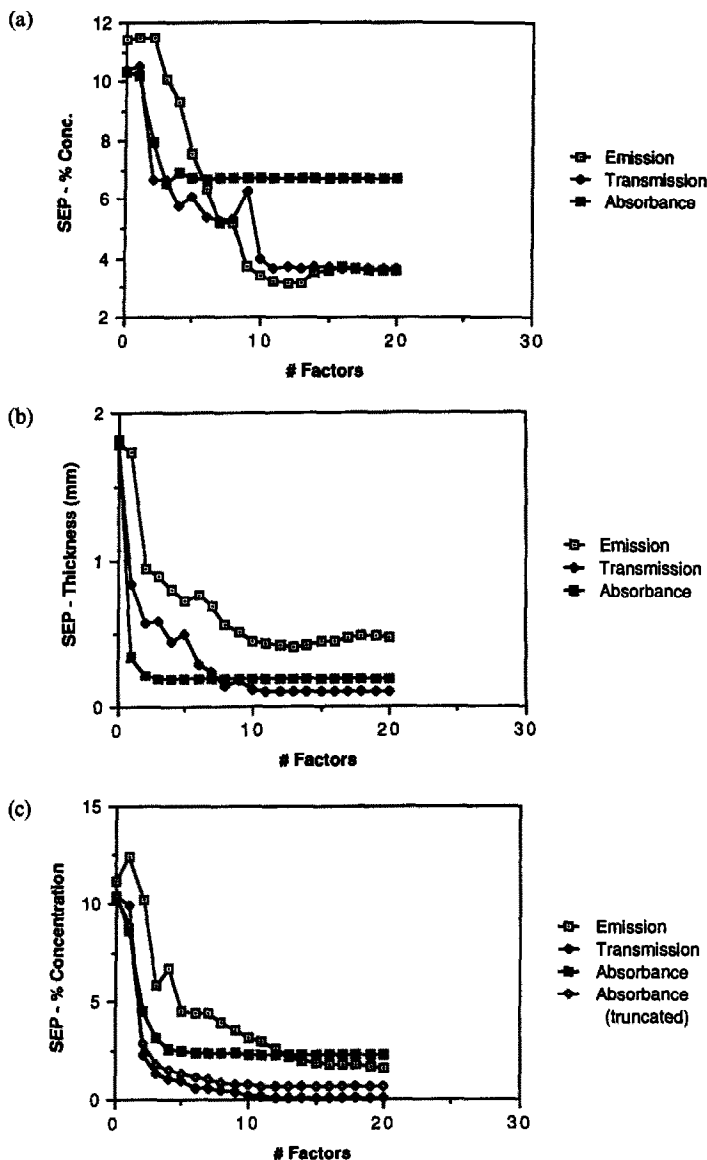

Fig. 4. Standard error of prediction (SEP) vs. number of factors retained in the model used for prediction. (a) Prediction of squalene concentration (%) in samples 0.6–5 mm thick for absorbance, transmission and emission spectra. (b) Prediction of thickness of samples 0.6–5 mm thick for absorbance, transmission and emission spectra. (c) Prediction of squalene concentration (%) in samples 0.1–0.6 mm thick for emission, transmission, and absorbance spectra, including absorbance spectra truncated at 3.

a viable tool. And the better prediction observed for emission spectra on the thicker samples indicates that it may in fact be the best method for prediction in some applications.

POLAROGRAPHIC BEHAVIOUR OF URANIUM β -DIKETONATES IN CHLOROFORM

APPLICATION OF AC POLAROGRAPHY TO THE ANALYSIS OF URANIUM MINERALS

M. H. POURNAGHI-AZAR* and J. ORDOUKHANIAN

Electroanalytical Chemistry Laboratory, Faculty of Chemistry, University of Tabriz, Tabriz, Iran

(Received 15 December 1990. Revised 23 April 1991. Accepted 14 May 1991)

Summary—The polarographic behaviour of U(VI) β -diketonates has been studied in chloroform. The conditions for reversible electrochemical reduction of U(VI) acetylacetonate and benzoylacetonate at a dropping mercury electrode was optimized by using a suitable ratio of piperidinium perchlorate and piperidine mixture as supporting electrolyte in chloroform. The one-electron nature of the reduction wave of U(VI) complexes was confirmed by controlled potential coulometry. The ac method preceded by a solvent extraction of U(VI) benzoylacetonate in chloroform was used for the determination of uranium. The calibration curve was linear over the range 0.5–20 $\mu\text{g/ml}$. The correlation coefficient was 0.9998 and the detection limit was about 0.2 $\mu\text{g/ml}$. The interference of some concomitant ions were examined and EDTA was used as an effective masking agent to separate uranium from other metals. The proposed method has been applied to the determination of uranium in uranium minerals.

In general a preliminary separation by solvent extraction provides good selectivity for instrumental methods of analysis that tend to be subject to matrix effects or interferences from concomitant elements. Analytical determination of metal ions following solvent extraction based on electrochemical methods, involving either direct measurement of the amount of the analyte in the organic phase diluted with a convenable supporting electrolyte solution,^{1–5} back-extraction into aqueous phase,⁶ or evaporation of the extracted phase and redissolution of the residue in some other polar solvent.

Such methods are however time-consuming and it is often very difficult to destroy the chelating agents. In addition, the large number of steps involved in the analytical process and the dilution of the extracted phase affect the precision and sensitivity of analytical methods.

Direct application of electroanalytical methods to the determination of analytes in pure extracts seem to be simple and sensitive.^{7–11} To carry out this, it is necessary to provide conditions for the electrochemical studies in extracting solvents with a low dielectric constant.

The study of electrochemical behaviour of organic and inorganic compounds in non-aqueous media was limited to solvents with high

dielectric constant; solvents with low dielectric constant which are used in liquid–liquid extraction (e.g., chloroform, dichloromethane, benzene etc.) have been rarely used.

Application of common methods such as cyclic voltammetry, polarography and controlled potential coulometry for the study of electrochemical behaviour of some organic compounds with several supporting electrolytes at the bright platinum and dropping mercury electrodes in chloroform have been reported recently.^{11–14}

In this paper we describe the study of polarographic behaviour of metal ion complexes such as uranium β -diketonates in chloroform. The alternating current (ac) polarography was applied as a convenable technique for the determination of uranium in mineral ores at the ppm level after optimization of polarographic conditions.

EXPERIMENTAL

Chemicals and reagents

Chloroform, piperidine, perchloric acid, acetylacetone, benzoylacetonate and thenoyltrifluoroacetone were Merck p.a grade. The supporting electrolyte, piperidinium perchlorate, was prepared by gradual neutralization of a given volume of piperidine with the required amount of

*Author for correspondence.

perchloric acid while cooling the solution in iced water. The neutral solution obtained was crystallized by successive concentration on the water bath and cooling at room temperature. The white crystals formed were dried at 50°.

Standard uranium solution. A $10^{-2}M$ aqueous solution of uranyl nitrate, $UO_2(NO_3)_2 \cdot 6H_2O$, from BDH was prepared as a stock solution. The standard solutions were prepared by successive dilutions of this stock solution.

Extraction solution. A 50% solution of acetylacetone, 1M benzoylacetone and 0.15M thenoyltrifluoroacetone solutions in chloroform were used.

Apparatus

A polarograph E 506 was used with an E 505 mercury dropping-electrode (METROHM) to plot the polarograms in connection with a V.A scanner E 612 and an X-Y recorder to record the cyclic voltamperograms. An E 524 coulostat connected to an E 478 recorder was used for coulometry at controlled potential.

Procedure

Transfer 10 ml of aqueous standard or uranium sample solution into a 100-ml separating funnel. Adjust the pH of aqueous solution with 0.01N sodium hydroxide or ammonia and 0.01N nitric acid to a pH at which the extraction of complexes are complete (optimum pH for quantitative extraction of acetylacetonate, benzoylacetone and thenoyltrifluoroacetone of uranium(VI) are 3, 4 and 7 respectively¹⁵). Shake with an equal volume of chloroformic solution of β -diketone for 10 min on a shaker. Separate the chloroform extract and transfer it into a polarographic cell, add 1.40 g of piperidinium perchlorate and 0.25 ml of piperidine (0.75M PP + 0.25M P) as supporting electrolyte. Bubble nitrogen through the solution for 20 min, record the ac polarogram by sweeping the potential from 0 to -500 mV vs. Ag/AgI reference electrode at 2 mV/sec. When other metals were also present, 1 ml of 0.05M EDTA was added before the chloroformic solution of β -diketone.

RESULTS AND DISCUSSION

In chloroform in the presence of extracting agents and with 0.5M TBAP as supporting electrolyte, the uranium(VI) β -diketonates were not reducible at the dropping mercury electrode, but with piperidinium perchlorate (0.75M) and piperidine (0.25M) merged as supporting elec-

Fig. 1. Direct current (dc) polarograms of (1) 0.75M PP/0.25M P + 50% Acetylacetone, (2) (1) + 1mM U(VI) acetylacetonate, (3) (1) + 1mM U(VI) benzoylacetone.

trolyte, the reduction of acetylacetonate and benzoylacetone of U(VI) gives each one reduction wave with a half-wave potential of -0.240, -0.200 V, respectively (Fig. 1). The reduction wave of thenoyltrifluoroacetone was not a well-defined one. Controlled potential coulometry shows that the single cathodic wave of U(VI) β -diketonates corresponds to a one electron reduction process. A plot of $\log [(i_d - i)/i]$ vs. E gives a straight line with a slope of about 64 mV. Cyclic voltamperograms of U(VI) β -diketonates are shown in Fig. 2. For all scan-rates between 0 and -0.5 V one cathodic peak and one anodic peak are observed. Peak heights, as expected, increased with increasing scan-rate. The current function ($i_{pc}/V^{1/2}$) remains constant. The peak separation $E_{pa} - E_{pc}$ for scan-rates less than 20 mV/sec are 75 and 73 mV for U(VI) acetylacetonate and benzoylacetone respectively. The ratio of anodic to cathodic peak currents as a function of voltage scan-rate is unity and remains constant. These confirm that there is no kinetic complication for the reduction of U(VI) β -diketonates under optimized polarographic conditions.

Alternating current (ac) polarography presents well-defined peaks with E_p equal to $E_{1/2}$ of dc waves. The half-width of peaks are 90 mV. The calibration graphs were linear over the range 10^{-5} - $2 \times 10^{-4}M$ for acetylacetonate and 4×10^{-6} - $2 \times 10^{-4}M$ for benzoylacetone (Fig. 3). Correlation coefficient is 0.9998 and

Fig. 2. Cyclic voltamperograms of (a) 1mM U(VI) acetylacetonate (b) 1mM U(VI) benzoylacetonate in the presence of 0.75M PP/0.25M P as supporting electrolyte, scan-rate 5–100 mV/sec.

the detection limit for U(VI) benzoylacetonate is 10^{-6} or 0.2 $\mu\text{g/ml}$ of uranium in the original aqueous solution. The relative standard deviation for five replicate determinations of 1 $\mu\text{g/ml}$ uranium was 2.5%.

With the 0.75M PP/0.25M P as supporting electrolyte the differential pulse polarogram of U(VI) β -diketonates coalesce with the reduction wall of the solvent and therefore an accurate and quantitative measurement of these peaks cannot be made.

Fig. 3. Alternating current (ac) polarograms of (a) U(VI) acetylacetonate 1.5×10^{-3} – $1.5 \times 10^{-6}M$ (b) U(VI) benzoylacetonate (2×10^{-6} – $10^{-5}M$) in the presence of 0.75M PP/0.25M P $V = 10 \text{ mV}$ $t = 1 \text{ sec}$, $f = 75 \text{ Hz}$.

Interferences

The interferences from some concomitant elements such as V(V), Pd(II), Mo(VI), Cu(II), Fe(III), etc., have been examined. The experimental results show that among the concomitant elements extractable with β -diketonates in chloroform, only Fe(III) and Cu(II) are electroactive under the polarographic conditions of uranium. The potential of the copper(II) reduction peak is sufficiently positive in comparison with uranium and hence does not cause any severe interference. However, the presence of iron(III) is undesirable (Fig. 4). In this event, extraction at pH 7 with 1M benzoylacetonate solution in the presence of 0.05M EDTA masks Fe(III) and prevents the interference of 1000-fold molar excesses of this ion. Thus the extraction of uranium(VI) remains totally unaffected. The presence of F^- ion in aqueous solution prevents the extraction of U(VI), therefore decomposition of uranium minerals in the presence of hydrofluoric acid is undesirable (Fig. 5).

Application to the analysis of uranium minerals

Several sensitive electrochemical methods have been developed for the determination of U(VI), including polarography preceded by

Fig. 4. Alternating current (ac) polarograms of metal benzoylacetonate (a), U(VI), (b), Fe(III), (c), Cu(II) in the presence of 0.75M PP/0.25M P as supporting electrolyte $t = 1$ sec, $f = 75$ Hz, $V = 10$ mV.

liquid-liquid extraction,^{7,10,16} voltammetry after preconcentration on the surface of solid electrodes^{17,18} and cathodic stripping voltammetry preceded by adsorptive collection of surface active metal complexes on the hanging mercury drop electrode.¹⁹⁻²² But this method may not be suited to the determination of uranium in mineral ores.

Fig. 5. Polarograms of uranium mineral extracts, in chloroform in the presence of 0.75M PP/0.25M P as supporting electrolyte (1) decomposed with HNO₃, (2) decomposed with HNO₃ + HF $V = 10$ mV $f = 75$ Hz $t = 1$ sec.

The proposed ac polarographic method in this work was checked by analysing the uranium sample (from Ssagand-Iran), containing a certified amount of uranium. The samples were decomposed by the following procedure.

Transfer a powdered sample into a 100-ml beaker, add about 15 ml of 12N hydrochloric acid and boil on a hot plate, then add 5 ml of 16N nitric acid, boil the solution almost to dryness. Take the residue with a solution (1.1) of nitric acid and boil for 15 min. Filter and wash with a 5% hot solution of nitric acid. Transfer the filtrate into a 100-ml standard flask and dilute to volume. Subject an aliquot of the sample solution (10 ml) to the polarographic determination of uranium as described above.

The results of replicate determinations (3890 ± 25.5 ppm) confirm that the uranium content of such samples is consistent. The proposed extraction polarographic method is applicable to the rapid determination of uranium in rocks, minerals and uranium concentrates with sufficient accuracy and precision.

CONCLUSION

On the basis of results obtained from dc and ac polarography and controlled potential coulometry, the reduction of acetylacetonate and benzoylacetonate of uranium(VI) in the presence of 0.75M PP/0.25M P can be shown to be:

where X is the β -diketonate ion.

The plot of $\log[(i_d - i)/i]$ vs. E for the dc polarograms, the half-peak width in the ac polarograms and ΔE_p values in cyclic voltammetry are three criteria which indicate that the reduction of uranium β -diketonate is a one-electron reversible process. The reversible reduction of U(VI) in chloroform, the linear relationship between i_p and the concentration of uranium in the original aqueous phase, provide the possibility of determination of uranium by extraction polarography of its β -diketonates in chloroform at the μg level. The proposed method for U(VI) determination is highly selective, without any interference from concomitant elements.

AUTOMATIC KINETIC DETERMINATION OF Hg(II) BY ANODIC STRIPPING POTENTIOMETRY WITH CONSTANT CURRENT OXIDATION

(Received 15 November 1990. Revised 12 April 1991. Accepted 13 May 1991)

Summary—A new kinetic method for the determination of Hg(II) is proposed. It is based on the kinetic evolution of the anodic stripping potentiometric curves yielded by a gold electrode previously coated with mercury upon passage of constant electrical currents. The method features a linear determination range between 40 and 800 ppb of Hg(II) and a relative standard deviation of 5% ($n = 9$) for a mercury concentration of 200 ppb. The experiments were conducted on a customized automatic set-up, and instrumentation, data acquisition and processing were all governed by means of a QBASIC program (PSAKINEL) written by the authors.

