(Received 26 September 1990 Revised 5 December 1990 Accepted 10 December 1990)

Summary—The feasibility of determining chlorinated, purgeable organic compounds (POCs) in aqueous samples by flame infrared-emission (FIRE) spectrometry was evaluated with a specially designed, multichannel, dispersive spectrometer having sufficient resolving power to prevent interference from large amounts of non-halogenated POCs that could also be present in the sample. The polychromator was based on a Czerny–Turner optical mounting with a 0.15-m focal length, a nominal focal ratio of $f/3$, and a reciprocal linear dispersion of $0.15 \mu\text{m}/\text{mm}$ in the first order. The HCl and CO_2 infrared emission bands (3.77 and $4.42 \mu\text{m}$, respectively) were monitored in two analytical channels, while a third reference channel, used for background subtraction, monitored the H_2O background emission at $2.8 \mu\text{m}$. Instrumental performance was evaluated with dichloromethane, trichloromethane, trichloroethylene, 1,1,2,2-tetrachloroethane and monochlorobenzene as test compounds, and parameters such as the linear dynamic range, reproducibility, detection limit and signal-to-noise ratio, and extent of spectral crosstalk between channels were determined. The feasibility of performing a quantitative analysis of a two-component mixture of dichloromethane and trichloromethane at trace levels was demonstrated.

Flame/furnace infrared-emission (FIRE) spectrometry is a relatively new laboratory technique that shows considerable promise in a number of important analytical areas.¹ The FIRE detector monitors well-defined infrared emission bands resulting from vibrationally excited molecules, such as CO_2 , H_2O , HCl and HF, that are produced when organic compounds containing C, H, Cl and F are combusted in a low-background hydrogen/air flame.² Alternatively, an electrically heated furnace can be used to produce infrared emission from vibrationally excited analyte molecules, without decomposition.³

Because FIRE spectrometry is a relatively new analytical technique, most of the initial studies have focused on exploring potential applications^{4–9} and improving instrumental performance.¹⁰ To date, FIRE spectrometry has been used for element-selective detection (of C, Cl and F) in gas and liquid chromatography,^{4–7} for determination of total inorganic carbon (TIC) in environmental water samples,⁸ for de-

termination of chloride and available chlorine in aqueous samples⁹ and for determination of ethanol in gasohol.³

In almost all previous FIRE applications,^{3,6–9} the infrared emission band was detected by using a simple filter radiometer consisting of transfer optics, a chopper, a commercially available optical notch filter for wavelength isolation, and a lead selenide photoconductivity detector. Although use of an optical notch filter to isolate the analytical emission band from the source background has the advantage of being simple, not subject to misadjustment, and capable of high optical throughput, commercially available stock interference filters were found to have a number of disadvantages. First, commercial filters were not always available for the optimum analytical wavelength,⁹ and the band-pass of the filter was sometimes too wide or too narrow for the infrared emission band of interest.⁹ Moreover, in some applications, combinations of filters were required to reduce spectral interference from intense background and concomitant emission bands.⁷ Finally, filter selection often required a compromise involving

*Author for correspondence

signal intensity, adequate background rejection and removal of spectral interference from other emission bands.^{7,9}

Because the FIRE system can detect chlorine-containing species that form HCl in the flame,^{2,7,9} one important application for FIRE spectrometry could be the determination of purgeable chlorinated organic compounds in aqueous samples.¹ Chlorinated organics are a type of environmental contaminant resulting from the improper disposal of such widely used industrial products as dry-cleaning agents, degreasing agents, and pesticides,¹¹ and from the chlorination of drinking water.¹² Many chlorinated compounds are either carcinogenic or have other associated health risks,¹¹ and their maximum contaminant level in drinking water is strictly regulated.¹²⁻¹⁴ Because water utilities must monitor chlorinated organics on a regular basis, FIRE might serve either as a method for the determination of purgeable total organic halides (purgeable TOXs) or as a rapid inexpensive screening procedure to determine whether an environmental sample required more extensive analysis by gas chromatography-mass spectrometry (GC-MS).

The FIRE analytical system developed for TIC determinations⁸ has been shown to be potentially useful for the determination of purgeable organic compounds (POCs) in water samples¹ when the detector is operated in the carbon-selective mode. Problems were encountered, however, when the FIRE system was used for the determination of chlorinated POCs¹⁵ in the chlorine-selective mode. Because the transmission characteristics of the 3.8- μm optical notch filter used to monitor the emission from HCl⁹ had a 0.1% transmittance in the vicinity of the 4.42- μm CO₂ infrared emission band, significant optical leakage of this band through the chlorine filter was observed whenever large amounts of CO₂-producing materials were also present in the flame. Filter bleed was not a serious obstacle in the chlorine-specific detection of compounds in gas chromatography⁷ because prior separation of the mixture always ensured that the amount of CO₂ present in the flame was relatively low. In the determination of chlorinated POCs, however, significant amounts of volatile, non-chlorinated organics presented a serious problem,¹⁵ requiring an improved wavelength isolation system.

The ideal wavelength isolation system for FIRE spectrometry would have a high luminosity-resolving power product,¹⁶ be capable of

producing the highest possible analyte-band-to-background ratio, have a variable spectral bandwidth, be tuneable for different wavelengths and permit selective wavelength monitoring of desired emission bands on a continuous basis. Wavelength isolation systems based on Fourier transform¹⁷ or Hadamard transform spectroscopy¹⁸ offer no multiplex or luminosity advantage¹⁶ in the case of FIRE spectrometry because the FIRE system appears to be flame-noise limited rather than detector-noise limited.^{6,7} Moreover, acquiring the complete infrared spectrum from an initial wavelength to a final wavelength is completely unnecessary, since only very specific regions of the infrared spectrum are of interest from a quantitative analytical standpoint.¹ Therefore, a non-transform approach involving a dispersive, multichannel spectrometer could be beneficial for FIRE spectrometry provided an optically fast system could be employed.

This paper reports the development of a direct-reading, multichannel spectrometer specifically designed for the determination of chlorinated POCs by flame/furnace infrared emission spectrometry. To evaluate the analytical performance of this newly developed FIRE spectrometer, the determination of five chlorinated POCs in aqueous samples was studied.

EXPERIMENTAL

FIRE detection system

The multichannel FIRE detector, shown schematically in Fig. 1, consists of an optical section and an electronic signal-processing section. The optical system collects, disperses and focuses the infrared radiation from the flame onto the infrared detector array which is located at the exit focal plane of the polychromator. The components were mounted on a 30.5 \times 53.3 \times 1.0-cm aluminum plate and consisted of a miniature capillary-head, hydrogen/entrained-air burner, external light collection optics, a polychromator, and three PbSe infrared detectors arranged in an array. As shown in Fig. 1, one of the detectors provides a reference signal, while the other two detectors provide analytical signals.

The miniature capillary-head burner was fabricated from an aluminum block and has been described previously.^{1,5} The burner head consists of a circular array of six capillaries surrounding a seventh, central capillary used for sample introduction into the flame. The

optimum flow-rate of hydrogen to the burner was 324 ml/min, with combustion supported only by entrained air. The hydrogen supply pressure was regulated at 0.75 atm with triple-stage regulation. The burner was enclosed in an aluminum shield and chimney assembly to minimize temperature fluctuations resulting from air drafts and other environmental effects.

The infrared emission from the flame was collected and focused onto the entrance slit of the polychromator by a back-collection mirror and two lenses. An $f/1$, 2.5-cm focal length, concave back-collection mirror (Model 44341, Oriel Corp., Stratford, CT) was positioned at the $2f$ point behind the flame to focus a 1:1 image of the flame onto itself. An $f/2$, 5-cm focal length CaF₂ lens (Model 43150, Oriel Corp.) was used to collect and collimate the flame infrared emission onto a second, identical CaF₂ lens that focused this radiation onto the entrance slit of the polychromator. A laboratory-constructed chopper, placed between the focusing lens and the entrance slit, modulated the infrared radiation at 530 Hz.

The polychromator, fabricated in the laboratory, was based on the symmetrical Czerny-Turner design.¹⁶ The optical components and adjustable optical mounts utilized in the polychromator were mounted in a

19.0 × 18.1 × 13.3-cm light-tight box constructed from aluminum sheet. The inside of the box was painted flat black to reduce reflections. The entrance slit of the polychromator was constructed by splitting a two-edged razor blade in half and placing the sharp edges over a 5-mm diameter hole drilled in the front plate of the polychromator. The two portions of the razor blade were held in place by screws in the front plate of the polychromator and could be adjusted to form any desired slit width. In this study, the slit width was fixed at 2 mm for all experiments.

The infrared radiation passing through the entrance slit of the polychromator was collimated and directed onto a grating by an $f/3$, 15-cm focal length, concave mirror. The mirror was placed at an angle of 15° to the entrance optical axis (Fig. 1). The 5 × 5-cm plane diffraction grating was ruled at 40.96 grooves/mm and was blazed for 3.2 μm (Model 35-63-06-811, Milton Roy Co., Rochester, NY). The dispersed infrared radiation from the grating was focused onto the PbSe detectors by a second, $f/3$, 15-cm focal length concave mirror. A long-pass filter with a cut-on wavelength of 3.0 μm at 5% absolute transmittance (Part R1-3000F, Corion, Holliston, MA) was placed over the entrance slit as an order-sorting filter.

Three infrared emission bands were detected with three PbSe infrared detectors located in the exit focal plane of the spectrometer (Fig 1). Two 1 × 1-mm detectors (Part #BF1, Cal-Sensors, Inc, Santa Rosa, CA) were used to detect portions of the emission bands due to CO₂ and H₂O. A 2 × 2-mm PbSe detector (Part #BR2, Cal-Sensors, Inc) was used to detect a portion of the P-branch of the HCl stretching vibration. The overall detector dimensions were 3.0 × 1.5 × 0.64 mm and 4.5 × 2.5 × 0.64 mm for the 1 × 1-mm and 2 × 2-mm response areas, respectively. Segments of tinned copper wire (0.76 mm diameter × 25.4 mm long) were soldered to the detector leads and served as the electrical connection.

The PbSe infrared detectors were placed in a detector carriage (Fig. 2) fabricated from a 2.54 × 3.81 × 1.25-cm block of plexiglas[®]. A slot in the plexiglas[®] block (Fig 2) allowed the detectors to be adjusted for maximum signal response. The detectors were glued to plexiglas[®] mounts with silicone sealant. The detector mounts were placed in the slot of the detector carriage, and holes (1.0-mm diameter) for each detector lead were drilled approximately 0.8 cm from the top and bottom of the detector carriage. Segments of standard, solid-core, electrical wire (1-mm diameter, 2-cm long) were positioned in these holes, flush with the front of the detector carriage. The leads of the detectors were soldered onto the wire segments (allowing some movement of the detectors in the detector carriage), and the surplus lead was removed. The connections to the preamplifier circuits were made from the ends of the wire segments

that protruded from the back of the detector carriage.

The detector carriage with the detectors placed inside was mounted over a 2.54 × 2.54-cm opening in the front plate of the polychromator at the exit focal plane. In this study, the 1 × 1-mm detectors monitored a portion of the flame water-emission band centered at 2.9 μm (detector D₁, Fig. 2) and the asymmetric stretching vibration of CO₂ centred at 4.42 μm (detector D₃, Fig. 2). A portion of the P-branch of the HCl stretching vibration centered at 3.77 μm was detected with the 2 × 2-mm detector (detector D₂, Fig. 2).

The electronics associated with the FIRE detector include an optical chopper, lock-in amplifier (LIA), detector and operational amplifier power supplies, preamplifier circuits and a recorder/integrator. The preamplifier circuits used with the PbSe detectors have been described previously.⁶ The three circuits were placed on a single breadboard and located in close proximity (approximately 4 cm) to the detector carriage. A 9.5 × 5.8 × 8.3-cm aluminum housing, mounted on the front plate of the polychromator, was used to enclose the detectors, detector carriage, and preamplifier circuits.

The detectors were operated at room temperature and powered from a common split source consisting of a 122 V battery supply. The bias voltage for each PbSe detector was independently controlled by a separate potentiometer in series with the common power supply. For this study, the bias voltage (*i.e.*, the actual voltages across the detector itself) for the 2 × 2-mm HCl detector was fixed at 66 V, and

Fig 2 Schematic diagram and dimensions for the plexiglas[®] detector carriage. D₁, detector for H₂O reference channel, D₂, detector for HCl analytical channel, D₃, detector for CO₂ analytical channel, ●, holes for detector leads

the bias voltages of the 1×1 -mm H_2O and CO_2 detectors were adjusted with the potentiometers as described below. The operational amplifiers (Part #TLO71, Texas Instruments, Dallas, TX) employed in the preamplifier circuit were powered at ± 15 V from a regulated bipolar power supply (Part #2718, Heath Co., Benton Harbor, MI). The amplifier output signals from the preamplifier circuits were demodulated by a lock-in amplifier (Model #3962, Ithaco, Ithaca, NY) operated in the differential input (*i.e.*, subtracted) mode. A 1-sec time constant was used for all measurements. The signal was recorded on a recorder/integrator (Model #3394A, Hewlett-Packard Corp., North Hollywood, CA).

Purging apparatus

The purging apparatus has been described previously^{8,9} and consists of two 5-ml demountable purge tubes connected in parallel by polyethylene tubing and two three-way switching valves (Fig. 1). One of the purge tubes serves as the sample chamber and the second as the reference chamber. An opening located at the top of each purge tube was fitted with a rubber septum to allow samples to be introduced by a syringe (Model 1001, Hamilton Co., Reno, NV). Each purge tube can be disconnected easily for removal of the spent aqueous sample and for cleaning.

The volatile components in the aqueous samples were purged into the flame of the FIRE detector with helium maintained at a flow-rate of 100 ml/min with a rotameter (Model 1110-05F1A1A, Brooks Instrument Div., Emerson Electric Co., Hatfield, PA). The supply pressure of the helium was regulated at 0.75 atm with triple-stage regulation.⁸

Reagents

All chemicals were reagent grade and used without further purification. Dichloromethane was obtained from Mallinckrodt, Inc. (St Louis, MO), trichloromethane from Sargent-Welch Scientific Co. (Skokie, IL), trichloroethylene from Aldrich Chemical Co., Inc. (Milwaukee, WI), monochlorobenzene from J. T. Baker Chemical Co. (Phillipsburg, NJ), and 1,1,2,2-tetrachloroethane from Fisher Scientific Co. (Fair Lawn, NJ). Aqueous standard solutions having concentrations of 5, 10, 20, 40, 60, 80, and 100 ppm v/v were prepared in standard flasks by measuring the appropriate volume of the compound with a μl syringe (Model 701,

Hamilton Co.) and diluting it to volume with demineralized water.

Procedure

Before use, the multichannel FIRE detection system was allowed to warm up for approximately 1 hr. During this initial stabilization period, the switching valves were set so that the helium purge gas was directed through the dry reference purge tube (Fig. 1) and into the flame. When the instrument had stabilized, the phase angle of the LIA was set in the unsubtracted mode of operation^{6,7} by using the background signal from the HCl detector. Once the phase angle was set, the LIA was returned to the subtracted mode of operation. The bias voltage of the H_2O detector was then adjusted until the reading of the LIA fluctuated around 0.0 mV. After this adjustment, the HCl analytical channel was disconnected from the LIA, and the CO_2 analytical channel was connected. In a similar manner, the bias voltage of the CO_2 detector was adjusted until the output of the LIA fluctuated around 0.0 mV. Sample determinations in either analytical channel could then be made by connection of the appropriate detector output to the LIA, or by employing two LIAs and two chart recorders.

After the initial establishment of the operating conditions of the LIA, the helium purge gas was redirected through the sample purge tube and after about 30 sec a 1.0-ml aliquot of the sample containing a chlorinated POC was injected through the septum located at the top of the purge tube. The volatile components in the aqueous sample were purged from solution and carried into the flame for combustion and vibrational excitation of the CO_2 and HCl. After the peak profiles had been acquired, the helium purge gas was redirected to the reference purge tube. The sample purge tube was then disconnected from the purge device and rinsed with demineralized water to remove the spent aqueous sample. Calibration graphs of peak height *vs* concentration for each individual compound were prepared by repeating the procedure with the other chlorinated POC standards.

All data reported in the CO_2 analytical channel were corrected for spectral crosstalk between the channels by subtracting 1.35% of the peak-height signal recorded in the HCl channel from the peak-height signal in the CO_2 channel. No corrections were required for data obtained in the HCl channel.

RESULTS AND DISCUSSION

Optical design

Although a dispersive optical system is expected to provide superior wavelength isolation compared with a filter instrument, the luminosity¹⁶ of the dispersive system is expected to be much less. If luminosity is sufficiently reduced, no signal will be detected. As a result, the light throughput of the optical system was an important consideration in the design of the polychromator used in this study. An initial attempt to design an $f/2$ polychromator was not successful because a large off-axis incident angle (approximately 50°) was required to fill the grating with light. Because of coma and astigmatism,¹⁶ this large mirror angle severely distorted the entrance-slit images that were formed at the exit focal plane of the polychromator. As a result, the direct-reading, multichannel, infrared spectrometer ultimately employed in this study was based on a Czerny–Turner optical configuration with a 0.15-m focal length and an $f/3$ nominal focal ratio.

In order to maximize the light throughput of the polychromator, the collimating mirror should be completely filled with light. Since an $f/3$ lens was not available, a dual-lens system (Fig. 1), consisting of two CaF_2 lenses that formed a 1:1 image of the flame on the entrance slit of the polychromator, was employed to maximize the light throughput. Although the dual-lens arrangement overfilled the collimating mirror of the polychromator, no significant problems from stray light were observed. The light-collection efficiency of the optical system was increased by an additional factor of two by placing a back-collection mirror behind the burner at twice the focal length of the mirror so as to form a 1:1 image of the flame on itself.

Optical alignment of the system

The detector carriage (Fig. 2) was designed to allow detectors to be easily positioned in the vertical and horizontal directions of the exit focal plane. A slot, machined in the carriage, allowed the detector mounts (with the detectors glued onto them) to move freely in the horizontal direction, and yet be held firmly enough to stay in position in the exit focal plane. (Vertical adjustment could be attained by raising or lowering the entire carriage.) Thus, different wavelength regions within the exit focal plane of the polychromator could be monitored by the appropriate positioning of detectors. In ad-

dition to providing a convenient means of detector positioning, the plastic detector carriage also prevented contact of the detector leads with the aluminum polychromator housing.

From previous work,^{2,7} the combustion of chlorinated organic compounds in a hydrogen/air flame was known to produce infrared emission bands from HCl as well as from CO_2 and H_2O . The spectra shown in Fig. 3 were obtained with a Fourier transform infrared spectrometer (appropriately reconfigured for emission²) and illustrate the regions where the infrared emission from CO_2 , H_2O and HCl occurs. As shown in Fig. 3B, the CO_2 emission band is centered at $4.42 \mu\text{m}$, while the R- and P-branches of the HCl emission band (Fig. 3C) occur in the $3.17\text{--}4.55 \mu\text{m}$ wavelength region. Although the R-branch of the HCl emission is completely free from spectral overlap with the CO_2 emission band, a small amount of spectral overlap does occur between the P-branch of the HCl emission and the emission from CO_2 . The corresponding flame background spectrum due

Fig. 3 Fourier-transform infrared emission spectra (A) Transmission spectrum of the long-pass filter used in the multichannel FIRE detector (maximum T, 75%, cut-on wavelength of $3.0 \mu\text{m}$ at 5% T, <0.10% T elsewhere), (B) FIRE spectrum from a hydrogen/entrained-air flame containing CO_2 , (C) FIRE spectrum from a hydrogen/entrained-air flame containing HCl, (D) background emission from a hydrogen/entrained-air flame in the absence of CO_2 and HCl.

to water emission bands is shown for comparison in Fig. 3D. Figure 3A shows the spectrum of the 3.0- μm long-pass filter used for order sorting and attenuation of the water reference band for subtraction, as discussed in the following section

The width of the spectral observation window selected for this study, although adjustable, was determined by the need to monitor simultaneously the emission bands from H_2O and CO_2 , centered at 2.9 μm and 4.42 μm , respectively. Since the more intense portion of the P-branch of the HCl stretching vibration (centered at 3.77 μm) was approximately at the center of the spectral region of interest, the alignment of the polychromator was performed for this wavelength by positioning the HCl detector in the middle of the detector carriage. The wavelength axis of the polychromator was set by replacing the 3.0- μm long-pass filter with a 3.7- μm band-pass filter⁹ (full width at half-maximum transmission, FWHM, of 0.11 μm) and rotating the grating until the maximum signal due to background water emission was detected in the HCl analytical channel

The optimum locations of the CO_2 and H_2O detectors in the exit focal plane were determined in a manner similar to that used to optimize the HCl analytical channel. To set the position of the CO_2 detector, a 4.4- μm band-pass filter⁸ (FWHM 0.15 μm) that isolated the CO_2 emission band was placed in front of the entrance slit of the polychromator. The CO_2 detector was then moved horizontally along the detector carriage until the maximum signal due to background water emission was found.

Finally, a 3.0- μm band-pass filter⁶ (FWHM 0.12 μm) was placed in front of the entrance slit, and the H_2O detector was moved horizontally along the detector carriage until the signal from the water background emission was maximized. After this horizontal alignment with the 3.0- μm filter, the H_2O detector was moved approximately 1 mm toward the short-wavelength side of the detector carriage. This slight adjustment reduced spectral overlap from the R-branch of the HCl stretching vibration and placed the detector in a region of the spectrum that was attenuated by the 3.0- μm long-pass filter. Partial attenuation of the water emission intensity was found to be beneficial because it reduced the magnitude of the water background signal to a level more closely matching that experienced by the HCl and CO_2 detectors

All detectors were maintained at the same vertical height in the detector carriage. This ensured that each detector sampled the same vertical portion of the flame.

Detector dimensions

Once the detector is properly positioned in the focal plane of the polychromator, increasing the width of the detector causes a larger spectral band-pass to be monitored. An increase in spectral band-pass may cause an increase in detector noise (due to increased detector area¹⁹), an increase in background noise (due to flame water emission), and, for analytical signals which are broader than the band-pass of the instrument, an increase in signal from the analyte

In the case of FIRE, the increase in detector noise will not be significant because detector noise is much less than flame background noise^{6,7}. Thus, as long as the signal from the analyte increases faster than the flame background noise, an increase in spectral band-pass will result in an improvement in signal-to-noise ratio (SNR). This situation will be encountered in cases where the detector monitors a region of the spectrum in which the analytical signal is relatively diffuse and the flame water bands are relatively weak

In the case of HCl emission, the rotational fine structure spreads the analytical signal out over a large wavelength region, which is mostly free from intense flame water background emission. Thus, increasing the width of the detector is expected to improve the SNR in the HCl channel, as long as the system remains flame-background limited. For spectral bands such as that of CO_2 , however, the analytical signal is relatively dense, and the water background emission is more intense (Fig. 3). Thus, increasing the spectral band-pass (detector area) does not substantially increase the percentage of the CO_2 emission band sampled, compared with the increase in background, and the SNR is not improved.¹⁹ For these reasons, the HCl detector was able to utilize an area which was four times larger (2 \times 2 mm) than that employed by the detector in the CO_2 channel (1 \times 1 mm)

Reciprocal linear dispersion

The theoretical reciprocal linear dispersion of the multichannel FIRE polychromator may be calculated¹⁶ from equation (1)

$$R_d = \frac{d \cos \theta}{fm} \quad (1)$$

where R_d is the reciprocal linear dispersion, θ is the angle of diffraction, f is the focal length of the system, m is the order, and d is the grating constant. From equation (1), the reciprocal linear dispersion for the FIRE polychromator was found to be $0.16 \mu\text{m}/\text{mm}$ in the first order for a 15° angle of diffraction. From this value of R_d and the width of the detectors, the spectral band-pass of each detector could be calculated. The $2 \times 2\text{-mm}$ detector in the HCl channel sampled a wavelength region of $0.32 \mu\text{m}$, centered at $3.7 \mu\text{m}$. The $1 \times 1\text{-mm}$ detectors in the H_2O reference channel and the CO_2 analytical channel each sampled a bandwidth of $0.16 \mu\text{m}$, centered at 2.8 and $4.4 \mu\text{m}$, respectively.

For comparison purposes, the value of R_d for the polychromator was determined experimentally by measuring the distance between the centers of the HCl and CO_2 detectors. From the measured distance and the known wavelength interval between the HCl and CO_2 detectors, an R_d of $0.15 \mu\text{m}/\text{mm}$ was obtained—in good agreement (6%) with the theoretically expected value ($0.16 \mu\text{m}/\text{mm}$). From the experimental R_d , the center wavelength sampled by the H_2O detector was calculated from the measured distance (center-to-center) between the HCl detector and the H_2O detector and found to be $2.8 \mu\text{m}$.

Spectral overlap in the polychromator system

Spectral overlap by a portion of the HCl emission band (Fig. 3) results in a spectral interference that increases the signal level in the CO_2 analytical channel whenever a chlorinated organic compound is combusted. In order to determine the extent to which this spectral overlap affects the performance of the instrument, the signal intensities due to the combustion of Cl_2 gas in the flame were recorded in both the HCl and CO_2 channels under identical conditions. The Cl_2 gas was produced by oxidation of a 10 mM sodium chloride solution with permanganate/sulfuric acid mixture as described earlier.⁹ From this experiment, it was found that the ratio of the peak-height signal in the CO_2 channel (due to HCl) to the peak-height signal in the HCl channel was 1.74 , and that the signal recorded in the HCl channel would contribute 1.35% of its total intensity to the signal in the CO_2 channel. To compensate for this spectral overlap (channel crosstalk), all measured peak-height signals for the CO_2 channel were corrected by subtracting 1.35% of the peak-height signal recorded in the HCl channel

The effect of spectral overlap by a portion of the CO_2 emission band on the signal observed in the HCl channel was also investigated. This was accomplished by injecting 0.1-ml aliquots of CO_2 gas into the sample purge tube (Fig. 1) and recording the peak-height signals in both analytical channels. (This amount of CO_2 is equivalent to that obtained by purging 1 ml of an aqueous sample containing 64.3 mg/l of pentane.) Since no signal was observed in the HCl channel upon injection of the CO_2 gas sample, it was assumed that any signal that might have been present had a peak height between zero and one-half of the background peak-to-peak noise ($N_{\text{p-p}}$) in the HCl channel. Using one-half $N_{\text{p-p}}$ in the HCl channel as an estimate of the worst possible situation, the *minimum* ratio of the intensity in the HCl channel to that in the CO_2 channel was calculated to be 1.3192 . This result indicates that for the sample concentrations used in this study, the wavelength region monitored by the HCl detector is relatively free from interfering effects due to CO_2 emission. Therefore, no correction for CO_2 -producing species was applied to the signal measured in the HCl channel.

Background subtraction

Under flame-noise limited conditions, background subtraction has proven to be an effective means of increasing the signal-to-noise ratio (SNR) obtained with the FIRE detector.^{6,7} For background subtraction to be successful, however, certain prerequisites must be satisfied. (1) Background fluctuations in the analytical channel must be sampled independently of the analytical signal. (2) Background fluctuations must be additive with respect to the analytical signal. (3) Background fluctuations in the reference and analytical channels must be temporally correlated. Background subtraction will not compensate for detector noise, because detector noise (excluding such common-mode noise as power supply ripple) in each channel is independent (*ie*, not temporally correlated). In fact, whenever a detector-noise limited situation is encountered, subtraction of the signal in the reference channel from that in the analytical channel can actually increase the noise and degrade the SNR through a combination of the two independent noise sources¹⁶ according to

$$N_t = \sqrt{N_a^2 + N_r^2} \quad (2)$$

where N_a is the detector noise in the analytical channel, N_r is the detector noise in the reference

channel, and N_t is the total detector noise resulting from background subtraction

In previous work employing background subtraction as a means of noise reduction,^{6,7} a dual-channel system was formed by using a beam splitter to divide the radiation from the flame into two spatially separated beams. Although the beam-splitter approach is convenient when filters are used as the means of wavelength isolation, a beam splitter also reduces the intensity of available radiation in the analytical channel. In the polychromator system, no beam splitter is needed, and the three optical channels are separated spatially by means of the diffraction grating. As a result, more of the radiation from the source can be made available for detection.

With the polychromator system, two detector signals were fed into the LIA, which was capable of subtracting the signal in the reference channel (*i.e.*, the flame background) from the signal in the analytical channel (*i.e.*, the analytical signal plus the flame background). As in previous work,^{6,7} the background signal in the HCl channel was used in the unsubtracted mode of operation to set the phase angle automatically

After phase-angle adjustment, the amplifier was returned to the subtracted mode, and the output from the LIA was then adjusted to zero by equalizing the background signal levels in each channel. In the dual-channel, filter, FIRE detector, equalization was accomplished opti-

cally by means of an iris diaphragm.^{6,7} With the polychromator system, this approach cannot be used, and equalization was accomplished by adjusting the bias voltage of the reference detector (approximately 27 V) until the background level from the reference detector matched that from the HCl detector. The bias voltage for the HCl detector was set at 66 V, which was the highest obtainable with the 122 V power supply. (In the preamplifier circuit, the load resistor was in series with the detector, so the circuit behaved as a voltage divider.) In a similar manner, the bias voltage to the CO₂ detector was subsequently adjusted to approximately 32 V with the potentiometer to match the background level in the CO₂ analytical channel with that in the H₂O reference channel. (The magnitude of this voltage adjustment could be experimentally determined. When the background levels were properly equalized, blocking the entrance slit of the polychromator did not change the subtracted output of the LIA.)

To demonstrate the correlation of the noise fluctuations in the three channels (H₂O, HCl, CO₂), background noise profiles as a function of time were obtained simultaneously in the unsubtracted mode of operation (Fig 4A) by using three lock-in amplifiers and three recorders. Figure 4A shows that the noise in the single-channel FIRE mode of operation is comparable for all three channels, even though the HCl detector area is four times that of the other two detectors—behavior characterizing a

Fig 4 Comparison of (A) flame background and (B) detector noise fluctuations for the three FIRE polychromator channels

flame-noise limited situation.¹⁹ Figure 4A also shows that the fluctuations in the two analytical channels (HCl and CO₂) are temporally correlated with the background fluctuations in the H₂O reference channel. Thus, real-time subtraction of the flame background in the reference channel from the background in the analytical channels should result in a lower noise level.

Deviations from perfect noise correlation in Fig 4A are most probably due to uncorrelated detector noise. Detector noise profiles (Fig. 4B) were obtained by blocking the entrance slit of the polychromator and recording the associated noise under the conditions used to obtain the background noise profiles (Fig. 4A). In a detector-noise limited situation, the root-mean-square (rms) noise is often proportional to the square root of the detector area,¹⁹ and, as expected, the noise in the HCl channel (Fig. 4B) is approximately twice that observed in either the H₂O or CO₂ channel.

The effect of the background subtraction procedure was studied by recording the peak-to-peak noise (N_{pp}) in the subtracted signal as a function of the magnitude of the subtracted output. Figure 5 shows a plot of the rms noise (taken as 1/5 of the measured N_{pp}) as a function

of different levels of background compensation from undercompensated ($A - B > 0$) to overcompensated ($A - B < 0$). In Fig. 5A, background water emission in the reference channel is being subtracted from the background water emission present in the HCl analytical channel. In Fig. 5B, background water emission in the reference channel is being subtracted from the background water emission present in the CO₂ analytical channel. It is readily apparent from Fig. 5 that the minimum rms noise in both analytical channels occurs when the magnitude of the subtracted output from the lock-in amplifier is zero. This indicates that the flame-background noise in all channels is correlated in magnitude as well as in time.

Subtraction of the H₂O background reduced the noise by factors of 3.2 and 3.5 for the HCl and CO₂ analytical channels, respectively. From equation (2) and the noise profiles in Fig 4, it can be readily determined that the residual noise in the subtracted output can be almost entirely accounted for by summing the detector noise in the reference and analytical channels [equation (2)]. This indicates that the majority of the flame noise has been removed by the subtraction process, and that the dual-channel FIRE system is nearly detector-noise limited.

Fig 5 Relative rms noise in the HCl (A) and CO₂ (B) analytical channels, plotted as a function of amplifier output resulting from subtraction of different levels of background compensation

Selection of analytical conditions

In single-component determinations, the instrumental operating conditions are optimized for the particular component of interest. However, in simultaneous multicomponent determinations a compromise must be reached for all components, since the operating conditions cannot be optimized for each component individually.²⁰ Since the HCl emission intensity that occurs from the combustion of a chlorinated organic compound is lower than the corresponding CO₂ emission intensity,² the multi-channel FIRE detection system was optimized to produce the highest possible SNR in the HCl analytical channel.

For these studies, a 50 ppm v/v aqueous standard solution of trichloromethane was used to determine the effect of helium purge gas flow-rate and flame fuel-to-oxidant ratio on the SNR in the HCl analytical channel. As observed in previous studies,^{7,9} the hydrogen/entrained-air flame produced SNRs for chlorine that were approximately 8.5 times greater than those obtained under fuel-lean flame conditions.

Analytical performance of the multichannel FIRE detector

The performance of the multichannel, dispersive FIRE spectrometer was evaluated by injecting aqueous solutions of five chlorinated POCs into the sample purge device according to the procedure outlined in the experimental section. Dichloromethane, trichloromethane (trihalomethane or THM), trichloroethylene, monochlorobenzene and 1,1,2,2-tetrachloroethane were selected for study because of their potential importance in environmental monitoring.

Figure 6 shows typical peak profiles obtained in the HCl and CO₂ analytical channels (CO₂ shown at one-eighth actual height) by purging the five volatile compounds (40 ppm v/v) into the hydrogen/entrained-air flame. The differences in the trailing edges of the peak profiles obtained for each compound are undoubtedly due to differences in the purging efficiencies for the individual compounds. The purging efficiency determines the rate at which a compound is released from solution and is a function of a number of factors such as volatility, boiling point and solubility of the compound in water.²¹⁻²³

Small negative signals were observed in the leading edge of the peaks obtained in the HCl channel. These negative pen deflections, which may result in part from the difference in size of the HCl and H₂O detectors, have been observed in previous work⁹ and do not affect the analytical results.

The total time required for signal acquisition from a chlorinated POC standard was approximately 3 min (from sample injection to purge-tube disconnection and clean-up). Maintaining

Fig. 6. Peak profiles obtained with the multichannel FIRE detector. Signals obtained from 1.0-ml injections of 40 ppm v/v aqueous standards: (1) Dichloromethane, (2) trichloromethane, (3) trichloroethylene; (4) 1,1,2,2-tetrachloroethane, (5) monochlorobenzene. Peaks shown for CO₂ channel are 1/8 of actual height.

a flow of dry helium through the reference purge device (Fig. 1) to the flame between sample determinations was found to be beneficial in reducing baseline drift and removing residual moisture on the inside walls of the sample introduction capillary.

Reproducibility The precision of the signals obtained by the FIRE technique was studied by recording the peak-height signals from eight injections of 20 ppm v/v standard solutions of the five chlorinated POCs. Peak heights were measured from the baseline and negative pen deflections observed for the HCl channel were ignored. The results are shown in Table 1.

For the five compounds studied, the average relative standard deviation (RSD) of the peak-height measurements was 3.8% and 3.4% for the HCl and CO₂ analytical channels, respectively. The poorest reproducibilities were obtained for 1,1,2,2-tetrachloroethane and chlorobenzene—compounds with relatively high boiling points (146 and 132°, respectively). Since broad peak profiles were observed in both the HCl and CO₂ channels for 1,1,2,2-tetrachloroethane (Fig. 6), poorer purging efficiency most probably accounts for the poorer reproducibility of the peak-height measurements. In the case of chlorobenzene, however, the peak profile obtained in the CO₂ channel indicates relatively good purging efficiency. In this case, poorer reproducibility for peak-height measurements in the HCl channel may simply reflect the relatively small amount of chlorine present in the standard solution.

Calibration graphs Calibration plots for each compound were prepared by purging 1-ml injections of 5–100 ppm v/v standard solutions according to the experimental procedure. The correlation coefficients (Table 1), based on only concentrations within the linear dynamic range of the system, indicate that the overall linearity of the individual curves is reasonably good.

The slopes of the individual calibration lines for the HCl and CO₂ channels are reported in Table 1 as mm/μmole Cl and C, respectively. If the combustion and purging efficiencies for each compound were the same, the slopes obtained within each channel for the five different compounds would be equal. It is clear from Table 1 that this is not the case. The smallest slopes are observed for 1,1,2,2-tetrachloroethane in both the HCl and CO₂ channels, again suggesting poor purging and possibly poor combustion efficiency for this compound. The lack of agreement in the slopes means that the FIRE system,

as currently configured, cannot be used for the determination of total organic halide (TOX) in unknown aqueous multicomponent mixtures of chlorinated hydrocarbons without prior separation of the mixture

Detection limits The detection limits for the five compounds, defined as twice the rms noise, are given in Table 1 for both the HCl and CO₂ channels. Although the detection limits in the HCl channel with the present system are all in the low ppm range, they are too high by a factor of about 100 to be useful for screening drinking water samples. The sample size used in this study (1 ml), however, is less than that generally employed in such analyses (5–10 ml volumes are more typical²⁴) Lower detection limits could be obtained by purging a larger volume of sample, by increasing the efficiency of the purging process by heating the sample, and by employing existing purge-and-trap technology.²⁴

Two-component mixture analysis. Although it is not possible to analyze a mixture of several unknown components directly with the information available in a single channel, because the calibration curves are different for different compounds, analysis of a mixture of two known components should be possible by use of information available from two analytical channels. To demonstrate the feasibility of using the system in the determination of individual component concentrations in a two-component mixture, three dichloromethane/trichloromethane mixtures in water were prepared and analyzed. The concentrations of dichloromethane and trichloromethane in the aqueous samples were 10/10, 20/10, and 10/20 ppm v/v, respectively. The peak-height emission signals from each mixture were recorded simultaneously in both the HCl and CO₂ analytical channels, according to the procedure outlined in the experimental section. The slopes of previously prepared calibrations graphs for dichloromethane and trichloromethane in the HCl and CO₂ channels were used to perform the necessary calculations.

Since the total emission intensity recorded for each channel should be equal to the sum of the individual emission intensities due to dichloromethane and trichloromethane, their individual concentrations in the mixture may be found by solving the following matrix equation

$$\begin{bmatrix} I_T^{\text{HCl}} \\ I_T^{\text{CO}_2} \end{bmatrix} = \begin{bmatrix} m_{\text{dichloro}}^{\text{HCl}} & m_{\text{trichloro}}^{\text{HCl}} \\ m_{\text{dichloro}}^{\text{CO}_2} & m_{\text{trichloro}}^{\text{CO}_2} \end{bmatrix} \begin{bmatrix} C_{\text{dichloro}} \\ C_{\text{trichloro}} \end{bmatrix} \quad (3)$$

where I_T represents the total intensity in the given channel, m is the slope of the calibration

curve for the given component in a given channel, and C is the concentration of the given component. Solving equation (3) for the individual concentrations of the two components gives

$$\begin{bmatrix} C_{\text{dichloro}} \\ C_{\text{trichloro}} \end{bmatrix} = \begin{bmatrix} m_{\text{dichloro}}^{\text{HCl}} & m_{\text{trichloro}}^{\text{HCl}} \\ m_{\text{dichloro}}^{\text{CO}_2} & m_{\text{trichloro}}^{\text{CO}_2} \end{bmatrix}^{-1} \begin{bmatrix} I_{\text{T}}^{\text{HCl}} \\ I_{\text{T}}^{\text{CO}_2} \end{bmatrix} \quad (4)$$

Table 2 compares the actual and experimentally determined concentrations of dichloromethane and trichloromethane in the three synthetic two-component mixtures. The results obtained with the FIRE detector were based on the average peak-height signals for four replicate injections of 1-ml aliquots of the synthetic mixture. As shown in the table, the average relative error between the results obtained with the FIRE detector and the nominal concentrations in the synthetic mixture was of the order of 12%—a reasonable value from a trace analytical standpoint.

CONCLUSIONS

The feasibility of fabricating a multichannel, dispersive spectrometer with sufficiently high optical throughput for use in flame infrared emission spectrometry was demonstrated. Because of spectral overlap of the HCl emission band with the CO₂ emission band, signals in the HCl channel were found to contribute 1.35% of their intensity to those in the CO₂ channel. The wavelength region isolated by the HCl detector was found to be free from measurable interfering effects from CO₂ emission. Therefore, this instrument could be useful for the determination of chlorinated POCs in aqueous samples, even in the presence of significant amounts of volatile, non-chlorinated, CO₂-producing contaminants.

The feasibility of using the specially designed polychromator to determine chlorinated POCs in aqueous samples by flame infrared emission spectrometry was demonstrated with dichloromethane, trichloromethane, trichloroethylene, 1,1,2,2-tetrachloroethane and chlorobenzene as test compounds. With a 1-ml aqueous sample,

detection limits for Cl were found to be in the 0.76–4.8 mg/l range. Analytical plots of peak height *vs.* concentration were linear up to 100 ppm v/v for dichloromethane, trichloromethane, trichloroethylene, and 1,1,2,2-tetrachloroethane, and 40 ppm v/v for chlorobenzene.

The signal obtained in the CO₂ analytical channel gives the FIRE detector an alternative way of determining halogenated POCs as well as the potential for determining non-halogenated POCs. With the CO₂ analytical channel and a 1-ml aqueous sample size, detection limits for C in the five compounds were found to be in the 52–280 µg/l. range. Plots of peak height *vs.* concentration were linear up to 100 ppm v/v for dichloromethane, trichloromethane and 1,1,2,2-tetrachloroethane, and about 40 ppm v/v for trichloroethylene and chlorobenzene.

It was shown that a two-component mixture of dichloromethane and trichloromethane at trace levels could be analysed quantitatively with precisions that were reasonable for trace analysis levels (about 12%). Because the slopes of the calibration graphs for the two compounds were not identical, the determination required data from both the HCl and CO₂ analytical channels. Extension of the method to mixtures containing a larger number of components is theoretically feasible, if additional analytical channels can be employed (the HF channel,⁷ for example).

Although the detection limits obtained with the present FIRE system in the chlorine mode for the chlorinated hydrocarbons in aqueous samples are too high by a factor of 10–100 for routine environmental screening applications,^{12–14} the sample size used in this feasibility study was quite small. Lower detection limits should be easily achievable through a number of improvements, however, such as purging a larger sample volume, heating the purge device to increase purge efficiency, and/or using conventional purge-and-trap technology to preconcentrate the sample prior to discharge into the flame.²⁴ Even at its present stage of development, the FIRE polychromator may still

(Received 14 April 1990 Revised 15 August 1990 Accepted 21 September 1990)

Summary—An electrolytic device for decomposition of water has been developed which readily gives hydrogen and oxygen for isotopic measurement with a mass spectrometer. A 20- μ l sample can be decomposed quantitatively in 10 min with good reproducibility. The results produced are comparable with those obtained by reduction with uranium.

Production of hydrogen from water is vital in the mass spectrometric analysis of water for isotopic ratio determinations. The methods available in the literature¹ are: (a) reduction with heated metals such as uranium and zinc, (b) reduction on heated filaments, (c) reduction by compounds such as calcium hydride and lithium aluminium hydride, (d) equilibration of water with hydrogen of known composition and (e) electrolysis. The first method is usually used for routine work. The other methods are less frequently used owing to their lower efficiency or greater fractionation problems. All these methods except electrolysis involve the interaction of water with some other reagent, which may be a source of fractionation or memory effects to a variable degree. Electrolysis appears to be a neat method; the fractionation problems associated with it may be overcome if the sample is completely electrolysed. In the electrolysis of water, the electrolytic fractionation factor with respect to the ¹⁶O/¹⁸O isotopes is only about 1.01–1.03. Thus, electrolysing only 90% of the water introduces a maximum error of only 0.6% in oxygen isotope analysis. However, the fractionation factor with respect to the ¹H/²H isotopes has been reported to range from 3 to 10.¹ It can be shown that even with a fractionation factor of only 3, electrolysing 99.72% of a sample of natural water will result in a deuterium concentration in the gas that is 14% too low and even electrolysing all but 0.0085% of the

water will result in a 4% negative error in the deuterium determination.¹

Wright² developed a method in which water was fed continuously into a V-shaped electrolytic cell operated under constant volume, temperature and current conditions. At equilibrium, which was reached within seven days, the number of moles of deuterium put into the cell as feed water was equal to the number of moles of deuterium leaving the cell as electrolysed gas and water vapour. The average deviation from the mean was 0.0002 mole%. If we could avoid the long equilibration time and electrolyse water quantitatively the electrolytic method would be advantageous in that it provides oxygen for ¹⁸O and ¹⁷O analysis in the same sample without any additional work. In the present work we report an electrolytic device by which small amounts of water can be quantitatively electrolysed in about ten minutes, making this method rapid, efficient and hence acceptable for routine work.

EXPERIMENTAL

Construction of the electrolytic device

The device is shown in Figs. 1 and 2. The upper part is made of Perspex and consists of an injection port and one nozzle for connection to a vacuum line through a valve by the use of Swagelok fittings (with Teflon ferrules). The injection port is provided with a rubber septum capped with a screw-on nut. The lower part (called the cell) consists of two stainless-steel (SS 316L) blocks (28 × 15 × 15 mm) held together by two bolts. A thin (0.2 mm) sheet of Teflon is placed between the blocks for insulation. The

*Author for correspondence. Present address: Pakistan Atomic Energy Commission, DNFM, P O Box 1114, Islamabad, Pakistan

Fig 1 Perspective view of the electrolytic device

Fig 2 Cross-sectional view

bolts run through Teflon sleeves in one block (for insulation) and screw into the other. A Perspex sheet is provided between the heads of the bolts and the block for insulation. When joined together the blocks are well insulated and measure $30 \times 28 \times 15$ mm. One of the two 30×28 -mm surfaces of this piece, taken as the top, is machined to provide a 2-mm high circular platform about 20 mm in diameter. Each of the two blocks is machined at the top so that when they are joined together there is a conical cavity (about 5 mm deep and 8 mm in diameter) where the sample is placed for electrolysis. The injection port and the cell, with a rubber O-ring between them, are held together by two screws which also serve as connectors to a 6-V 10-A d.c. supply (or an ordinary car battery). Thus the two steel blocks act as the electrodes of the cell. A sample placed in the cavity is readily quantitatively electrolysed. The device is dismantled for cleaning by unscrewing the two screws joining the two parts. The dimensions are arbitrary and not critical except that the insulating Teflon sheet between the electrodes should be as thin as practicable to ensure contact of the liquid with both electrodes right up to the end, so that the maximum amount of water is electrolysed.

Sampling procedures

The device is connected to the inlet of the mass spectrometer by a Swagelok system and evacuated, after which the inlet valve is closed

and the metallic part of the device is immersed in liquid nitrogen so that the water vapour derived by evaporation of the sample into the evacuated system is condensed. When the sample is placed in the device it is put directly into the cavity, which is colder than the upper part. The water sample (around $20 \mu\text{l}$) is injected with a microsyringe through the rubber septum into the cavity. A small bead of a solid polymeric electrolyte (Nafion type, du Pont de Nemours), with a radius similar to that of the curvature at the bottom of the cone, is placed in the cavity, and no other electrolyte is required for the electrolysis. The liquid nitrogen bath is removed and as soon as defrosting at the outer surface starts, current is passed for about 10 min for electrolysis of a $15\text{--}20 \mu\text{l}$ sample. After this time the electrodes are again immersed in liquid nitrogen, with the current kept on so that any unelectrolysed water is trapped and electrolysed. Our experience indicates that 10 min is sufficient for complete electrolysis of $20 \mu\text{l}$ of water. The cell is allowed to warm to near ambient temperature and the valve to the inlet is opened to introduce the hydrogen-oxygen mixture thus obtained into the inlet for mass spectrometric measurements.

Analysis of tap water

A tap water sample ($20 \mu\text{l}$) was injected into the device and electrolysed for 10 min. The gaseous product was transferred to the "sample"

port of a Delta E (Finnigan MAT) mass spectrometer, which has a dual inlet system. The inlet is designed so that the gas enters pre-evacuated (5×10^{-5} bar) reservoirs of variable size (capacity 2–20 ml) through stainless-steel tubes (i.d. 3 mm, length 90 mm) on the “standard” and “sample” sides. Here the gas is kept for at least 1 min for equilibration, as the total volume of the system (reservoir cell and lines) is about 40 ml, the risk of overpressure and fractionation in the lines is covered. From the reservoir the gas is introduced into the mass spectrometer through capillaries by the use of pneumatically controlled valves. A working standard (20 μ l) is similarly electrolysed with the same device and transferred to the “standard” port of the mass spectrometer. Three sets of mass spectrometric measurements of the gaseous electrolysis product, each set consisting of twelve measurements for $\delta D/H$, were obtained with background measurement before and after each set. The $\delta D/H$ ratio is defined as:

$$\delta D/H = \frac{(D/H)_{\text{sample}} - (D/H)_{\text{std}}}{(D/H)_{\text{std}}} \times 1000\text{‰}$$

The mass spectrometer instrumental error thus evaluated was less than 0.2‰. The same procedure was repeated by taking ten more aliquots of the sample and the standard to determine the reproducibility of the electrolysis method. To compare the results with another method, ten aliquots of the sample and the standard were reduced over heated uranium according to the standard procedure^{3,4} and subjected to mass spectrometric analysis as before.

RESULTS AND DISCUSSION

The $\delta D/H$ values obtained for the tap water sample by the electrolytic and uranium-reduction techniques are listed in Table 1. The reproducibility of the electrolytic method is quite good (S.D. 0.135‰) and the results obtained by the two techniques are very close. In another experiment to demonstrate the “completeness” of electrolysis, the sample and the standard were taken from the same source, one being treated by electrolysis and the other by uranium-reduction. The mean $\delta D/H$ thus obtained was $-0.0258 \pm 0.005\text{‰}$ (see Table 2). The mean $\delta D/H$ value obtained by the uranium-reduction method in the experiment was $-0.0261 \pm 0.004\text{‰}$. Both values are statistically equivalent to zero and very close to each other, suggesting that the electrolysis is complete to

Table 1 Mean $\delta D/H$ values for 10 aliquots of tap water analysed by the electrolytic and uranium-reduction methods

an acceptable extent. The sample preparation time for the uranium-reduction method was 20–30 min, which is about 2–3 times more than that for the electrolytic device. The new electrolytic device reported here therefore provides a rapid, efficient and precise decomposition method for water for subsequent mass spectrometric measurements.

(Received 28 October 1989 Revised 22 November 1990 Accepted 6 December 1990)

Summary—The use of an in-line photolysis coil in a continuous-flow system of high-performance liquid chromatography coupled with hydride generation and flame atomic-absorption spectrometry for the speciation of tin in natural waters is described. Irradiation with ultraviolet light is shown to convert tributyltin into organic tin(IV), from which a volatile hydride can be produced in the conventional way. The effect of various conditions on the analytical performance is discussed. A detection limit of 2 ng for tin was obtained, and the tin species could be completely separated within 6 min. Use of the technique for quantification of tributyltin compounds in local coastal waters is described.

Investigation of the forms in which a trace metal occurs, so-called "speciation", is now recognized as vitally important in determining the toxicity and environmental fate of the metal. This has stimulated interest in new techniques for trace metal speciation. One approach which appears to be particularly successful is chromatographic separation coupled with detection by atomic spectrometry.^{1,2} The specificity of detection allows use of less than optimum chromatographic separation from other metals, with a consequent saving in time for sample clean-up and analysis.

The demand for sensitive techniques for speciation of organotin compounds has markedly increased in recent years. The presence of butyltin³ and methyltin⁴ species at concentrations in the ng/l range in a variety of natural waters has been reported. More recently, however, particular attention has been paid to the organotin compounds used in the formulation of anti-fouling paints, *e.g.*, bis(tributyltin)oxide and tributyltin fluoride.⁵ Such paints, containing about 12% tributyltin (TBT) in the dry paint film, were introduced in the late 1960s and became widely used in the 1970s. However, following initial studies into the decline of the shellfish industry in parts of France,⁶ and more recent detailed studies on the effects on shellfish in the U.K.,^{7,8} the governments of both countries have now banned the use of organotin-based paints and waxes on boats under 25 m

in length, and also on various structures, including fish cages, in both freshwater and marine environments. Obviously, concern remains over the levels of TBT already in the environment,⁹ particularly since the new legislation excludes larger vessels, the effect of which has already been reported.¹⁰

In a previous paper,¹¹ we described a simple yet effective coupling of high-performance liquid chromatography (HPLC) with flame atomic-absorption spectrometry (FAAS), utilizing pulsed nebulization and a slotted-tube atom-trap for the speciation of tin. The detection limit for this system was 200 ng of Sn; preconcentration allowed detection of the 20 ng/l tributyltin concentration taken by the U.K. Department of the Environment (DoE) as the limit for TBT in water. In later work,¹² tributyltin ions were determined by HPLC and fluorimetric detection with morin in a micellar solution. The sample was preconcentrated on an ODS column to give a detection limit of 16 ng of Sn. Here we present a further development of the HPLC-FAAS technique utilizing hydride generation to improve the sensitivity still further and allow the determination of tributyltin at well below the DoE target of 20 ng/l (7.3 ng/l Sn) in ambient waters.

In recent years the hydride-generation method for the determination of certain metalloid elements, notably arsenic and selenium, has proved extremely popular. The hydride is

generated by chemical reduction, entrained in a current of inert gas, and led into the observation zone, where it is decomposed by heat to form the atomic vapour. Several methods have been based on this principle, but differ in the means of reduction and atomization¹³

The use of hydride generation after separation by HPLC has been reported by several groups of workers. For example, arsenite, arsenate and the mono- and dimethylarsenic species, may be separated by reversed-phase HPLC on an ion-exchange column and then pumped with sodium tetrahydroborate solution and hydrochloric acid into a gas/liquid separator. The hydrides produced may then be swept into an atom cell for flame atomic-absorption spectrometry, flame atomic-fluorescence spectrometry or inductively coupled plasma atomic-emission spectrometry¹⁴. Unfortunately such a simple approach is not applicable to tributyltin ions, because tributyltin hydride is a liquid at room temperature. Thus this approach to the speciation of solutions containing tributyltin requires further investigation. In one such study¹⁵ it was found that hydride generation coupled with electrothermal atomization atomic-absorption spectrometry readily allows the determination of tin in organotin compounds after mineralization, and has the advantage over gas-liquid chromatographic systems for the methyltin series that no redistribution reactions take place¹⁶. For tetramethyl- and tetraethyltin the response was similar to, but not

identical with, that for inorganic tin, but the response for other tin compounds, although linearly related to concentration, was a function of the thermal stability and volatility of the hydrides produced.

The tributyltin ion is extremely stable and is only decomposed under vigorous mineralization conditions, which are considered unsuitable for in-line operation owing to problems of dilution, contamination, and disintegration of pump tubing. However, in-line ultraviolet photolysis of organic matter is an established technique for the decomposition of organic species¹⁷ and was selected for the present work to convert the tributyltin compounds into inorganic tin(IV) species, and thus allow a continuous-flow hydride-generator to be used for the determination of both the inorganic and organic tin species present.

EXPERIMENTAL

Apparatus

The continuous-flow hydride-generation system and atom cell are shown in Fig 1. Two small peristaltic pumps (Minipump, Schuco Scientific) were used to pump the sodium tetrahydroborate and sample solutions through a 6-turn mixing coil into the gas/liquid separator. The separator was fitted with a constant-head device. The hydrides were swept by a slow flow of nitrogen to the base of the burner, where they were mixed with a slow flow of hydrogen prior to decomposition in the flame. Full details of this continuous-flow system are given elsewhere¹⁸.

The burner consisted of a borosilicate glass tube (8.5 mm i.d., 100 mm long) with inverted "V" side-arms to act as gas inlets. It was positioned vertically in the spectrometer, replacing the conventional burner/nebulizer assembly. The atomic-absorption spectrometer (Pye Unicam model SP192), was fitted with a tin hollow-cathode lamp and the 286.3-nm tin line was used. The observation height was 10 mm above the burner top. The output from the spectrometer was displayed on a chart recorder (Pye Unicam model AR25).

The tin species were separated by use of a solvent delivery system (Pye Unicam model PU4010) equipped with an injector (Waters Associates, model U6K) with either a 1-ml or 100- μ l sample loop, and connected to a Whatman Partisil-10-SCX analytical column (10 μ m particle size, 25 cm \times 4.6 mm). Samples

Fig 1 Continuous-flow system for the generation of gaseous hydrides

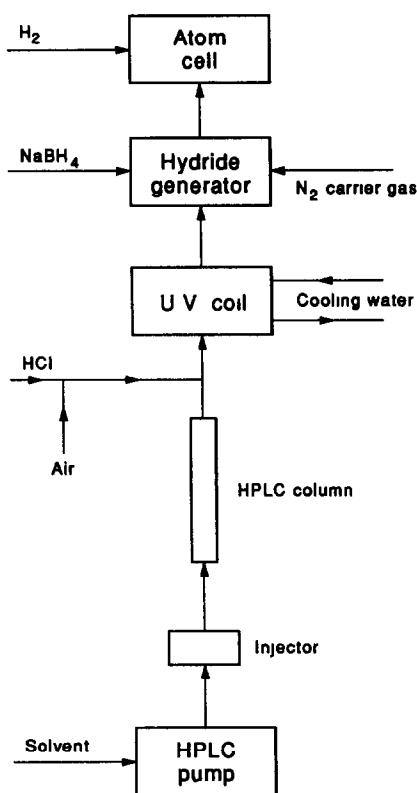

Fig 2 Schematic diagram of the analytical system

were injected directly into the column with a 100- μ l syringe (Scientific Glass Engineering).

Reagents

Unless otherwise stated, all reagents were of analytical reagent grade.

A solution of 1 g of sodium tetrahydroborate (G.P.R., Fisons Scientific) in 100 ml of 0.1M sodium hydroxide was used as the reductant; it was usable for 2–3 days.

A standard tin(IV) stock solution (100 μ g/ml Sn) was prepared by dissolving granulated tin in concentrated sulphuric acid and diluting the solution appropriately.¹⁹ Working standard solutions were prepared daily from the stock solution.

Tributyltin chloride (TBTC, Aldrich) was used as a solution in methanol.

Preservation of standards

It has been shown²⁰ that tin(IV) ions are rapidly adsorbed onto glass surfaces but not onto polyethylene. The reverse is true for organotin compounds, especially the R_3SnX compounds, solutions of which are stable for up to 1 year when stored in borosilicate glass.²¹ All

standards were therefore stored in the appropriate type of container.

Ultraviolet photolysis system

Tributyltin was decomposed in an in-line irradiation coil of the type used in an automatic dissolved organic carbon analyser.¹⁷ A 25-m long coil (of fused-silica capillary) (1.5 mm i.d.) was wound on a glass former with a diameter large enough for an ultraviolet lamp (Engelhard Hanovia) to be inserted in the centre of the coil. One end of the coil was connected to the outlet of the HPLC column, and the other to the inlet of the hydride generator, thus allowing continuous-flow operation. A schematic diagram is shown in Fig 2.