Anodic stripping potentiometry (ASP) was originally developed by Jagner,¹⁻³ who proposed its use for the determination of heavy metals such as Cd, Pb, Bi, Cu, Tl and Zn. This technique relies on recording anodic stripping potentiometric curves generated upon the deposition of metals on mercury-coated graphite electrodes caused by the presence of oxidants such as Hg(II) and oxygen¹⁻⁷ or the passage of a constant electric current.⁸⁻¹¹ Jagner¹² addressed the determination of mercury by using a variation of the original technique involving the deposition of the metal in the presence of copper and the joint stripping of the two metals with an oxidant such as potassium permanganate or dichromate. In both variants, the analytical signal typically obtained is a potentiometric $E-t$ curve where the potential changes rapidly in the absence of an oxidation process and remains constant and parallel to the time axis in its presence. The length of the plateau is proportional to the analyte concentration and is also related to the pre-electrolysis potential and time, the concentration and nature of the oxidant, the stirring rate, pH and background of the working electrode.

Anodic stripping potentiometry equals its voltammetric counterpart in sensitivity and even surpasses it in instrumental simplicity and scope as it can be applied to multideterminations. However, its low reproducibility and the time-consuming operations involved in its appli-

cation are two major weaknesses. The sluggishness of ASP determinations has so far been overcome by automating the process involved¹³ or by using powerful collection systems allowing data to be acquired at rates as high as 30 kHz,^{8-11,14} which in turn allow the analytical and blank signals to be discerned by using short pre-electrolysis times.

With the aim of improving the reproducibility of this technique—particularly in the automatic determination of several samples—without resorting to the electrode repolishing and regeneration we studied the optimal acidity, nature and concentration of various oxidants and types of electrodes. In the course of the study we found that the potentiometric oxidation curves yielded upon oxidation of mercury with the periodate/iodide system at a gold electrode deviated from the typical behaviour of ASP curves and resemble those normally obtained with kinetic methods (spectrophotometric, fluorimetric and thermometric). As we found no literature reference accounting for this phenomenon, we tackled its study in order to interpret this anomalous behaviour and develop a kinetic method for the determination of mercury by ASP.^{15,16} Since preliminary experiments showed that the use of chemical oxidants complicated the application of the method, we assayed the kinetic determination by ASP with an electric current for oxidation. The instrumentation required for this purpose and the results thus obtained are discussed below.

EXPERIMENTAL

Apparatus

All experiments were carried out on a fully automatic set-up designed and constructed by the authors. It consisted of the following elements: a PC-compatible system, a Metrabyte DASH-8 A/D converter board, a custom-made optocoupling system for triggering relays, a CRISON autoburette furnished with an RS-232C interface, a CRISON autosampler also furnished with an RS-232C interface, two custom-made potentiostats/galvanostats, and an electrode system composed of gold (working, $S = 0.2 \text{ cm}^2$), calomel (reference) and platinum wire (counter-electrode). The complete assembly is depicted in Fig. 1.

The instrumentation was governed by a computer system which controlled the operation of the automatic burette and the sampler via their respective RS-232C interfaces by using the manufacturer's communication protocol. The pre-electrolysis and electric oxidation steps were carried out by using a potentiostat and a galvanostat, respectively, which were switched via two relays actuated by the computer through the digital outlets of the DASH-8 board and the optocoupling system. Finally, experimental data were acquired through one of the analogical lines of the DASH-8 board (sampling rate = 10/sec) connected to the working and reference electrodes via an RC filter ($R = 500 \text{ kohm}$, $C = 1 \mu\text{F}$).

Reagents

The reagents used, all of which were pro-analysis grade, included a standard 1000 ppm Hg(II) solution prepared from $\text{Hg}(\text{NO}_3)_2$, H_2O and 4M and 2.5M sodium chloride and hydrochloric acids respectively.

Procedure

In a 50-ml standard flask were placed 5 ml of 4M sodium chloride and 2 ml of 2.5M hydrochloric acid; the solution was made to the mark with distilled water. The solution was then transferred to the autosampler and a blank signal was obtained by using a pre-electrolysis potential of -0.5 V and an oxidation current of $15 \mu\text{A}$. The Hg(II) was added and the pre-electrolysis repeated to obtain the analytical signal. The whole process was performed automatically via an automatic burette for adding the sample.

Software

The instrumentation, data acquisition and processing were controlled by means of a QBASIC program written specifically for this purpose by the authors; the original BASIC code was compiled and linked to the subroutines for handling of the DASH-8 board supplied by the manufacturer.

The program performed two distinct functions, namely:

Experimental control. The software allows a specific procedure to be applied to the same

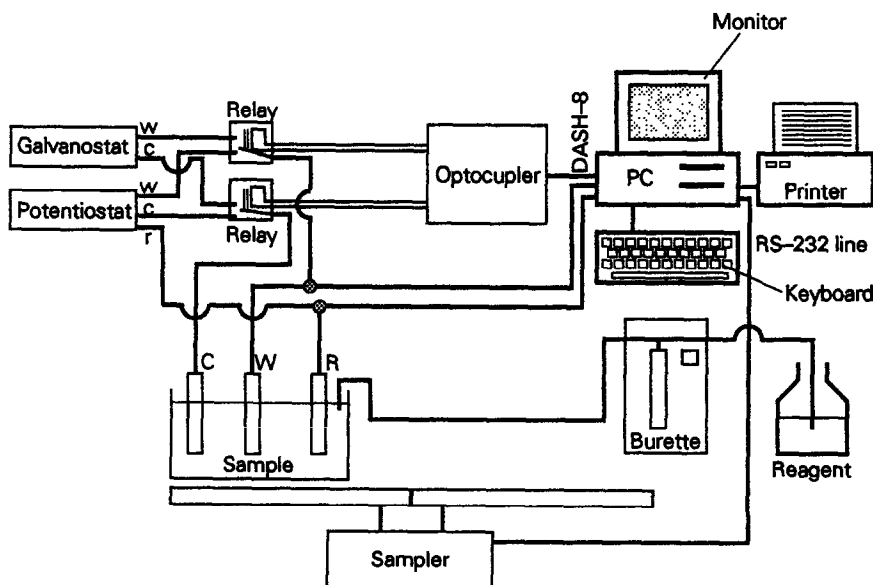

Fig. 1. Block diagram of the automatic set-up.

sample by having the automatic burette add preset volumes between measurements. The acquisition of experimental data is started by setting the autosampler to the required position and—if required—adding some reagent from the burette and switching the potentiostat on for a preset time (pre-electrolysis step). Next, the computer switches the potentiostat off and the galvanostat on and starts experimental data acquisition (potential of the working electrode as a function of time).

Additions from the autoburette can be effected from an external reservoir or even from one of the autosampler cups. In the latter case, the sample is aspirated and discarded through the same burette channel, the loop volume of which is somewhat larger than the injected volume. The aspirated sample volume is always slightly larger than that to be added to include a few milliliters for flushing to avoid sample carry-over.

Thus, by loading one half of the sampler with blanks and the other with samples, up to six samples can be analyzed completely automatically by using their respective blanks. Each experiment involves applying the above-described procedure to the blank, which is subsequently added to the sample to be assayed. The difference between the sample and blank response yields the analytical measurement sought. The acquired data can be processed at once or stored on disk for later treatment.

Data processing. The PSAKINEL program allows experimental data to be processed by the three typical procedures for kinetic data, namely the initial-rate (slope of the $E-t$ curve), fixed-time (potential reached at a prefixed time) and fixed-potential (time passed between the start of the stripping and a prefixed potential is reached).

Prior to the treatment proper, the experimental curves can be smoothed by the Sawitzki-Golay method,¹⁷ and their first and second derivative readily obtained.

The treatment can be effected manually or fully automatically. The manual processing option is included on the corresponding menu in order to establish the most suitable criteria for obtaining results or as an alternative to the automatic procedure when this yields spurious results for some reason.

Trials on the different treatments possible revealed that the fixed-potential option yielded the most satisfactory results as the initial-rate method involved the difficulty arising from the

drawing of the tangent to the $E-t$ curve at the most appropriate point, and the fixed-time method required finding a time suitable for quite a wide concentration range.

RESULTS

The influence of the different experimental variables on the system was investigated.

pH. Figure 2 shows the time results obtained at a fixed-potential by changing the hydrochloric acid concentration in the blank and a sample containing 800 ppb Hg(II). As can be seen, the H^+ hardly influences the signal over the pH range tested. We thus chose 0.1M hydrochloric acid for subsequent experiments.

Oxidation current. Figure 3 shows the variation of the signal with the oxidation current. As expected, the sensitivity decreased with increasing current. However, small currents resulted in the ill-defined, difficult-to-process curves shown in Fig. 4, which displays the potentiograms obtained at different oxidation currents for a sample containing 800 ppb Hg(II). A current of 15 μA was chosen for subsequent experiments.

Pre-electrolysis time. Figure 5 reflects the variation of the blank signal and that provided by a sample containing 800 ppb Hg(II) with the pre-electrolysis time. As can be seen, the sensitivity increased with the pre-electrolysis time up to 5 min, where the $E-t$ curve became a plateau and the blank and sample signals ran virtually parallel. Thus, we chose a pre-electrolysis time of 5 min as optimum to ensure maximum sensitivity while avoiding reaching the aforesaid plateau.

Effect of foreign ions. The effect of various ions on the shape of the kinetic curves was studied. When the Cu^{2+} ion is present in the sample, the kinetic effects disappear and potentiometric curves with two typical plateaus were

Fig. 2. Influence of HCl concentration on the signal (T_{Efx}). $[NaCl] = 0.4M$; $I = 15 \mu A$; 1 min pre-electrolysis at $-0.5 V$.

Fig. 3. Influence of the oxidation current on the signal (T_{Efix}). $[\text{HCl}] = 0.1\text{M}$; $[\text{NaCl}] = 0.4\text{M}$; $I = 15 \mu\text{A}$; 30 sec pre-electrolysis at -0.5V .

Fig. 5. Influence of the pre-electrolysis time on the signal (T_{Efix}). $[\text{HCl}] = 0.1\text{M}$; $[\text{NaCl}] = 0.4\text{M}$; $I = 15 \mu\text{A}$; pre-electrolysis voltage, -0.5V .

obtained. This effect can be avoided by performing the pre-electrolysis step at a greater potential where the Cu^{2+} is not reduced. This solution, however, causes an important diminution in the sensibility of the kinetic method. Another interfering ion is the As^{3+} which causes an important diminution in the slope of the kinetic curves. Other ions like the Sn^{2+} don't affect the kinetic curves obtained.

Analytical parameters. We studied the linearity and applicability range of the proposed method. For a given, fixed potential, the time and the slope of the linear portion of the potentiometric curve were found to vary linearly with the concentration and its logarithm, respectively. In the fixed-potential method, the measurement potential is chosen from the linear range of the kinetics curves of all of the standards (see Fig. 6) which is 300–400 mV. A potential of 400 mV was chosen. The most representative parameters of the curves obtained are summarized in Table 1.

The reproducibility of the method was checked on 9 individual samples containing 200 ppb by applying the above-described procedure. The relative standard deviation thus obtained

was 4.9 and 4.2% for the fixed-time and slope methods, respectively.

DISCUSSION

A careful study of the working conditions and influence of the different variables affecting the experimental system allowed us to interpret the overall process involved in the ASP of mercury as follows: in the electrolysis step, mercury is reduced on the gold surface, with which it amalgamates according to

Once the amount of deposited mercury is large enough, we may assume the formation of an additional layer of unamalgamated mercury.

When the amount of mercury present is quite large, the metal cannot fully penetrate the electrode surface, so, in the first few moments, the situation is equivalent to working with a pure mercury electrode which gives rise to the typical plateau of ASP curves during the stripping. Once the entire mercury surface has been depleted or if the deposited amount is small enough to penetrate the gold electrode, the redox process may be limited by the kinetics of

Fig. 4. Potentiograms obtained at different oxidation currents. $[\text{Hg}(\text{II})] = 800\text{ppb}$; $[\text{HCl}] = 0.1\text{M}$; $[\text{NaCl}] = 0.4\text{M}$; 30 sec pre-electrolysis at -0.5V .

Fig. 6. Potentiograms obtained at different $\text{Hg}(\text{II})$ concentrations. $[\text{HCl}] = 0.1\text{M}$; $[\text{NaCl}] = 0.4\text{M}$; $I = 15 \mu\text{A}$; 5 min pre-electrolysis at -0.5V .

Table 1. Parameters of interest of the potentiometric curves

Method	Equation	<i>r</i>	Linear range, ppb
Slope	$T_{g\infty} = -0.0156 + 6.98 \times 10^3 \ln(\text{conc})$	0.993	80-400
Fixed-potential	$T_{\text{Eax}} = 0.116 + 0.0196 \text{ conc}$	0.998	80-400

transfer from the bulk of the electrode to the interface. This phenomenon, together with slower transfer kinetics than that of the chemical oxidation reaction, accounts for the attainment of kinetic curves after the typical plateau or even from the beginning of the stripping if the amount of deposited mercury is rather small. This interpretation is supported by the fact that the copperized graphite electrode only gives rise to the expected plateau, *i.e.*, that of copper, followed by that of mercury.¹⁶ As the copper has already been stripped before the mercury, the latter does not have to diffuse throughout the electrode and is only reoxidized in a step controlled by the chemical process and oxidant diffusion. On the other hand, experiments carried out with a gold thin film electrode¹⁶ gives curves with a smaller kinetic effect than that obtained with the gold electrode.

The shape of the kinetic curves, which show two distinct slopes, can be interpreted by first assuming the electrode potential to be determined by the Hg concentration at the electrode surface, which in turn depends on its rate of diffusion through the gold. Once all the mercury has been oxidized, the slope changes again and becomes steeper as it reaches the plateau yielded by the blank.

The kinetic curves obtained with the gold electrode disappear when important quantities of Cu²⁺ are present in the sample. This means that the deposition of Cu on the electrode surface reduces the diffusion of the Hg into the Au bulk.

From the results given it must, however, be concluded that the kinetic approach does not give very satisfactory results from an analytical point of view as compared to other stripping techniques.

ADSORPTIVE VOLTAMMETRIC DETERMINATION OF COPPER WITH A BENZOIN OXIME GRAPHITE PASTE ELECTRODE

GUORONG ZHANG and CHONGGANG FU

Department of Chemistry, Liaocheng Teachers' College, Shandong, People's Republic of China

(Received 2 January 1991. Revised 12 April 1991. Accepted 23 April 1991)

Summary—A method for the determination of trace amounts of copper with a chemically modified carbon press-formed electrode is described. Copper could be accumulated at the electrode by complexing with benzoïn oxime in ammonia buffer, then reduced at a constant potential of -0.4 V (*vs.* SCE) in nitric acid solution. Finally, a well-defined stripping peak could be obtained by scanning the potential in a positive direction. The response depends on the concentration of copper and accumulation time. For an accumulation time of 5 min the detection limit is about 1 ng/ml and the linear range is from 2 ng/ml to 4000 ng/ml, with a relative standard deviation of 5%. Many common metal ions have little or no effect on the determination of copper. The recommended procedure was applied to the determination of trace amounts of copper in natural water, and the results are in agreement with those of atomic-absorption spectrometry.

In electroanalysis the most sensitive and commonly used approach for trace metal analysis is undoubtedly stripping voltammetry. However, because of problems ranging from inordinately negative reduction potentials and slow electron transfer kinetics to the formation of intermetallic compounds upon electrodeposition, widespread utilization of this approach for practical solution analysis problems has been limited. Recently, a number of investigators have described a new variation of this approach in which analyte preconcentration is carried out at chemically modified electrodes (CMEs) possessing surfaces specifically designed for the ability to react with and bind the target solute.¹⁻¹² In this approach, the CMEs preconcentrate via a non-electrochemical mechanism and overcome disadvantages arising from electrochemical preconcentration. Further, preconcentration can be extended to analytes that cannot be reductively deposited directly or that require excessively negative deposition potentials. Also, the selectivity of the chemical step involved in the preconcentration can be used to increase overall selectivity of the analysis.