RESULTS AND DISCUSSION

Initial studies showed that though the system would convert tributyltin into a form of tin suitable for producing a volatile hydride, it needed various modifications for optimal performance. One of the main problems resulted from the wide bore (1.5 mm) of the fused-silica coil, which allowed back-diffusion of the sample. This was overcome by segmenting the flow through the coil with air bubbles in a manner similar to that proposed by Skeggs.²² It was found, however, that the size of the bubbles was also important: if too large they tended to break up, and if too small they left pockets of solution behind and hence allowed mixing. A bubble with a length 2–3 times the bore of the tubing appeared to be ideal.

To optimize the system the HPLC instrument was disconnected and the sample was supplied to the rest of the apparatus by means of a peristaltic pump. The optimum conditions found by varying the acid and sodium tetrahydroborate solution flow-rates to the hydride generator, the flow-rate of nitrogen carrier gas, and the pH for decomposition of tributyltin in the coil, are summarized in Table 1.

Table 1 shows that the optimum pH for the irradiation step is lower than the pH that would be achieved by mixing the acid and reductant streams recommended as optimal for efficiency of hydride generation. It has been reported²³ that the response for tin decreases if the acid concentration in the hydride generator exceeds 0.7M. However, from the kinetic curve plotted to find the efficiency of decomposition in the coil (Fig. 3) it was noted that the signal for tin originally present as TBT^+ in a solution at pH 1

Table 1 Optimum conditions for the hydride-generation determination of tributyltin ions after photolysis

<i>Hydride generator</i>	
Acid	0.2 M HCl

Reductant	1% solution of NaBH ₄ in 0.1 M NaOH
Flow-rate	1.8 ml/min
Carrier-gas flow-rate	120 ml/min
<i>Photolysis of sample</i>	
pH < 1 for maximum yield	

was only 84% of that for the same amount of inorganic tin(IV) at the same pH. The possible use of pH adjustment for further improvement was considered, but not incorporated into the system, because it was thought likely that the resulting sample dilution would counteract any increase of the 84% conversion already obtained. To ensure maximum conversion in 20 min it was essential to keep the inside of the fused-silica coil clean by occasionally flushing it with concentrated hydrochloric acid to remove any deposits of SnO₂, which would impair the irradiation process (they would also account for at least part of the incompleteness of conversion)

The optimum pH for the decomposition in the irradiated coil reflects the variation in the forms of tin in solution, as shown in Fig. 4. The soluble forms would be expected to be Sn⁴⁺ species at low pH, and stannate ions at high pH. In the neutral region, less soluble tin species such as Sn(OH)₄ will exist. Thus the efficiency of the photolysis will probably depend on the solubility of the tin species present, so acidic conditions were maintained in all later work.

Once these parameters had been optimized, the chromatograph was reconnected. Ideally a completely aqueous elution system would be employed to minimize absorption in the ultra-

violet region by the organic solvent. However, the HPLC system we have reported previously for tin speciation,¹¹ consisting of a cation-exchange column and a mobile phase of 80:20 v/v methanol/0.1 M ammonium acetate, was found to give acceptable results. A detection limit of 20 ng of tin was obtained with this system, *i.e.*, two orders of magnitude better than before. A typical chromatogram (100 μl injection of a solution containing 500 μg/ml Sn⁴⁺ and 250 μg/ml TBTC) is shown in Fig. 5. It should be noted that the chromatography takes only 6 min for the separation, the extra time needed for the complete chromatogram to be obtained being due to the time the sample spends in the photolysis coil. However when a series of samples is to be analysed, injections may be made in the conventional way, *i.e.*, every 6 min, the results from each injection following consecutively on the chromatographic record.

Finally the technique was tested for the determination of tin species in a sample of harbour water. The organotin compounds were quantitatively extracted from 1 litre of sample into chloroform,¹¹ and after evaporation of the chloroform, were redissolved in 10 ml of methanol for injection into the HPLC column. This procedure gives a concentration factor of 100. The results obtained are shown in Fig. 6. The peaks for Sn⁴⁺ and TBT⁺ were identified by co-injection of appropriate spikes, and the level

Fig 5 Typical chromatogram obtained by use of hydride generation after photolysis, injection of 100 μ l of solution containing 500 μ g/l Sn^{4+} and 250 μ g/l TBT^+

Fig 6 Chromatogram obtained from injection of 100 μ l of methanol solution derived by 100-fold pre-concentration from 1 litre of harbour water

of TBT^+ was found to be 0.20 μ g/l. in the original sample. The third species was not identified at the time, but later work indicated that it was probably dibutyltin.

CONCLUSIONS

The use of a photolysis coil has been shown to enable the sensitive technique of in-line hydride generation to be extended to the determination of species (such as tributyltin) that do not themselves form volatile hydrides

The chromatograms obtained have well defined peaks, indicating good resolution and the absence of carry-over between samples. The detection limit of 2 ng of Sn is the lowest yet

reported for the determination of tin species by directly coupled HPLC-AAS. The technique has been applied here for the determination of organotin compounds, but it is obviously potentially useful for many other hydride-forming elements, such as arsenic, which can occur in forms which do not readily yield volatile hydrides.

Acknowledgements—The authors thank Dr R F C Mantoura of IMER, Plymouth, for the loan of the fused-silica coil, and the SERC for provision of a studentship (to S J H)

DETERMINATION OF CADMIUM, LEAD AND COPPER IN WATER SAMPLES BY FLAME ATOMIC-ABSORPTION SPECTROMETRY WITH PRECONCENTRATION BY FLOW-INJECTION ON-LINE SORBENT EXTRACTION

ZHAOLUN FANG*, TIEZHENG GUO† and BERNARD WELZ‡

Department of Applied Research, Bodenseewerk Perkin-Elmer GmbH, D-7770 Überlingen,
Federal Republic of Germany

(Received 3 March 1990 Revised 7 September 1990 Accepted 7 December 1990)

Summary—Cadmium, lead and copper were determined in synthetic sea-water, drinking water and the NBS 1643b Trace Elements in Water standard reference material at $\mu\text{g/l}$ levels by flame atomic-absorption spectrometry after on-line preconcentration by sorbent extraction with a flow-injection system Bonded silica with octadecyl functional groups packed in a micro column of 100 μl capacity was used to collect diethylammonium diethyldithiocarbamate complexes of the heavy metals in the aqueous samples The sample loading time was 20 sec at a flow-rate of 3.3 ml/min Ethanol or methanol was used to elute the adsorbed analytes into the spectrometer The sample loading rate, elution rate and pH were optimized Enrichment factors of 19–25 for Cd, Pb and Cu were achieved at sampling frequencies of 120/hr with precisions of 1.4, 1.0 and 1.3% *rsd* ($n = 11$), respectively The detection limits (3σ) for Cd, Pb and Cu were 0.3, 3 and 0.2 $\mu\text{g/l}$, respectively Determination of Cd, Pb and Cu in NBS SRM 1643b showed good agreement with the certified values Recoveries of Cd and Pb added to sea-water were 95 and 102%, respectively

On-line separation and preconcentration have evolved into two of the most prominent contributions of the flow-injection (FI) technique to atomic spectrometry Conventional procedures for separation and preconcentration, including ion-exchange, adsorption, solvent extraction, precipitation *etc*, although effective, are often extremely tedious, consume large quantities of sample and reagent, and are vulnerable to contamination. The FI approach, in contrast, can offer a highly efficient and economical technique which is capable of separating interfering matrices, producing 20–30-fold enhancement in sensitivity, with about 1 ml of sample, at sampling frequencies of 120 samples/hr in flame-atomic absorption spectrometry (FAAS).^{1,2} The majority of work conducted in this area has been associated with preconcentration on packed columns either by ion-exchange or by adsorption. Solvent extraction on-line preconcentration for FAAS has also been shown to be

very efficient.^{3,4} Its rather limited popularity might be due to the more complicated experimental set-up, the relatively short lifetime of the separation membranes and the need for stricter control of experimental parameters than for column techniques. Recent publications by Karlberg⁵ and Ruzicka and Arndal⁶ have shown that sorbent extraction may be used as an alternative to solvent extraction in FI systems. Sorbent extraction can be performed on packed columns, analogously to procedures established for ion-exchange preconcentration, with all the specificity of well accepted solvent extraction separation procedures. Sorbent extraction is achieved with a hydrophobic sorbent solid phase which collects analyte complexes formed in the aqueous phase. The metal complexes are later eluted by an organic solvent which is not necessarily immiscible with water, thus providing more flexibility to the technique Ruzicka and Arndal⁶ have demonstrated the outstanding versatility of preconcentration by on-line sorbent extraction for FAAS, and predicted a promising future for this combination. Of the three chelating systems they studied, the one based on diethyldithiocarbamate (DDC) appears to be the most broadly applicable to heavy metals in various sample matrices. The

‡Author for correspondence

DDC complexes have been studied thoroughly, and detailed information on their behaviour is readily accessible in the literature.^{9,10} Ruzicka and Arndal used a bonded silica sorbent with octadecyl functional groups (C_{18}) to collect the complexes, followed by elution with ethanol or methanol.⁶ A $10\text{-}\mu\text{g/l}$ detection limit was reported for Pb with 80 sec preconcentration, and an estimated sampling frequency of 20–30/hr.

In the work reported here, the performance of the DDC- C_{18} -ethanol scheme of sorbent extraction preconcentration for FAAS was further improved by using an efficient on-line column preconcentration system reported previously^{1,2} for ion-exchange preconcentration by FAAS. The method was applied successfully to the determination of Cd, Pb and Cu in various water samples

EXPERIMENTAL

Perkin-Elmer models 3030 and 2100 atomic-absorption spectrometers equipped with deuterium-arc background correction were used throughout. Hollow-cathode lamps were used for the determination of lead, cadmium and copper at their primary resonance lines at 283.3, 228.8 and 324.7 nm respectively. Flame conditions slightly leaner than recommended were chosen, to compensate for the effect of the organic solvents which were introduced during elution and acted as an additional fuel. Flow spoilers were used in the spray chambers, for all measurements

With the 3030 instrument, the graphite-furnace mode was used in order to study the FI peak with high time-resolution. Peaks were recorded by a Perkin-Elmer model 56 strip-chart recorder and printed by a model PR-100 printer. The time constant for peak-height evaluation was 0.2 sec, with a measuring time of 10 sec initiated by the actuation of the injector for column elution.

The 2100 instrument was operated in the FI mode. Peaks, peak heights and statistical data were printed by an Epson EX-800 printer.

Two FI systems were used. The first, used with the 3030 instrument, was a Bifok 8410 modular FI system with two 4-channel 40 rpm peristaltic pumps. Tygon tubes were used for sample loading and for propelling the complexing reagent. A Perkin-Elmer Series 2 HPLC pump was used to propel the ethanol eluent. A modified Bifok/Tecator V-100 sample injector described previously,⁷ with its by-passes

blocked but with three additional ports on the rotor instead of two, was used throughout. The second system was a prototype of the Perkin-Elmer model FIAS-200 FI unit for atomic spectrometry, which was coupled to the 2100 instrument, and employed the same sample injector as the first system. Silicone rubber tubes were used for propelling ethanol and methanol, and Tygon tubes were used for all other solutions. The FI on-line column preconcentration manifold used is illustrated in Fig. 1. The micro sorbent-extraction columns were made from sections of plastic Eppendorf pipette tips with 5 mm i.d. at the top end and 4 mm i.d. at the other, and packed tightly over a length of 5 mm with C_{18} -bonded silica, 40–63- μm particle size (J. T. Baker, "Bakerbond"). The packing was kept in place by small plugs of plastic foam. The upper end of the column was sealed by a small section of silicone rubber tubing pushed into the column. To minimize dispersion, the column was arranged in the manifold so that the sample and reagent stream flowed from the narrower end of the column to the broader, and the eluent flowed through it in the reverse direction. The column was connected to the injector, and the injector to the nebulizer, with 0.35 mm i.d. PTFE tubing. A 10 cm length of straight tubing or a 25 cm length of three-dimensionally disoriented knotted reactor (made as described previously¹) was used for the latter connection. Similar sensitivities were obtained with both

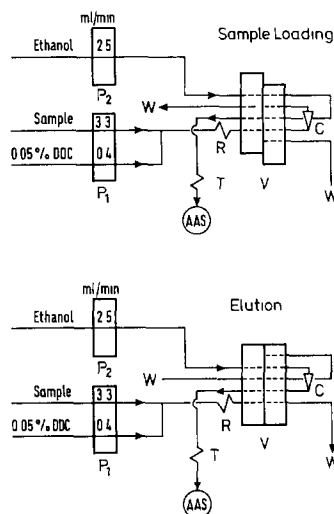

Fig. 1 FI manifold for on-line sorbent extraction column preconcentration. P₁, P₂—pumps, V—injector valve, C—conical column packed with C_{18} sorbent, W—waste, R—reaction coil, 0.5 mm i.d., 4 cm long, T—transport conduit, 0.35 mm i.d., 25 cm long knotted reactor, AAS—flame atomic-absorption spectrometer

but the knotted reactor connection gave slightly better precision. The FI instruments were programmed for a 20 sec loading period and a 10 sec elution period. The sample loading rate was 3.3 ml/min. DDC solution (0.5 mg/ml) was introduced at 0.4 ml/min and mixed with the acidified sample (pH 2) at a confluence point on a "chemifold" (integrated connector block). The optimum elution rate was found to be 2.5 ml/min. At first the solvent used for elution (ethanol or methanol) was continuously pumped into the nebulizer to maintain constant flame conditions. Later it was found that stopping the organic solvent flow during the sample loading period had no detrimental effect on the overall performance. The pump for the solvent was therefore programmed to stop after the elution period and to resume action 5 sec before the next elution. All elutions were done with a free nebulizer uptake rate optimized for the analyte in alcoholic solution (corresponding to 7.2 ml/min for aqueous solutions). Identical results were obtained for the two FI systems, with the same manifold.

All reagents were of analytical-reagent grade and demineralized water was used throughout. The diethylammonium diethyldithiocarbamate (Merck) solution (0.5 mg/ml) was prepared by dissolving the reagent in an aqueous 0.01M acetic acid/0.02M ammonia mixture (pH 9.2). Standard solutions of cadmium, lead and copper were prepared by diluting 1000 mg/ml. stock solutions (Merck, Titrisol) and acidified to pH 2 with nitric acid. A synthetic sea-water matrix containing 35000 mg/l. sodium chloride, 1300 mg/l. magnesium, 400 mg/l., calcium was prepared (with magnesium chloride and calcium nitrate) and acidified to pH 2 after spiking with the analytes. Ethanol and methanol (Merck) were degassed before use to prevent the formation of air bubbles in the stream during elution, which would degrade the precision.

RESULTS AND DISCUSSION

Optimization of the on-line preconcentration system

The design of the on-line sorbent extraction preconcentration system was based on that of a high-efficiency, low sample-consumption on-line ion-exchange preconcentration FAAS system which had provided good performance for the determination of trace metals in water.^{1,2} The system was modified as described in the experimental section, to meet the special

requirements and conditions of the sorbent extraction approach

First, the intermittent introduction of water between elutions (which was previously used to remove the acid eluate from the spray chamber in order to minimize corrosion) was no longer necessary. Instead, it was found beneficial to precondition the flame before the elution, by introducing the organic solvent during the sample loading phase, for at least 5 sec prior to initiation of the readout. The organic solvent flow may be discontinued for the preceding part of the loading phase in order to save reagent. An extra channel was drilled in the rotor of the injector to provide this capability (see Fig. 1).

Secondly, the column design had to be modified because of the smaller particle size (40–63 μm) of the sorbent material used in this study. When the C_{18} sorbent was packed in a conical column identical to the 65- μl column described by Fang and Welz,¹ excessive pressure developed in the system at the normal flow-rates used for sample loading, causing leakages at the connections. It was also difficult to increase the sample loading rate above 1 ml/min because of limitations in the peristaltic pumps, which are designed for relatively low-pressure systems. The diameter of the column was therefore increased by using a wider section of the Eppendorf pipette tip, and a packing thickness of only 5 mm. This modification has proved to permit trouble-free operation at a 3.3 ml/min sample loading rate for over 500 repeated injections. Such modifications may not be necessary if larger particle sizes of the C_{18} sorbent, as used by Ruzicka and Arndal⁶ (150 μm), are employed. However, the smaller particle size may favour more efficient sorption and elution of the metal chelates and may be one of the reasons for the better performance obtained in this study, in spite of the larger dispersion effects in the larger columns. It should be noted that the sample loading rate of 3.3 ml/min in this study, which was limited by the column packing, was considerably lower than that of 4.8 ml/min used for ion-exchange preconcentration.¹ This was one of the reasons for the lower concentration efficiency of the present system compared to that of ion-exchange systems (see following sections). Larger particle sizes will lead to higher flow-rates and may be expected to more than compensate for the loss in enrichment factor associated with their less favorable kinetic properties.

Table 1 The effects of reaction coil configuration and length on the enrichment factor for Cd (10 $\mu\text{g/l}$), Pb (200 $\mu\text{g/l}$) and Cu (50 $\mu\text{g/l}$), PTFE tubing (0.5 mm i.d.) was used throughout

Configuration	Reaction coil Length, cm	Enrichment factor		
		Cd	Pb	Cu
Straight	4	25	20	19
Straight	24	22	18	18
Knotted	24	18.5	16	16.5

Thirdly, the dimensions and configuration of the reaction coil between the confluence point of the sample and reagent solutions and the injector which incorporated the sorbent column were found to have a significant effect on the enrichment factor for analytes such as lead and cadmium (see Table 1). This is a phenomenon which has not been observed in ion-exchange preconcentration and may be associated with kinetic aspects of the adsorption of the metal chelates on the sorbent. The shortest connection (4 cm, 0.5 mm i.d.) with the shortest residence time produced the highest enrichment factor. The differences in results for the straight 24 cm, 0.5 mm i.d. reaction conduit and the knotted^{1,8} reactor made from the same tubing imply that, as well as the reaction time, the mixing conditions have a substantial influence on the enrichment factor. It seemed quite surprising that the more complete radial mixing in the knotted reactor should lead to inferior results. The phenomenon seems to favour the assumption that the metal chelates should be formed shortly before their sorption and that sample and reagent should not be allowed to be in contact for any longer period of time. However, the studies conducted thus far are not sufficient to provide a satisfactory explanation and more work will be necessary for the elucidation of

this phenomenon. Nevertheless, the confluence point for sample and reagent was placed as close as possible to the injector in order to achieve the best enrichment factors.

The exclusion of a washing step between sample loading and elution has been proved to be beneficial in on-line preconcentration with ion-exchange columns.¹¹ This procedure was equally effective in this work with the sorbent extraction preconcentration system. The application of the method to the determination of trace elements in sea-water (as representative of a concentrated and complex matrix) was quite successful (see section on performance).

Effects of experimental parameters on the performance of sorbent extraction preconcentration

The effect of eluent flow-rate on peak absorbance and precision for the measurements of 50 $\mu\text{g/l}$ Cu are shown in Fig. 2. It can be seen that, as was the case with on-line ion-exchange preconcentration, the peak absorbance remained essentially constant for eluent flow-rates ranging from 1.3 to 4 ml/min, implying higher elution and nebulization efficiencies at the lower flow-rates, but the precision was considerably degraded at elution flow-rates below 1.6 ml/min. Another unfavourable aspect of the lower flow-rates was that the elution peak was broader, which meant that it took longer to complete the elution, thus reducing the sampling frequency and concentration efficiency CE (enrichment factor \times samples per min). An elution flow-rate of 2.5 ml/min was selected as optimal with respect to overall performance and economy of reagents.

DDC reagents have been reported to form chelates with metals at high acidities.^{9,10} As the water samples used in this work are always acidified during collection to a pH of 2 or even lower, a study on the effects of acidity on the preconcentration was undertaken to assess its limits and to investigate the necessity for buffering the sample solutions. Concentrations of 6 $\mu\text{g/l}$ Cd, 200 $\mu\text{g/l}$ Pb and 50 $\mu\text{g/l}$ Cu acidified to different degrees with nitric acid were analyzed and the peak absorbances compared to those obtained at pH 3. The peak signals for lead and copper were not influenced at all by the acidity, even by 1M nitric acid (pH 0), whereas a 10% lower signal was obtained for cadmium under these conditions. The acidity limit for cadmium was found to be approximately 0.8M nitric acid (pH 0.1), which is well above the acidity of normal water samples. It was

Fig. 2 Effect of elution flow-rate on peak absorbance (A) and precision (P) for on-line sorbent extraction preconcentration of copper (50 $\mu\text{g/l}$) with the FI manifold in Fig. 1, loading period 20 sec

Fig 3 Effect of sample acidity on the recovery of 6 µg/l cadmium in demineralized water (D) and sea-water (S) with the manifold in Fig 1, loading period 20 sec

therefore considered unnecessary to buffer the samples during complexation. The buffer solution in the DDC reagent was added only for the purpose of stabilizing the reagent, which decomposes much faster at lower pH. For sea-water, however, in contrast to the observations for simple aqueous standards, when the pH of the sample was lower than 1.5 the recovery for cadmium gradually deteriorated to about 20% at 0.8M nitric acid (Fig. 3). The difference in behaviour in the sea-water matrix might be due to the higher ionic strength. The acidity limit for determination of cadmium in sea-water was therefore considered to be pH 2. The eluents, ethanol and methanol, were found to be quite similar in performance. Ethanol was used in most of the experiments because of its lower toxicity. Longer chain alcohols such as *n*-butanol were also tested as eluents but were found to give much lower enrichment factors.

Performance of the on-line sorbent extraction preconcentration system

The enrichment factors, detection limits, precisions and sampling frequencies for Cd, Pb and Cu, as well as their recoveries in synthetic sea-water and tap water by use of the optimized on-line sorbent extraction system with FAAS, are shown in Table 2. The enrichment factors (EF) and sampling frequencies show that the CE values of the system, which are the products of the two parameters, are in the range 38–50 EF/min, somewhat lower than those achieved by preconcentration with a column packed with CPG-8Q (8-quinolinol immobilized on porous glass) ion-exchanger.^{1,2} In addition, it should not be overlooked that organic solvent effects in the flame produced a signal enhancement factor of about 2.2 in the case of sorbent extraction, so the actual increase in concentration at the peak maximum would be less than 12-fold at

Table 2 Performance of the on-line sorbent extraction preconcentration FAAS system sampling frequency 120/hr, sample volume 1.4 ml

	Cd	Pb	Cu
Concentration, µg/l	6	200	50
Enrichment factor	25	20	19
CE, EF/min*	50	40	38

Detection limit (3σ), µg/l	0.3	3	0.2
Recovery from sea-water†, %	94–96	98–102	—
Recovery from tap water‡, %	97–102	97–101	—

*Concentration efficiency = enrichment factor (EF) × samples per min

†Spiked with 20 µg/l Pb and 10 µg/l Cd

‡Spiked with 30 µg/l Pb and 3 µg/l Cd

sampling frequencies of 120 hr, corresponding to a CE value of only 17–23 EF/min. The lower CE is due to the slower release of the complexed metals from the sorbent into the organic solvent, compared to the elution of complexed heavy metals by strong acids from chelating ion-exchange columns. Nevertheless, the detection limits obtained for the two techniques were quite similar. Recovery studies in sea-water and tap water for the analytes Cd and Pb, which may be susceptible to interferences also show a better tolerance of interferences, with the sorbent extraction approach. This is best illustrated by the recoveries of cadmium in a sea-water matrix. With on-line ion-exchange preconcentration with CPG-8Q columns no satisfactory recoveries could be obtained, owing to competition in complex formation by the relatively high concentration of magnesium. The best recovery obtained was 73%. Only after a 1.2 dilution of the sea-water sample was it possible to come close to 90% recovery.¹ The Cd-DDC complex shows much higher stability even at very low pH, and DDC does not form stable chelates with the alkaline and alkaline-earth metals even at low acidity, hence excluding the possibility of their interference. However, the competition for adsorption sites on the sorbent by other heavy metals in the sample, which also form stable DDC chelates, has to be considered more carefully.

The tolerance for co-existing heavy metals was examined by adding relatively high concentrations of Pb and Cu to 100 µg/l Cd. Interferences begin to be significant (84% recovery) in a solution containing 4 mg/l each of Pb and Cu, which is not likely to be encountered except in waste water samples, and 96% recovery was obtained at half these interferent concentrations. The interference effects could be partially or completely overcome by using larger

Fig 4 Recorder traces for on-line sorbent extraction pre-concentration of 0.1 $\mu\text{g/l}$ Cd standard solution (B) and 0.1 mg/l Cd in synthetic sea-water (C) with the FI manifold in Fig 1, compared to the trace for 2 mg/l Cd standard solution with conventional aspiration (A). Sample uptake rate 7.2 ml/min. Preconcentration (loading) period 20 sec.

columns, at the expense of lower enrichment factors, as is also the case for ion-exchange preconcentration.¹¹ Alternatively, masking agents could be used to form stronger complexes with the interfering ions. However, these were not found to be necessary for the water samples studied. A recorder trace obtained with the 3030 instrument in the determination of 0.1 mg/l cadmium in sea-water by on-line sorbent extraction preconcentration FAAS is compared in Fig. 4 with the signals for 0.1 mg/l Cd in a simple aqueous standard and a signal obtained by conventional aspiration of a 2 mg/l Cd solution.

The performance of the on-line sorbent extraction preconcentration system was further tested by analysing NBS standard reference material 1643b, Trace Elements in Water. The normal sample loading period of 20 sec was sufficient for the determination of cadmium and copper but a longer loading period of 60 sec was required to achieve consistent results for lead. The results are shown in Table 3 and the time-resolved elution curves are depicted in Fig. 5. Substantial background absorbance was observed in the cadmium and lead determinations. This was caused by the change in flame conditions when a small amount of sample matrix, remaining in the column at the end of the sample loading period, was flushed into the flame by the organic solvent. This had no effect

Table 3 Analytical results for determination of Cd, Pb and Cu in NBS SRM 1643b, Trace Elements in Water

Element	Measured value,* $\mu\text{g/l}$	Certified value, $\mu\text{g/l}$
Cd	19 ± 0.3	20 ± 1
Pb	$23 \pm 0.3 \dagger$	20.7 ± 0.7
Cu	22.0 ± 0.4	22.3 ± 0.4

on the peak-height measurements, particularly when background correction was used. In the case of lead (Fig 5c) a significant distortion of the elution curve was clearly visible. This was most probably caused by an over-correction of the background, owing to strong hydroxyl bands in the flame, which exhibit a fine structure at the wavelength used (283.3 nm). This phenomenon disappeared when a different wavelength (217.0 nm) was used. However, the signal distortion was found to have no effect on the peak-height absorbance, so the determination could be done at 283.3 nm, the wavelength with the best signal to noise ratio.

No contamination problems were encountered in this study, mainly because a closed preconcentration system was used. Owing to the small amount of reagent introduced during the sample loading, reagent blanks were absent or close to the detection limit. The reagent grade organic solvent used for elution never produced any noticeable blank values, because the contamination therein (if any) did not undergo preconcentration.

CONCLUSIONS

The on-line sorbent extraction column preconcentration system described in the present study has proved to be an extremely efficient and versatile means of improving the sensitivity and selectivity of FAAS. Detection limits for cadmium, lead and copper were improved by a factor of 20, with sampling frequencies and sample volumes matching those of conventional FAAS analysis.

The precision and recovery obtained in the analysis of sea-water, and the good agreement of the analytical results with the recommended values for the standard reference material 1643b show the reliability and accuracy of the method. The good recovery obtained for cadmium in the sea-water sample was particularly outstanding, because hitherto it has been rather difficult to obtain acceptable recoveries for this element with on-line ion-exchange preconcentration.^{1,11} Further work is in progress to extend the method to the analysis of other samples with more complex matrices. The detection limits achieved for the analytes studied show that the on-line sorbent extraction preconcentration FAAS system may be used for the control of water quality for environmental purposes, which until now could only be accomplished by graphite-furnace AAS.

CATALYTIC DETERMINATION OF ULTRATRACE AMOUNTS OF RUTHENIUM WITH OSCILLOPOLAROGRAPHIC DETECTION

JIANG ZHI-LIANG

Laboratory of Instrumental Analysis, Department of Chemistry, Guangxi Normal University,
Gulin, People's Republic of China

(Received 29 May 1990 Revised 10 November 1990 Accepted 6 December 1990)

Summary—The oscillopolarographic behaviour of Methyl Red in sodium hydroxide medium has been studied, and the results show that the wave at -0.79 V is an irreversible two-electron adsorption wave. A very sensitive and selective catalytic reaction—oscillopolarographic method for the determination of Ru down to 3 ng/l is described, based on the Ru(III)-catalysed redox reaction of Methyl Red and potassium periodate in hydrochloric acid medium. Potassium thiocyanate is used to quench the reaction and the oscillopolarography is then performed with sodium hydroxide as the supporting electrolyte. The influence of 41 foreign ions has been examined. Ruthenium in ore samples has been determined by the method, with satisfactory results.

Several polarographic methods have been reported for the determination of trace amounts of ruthenium,¹⁻⁹ but their sensitivity or selectivity is not very satisfactory. Many catalytic reaction systems¹⁰⁻¹⁵ have been proposed for determining trace amounts of Ru by spectrophotometric, potentiometric and thermometric methods, but no catalytic method with oscillopolarographic detection has yet been published for Ru. To develop such a method, some of the catalytic reaction systems of Ru were examined. The results demonstrate that some of the Ru-KIO₄-azo-compound systems can be utilized. In the present work, we investigated the Ru(III)-KIO₄-Methyl Red system in detail. A very sensitive and selective catalytic oscillopolarographic method for Ru was developed, with a detection limit of 3 ng/l. and a determination range of $8-220$ ng/l. by the fixed-time method.

EXPERIMENTAL

Apparatus

A model JP-2 single-sweep oscillopolarograph (Chendu Instrumental Factory) with a three-electrode system [dropping mercury electrode (DME), SCE and platinum electrode], was used. A thermostat was used to control the temperature.

Reagents

A standard solution of Ru(III) (100 μ g/ml in 2.4 M hydrochloric acid) was prepared with NH₄RuCl₄. Working solutions were prepared by dilution of the standard solution shortly before use, and also by the procedure used to prepare the sample. Solutions of potassium periodate (9.0×10^{-3} M, usable for a week) and Methyl Red (MR, 5.00×10^{-5} M) were used.

Procedure

Into a 25-ml graduated test-tube fitted with a glass stopper, a known volume of solution containing between 0.2 and 5.5 ng of Ru was transferred, 2.0 ml of 1 M hydrochloric acid and 0.40 ml of 9.0×10^{-3} M potassium periodate were added, and the solution was diluted accurately to 10 ml with doubly distilled water. The tube was placed in the thermostat (at $55 \pm 0.1^\circ$) and after about 5 min, 0.50 ml of 5.00×10^{-5} M MR was added, and the stop-watch was started while the tube was shaken vigorously to mix the solution. The tube was kept in the thermostat for 10 min, then the reaction was stopped by addition of 1.0 ml of 0.01 M potassium thiocyanate. The tube was cooled, 7.0 ml of 1 M sodium hydroxide were added and the solution was diluted accurately to 25 ml with water. A portion of the solution was transferred into a polarographic cell and the second derivative

peak current, $I''_{p,cs}$, was measured with scanning from -0.40 V in the positive direction. $I''_{p,uncat}$ for the uncatalysed reaction was measured in a similar manner. The $\log(I''_{p,uncat}/I''_{p,cs})$ values for a range of Ru concentrations were plotted as a function of Ru concentration to prepare a calibration graph.

Preparation of ore sample¹⁶

A 1.0 g sample of ore was weighed accurately into a nickel crucible and mixed with 5 g of sodium peroxide. The mixture was heated at 700° for about 25 min, cooled, and extracted with water. The solution was transferred into a distillation flask, acidified with 10M sulphuric acid, and treated with 10 ml of saturated potassium permanganate solution and 0.20 ml of 200 mg/ml sodium chloride solution. Ruthenium tetroxide was distilled, and absorbed in 10 ml of 0.1M sodium hydroxide. This solution was transferred to a 100-ml beaker, treated with about 5 ml of 12M hydrochloric acid, then evaporated almost to dryness, and cooled. About 40 ml of water and 5 ml of 12M hydrochloric acid were added, and the mixture was boiled for about 2 min, then cooled and transferred to a 500-ml standard flask and diluted to the mark with water. A suitable aliquot, further diluted if necessary, was analysed.

RESULTS AND DISCUSSION

Oscillopolarographic behaviour of MR

Tachi^{17,18} reported that MR in acid or base medium exhibits a d.c. polarographic wave, and Pittoni¹⁹ reported $E_{1/2}$ for Methyl Red, but the oscillopolarographic behaviour of MR does not seem to have been reported. Our experiments show that oscillopolarography is more sensitive for MR in sodium hydroxide medium than in hydrochloric acid medium. The influence of periodate, iodate, chloride and thiocyanate on oscillopolarographic measurement of MR in sodium hydroxide medium was examined at 25° , and no effect was observed. I''_p is maximal and constant when the sodium hydroxide concentration is 0.05–0.7M, and proportional to the MR concentration between 1.0×10^{-8} and $2.5 \times 10^{-5}M$. The electrocapillary curve is lower in the presence of $1.0 \times 10^{-6}M$ MR than in its absence, owing to adsorption of MR on the surface of the DME changing the surface tension of the mercury drop. The anodic and cathodic waves are

Fig 1 Cathodic and anodic waves for $5.00 \times 10^{-6}M$ MR in $-0.2M$ NaOH

shown in Fig 1, from which $-I_{pc}/I_{pa} = 0.77$ and $\Delta E_p = 40$ mV, so from ΔE (mV, 25°) = $58/n$, $n = 1.45$. The mean temperature coefficient is $-1.9\%/deg$ in the range $20-40^\circ$. The wave disappears when the surfactants polyvinyl alcohol, cetyltrimethylammonium bromide, TX-10 and TX-100 are added.

These results verify that the wave is a 2-electron irreversible adsorption wave.

Ru(III)-KIO₄-MR catalytic reaction system

Rysev *et al.*¹⁰ first found that Ru(IV) catalysed the decolorization reaction of MR and potassium periodate, and used it for the spectrophotometric determination of Ru from 2.0×10^{-4} to 3.0×10^{-3} $\mu g/ml$. In the present work, the system was adapted to oscillopolarographic analysis and based on the catalytic effect of Ru(III) on the reaction. Because thiocyanate can reduce periodate quickly in hydrochloric acid medium and MR exhibits a very sensitive oscillopolarographic wave in sodium hydroxide medium, potassium thiocyanate and sodium hydroxide were selected as the quenching reagent and the supporting electrolyte, respectively. $I''_{p,cs}$ and $I''_{p,uncat}$ remain constant for 60 min after addition of 1.0 ml of 0.01M potassium thiocyanate.

The overall reaction may be expressed as

Under the chosen conditions, the periodate concentration is greater than the MR concentration, and it is presumed that a pseudo first-order reaction (with respect to MR) occurs. Since the catalytic and uncatalysed reactions

occur simultaneously in the analytical system, the rate equation of the overall reaction is

$$V_{cs} = -d[MR]/dt = k_c[MR][Ru] + k_{un}[MR] \quad (1)$$

$$-d[MR]/[MR] = (k_c[Ru] + k_{un}) dt \quad (2)$$

where k_c and k_{un} are the rate constants of the catalytic and uncatalysed reactions, respectively, for use of a fixed concentration of periodate and hydrochloric acid. Integration of equation (2) gives

$$-\log[MR]_{t,cs} = (k_c[Ru] + k_{un})t + \log B \quad (3)$$

where $B = [MR]_{0,cs}$, the initial concentration of MR in the catalytic reaction solution. When $[Ru] = 0$, only the uncatalysed reaction takes place, and equation (3) has the form

$$-\log[MR]_{t,un} = k_{un,t} + \log B \quad (4)$$

where $[MR]_{t,un}$ is the concentration of MR in the uncatalysed-reaction solution at time t . Combining (3) and (4), we obtain

$$\log([MR]_{t,un}/[MR]_{t,cs}) = k_c[Ru]t \quad (5)$$

Since $I_p'' = k'[MR]$, where k' is a constant equation (5) may be rewritten as

$$\log([I_p'']_{t,un}/[I_p'']_{t,cs}) = k_c[Ru]t \quad (6)$$

Equation (6) suggests that the best method of calibration is to plot the logarithmic term against the ruthenium concentration, with the other variables and the reaction time and temperature held constant for the given system.

Effects of variables

The effect of the concentrations of periodate, MR and hydrochloric acid, and the reaction

Fig 2 Effect of KIO_4 concentration on the log term. Other conditions as in the procedure

Fig 3 Effect of HCl concentration on the log term

time and temperature on the rate (expressed as the logarithmic term) of the indicator reaction was studied. The logarithmic term increases with time up to 20 min. A fixed reaction time of 10 min was chosen for use, giving a good compromise between high sensitivity and short analysis time. Figures 2-5 show that $1.4 \times 10^{-4} \text{ M}$ periodate, 0.08 M hydrochloric acid and $1.00 \times 10^{-6} \text{ M}$ MR in the final solution and a reaction temperature of 55° are best, so these values were chosen as optimal

Effect of foreign ions

The influence of 41 foreign ions on the system was examined with $4.0 \times 10^{-5} \mu\text{g/ml}$ Ru. The results are summarized in Table 1, and show that the catalytic-reaction oscillopolarographic method has high selectivity. The tolerance limit is that giving not more than $\pm 5\%$ error.

Calibration graph

The two types of working solution gave very similar calibration plots. The relationship

between $\log(I''_{p,un}/I''_{p,cs})$ and Ru concentration in the final solution is linear from 8.0×10^{-6} to 2.20×10^{-4} $\mu\text{g/ml}$. The relative standard deviation for 4.0×10^{-5} $\mu\text{g/ml}$ Ru was 4.7% (10 replicates). The detection limit was 3×10^{-6} $\mu\text{g/ml}$.

Analysis of samples

The method was applied to analysis of ore samples, which were also analysed by the catalytic Ru-Ce(IV)-As(III) spectrophotometric method.²⁰ Recovery of standard additions of Ru to the sample was also determined. The results are given in Table 2.

CONCLUSION

With respect to sensitivity, working range and selectivity, the method is superior to the catalytic spectrophotometric method¹⁰. The method is the most sensitive oscillopolarographic method for Ru and also one of the most sensitive catalytic methods at present.

CATALYTIC KINETIC DETERMINATION OF ULTRATRACE AMOUNTS OF RUTHENIUM(III) BASED ON THE OXIDATION OF BENZYLAMINE BY ALKALINE HEXACYANOFERRATE(III)

SURENDRA PRASAD* and PREM C NIGAM

Department of Chemistry, Indian Institute of Technology, Kanpur 208016, India

(Received 19 July 1989 Revised 31 December 1990 Accepted 16 January 1991)

Summary—A kinetic method is proposed for the determination of ruthenium(III) by means of its catalytic effect on the oxidation of benzylamine by hexacyanoferrate(III) in alkaline medium. The reaction is followed spectrophotometrically by measuring the decrease in the absorbance of hexacyanoferrate(III) at 420 nm. Under the optimum experimental conditions ruthenium(III) can be determined in the range 10–121 ng/ml with an average error of 1.7% and maximum relative standard deviation of 1.3%. The influence of many potential interferents has been examined and the method has been tested for determination of ruthenium(III) in synthetic mixtures. The method is convenient, reliable and rapid.

Ruthenium and its chloro-complexes, particularly in the tervalent oxidation state, have become of interest in recent years because of their use in homogeneous and heterogeneous catalysis of the oxidation of a wide range of organic substrates.¹⁻⁴ Despite the large number of reactions which are catalysed by ruthenium,⁵ only a few have been used for determining traces of ruthenium, mostly in its higher oxidation states, because of their poor selectivity. Ruthenium(VIII) has been determined by Worthington and Pardue⁶ by its catalytic effect on the Ce(IV)–As(III) reaction. The catalytic effect of Ru(III) on the oxidation of Indigo Carmine by iodate has been used for the determination of ruthenium in synthetic mixtures.³ Viñas *et al.*⁷ were the first to propose the use of an activator, *viz.* iodide, in the selective determination of Ru(III) by its catalytic effect on the *p*-ethoxy-chrysoidine-periodate reaction, but for high sensitivity the reaction has to be performed at 45°.

In the present paper we report a rapid and simple kinetic method for the determination of Ru(III), based on its catalysis of the oxidation of benzylamine by alkaline hexacyanoferrate(III). The method permits the determination of Ru(III) concentrations down to 10 ng/ml with good accuracy and reproducibility. We have tested the method for the

determination of Ru(III) in synthetic mixtures and shown it to be sensitive and selective.

EXPERIMENTAL

Reagents

Redistilled water was used throughout for preparation of solutions. A 0.04M stock solution of benzylamine (analytical grade, Sigma) that had been purified by distillation under reduced pressure was prepared. A 0.04M stock solution of potassium hexacyanoferrate(III) (analytical grade, S.D.S.) was prepared, and standardized iodometrically,⁸ it was stored in dark amber-coloured bottles and diluted to the required concentration just before use. Sodium hydroxide and perchloric acid were used to adjust the pH to the desired value. Standard B.D.H. buffers were used for standardization of the pH-meter. Sodium perchlorate (*purum*, Fluka) was used to maintain the ionic strength at 0.5M. A stock solution of ruthenium(III) ($5 \times 10^{-3}M$) was prepared by dissolving the appropriate amount of ruthenium trichloride ($RuCl_3 \cdot 3H_2O$, Johnson Matthey) in 1M hydrochloric acid,⁹ working solutions were prepared immediately before use, by dilution as required. All other reagents used were of certified analytical-reagent grade.

Instrumentation

A Shimadzu double-beam spectrophotometer, model UV-240, equipped with 1-cm

*Author for correspondence

path-length fused-silica cells and an automatic digital recorder, was used for recording spectral changes and absorbances. The cell compartment was kept at a constant temperature of $35.0 \pm 0.1^\circ$ by circulation of water from a Remi Ultra Cryostat model C-702 thermostatic bath. All pH measurements were made on an Elico digital pH-meter, model LI-120, fitted with an Elico CL-51 combined glass and saturated calomel electrode. The glassware used was scrupulously cleaned to eliminate any traces of metal ions from the glass surface. The cells were cleaned after use, by immersion in nitric acid (1 + 1) for 15 min to remove traces of ruthenium adsorbed on their walls.

Procedure

Adjust all the sample solutions to pH 10.5 ± 0.1 and bring them to the same temperature by immersion in a thermostat at $35.0 \pm 0.1^\circ$ for 30 min.

To a 10-ml glass-stoppered standard flask (kept in the thermostat) add 2.0 ml each of $2.0 \times 10^{-3}M$ potassium hexacyanoferrate(III) and $4 \times 10^{-2}M$ sodium hydroxide in that order, followed by 2.0 ml of 4×10^{-7} – $4.8 \times 10^{-6}M$ ruthenium(III) immediately before the run, to avoid any possible interaction between these reagents. Initiate the reaction by injecting 2.0 ml of $4 \times 10^{-3}M$ benzylamine solution. Shake the mixture and transfer a portion to a 1-cm

Fig 1 Repetitive scan of the reaction mixture during a typical kinetic run $[\text{Fe}(\text{CN})_6^{3-}] = 4 \times 10^{-4}M$, $[\text{benzylamine}] = 1 \times 10^{-3}M$, $[\text{Ru}^{3+}] = 1 \times 10^{-6}M$, $[\text{NaOH}] = 1 \times 10^{-2}M$, $\text{pH} = 10.5 \pm 0.1$, $I = 0.5M$ (NaClO_4), $\text{temp} = 35.0 \pm 0.1^\circ$

path-length cell in a temperature-controlled cell-compartment at $35.0 \pm 0.1^\circ$. Measure the change in the hexacyanoferrate(III) absorbance at 420 nm ($\epsilon = 1020 \text{ l.mole}^{-1}.\text{cm}^{-1}$) after exactly 5 min. Plot the change in absorbance vs. Ru(III) concentration. Analyse samples similarly.

RESULTS AND DISCUSSION

The calibration obtained by the fixed-time method (with a 5-min reaction time) is linear between 10 and 121 ng/ml Ru(III), and non-linear at higher concentrations. Linear plots can also be obtained with fixed-time intervals longer or shorter than 5 min, but the relative errors are larger.

The oxidation of benzylamine by alkaline hexacyanoferrate(III) is slow but is catalysed by ruthenium(III). The kinetics and mechanism of this reaction have been reported by Nath and Singh¹⁰ After some valid approximations the rate expression for the catalysed reaction was reported as

$$\frac{d[\text{Fe}(\text{CN})_6^{3-}]}{dt} = \frac{kK_1K_2[\text{Substrate}][\text{Ru}^{3+}]}{1 + K_1[\text{OH}^-]} \quad (1)$$

where k is the rate constant for formation of the benzylamine oxidation product from the intermediate Ru-benzylamine complex, and K_1 and K_2 are the stability constants of the reactive Ru species and of the intermediate Ru-benzylamine complex, respectively

Thus with other conditions fixed, the rate of disappearance of hexacyanoferrate(III) is linearly related to the Ru(III) concentration. The spectral changes occurring during a typical kinetic run are shown in Fig 1, and confirm the coexistence of $[\text{Fe}(\text{CN})_6^{3-}]$ and $[\text{Fe}(\text{CN})_6^{4-}]$ during the reaction, and formation of the latter as assumed in the proposed mechanism¹⁰

The detection limit was evaluated according to the method of Tanaka¹¹ by using the expression

$$X_D = \bar{X}_{B1} + tS_{B1}\sqrt{2} \quad (2)$$

where \bar{X}_{B1} is the average and S_{B1} the standard deviation of the blank values, and t is a constant, S_{B1} is taken as R/d_2 , $1/d_2$ being the factor for obtaining S from the range R Tanaka recommends using $t = 3$; $1/d_2$ is 0.59 when the range of three blank measurements is used. The sensitivity, expressed as the slope of the calibration function, was sufficiently high ($1.98 \times 10^5 \text{ l mole}$), and it can be improved by

*Maximum ratio tested

increasing the time interval to 7 minutes or more, but loss in precision. The relative standard deviation for triplicate determination ranges from 0.1 to 1.3% and the error from -4 to +1.7% in the ruthenium concentration range 10-121 ng/ml

The selectivity was tested by studying possible interferences in the kinetic determination of $7 \times 10^{-7}M$ ruthenium(III). Table 1 shows the tolerance ratios to ruthenium. The tolerance limit is taken as the concentration which causes an error of no more than $\pm 4\%$ in ruthenium determination. Surasiti and Sandell¹² have described methods for conversion of osmium into Os(VIII) with retention of ruthenium as Ru(III)

Application to determination of ruthenium(III) in synthetic mixtures

To establish the reliability and applicability of the proposed method, recovery experiments were performed on laboratory mixtures con-

Table 2 Application of the method to synthetic mixtures

Sample	Composition of the synthetic mixture, ng/ml	Ruthenium found, ng/ml

SOME NEW ACRIDINIUM TRIFLUOROMETHANESULFONATES AS SPECTROPHOTOMETRIC DERIVATIZATION REAGENTS FOR AROMATIC AND ALIPHATIC PRIMARY AMINES

JAMES W. DUNNING JR and JAMES T STEWART*

Department of Medicinal Chemistry and Pharmacognosy, College of Pharmacy, University of Georgia,
Athens, GA 30602, U S A

(Received 17 July 1990 Revised 27 November 1990 Accepted 10 December 1990)

Summary—Some new 9-substituted 10-methylacridinium trifluoromethanesulfonate (triflate) salts have been synthesized and shown to react in methanol with the model aromatic and aliphatic amines, aniline and n-butylamine, to form derivatives which absorb strongly at 445 and 439 nm, respectively. The color development is affected by heat and heating time and by the quantity of acridinium triflate used. A 10–50-fold molar excess of the triflate should be used and the solution heated at 60° for 30 min. The linearity and reproducibility of the assay are improved by the presence of pyridine (for aniline) and triethylamine (for n-butylamine) in the reaction mixture. Beer's law is obeyed over the range 0–1860 ng/ml for aniline and 0–1440 ng/ml for n-butylamine, with each of the new reagents. The relative error and the precision of determination depends on the acridinium triflate used.

9-Chloroacridine has been demonstrated by Stewart and co-workers to have a number of useful applications as an analytical derivatization reagent for the determination of primary aromatic amines, both by colorimetry^{1,2} and by fluorescence quenching.³ It has also been shown that 9-methoxyacridine is of comparable value as an analytical reagent for primary aliphatic amines.⁴

These assay methods generally involved heating the analytical solution for various time periods with excess of acridine reagent in order to achieve reproducible results. Investigation of ways to further enhance the reactivity of the 9-position of the acridine ring toward nucleophiles such as amines, and thus make these acridine reagents significantly more useful as derivatization agents, has led us to synthesize some new 9-substituted 10-methylacridinium trifluoromethanesulfonate (triflate) salts (Table 1).

The goal of this study was to investigate the reaction of these new 9-substituted 10-methylacridinium salts, featuring highly labile leaving groups at C-9, with aniline and n-butylamine as model aromatic and aliphatic primary amines. Spectrophotometric applications of these reactions are reported here.

EXPERIMENTAL

Materials

9-Chloroacridine and triethylamine were obtained from Eastman Kodak, Rochester, NY. 6,9-Dichloro-2-methoxyacridine, methyl trifluoromethanesulfonate (methyl triflate), aniline, and n-butylamine were purchased from Aldrich Chemical Co., Milwaukee, WI. 9-Methoxy and 9-ethoxy acridines were prepared from 9-chloroacridine by a reported method.⁵ Aniline and n-butylamine were distilled prior to use. Absolute methanol and acetonitrile were supplied by J. T. Baker Chemical Co., Phillipsburg, NJ. All other chemicals were obtained commercially and used as received.

Apparatus

Ultraviolet spectra and single-wavelength measurements were recorded with a Beckman Model DU-7 UV/VIS spectrophotometer interfaced to a PE Model 7500 computer equipped with a Hewlett-Packard 2-pen plotter.

Melting points were determined in open capillary tubes with a Hoover Uni-melt apparatus, and were uncorrected. Proton NMR spectra were obtained with a JEOL FX90-Q spectrometer. Infrared spectra (KBr discs) were recorded with a Perkin-Elmer Model 684 IR Spectrophotometer also interfaced with the PE

Syntheses of acridinium triflates

9-Chloro-10-methylacridinium triflate (1). In an oven-dried flask, 9-chloroacridine (6.07 g) was dissolved in 60 ml of dichloromethane with stirring, at ambient temperature. After the addition of 10 ml of methyl triflate, a dark turbidity appeared, instantaneously followed by a copious, bright yellow precipitate. After continued stirring at ambient temperature for 3 hr, the reaction mixture was filtered and the crystals were washed with cold dichloromethane and dried under vacuum.

6,9-Dichloro-2-methoxy-10-methylacridinium triflate (2) 6,9-Dichloro-2-methoxyacridine (5.0 g) was dissolved in 150 ml of dichloromethane with stirring in an oven-dried flask at ambient temperature, and 2.5 ml of methyl triflate was added. The mixture was stirred for 30 min and the fine yellow crystalline deposit produced was then collected by filtration. The mother liquor was further concentrated under reduced pressure and a second crop of crystals was collected. The two lots of crystals were combined, washed with cold dichloromethane and dried under vacuum.

9-Methoxy-10-methylacridinium triflate (3). In an oven-dried flask, 9-methoxyacridine (2.0 g) was dissolved in 40 ml of dichloromethane and 2.5 ml of methyl triflate were added. Precipitation took place after stirring of the reaction mixture for 4–5 hr at ambient temperature. The reaction mixture was filtered and the brilliant yellow crystals collected were washed with cold, dried tetrahydrofuran. The mother liquor was further concentrated by mild heating (45°) to yield additional crystals.

9-Ethoxy-10-methylacridinium triflate (4). 9-Ethoxyacridine (2.0 g) was dissolved in 20 ml of

dichloromethane and methyl triflate (1.5 ml) was added. The reaction mixture was stirred at ambient temperature for 2 hr, an additional 1.5 ml of methyl triflate were added, and the mixture was refluxed for another hour. The reaction mixture was filtered and the brilliant yellow crystals were washed with cold tetrahydrofuran and dried under vacuum.

Preparation of stock solutions

Stock solutions were prepared by dissolving weighed quantities of each acridinium triflate in absolute methanol. Final concentrations of $10^{-2}M$ for **1**, $2 \times 10^{-2}M$ for **2**, $5 \times 10^{-2}M$ for **3**, and $3 \times 10^{-2}M$ for **4** were obtained. Prior to dilution to volume with methanol, pyridine (for aniline assay) or triethylamine (for n-butylamine assay) was added to give a concentration of 50 μ l/ml in the stock solution. Stock solutions ($10^{-3}M$) of aniline and n-butylamine were also prepared in absolute methanol.

Preparation of calibration graphs

Into 1-ml standard flasks equipped with ground-glass stoppers were placed 200- μ l aliquots of acridinium triflate/pyridine or acridinium triflate/triethylamine stock solution, 0, 25, 50, 100 and 200 μ l of aniline or n-butylamine stock solution (as appropriate) were added and the solutions were mixed on a Vortex mixer for 30 sec. Enough methanol was added to give a total volume of about 400 μ l in each flask. The flasks were tightly stoppered, and placed in a shaking water-bath at 60° for 30 min. After cooling, the mixtures were transferred quantitatively to 10-ml standard flasks and diluted to volume with absolute methanol, and their absorbances were read at 445 nm for the aniline mixtures and 439 nm for the n-butylamine mixtures.

Assay procedure

A 200- μ l aliquot of approximately $10^{-3}M$ amine solution was mixed with 200 μ l of the appropriate acridinium triflate/pyridine or acridinium triflate/triethylamine stock solution in a 1-ml standard flask, shaken on the Vortex shaker for 30 sec, then heated *etc.* as described above. The concentration of amine was calculated from the absorbance and the calibration data

RESULTS AND DISCUSSION

The acridinium triflates were prepared by adding a slight excess of methyl triflate to a solution of the substituted acridine in dichloromethane and stirring for various time periods. One of the triflates (compound 4) also required refluxing of the dichloromethane solution. Table 2 presents a summary of selected spectral properties of these new compounds.

Aromatic nucleophilic substitution is enhanced in structures which contain an electronegative heteroatom,⁶ and is further enhanced when the heteroatom is rendered quaternary by alkylation.⁷ This ease of nucleophilic substitution can be harnessed for the purposes of analytical chemistry when the 9-position of the

acridine ring bears a facile leaving group. The reactions of aniline and n-butylamine with each of the acridinium triflates were observed to be more spontaneous than the corresponding reaction with tertiary acridines previously reported by this laboratory.¹⁻⁴ Absorption spectra of the reaction products of aniline and n-butylamine with 9-chloro-10-methylacridinium triflate are shown in Fig. 1, along with the reagent blank spectra. The reaction conditions were optimized by a series of univariate experiments designed to select the best ratio of acridinium triflate to analyte, reaction temperature and of reaction time, in that order.

Up to 50-fold excess of each acridinium triflate was reacted with aniline and n-butylamine at ambient temperature, the absorbance being measured at 30-min intervals. It was found that different molar excesses of the various acridinium triflates were needed for the aniline assay, but a 30-fold excess of each reagent was suitable for the n-butylamine determination. For aniline, a 10-fold excess of compound 1, 20-fold excess of compound 2, 50-fold excess of compound 3, and a 30-fold excess of compound 4 were necessary for best results.

Next, reaction temperatures of 25, 40, 50 and 60° were investigated with the optimized excess

*Molar absorptivity ($l \text{ mole}^{-1} \text{ cm}^{-1}$) in parentheses

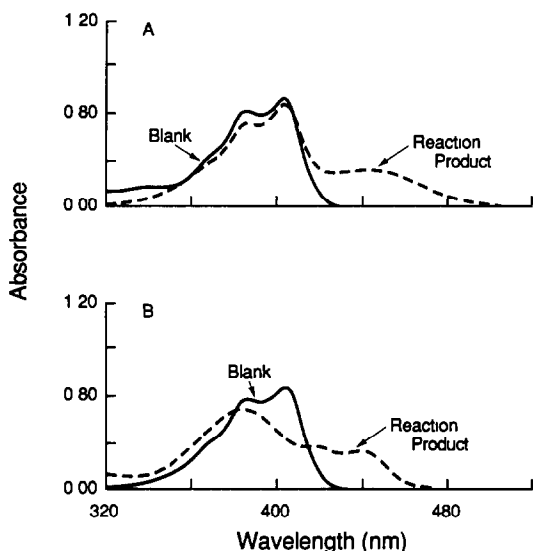

Fig 1 Typical absorption spectra of the product of reaction of $10^{-3}M$ aniline (A) and $10^{-3}M$ n-butylamine (B) with $10^{-2}M$ 9-chloro-10-methylacridinium triflate, and of the reagent blank

of reagent, and 60° was found to give the best precision and accuracy. Finally, samples with optimum reagent composition were heated at 60° for 0, 2.5, 5, 10, 15, 30, 45, and 60 min and heating for 30 min was found to give not only maximum absorbance but also the best linearity of calibration.

It was interesting that though the maximum absorbance was obtained within minutes after preparation of the analytical solution, the linearity and reproducibility were poor until the solution had been heated at 60° for 30 min.

It appears necessary to degrade the excess of acridinium triflate by heating for a sufficient time, to minimize its interference.

It was found that addition of the tertiary amines, pyridine and triethylamine, to the acridinium triflate stock solutions aided in improving the linearity. It was hypothesized that the reaction of triflates 1 and 2 with amines released free protons into the reaction solution, which probably prevented the nucleophilic addition product from being quickly formed, and that a proton-scavenger such as pyridine or triethylamine might be useful to force the reaction to proceed at a faster rate. What was discovered, however, was that their addition dramatically improved the linearity even for those reagents (*i.e.*, the 9-alkoxy triflates) with which no free protons would be formed in the reaction. The exact mechanism of the effect of the tertiary amines in the acridinium triflate-amine reaction remains unknown. Nucleophilic addition of the tertiary amine at the 9-position of the acridinium salt, resulting in *in situ* generation of a 9-quaternary ammonium intermediate, is an interesting possibility. Table 3 gives the results of a study comparing the absorbance at 445 nm for an analytical sample containing triflate 1, aniline, and pyridine, with that of a solution containing only triflate 1 and aniline. Linearity of the calibration plot is clearly superior when pyridine is present. Similar results were obtained with triethylamine for n-butylamine and triflate 1. The other triflates follow the same pattern with both amines.

Despite their high reactivity, the acridinium triflates are chemically stable for up to 18 months when stored in tightly sealed bottles at ambient temperature. However, methanolic solutions of the compounds rapidly degenerate and must be prepared not more than 10 min before use.