In our work, we describe the construction and behaviour of a chemically modified carbon press-formed electrode (CMCPFE) system appropriate for the chemical preconcentration and voltammetric quantitation of copper. Here, the electrode was prepared by pressing a mixture of benzoïn oxime (BO), graphite powder

and liquid paraffin into a glass tube (4 mm i.d.). Such CMCPFEs are simple to prepare and permit convenient variation of the modifier surface coverage, and they have small resistance and long lifetime. Also, a fresh modifier surface can be easily regenerated in a rapid and reproducible fashion. The principal characteristic required for the success of the modification approach is that the solubility of the modifier must be sufficiently slight in the solvents employed so that it remains stably incorporated in the carbon paste mixture. The reason for choosing BO as a modifier was because BO and its complexes all possess very limited solubility in the aqueous solvents commonly used in connection with carbon paste electrodes.^{13,14}

EXPERIMENTAL

Apparatus

An MP-1 stripping analyzer was used for voltammetric measurements (Shandong Electronic 7th Factory, Jining). A magnetic stirrer (Taixian Electronic Factory) was used in the accumulation step. The three-electrode system used was a CMCPFE working electrode, a platinum wire auxiliary electrode and a SCE (with a 0.1M nitric acid bridge). All potentials were referred to the SCE. A model PHS-3c pH meter (Shanghai Second Analyzer Factory) was used for measurement of pH. A Hitachi model 180-80 polarized Zeeman atomic-absorption

spectrometer equipped with pyrolytically coated graphite tubes was used for atomic absorption measurements.

Reagents and chemicals

A copper stock solution (1 g/l.) was prepared by dissolving pure copper (99.999%, Germany) in nitric acid, and working solutions were prepared by diluting the stock solution. Graphite powder (Shanghai Graphite Factory) was spectroscopic grade. Benzoin oxime (Beijing Chemical Reagent Institute) and all other reagents were analytical-reagent grade. Triply distilled water was used in all experiments.

Preparation of the CMCPFE

Take 0.8 g of pure graphite powder and 0.2 g of BO in a mortar with a pestle, grind and mix well, add 0.16 ml of liquid paraffin and mix well again. The mixture is filled into the end of a glass tube (50 mm length, 6 mm o.d., 4 mm i.d.) and pressed with a steel bar (4 mm o.d.) under a pressure of 6.2 Mpa. Make the electrical connection with a nickel-chromium wire which is passed through a rubber plug. The electrode surface (0.13 cm²) was polished on transparent paper until the surface had a shiny appearance. The renewal of the electrode surface was achieved by pushing the rubber plug 0.5–1.0 mm, scraping off the mixture with a blade and then polishing the surface of the electrode.

Procedure

Chemical accumulation. The electrode was immersed in 20 ml of copper sample solution containing 0.16M ammonium chloride and 0.02M ammonia which was stirred with a magnetic stirrer (500 rpm) for a fixed period of time.

Electrochemical reduction. After accumulation, the electrode was removed from the solution and rinsed thoroughly with water, then dipped into 0.015M nitric acid and electrolysed at -0.4 V for a fixed time without stirring.

Anodic stripping. The electrode was scanned anodically from -0.4 to $+0.5$ V and the wave height was measured at about $+0.2$ V.

Following measurements, the electrode was cleaned at $+0.5$ V for 20 sec.

RESULTS AND DISCUSSION

Composition of the electrode

The effect of the amount of BO on accumulations of copper was investigated by altering the weight ratio of BO to graphite powder. The

height of the peak increased with increasing amounts of BO up to 15% and then remained constant. The resistance of the electrode increased when the amount of BO was increased. A ratio of BO to graphite powder of 1:4 was used for most of this work. The resistance of the electrode is in the range 2–10 ohms.

Behaviour of the CMCPFE

Figure 1 shows the cyclic voltamperograms in 0.015M nitric acid, showing stable and relatively low residual current over a wide potential range recorded at the CMCPFE. The anodic wave at about $+0.2$ V is the oxidation current of copper electrochemically reduced at the CMCPFE, following the chemical accumulation. The cyclic voltamperograms had no obvious cathodic wave, showing that the oxidation of copper is irreversible and means that the electrochemically deposition rate is much less than the stripping rate. The first scan (designated as 1) exhibits a large anodic peak, due to the oxidation of the

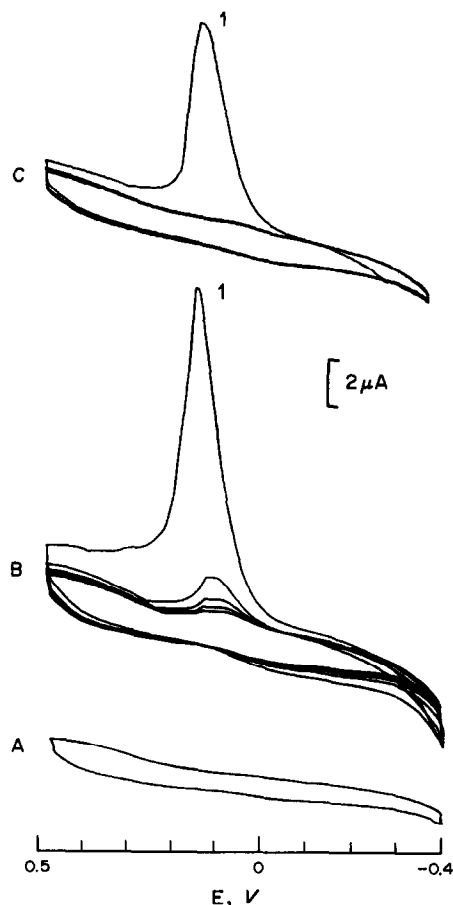

Fig. 1. Cyclic voltamperograms in 0.015M nitric acid: A—blank; B—500 ng/ml copper, T_a —120 sec, T_r —80 sec, without stirring; C—500 ng/ml copper, T_a —60 sec, T_r —80 sec, under stirring; scan rate -100 mv/sec.

accumulated copper. The anodic peak decreases gradually on continued scanning without stirring, reflecting the gradual diffusion of the product from the surface of the CMCPFE (Fig. 1, B). If the scan is carried out with stirring, the anodic peak disappears on continued scanning (Fig. 1, C).

Various voltammetric measurements methods for the ASV of copper are illustrated in Fig. 2. The sensitivity is greatly improved by using second-order derivative voltammetry; a better discrimination against background is obtained and the sharper anodic stripping peak is easier to measure, so the sensitivity for the determination of copper was greatly increased. Hence, it is more suitable for practical analysis. Figure

3 gives the second-order derivative voltamperograms of 4–8 ng/ml copper.

Reduction time

The effect of the reduction time, T_r , on the peak height is illustrated in Fig. 4. It confirmed that the reduction of copper was easily accomplished, so that when the concentration of copper is less than 100 ng/ml, the T_r chosen is 30 sec; for 100–500 ng/ml it is 50 sec; 500–1000 ng/ml, 80 sec, 1000–4000 ng/ml, 100 sec.

Effect of pH

The effect of the pH on the peak height is illustrated in Fig. 5. The optimum pH range

Fig. 4. The effect of T_r on the peak height. (a) 100; (b) 500 and (c) 1000 ng/ml copper. T_a —2 min, T_r —100 sec, other conditions as in Fig. 1.

Fig. 5. The effect of pH on the peak height. 250 ng/ml copper T_a —4 min., other conditions as in Fig. 1.

is 7.0–10.0, so that 0.16M ammonium chloride–0.02M ammonia medium (pH 8.5) was selected for chemical accumulation.¹⁵

Working range

Under the selected conditions, the linear range of peak height *vs.* copper concentration is from 2 ng/ml to 4000 ng/ml for an accumulation time of 5 min, and the detection limit is 1 ng/ml with a relative standard deviation of 5% ($n = 10$). For a 10-min accumulation time, the detection limit can be lowered to 0.5 ng/ml.

Interference effects

Many common cations and anions were examined as possible interferents in the determination of 50 ng/ml copper by second-order derivative voltammetry. The results showed that 500-fold Al^{3+} , Fe^{3+} , Fe^{2+} , Pb^{2+} , Cd^{2+} , Zn^{2+} , Cr^{3+} , Sn^{2+} , In^{3+} , Ti^{4+} , Tl^+ , V^{5+} , 400-fold Co^{2+} , Ni^{2+} , Hg^{2+} , Bi^{3+} , Ag^+ , 100-fold Mn^{2+} , Mo(VI) , W(VI) , 40-fold Sb(III) , Se(IV) , and 500-fold PO_4^{3-} , SO_4^{2-} , NO_3^- , ClO_4^- , Ac^- , F^- , Br^- , Cl^- , 80-fold S^{2-} , I^- , CNS^- , do not interfere under the experimental conditions (less than 10% different). In the determination of copper by conventional ASV with an unmodified CPE, Bi(III) , Ag^+ and Sb(III) interfere seriously, because their ASV peaks overlap with that of copper. However, with the CMCPFE, Bi(III) , Ag^+ and Sb(III) show no interference.

Reproducibility

The analytical responses obtained after 30 sec chemical accumulation from 50 ng/ml copper in ammonia buffer were measured and compared for a series of different CMCPFE surfaces. Fresh electrode surfaces were generated simply by scraping off the old surface and polishing the newly exposed layer in the same manner as above. The reproducibility measured in this manner as the relative standard deviation of the peak height was typically in the 10% range (for 10 measurements). Alternatively, the same-initially conditioned-electrode surface, subjected after each preconcentration/reduction/oxidation to the cleaning procedure, was used for a series of consecutive determinations of copper employing the same deposition conditions. In this manner, the surface-to-surface variability occurring when the electrode surface was manually refreshed could be avoided, the resulting reproducibility, again computed as the relative standard deviation, of 10 consecutive measurements, was only 5%.

Life-time

The CMCPFE must be kept from sunlight when not in use. The first CMCPFE prepared has not exhibited significant changes in performance over half a year.

Practical application

The proposed method has been used for the determination of trace amounts of copper in natural waters. Any sample treatment is not necessary. The results agreed well with those obtained by atomic-absorption spectrometry, as shown in Table 1.

5-[(*p*-METHYL-PHENYL)AZO]-8-AMINOQUINOLINE AS A NEW REAGENT FOR TRACE DETERMINATION OF NICKEL BY ADSORPTIVE CATHODIC STRIPPING VOLTAMMETRY

ZHENG-QI ZHANG, ZHAO-PENG CHENG, SHENG-ZONG CHENG and GUI-FA YANG

Department of Chemistry and Chemical Engineering, Hunan University,
Changsha, People's Republic of China

(Received 15 January 1991. Revised 11 March 1991. Accepted 29 March 1991)

Summary—The synthesis of *p*-MPAQ and the electroanalytical chemical properties of the nickel(II)-*p*-MPAQ complex are reported in this paper. A sensitive adsorptive cathodic stripping procedure for trace nickel determination was developed. For a 3-min preconcentration time the detection limit is $3.0 \times 10^{-11}M$.

Adsorptive stripping voltammetry is widely recognised as one of the most sensitive methods in electroanalytical chemistry.¹⁻⁷ It has been shown that adsorption of metal chelates can be used as a preconcentration step to improve the detection limit of the electroanalytical determination. The surface concentration of a metal complex at a mercury electrode is related to the structure of the ligand. The synthesis of new organic chelating agents is one of the available approaches for increasing the sensitivity of adsorptive stripping voltammetry.⁸ Dimethylglyoxime (DMG) has been used as a complexing agent for the voltammetric determination of cobalt and nickel with a detection limit of $5.0 \times 10^{-11}M$.^{2,9,10} Dimethylglyoxime has the functional group

The ligands suitable for adsorptive stripping voltammetry are characterized by the presence of aromatic rings.¹ 8-Aminoquinoline and its derivatives possess not only the above-mentioned functional group but aromatic rings as well. Recently we have synthesized a series of azo compounds derived from 8-aminoquinoline, including 5-[(*p*-methylphenyl)azo]-8-aminoquinoline (*p*-MPAQ), 5-[(*p*-acetylphenyl)azo]-8-aminoquinoline (*p*-APAQ), 5-[(*p*-nitrophenyl)azo]-8-aminoquinoline (*p*-NPAQ), 5-[(*m*-nitrophenyl)azo]-8-aminoquinoline (*m*-NPAQ) and 5-[(*o*-nitrophenyl)azo]-8-aminoquinoline (*o*-NPAQ). The reagent *p*-MPAQ has been used as

a spectrophotometric reagent for palladium and a fluorogenic reagent for iron.¹¹ It also possesses excellent electroanalytical characteristics. The adsorptivity of *p*-MPAQ is stronger than that of DMG because its π -orbital interaction is greater than DMG's. The experimental results show that the reduction potential of *p*-MPAQ (−0.55 V under optimum conditions) is more positive than that of the Ni(II)-*p*-MPAQ complex (−0.95 V) but the reduction potential of DMG (−1.63 V) is more negative than that of Ni(DMG)₂. Therefore, at the adsorption potential the excessive *p*-MPAQ doesn't compete with the Ni-*p*-MPAQ complex for the adsorption site on the electrode surface, but DMG does. Our previous works show that the greater the ratio of the coverage of the complex to the ligand, the lower the detection limit of the adsorptive-complex wave.¹² Obviously, using *p*-MPAQ as a ligand is advantageous as it lowers the detection limit of nickel. The present paper describes a very sensitive cathodic stripping procedure for the determination of nickel by adsorptive accumulation and reduction of its *p*-MPAQ complex at the hanging mercury drop electrode, the detection limit being 3.0×10^{-11} for an adsorption time of 3.0 min.

EXPERIMENTAL

Apparatus

The single-sweep polarograms were recorded on a JP-1A polarograph. The polarographic cell has the three electrode system: a dropping

mercury electrode (DME), a working electrode, a silver/silver chloride (saturated potassium chloride) reference electrode and a platinum wire auxiliary electrode. An XJP-821 neopolarograph in connection with an LZ3-100 X-Y recorder and a JM-01 (manual micrometric screw delivery) hanging mercury drop electrode (HMDE) were used for linear scan voltammetry and cyclic voltammetry measurements. The solution was stirred with a Model GSP-84-01 stirrer.

Reagents

Standard nickel solution. A stock solution of nickel (II) was prepared by dissolving 0.291 g of nickel nitrate $\text{Ni}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$ in 50 ml of 0.1M hydrochloric acid and diluting to 1 litre. The solution was standardized volumetrically with EDTA. Prepare solutions of lower concentration by serial dilution.

***p*-MPAQ ethanolic solution, 10^{-3}M .** Dissolve 0.262 g of *p*-MPAQ in 1 litre of absolute ethanol.

Synthesis of *p*-MPAQ. Dissolve 1.2 g of *p*-methyl-aniline (0.01 mole) in 20 ml of 5M hydrochloric acid solution and cool to below 5°C in ice. While stirring, add dropwise 20 ml of ice-cold water containing 4.0 g of sodium nitrite. The mixture is stirred for a further 30 min and the diazonium salt is poured in a thin stream, with constant stirring, into 10 ml of cold *N,N*-dimethylformamide containing 1.4 g of 8-aminoquinoline. After standing aside for 1 hr the resulting mixture is neutralized by adding dilute alkaline solution and allowing to stand for 24 hr. The separated crystals are recrystallized from 1:1 ethanol solution and dried at room temperature under vacuum. The product is a red solid yield of about 70%. The purity of the product was examined by thin-layer chromatography with ethanol-benzene (1:3). It was considered pure if the chromatogram showed only a yellow spot at $R_f = 0.74$. Analysis: $\text{C}_{16}\text{H}_{14}\text{N}_4$ requires 73.26% C, 5.38% H, 21.36% N; found, 72.93% C, 5.58% H, 20.73% N. The principal infrared bands were at 3420, 3302, 3030, 1332, 1280, 1430 and 1385 cm^{-1} .

Other reagents were of suprapure or analytical-reagent grade. Water, redistilled in a fused-silica apparatus, was used throughout.

Procedure

Adsorptive cathodic stripping voltammetry of pure nickel solution. Mix 0.10 ml of $1.0 \times 10^{-3}\text{M}$

p-MPAQ solution, 2.0 ml of buffer solution (pH 6.8) and a varied amount of nickel standard solution. Dilute to 10 ml with redistilled water. After standing for 15 min for complete complex formation the solution was transferred to the voltammetric cell, and purged with oxygen-free nitrogen for 10 min. A flow of nitrogen was maintained over the cell throughout the analysis to prevent interference from oxygen. The adsorption potential (usually -0.70 V) was applied to a fresh mercury drop while the solution was stirred. Following the adsorption step, the stirring was stopped, and after 30 sec the voltamperogram was recorded by applying a linear scan terminating at -1.2 V . The stripping voltammetric peak of the complex of nickel with *p*-MPAQ appears at about $-0.95\text{ V vs. Ag-AgCl-KCl(satd)}$.