Tables 4 and 6 show the linear regression data obtained for the acridinium triflates 1-4 when each is reacted with aniline and n-butylamine at 60° for 30 min and the absorbances are measured at 445 and 439 nm, respectively. Tables 5 and 7 give the relative error (*i.e.*, the

accuracy) and precision data (RSD) for spiked samples of aniline and n-butylamine, respectively, assayed by the method described, with each triflate. All the triflates except 4 provide reasonable accuracy and precision in the determination of these model amines. Triflates 1 and 2 appear to provide the best overall accuracy and precision. In this laboratory, triflate 1 has recently been shown to be applicable for the determination of some primary aromatic amine type drugs in an on-line HPLC procedure where the triflate is added to the flowing stream post-column and derivatization is achieved in a mixing coil before the detector. In another example, triflate 1 was reacted with cycloserine in an HPLC pre-column method in which the resulting cycloserine-acridinium triflate product was separated from the rest of the reaction matrix by a silica HPLC column and was quantified by measurement of its fluorescence intensity.

Even though compound 4 possesses the strongest native absorbance in the 439-445 nm range, interference from the excess of reagent is most formidable, even after lengthy heating of the analytical solution. It may be that this interference can only be minimized by use of a flowing stream system such as HPLC, where reagent and product can potentially be separated.

Aligarh Muslim University, Aligarh-202 002, India

(Received 22 March 1989 Revised 7 December 1990 Accepted 28 January 1991)

Summary—An indirect determination of ascorbic acid is based on extraction of the iodine produced by reduction of potassium iodate. Beer's law is obeyed over the range 0.02–0.36 mg/ml ascorbic acid.

The detection and determination of ascorbic acid has been reviewed.¹ It has been determined spectrophotometrically with the Folin phenol reagent,² chloranil,³ sulphonated ferrozine⁴ and a new ferriox type reagent.⁵ The 2,4-dinitrophenylhydrazine and phosphotungstic acid methods for spectrophotometric determination of ascorbic acid have been compared.⁶ It has been determined spectrophotometrically by reaction with tetrazolium chloride derivatives⁷ and by first-derivative direct spectrophotometry.⁸ The silver-gelatin complex has been used in a reductive spectrophotometric method.⁹ Oxidation with bromine has been applied kinetically, spectrophotometrically and titrimetrically.¹⁰ The colour reaction with ferricinium trichloroacetate has been used for extraction spectrophotometry.¹¹ Ascorbic acid has been titrated with chloranil in the presence of hexamethylenetetramine in acetone-water mixture.¹² Heating an ascorbic acid solution with acidified ammonium vanadate yields a green product which can be measured at 680 nm.¹³ Other spectrophotometric methods are based on reduction of iron(III) in presence of dimethylglyoxime and of the iron(III)-EDTA complex in the presence of 2,2'-bipyridyl.¹⁵ In our studies, ascorbic acid has been found to react with potassium iodate in presence of hydrochloric acid to produce a yellow product, which on extraction with carbon tetrachloride gives a pink solution which can be used for spectrophotometric determination.

EXPERIMENTAL

Reagents

A 10 mg/ml ascorbic acid solution, a 0.1M potassium iodate solution and 0.01M hydro-

chloric acid were prepared with conductivity water.

Procedure

To a known volume of solution containing 0.1–1.8 mg of ascorbic acid add 1 ml of 0.1M potassium iodate followed by 1 ml of 0.01M hydrochloric acid. Shake the solution with 5 ml of carbon tetrachloride for a few minutes and separate the organic layer. Dry it over anhydrous sodium sulphate and measure its absorbance at 520 nm against carbon tetrachloride.

Analysis of formulations

Weigh several tablets individually, grind them to a powder and mix it. Similarly weigh and mix the contents of several capsules. Weigh an amount of sample equivalent to about 50 mg of ascorbic acid, stir it with 30 ml of conductivity water, let stand for 15 min, filter off the residue on a Whatman No. 42 paper and wash it with water. Dilute the filtrate and washings to volume in a 50-ml standard flask and proceed as above.

Determination of ascorbic acid in urine

To 40 ml of urine sample add 10 ml of 20% metaphosphoric acid and analyse for ascorbic acid by the procedure above.

Determination of ascorbic acid in fruit juices

Squeeze the juice from the fruit, add 50 ml of 20% trichloroacetic acid solution to a known volume of the juice to prevent oxidation of the ascorbic acid, centrifuge, and mix the supernatant liquid with 10 ml of 3% metaphosphoric acid solution and filter. Dilute the filtrate to a

suitable total volume and analyse a 1-ml aliquot as above.

RESULTS AND DISCUSSION

Determination of ascorbic acid

The absorption spectrum of the yellow extract in carbon tetrachloride has a maximum at 520 nm. In an optimization study it was found that

1 ml of 0.1M potassium iodate and 1 ml of 0.01M hydrochloric acid are adequate for the determination. Beer's law is obeyed over the range 0.1–1.8 mg of ascorbic acid in the organic phase

Results for the determination of ascorbic acid in pharmaceutical preparations, urine and fruit juices are given in Tables 1 and 2 and are compared with those obtained by reference

Hurka gave an early review of organic compounds which can be determined by oxidation with potassium iodate,¹⁶ and Erdey *et al.*¹⁷ have reported that iodate oxidizes ascorbic acid in moderately acidic medium and if present in excess is reduced to iodine, which can be extracted into carbon tetrachloride. The reaction may be regarded as the composite result of reduction to iodide, followed by the well known iodide/iodate reaction to yield iodine.

COMPARISON OF THREE COLORIMETRIC METHODS FOR THE DETERMINATION OF MANGANESE IN FRESHWATERS

B CHISWELL and K R O'HALLORAN

Department of Chemistry, The University of Queensland, Brisbane, QLD 4072 Australia

(Received 6 February 1989 Revised 21 January 1991 Accepted 28 January 1991)

Summary—Three colorimetric methods for the determination of manganese in freshwaters have been investigated and compared with the atomic-absorption spectrometry (AAS) method. Two of the methods, viz the formaldoxime (FAD) and pyridylazonaphthol (PAN) methods were found to yield poor calibration curves upon standardization, and to have high average errors for the estimation of manganese concentrations in standard solutions. The FAD method, when applied to freshwater samples, was found to be subject to an interfering UV absorbance which could not be negated successfully by a reagent blank, the method thus tended to give high estimations at low concentrations of manganese, but the results obtained also appear to be very sensitive to the nature of the freshwater matrix. On the other hand the PAN method was found to give very high estimations for the concentration of manganese, in both standard solutions and in freshwater samples, owing to the nature of the absorbance of the ligand used for manganese determination. This method also appears to be affected by the freshwater matrix, leading to gross overestimation of manganese levels. A third method, based on a porphyrin ligand [T-(4-CP)P], was found to give results comparable with those of the AAS method in estimating the soluble manganese content in freshwaters.

Standard Methods for the Analysis of Water and Wastewater describes only one colorimetric method for the determination of manganese in water.¹ This method is based on the persulphate oxidation of lower oxidation states of manganese to the purple permanganate ion. However, the molar absorptivity of MnO_4^- is only about $2.4 \times 10^3 \text{ l. mole}^{-1} \cdot \text{cm}^{-1}$, and even with the use of 5-cm spectrophotometric cells, the lower level of manganese detectable by this method is only approximately 40 $\mu\text{g/l.}$

Although World Health Organization limits for manganese in potable water have been put at 100 $\mu\text{g/l.}$, many water authorities find that manganese levels in excess of 50 $\mu\text{g/l.}$ in reticulation systems can lead to problems associated with black deposits in pipes and, consequently, black water from taps.

The two colorimetric methods that have found wide usage for the determination of manganese in freshwater, down to a concentration of 15 $\mu\text{g/l.}$, are those employing either formaldoxime (FAD) or 1-(2'-pyridylazo)-2-naphthol (PAN) as reagent. Both techniques have a minimum detectable concentration of manganese of roughly 15 $\mu\text{g/l.}$, but the work reported here indicates that both methods have

difficulties in yielding accurate results for manganese in dam waters.

In an earlier paper² we reported upon the development of a very successful colorimetric method for the determination of manganese, based on the use of the reagent $\alpha, \beta, \gamma, \delta$ -tetrakis(4-carboxyphenyl)porphine [T(4-CP)P], which we have comprehensively tested for down to 10 $\mu\text{g/l.}$ manganese in dam waters, and which can be used either for batch analysis in the laboratory, or in an autoanalyser unit.

The work here reported demonstrates the clear superiority of the T(4-CP)P method over both the FAD and PAN methods of manganese determination, and demonstrates how well its results correlate with those obtained by atomic-absorption spectrometry (AAS), for manganese determination in freshwaters.

EXPERIMENTAL

Sampling and sample pretreatment

Dam waters were sampled by use of a portable double-ended PVC cylindrical depth-sampler manufactured by Research Instruments MFG of Canada. Samples were transferred into polythene bottles which had been previously twice washed with 2M nitric acid and then

thoroughly washed with reagent-grade water. It should be noted that although samples for AAS analysis were stored at pH < 2 prior to analysis, samples to be analysed by other techniques were not necessarily acidified upon collection, unless the sample was to be analysed for total manganese.

Immediately after collection, samples were filtered through 0.45- μ m cellulose acetate membranes (Sartorius) with a Sartorius polycarbonate SM16510 filter holder and a Nalgene Mityvac (Newark, U.S.A.) hand vacuum pump.

The reproducibility of the filtration technique was found to be approximately 4% in terms of manganese concentration found in the filtrates and the residues retained.³ On two different days, ten replicate samples were drawn from the depth samples, filtered, and analysed for manganese by AAS, with the results shown in Table 1.

Colorimetric methods

All reagents used were of analytical grade unless otherwise specified. All distilled water was further purified by passage through a "Milli-Q" purification unit (Waters), this is hereafter termed reagent-grade water. A Hewlett-Packard HP8540 spectrometer was used for taking spectra and measuring absorbances.

Formaldehyde (FAD) method. The FAD reagent was prepared by mixing hydroxylamine hydrochloride (8.0 g) in reagent-grade water (50 ml) with formaldehyde solution (30% w/w, 4 ml) and making up to 100 ml with reagent-grade water. The EDTA reagent was prepared by dissolving the disodium salt (9.3 g) in reagent-grade water (100 ml).

To 20 ml of water sample (in a 25-ml standard flask) were added FAD reagent (1 ml) and ammonia solution (15% w/w, 1 ml). After mix-

ing and being allowed to stand for 2 min, the sample solution was treated with EDTA reagent (1 ml) and hydroxylamine hydrochloride solution (10% w/w, 2 ml). The absorbance of the red-brown solution was measured at 450 nm after 10 min, against a reagent blank.

Pyridylazonaphthol (PAN) method. A buffer solution of pH 9.2 was prepared by mixing 2M ammonia solution (30 ml) and 2M ammonium chloride solution (70 ml) and diluting to 1 litre with reagent-grade water.

To 10 ml of water sample (in a 25-ml standard flask) were added sodium ascorbate (10 mg), triethanolamine solution (20% v/v, 1 ml), buffer solution (1 ml), Triton X-100 solution (20% v/v, 1 ml), potassium cyanide solution (5% w/w, 0.5 ml) and PAN solution (10 mg/ml in methanol, ml), with mixing after each addition. The mixture was made up to volume with reagent-grade water and the absorbance of the red-orange solution was measured at 562 nm against a reagent blank.

Porphyrin [T-(4-CP)P] method. T-(4-CP)P was prepared by refluxing a propionic acid solution of 4-carboxybenzaldehyde and pyrrole (both 0.24M) for 6 hr. Upon cooling, purple crystals of T-(4-CP)P separated out; these were recrystallized by dissolution in warm methanol followed by filtration under gravity, cooling, and initiation of crystallization by addition of the minimum amount of chloroform needed. The 2×10^{-4} M reagent solution was prepared by dissolving the porphyrin (79.1 mg) in 0.1M sodium hydroxide (5 ml) and diluting to 500 ml with reagent-grade water and storing in an amber glass bottle. Cadmium chloride solution, 6×10^{-4} M, was prepared by dissolving 0.0505 g of CdCl₂ in 500 ml of reagent-grade water. A buffer solution of pH 8.0, which was 0.15M with respect to imidazole, was prepared by adding successively 0.025M sodium tetraborate (50 ml), 0.1M hydrochloric acid (20 ml) and imidazole (1.02 g in 25 ml of water), the pH, adjusted to 8.0 by addition of 0.1M hydrochloric acid, and diluting to volume in a 100-ml standard flask.

To the water sample (20 ml for 0–100 μ g/l manganese) in a 25-ml standard flask with its outside painted black (except for the area around the graduation mark), were successively added cadmium chloride solution (1 ml), buffer (1 ml) and T-(4-CP)P solution (3 ml). The mixture was made up to volume with reagent-grade water, and the absorbance of the green-brown solution measured at 468 nm after 5 min, against a reagent blank.

Table 1. Reproducibility of the effect of 0.45- μ m filtration on ten duplicate samples drawn from dam water on two different days, as evidenced by manganese analyses performed by AAS.

	Mean, ng/ml	Standard deviation, ng/ml	Relative standard deviation, %

Residual Mn	360	9	2.4
Total Mn	1325	19	1.4
Day 2			
Filterable Mn	714	2	0.3
Residual Mn	565	3	0.5
Total Mn	1279	5	0.4

Atomic-absorption spectrometry

Water samples for analysis were always acidified to $\text{pH} < 2$ by dropwise addition of concentrated hydrochloric acid. Analysis measurements were done on a Varian AA875 spectrometer at wavelengths of either 279.5 or 403.1 nm, using an oxidizing air/acetylene flame. Manganese standards up to 1000 $\mu\text{g/l}$ were prepared by suitable dilution of an Aldrich 1000 mg/l atomic-absorption standard solution. As the range of concentrations was large, two calibration graphs were prepared, covering the ranges 0–100 and 100–1000 $\mu\text{g/l}$, their correlation coefficients are given in Table 2.

RESULTS AND DISCUSSION

Formaldehyde (FAD) method

The method widely used is that described by Abdullah,⁴ which includes the addition of ascorbic acid to remove iron interference. We have found that at the 450 nm wavelength used, the rate of decrease in absorbance with time introduces a large error when batch analyses are undertaken in which there are variable times between mixing of reagents and the taking of spectrophotometric readings (see Fig. 1). We believe that the instability of the Mn–FAD complex, in the presence of ascorbic acid, is due to the reducing nature of the latter. The Mn–FAD complex is reported to be a six-coordinate Mn(IV) compound,⁵ which would be amenable to reductive decomposition, resulting in destruction of the complex and decrease in the absorbance at 450 nm.

The method of Goto *et al.*⁶ was used in the work described here, as the colour developed in this method is relatively stable with time (see Fig. 1). The method of Henriksen,⁷ which in-

Fig. 1 Comparison of colour stability for the two methods of manganese determination by the formaldehyde method

volves the addition of iron(II) to assist in removal of the Fe–FAD interference by use of an EDTA–hydroxylamine mixture, gave no improvement in results for the range of manganese concentrations studied.

The value of both the Goto *et al.* and Henriksen methods may, of course, depend on the level of iron present in the sample under analysis. Iron concentrations in the dam waters sampled were of the same order of magnitude as those of manganese, *i.e.*, from $< 10 \mu\text{g/l}$ to 1 mg/l.

A guide to the precision of any colorimetric method can be found in the correlation coefficients, which represent the adherence to the Beer–Lambert law over a given analyte concentration range. The accuracy can be best judged by comparing experimentally determined results either with known values, or with the results obtained by a reference technique, which in this case was the AAS method. Table 2 gives a comparison of the correlation coefficients and average absolute errors for the three colorimetric techniques and the AAS method, over two analyte concentration ranges.

For the 0–100 $\mu\text{g/l}$ range the FAD method shows poor linearity. Over this range the average error for an unknown manganese concentration is 11%. However, for the 100–1000 $\mu\text{g/l}$ range the average error improves significantly to 3.8%. It is reasonable to conclude that the accuracy of the FAD method is doubtful over the 0–100 $\mu\text{g/l}$ range, without any additional sources of interference associated with real sample analysis.

Based on results obtained over a twelve-month period for filtered (0.45 μm membranes) water samples collected from two dams in south-east Queensland, it was found that the FAD method gave higher results than AAS for manganese concentrations $< 100 \mu\text{g/l}$, but lower results than AAS for manganese concentrations $> 100 \mu\text{g/l}$. We believe that these differences are related to both the nature of the dam water matrix and the changes in manganese speciation with time and depth of sampling. The possibility that the (variable) presence of iron in the samples analysed could lead to the discrepancies in the results obtained by the two analytical methods could not be substantiated, no correlation could be observed between iron concentration and discrepancy.

Figure 2 shows a typical spectrum obtained with the FAD method for a dam water sample. For this sample the manganese concentration found by AAS was below the AAS detection

Fig 2 Spectrum obtained when a North Pine Dam water sample, containing no AAS-determinable manganese, is analysed by the FAD method, with a reagent blank in the reference beam

limit for manganese quoted by the instrument manufacturers,⁸ the FAD method gave 13 $\mu\text{g/l}$. The feature to note is the prominent peak at 260 nm. Its cause is not known, but it occurs in all spectra for dam water samples, varying both in wavelength of absorption maximum and in absorbance. We believe that the peak is probably associated with humic materials in the dam water matrix, which, depending on their chemical nature, absorb in the 250–300 nm region.⁹

Humic material varies, both in concentration and nature, with dam water depth, which accounts for the variability in wavelength and absorbance values between samples. This high absorbance in the ultraviolet region greatly increases the apparent manganese concentration determined by the FAD method. We conclude that for natural water samples containing humic matter (especially in cases of low concentration of manganese) the FAD method, which lacks sensitivity, will tend to overestimate the manganese concentration significantly.

To provide a reagent blank which successfully negates the ultraviolet absorbance of the humic material, thereby removing the interference in the manganese determination in the visible region, would require the preparation of different blanks, constituted from the raw water being analysed, for each analysis, as the dam water matrix constitution changes with depth. Such an approach is impractical for a large number of samples and the method is not amenable to automation.

The reason why the FAD method underestimates manganese concentrations above 100 $\mu\text{g/l}$ is not known.

Pyridylazonaphthol (PAN) method

The complex formed between manganese and PAN is not soluble in aqueous solution, so various methods of extraction into organic phases prior to spectrophotometric reading have been proposed.^{10,11} The method used in this work avoided this tiresome step by adaptation of the method of Goto *et al.*,¹² which uses a synthetic surfactant, Triton X-100, to avoid the need for extraction. Although these workers propose the use of sodium ascorbate to keep the manganese complex in the bivalent state, which stops discoloration of the complex, we have found that the Mn–(PAN) colour is stable for at least 2 hr and that the use of sodium ascorbate is not necessary in analysis of the waters studied here.

Table 2 indicates that the precision and accuracy of the PAN method in the present work were poor over the manganese concentration range 0–100 $\mu\text{g/l}$., with an average error of 11% for a set of 10 samples containing a known manganese concentration. The plot of absorbance against manganese concentration was markedly non-linear, with an obvious scatter of points (see Fig 3). This suggests that the method is useless for low manganese concentrations. For the 100–1000 $\mu\text{g/l}$ range better linearity was observed, the average error for known manganese concentrations being 7.2%, but even at these concentrations such a large error makes the PAN method unacceptable.

The major failure of the method arose from the nature of the spectrum close to the peak (at 562 nm) used for manganese determination. Figure 4 shows the spectrum of PAN in reagent-grade water, measured against a reagent-grade

Table 2 Correlation coefficients of calibration curves and average percentage errors for the four analysis methods used to determine manganese in standard solutions

Method	[Mn], 0–100 $\mu\text{g/l}$		[Mn], 100–1000 $\mu\text{g/l}$	
	Linear correlation coefficient	Average error, %	Linear correlation coefficient	Average error,* %
FAD	0.9882	11	0.9983	3.8
PAN	0.9844	11	0.9931	7.2
T-(4-CP)P	0.9996	2.0	0.9999	0.4
AAS	0.9999	1.5	0.9999	0.5

*Average error (%) in Mn determination was obtained by preparing a set of 10 samples containing known amounts of manganese and determining the concentration by using previously prepared calibration curves for both the colorimetric and AAS methods. The average errors in these analyses were than calculated.

Fig 3 Plot of absorbance against manganese concentration, for standard solutions (0.0–0.1 mg/l) analysed by the PAN method (with a reagent blank in the reference beam), showing the non-linearity of the calibration data

water blank at pH 9.2; two main features are discernible (a large peak at about 470 nm and a shoulder at about 400 nm) but no peak is seen at 562 nm.

Absorption bands at 440, 470 and 495 nm are said to arise from the successive dissociations of the ligand.¹³

where $\text{p}K_1$ for dissociation of a proton from the pyridinium group in the protonated reagent is 2.9, and $\text{p}K_2$ for dissociation of the phenol proton is 11.6. H_2PAN^+ gives a broad band at 400–450 nm, HPAN a band at about 470 nm with a shoulder at 400 nm, and PAN^- gives a peak at 495 nm.

When manganese is added to a PAN solution at pH 9.2 a peak at 562 nm appears (Fig. 5),

Fig 4 Spectrum of PAN ligand solution at a concentration equivalent to that of a reagent blank, with reagent-grade water in the reference beam

Fig 5 Spectrum of a PAN ligand solution at a concentration equivalent to that of a reagent blank, to which has been added 10 ml of 1 mg/l Mn^{2+} solution, with reagent-grade water in the reference beam

presumably by the formation of $[\text{Mn}(\text{PAN})_2]$, in which both PAN moieties have lost their dissociable protons.

If the reagent-grade water reference used to obtain Fig 5 was replaced by the reagent blank (containing PAN) described in the experimental section, the peak at 562 nm became much more easily distinguishable from the shorter wavelength peaks (Fig 6), as the reagent blank then cancelled out the peaks due to the uncomplexed ligand. However, a further peak was apparent at about 525 nm, and its amplitude indicated that it was associated with the Mn–PAN complex and thus was not negated by the reagent blank. A similar double peak appears in the spectrum of Mn–PAN in ether solution.^{14,15} It seems likely that this strong peak at 525 nm may affect the Mn–PAN absorbance measured at 562 nm, which is used to determine the manganese concentration

The problem is exemplified by reference to Fig 7, in which the PAN signal at 562 nm (for

Fig 6 Spectrum of a PAN ligand solution at a concentration equivalent to that of a reagent blank, to which has been added 10 ml of 1 mg/l Mn^{2+} solution, with a reagent blank in the reference beam

Fig 7 Spectrum obtained when a North Pine Dam sample, containing $62 \mu\text{g/l}$ AAS-determinable manganese, is analysed by the PAN method with a reagent blank in the reference beam

a sample of filtered North Pine Dam water (taken at the 9-m level) appears only as a shoulder and gives a manganese result of $220 \mu\text{g/l}$, whereas the value found by AAS was only $62 \mu\text{g/l}$. Such a large error cannot be entirely attributed to the poor calibration curve associated with the PAN method. It would appear that the water matrix is affecting the PAN ligand, resulting in a greatly overestimated manganese concentration.

Two sets of analyses of ten samples collected on two different days, at 3-m intervals from the surface down to 21 m (including samples at 10 and 11 m) showed that the PAN method consistently gave higher results than the AAS method. On average, the PAN results were about three times those obtained by AAS, with the largest relative errors at the lowest manganese values.

The PAN method is not amenable to automation, as the insoluble nature of the Mn-PAN complex results in significant build-up on the walls of the flow-through cells often used in Auto-Analyser or FIA systems.

Porphyrin [T-(4-CP)P] method

The method used was that of Ishii *et al.*, who used the porphyrin ligand to determine manganese in tea leaves¹⁶. The porphyrin, being a macrocyclic ligand, gives complexes of high stability and appears to be more selective than either FAD or PAN, as no masking agents are required when it is used. Furthermore, the water-soluble nature of the Mn-[T-(4-CP)P] complex results in a method which is simple, rapid, inexpensive and amenable to Auto-Analyser operation.² The selectivity of the T-(4-CP)P ligand is no doubt linked to the process by which the manganese complex is formed. At pH

8, Cd^{2+} is complexed by the porphyrin ligand in preference to Mn^{2+} , presumably for kinetic reasons. However, the higher stability constant of the Mn-[T-(4-CP)P] complex results in exchange of the Cd^{2+} for Mn^{2+} , although the exchange reaction is very slow. Imidazole is employed as a catalyst, allowing the exchange reaction to go to completion within 5 min. The Mn(II) complex formed is oxidized to an Mn(III) complex by dissolved oxygen.¹⁶ The result is a very selective method for determining Mn^{2+} in solution.

A further advantage of the method is that the molar absorptivity of the Mn-[T-(4-CP)P] complex is $7.6 \times 10^4 \text{ l mole}^{-1} \cdot \text{cm}^{-1}$, greater than that of either the Mn-PAN ($4.6 \times 10^4 \text{ l mole}^{-1} \cdot \text{cm}^{-1}$) or Mn-FAD complex ($1.6 \times 10^4 \text{ l mole}^{-1} \cdot \text{cm}^{-1}$). The sensitivity of the porphyrin method is thus superior to that of either of the other two methods, and the peak used for manganese determination is far less prone to dam water matrix interference, such as that found with the FAD method.

Figure 8 shows the spectra obtained during the exchange process. The significant feature is the large bathochromic shift between the Soret bands of the T-(4-CP)P ligand, the Cd(II)-[T-(4-CP)P] complex and the Mn(III)-[T-(4-CP)P] complex, which allows measurement of the Mn(III)-[T-(4-CP)P] band without possible interference from neighbouring absorbance peaks, which was found to be a major drawback of the PAN method.

Table 2 illustrates the precision and accuracy of the T-(4-CP)P method for both manganese concentration ranges studied. It can be seen that

Fig 8 — Spectrum of a T-(4-CP)P ligand solution at a concentration equivalent to that of a reagent blank. Spectrum of the same solution to which has been added 1 ml of $6 \times 10^{-4} \text{ M Cd}^{2+}$ ---- Spectrum of the ligand/ Cd^{2+} solution to which has been added 10 ml of 1 mg/l Mn^{2+} solution. Reagent-grade water is used in the reference beam throughout.

Table 3 Results for manganese determinations by the three colorimetric methods and AAS for filtered water samples from North Pine Dam

Sample depth, <i>m</i>	Manganese concentration, $\mu\text{g/l}$			
	FAD	PAN	T-(4-CP)P	AAS
0	0.06	0.20	0.047	0.056
3	0.02	0.03	0.014	0.016
6	0.01	0.02	<0.010	<0.003
8	0	0.03	<0.010	0.007
9	0.04	0.16	0.024	0.034
10	0.02	0.03	0.017	0.016
11	0.02	0.03	<0.010	0.012
15	0.08	0.20	0.071	0.065
18	0.09	0.24	0.100	0.105
21	0.12	0.26	0.126	0.127

the correlation coefficients and average errors in manganese determination by the T-(4-CP)P method are very similar to those for the AAS method

CONCLUSIONS

The results in Table 3 allow comparison of the three colorimetric methods with each other and with the AAS method for filtered dam water samples. It is clear that the T-(4-CP)P and AAS results are in excellent agreement though with a general tendency of the former results to be lower. The FAD method also gives results in relatively good agreement with AAS. On the other hand the discrepancy between results ob-

tained by the PAN method and those of the three other analytical techniques is only too obvious; the use of this ligand gives gross over-estimation of the manganese present in dam water samples

(Received 17 January 1989 Revised 31 December 1990 Accepted 11 January 1991)

Summary—A selective and sensitive method for the extraction and spectrophotometric determination of vanadium(V) in microgram quantities is described. The molar absorptivity of the yellow vanadium(V)—caffeic acid—Aliquat 336 extract is $1.3 \times 10^4 \text{ l mole}^{-1} \text{ cm}^{-1}$ at 370 nm. The method is compared with the atomic-absorption spectrometric method and applied to the trace determination of vanadium in steel, alloys, a rock and environmental samples.

Caffeic acid (I) is a versatile reagent used in organic, inorganic and pharmaceutical analysis.¹⁻³ In acidic medium it forms a stable yellow complex with vanadium(V) which can be extracted with isoamyl alcohol. This paper describes the extraction of the vanadium(V)—caffeic acid complex with the liquid ion-exchanger Aliquat 336, which can be applied to the determination of microgram amounts of the metal. The spectrophotometric method developed has been compared with the AAS method

EXPERIMENTAL

Reagents

All chemicals used were of guaranteed reagent (Merck) or AnalaR (BDH) grade. Vanadium(V) stock solution was prepared by dissolving 0.0585 g of ammonium metavanadate in 500 ml of doubly distilled water and standardized spectrophotometrically.⁴ It was further diluted as required. A 1 mg/ml caffeic acid solution was prepared in methanol

Buffer solutions in the pH range 2.0–6.0 were prepared from mixtures of 0.1 M sodium citrate and 0.1 M hydrochloric acid, or 0.2 M sodium acetate and 0.2 M acetic acid.⁵

Amberlite LA-1 (*N*-dodecyltrialkylamine, Rohm and Hass, Philadelphia), Aliquat 336 (tricaprylmethylammonium chloride, Fluka) and trioctylamine (Fluka) were dissolved in suitable diluents in various proportions.

Apparatus

A VSU 2 P spectrophotometer (Carl Zeiss, Jena) with matched fused-silica cells was used for spectral measurements. A GBC 901 atomic-absorption spectrometer equipped with a vanadium hollow-cathode lamp was used. The 318.4 nm vanadium line and a nitrous oxide–acetylene flame were used.

Dissolution of samples

General analytical procedures⁶⁻⁸ for bringing the samples into solution were followed. In all cases, complete oxidation to vanadium(V) was ensured by adding 0.05 M potassium permanganate dropwise to the solution until a light pink colour persisted for 1–2 min.

Rock samples. A 0.5-g sample was transferred into a 100-ml Teflon beaker and a mixture of concentrated hydrofluoric acid (10 ml), sulphuric acid (15 ml) and nitric acid (5 ml) was added. The mixture was then digested on a

steam-bath for 2–3 hr, diluted with water and filtered. The residue was washed and the filtrate and washings were finally diluted to volume in a 100-ml standard flask with distilled water.

Steel samples. A 1.0-g sample was transferred into a 150-ml borosilicate glass beaker and 25 ml of concentrated hydrochloric acid were added, followed by digestion on a sand-bath for 1 hr and evaporation to dryness. The residue was dissolved in 10–15 ml of concentrated hydrochloric acid along with 0.5 g of ammonium persulphate. The solution was diluted and filtered, and finally diluted to volume in a 100-ml standard flask with distilled water.

Plant samples. A known weight of sample (~100 g) was ashed, and 10 g of the ash was transferred into a 250-ml borosilicate glass beaker and digested on a sand-bath with 100 ml of concentrated hydrochloric acid and 20 ml of concentrated nitric acid for about 1 hr. The hot solution was centrifuged, and the supernatant liquid was decanted from any siliceous matter. The residue was washed with 10 ml of 0.1M hydrochloric acid and the combined solution was evaporated to dryness. The residue was taken up in 0.1M hydrochloric acid and accurately diluted to 100 ml with distilled water.

Soil samples. A 1–2 g sample of the dried soil was digested with 50 ml of concentrated hydrochloric acid and 10 ml of concentrated nitric acid for 1 hr on a sand-bath, then the solution was evaporated to dryness. The residue was boiled with 50 ml of 0.1M hydrochloric acid and filtered, then the filtrate and washings were evaporated to dryness and the residue was taken up and the solution diluted accurately to 100 ml with 0.1M hydrochloric acid.

Blood samples. A 2-ml blood sample was digested with 20 ml of concentrated hydrochloric acid and 0.25 g of ammonium persulphate for 1 hr, then the mixture was diluted and filtered. The filtrate and washings were evaporated to dryness and the residue was taken up and the solution diluted to volume in a 25-ml standard flask with 0.1M hydrochloric acid.

Water samples. A known volume of sample was evaporated to dryness and the residue was treated in the same way as plant ash.

Dissolution of Nb₂O₅ and Ta₂O₅

Niobium. Niobium oxide (1.79 g) was fused with 10.0 g of potassium bisulphate and the cooled melt was dissolved in 1M tartaric acid; the solution was diluted to 500 ml. The final

Table 1 Effect of pH on the extraction of 49 µg of vanadium(V) with caffeic acid and Aliquat 336 (conditions as in procedure)

pH	Absorbance	Extraction, %
3.0	0.060	12.0
3.2	0.180	36.0
3.5	0.360	72.0
3.9	0.500	99.9

4.2	0.500	99.9
4.5	0.250	49.9
5.0	0.050	10.0
6.0	0.020	4.0

concentration (2.5 mg/ml) of niobium was determined spectrophotometrically.⁹

Tantalum. Tantalum oxide (2.99 g) was fused with 10.0 g of potassium bisulphate and the cooled melt was dissolved in 1M ammonium oxalate; the solution was diluted to 250 ml. The final concentration of tantalum (9.8 mg/ml) was determined gravimetrically.¹⁰

Procedure

A suitable aliquot of sample solution containing 2.5–125 µg of vanadium was transferred into a 60-ml separatory funnel, 5 ml of 1-mg/ml caffeic acid solution were added and the pH was adjusted initially with alkali and finally with buffer to 4.0. The mixture was shaken gently with 5 ml of a 10-mg/ml solution of Aliquat 336 in isoamyl alcohol for about 1 min. The organic extract was collected and dried over anhydrous sodium sulphate and finally diluted to volume with isoamyl alcohol in a 25-ml standard flask. The absorbance was measured at 370 nm against a reagent blank.

For AAS measurements, the same extraction procedure was applied and the extracts were analysed by the EPA method¹¹ either directly or after back-extraction of the vanadium into 0.01M nitric acid.

Table 2 Effect of various diluents on the extraction of 49 µg of vanadium(V) at pH 4 with 5 ml of 1-mg/ml caffeic acid solution and 5 ml of Aliquat 336 solution (concentration A, 10 mg/ml, B, 20 mg/ml, C, 30 mg/ml)

	Benzene	3.5

RESULTS AND DISCUSSION

The yellow vanadium(V)-caffeic acid complex is readily extracted into a 10-mg/ml solution of Aliquat 336 in isoamyl alcohol from an aqueous medium of pH 4.0. The species extracted has maximum absorbance at 370 nm. The reagent blank does not show appreciable absorbance at this wavelength. The molar absorptivity is $1.3 \times 10^4 \text{ l mole}^{-1} \text{ cm}^{-1}$. The system obeys Beer's law in the range 0.1–5.0 ppm vanadium at 370 nm and the optimum range (Ringbom plot) is 0.1–4.8 ppm.

Effect of experimental variables

The vanadium(V) complex was found to be completely extracted into isoamyl alcohol over the pH range 3.9–4.2 (Table 1) and 5 ml of 1-mg/ml caffeic acid solution was found to be sufficient for complex formation. A larger excess of reagent has no adverse effect.

The optimum concentration of Aliquat 336 was studied by varying the concentration from 10 to 60 mg/ml in isoamyl alcohol. The extraction was quantitative over this range and 5 ml of 10-mg/ml solution was adopted for use. Various solvents for the Aliquat 336 were tested (Table 2). Isoamyl alcohol was found to be the most suitable. Aliquat 336 was selected as the liquid-anion exchanger, since it was found that of the three reagents tested (Table 3) it was the only one that gave complete extraction. It

was found that a second extraction was not necessary.

Effects of diverse ions

Solutions containing a fixed concentration (1.32 ppm) of vanadium(V) and various amounts of a potentially interfering ion were extracted as described in the procedure. Barium, cadmium, calcium, cobalt(II), copper(II), nickel, titanium(IV) and tungstate can be tolerated up to 40 mg in the determination of 33 μg of vanadium. Mercury(II) and manganese(II) can be tolerated up to 50 mg, aluminium, lead and uranyl ion up to 60 mg. Tantalum and molybdenum interfere at 200 μg , and niobium at 225 μg , but in the presence of oxalate and tartrate as masking agents can be tolerated in amounts up to 40 mg, and so can zirconium. However, molybdenum interfered in the atomic-absorption determination of 33 μg of vanadium in the presence of 40 mg of Na, Ca, Mg, Cu, Ni, Zn, Pb, Cr, Al, Bi, Mo or Sb.

Determination of vanadium in various samples

The present method was compared with an AAS method with a reported detection limit of 0.2 ppm for vanadium.¹² Chromium(VI), iron(III), tin(IV) and molybdenum(VI) suppressed the absorption seriously for the direct determination but they did not interfere after extraction

of vanadium with the caffeic acid and Aliquat 336.

The results for the analysis of standard samples for vanadium are given in Table 4, and for rock, soil, blood samples *etc* in Table 5. The values are in good agreement with those obtained by AAS.

PRECIPITATION AND EXTRACTION OF SOME BIVALENT METAL IONS WITH BIS(DIPHENYLPHOSPHINYL)METHANE AND PERCHLORATE

SHIGEO UMETANI,* NAOKI SHIGEMURA,† SORIN KIHARA and MASAKAZU MATSUI
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611, Japan

(Received 1 August 1989 Revised 22 January 1991 Accepted 1 February 1991)

Summary—The solvent extraction of alkaline-earth and some bivalent transition metal ions such as Co^{2+} , Ni^{2+} , Cu^{2+} , Zn^{2+} and Cd^{2+} with the bidentate phosphine oxide compound, bis(diphenylphosphinyl)methane (BDPPM), and perchlorate into 1,2-dichloroethane has been investigated. When benzene is used as the solvent, the complexes consisting of metal ion, BDPPM and perchlorate are not extracted but are precipitated at the liquid-liquid interface. The precipitates have been isolated and their compositions determined.

The specificity of the adduct formation reactions of the bidentate neutral ligands, bis(diphenylphosphinyl)methane (BDPPM) and its ethane analogue, has been examined by investigation of the synergistic extraction of alkaline-earth,¹ rare-earth² and some bivalent³ metal ions. In the synergistic extraction of alkaline-earth metal ions with acylpyrazolone derivatives and BDPPM into benzene,¹ it was found that when sodium perchlorate was present, a precipitate appeared at the benzene-water interface, and the metal ions were not detectable in either the organic or the aqueous phase. A similar reaction was observed in the synergistic extraction of some bivalent metals into benzene with 1-phenyl-3-methyl-4-benzoyl-5-pyrazolone and BDPPM.³ These precipitation reactions suggest that ion-association complexes consisting of metal ion, BDPPM and perchlorate are formed, and precipitated because of their low solubility in both the benzene and water phases. This suggests that the complexes might be extractable into a more polar organic solvent. The possible use of BDPPM as a solvating extractant is interesting, since BDPPM is expected to be a more powerful ligand than 1,10-phenanthroline (phen),⁴ trioctylphosphine oxide (TOPO)⁵ and tributyl phosphate (TBP),⁶ owing to its strong

complex-formation ability and the high hydrophobicity.⁷⁻¹⁰ This possibility was examined in the present work.

BDPPM

EXPERIMENTAL

Reagents

BDPPM^{11,12} was prepared by oxidation of bis(diphenylphosphino)methane (Aldrich) with dilute hydrogen peroxide solution and purified by recrystallization from toluene. All other reagents were reagent-grade and used without further purification.

Apparatus

Metal-ion concentrations were measured with a Hitachi 180-70 polarized Zeeman atomic-absorption spectrophotometer and a Japan Jarrel Ash ICAP-500 inductively coupled argon-plasma emission spectrophotometer. A Shimadzu UV-180 double-beam spectrophotometer was used for spectrophotometric measurements. Infrared spectra were taken with a Hitachi 260-50 infrared spectrophotometer. The pH measurements were performed with a Hitachi-Horiba F-7ss pH-meter, equipped with a combination glass electrode.

†Present address: Kimoto Electric Co., Ltd., 3-1 Funahashi-cho, Tennoji-ku, Osaka 543, Japan

Extraction of perchloric acid

A 5-ml portion of 1M perchloric acid was equilibrated at $25 \pm 1^\circ\text{C}$ in a 30-ml centrifuge tube with an equal volume of an organic solvent containing the required amount of BDPPM, for 1 hr. The acid concentration in the aqueous phase was measured by titration with sodium hydroxide. The acid content in the organic phase was measured by titration after back-extraction into water. The sum of the perchlorate concentrations in the two phases agreed well with the initial concentration.

Precipitation reaction

The precipitation reaction was examined in a similar way. A 10-ml portion of an aqueous phase containing the metal ion and sodium perchlorate was shaken with an equal volume of 0.01M BDPPM solution in benzene, at $25 \pm 1^\circ\text{C}$ for 1 hr. The pH of the aqueous phase was adjusted to *ca.* 2.0 with hydrochloric acid. The aqueous phase was filtered and the concentration of metal ion in it was measured by atomic-absorption spectrometry or ICP atomic-emission spectrometry. The amount of metal ion in the precipitate was obtained by subtracting the metal concentration found in the aqueous phase from that initially taken.

Determination of composition of the precipitates

The precipitates were collected by filtration, washed with water and dried under reduced pressure. A dichloroethane (DCE) solution of the precipitate was shaken with dilute hydrochloric acid and the amount of metal ion extracted into the aqueous phase was measured. The amount of BDPPM in the DCE solution was measured spectrophotometrically, and so was the amount of perchlorate in the aqueous solution, after extraction into chlorobenzene with Crystal Violet.¹³

Extraction of metal ions

A 5-ml portion of 0.01M hydrochloric acid (pH 2.0) containing $1-2 \times 10^{-5}\text{M}$ metal ion and the required amount of sodium perchlorate was equilibrated with an equal volume of 0.01M BDPPM solution in DCE for 1 hr at $25 \pm 1^\circ\text{C}$. The ionic strength was adjusted by addition of sodium nitrate to the aqueous phase to keep the sum of $[\text{NaClO}_4]$ and $[\text{NaNO}_3]$ at 0.1M. After phase separation, the concentration of the metal ion in the aqueous phase was measured. The concentration of metal ion in the organic phase was determined in the same way after stripping

with dilute hydrochloric acid. The sum of the metal concentrations in the two phases agreed well with the initial concentration.

RESULTS AND DISCUSSION

Extraction of perchloric acid

The equilibrium for extraction of a metal ion (M^{n+}) or perchloric acid ($\text{M}^{n+} = \text{H}^+$) and the extraction constant, K_{ex} , can be expressed as

$$K_{\text{ex}} = \frac{[\text{M}(\text{BDPPM})_s(\text{ClO}_4)_n]_{(\text{o})}}{[\text{M}^{n+}][\text{ClO}_4^-]^n[\text{BDPPM}]_{(\text{o})}^s} \quad (2)$$

where subscript (o) denotes a species in the organic phase and s is the number of BDPPM molecules in one "molecule" of the extracted species. The distribution of perchloric acid is shown in Fig. 1, as a function of $\log [\text{BDPPM}]_{(\text{o})}$. The slopes of the straight portion of the plots is found to be very close to 2, indicating that two moles of BDPPM react with one mole of perchloric acid to form an $\text{H}(\text{BDPPM})_2(\text{ClO}_4)$ ion-pair. The extraction constants were calculated by use of equation (2). The values of $\log K_{\text{ex}}$ are 2.27 for DCE, 1.90 for benzene and 0.20 for chloroform. A similar trend in the effect of the organic solvent on the K_{ex} value has been reported for the extraction of some acids with TOPO.^{14,15} The poor extraction

Fig. 1 Extraction of perchloric acid into various organic solvents, as a function of $\log [\text{BDPPM}]_{(\text{o})}$.

into chloroform suggests a strong hydrogen-bonding interaction of chloroform and the extractant, as suggested in the literature^{14,15} The deviation from the straight line at lower $[\text{BDPPM}]_{(o)}$ in the DCE system might be due to dissociation of the complex, because the dielectric constant of DCE is fairly large (10.36 at 25°), and in such conditions dissociation of the ion-pair could be considered dominant, especially when both the cation and the anion are singly charged and bulky, and the concentration is low¹⁶ The dissociation would be regarded as

Alternatively, the deviation could be the result of extraction of $\text{H}(\text{BDPPM})(\text{ClO}_4)$ when the BDPPM concentration is very low

Precipitation

The precipitation reactions of metal ions with BDPPM and perchlorate are illustrated in Figs 2 and 3, as a function of $\log [\text{ClO}_4]$ The precipitation reaction sets in suddenly when the perchlorate concentration exceeds a certain value, and the metal complexes are then precipitated completely. As $[\text{ClO}_4]$ increases, the alkaline-earth metal ions are precipitated in the order Ba^{2+} , Sr^{2+} , Ca^{2+} , Mg^{2+} , *i.e.*, the largest ion first and the smallest last. The bivalent transition metal ions are precipitated in the order Cd^{2+} , Zn^{2+} , Co^{2+} , Cu^{2+} , Ni^{2+} .

The compositions of the precipitates isolated are summarized in Table 1. The infrared absorption spectra of the complexes were measured by the KBr method and the characteristic bands

Fig 2 Precipitation of bivalent transition metals with BDPPM, as a function of $\log [\text{ClO}_4]$ BDPPM 0.01M in benzene, pH ca 2.0

Fig 3 Precipitation of alkaline-earth metals with BDPPM, as a function of $\log [\text{ClO}_4]$ BDPPM 0.01M in benzene, pH ca 2.0

attributed to the $\text{P}=\text{O}$ group are also given in Table 1. The mole ratios for $\text{M}:\text{BDPPM}:\text{ClO}_4$ were found to be close to 1.4:2 for strontium and barium, and 1.3:2 for the other metals. The composition of the magnesium complex could not be expressed as the ratio of small whole numbers. The "theoretical" carbon and hydrogen contents were calculated from the proposed molecular formulae. The calculated values exhibit satisfactory agreement with the values found except for the Cd complex. The values found for the Mg complex are close to those for a 1:3:2 complex. The apparent deviation from simple stoichiometry is probably due in part to impurity in the precipitates, since no attempt was made to purify them.

Extraction of metal ions

Various organic solvents were examined. The metal ions examined are extractable into 1,2-dichloroethane (DCE) with BDPPM and perchlorate and can be stripped into water. Although the precipitates consisting of BDPPM, the metal ion and perchlorate are soluble in chloroform, no extraction into chloroform was observed under the conditions used. The complexes are completely extracted into nitrobenzene, but the metal ions cannot be back-extracted into water. A precipitate was observed at the benzene-water interface when the phases were separated by centrifugation. This precipitate dissolved if the aqueous phase was removed and the benzene phase replaced by the same volume of 0.01M hydrochloric acid and the phases were shaken; this occurred because equilibrium (1) is shifted to the left in the absence of perchlorate in the aqueous phase

Table 1 Composition of the metal complexes

M	BDPPM	ClO ₄	Found, %		Calcd, %		P=O band, cm ⁻¹
			C	H	C	H	
Mg	—	—	60.3	4.45	61.18*	4.52*	1175
Ca	1.292	1.94	60.4	4.41	60.53	4.47	1175

*Values for 1:3:2 complex

The same amount of metal ion as added initially was found in this new aqueous phase. Hydrocarbons such as cyclohexane are not suitable for use with BDPPM because of its low solubility in them. Accordingly, DCE was selected as the organic phase in the investigation of solvent extraction.

The extraction of metal ions into DCE with BDPPM, as a function of [ClO₄], is illustrated in Figs 4 and 5. The orders of efficiency of extraction of metal ions are Cd²⁺ > Zn²⁺ > Co²⁺ > Cu²⁺ > Ni²⁺ and Ca²⁺ > Ba²⁺, Mg²⁺ > Sr²⁺. The extraction order in Fig. 4 is the same as that of precipitation shown in Fig. 2. The order of precipitation of alkaline-earth metal ions (Fig. 3) is also the order in which their ionic radii decrease, but not the order of extraction shown in Fig. 5. This could be considered to indicate that the extractability of these metals is

not simply governed by formation of a complex cation with BDPPM and distribution of the ion-pair with perchlorate into the organic phase. As can be seen in Table 1, the characteristic bands attributed to the P=O group in the complexes are observed at 1150–1190 cm⁻¹. The decrease in wave number from that of BDPPM (1200 cm⁻¹) could be considered to correspond to the stability of the BDPPM complex. However, the order of the extraction and precipitation reactions (Figs. 2–5) cannot be accounted for only in terms of the stability of the complex (as derived from Table 1). For example, Cu²⁺ forms very stable complexes with many chelating reagents and these are readily extracted into an organic phase. Its BDPPM complex absorbs at 1150 cm⁻¹ (Table 1) suggesting that this complex is the most stable of those examined. In practice, however, of the transition metals tested, copper is one of the most difficult to extract or precipitate in this system as also is

Fig. 4 Extraction of bivalent transition metals with BDPPM, as a function of log [ClO₄]. BDPPM 0.01M in DCE, [NaClO₄] + [NaNO₃] = 0.1M, pH ca 2.0

Fig. 5 Extraction of alkaline-earth metals with BDPPM, as a function of log [ClO₄]. BDPPM 0.01M in DCE, [NaClO₄] + [NaNO₃] = 0.1M, pH ca 2.0

nickel. This suggests that the copper and nickel complexes may differ from the others in structure.

It is difficult to explain the extraction behavior of the alkaline-earth metals. As suggested by the wave numbers for the P=O bands (Table 1), the stability of the complexes increases as the ionic radii of the metals decrease, as expected, but the extraction order is not that of the stabilities or of the ionic radii. In any event, it is notable that the alkaline-earth metals, which are among the least extractable bivalent elements, are readily and quantitatively extracted.

The slopes of the straight portion of the plots in Figs 4 and 5 are found to be 1.5–1.8. If the extraction equilibrium is truly described by equation (1), a logarithmic plot of the distribution ratio of the metal ions, $\log D$, vs $\log [\text{ClO}_4^-]$, for $[\text{BDPPM}]_0$ constant, should be a straight line with slope of 2. Any decrease in perchlorate concentration in the aqueous phase (owing to extraction with BDPPM) is negligible, since the extraction constant is not large enough for the degree of extraction to be significant under the conditions set in Figs. 4 and 5. An experiment on the extraction of sodium with BDPPM and perchlorate indicated that decrease in the concentration of perchlorate and BDPPM, caused by the extraction of sodium, is negligible. The lower value of the slope is again attributable to dissociation in the organic phase

The metal ions studied in the present work were not extracted with TOPO, a monodentate neutral ligand, under the same conditions as for BDPPM. This greater extractability with BDPPM could be attributed to its chelating ability and the highly hydrophobic nature of the ion-pair formed with perchlorate.

BDPPM has some advantages over *N,N*-bidentate ligands such as 1,10-phenanthroline (phen) or 2,2'-bipyridyl, as follows. The extraction of "hard metals", such as the alkaline-earth and rare-earth metals, as ion-pairs of their complexes with phen, is not satisfactory, prob-

ably owing to the very low stability of the chelates. Further, such extraction with phen is impossible in acidic media, because of protonation of the nitrogen atoms in phen. In contrast, the extraction of alkaline-earth metals (and others) with BDPPM and perchlorate is satisfactory, and the distribution of BDPPM does not depend on the pH, unlike that of phen or 2,2'-bipyridyl. It is therefore possible to use the BDPPM system at increased acidity provided that this is not so high that extraction of $\text{H}(\text{BDPPM})_2\text{ClO}_4$ takes place and decreases the concentration of free BDPPM. This type of extraction system could be considered to be analogous to that employing phenanthroline or crown ethers, namely extraction with a solvating reagent. It is expected that the BDPPM could be more widely applied, owing to its strong co-ordinating ability and hydrophobic nature. It may also be expected to give greater selectivity than that of conventional extraction systems.

ON THE APPLICATION OF THE DUMAS TECHNIQUE FOR THE DETERMINATION OF NITROGEN IN REFRACTORY NITRIDES

WALTER LENGAUER

Institute for Chemical Technology of Inorganic Materials, Technical University of Vienna,
Getreidemarkt 9, A-1060 Vienna, Austria

(Received 30 November 1990 Accepted 29 January 1991)

Summary—The classical Dumas apparatus has been modified. The generally recommended oxidants CuO and V₂O₅ were found to give relatively high blank values and were therefore replaced by Cu₂O. The preparation of the Cu₂O is described. It is an exceptionally suitable oxidant for the Dumas analysis of the Group Va nitrides as well as manganese nitrides and molybdenum nitrides because it does not release oxygen into the gas phase. The reaction of the Group IVa nitrides as well as of CrN with CuO and Cu₂O is, however, not completely quantitative at 1000–1150° in reasonable reaction times. The results of the Dumas analysis of a Group IVa nitride should be corrected by measuring the nitrogen content of the residue (*e.g.*, by hot extraction). The relative standard deviations do not exceed 0.38%. The nitrogen contents (% w/w) of the residues range from <0.001% for Mo₂N + MoN to 0.54% for Cr₂N + CrN. BN, Si₃N₄ and AlN could not be decomposed with copper oxides under the conditions used. AlN could be analysed by adding V₂O₅, but the *rsd* was 0.55% and the nitrogen content in the residue was 0.52% w/w. Neither BN nor Si₃N₄ could be analysed by addition of V₂O₅.

Transition-metal (mono)nitrides exist over an extended range of homogeneity of up to 10–30 atom% N¹. In this homogeneity region the solid-state properties (*e.g.*, lattice parameter, superconduction transition temperature, micro-hardness) show a substantial dependence on the chemical composition. An accurate chemical analysis for the main constituents as well as the impurities is therefore not only of considerable interest in itself, but is essential if the variation of physical properties with composition within the homogeneity region is to be studied.

In the Dumas analysis the sample is oxidized and the nitrogen evolved is measured volumetrically. It is one of the methods with the greatest accuracy and precision. In recent years improved equipment has been constructed which permits determination of nitrogen by gas chromatography (GC) with an error not exceeding about 1 atom%. This Dumas–GC technique appears to be the most accurate technique that is suitable for automation.^{2,3} The conditions for automatic Dumas–GC analysis of refractory transition-metal nitrides have been studied only recently,⁴ and the main disadvantages are the low sample loads and the relatively low decomposition temperatures that can be used. In addition, this technique needs well characterized standards.

The most accurate modification of the Dumas technique at present still appears to be the method described by Kern and Brauer.⁵ These authors heated titanium, niobium and tantalum nitrides in a stream of pure CO₂ with CuO or CuO + Cu₂O (for niobium nitrides) as the oxidant. They obtained excellent accuracy. Their method, however, has several experimental disadvantages such as low measured volumes of nitrogen (and thus low sample loads) as well as complicated CO₂ storage, sample heating and temperature control, making the apparatus difficult to handle.

Several modifications have been suggested for the oxidation or decomposition of the sample in the Dumas analysis,^{6–12} but all have given generally less precise results. However, no studies have been made of the nitrogen contents of the residues (reacted nitride + copper oxides) to determine whether or not the reaction is quantitative.

The present study was performed in order to update the classical technique described by Kern and Brauer⁵ and to investigate whether the combustion procedure is quantitative. For the latter purpose the reaction products were analysed by hot extraction. An improved technique for the Dumas analysis was also used. The apparatus allowed easier and faster handling

and produced data with an accuracy of the same order of magnitude as that given by the Kern and Brauer method, when corrected for the nitrogen contents of the residues (determined by hot extraction).

EXPERIMENTAL

Oxidant requirements and preparation of Cu₂O

It has been stated that there is no need for an additional oxidant, since CO₂ reacts with all transition-metal nitrides quantitatively, setting free all combined nitrogen.¹⁰⁻¹² This reaction, however, leads to the conversion of CO₂ into CO, the removal of which would complicate the experimental arrangements and present an additional source of error.

CuO and V₂O₅ have been recommended as oxidants. We have tested them, and found that both substances gave such high blank values that they led to unreliable results. Therefore we also performed blank tests with Cu₂O and investigated the reaction of this compound during analysis. Cu₂O is an excellent oxidant which gives a blank value below the nitrometer's determination limit of 0.005 ml.

The replacement of CuO by Cu₂O does not significantly alter the conditions of thermodynamic equilibrium. During the analysis Cu₂O is reduced according to

and CuO according to

where ΔG_{1400} is the free-energy change at 1400 K.

In order to decide whether an admixed nitride can be oxidized by reaction with copper oxide, it is necessary to check whether the free energy of the reaction products is lower than the free energy of the nitride-copper oxide mixture. Only in the latter case will the reaction proceed (negative free-energy change) as required for the Dumas analysis.

The stabilities of the nitride and the oxide (TiO is chosen as the least stable titanium oxide) are

Hence, the free-energy change of the oxidation reaction with Cu₂O is

and of that with CuO

It is obvious that the free-energy change of the total reaction is largely influenced by the difference between the free-energy changes of the nitridation and oxidation reactions. Hence the oxidation reaction should proceed completely to the right irrespective of the oxidation state of the copper in the oxide used. Since the nitrides are all thermochemically less stable than the oxides, these considerations are valid for any compound with respect to the Dumas analysis.

Some of the oxides and nitrides (e.g., TiO and TiN) form solid solutions. Therefore a thermochemical model which introduces the partial molar free-energy values would more nearly represent the true situation, especially when the nitrogen contents in the reaction products are of interest. However, the pertinent data are not available for the oxynitride systems and—as discussed below—the amount of residual nitrogen is influenced more by kinetic effects (oxygen diffusion) than by equilibrium conditions.

For use in the Dumas analysis Cu₂O was prepared in the following way. A porcelain boat containing CuO was placed in a fused-silica tube, one end of which had been sealed and the other connected to a rotary pump. The silica tube was then evacuated and the end with the boat was heated to 900° for 2 hr, after which the internal oxygen pressure had dropped to 6×10^{-2} mbar. The silica tube with the sample was then allowed to cool to room temperature outside the furnace but still under vacuum. The product so obtained was purple and consisted of single-phase Cu₂O (as shown by X-ray diffraction). The composition was checked by weighing before and after vacuum heating as well as by reduction of Cu₂O to Cu by heating in hydrogen.

Apparatus and procedure

The apparatus and the procedure are essentially the same as described by Kern and Brauer,⁵ but with a few modifications in the

construction of the apparatus.

1. Instead of two separate heated nets of Cu and CuO, one partially oxidized "Cu-Cu₂O" net was used
2. The high-purity CO₂ was supplied from a cylinder so that the flow-rate could be easily adjusted.
3. An electric furnace with three independently adjustable heating zones was used.
4. A water-jacketed nitrometer was used to keep the measured nitrogen at constant temperature. The maximum nitrogen volume which could be determined was increased to 10 ml
5. Pirani- and Bourdon-type manometers were introduced

The entire apparatus was made of glass or metal lines and joints. The leakage rate could be kept very low. In several trial runs for test purposes a vacuum of better than 10⁻² mbar could be maintained over a period of several days. The apparatus is illustrated in Fig. 1

RESULTS AND DISCUSSION

Table 1 lists the nitrogen contents of the nitrides analysed with a 3-10-fold amount of

Cu₂O. The temperatures applied for the analyses are also given. It can be seen that in several cases excellent precision was obtained. To check the completeness of the reaction between the nitride and copper(I)oxide the nitrogen contents of the residues from the nitrogen analyses (reacted nitride + Cu₂O) were determined by hot extraction. These contents, which refer to the amount of nitride, are also listed in Table 1. Since the compounds are in most cases not stoichiometric, the corresponding theoretical nitrogen contents are not listed. Obviously the Group Va and molybdenum nitrides react quantitatively. The nitrogen contents of these residues were very low. In contrast, the nitrogen values of the residues of the Group IVa metal nitrides are somewhat higher. The lengths of the reaction times (and analysis times) for the latter are also longer. This can be attributed to the substantial influence of kinetic parameters (diffusion rate of oxygen) on the oxidation reaction and to a minor extent to the greater stability of Group IVa nitrides as compared to Group Va nitrides. It is clear that the melting process occurring during the reaction of both VN and NbN with Cu₂O as well as the sublimation of MoO₃ during the reaction of MoN or Mo₂N with Cu₂O

§Analysed by use of 150 mg of V₂O₅

increases the rate of the oxidative attack. However, TaN and Mn₂N_{1-x} (no occurrence of a liquid phase during the analysis) also react faster than the Group IVa nitrides. The latter are known to form dense oxide layers which protect them from further oxidation.