Analysis of samples. Blood serum was prepared by centrifuging blood samples three times followed by digestion in perchloric acid at 200° with a digester until the sample was colourless. Market milk was digested with $\text{HNO}_3\text{-HClO}_4\text{-H}_2\text{SO}_4$. Transfer a moderate amount of natural water, the digested blood serum or the treated milk sample into a 10-ml standard flask, and continue as above.

Recovery experiment. Add the amounts of nickel shown in Table 1 into a 50-ml beaker containing the samples and treat as described above.

RESULTS AND DISCUSSION

Adsorptive stripping voltammetry

The five synthesized azo compounds all give one or two polarographic reduction waves, the peak potentials shifting to negative direction with increasing pH value of test solution. In a neutral or weakly basic solution these reagents form with nickel(II) purple-red complexes which give a new polarographic reduction wave. Among them, the $\text{Ni(II)-}p\text{-MPAQ}$ complex [$\text{Ni}(p\text{-MPAQ})_2$] from continuous variation and molar ratio measurements, shows higher sensitivity. Figure 1 shows linear scan voltamperograms for $1.0 \times 10^{-8}\text{M}$ nickel(II), in the presence of $5.0 \times 10^{-6}\text{M}$ *p*-MPAQ after different preconcentration periods. The $\text{Ni(II)-}p\text{-MPAQ}$ complex yields a well-defined cathodic stripping peak at -0.95 V . Its peak height increases rapidly with increasing preconcentration time. A concentration of $3.0 \times 10^{-11}\text{M}$ can be detected if a preconcentration time of 180 sec is used; the detection

limit was taken as the concentration that gave a signal equal to three times the standard deviation of the blank signal, calculated from the calibration slopes. The reproducibility was evaluated by ten repetitive experiments on a $1.0 \times 10^{-8} M$ nickel(II) solution with a preconcentration time of 120 sec. The relative standard deviation was 2.3%.

Effect of pH and buffer concentration. The buffer concentration and pH are the important factors influencing the peak height and the stability of the complex. The pH doesn't affect the peak potential of the Ni(II)-*p*-MPAQ complex, but strongly affects its peak current. If the pH is less than 3, no wave appears. If the pH is 5.5–8.0, the peak current is the largest; after that, the wave height decreases gradually with an increase in pH and finally disappears. In our experiments pH is kept at 6.8, using ammonium acetate as buffer. The peak current increases

linearly with increasing buffer concentration from 0.01 to 0.05 *M* and decreases slightly when the buffer concentration exceeds 0.10 *M*. In this paper the ammonium acetate concentration is 0.08 *M*.

Effect of *p*-MPAQ concentration. The concentration of *p*-MPAQ affects both peak height and linear range. The peak currents increase rapidly with *p*-MPAQ concentration and maximum values are attained from 3.0×10^{-6} to $1.0 \times 10^{-5} M$ *p*-MPAQ. As *p*-MPAQ concentration is larger than $1.0 \times 10^{-5} M$, the peak currents decrease and the linear range becomes narrower. A $5.0 \times 10^{-6} M$ *p*-MPAQ concentration is suitable for the experiment.

Effect of the preconcentration potential. The dependence of the stripping peak current on the preconcentration potential was examined over the range from -0.1 to -0.8 V (Fig. 2, curve A). Potentials ranging from -0.1 to -0.6 V yielded similar peak heights. At potentials more negative than -0.6 V the peak height increased rapidly. The maximum peak current was

Fig. 1

Fig. 2

obtained at -0.7 V, which was used in all subsequent work.

Effect of the preconcentration time. The accumulated amount on the surface depends on the length of time over which the adsorption is allowed to proceed. Figure 2 curve B shows the dependence of the adsorptive stripping peak current on the adsorption time for nickel present at the 0.60 ng/ml level. The peak current increases non-linearly with preconcentration time and then remains constant after 4 min. Obviously, a compromise between increase in sensitivity and speed is required in selecting the optimum preconcentration time. The preconcentration time was chosen to be 180 sec in all subsequent work.

Interferences

Interference by diverse ions was investigated by adding appropriate amounts of various ion solutions to 10 ml of solution containing 5.0 ng of nickel. Interference was taken as causing an error in excess of 10%. The amounts of some foreign ions which did not interfere are as follows: 4.0 mg of K^+ and Na^+ ; 10 μ g of Al^{3+} ; 5 μ g each of Ca^{2+} , Ba^{2+} and Mg^{2+} ; 0.5 μ g each of Be^{2+} , Mn^{2+} , Pb^{2+} and Bi^{3+} ; 0.3 μ g of Cr^{3+} and Fe^{3+} ; 0.1 μ g of Pd^{2+} ; 0.08 μ g each of Cd^{2+} , Cu^{2+} and Zn^{2+} ; 0.05 μ g of Co^{2+} ; 8.0×10^{-5} mmol of tartrate and citrate; 2.0×10^{-5} mmol of PO_4^{3-} , $C_2O_4^{2-}$ and EDTA. The reduction potential of the $Co(II)$ - p -MPAQ complex is -1.34 V, well removed from the nickel peak. But the cobalt competes with the nickel for the ligand, causing a negative interference above 0.05 μ g: -14 – 45% and -73% at 0.10, 0.50 and 5.0 μ g $Co(II)$, respectively.

Adsorptive characters of $Ni(II)$ - p -MPAQ complex

The adsorption of the complex of nickel(II) with p -MPAQ at the mercury drop electrode was demonstrated by constructing electrocapillary curves and by carrying out medium-exchange experiments.

The electrocapillary curve of a buffer solution containing p -MPAQ is lower than that of the pure buffer, and the electrocapillary curve of the solution containing the $Ni(II)$ - p -MPAQ complex was lower still than the p -MPAQ solution, indicating that p -MPAQ and its nickel(II) complex are both adsorbed at the mercury drop electrode.

For medium-exchange studies, the static mercury drop electrode (SMDE) used as a

working electrode, was kept in contact with a solution containing the $Ni(II)$ - p -MPAQ complex for 240 sec with stirring. Following this, the electrode was cleaned carefully and transferred into another cell containing the background solution only. The reduction process shown in the voltamperogram obtained in the new cell closely resembled those in the original cell.

Cyclic voltammetry

The redox and interfacial behaviour of chelate of nickel(III) with p -MPAQ can be evaluated by using cyclic voltammetry. Figure 3 shows cyclic voltamperograms for 1.0×10^{-8} nickel(II) in 5.0×10^{-6} M p -MPAQ solution in 0.08 M ammonium acetate (pH 6.8). Stirring the solution for 3 min at -0.35 V before starting the first scan (Fig. 3 curve 1), resulted in two distinct cathodic peaks due to the reduction of the adsorbed dye (at -0.55 V) and of the adsorbed chelate (at -0.95 V). The oxidation peak of the chelate was observed in the anodic branch. Subsequent repetitive scans yielded significantly smaller (but stable) cathodic peaks corresponding to the reduction of dissolved species. This behaviour indicates that the adsorption of dye and chelate at the mercury electrode is reactant adsorption.¹³ The difference in peak potentials between E_{p_2} and $E_{p_2'}$ is 30 mV, which shows that the number reacted electrons of the complex equals two.

Application

The proposed method has been applied to the determination of nickel in natural water, human blood and milk samples.

Calibration graphs. Treat the standard nickel(II) solutions used for preparation of the

Fig. 3

calibration line in the procedure as described in the section of analysis of samples. The regression equation of the calibration line has the form:

$$Y = 5.13X - 0.008 \quad (1)$$

where Y is the stripping peak current in nA and X is the concentration of nickel(II) in ng ml. The correlation coefficient was 0.996. The results of the determination of nickel and recovery of added nickel by using the recommended method are summarized in Table 1.

DETERMINATION OF GERMANIUM BY POTENTIOMETRIC STRIPPING ANALYSIS AND ADSORPTION POTENTIOMETRIC STRIPPING ANALYSIS

FENG DEXIONG, YANG PEIHUI and YANG ZHAOLIANG

Department of Chemistry, Jinan University, Guangzhou, People's Republic of China

(Received 24 July 1990. Revised 27 November 1990. Accepted 14 December 1990)

Summary—Potentiometric stripping analysis was applied to determination of germanium(IV) in 0.2M $\text{NH}_3\text{-NH}_4\text{Cl}$ (pH 8.4) buffer solution at -1.8 V (vs. Ag/AgCl), with dissolved oxygen or Hg(II) as oxidant. The sensitivity was 8.5×10^{-9} M in the presence of 2.0×10^{-5} M Hg(II) with plating for 15 min after deaeration for 20 min. Cyclic voltammetry revealed that Ge(IV) \rightarrow Ge at the surface of the mercury-film electrode in a one-step irreversible reduction reaction, and the Ge at the electrode was oxidized by dissolved oxygen in the solution. The presence of complexing agents such as Alizarin Red (ARS), which forms a Ge(IV) complex adsorbed at the electrode, improved the sensitivity by one order of magnitude. The presence of adsorption was revealed by the temperature coefficient, the electrocapillary curve and cyclic voltammetry. Ge-containing samples were analysed by the proposed methods and agreement with the results obtained by other methods was excellent.

In the last decade potentiometric stripping analysis (PSA)^{1,2} has become of increasing interest because of certain advantages it possesses (e.g., no interference by oxygen, less susceptibility to adsorption phenomena, and cheapness and simplicity of instrumentation).³ It has been recognized as an electroanalytical technique for the determination of trace amounts of heavy metals such as Cu, Pb, Zn, Cd, Bi, Tl, Ga and Hg. The high sensitivity and specificity and the possibility of simultaneous determinations inherent in stripping analysis are distinctive features that make it attractive in environmental, clinical, industrial and other fields of analytical chemistry. However, potentiometric stripping analysis of germanium has not yet been reported.

In an early study of the polarographic behaviour of germanium,⁴ it was observed that germanium(IV) could be reduced to elemental germanium in two steps in 6M hydrochloric acid. Sauvenier and Duyckaerts⁵ and Dhar⁶ found that germanium(IV) could be reduced to elemental germanium at the dropping mercury electrode in ammonia or boric acid buffer solution with a half-wave potential of -1.5 V. Recently, several electroanalytical techniques have been applied to the determination of germanium. Kalvoda⁷ observed that adsorptive accumulation of the germanium–Pyrocatechol

complex on a hanging mercury drop electrode produced increased sensitivity in differential pulse polarography. An analogous procedure using the germanium complex with pyrogallol has been described.⁸ Li *et al.*^{9,10} studied the polarographic adsorptive complex wave of the germanium–Alizarin Red (ARS) and germanium–Alizarin systems, which were applied to the determination of germanium(IV) down to 0.1 mg/l. Deng *et al.*¹¹ used a gold-film electrode for an anodic stripping voltammetric study of the reduction of Ge(IV). Two stripping peaks were reported, the first corresponding to the oxidation of Ge to Ge(II) and the second to the oxidation of Ge(II) to Ge(IV), detection limits of 5 $\mu\text{g/l}$. being observed when the first peak was used for quantification. No report of potentiometric stripping analysis for Ge(IV) at a mercury-film electrode has been found.

The aims of the present work are to offer another simple and sensitive method of analysis for germanium and to extend the application of potentiometric stripping analysis. The paper deals with the study of the potentiometric stripping behaviour of germanium and adsorption potentiometric stripping analysis (APSA) for germanium, in which an ARS complex is formed and adsorbed at the electrode to increase the sensitivity. Some generally applicable conditions for this method are discussed. The

method is applied to the analysis of samples from plants and mineral water.

EXPERIMENTAL

Apparatus

A Metrohm E-524 potentiostat was used for constant-potential electrolysis. The potentiometric stripping curve was recorded with an LZ 3-04 $x-y$ recorder (Shanghai), which was connected to a meter with high input-impedance (pH s-3, Shanghai). A model FA-1 cyclic voltammetry instrument (Changchun) was used. A rotating glassy-carbon disc electrode (ATA-1A, Jiangsu) with a mercury film was used as the working electrode (diameter 4 mm). A spiral Ag/AgCl electrode was used as the reference electrode, with a saturated potassium nitrate agar salt bridge. A platinum wire was used as the counter-electrode.

Reagents

All reagents were of general or analytical reagent grade and were prepared with doubly distilled water. A stock standard solution of $1.0 \times 10^{-2} M$ germanium(IV) was prepared by dissolving 0.0726 g of Ge powder (99.999% pure) in a beaker containing 1 g of sodium hydroxide and 10 ml of 30% hydrogen peroxide solution, then adding 15 ml of 1:1 v/v sulphuric acid to the beaker, heating gently to expel excess of hydrogen peroxide, cooling, and diluting accurately to 100 ml. Ammonia buffers of different pH were prepared from mixtures of 0.2M ammonia and 0.2M ammonium chloride.

Preparation of the working electrode

The working electrode must be coated with mercury before the start of the analysis. This was achieved by keeping the working electrode

rotating for 4 min at $-0.90 V$ vs. Ag/AgCl in 50 ml of 0.1M hydrochloric acid containing 25 mg/l. mercury(II). The rotation was stopped and at the same time the working and reference electrodes were connected to a recorder. A stripping curve was registered and a steady baseline established. After that, the working electrode was washed immediately with distilled water and stored in distilled water for later use.

Procedure

Measure 50 ml of germanium solution in 0.2M ammonia buffer (pH 8.4) into an electrolysis cell. In routine analysis, dissolved oxygen is preferred as the oxidant in order to save time. If it is necessary to enhance the sensitivity, add Hg(II) as oxidant to the solution and deaerate with purified nitrogen for 20 min. After that, let the stream of nitrogen pass over the surface of the solution to prevent oxygen from redissolving in the solution. Immerse a glassy-carbon electrode coated with a mercury film in the solution and connect the cell to an Ag/AgCl reference electrode. Electrolyse at $-1.8 V$ with the electrode rotating at 2000 rpm, then stop the rotation and at the same time connect the electrodes to a recorder to trace the potential-time curve.

RESULTS AND DISCUSSION

PSA for germanium(IV)

Selection of supporting electrolyte. Values for the stripping time, τ , in different media are shown in Table 1 and indicate that ammonia buffer is the optimum supporting electrolyte.

Effect of pH. The sample pH was adjusted to the optimum value (8.4), which gives the maximum signal, as shown in Fig. 1.

Plating potential E_p . Table 2 demonstrates that there was no signal at potentials more positive than $-1.55 V$, because Ge(IV) cannot then be reduced to Ge. The signal increased with more cathodic potentials in the range from -1.55 to $-1.80 V$ and stayed constant for $E_p < -1.80 V$. Therefore E_p was chosen to be $-1.80 V$.

Dependence of τ on concentration. The stripping signals increased linearly with the concentration of Ge(IV). Figure 2 illustrates the effect

Table 2. Dependence of τ on E_p for $2.0 \times 10^{-5} M$ Ge(IV), t_p 4 min, pH 8.4

Fig. 1. Dependence of τ on pH: $10^{-4}M$ Ge(IV); $0.2M$ NH_3-NH_4Cl ; E_p -1.6 V; pre-electrolysis time 2 min; dissolved oxygen as oxidant.

Fig. 3. Typical stripping curve for (a) $8.5 \times 10^{-9}M$ Ge(IV) and (b) the corresponding blank: t_p 15 min, $2 \times 10^{-5}M$ Hg(II), deaeration for 20 min.

of standard additions to a $1.0 \times 10^{-8}M$ Ge(IV) solution in $0.2M$ NH_3-NH_4Cl (pH 8.4).

The detection limit in PSA depends on the plating time, the oxidant concentration and, to some extent, the recording speed. Figure 3 gives a typical set of stripping curves for $8.5 \times 10^{-9}M$ Ge(IV) and $2.0 \times 10^{-5}M$ Hg(II), with plating for 15 min after deaeration with purified nitrogen for 20 min.

Interferences. The interfering action of 10-fold or 100-fold excesses of co-existing ions on the determination of $1.0 \times 10^{-6}M$ Ge(IV) was investigated. Decreases in the Ge(IV) signal were caused by Sn(IV), Fe(III) and Mn(II) and increases by Co(II) and Cu(II) when these ions were present in 10-fold molar ratio to Ge(IV). No interference was observed from Tl(III), Bi(III), Zn(II), Pb(II), Cd(II), Se(IV), even in 100-fold molar ratio to Ge(IV).

The interferences may be classified into three categories.

(i) An increase in the analytical signal is caused by overlapping of the stripping signals owing to similarity of the stripping potentials of the interferent ion and Ge(IV). An example is

the interference by copper, which can be eliminated by employing plating potentials of -0.90 and -1.80 V and obtaining the difference in stripping time ($\Delta\tau$).

(ii) A decrease in the analytical signal is caused by simultaneous oxidation of the deposited Ge(Hg) by the interferent ion, e.g., by Sn(IV) and Fe(III).

(iii) An increase or decrease in the analytical signal may be caused by formation of an intermetallic compound or by chemical interaction between the interferent and germanium. Co(II) and Mn(II) do not fit into class (i) or (ii) and are probably to be included in this class.

Studies on the electrode processes

Cyclic voltamperograms of the supporting electrolyte and the Ge(IV)-containing solution at the mercury-film electrode are shown in Fig. 4. There is a cathodic peak at -1.45 V during the negative potential scan and no peak during the positive scan. The cathodic peak height decreases with continued scanning. If the circuit is broken and the electrode allowed to rotate for a few seconds, and the circuit is then

Fig. 2. The relationship between τ and concentration (C): 1, $C = (2-10) \times 10^{-7}M$, t_p 4 min; 2, $C = (1-10) \times 10^{-8}M$, t_p 8 min; $2 \times 10^{-5}M$ Hg(II), deaeration for 20 min.

Fig. 4. Cyclic voltamperograms: (1) without and (2) with $10^{-4}M$ Ge(IV) in $0.2M$ NH_3-NH_4Cl buffer at pH 8.4; sweep rate 200 mV/sec.

Fig. 5. The effect of ARS concentration (C) on τ : $C = (2-12) \times 10^{-5}M$; $2 \times 10^{-6}M$ Ge(IV); $0.2M$ NH_3-NH_4Cl (pH 8.8); $E_p = -1.6$ V; $t_p = 2$ min; $3 \times 10^{-5}M$ Hg(II).

Fig. 7. Relationship between τ and concentration (C): (1) $C = (2-10) \times 10^{-7}M$, $t_p = 3$ min; (2) $C = (2-10) \times 10^{-9}M$, $t_p = 8$ min; $3 \times 10^{-5}M$ Hg(II); deaeration for 20 min.

closed and the scan repeated, the peak height increases to its previous value. The same phenomenon occurs after deaeration of the solution, but finally the peak disappears. It can be deduced that $Ge(IV) \rightarrow Ge$ is an irreversible one-step reaction and dissolved oxygen in the solution can oxidize Ge at the surface of the electrode. This is why oxygen dissolved in the solution can be used as the oxidant in PSA for Ge(IV).

APSA for germanium(IV)

A complex may be formed and adsorbed at the electrode when the germanium solution contains a complexing agent such as ARS. The stripping signal increases significantly and the sensitivity for Ge(IV) can be enhanced. Optimization of the experimental conditions and the characteristics of the adsorption are discussed below.

pH and concentration of ARS. The stripping time in ammonia buffer media of different pH was measured and was shown to be constant in

the pH range 8.4–9.1. Therefore the pH value was chosen to be 8.8.

Figure 5 gives the dependence of τ on the concentration of ARS; τ reaches a constant value when $C_{ARS} > 8.0 \times 10^{-5}M$, which is, therefore, the concentration of ARS necessary to saturate the electrode surface.

Effect of plating potential. The $\tau-E_p$ curve takes on a peak shape in the potential range from -1.35 to -1.60 V. As shown in Fig. 6, τ is maximal when E_p is -1.5 V under the experimental conditions and this indicates an adsorption effect which will be verified later. From comparison of Fig. 6 with Table 2, we can see that the Ge-ARS complex adsorbed at the electrode is reduced at a more positive potential (-1.5 V) than germanium itself (-1.8 V). It is probable that ARS adsorbed at the electrode catalyses the reduction of germanium.

Effect of electrode speed. Rotation at 570 rpm during pre-concentration and stripping gives a satisfactory signal without sacrifice of sensitivity.

Relationship between τ and concentration. A linear relationship between τ and concentration, C , was obtained (Fig. 7) and extended down to $10^{-9}M$. A typical stripping curve for $8.0 \times 10^{-10}M$ Ge(IV) is shown in Fig. 8.

Fig. 6. The effect of plating potential on τ : $5 \times 10^{-7}M$ Ge(IV); $10^{-4}M$ ARS; $3 \times 10^{-5}M$ Hg(II); $t_p = 3$ min.

Fig. 8. Stripping curves for (a) $8 \times 10^{-10}M$ Ge(IV) and (b) blank; $t_p = 12$ min; $3 \times 10^{-5}M$ Hg(II); deaeration for 20 min.

Fig. 9. Effect of temperature on stripping time: $2 \times 10^{-6}M$ Ge(IV); $0.2M$ NH_3-NH_4Cl (pH 8.8), $3 \times 10^{-5}M$ Hg(II); t_p 1 min.

Verification of adsorption characteristics

Effect of temperature. The τ -temperature curve (Fig. 9) is characteristic of a general adsorption wave. At temperatures $<18^\circ$ the adsorptive capacity is controlled by adsorption kinetics. The adsorption rate increases with temperature and the temperature coefficient is positive. At $18-25^\circ$ the adsorptive capacity is controlled by the equilibrium between adsorption and desorption. At temperatures $>25^\circ$, the equilibrium shifts toward desorption and the adsorptive capacity decreases. The temperature coefficient then becomes negative.

Electrocapillary curves. The change in the electrocapillary curves (Fig. 10) shows that ARS and the Ge-ARS complex are adsorbed in the potential range from -0.2 to -1.5 V.

Cyclic voltammetry. Cyclic voltamperograms of ARS, Ge(IV) and ARS + Ge(IV) at a mercury-film electrode are shown in Fig. 11. Figure 11(a) shows a pair of redox peaks, in which the potential is -0.62 V for the reduction

Fig. 10. Electrocapillary curves in $0.2M$ NH_3-NH_4Cl (pH 8.8); (1) blank; (2) with $3 \times 10^{-4}M$ ARS; (3) with $10^{-4}M$ Ge(IV) and $3 \times 10^{-4}M$ ARS; \bar{t} mean time for 20 drops of mercury.

Fig. 11. Cyclic voltamperograms in $0.2M$ NH_3-NH_4Cl (pH 8.8) at 100 mV/sec: (a) $10^{-4}M$ ARS, (b) $5 \times 10^{-5}M$ Ge(IV), and (c) — $5 \times 10^{-5}M$ Ge(IV) + $2 \times 10^{-4}M$ ARS; --- $5 \times 10^{-5}M$ Ge(IV).

peak and -0.56 V for oxidation. The plot of the peak height, h , vs. the square root of scan rate, \sqrt{v} , as in Fig. 12, shows some deviation from the linear relationship predicted by the Randles-Ševčík equation. This behaviour is characteristic of adsorption at the electrode, the product being adsorbed more weakly than the reactant. An irreversible reduction peak for Ge(IV) appears at -1.43 V [Fig. 11(b)], which is shifted to -1.18 V in the presence of ARS (Fig. 11(c)), with an increase in reduction current. This is consistent with the discussion of the dependence of τ on E_p shown in Fig. 6. It is deduced that a Ge-ARS complex is formed and adsorbed at the mercury-film electrode. Figure 11(c) presents a pair of redox peaks with similar peak potentials to those in Fig. 11(a), but with broader shapes. This is probably caused by overlap with the adsorption wave of the complex. Furthermore, the deviation from linearity of the $h-\sqrt{v}$ curve is more serious for the Ge-ARS complex (Fig. 13) than for ARS itself (Fig. 12), indicating that the complex is more strongly adsorbed than ARS. These results agree with those for the electrocapillarity.

Fig. 12. Effect of scan rate on peak height for $10^{-4}M$ ARS: (●) reduction peak, (×) oxidation peak.

*Mean \pm mean deviation of three measurements.

$\dagger\mu\text{g/g}$ for garlic and *lycium chinense* and $\mu\text{g/l.}$ for mineral waters.

Fig. 13. Effect of scan rate on peak height for $10^{-4}M$ ARS + $5 \times 10^{-5}M$ Ge(IV): (●) reduction peak, (×) oxidation peak.

Analysis of samples

Samples of garlic and *lycium chinense* were digested in a minimum volume of a 3:1 v/v mixture of concentrated nitric and perchloric acids until the first appearance of perchloric acid fumes, after which the samples were cooled and diluted accurately to 100 ml. The final H^+ concentration of the sample solutions was approximately $0.7M$. The samples of mineral water were concentrated prior to analysis.

The samples were analysed by the proposed methods, and by anodic-stripping voltammetry (ASV)¹¹ and flow-injection potentiometric stripping analysis (FIPSA).¹² The results are compared in Table 3.

CONCLUSIONS

In a Ge(IV) solution containing ARS, both ARS and its Ge-complex are adsorbed at the mercury-film electrode, enhancing the sensitivity of determining Ge by PSA. The enhancement has two main causes: (a) in the deposition step adsorption raises the preconcentration efficiency and (b) in the stripping step the metallic Ge in the mercury film is oxidized with more difficulty than expected (shown by the more positive stripping potential in the cyclic voltammetry, which means that adsorption persists during stripping).

BOOK REVIEWS

SolvEq: FOSTER ROEGIERS, BIOSOFT, Cambridge, 1990. £149, US\$299.

SolvEq is described as "a general purpose equation solver and numerical modelling tool for science and technology". It runs on IBM PC and compatible computers with 640K of memory and DOS 3.1 or later. A math coprocessor is used if present. Output can be to an IBM, Epson or HP Laserjet printer, or to an HPGL plotter. The program runs best from hard disc, but can also be used on a double floppy system provided that at least one drive has a capacity of 720K or more.

I found the manual excellent. It offers an extended tutorial section, followed by a reference section covering all the possible options and variations. I therefore found it quick and easy to learn to use SolvEq.

The program operates from submenus that drop down from the main menu bar. The equations to be solved are first of all entered in the EDIT screen. Later, they can be reLOAded from files that have previously been SAVEed. Equations are entered in algebraic form just as they would be written down on paper. A single equation can be entered, or several equations can be solved simultaneously. The equations may involve real, vector, and/or complex numbers; they may include integrals, summations, differentials; and many algebraic, trigonometric, hyperbolic and exponential functions. Arrays of variables are possible, but matrix operations are not supported.

In the VALUES screen, variables are designated as known or unknown, and values are assigned to those that are known. A known variable can be made to take a whole series of values (a "parametric study"); and an unknown variable can be designated as an optimization variable, which the program can either maximize or minimize.

I tested solvEq by using it to solve many of the equations for acid-base equilibria commonly found in analytical text-books. The usual book approach is to give the exact equation, then show how it can be simplified to allow solution. For every case I tried, SolvEq was able easily to solve the exact equation; solutions could be found in just a few seconds for entire titration curves. It was also easily possible to calculate values of Ringbom alpha-coefficients and conditional stability constants.

When solutions had been obtained for a series of values of a variable (a "parametric study"), the output could be presented as a graph, and the axes could be transformed if desired into log-lin, lin-log or log-log form.

The following equations for the titration of a dibasic acid were solved in about thirty seconds for 65 values of Vb, and a graph of the titration curve was obtained by plotting pH against Vb.

$$H^4 + (Cb \cdot Vb \div V_{tot} + K_1) \cdot H^3 + K_1 \cdot \left(-K_w \div K_1 + \frac{Cb \cdot Vb - Ca \cdot Va}{V_{tot}} \right) \cdot H^2 + \dots$$

$$K_1 \cdot K_2 \cdot \left(-K_w \div K_2 + \frac{Cb \cdot Vb - 2 \cdot Ca \cdot Va}{V_{tot}} \right) \cdot H - K_1 \cdot K_2 \cdot K_w = 0$$

$$H = 10^{-pH}$$

$$V_{tot} = Va + Vb$$

I very much enjoyed using SolvEq, and I feel that I can still discover many more applications for it in analytical chemistry, particularly for optimization. I think, too, that SolvEq could find a useful place in the teaching of analytical chemistry.

MARY MASSON

P. FIT: FIG.P Software Corporation, BIOSOFT, Cambridge, 1990. £125, US\$199.

P. Fit is a non-linear curve-fitting program for IBM PC and compatible computers with at least 512K of RAM, DOS 2.0 or later, and a hard disk. The program is controlled from a main menu screen which gives the various options in the order in which they should be performed. Data are entered in a spreadsheet-type format, and can be saved before further processing. Data can instead be imported from ASCII files produced by other applications.

A varied selection of possible equations for curve-fitting is built into the program, and others can easily be added, either temporarily or permanently.

I tested a range of types of data—linear, curved, and sigmoid—and was always satisfied with the fit obtained. I was pleased with the statistical reports produced by P. Fit, particularly with the plots of residuals, but also with the confidence limits, goodness-of-fit index, correlation, chi-squared, sign-test and run-test. The print-out I obtained from a laser printer was of excellent quality, though the range of styles was limited.

The only thing that worries me about P. Fit is the manual, in that it assumes that the reader already has a good knowledge of statistics. My feeling is that an easy-to-use program like P. Fit is likely to attract many users with virtually no statistical knowledge, and I think that the manual should have catered for such users by providing more basic background information. I hope that the publishers will give some thought to improving the manual, perhaps initially by adding references to suitable statistical text-books, but later by providing a much more extensive guide to the practice of curve-fitting.

MARY MASSON

Electrochemistry, Past and Present: J. T. STOCK and M. V. ORNA (editors), ACS, Washington, DC, 1989. Pages ix + 606. \$89.95 (US and Canada), \$107.95 (elsewhere).

This book consists of 38 chapters "developed" from a symposium held in 1988 and unequally spread between *Foundations of Electrochemistry*, *Organic and Biochemical Electrochemistry* (the smallest and weakest section), *Electroanalytical Chemistry* and *Industrial Electrochemistry*. With such an arrangement and so many authors, variability of material and writing must be expected. The most obviously historical pieces, centred on chemists from Faraday to Heyrovský, are good and also reveal curiosities such as Wilmore's role in the hydrogen electrode debate. I commend Leddy's piece on industrial electrochemistry, as it is very instructive and does not depend on the cachet of Great Names. The chapters on analytical instrumentation were generally interesting, but some of those on recent developments were curiously flat and inhibited, amounting to no more than sketchy literature reviews, as if the authors were not really interested in this type of writing. I counted 13 very good chapters, 12 that were worthwhile, 5 that were rather poor and 8 that were either suspiciously idiosyncratic or a courtesy to the author rather than the reader. That is not a bad score and the book as a whole meets the editors' claim to "educate and engage" the reader. For camera-ready copy, the book is not cheap and I wish it had been published in paperback (with some chapters omitted) to widen the readership, for this is as near a bedside book as the chemist is likely to get. Recommended.

D. MIDGLEY

Spectroscopic and Structural Studies of Biomaterials—I Proteins: J. TWARDOWSKI (editor). Sigma Press, Wilmslow, Cheshire, 1988. Pages viii + 289.

This book contains a collection of lectures and selected communications presented at the Third International Scientific School, entitled "Spectroscopic and structural studies of materials and systems of fundamental importance to biology and medicine" in Ustron, Poland, 1987. The authors' original manuscripts are reproduced for this book, which gives a mixture of print types, sizes and quality. The book also suffers from numerous spelling and linguistic mistakes which have not been corrected.

It has a very heterogenous content and covers a wide range of topics and research fields. Some papers describe new work carried out by the authors but many are review articles within a particular field. The topics include sections on methodology, medical aspects, hemeproteins, membrane proteins and protein complexes. As such, it is considered by the reviewer to be a book for the library, where it will be of interest to and can be read by multi-discipline users, rather than a book for individuals.

ERRATA

In the article entitled "Kinetic determination of EDTA and citrate by the displacement of fluoride from $Al^{3+}-F^-$ complexes and use of a fluoride ion-selective electrode" by Pentari *et al.* (*Talanta*, 1991, 38, 295) equation (12) should have been

$$[F^-] \left(1 + \frac{[H^+]}{K_{HF}} \right) + \frac{\sum_{i=1}^4 \left(i [F^-]^i \prod_{j=1}^i K_j \right)}{1 + K_h/[H^+] + \sum_{i=1}^4 \left([F^-]^i \prod_{j=1}^i K_j \right)} C_{Al} = C_F$$

and in the article entitled "Analytical applications of 1,10-anthraquinones: A review" by Diaz (*Talanta*, 1991, 38, 571) "1,10-anthraquinones" should have been "9,10-anthraquinones".