The role of oxygen diffusion within the solid-solid reaction mixture becomes more obvious in the case of CrN. Because of the formation of a dense chromium oxide layer on the particle surfaces, CrN cannot be quantitatively decomposed at temperatures up to 1150° within reasonable reaction times. For higher reaction temperatures the fused-silica tube must be replaced by a fully dense ceramic tube.

The nitrides AlN, Si₃N₄ and BN react even more sluggishly with copper oxides. Replacement of Cu₂O by V₂O₅ (which is liquid at the reaction temperatures) brought some improvement, but only for AlN. The nitrogen content of the residue was 0.52% by weight (relative to AlN).

As observed from a comparison between the behaviour of Cu₂O and V₂O₅, the entire oxygen content from copper(I)oxide is available for the oxidation whereas only a small part of that in vanadium(V)oxide (probably about one mole of oxygen per mole of oxide, depending on the temperature) is available under the conditions prevailing for the Dumas analysis performed here. Because of the sometimes violent reaction of vanadium(V)oxide with transition-metal nitrides (e.g., with HfN, but not with ZrN) a blank value for V₂O₅ cannot be given with the desired accuracy. Also, with different amounts and kinds of samples, different maximum reaction temperatures are reached, which influence the amount of oxygen released into the CO₂ atmosphere.

In order to obtain figures for the accuracy of the Dumas modification applied here, the nitrides would have to be measured by other methods of nitrogen determination. We observed that the vanadium content of VN_{1-x}, determined by oxidation as well as by titration,¹⁴ together with the nitrogen value from the present Dumas analysis adds up to 100 ± 0.1%. Similar results were obtained for TiN, when the nitrogen content of the residue was taken into consideration. Thus it can be concluded that in such cases, where the decomposition is practically quantitative, the error is of the same order of magnitude as the precision. For the Group IVa nitrides the nitrogen content in the residue must be added to the Dumas value (Table I).

CONCLUSIONS

In the present study an improved technique for the Dumas analysis was used. The apparatus allowed more convenient handling and produced data with an accuracy of the same order of magnitude as that reported by Kern and Brauer.⁵ It is recommended as a reference apparatus for use with determination techniques which require well-characterized standards (Dumas-GC, hot extraction). However, as can be seen from the analysis of the reaction products, attention must be paid to the fact that in certain cases a small, but certainly quantifiable, nitrogen content remains, which has not hitherto been taken into consideration in the literature.

NON-AQUEOUS CERIMETRIC DETERMINATION OF DITHIOCARBAMATES AND ITS APPLICATION TO THE DETERMINATION OF AMINES

D K SHARMA* and R D SHARMA

Department of Chemistry, Himachal Pradesh University, Summer Hill, Shimla-171005, India

(Received 22 May 1990, Revised 14 November 1990 Accepted 21 November 1990)

Summary—A non-aqueous titrimetric method for determination of dithiocarbamates with cerium(IV), is described. The compounds are titrated at room temperature, with visual and potentiometric end-point detection. In visual titrations, the reagent serves as self-indicator and turns the solution yellow at the end-point. Methyl Red can also be used as the indicator. The method has been applied to the determination of amines after their quantitative conversion into dithiocarbamates by reaction with carbon disulphide. The proposed method is accurate to $\pm 0.8\%$ with a relative standard deviation of $\pm 0.7\%$.

Non-aqueous redox methods are frequently used for determination of organic compounds which are insoluble in water, or react with it through hydrolysis or redox reactions. The scope of these methods can be further extended to the determination of compounds which tend to react with the media of aqueous redox titrations or yield products which interfere with determinations in aqueous media.

Dithiocarbamates find extensive use as agricultural fungicides and as vulcanization accelerators in the rubber industry. These compounds are easily oxidized to the corresponding thiram disulphides (I), but conventional oxidimetric methods cannot be used for their determination, owing to their tendency to undergo decomposition with acids^{1,2} (which serve as the media for a variety of redox titrations) and also to interference by their water-insoluble oxidation products^{3,4} (II) in neutral aqueous media. These problems can be overcome if non-aqueous redox methods are used for the determination

Ammonium hexanitratocerate(IV) is a suitable oxidimetric reagent in acetonitrile media.

It has a standard potential of 0.755 V vs. an Ag/AgNO₃ reference electrode.⁵ Rao and Murthy⁶ found the solution of the oxidant to be relatively stable, no decrease in titre being observed over several days. The present work uses this reagent (in acetonitrile) for titration of dithiocarbamates in acetonitrile-dimethylformamide media, with visual or potentiometric end-point detection. The acetonitrile solution of the reagent is orange-red and imparts a distinct yellow colour to the solution at the end-point. Alternatively, Methyl Red may be used as an indicator. The potentiometric titrations are performed with a platinum and modified calomel electrode assembly.

The ease with which carbon disulphide quantitatively transforms primary and secondary amines into the corresponding monoalkylammonium monoalkyl dithiocarbamates (II) and dialkylammonium dialkyldithiocarbamates⁷ (III), respectively, in acetonitrile medium, and

the simplicity and reliability of the titration of dithiocarbamates with ammonium hexanitratocerate(IV) in acetonitrile-dimethylformamide, prompted us to extend the method to the determination of amines. Excess of carbon disulphide does not interfere in any way. The amount of parent amine is stoichiometrically related to the amount of dithiocarbamate produced. The proposed methods have significant advantages over the acidimetric methods commonly

*Author for correspondence

employed for the determination of amines. First, the amines can be determined in the presence of basic compounds that might interfere in an acidimetric determination. Secondly, as tertiary amines cannot react with carbon disulphide, the methods can be extended to the determination of primary or secondary amines in the presence of tertiary amines.

EXPERIMENTAL

Apparatus

Potentiometric titrations were performed with a Toshniwal CLO6A type potentiometer with a bright platinum wire as indicator electrode and a modified calomel electrode (saturated methanolic potassium chloride solution) as reference.

Reagents

Acetonitrile. Purified by distilling twice from phosphorus pentoxide (5 g/l.).

Dimethylformamide. Purified by storing over anhydrous analytical grade sodium carbonate for 2 days, decanting and distilling. The fraction distilled at 148.5–149.5° was collected in coloured bottles

Carbon disulphide. The Baker analysed product, estimated chromatographically to be 100% pure, was used as received.

Ammonium hexanitratocerate(IV), 0.04M solution in acetonitrile Prepared by dissolving a little more than the calculated amount of the oxidant (Fluka) in acetonitrile and standardized by titration with standard ferrous ammonium sulphate solution in the presence of dilute sulphuric acid, with ferroin as indicator.

Methyl Red. A 1-mg/ml solution in dimethylformamide

Dithiocarbamates. Sodium diethyldithiocarbamate was recrystallized before use. The sodium salts of methyl, ethyl, n-propyl, n-butyl, isobutyl, dimethyl, di-n-propyl, di-n-butyl, and dibenzyl dithiocarbamic acids were prepared and purified by known methods.⁸⁻¹¹ Alkylammonium alkyl dithiocarbamates were prepared by the method of Anschutz^{12,13} by mixing the primary or secondary amines with carbon disulphide in dry diethyl ether. Monoalkylammonium monoalkyl dithiocarbamates, $\text{RHN} \cdot \text{CS} \cdot \text{S}^- \cdot (\text{NH}_3\text{R})^+$ with R = methyl, ethyl, n-propyl, n-butyl and n-pentyl, and dialkylammonium dialkyl dithiocarbamates, $\text{R}_2\text{N} \cdot \text{CS} \cdot \text{S}^- \cdot (\text{NH}_2\text{R}_2)^+$, with R = methyl, ethyl, n-propyl and n-butyl, were prepared and

kept in a vacuum desiccator. The purity of each dithiocarbamate was checked by non-aqueous titration with iodine monobromide¹⁴

Amines. Methylamine (40% aqueous solution), ethylamine (50% aqueous solution), dimethylamine (40% aqueous solution) and diethylamine (60% aqueous solution) were used as received. n-Propylamine, n-butylamine, n-pentylamine, di-n-propylamine, di-n-butylamine, dibenzylamine and isobutylamine (Fluka) were distilled before use

Procedures

Determination of dithiocarbamates. Dissolve a known weight of the dithiocarbamate in an accurately known volume of acetonitrile, and transfer a known volume (containing 5–10 mg of the dithiocarbamate) into a titration vessel, dilute to 10 ml with acetonitrile and add 20 ml of dimethylformamide. Titrate the solution at room temperature ($\sim 23^\circ$) with the ammonium hexanitratocerate(IV) solution (in acetonitrile). In visual titrations, the end-point is shown by a pale yellow colour imparted to the solution by the first drop of the oxidant added in excess. The colour is stable for about 1 min. Alternatively use 3 drops of Methyl Red indicator, the red solution turns yellow at the end-point. In potentiometric titrations, sharp jumps in potential are obtained at the equivalence point. Typical results are given in Table 1. The results obtained in visual titrations with or without indicator

agreed so well that only results obtained without indicator are given

Determination of amines

Prepare a solution of a known weight of amine in a known volume of acetonitrile, transfer a suitable fraction (containing 6–8 mg of amine) into a titration vessel, add one drop of carbon disulphide and dilute to 10 ml with acetonitrile. Add 20 ml of dimethylformamide and titrate as for dithiocarbamates. Typical results are given in Table 2

RESULTS AND DISCUSSION

The method commonly employed for the determination of dithiocarbamates involves hydrolysing them with hot mineral acids to the corresponding amines and carbon disulphide, either of which may be determined. Usually carbon disulphide is selected and measured by the xanthate method,¹⁵ i.e., the gas is absorbed in alcoholic potassium hydroxide solution and the resulting xanthate titrated with iodine in neutral solution. The hydrolysis method is quite laborious and time-consuming. Special appar-

Table 4 Results of single titrations of ten independent samples of a secondary amine (di-n-propylamine)

Amount taken, mg	Amount found, mg	
	Visual method	Potentiometric method
5.2	5.25	5.20
6.5	6.45	6.54
7.8	7.86	7.75
9.1	9.18	9.02
11.7	11.61	11.78
13.0	13.10	13.06
15.6	15.48	15.72
16.9	16.75	16.98
18.2	18.32	18.10
19.5	19.32	19.62

atus is required, and the experimental conditions must be closely adhered to for the evolution of carbon disulphide to be quantitative. Hence there is a need for methods which are accurate, precise, simple and rapid. The oxidimetric method described here meets these requirements and has been found useful for the determination of dithiocarbamates. The overall standard deviations calculated from the pooled results of all the visual and potentiometric titrations performed with 8-mg samples of each dithiocarbamate were 0.044 and 0.066 mg, respectively and the corresponding values for 20-mg samples were 0.036 and 0.057 mg, only the results for the 8-mg samples are given in Table 1. The scope of the method was extended to determination of amines, and the overall standard deviations for all the visual and potentiometric titrations performed with 6-mg samples of each primary and secondary amine were 0.043 and 0.065 mg, respectively, the values for 18-mg samples being 0.035 and 0.056 mg; only the results for the 6-mg samples are given, in Table 2.

The replicate samples of each amine were not weighed individually, but were aliquots from a bulk solution. Acidimetric titrations were also performed to confirm that the aliquots contained the same amount of amine. The quantitative nature of the reaction with carbon disulphide was verified by use of different amine sample sizes. The results are given in Tables 3 and 4.

REVERSED-PHASE HPLC DETERMINATION OF SOME NOBLE METALS AS THEIR THIAZOLYLAZORESORCINOL CHELATES

LIU QIPING, ZHANG HUASHAN and CHENG JIEKE*

Department of Chemistry, Wuhan University, Wuhan 430072, People's Republic of China

(Received 30 October 1989 Revised 1 December 1990 Accepted 16 January 1991)

Summary—The first use of 4-(2-thiazolylazo)resorcinol (TAR) as a chelating reagent in the reversed-phase HPLC separation and determination of Os, Rh and Ru is reported. A precolumn derivatization method is used, followed by separation on an octadecyl-bonded silica stationary phase with a methanol–water mobile phase. The coloured complexes of Os, Rh, and Ru are completely separated within 8 min with a 60:40 v/v methanol–water mixture (pH 4.0, tetrabutylammonium as counter-ion). The detection limits for Rh, Ru and Os at 550 nm are 5, 6 and 17 ng/ml respectively. Recoveries of 94–102% have been obtained for these trace noble metals in analysis of anode slime.

The application of HPLC to the separation and determination of metal ions has increased rapidly in recent years. The development of inorganic HPLC has involved many organic chromogenic chromatographic reagents, and increased the use of many organic chelating agents, such as PAR,¹ PAN,² dithizone,³ dithiocarbamates,^{4,5} diacetyldioxime,⁶ β -diketones,⁷ and porphyrins.⁸ However, there is no reported use of thiazolylazo reagents in HPLC separations.

The determination of noble metals has long been an active field in analytical chemistry. The development of HPLC has made it possible to separate and determine them in a rapid, sensitive and effective way. The reversed-phase ion-chromatography method originated from the separation of Ru–bipyridyl complexes.⁹ The use of PAN¹⁰ and PAR¹¹ as precolumn derivatization agents for separation of platinum group metals has been reported. Mueller and Lovett¹² separated Rh and Pd with diethyldithiocarbamate. Gurira and Carr¹³ separated Co, Be, Rh, Cr(III), Pb, Pt and Ru as acetylacetone and benzoylacetone complexes. Ebina *et al.*¹⁴ separated Pt(II) and Pd(II) with dimercaptomaleonitrile.

Much attention has been paid to the HPLC separation and determination of Pt and Pd, but fewer reports on Os, Rh, Ru, and Ir have appeared. Although other instrumental or chemical methods have been utilized for deter-

mination of Os, Rh and Ru, a simple and rapid method for analysis of their mixtures has never been developed.

In this work, a thiazolylazo reagent was used for the first time as a chelating agent for the separation and determination of noble metals by a precolumn derivatization method. The complexes of Os, Rh and Ru were completely separated within 8 min on a YQG-C₁₈ column with methanol–water mixture as the mobile phase. The method was rapid and simple. The detection limits were 5, 6 and 17 ng/ml for Rh, Ru, and Os, respectively, with measurement at 550 nm.

EXPERIMENTAL

Apparatus

LC-10 HPLC equipment (Japan Analytical Ind.) was used with a YQG-C₁₈H₃₇ (ODS) column (5 μ m particle diameter, 150 \times 4.6 mm) and an S-3702 UV-VIS detector (AJC, Japan).

Reagents

Stock solutions of Os(IV), Rh(III) and Ru(III) in 1M hydrochloric acid were prepared from (NH₄)₂OsCl₆, RhCl₃ and RuCl₃. 4-(2-Thiazolylazo)resorcinol (TAR) was synthesized according to Hovind¹⁵ and a 0.5 mg/ml solution was prepared by dissolving it in absolute alcohol. Tetrabutylammonium bromide (TBABr) (analytical grade, Shanghai Chemical Co., Shanghai), was used as the ion-pairing reagent. Doubly distilled water was used for all solution

*Author for correspondence

preparation. The mobile phase was a 60.40 v/v methanol-water mixture containing 10mM TBABr and 10mM acetate buffer (pH 4.0).

Procedure

A 5.0-ml portion of 1.0M acetate buffer (pH 6.0) and 2.0 ml of 0.5 mg/ml TAR solution were mixed with a known volume of the sample solution, and the mixture was diluted to 25.00 ml with water, heated in boiling water for 1 hr, then cooled to room temperature before HPLC analysis.

Separation of the complexes and reagent

For the HPLC analysis, the ODS column was equilibrated with methanol-water (60.40 v/v, containing 10mM TBABr and 10mM acetate buffer, pH 4.0). A 20- μ l aliquot of the prepared test solution was injected into the ODS column and the complexes were eluted at a flow-rate of 1.0 ml/min. The detection wavelength was 550 nm, and the sensitivity was set at 0.02 absorbance for full scale deflection. The peak areas were measured

RESULTS AND DISCUSSION

Hovind has reported that Os(IV), Rh(III) and Ru(III) can be complexed with TAR at pH 6.0 and 100°. At room temperature, Ga(III),

Fig 1 Effect of MeOH concentration on k' 10mM pH 3.19 buffer, 10mM TBABr

Fig 2 Effect of TBABr concentration on k' MeOH H₂O = 50:50 v/v, 10mM pH 3.19 buffer

In(III) and V(V) form chelates with TAR at pH 5.0, whereas Cu(II), Fe(III), Ni(II) and Co(II) react with it at pH 6.0. Our experiments showed that the Os, Rh, Ru, Cu, Fe, Ni and Co complexes are all stable at 100°, but those of Ga, In and V are not. The wavelengths of the absorption maxima of the Os, Rh, Ru, Co, Cu, Ni and Fe complexes range from 540 to 560 nm (Os 560, Rh and Ru 550, Co, Cu, Ni and Fe 540 nm). The molar absorptivities (ϵ) range from 0.93×10^4 to 4.4×10^4 l. mole⁻¹. cm⁻¹. A wavelength of 550 nm was chosen for the determinations.

Separation of the Os, Rh and Ru complexes

The effects of methanol, acetone and acetonitrile on the separation of Os, Rh and Ru, were investigated. It was found that aqueous methanol was most suitable as the mobile phase. Figure 1 shows the effect of the methanol concentration on the capacity factors (k'). Two curves were found for Rh, and this may be due

Fig 3 Effect of pH on k' MeOH H₂O = 50:50 v/v, 10mM TBABr

to different oxidation states or species. The two curves coincide when the ratio of methanol to water is >57.43 v/v. When the ratio was 60:40, Rh gave only one peak on the chromatogram, so this eluent composition was selected.

Tailing of the peaks occurred in the absence of TBABr, but the presence of >5 mM TBABr resulted in peaks that were sharp and symmetric, and in stable k' values, as shown in Fig. 2. A TBABr concentration of 10 mM was chosen. Figure 3 shows that Rh should give a single peak at about pH 2–2.5, but two peaks at pH >3 . Variation of the buffer concentration in the range 5–30 mM had no effect on the results, and 10 mM buffer was chosen.

All three complexes could be separated and determined in 8 min. Linear calibration plots were obtained for Os, Rh and Ru, in the ranges 0.14–2.28, 0.02–1.00 and 0.05–0.39 $\mu\text{g}/\text{ml}$ respectively.

Effect of foreign ions

The potential interference of numerous ions was examined by determination of 5.0 μg of Os,

Fig. 4 Separation of Os, Rh, Ru, and Co TAR complexes by HPLC MeOH:H₂O = 50:50 v/v, 10 mM pH 3.19 buffer, 10 mM TBABr

Fig. 5 Separation of Os, Rh, and Ru TAR complexes by HPLC MeOH:H₂O = 60:40 v/v, 10 mM pH 4.0 buffer, 10 mM TBABr

Rh or Ru in the presence of each foreign ion. The amounts (μg) found to be tolerable were as follows. V(V), V(IV), Cr(III), Cr(VI), Mn(II), Nb, Ta, W, Ga, In, Al, Bi, 100; Zn, Pb, Hg(II), Cd, Ag, Pt(II), Pd(II), Au(I), Ir(VI), 60; Fe(III), Co(II), Ni, Cu(II), 20.

The behaviour of cobalt was particularly interesting. Figures 1 and 3 show that the peak for elution of cobalt will coincide with one or both of the rhodium peaks under certain conditions, but at pH 4.0, with 50:50 v/v methanol–water mobile phase one of the rhodium peaks will be usable for analysis, though with lower sensitivity. Figures 4 and 5 show separations obtained (under optimum conditions) in the presence and absence of cobalt.

Analysis of an anode slime

An anode slime from electrolytic refining of copper was spiked with Os, Rh and Ru and analysed for these three metals. The slime sample was ground to 100-mesh particle size

Table 1 Reproducibility of retention times

and dried at 110° for 2 hr. A 5.0 g sample was gently heated with 40 ml of nitric acid (1 + 1), and then filtered. The residue was heated with concentrated hydrochloric-nitric acid mixture (1 : 1 v/v) until it had all dissolved. The solution was cooled, 1 ml of 100 mg/ml sodium chloride solution was added, and the mixture was evaporated nearly to dryness, then washed into a 100-ml standard flask, and diluted to the mark with water. A 10 ml portion was analysed as above. The results are shown in Table 3.

(Received 9 November 1990 Accepted 10 January 1991)

Summary—The application of deuterium-palladium electrodes as generator, indicator and reference electrodes for the determination of organic bases in acetone and methyl ethyl ketone has been investigated. Deuterium dissolved in palladium is oxidized at a potential that is close to the oxidation potential of hydrogen in palladium and more negative than the oxidation potentials of the bases titrated, indicator, and the solvents used. The anodic oxidation of deuterium dissolved in palladium proceeds with 100% current efficiency in the solvents investigated. The relative errors for the determination of $5 \times 10^{-4} M$ solutions of bases are less than 1%.

Palladium-hydrogen electrodes at which the hydrogen is continually generated have been used for pH measurements¹ and in acid-base titrations in water and non-aqueous solvents.² Palladium wires previously saturated with hydrogen by electrolysis of water have been used as indicator and reference electrodes in the titration of bases³ and phenol⁴ in non-aqueous solvents and as generator electrodes in coulometric-potentiometric titrations in water and non-aqueous solvents.⁵⁻⁷ Recent work by Fleischmann and Pons⁸ prompted interest in the deuterium-palladium electrode and this paper describes its applications as generator, indicator and reference electrodes in the coulometric titration of bases in acetone and methyl ethyl ketone.

EXPERIMENTAL

Reagents

Analytical-reagent grade chemicals (Merck or Fluka) were used, but acetone and methyl ethyl ketone were further purified.⁹ Solutions of bases were standardized by titration with hydrogen ions generated at an H_2/Pd anode with potentiometric end-point detection by means of the couples glass electrode-SCE and H_2/Pd_{ind} -SCE. The supporting electrolyte was 0.1 M sodium perchlorate in the appropriate solvent. A 1 mg/ml solution of Methyl Red in acetone was used as the indicator for visual end-point

detection. Deuterium oxide (99.8% pure, ZGN Chemical Radioisotope Division) was used for the generation of deuterium.

Apparatus

The apparatus for titrations with visual end-points has been described elsewhere.⁷ That for titrations with potentiometric end-points is essentially the same as that used before,⁷ except that (a) D_2/Pd electrodes were used, (b) the cathode compartment (a glass tube with a porosity-4 glass sinter at the end) was inserted through the top of the cell instead of being integral with it, and (c) the reference electrode was a D_2 -saturated Pd wire in a 0.1 M sodium perchlorate solution in the appropriate solvent. The reference electrode was contained in a tube similar to the cathode compartment. The volumes of anolyte and catholyte solution were 50 and 10 ml respectively.

Procedures

Visual end-point detection. The procedure was the same as for titration with protons,⁷ except for the use of a D_2/Pd anode giving deuterium ions. Two or three drops of indicator and 0.6-1 ml of base solution were added to the anolyte solution (ca 5 ml) for titration.

Potentiometric end-point detection. The procedure was the same as for titration with protons,⁷ except that deuterium ions were generated

from the D_2/Pd anode. End-points were calculated from the second derivative curve

RESULTS AND DISCUSSION

The D_2/Pd electrode as the generator electrode

To check whether deuterium dissolved in palladium can be used as a source of deuterium ions for the coulometric determination of bases in ketones, we have recorded current-potential curves for the solvent, indicator, titrated bases, hydrogen in palladium and deuterium in palladium. Figure 1 shows the current-potential curves for acetone, Methyl Red, N,N -diphenylguanidine, hydrogen dissolved in palladium, and deuterium dissolved in palladium. From Fig. 1 it is seen that deuterium dissolved in palladium is oxidized at a potential which is very close to the oxidation potential of hydrogen in palladium and much more negative than the oxidation potentials of the other components in the solution. Similar current-potential curves were obtained with methyl ethyl ketone as the medium.

The deuterium ions obtained by oxidation of deuterium dissolved in palladium were used for the titration of N,N -diphenylguanidine and brucine in acetone and methyl ethyl ketone, respectively, with visual and potentiometric end-point detection. The results obtained (Table 1) show that the oxidation of deuterium is quantitative and proceeds with 100% current efficiency.

The results obtained by the application of the D_2/Pd electrode as the generator electrode are consistent with the results obtained with H_2/Pd

generator electrodes. Therefore, further investigations on the behaviour of the D_2/Pd electrode as reference and indicator electrodes in the potentiometric determination of bases were made, with H_2/Pd generator electrodes

D_2/Pd indicator and reference electrodes

To investigate the application of D_2/Pd indicator and reference electrodes, we first followed their changes in potential in 0.1M sodium perchlorate solutions in the solvents investigated, at 25.0°. When the D_2/Pd electrode was used, relative to a modified SCE as the indicator electrode, the potential changed by 5–8 mV in 8 hr, but when it was the reference electrode the potential changed by only 2–3 mV over the same time period. Since one titration lasts 30 min at the most, these changes in potential can be neglected

The behaviour of the D_2/Pd electrode as the indicator and reference electrodes in acetone and methyl ethyl ketone media was checked by titrating several bases of different strengths. The titration curves obtained are shown in Fig 2. The potentials in the course of the titration and at the equivalence point were rapidly established. The titration curves obtained with the D_2/Pd electrode have shapes similar to those obtained with glass and H_2/Pd indicator electrodes. The largest jump at the end-point was obtained with the glass electrode, a somewhat

Methyl ethyl ketone	Aminopyrine	7 557	100.1 \pm 0.4 (5)‡	D_2/Pd_{ind} -SCE
Methyl ethyl ketone	Brucine	14 711	100.2 \pm 0.6 (5)‡	D_2/Pd_{ind} -SCE
Methyl ethyl ketone	Brucine	14 711	99.8 \pm 0.4 (3)‡	D_2/Pd_{ind} - D_2/Pd_{ref}

*Mean standard deviation for the number of titrations given in brackets

† H_2/Pd generator electrode

‡ D_2/Pd generator electrode

smaller jump was obtained with the D_2/Pd electrode and the smallest jump was given by the H_2/Pd electrode. Thus, in the titration of $5 \times 10^{-4}M$ *N,N*-diphenylguanidine in methyl ethyl ketone, the potential change at the end-point was about 350 mV with the glass electrode, 250 mV with the D_2/Pd electrode and about 120 mV with the H_2/Pd electrode. The results obtained in coulometric titrations of bases in 0.1M sodium perchlorate media in acetone and methyl ethyl ketone are listed in Table 1.

On the basis of these results it may be concluded that the deuterium-palladium electrode can be successfully applied as the generator, indicator and reference electrode in the coulometric-potentiometric determination of bases in acetone and methyl ethyl ketone

KINETIC DETERMINATION OF SELENIUM, BASED ON INHIBITION OF THE Pd(II)-CATALYSED REACTION BETWEEN PYRONINE G AND HYPOPHOSPHITE

C SANCHEZ-PEDREÑO, M I ALBERO, M S GARCIA and A SAEZ

Department of Analytical Chemistry, Faculty of Sciences, University of Murcia, Murcia, Spain

(Received 27 November 1989 Revised 22 November 1990, Accepted 21 January 1991)

Summary—A new kinetic method for determination of selenium is based on its inhibitory effect on the Pd(II)-catalysed reaction between Pyronine G and hypophosphite. Under the optimum experimental conditions ($6 \times 10^{-5} M$ Pyronine G, $0.4 M$ hypophosphite, $0.4 \mu\text{g/ml}$ Pd(II), pH 2.8, temperature $22.0 \pm 0.2^\circ$), Se can be determined in the concentration range 0.033 – $0.50 \mu\text{g/ml}$. The method suffers from numerous interferences and is thus limited in application. It has been applied to the determination of selenium in spring waters and pharmaceutical preparations.

In an earlier paper we reported on use of the Pd(II)-catalysed reduction of Pyronine G by hypophosphite for kinetic determination of palladium.¹ We found that several ions strongly inhibit this system, and have used this to develop sensitive kinetic methods for the indirect determination of Ag(I), I^- and As(III).^{1,2} We now report a similar application for determination of selenium.

The toxicological and physiological significance of selenium^{3,4} necessitates its determination, which is most often achieved by spectrophotometric or fluorimetric measurement of the piarselenol formed by the reaction with an aromatic *o*-diamine.^{5,6}

Selenium can also be determined by catalytic methods, such as those based on its catalysis of the sulphide reduction of some organic substrates such as Methylene Blue,⁷⁻¹¹ Tolidine Blue¹² and picrate.^{13,14}

Kawashima and Tanaka¹⁵ have determined selenium by its catalysis of the reduction of 1,4,6,11-tetra-azanaphthacene with hypophosphorous acid, but this method suffers from non-linear calibration. A method based on the Landolt reaction, *viz* the chlorate–chloride–hydrazine sulphate system, has been reported¹⁶ and methods based on the oxidative coupling of *p*-hydrazinobenzenesulphonic acid with 1-naphthylamine or *m*-phenylenediamine have been proposed.^{17,18} The catalytic effect of selenium on the reduction of the tetranitro blue

tetrazolium ion by dithiothreitol has also been used.¹⁹

EXPERIMENTAL

Apparatus

Absorbance *vs.* time (*A*–*t*) curves were recorded with a Perkin–Elmer 550SE spectrophotometer furnished with 1-cm path-length cells kept at constant temperature by an MCIII Minicyostat. The pH-measurements were made with a Radiometer PHM63 pH-meter.