European Analytical Column 14 (Sept. 1990)

Letter of Information of the Working Party on Analytical Chemistry of the Federation of European Chemical Societies (WPAC/FECS)

Chairman: L. NIINISTÖ, Helsinki

Secretary: R. KELLNER, Vienna

WPAC held its 21st meeting on 26 August 1990 in connection with Euroanalysis VII in Vienna. The attendance was 38 delegates from chemical societies in 24 countries, the highest number so far and an almost complete representation. FECS and WPAC cover practically the whole of Europe, as the Romanian Society of Analytical Chemistry joined FECS as a full member this year.

The major event of WPAC this year was Euroanalysis VII, held at the University of Technology, Vienna (26–31 August 1990). A very high attendance of 1100 active participants was recorded for this latest event of the triennial series of European conferences of Analytical Chemistry.

The conference was organized on behalf of the WPAC by the Austrian Society for Analytical Chemistry with Prof. J. F. K. Huber as chairman and Prof. M. Grasserbauer as secretary general. The opening session was held in the beautiful golden hall of the Vienna Musikverein with a programme consisting of short addresses by Prof. Huber, Dr. Fritsche, Chairman of FECS, and Prof. Niinistö and much Viennese music. The traditional historic lecture was given by Prof. H. Malissa. Numerous awards and prizes were also given at this occasion including the H. E. Merck Prize for Analytical Chemistry to Dr. B. A. Bidlingmeyer and Prof. R. Nießner and the Robert Boyle Gold Medal to Prof. H. Malissa.

Euroanalysis conferences are broad-scope Analytical Chemistry meetings and consequently the Vienna meeting covered all main fields in Analytical Chemistry, with 95 invited lecturers and 618 contributed papers in oral and poster sessions. For compiling the programme, the "convener-system" was used and this and the high number of invited lectures were the key features which guaranteed an interesting high-level programme.

Euroanalysis VII was not only characterized by a record attendance right up to the closing session, but by the active participation of numerous delegates in the "Special Sessions" (Quality Assurance, Education, Computer Based Analytical Chemistry and Sampling) that are among the key areas in the field today. Special reports about these fields will follow.

Besides the discussion of regular technical questions (a detailed report will appear in TRAC, Analytical Chemistry and most other Analytical Chemistry journals, proceedings will appear in Mikrochimica Acta, contributed papers in Fresenius Journal of Analytical Chemistry) Euroanalysis VII was a forum for 2 important resolutions:

1. Recommendations for the future in Education in Analytical Chemistry
2. Declarations of Vienna by the members of WPAC

Both resolutions were unanimously supported by WPAC at its meeting on 26 August 1990 (38 participants) and accepted by Euroanalysis VII.

Further—facing the fact that Analytical Chemistry has developed worldwide into "a key for a safer future for mankind" by controlling technological progress, food and the environment—closer formal contacts were established between WPAC and the Analytical Divisions of IUPAC, ACS, the Japanese Chemical Society and the Chinese Academy of Sciences.

NOTICES

THE RONALD BELCHER MEMORIAL AWARD FOR 1992

Applications are invited for the Ronald Belcher memorial Award, in commemoration of the late Professor Belcher's outstanding contributions to analytical chemistry, international relations and understanding, his interest in student welfare, and continued association with *Talanta* from his conception of the journal in 1957 right up to his death. The award takes the form of a travel grant of US\$1000 to enable a young analytical scientist to undertake travel abroad and is made in even-numbered years. Candidates may be of either sex and any nationality, but must be under 30 years of age at the time of application, and not have had more than one year of post-doctoral experience. Applications may be sent by the candidates themselves, or on their behalf by a responsible senior (*e.g.*, Head of Department, research supervisor), and must be submitted by the end of the year preceding the award. They must include a brief curriculum vitae, a short statement of the purpose of travel and the places to be visited, a testimonial of ability, and a recommendation from a senior research worker.

Applications for the 1992 award should be sent to

Professor J. D. Winefordner
Department of Chemistry
University of Florida
Gainesville, Florida 32611, U.S.A.

to arrive before 31 December 1991.

4th INTERNATIONAL SYMPOSIUM ON DRUG ANALYSIS

5-8 May 1992
Palais des Congrès
LIEGE, BELGIUM
FIRST CIRCULAR

Scope

The purpose of DRUG ANALYSIS '92 is to bring together people from Industry, Universities, Control Laboratories and Hospitals to discuss the current status of analytical techniques including instrumental applications and theoretical developments.

Topics

1. Fundamental Aspects of Drug Analysis.
2. Quality Control of Natural and Synthetic Raw Materials.
3. Analysis of Pharmaceutical Preparations.
4. Determination of Drugs in Biological Media.
5. Automation in Drug Analysis.

Programme

Plenary and keynote lectures will be given by invited speakers. A limited number of contributed papers will be presented as oral communications. The preference will be given to poster presentations. Discussion sessions will also be organized.

Language

The official language of the Symposium is English. No simultaneous translation will be provided.

CORRIGENDUM

In the announcement of the Ronald Belcher Memorial Award winners (*Talanta*, 1990, 37, No. 11, V) there was an error in the name of one of them, "Dr. R. Kobinski" should have been "Dr. R. Łobiński", and we apologise to him for the error.

1992 WINTER CONFERENCE ON FLOW INJECTION ANALYSIS

12–15 January 1992
Scottsdale, Arizona

WCFA 92 will be held in Scottsdale, Arizona, 12–15 January, 1992. It will focus on how industrial FIA techniques have helped solve real world problems. New hardware and software-driven applications will be presented. The following areas will be highlighted: process chemistry, biotechnology, instrument design, new methods, atomic spectroscopy, electrochemistry. There will be a vendor exhibition. Deadline for abstracts for presentation (20 min.) and posters, and for preregistration, is 3 December, 1991.

Euroanalysis VII was a further landmark in the development of this conference series. After Euroanalysis I in Heidelberg (1972) where WPAC was founded (spiritus rector: Dr. W. Fritsche, GDCh, Frankfurt) this triennial event has taken place in Budapest (1975), Dublin (1978), Helsinki (1981), Cracow (1984) and Paris (1987). WPAC is most grateful to the Austrian Society for Analytical Chemistry (ASAC) for having hosted this most successful Viennese Congress of Analytical Chemistry, which was also a social event to be remembered.

The next Euroanalysis will take place in Edinburgh, 5–11 September 1993 (Chairman: Prof. D. T. Burns). Details about Euroanalysis and other WPAC activities (e.g., in Quality Assurance and Education) are available from the WPAC secretariat upon request:

Prof. R. Kellner
Institute for Analytical Chemistry
Technical University Vienna
Getreidemarkt 9
A-1060 Vienna
Fax. +43-1-567813

The following motions have been proposed by the members of the Working Party on Analytical Chemistry of the Federation of European Chemical Societies (WPAC/FECS) and approved in the closing session of Euroanalysis VII on Friday, August 31, 1990.

“Declarations of Vienna”

Motion 1

The delegates of Euroanalysis VII strongly affirm that only a good and sound *education in Analytical Chemistry* gives proper provision for adequate progress in science and research, and for control of production, consumable goods and the environment.

Motion 2

With respect to progress in the political and economic integration of Europe, Euroanalysis VII recommends that the WPAC takes the necessary steps towards advancing harmonization of analytical chemistry curricula according to the recommendations of the WPAC based on the survey of 1989/90 as reported to Euroanalysis VII in session C4 on Tuesday, 28 August 1990.

Motion 3

Since high standards of analytical quality in any one European country directly concern and benefit every other country, Euroanalysis VII strongly recommends that in order to ensure and enhance the quality of analysis the WPAC aims to encourage that consistent rules and commitments for analytical quality assurance are valid throughout Europe by the harmonization of existing and new “accreditation systems” within Europe.

Vienna, August 31, 1990

Prof. Dr. L. Niinistö
(Chairman WPAC/FECS)

European Analytical Column 15 (Jan. 1991)

Letter of information of the Working Party on Analytical Chemistry of the Federation of European Chemical Societies (WPAC/FECS).

Chairman: L. Niinistö, Helsinki

Secretary: R. Kellner, Vienna

Education in Analytical Chemistry—New Developments

In addition to the publication of the “WPAC-Recommendations for the Future in Education in Analytical Chemistry” (see European Analytical Column 14) we are happy to inform you about

very positive comments about this major WPAC activity from outside Europe (see editorial by G. Morrison, *Analytical Chemistry*, 1 Nov. 1990) and about further actions:

- The complete Special Session on Education will be documented in a convener-edited part of the proceedings of EUROANALYSIS VII (to appear in *Mikrochimica Acta*, 1991).
- The WPAC-secretariat will stimulate activities in the field of new textbooks of Analytical Chemistry.
- A high-level postgraduate training system in Europe was proposed under the name "WPAC-Euro-Courses". Final statutes are under discussion.
- Further aspects of education in Analytical Chemistry at university level will be discussed at depth at the "2nd FEICHEM Conference on Education in Analytical Chemistry" to be held in Prague, at the famous Charles University in the beginning of September 1992. Professor Štulík has already obtained support from the Czechoslovak Chemical Society which will organize the conference in connection with the 16th International Competition in Analytical Chemistry (ICAC 16).
- We would like to thank Professor Krofta and his colleagues from the ICAC for their personal efforts to make the 15th ICAC 1990 a success, and we finish the column with their report.

Report of the 15th International Competition in Analytical Chemistry

From 3rd to 7th September 1990 the Department of Analytical Chemistry of the Prague Institute of Chemical Technology again organized the 15th ICAC—International Competition in Analytical Chemistry.

The Competition was held under the sponsorship of the Rector of the Prague Institute of Chemical Technology, the Ministry of Education, Youth and Sports of the Czech Republic, and the Czechoslovak Chemical Society. The Competition is one of the events supported by the Working Party on Analytical Chemistry (WPAC) of the Federation of European Chemical Societies (FECS).

The official opening of the Competition, which took place in the Schooling Club, was attended by the chairman of the Working Party on Analytical Chemistry of FECS, Professor L. Niinistö, and its secretary, Professor R. Kellner, the Rector of the Prague Institute of Chemical Technology Professor Cerny, and a representative of the Czechoslovak Chemical Society, Professor Horak.

The Competition was attended by students from 24 universities and technical universities, guided by their teachers, from 9 European countries: Poland (1), USSR (4), GDR (5), Hungary (5), Romania (1), Yugoslavia (1), Italy (1), Holland (1), and Czechoslovakia (5).

The Competition involved a theoretical part and a practical one. In the theoretical part the students were solving 25 tasks and problems covering the most widely used analytical methods. In the practical part they were determining the contents of copper and nickel in a mixture, by titration with EDTA. The time limit for solving the set tasks in both parts of the Competition was 150 minutes. The official language of the Competition was English.

The results of the respective parts of the Competition were evaluated by an International Jury formed by the university teachers who guided the individual teams. The chairman of the Jury was Associate-Professor Popl from the Prague Institute of Chemical Technology, the vice-chairman was Dr. F. Gerhartl (Arrhem, Holland). Intermediate results, after being evaluated by the International Jury, were always made public on notice boards.

In the individuals competition Mr. A. Kotschy won 1st place, Mr. Hantosi Zolt the 2nd (both are from Lorand Eötvös University in Budapest) and Mr. A. Granovski from the Moscow State University won 3rd place.

In the team competition the placement was as follows: 1. Lorand Eötvös University, Budapest; 2. Lajos Kossuth University, Debrecen; 3. Moscow State University.

Besides the Competition, the organizers provided for the participants a social programme including a sightseeing tour of Prague, attendance at a performance of *Laterna Magica*, a social evening and a closing festive dinner following by music and dancing.

The participants highly appreciated the organization and the professional programme as well as the Competition itself.

Organization Committee of the 15th ICAC

NOTICES

THIRD INTERNATIONAL SYMPOSIUM ON PHARMACEUTICAL AND BIOMEDICAL ANALYSIS

28 April-1 May 1991

Boston, Mass., U.S.A.

The Third International Symposium on Pharmaceutical and Biomedical Analysis will be held in the Boston Park Plaza Hotel, Boston, U.S.A. from Sunday 28 April to Wednesday 1 May 1991. This Symposium continues the series of successful meetings held in Barcelona, Spain (1987) and York, U.K. (1990). All those involved in the analysis of drugs, related materials and endogenous compounds, in any area of the pharmaceutical and biomedical sciences, are invited to participate. The principal scientific themes include:

- Analytical aspects of biotechnology
- Current analytical issues in TDM and sports medicine
- Novel methods for ADME studies
- Novel chromatographic methods for the analysis of enantiomeric drugs
- Advances in drug analysis by high-resolution NMR and MS
- Advances in detector technology, including UV, FL, EC and MS
- New approaches to sample handling and sample pre-treatment
- Novel analytical techniques and applications for QC, QA, drug formulations, assay validation, stability testing, bioanalysis, pharmacokinetics, biopharmaceutics, clinical chemistry, toxicology, drug metabolism and environmental control

The meeting will consist of opening and closing Plenary Lectures and 14 invited Keynote Lectures given by internationally renowned scientists in their respective fields. There will be a limited number of Oral Presentations available. Preference will be given to Poster Presentations, as the central feature of the Symposium. A unique feature will be the Poster Discussion Sessions, based on short presentations by each author, and structured around topical themes. A series of Workshops will also be presented on Chiral Separations; Capillary Electrophoresis; Sample Preparation; Detector Technology; and Microdialysis.

All papers presented will be published, after refereeing, in a special issue of the *Journal of Pharmaceutical and Biomedical Analysis*. Registered participants will receive a complimentary copy of the Proceedings, the Book of Abstracts, and entry to the Exhibition.

THIRD INTERNATIONAL SYMPOSIUM

Under the aegis of IUPAC

Analytical chemistry in the exploration, mining, and processing of materials

2-7 August 1992, Sandton Sun Hotel, Sandton, South Africa

The organizers cordially invite you to attend this, the third symposium in the series, which will be held at the Sandton Sun Hotel, Sandton, from Sunday 2 to Friday 7 August 1992. The occasion will once again provide an opportunity for analytical scientists and their counterparts in the mining and metallurgical fields worldwide to exchange experiences.

The technical programme will consist of plenary lectures, parallel sessions of oral presentations and poster presentations. Detailed information and instructions to participants and to those presenting papers will be given in the Second Circular.

Those interested in presenting papers and/or posters are invited to submit preliminary abstracts. The general theme will be

The role of contemporary chemical analysis in mining and industrial technology.

The following topics will be covered:

- (1) Geochemical exploration
- (2) Extraction and beneficiation of materials
- (3) Value-added products
- (4) Environmental aspects
- (5) Coal
- (6) Metals and alloys
- (7) Rare earths
- (8) Noble and base metals
- (9) Analytical assurance and laboratory management
- (10) Automation and process control
- (11) High-technology materials.

Innovation in analytical techniques will be particularly welcome.

For further information please contact:

COMPANA '92

5th Conference
Computer Application in Analytical Chemistry
24-27 August 1992
Jena/Thuringia

The 5th Conference Computer Applications in Analytical Chemistry—COMPANA '92 continues the conferences organized in 1977 in Leipzig, 1980 in Dresden, 1985 and 1988 in Jena.

**THE 3rd INTENSIVE COURSE ON PRINCIPLES & APPLICATIONS
OF CHEMICAL SENSORS**

11–14 June 1991

Wildbad Kreuth, Bavaria, Germany

Lecturers for this course will include:

S. Brukenstein, E. Hall, J. Janata, M. Josowicz, H. D. Liess, D. Lubbers, H. L. Schmidt and E. Obermeier.

For further information contact:

Dr. Mira Josowicz

COMPANA '92

5th Conference
Computer Application in Analytical Chemistry
24-27 August 1992
Jena/Thuringia

The 5th Conference Computer Applications in Analytical Chemistry—COMPANA '92 continues the conferences organized in 1977 in Leipzig, 1980 in Dresden, 1985 and 1988 in Jena.

The Conference is organized by the Institute of Inorganic and Analytical Chemistry of the Friedrich Schiller University in collaboration with the Chemical Society of GDR, particularly the group of Analytical Chemistry and the group of Chemometrics and takes place in the main building of the Friedrich Schiller University, Goetheallee 1.

Language: The Conference languages will be German and English.

No simultaneous translation or interpretation will be provided.

Topics

- Chemometrics for environmental analysis and monitoring. Quality control/assurance of the environment
- Expert systems, principles of artificial intelligence in analytical chemistry
- Explorative and statistical data analysis, interactive scientific processing
- Multivariate experimental design and optimization
- Structure-activity and composition-quality relations
- Simulation and modelling of processes
- Complex application of chemometric procedures
- Evaluation of spectroscopic and chromatographic data
- Computer-coupled tandem methods in analytical chemistry
- Laboratory automation and information management
- Principles of image analysis in analytical chemistry
- Schooling and further training in the field of computer chemistry and chemometrics.

Key dates:

Return of preliminary application	to JUNE 1991
Distribution of 2nd Circular	SEPTEMBER 1991
Submission of contributions	NOVEMBER 1991
Deadline for submission of abstracts	FEBRUARY 1992
Notification of acceptance	APRIL 1992
Distribution of final programme	JUNE 1992

Address: COMPANA '92
 Friedrich Schiller University Jena
 Institute of Inorganic and Analytical Chemistry
 Steiger 3, Haus 3, Jena, Germany 6900
 Prof. Dr. K. Danzer (Scientific Committee) Tel.: 82-25467
 Dr. W. Ludwig (Organizing Committee) Tel.: 82-25029

SAC 92

An International Conference on Analytical Chemistry

20–26 SEPTEMBER 1992

UNIVERSITY OF READING

Organized by the Analytical Division of The Royal Society of Chemistry
 and the

Laboratory of the Government Chemist in its 150th year

An International Conference on Analytical Chemistry (SAC 92) organised jointly by the Analytical Division of The Royal Society of Chemistry and the Laboratory of the Government Chemist will be held in the Palmer building at the University of Reading. This is the tenth in the series of triennial Conferences originally started by the Society for Analytical Chemistry (hence SAC) and on this occasion also celebrates the 150th anniversary of the founding of the Laboratory of the Government Chemist (LGC). The conference will be held from Sunday 20 to Saturday 26 September 1992.

OBITUARY

PROFESSOR HERBERT A. LAITINEN

Professor Herbert A. Laitinen, one of the world's premier analytical chemists, died at his home in Gainesville, Florida, on 22 March 1991 at the age of 76. He was born on a farm in Ottertail County, Minnesota, of second-generation Finnish parents from whom he learned to speak Finnish before English. He attended the University of Minnesota, receiving the Ph.D. degree in 1940, having studied with Professor I. M. Kolthoff.

Dr Laitinen joined the chemistry faculty of the University of Illinois in 1940, becoming Head of Division of Analytical Chemistry in 1953. During World War II, he was a group leader in synthetic rubber research. An outstanding educator, he trained many of the analytical chemists presently influential in industry and academia. He lectured widely in Europe, Japan, China, and was a visiting professor at UCLA, Birmingham (England), Nanking, Seoul, and Munich, as well as an exchange visitor to Yugoslavia. A considerable number of scientists from abroad were attracted to Urbana for advanced study under his direction. His advanced text *Chemical Analysis* (second edition co-authored with W. E. Harris) is well known to two generations of chemists. In 1974, Dr Laitinen accepted an appointment as Graduate Research Professor at the University of Florida, a position he occupied at the time of his death. From 1966 to 1979, he served as editor of *Analytical Chemistry*.

Dr Laitinen's interests covered a wide spectrum of analytical chemistry. His major research interests were in electroanalytical chemistry, and in the early years he addressed problems in potentiometry and voltammetry. Later he emphasized the properties of molten salts, surface phenomena and catalysis. He had much to do with the revitalization of electroanalytical chemistry in the 1970s-1980s.

His career brought him numerous awards and honorary appointments. These include the American Chemistry Society's Award in Analytical Chemistry, the SOCMA Gold Medal in Environmental Chemistry, the Pittsburgh Society for Analytical Chemistry Award, the Kuebler Award of Alpha Chi Sigma, the Gadolin Medal Award of the Finnish Chemical Society, the ACS Analytical Chemistry Division Award for excellence in Teaching, The Talanta Medal in 1989, and the outstanding Alumni Achievement Award of the University of Minnesota. He was an honorary member of the Finnish Academy of Sciences, The Japan Society for Analytical Chemistry, and the Royal Society of Chemistry (London). He was a fellow of the AAAS and a member of the Electrochemical Society and the ACS, having been chairman of the latter's Division of Analytical Chemistry. He had also served as Secretary of the Commission on Electrochemical Data of the International Union of Pure and Applied Chemistry.

Although his personal research accomplishments were immeasurable and ground-breaking in many cases, I feel Herb Laitinen's major contributions to science were in the areas of teaching and analytical chemistry as a discipline. As an undergraduate and graduate student at the University of Illinois, I remember well the elegance, rigor, enthusiasm, and interest shown by Herb in his undergraduate and graduate classes at the U of I. I still have my notes from his courses, even though I discarded long ago the notes from most other courses. His books have greatly affected the teaching of analytical chemistry and his *History of Analytical Chemistry* with Galen Ewing as co-editor was a labor of love and a major accomplishment. Herb received in 1986 the American Chemical Society Analytical Division Award for Excellence in Teaching. Herb's contribution to analytical chemistry as a discipline is perhaps even more significant. As the Editor of the journal *Analytical Chemistry*, he brought new respect to the journal and to the discipline.

Herb Laitinen was always all business. He imparted his own enthusiasm, interest, and excitement to his students, even those who initially had little interest in the subject. At the University of Illinois

and the University of Florida Herb's wide-ranging scientific curiosity was always apparent in the stimulating and significant questions asked by him at seminars. Finally, within the last several months of his life, Herb had gone back into the laboratory to do his own research. I'll remember Herb Laitinen not only as a great scientist, scholar, and teacher but also as a friend, who gave me and many others excellent advice and support.

JIM WINEFORDNER

EDITORIAL

SENSORS PROVIDE IMMEDIATE ANALYTICAL RESULTS ON A CONTINUOUS OR REPETITIVE BASIS

Starting with this issue, Talanta will publish papers dealing with chemical sensors in a separate section. I will be serving as the first editor of this section, assisted by a distinguished board of sensor scientists who are introduced in this issue.

To decide what manuscripts will be appropriate for the new section, it is necessary to develop a working definition of a "chemical sensor". The "traditional" types of chemical sensors include electrodes and acoustic devices. More recently fiber optic devices have been widely accepted as chemical sensors. These devices share two common features; they are relatively low in cost, and they involve insertion of a device into the sample. However, there are many differences among "traditional" sensors. Some respond continuously. Others can be used for multiple single measurements with a "recharging" step in between. Still others can only be used for a single measurement. A few devices can be inserted directly into a sample. Many others require the addition of reagents to modify the sample, such as buffers to adjust pH and salt solutions to control ionic strength.

Rigor can be introduced into the definition of a chemical sensor by restricting the term to devices that have a specific set of properties. For example, an "ideal" sensor may be described as a device which is low in cost, responds continuously, does not perturb the sample and does not require the addition of reagents to the sample. However, many devices that are widely considered to be sensors do not satisfy this definition.

I prefer to define sensors, not in terms of device properties, but rather in terms of the kinds of problems that they solve. These problems have two elements. One is the need for multiple measurement. This can be met by continuous measurement or repetitive single measurements. The crucial parameter is the response time, either the intrinsic response time of a continuous sensor or the time between multiple single measurements. Low cost, frequently considered to be a property of a chemical sensor, is implicit in this aspect of single measurement devices since it is rarely practical to make multiple measurements by techniques having a high cost per measurement.

The second element of sensing is that analytical results are required immediately, *i.e.*, there is not a significant time interval between taking the sample and making the measurement. Making the measurement directly on the sample is the most effective way of accomplishing this. However, on site measurements, *e.g.*, field measurements of pollutants or home measurements of blood glucose, also involve a minimal interval between taking the sample and making the measurement.

I look forward to seeing how this guideline works out in practice. I invite you, my colleagues, to share with me your thoughts about chemical sensing. I also invite you to contribute manuscripts to Talanta: Chemical Sensors. I hope that together we will define and advance "chemical sensors" as a subdiscipline within analytical chemistry.

W. RUDOLF SEITZ

LOUIS GORDON MEMORIAL AWARD

Their Louis Gordon Memorial Awards were presented to Professor Yu. A. Zolotov (Kurnakov Institute of General and Inorganic Chemistry, U.S.S.R. Academy of Sciences, Moscow) and Dr. J. Šrámková and Dr. S. Kotrlý (University of Chemical Technology, Pardubice, Czechoslovakia) by Dr. R. A. Chalmers.

EDITORIAL

The Publisher and Editorial Board of *Talanta* regret to announce that owing to pressure of work Professor David Littlejohn has felt obliged to resign as joint Editor-in-Chief, and they take this opportunity to thank him on behalf of contributors and readers for the valuable work done by him for the journal during his all too brief tenure of the position, and for his enthusiasm in making innovations in it. From 1 January 1991 he will be replaced as joint Editor-in-Chief by Professor Elo H. Hansen, of the Technical University of Denmark, whose name will be well known to all in connection with flow-injection analysis. Papers that would previously have been sent to Professor Littlejohn should now be sent to:

Professor E. H. Hansen
Chemistry Department A
Building 207
Technical University of Denmark
DK-2800 Lyngby
Denmark

This issue is the first in the year that will see the introduction of a new feature in the journal, the Chemical Sensors Section, which will be edited by Professor Rudolf Seitz, of the University of New Hampshire, with the assistance of a separate Advisory Board, so it is particularly fitting that it should be a Special Issue on Sensor Electrodes, organized by Professor Lars Kryger, of Aarhus University, Denmark, who is warmly thanked for his work in compiling it. This special issue may be regarded as the forerunner of the new Chemical Sensors Section, giving a taste of things to come. The aims and scope of the new section appear elsewhere in this issue. Papers intended as contributions to this section should be sent to:

Professor W. Rudolf Seitz
Department of Chemistry
University of New Hampshire
Durham, NH 03824
U.S.A.

The Conference is organized by the Institute of Inorganic and Analytical Chemistry of the Friedrich Schiller University in collaboration with the Chemical Society of GDR, particularly the group of Analytical Chemistry and the group of Chemometrics and takes place in the main building of the Friedrich Schiller University, Goetheallee 1.

Language: The Conference languages will be German and English.

No simultaneous translation or interpretation will be provided.

SAC 92

An International Conference on Analytical Chemistry

20–26 SEPTEMBER 1992

UNIVERSITY OF READING

Organized by the Analytical Division of The Royal Society of Chemistry
 and the

Laboratory of the Government Chemist in its 150th year

An International Conference on Analytical Chemistry (SAC 92) organised jointly by the Analytical Division of The Royal Society of Chemistry and the Laboratory of the Government Chemist will be held in the Palmer building at the University of Reading. This is the tenth in the series of triennial Conferences originally started by the Society for Analytical Chemistry (hence SAC) and on this occasion also celebrates the 150th anniversary of the founding of the Laboratory of the Government Chemist (LGC). The conference will be held from Sunday 20 to Saturday 26 September 1992.

The scientific programme will be organized around plenary, invited and contributed papers and posters covering the whole field of analytical chemistry. The language will be English and the programme will include workshops where research workers can demonstrate new apparatus and techniques. An opportunity will be made for all participants to visit The Laboratory of the Government Chemist and other scientific establishments.

As for previous SAC Conferences a special issue of *The Analyst* will be published, and intending authors who would like their papers to be published therein are invited to include novel or relevant review material to satisfy the normal criteria for *The Analyst*. Papers may also be offered for publication in *The Journal of Analytical Atomic Spectrometry* and *Analytical Proceedings*.

All aspects of analytical science can be included in SAC 92, some suggested areas are:

Accreditation	Enzyme techniques	Preconcentration and separation
Agricultural	Flow injection methods	Probe methods
Atomic spectrometries	Food and drink	Process analysis
Atmospheric	Forensic	Professional and technical aspects of 1992
Automation and robotics	Genetic fingerprinting	Quality assurance
Bioanalytical techniques	Geological	Radiochemistry
Biochemical methods	Immunoassay	Reference materials
Biological and microbiological	Industrial	Remote sensing
Biotechnology	Instrumentation	Sample preparation
Catalytic and kinetic methods	Ion exchange	Sampling
Chemicals and petrochemicals	Laboratory design	Sensors
Chemometrics	Laboratory information	Standards
Chromatography	Management systems	Statistics in analysis
Clinical	Mass spectrometry	Surfaces
Collaborative analytical studies	Metallurgical	The integrated laboratory
Consumer protection	Methods of validation	Thermal methods
Data processing	Microanalysis	Toxicology
Drugs in sport	Molecular recognition	Water and effluents
Education	Molecular spectrometries	X-Ray methods
Electroanalytical methods	Nuclear magnetic resonance	
Electrophoresis	Pharmaceutical	
Environmental	Plastics, rubbers and textiles

EUROANALYSIS VIII

5-11 September 1993
Edinburgh, U.K.

The Working Party on Analytical Chemistry of the Federation of European Chemical Societies and the Analytical Division of the Royal Society of Chemistry cordially invite your participation in the eighth triennial European Conference on Analytical Chemistry to be held at the University of Edinburgh from 5 to 11 September 1993.

Euroanalysis VIII will emphasise the role of analytical chemistry as a tool for problem solving in major areas of science as well as methodological developments. The programme will be designed to appeal both to practising analytical chemists in industry and to those in academia who are teaching and undertaking research.

OBITUARY

On March 11, 1991, Professor Gaston Jules Patriarche, internationally known in the field of electroanalytical and pharmaceutical chemistry, passed away.

G. J. Patriarche was born in Obaix-Buzet, near Brussels, on March 10, 1930. He studied at the Free University of Brussels (ULB) to become a pharmacist in 1956. Remaining faithful to his "Alma Mater", all his academic career has been devoted to ULB. Starting this career in 1957 as an assistant to Professor Louis Maricq in the analytical chemistry department of the Pharmaceutical Institute, he became immediately interested in electrochemical techniques which were being developed in the department. Encouraged by Professor James Lingane, visiting professor at the Faculty of Sciences, he was among the first European scientists to conduct coulometric measurements. Investigating the electrogeneration of bromine and iodine, he was able to determine about twenty different metal ions, directly or after complexation with 8-hydroxyquinoline, as well as numerous pharmaceutically interesting organic compounds. These studies allowed him to acquire

his Ph.D. in Pharmaceutical Sciences in 1963 with a thesis entitled "Contribution to coulometric analysis. Application to pharmaceutical sciences". Three subsidiary works were presented at the same time, devoted to polarimetry of antimony, polarographic separation of cobalt and nickel and thin layer chromatographic separation of As, Sb and Sn. He completed his education in Saclay, France where he acquired a radioelements manipulator degree.

Becoming a Main Assistant at ULB in 1964, he developed polarographic techniques and created a research unit in electrochemistry in the analytical department. He was a Research Associate in Chemistry at Harvard University in the laboratory of Professor J. Lingane in 1966 and 1969 and Visiting Professor in 1976. Promoted to Associate Professor in 1969 and Full Professor in 1977 at the Pharmaceutical Institute of ULB, he divided his time between teaching general chemistry, analytical chemistry and electrochemistry, and the development of his research laboratory. While modern polarographic techniques and voltammetry as solid electrodes remained the basis for his activities, he rapidly understood and developed considerable interest in modified electrodes and enzyme electrodes in pharmaceutical research. He was particularly fond of developing new biosensors and their application to pharmaceutical and biomedical analysis. He also contributed to the development of spectrophotometric and chromatographic techniques. Undefatigable in his approach to research, his whole life can be characterized by a need for knowledge

Professor Patriarche is author or co-author, with Ph.D. students and colleagues, of more than 250 scientific papers, including book chapters. All his publications as well as the hundreds of lectures given around the world were characterized by the will to demonstrate that electrochemical techniques are well adapted to pharmaceutical analysis. It was in this way that he directed the research work of his students in which he was always attentive and ready to assist.

The important role played by Professor Patriarche in scientific research is reflected by the positions he has occupied. He was the youngest member of the Belgian Royal Academy of Medicine, past-president of the Belgian Society of Pharmaceutical Sciences and the Analytical Section of the Belgian Royal Chemical Society. Among others, he was a member of the American Chemical Society since 1966, the Electrochemical Society, the International Society for Electrochemistry, the Society for Electroanalytical Chemistry and the Analytical Division of the International Union of Pure and Applied Chemistry. He was also a member of the Commission of the Belgian Pharmacopoeia and of the Scientific Council of the Belgian Department of Drug Control.

He was an active member of scientific committees of numerous international congresses devoted to electrochemistry or to pharmaceutical sciences, and he was the organizer of several.

His outstanding activity in the analytical, electroanalytical and pharmaceutical field was also reflected by his membership on the editorial boards of *Electroanalytical Abstracts*, *Clinical Letters*, *Analytical Letters*, *Journal of Pharmaceutical and Biomedical Analysis*, *Trends in Analytical Chemistry* and *Journal de Pharmacie de Belgique*. He was also Regional Editor for Europe of *Electroanalysis* at the time of his death.

He was awarded the Quinquennial Prize of the Belgian Royal Academy of Medicine and Doctor Honoris Causa of the Complutena University of Madrid.

The fruitful life of this outstanding electroanalytical pharmacist has been interrupted too early. However, he will remain in the memory of everybody who knew him.

Jean-Claude Viré
Institut de Pharmacie
Université Libre de Bruxelles

Editor's Note: Professor Patriarche was a close personal friend and colleague, and was a frequent referee for *Talanta* as well as contributor. Those who knew him will remember his jovial nature and his devotion to his family as well as to his teaching and science.

G.D.C.

The scientific programme will be organized around plenary, invited and contributed papers and posters covering the whole field of analytical chemistry. The language will be English and the programme will include workshops where research workers can demonstrate new apparatus and techniques. An opportunity will be made for all participants to visit The Laboratory of the Government Chemist and other scientific establishments.

EUROANALYSIS VIII

5-11 September 1993
Edinburgh, U.K.

The Working Party on Analytical Chemistry of the Federation of European Chemical Societies and the Analytical Division of the Royal Society of Chemistry cordially invite your participation in the eighth triennial European Conference on Analytical Chemistry to be held at the University of Edinburgh from 5 to 11 September 1993.

Euroanalysis VIII will emphasise the role of analytical chemistry as a tool for problem solving in major areas of science as well as methodological developments. The programme will be designed to appeal both to practising analytical chemists in industry and to those in academia who are teaching and undertaking research.

The programme will consist of invited plenary and keynote lectures, contributed papers, and posters and workshops. In order to ensure the high quality of the programme all contributed papers will be refereed by an international panel.

The conference organizer to whom all correspondence should be addressed is:

Miss P. E. Hutchinson

The Royal Society of Chemistry
Burlington House
Piccadilly
London W1V 0BN, U.K.

XXI. European Congress on Molecular Spectroscopy

EUCMOS XXI

23–28 August 1992

Technical University Vienna, Physics Department, Vienna, Austria

This 21st event in the well established series of EUCMOS-conferences will be organized by the Working Group Molecular Spectroscopy of the Austrian Society for Analytical Chemistry (ASAC) in the GÖCh, in the historic mid-European city of Vienna on behalf of the International Committee of EUCMOS. EUCMOS XXI is supported by the Working Party on Analytical Chemistry of the Federation of European Chemical Societies (WPAC/FECS) and will highlight modern trends and recent developments in the rapidly expanding field of molecular spectroscopy. Methods and applications will be treated in 9 sessions including plenary, keynote and contributed oral and poster presentations.

Main Topics:

- 1 Molecular Structure and Interactions
- 2 Surface Analysis—Methods and Applications
- 3 Hyphenated Techniques (Chromatography–Spectroscopy)
- 4 Optical Sensors
- 5 Computer Aided Molecular Spectroscopy
- 6 Theoretical Aspects
- 7 Biological Pathways
- 8 Phase Transition and Order Phenomena
- 9 General

FOREWORD

This special issue of *Talanta* is devoted to sensor electrodes for amperometric, potentiometric, and voltammetric analysis.

Over the past few years electrochemical probes have received a significant share of the attention which is currently focused on the construction of chemical sensors. Several types of ultramicro-electrodes, for instance, have been developed, and many have proved useful in the analysis of solutions with low electrolyte content, as low capacitance voltammetric sensors, and as sensors in the electroanalysis of microvolumes of solutions. A large variety of chemically modified electrodes, with functional groups incorporated on their surfaces, have been constructed for non-electrolytic preconcentration of trace analytes and for utilization of catalytic electrode processes. Also new potentiometric electrodes and calibration procedures have been introduced. As a result of these activities, electroanalytical approaches have progressively become more selective and sensitive, and the class of species which can be accessed by means of electroanalysis has been steadily expanding. The fifteen research papers and reviews in this issue are all written by authors who have contributed significantly in the area of sensor electrode research. It is my hope that the publication of their results and points of view will actuate further research and intensify the flow of knowledge between research and routine analytical laboratories.

I take this opportunity to thank the research groups who have contributed to this issue. Also, I wish to thank the Consultant Editor of *Talanta*, Dr. R. A. Chalmers, for his helpful suggestions, and Mrs. Anne-Lise Mikkelsen for her friendly and patient help with correspondence and coordination.

LARS KRYGER

The programme will consist of invited plenary and keynote lectures, contributed papers, and posters and workshops. In order to ensure the high quality of the programme all contributed papers will be refereed by an international panel.

The conference organizer to whom all correspondence should be addressed is:

Miss P. E. Hutchinson
Analytical Division
The Royal Society of Chemistry
Burlington House
Piccadilly
London W1V 0BN, U.K.

XXI. European Congress on Molecular Spectroscopy

EUCMOS XXI

23–28 August 1992

Technical University Vienna, Physics Department, Vienna, Austria

This 21st event in the well established series of EUCMOS-conferences will be organized by the Working Group Molecular Spectroscopy of the Austrian Society for Analytical Chemistry (ASAC) in the GÖCh, in the historic mid-European city of Vienna on behalf of the International Committee of EUCMOS. EUCMOS XXI is supported by the Working Party on Analytical Chemistry of the Federation of European Chemical Societies (WPAC/FECS) and will highlight modern trends and recent developments in the rapidly expanding field of molecular spectroscopy. Methods and applications will be treated in 9 sessions including plenary, keynote and contributed oral and poster presentations.

Main Topics:

- 1 Molecular Structure and Interactions
- 2 Surface Analysis—Methods and Applications
- 3 Hyphenated Techniques (Chromatography–Spectroscopy)
- 4 Optical Sensors
- 5 Computer Aided Molecular Spectroscopy
- 6 Theoretical Aspects
- 7 Biological Pathways
- 8 Phase Transition and Order Phenomena
- 9 General

Conveners:

- (A. J. Barnes)
(M. Grasserbauer)
(J. F. K. Huber)
(R. Kellner)
(W. Wegscheider)
(A. Karpfen)
(A. Müller)
(H. Ratajczak)

International Committee:

- President: W. J. Orville-Thomas (GB)
President Elect: A. J. Barnes (GB)
Vice Presidents: A. Müller (D), H. Ratajczak (P)

Organizing Committee:

- R. Kellner (Chairman) (A)
A. J. Barnes (GB)
J. Bellanato (E)
J. G. Grasselli (USA)
J. A. Lercher (A)
J. van der Maas (NL)
H. H. Mantsch (CDN)
Z. Meic (YU)
J. Mink (H)
A. Neckel (A)
B. Schrader (D)
K. Taga (Secretary) (A)

Programme Committee:

- W. Landvoigt (Chairman) (A)
A. Benninghoven (D)
M. Grasserbauer (A)
E. H. Korte (D)
J. Lascombe (F)
H. Malissa (A)
E. Pretsch (CH)
C. N. R. Rao (IND)
M. Tasumi (J)
L. A. Gribov (USSR)
W. Wegscheider (A)
G. Zerbi (I)

Copenhagen Opt(r)ode Workshop: Opt(r)odes for charged species

4 November 1991

Risø and Radiometer A/S, Denmark.

For further information contact:

Dr. B. Skytte Jensen
MODECS, Risø National Laboratory
P.O. Box 49
DK-4000 Roskilde
Denmark

Sixth Biennial National Atomic Spectroscopy Symposium

will be held at

Polytechnic South West, Plymouth, UK

22–24 July 1992

The symposium will provide a forum where interesting and useful applications of atomic spectroscopy can be reported and discussed. In addition to plenary, invited and submitted lectures, a particular feature of the meeting will be the presentation of posters. There will also be an exhibition and a social programme for delegates and their guests.

Scientific programme will include:

Plenary Lecturers—

M. W. Blades (Vancouver, BC, Canada)
B. V. L'vov (Leningrad, USSR)
J. W. McLaren (Ottawa, Ontario, Canada)

K. Niemax (Dortmund, Germany)
B. L. Sharp (Loughborough, UK)

Invited Lecturers—

J. S. Crighton (Sunbury-on-Thames, UK)
H. Falk (Kleve, Germany)
S. J. Hill (Plymouth, UK)
D. Littlejohn (Glasgow, UK)
C. McLeod (Sheffield, UK)

G. Schlemmer (Überlingen, Germany)
P. Stockwell (Sevenoaks, UK)
J. F. Tyson (Amherst, MA, USA)
A. M. Ure (Glasgow, UK)
J. G. Williams (Egham, UK)

This meeting is organized by the Atomic Spectroscopy Group, Analytical Division of The Royal Society of Chemistry.

Further information can be obtained from the Chairman of the organizing committee:

Dr S. J. Hill, Department of Environmental Sciences, Polytechnic South West, Drake Circus, Plymouth, Devon PL4 8AA, UK.

TALANTA: CHEMICAL SENSORS ADVISORY BOARD

The Publisher and Editorial Board of *Talanta* welcome the following as members of the Advisory Board of *Talanta*: Chemical Sensors, a new feature that is inaugurated in this issue of the journal.

A. G. FOGG M. MASCINI
J. JANATA T. SHONO
S. J. MARTIN M. THOMPSON
 N. YAMAZOE

After working for ICI (Dyestuffs Division) in Manchester on pharmaceutical analysis, in the days before ICI had a pharmaceuticals division, Arnold Fogg obtained an external degree from the University of London, partly by part-time study. He then studied under Bob Chalmers and Wolf Moser at the University of Aberdeen and obtained a Ph.D. degree in 1961. From Aberdeen he came to the institution which is now Loughborough University of Technology, where he has been Reader in Analytical Chemistry since 1981. He has published 180 papers from his research. He obtained a D.Sc. degree from the University of London in 1986 and was awarded the Royal Society of Chemistry (RSC) Electroanalytical Chemistry Award in 1989. In 1988-90 he was a Vice-President of the Analytical Division of the RSC. In various roles in the RSC Electroanalytical Group, including that of Chairman, he has helped organize numerous international conferences, including the series of Anglo-Czech Electroanalytical meetings. He is a member of the Portuguese Electrochemical Society. His main interests are in electroanalytical chemistry, UV/visible spectrophotometric methods, automatic methods, and analytical solution chemistry. Current research interests are in the development of amperometric and spectrophotometric flow-injection monitors and disposable sensor devices, and the chemistries related to these. Complementary studies are of the direct adsorptive stripping voltammetry of pharmaceuticals and other large and small molecules of biological significance, and of their labelled compounds and metal complexes.

Jiri Janata received his Ph.D. in analytical chemistry from Charles University, Prague, in 1965. After postdoctoral studies at the University of Michigan he spent six years in the Corporate Laboratory of ICI in England, and in 1976 joined the faculty of the University of Utah. In 1986/85 he was on sabbatical leave at UKAEA Harwell in England, and at the Universität der Bundeswehr Munich, Germany, where he holds a Visiting Professorship in the Department of Physics. He is Professor of Materials Science and Engineering and Director of the HEDCO Microengineering Facility at the University of Utah. In 1987 he received the Senior Scientist Alexander von Humboldt Prize. His research interests include chemical sensors and electrochemistry. In this area he has published over 100 research papers, 16 chapters in co-authored books and one textbook: *Principles of Chemical Sensors*. He is inventor or co-inventor of 15 patented devices.

Stephen J. Martin received his B.S. degree in electrical engineering from Rensselaer Polytechnic Institute, Troy, New York, in 1978. He received his M.S. and Ph.D. degrees in electrical engineering from Purdue University, West Lafayette, Indiana, graduating in 1983. Since then he has been a member of Sandia National Laboratories' Microsensor Research Division in Albuquerque, NM. His current research focuses on the use of acoustic wave devices for physical and chemical sensing and for thin-film materials characterization. These sensors include surface acoustic wave (SAW) devices, acoustic plate mode (APM) devices and quartz crystal microbalances (QCMs). His sensor research has been directed towards characterization and development of novel gas and liquid phase microsensors for species detection, viscosity sensing, and corrosion monitoring. Material characterization studies have included the investigation of polymer viscoelastic properties, cross-linking reactions, as well as determination of surface area and pore size distributions in porous films. He is particularly interested in interaction mechanisms between acoustic devices and the environment.

Marco Mascini is now full Professor of Analytical Chemistry at the University of Florence. From 1963 till 1986 he was Associate Professor at the University La Sapienza and at the University Tor Vergata in Rome. In Florence he is also the co-ordinator of Ph.D. courses in Analytical Chemistry. He was among the early researchers on ion-selective electrodes, being engaged on their preparation, characterization and analytical applications. He then directed his research interests to the development of electrochemical biosensors by coupling immobilized enzymes, bacteria and whole tissues with ion-selective electrodes and amperometric probes, to obtain new devices for clinical applications, especially in the field of continuous monitoring by developing probes and procedures for *ex vivo* and *in vivo* biosensors. He is also concerned in applying biosensors for the analysis of food and drugs and developing optical biosensors. He has published over 100 papers in these areas. He was the organizer of several international meetings on Chemical Sensors and Biosensors in Italy.

Toshiyuki Shono graduated on 1954 and received his Ph.D. (Dr. of Engineering) in 1960 from the Department of Applied Chemistry, Faculty of Engineering, Osaka University. He remained at Osaka University as an Associate Professor and became Professor for Analytical Chemistry in 1974 and moved to the Osaka Institute of Technology in 1990. He was recipient of the 1984 award presented by the Japan Society for Analytical Chemistry for his contribution to the host-guest chemistry of synthetic ionophores. His current research interests lie in analytical reagents, that is, development and synthesis of ionophores, application of ion-selective membrane electrodes and derivatization in chromatography. He has co-authored more than 250 articles on these topics.

Michael Thompson was born in Rotherham, U.K., in 1942. He received the B.Sc. degree in chemistry from the University College of Swansea, U.K. in 1966, and the Ph.D. degree in analytical chemistry from McMaster University, Canada in 1970. After a period as Science Research Council Post-Doctoral Fellow at the University College of Swansea, working on vacuum ultraviolet photoelectron spectroscopy, he became a Lecturer in Instrumental Analysis at Loughborough University of Technology, U.K. In 1976 he moved to the University of Toronto where he is now Professor of Analytical Chemistry. Currently, he also holds the position of Staff Research Scientist at Toronto General Hospital. Over recent years his research interests have been in photoelectron and Auger electron spectroscopy, lipid bilayer and Langmuir-Blodgett monolayer chemistry, and chemical and biosensor technology in general. Dr. Thompson is a fellow of the Royal Society of Chemistry and the Chemical Institute of Canada. In 1982 he was presented with the Ontario Confederation of University Faculty Associations Teaching Award for his efforts in education in analytical chemistry. The D.Sc. degree was awarded by the University of Wales in 1986. Dr. Thompson received the 1989 Fisher Scientific Lecture Award of the Canadian Society for Chemistry for his research in analytical chemistry. He serves on the Editorial Boards of several international journals.

Noboru Yamazoe, born in 1940, obtained his Dr. Eng. degree from Kyushu University in 1968 after majoring in applied chemistry. He became a Research Associate in 1968, an Associate Professor in 1969, and a full Professor in 1981 at Kyushu University. He has been interested in materials science and application of functional inorganic materials such as oxide semiconductors, solid electrolytes, and oxide catalysts, and is deeply concerned with chemical sensors. His laboratory has housed the office of the Japan Association of Chemical Sensors since the foundation of the Association. He has received awards from the Electrochemical Society of Japan (1988) and the Chemical Society of Japan (1990).