Reagents

Pyronine G. An aqueous $6 \times 10^{-4} M$ solution (0.1816 g/l.) was prepared from 3,6-bis(dimethylamino)xanthene hydrochloride (C.I. 45005).

Sodium hypophosphite solution (3M). This should be freshly prepared.

Palladium chloride solution. Prepared [100 mg/l. PdCl_2 , which corresponds to $60 \mu\text{g/ml Pd(II)}$] with $2 \times 10^{-2} M$ hydrochloric acid.

Selenite stock solution. This contained $500 \mu\text{g/ml}$ selenium and was prepared by dissolving previously dried $\text{Na}_2\text{SeO}_3 \cdot 5\text{H}_2\text{O}$ (Merck) in water. Working standards were prepared by dilution with water.

Britton–Robinson buffers. These were prepared for pH values between 1.7 and 4.4.

Solutions of various metal nitrates and the sodium salts of different acids were prepared for the study of interferences.

All solutions were made from analytical-grade reagents and doubly distilled water, and diluted as required

Recommended procedure for calibration

In a dry spectrophotometer cell place 0.30 ml of $6 \times 10^{-4} M$ Pyronine G, 0.50 ml of pH 2.80 buffer, 0.20 ml of 6.00 $\mu\text{g/ml}$ Pd(II) solution and an accurately measured volume (0.10, 0.15, 0.20–1.50 ml) of standard Se(IV) solution containing 1.00 $\mu\text{g/ml}$ selenium. Dilute the mixture to 2.60 ml with distilled water and place the cell in a thermostat at $22.0 \pm 0.2^\circ$ for 10 min. Then add 0.40 ml of 3M sodium hypophosphite and start the spectrophotometer recorder. Homogenize the solution by stirring, dry the faces of the cell, place it in the spectrophotometer compartment and record the absorbance at 548 nm as a function of total elapsed time. Repeat for volumes of selenium solution corresponding to final concentrations of 0.033–0.50 $\mu\text{g/ml}$. Plot the reciprocal of the time required for the initial absorbance to decrease by 0.100, against the selenium concentration

Determination of selenium in pharmaceuticals

Heat the sample (0.25–0.50 g) with concentrated hydrochloric acid and evaporate the mixture almost to dryness. Add some concentrated nitric acid, heat and again evaporate the mixture almost to dryness. Cool, take up the residue in water, filter, and adjust the pH to between 6 and 8 with 1M sodium hydroxide. All the selenium is then present as selenite. Dilute this solution to volume with water in a 250-ml standard flask and determine the selenium in 50- μl aliquots, as described for calibration

Determination of selenium in spring waters

Remove metal ions from the sample by treatment with Amberlite IR-120 ion-exchange resin. Use the standard-addition method by use of 1-ml aliquots of sample plus 0.3, 0.4 or 0.5 ml of 1.14 $\mu\text{g/ml}$ selenium(IV) and application of the calibration procedure

RESULTS AND DISCUSSION

Previous work had demonstrated that over a wide pH range hypophosphite does not reduce Pyronine G at an appreciable rate, but that Pd(II) is an efficient catalyst for this process. We have found that selenite has no effect on the H_2PO_2^- -Pyronine G system, but a strong inhibi-

Fig. 1 $A-t$ curves run in the presence of 0.40 $\mu\text{g/ml}$ Pd(II) [Pyronine G] = $6 \times 10^{-5} M$, $[\text{H}_2\text{PO}_2^-] = 0.4 M$, pH 2.8, $22.0 \pm 0.2^\circ$, Se(IV) concentration (1) 0, (2) 0.04, (3) 0.12, (4) 0.20, (5) 0.27, (6) 0.34, (7) 0.42, (8) 0.57 $\mu\text{g/ml}$

tory effect on the Pd(II)-catalysed reaction. For a fixed amount of Pd(II) in the medium, the rate of the catalysed process is proportional to the Se(IV) concentration. The process is monitored spectrophotometrically at 548 nm by measuring the decrease in the absorbance of Pyronine G, and the reciprocal of the time required for the absorbance to decrease by 0.100 is plotted against the selenium concentration. Figure 1 shows that the rate of the process decreases with increase in the Se(IV) concentration, even at very low concentrations of this ion

Influence of pH

The influence of pH on the reaction rate was studied over the range 1.7–4.4, with Britton-Robinson buffers. Figure 2 shows that the rate of the process remained virtually constant over the pH range 2.5–3.6, the difference between the rate of the catalysed and the inhibited reaction being maximum in the range 2.3–3.2. We chose a pH of 2.8 for all subsequent experiments. The Pyronine G has an absorption maximum at 548 nm at this pH

Fig. 2 Influence of pH on the reaction rate [Pyronine G] = 6×10^{-5} , $[\text{H}_2\text{PO}_2^-] = 0.4 M$, (1) 0.40 $\mu\text{g/ml}$ Pd(II), (2) 0.40 $\mu\text{g/ml}$ Pd(II) plus 0.20 $\mu\text{g/ml}$ Se(IV)

Fig 3 Influence of the Pyronine G concentration on the reaction rate $[H_2PO_2^-] = 0.4M$, pH 2.8, (1) $0.40 \mu\text{g/ml}$ Pd(II), (2) $0.40 \mu\text{g/ml}$ Pd(II) plus $0.20 \mu\text{g/ml}$ Se(IV)

Influence of other variables

The influence of the other variables was studied by varying them one at a time, with the other conditions kept constant. Figure 3 shows that the rate of both the catalysed and the inhibited reaction increased with the concentration of Pyronine G up to $5.5 \times 10^{-5}M$, above which it remained constant and the rate difference was maximal. A $6 \times 10^{-5}M$ concentration of Pyronine G, which yielded suitable absorbances, was selected.

The rates of the catalysed and inhibited reactions increased with increasing hypophosphite concentration up to $0.7M$, above which they remained virtually constant. Figure 4 shows that the difference between the two rates was maximal and constant for hypophosphite concentrations between 0.3 and $0.6M$ and we chose $0.4M$ for further experiments.

Influence of temperature; activation energy

Figure 5 shows the influence of temperature on the rate of the catalysed and inhibited reac-

Fig 4 Influence of the hypophosphite concentration on the inhibitory effect of selenium.

Fig 5 Influence of temperature on the reaction rate $[Pyronine\ G] = 6 \times 10^{-5}M$, $[H_2PO_2^-] = 0.4M$, pH 2.8, (1) $0.40 \mu\text{g/ml}$ Pd(II); (2) $0.40 \mu\text{g/ml}$ Pd(II) plus $0.42 \mu\text{g/ml}$ Se(IV)

tions, and we chose a temperature of $22.0 \pm 0.2^\circ$ as optimum

The activation energies found for the Pd(II)-catalysed reaction in the absence of Se(IV) and for the inhibited reaction in its presence were 14.0 and 15.3 kcal/mole respectively

Influence of the Pd(II) concentration

At constant Se(IV) concentration, the rate of the process increased linearly with the catalyst concentration up to a constant value at Pd(II) concentrations between 0.2 and $1.9 \mu\text{g/ml}$. The study was finished by assaying two series of samples at the selected pH, temperature, and

0.34 µg/ml Se(IV) were 3.4 and 1.8%, respectively, and the relative errors were ±2.5 and ±1.3% respectively.

Under the recommended experimental conditions, the kinetic equation representative of the process is

$$-d[\text{Pyronine G}]/dt = k[\text{H}_2\text{PO}_2^-][\text{Pd(II)}]/[\text{Se(IV)}]$$

and the apparent rate constant, k , between 20 and 50°, ranges between 0.0157 and 0.23 min⁻¹.

Interferences

The interference of foreign ions with the proposed procedure was studied in experiments with 0.20 µg/ml of Se(IV) and various concentrations of the ion in question. The results are listed in Table 1, which also states the type of error caused. A given ion was considered to interfere when its presence resulted in an error larger than ±3% in the determination of Se(IV).

Applications

Because of the serious interference of numerous common ions, the proposed method is limited in its applications but has been satisfactorily applied to the determination of selenium in some pharmaceuticals, in which selenium is found as selenium sulphide (SeS₂). The results obtained by the proposed method and with a

piaszelenol method²¹ that uses *o*-phenylenediamine are given in Table 2. The results compare well but the method proposed in this paper is considerably quicker than the piaszelenol method. The results of some recovery experiments by the standard addition method are shown in Table 3.

The method has also been tested for its applicability to determination of selenium in some spring waters. As the natural selenium content was below the limit of detection, some recovery experiments were done with added selenium. The results obtained with three bottled spring waters (chloride content 8.4, 7.1 and 6.2 $\mu\text{g/ml}$, respectively) are summarized in Table 4.

(Received 19 November 1990 Revised 16 January 1991 Accepted 23 January 1991)

Summary—The fluorimetric determination of hydrogen peroxide by using the fluorescence reaction between *N*-(4'-hydroxyphenyl)-*N*-(4-methylquinolinyl)amine (HPMQ), cobalt(II) and hydrogen peroxide in the presence of trimethylstearylammmonium chloride (STAC) as a cationic surfactant was proposed. The calibration graph was linear in the range 0–2500 ng of hydrogen peroxide per 10 ml of solution at an emission wavelength of 522 nm with excitation at 410 nm. The recovery tests in foods were good.

Hydrogen peroxide has been used as a bleaching agent, as a disinfectant for medicine, and in food additives. Its carcinogenicity has raised interest in recent years and, therefore, a rapid and simple method for its microlevel determination is needed. In previous papers,^{1,2} we have discussed the fluorescence formation reaction between diarylamine compounds such as *N*-(4'-hydroxyphenyl)-*N*-(4-methylquinolinyl)amine (HPMQ) or *N*-(4'-hydroxy-3'-carboxyphenyl)-*N*-(4-methylquinolinyl)amine (MQAS) with cobalt(II) and hydrogen peroxide. In this paper, a simple and sensitive fluorimetric determination of hydrogen peroxide by using the fluorescence reaction of HPMQ or MQAS, cobalt(II) and hydrogen peroxide in the presence of the cationic surfactant trimethylstearylammmonium chloride (STAC) was systematically investigated.

EXPERIMENTAL

Apparatus and reagents

Spectrofluorophotometric measurements were performed on a Hitachi model 3000 spectrofluorophotometer with 10-mm silica cells and a 150-W Xenon arc source. A Hitachi-Horiba F-8 pH meter was used for all pH measurements.

Analytical-reagent grade chemicals were used throughout. Solutions of $1.0 \times 10^{-2} M$ cobalt(II), $1.0 \times 10^{-3} M$ HPMQ, methanol and STAC solutions were prepared according to previous reports.^{1,2} A solution of hydrogen peroxide was prepared by dilution of a 30% hydrogen peroxide solution (Mitsubishi gas Chemical Co., Ltd) and corrected by permanganimetry. Demineralized water was used throughout.

Recommended procedure

To a solution containing 2500 ng of hydrogen peroxide in a 10-ml standard flask were added 3.0 ml of borax buffer solution (pH 10.0), 2.0 ml of $5.0 \times 10^{-3} M$ STAC, 1.0 ml of $5.0 \times 10^{-5} M$ cobalt(II) and 0.75 ml of $1.0 \times 10^{-4} M$ HPMQ. The mixture was diluted to volume with water, kept at 50° for 20 min and cooled to room temperature (10–25°) (solution A). The difference between the relative fluorescence intensities (R.f.Int.) of solution A and a blank (solution B) prepared without hydrogen peroxide, was measured at an emission wavelength of 522 nm with excitation at 410 nm.

RESULTS AND DISCUSSION

Fluorescence reaction between hydrogen peroxide and anilinoquinoline derivatives

The fluorescence formation reactions between the *N*-(phenyl)-*N*-(4-methylquinolinyl)amine

*The application of diarylamine compounds in analytical chemistry, Part III

†Author for correspondence

Table 1 Fluorescence reaction of anilinoquinoline derivatives, hydrogen peroxide and cobalt(II)

No	Anilinoquinolines(R)	Em R fl Int, %		
		nm	R	R-H ₂ O ₂
I	(phenyl)-	395	1.1	2.3
II	(2'-hydroxyphenyl)-	395	1.4	24.0
III	(3'-hydroxyphenyl)-	395	1.0	4.3
IV	(4'-hydroxyphenyl)-(HPMQ)	460	7.6	49.6
V	(3'-hydroxy-4'-carboxyphenyl)-(MQAS)	395	1.0	14.3

I-V $1.0 \times 10^{-5}M$, cobalt(II) $1.0 \times 10^{-6}M$, hydrogen peroxide $2.0 \times 10^{-4}M$, pH 10.0, Ex 320 nm

derivatives: *N*-(phenyl)-, *N*-(2'-hydroxyphenyl)-, *N*-(3'-hydroxyphenyl)-, *N*-(4'-hydroxyphenyl)-*N*-(4-methylquinolinyl)amines and MQAS and hydrogen peroxide and cobalt(II) were systematically investigated in weakly basic media (pH 10) in the absence of STAC. As shown in Table 1 HPMQ was the optimum and gave a strong fluorescence

Fluorescence spectra

As shown in Fig. 1, the fluorescence product of HPMQ-cobalt(II)-hydrogen peroxide in the presence of STAC has a maximum emission wavelength (*Em*) at 522 nm with an excitation wavelength (*Ex*) at 410 nm (Fig 2). In the absence of STAC a maximum emission occurred at 460 nm with *Ex* at 240 nm *Ex*

Fig 1 Emission spectra of HPMQ-cobalt(II) and HPMQ-cobalt(II)-hydrogen peroxide in the presence and absence of STAC HPMQ $1.5 \times 10^{-5}M$, cobalt(II) $5.0 \times 10^{-6}M$, hydrogen peroxide $5.0 \times 10^{-6}M$, STAC $1.0 \times 10^{-3}M$, pH 10 ----- HPMQ-cobalt(II)-hydrogen peroxide (*Ex* 360 nm) --x-- HPMQ-cobalt(II) (*Ex* 360 nm) — HPMQ-cobalt(II)-hydrogen peroxide-STAC, (*Ex* 410 nm) —x— HPMQ-cobalt(II)-STAC (*Ex* 410 nm)

at 410 nm was chosen for considering the effect of emission wavelength for further investigation. The difference of R.fl.Int (ΔF) at *Em* 522 nm with *Ex* 410 nm between HPMQ-cobalt(II)-hydrogen peroxide-STAC (solution A) and HPMQ-cobalt(II)-STAC solutions (solution B) was proportional to the concentration of hydrogen peroxide

Effect of pH

A maximum and constant ΔF value at 522 nm was obtained in the limited range of pH 9.3-10.8 by addition of 2.0-3.0 ml of $2.0 \times 10^{-2}M$ Sørensen borax buffer in 10 ml of solution.

Effect of metal ions

Table 2 shows the relative effects of different metal ions on the fluorescence signal in the

Fig 2 Excitation spectra of HPMQ-cobalt(II)-hydrogen peroxide solution in the presence or absence of STAC HPMQ $1.5 \times 10^{-5}M$, cobalt(II) $5.0 \times 10^{-6}M$, hydrogen peroxide $5.0 \times 10^{-6}M$, STAC $1.0 \times 10^{-3}M$, — HPMQ-cobalt(II)-hydrogen peroxide-STAC solution (*Em* 522 nm), — HPMQ-cobalt(II)-hydrogen peroxide solution (*Em* 460 nm)

Table 2 Effect of metal ions

Metal ion	R fl Int at 522 nm, %	
	HPMQ-metal ion	HPMQ-metal ion-hydrogen peroxide
—	30.8	33.0
Cobalt(II)	38.0	55.3
Nickel(II)	24.9	25.6
Copper(II)	282.4	282.4
Manganese(II)	257.5	261.7
Iron(II)	25.7	29.8
Palladium(II)	7.6	7.6
Molybdenum(VI)	48.1	48.1

Hydrogen peroxide 850 ng/10 ml, STAC $1.0 \times 10^{-3}M$, Metal ions $5.0 \times 10^{-6}M$, HPMQ $1.5 \times 10^{-5}M$, pH 10.0, Ex 410 nm

presence of hydrogen peroxide. Cobalt(II) caused the greatest fluorescence intensity enhancement and its optimum concentration, at a hydrogen peroxide concentration of $1.0 \times 10^{-5}M$, was $5.0 \times 10^{-6}M$. Accordingly, $5.0 \times 10^{-6}M$ cobalt(II) was used for further investigation.

Effects of surfactant and HPMQ concentration

As recognized in previous reports,^{1,2} the fluorescence reaction between HPMQ, hydrogen peroxide and cobalt(II) was remarkably enhanced by the coexistence of cationic surfactants such as STAC. Anionic surfactants such as sodium dodecylsulphate (SDS), and non-ionic surfactants such as Tween 20, were not effective. Table 3 summarizes the results of the effects of different surfactants. Although the ΔF in the presence of STAC was relatively small in comparison to that in its absence, the R.fl.Int. of solutions A and B in the presence of STAC, out of the tested cationic surfactants

STAC, *N*-hexadecylpyridinium chloride (HPC), hexadecyltrimethylammonium chloride (HTAC), benzyldimethyl-tetradecylammonium chloride (Zephiramine, Zp), gave the more stable and reproducible fluorescence. Its presence was therefore most effective and its optimum concentration was $1.0 \times 10^{-3}M$.

Effects of temperature and time

The optimal reaction conditions of temperature and time were investigated for the assay of hydrogen peroxide and a standard procedure was established—standing for 20 min at 50°—when considering the stability and reproducibility of maximum ΔF and the simplicity of the procedure.

Calibration graph and reproducibility

A linear calibration graph was produced over the range 0–2500 ng of hydrogen peroxide per 10 ml. For 850 ng of hydrogen peroxide, the coefficient of variation (C.V.) estimated for 5 replicates was 2.4%. Thus, the proposed method was relatively sensitive, with good reproducibility in comparison to other methods e.g., the titanium,³⁻⁶ vanadium(V)–Xylenol Orange⁷ and chemical luminescence methods.^{8,9}

Effects of diverse ions

The influence of diverse ions on the determination of 85 ng of hydrogen peroxide per millilitre was examined, and the tolerance limits were taken as the amounts that caused about $\pm 3\%$ error in R.fl.Int. The coexistence of copper(II) and manganese(II) gave positive errors at concentrations 1/5-th that of hydrogen peroxide, and iron(III) gave a negative error at a concentration 1/50-th that of hydrogen peroxide

Table 3 Effect of surfactants

Surfactant	R fl Int at max Em, %			
	Ex, nm	Em, nm	HPMQ	HPMQ-hydrogen peroxide
—	360	460	4.9	13.2
STAC	410	522	38.0	71.8
HTAC	410	522	30.2	59.2
HPC	360	485	0.8	1.4
Zp	360	460	4.4	12.6
SDS	360	460	7.4	12.9
Brij 35	360	455	30.5	51.8
Tween 20	360	455	45.6	60.6

Cationic surfactants—STAC, hexadecyltrimethylammonium chloride (HTAC), *N*-hexadecylpyridinium chloride (HPC), benzyldimethyltetradecylammonium chloride (Zephiramine, Zp) $1.0 \times 10^{-3}M$, anionic surfactant—SDS, non-ionic surfactant—Brij 35, Tween 20 0.1%, HPMQ $1.5 \times 10^{-5}M$, pH 10.0, hydrogen peroxide $5.0 \times 10^{-6}M$

Table 4 Effect of foreign ions

Foreign ions	Added			ΔF, %
	as	μg/10 ml	molar ratio	
—	—	—	—	17.3
Cu(II)	sulphate	0.03	1/50	17.2
Ni(II)	nitrate	0.03	1/50	16.5
		0.29	1/5	11.8
Mn(II)	chloride	0.03	1/50	16.9
Fe(III)	sulphate	0.03	1/50	16.4
Mo(VI)	molybdate	4.80	2	17.0
Ca(II)	chloride	200.40	200	17.0
Mg(II)	oxide	24.30	40	17.0
NO ₂ ⁻	sodium	46.01	40	16.7
BrO ₃ ⁻	potassium	1279.02	400	16.9
Citrate	sodium	192.4	40	17.3
Tartrate	sodium	600.45	200	16.8
Oxalate	sodium	88.00	40	17.2
L-Ascorbate	—	440.03	100	15.1
Glucose	—	180.16	40	16.8
Albumin	—	20.00	—	14.0

Hydrogen peroxide taken 850 ng/10 ml, HPMQ $1.5 \times 10^{-5}M$, cobalt(II) $5.0 \times 10^{-6}M$, STAC $1.0 \times 10^{-3}M$, pH 10.0, Ex 410 nm

(see Table 4). However, the coexistences of calcium(II), magnesium(II), phosphate, chloride, tartrate and citrate ions did not interfere, and albumin was tolerated up to 20 μg per 10 ml. In addition, the proposed method did not suffer from interference by other oxidizing agents such as bromate, iodate and nitrate ions.

Application

The proposed method was applied to the assay and recovery of hydrogen peroxide in different foods such as vermicelli, noodles and fish galantine. The detection reaction by the proposed method was negative in these samples—addition of hydrogen peroxide in these foodstuffs was forbidden and the recovery test was good (99.4%) in comparison with other methods (4-aminoantipyrine-modified method¹⁰ was 92.0–86.3%).

BOOK REVIEWS

Aquatic Chemical Kinetics: W STUMM (editor), Wiley, Chichester, 1990 Pages xiii + 545 £70 50

This book consists of 18 chapters by different U S and European authorities. Rather more than half is concerned with homogeneous reactions in water, including complexation of metal ions, catalysis, photo-oxidation, enzyme reactions and the fate of organic pollutants. The remainder covers reactions at mineral surfaces, including adsorption, dissolution, redox reactions, weathering and colloids, and thus more than usual emphasis is given to this aspect of chemistry in natural waters. The basic principles are introduced and much useful matter is covered for the graduate student or working environmental chemist or geochemist. For the general analytical chemist, it is very much background reading, but this should not be discounted when speciation increasingly forms part of the analytical task and an understanding of the processes in solution is particularly helpful. The sub-title stresses natural waters, but how many such waters are completely unaffected by industrial or agricultural discharges, and what about acid rain? Some attention is paid to these problems, but those concerned with pollution might have wished for extra chapters. This well-produced volume is nevertheless a welcome addition to a valuable series which one hopes to see further extended.

D MIDGLEY

Flavour Science and Technology: Y BESSIERE and A F THOMAS (editors), Wiley, Chichester, 1990 Pages xii + 369 £60 00

This book contains (according to the editors) most of the papers presented at the 6th Weurman Symposium held in May 1990 in Geneva, Switzerland. Flavour science encompasses the chemistry and sensory properties of flavorful materials, but the organizers of the Symposium selected as its main topics the chemistry of flavours, energy applications and food flavour systems, and instrumentation and data treatment. Hence there are few articles on sensory assessment of flavour. About half of the 60 or so contributions should be of interest to readers of *Talanta* in that they deal with aspects of composition and analysis. Both separation and extraction of flavorful volatiles—often present in food at less than 10 ppm in total—from the matrix are covered. It is a feature of the organoleptic properties of a flavorful chemical that often both intensity and character differ quite markedly between enantiomers. Hence chiral analytical methods are becoming increasingly important in flavour research and several papers are directed to this topic.

Individual articles are short, no more than 4 pages, but the book as a whole gives a good overview of current interests in flavour chemistry. The book has been produced from authors' typescripts by photographic methods, but reproduction of both text and figures is clear.

P HOWGATE

X-Ray Absorption Principles, Applications, Techniques of EXAFS, SEXAFS and XANES: Edited by D C KONINGSBERGER and R PRINS, Wiley, New York, 1988 Pages xii + 673 £77 50

Extended X-ray absorption fine-structure methods are powerful tools for the determination of atomic arrangements and chemical bonding in both crystalline and amorphous substances. This book is aimed at the growing numbers of EXAFS users and is a collection of 11 chapters, divided into three parts, contributed by distinguished workers in the field. Part A comprises two chapters dealing with the theory of EXAFS and XANES in a particularly lucid manner, although h and \hbar are occasionally confused, this should not upset the alert reader unduly. The simplifying assumptions made in the derivation of the EXAFS equation are discussed at some length and appropriate corrections are given. Part B, 4 chapters, describes instrumentation, experimental design and data analysis. The use of both synchrotron and laboratory sources is described and their relative merits are compared. X-Ray optics are also treated. The remaining five chapters, Part C, deal with applications to biochemistry, catalysis and amorphous and liquid systems, and with SEXAFS (with a somewhat predictable, jokey title) and XANES.

The real usefulness of this book lies in its combination of rigorous theoretical treatment with practical advice and insights into the problems and pitfalls that may be encountered. Chapters 3-5 will be particularly useful for those wishing to set up their own instruments. Similarly, Chapter 6, which deals with data processing and analysis, gives much practical advice on such topics as the elimination of problems caused by various aspects of the instrumentation, the estimation and removal of background signals, and the effects of disorder. The interpretation of Fourier transforms is also discussed in this chapter.

The chapters on applications, which make up Part C, maintain the standards of the previous chapters. Additional theoretical treatment is given where necessary along with practical considerations before published results are detailed. A critical review of the literature is given rather than a simple regurgitation.

The book is well illustrated with diagrams and figures, and there is a comprehensive bibliography. It is certainly a vital text for anyone wishing to embark upon a career in X-ray absorption.

ERIC LACHOWSKI

Phosphorimetry—Theory, Instrumentation, and Applications: R J HURTUBISE, VCH, Cambridge, 1990 Pages xii + 370 DM 114 00, £70 50

This book is a well done introduction to phosphorimetry. It is written for the beginner as well as the user of phosphorimetric techniques. The writing is extremely good and the book is fun to read. Chapter 2 on photophysical aspects of luminescence is primarily directed towards the quantification aspects of luminescence rather than structure-spectra relationships. Chapter 3 on instrumentation is an excellent review of the principles, operation and use of various instrumental components in phosphorimeters. I would like to have seen a more thorough discussion of spectral correction for instrumental parameters. Chapter 4 on important analytical considerations concerns relationships between phosphorescence intensity or signal and concentration, and signal-to-noise ratio aspects, including limits of detection. Chapters 4 and 5 are primarily tutorial and are very useful for those students and researchers who are beginning work involving phosphorimetric measurements.

Chapter 5 on low-temperature phosphorimetry and Chapter 6 on solid-surface room-temperature phosphorimetry are both extremely well done. These chapters are very useful to both the beginner and the advanced researcher. Chapter 7 on physicochemical interactions in solid-surface phosphorescence gives a detailed and well done discussion of the important physical-chemical interactions in solid-surface RTP, and is the most extensive chapter in the book. Chapter 8, applications in solid-surface RTP, Chapter 9, sensitized and quenched phosphorescence in solution at room temperature, Chapter 10 on micelle-stabilized, cyclodextrin, and colloidal/microcrystalline RTP, Chapter 11 on phosphorescence of proteins, polypeptides, and peptides, and Chapter 12 on structural characterization of polymers are all well done and of considerable interest to anyone interested in the use of phosphorimetry in scientific applications. Chapter 13 on final comments and future trends is very short and not too useful.

Overall, this book is well worth having in your personal library. It is a well written book for analytical chemists as well as those scientists who use or could use phosphorimetry. The numerous tables, figures, and references are extremely useful for anyone working in the area of phosphorimetry. Dr. Hurtubise should be congratulated on this fine publication.

J D WINEFORDNER

PIXE—A Novel Technique for Elemental Analysis: S A E JOHANSSON and J L CAMPBELL, Wiley, Chichester, 1988 Pages xii + 347 £42 50

As a comprehensive introduction to a novel analysis technique, this is an admirable effort. The first half of the book is somewhat dry, of necessity in a discussion of the technical and mathematical basis of the PIXE technique, but the breadth of applications covered later compensates well for this. PIXE, Particle (or Proton) Induced X-Ray Emission, is competing in a difficult field, surrounded by something of a plethora of alternative techniques. That it has made such an impact, as represented in this book, is a consequence of the significant advantages inherent in the technique. These are primarily speed of analysis, extremely high sensitivity and the facility for simultaneous multielemental analysis. The fact that PIXE has "come of age some 15 years after its first demonstration" is testament to its capabilities as a high-speed technique with high absolute sensitivity. As with most new techniques, the development of significant new data-analysis techniques has been required and the importance of this is emphasised in this book. It appears, however, that at its present state of development, PIXE is the best elemental analysis technique in terms of absolute sensitivity for trace quantities.

A casual, or semi-casual, reader—that is, one who is not a PIXE expert—would be well advised to approach the book with the order of the halves reversed. The second half, dealing with applications, is far more likely to stimulate further reading and investigation into the method, dealing as it does with the manifold applications of the PIXE technique. These range from quasi real-time monitoring of the composition of acid rain, through analysis of geological samples and works of art, to the determination of the minute concentrations of life-sustaining trace elements in the various organs of the body. In addition, some of the more prosaic aspects are covered, such as where PIXE can be performed, how much it costs, how rapid it is, *etc*. Having read the book in order, I approached the last chapters asking three questions, and was somewhat relieved to find the answers therein.

With the invitation to further investigation supported by a comprehensive bibliography facilitating this, the book seems ideal even for those on the periphery of interest in the subject, and should help increase general awareness of the technique. In spite of being no expert in the field, I felt that the comprehensive coverage of the fundamentals of PIXE in the first half of the book also appeared to offer useful material for those with a deeper understanding of, and interest in, this obviously expanding technique.

FLOW-INJECTION STOPPED-FLOW KINETIC SPECTROPHOTOMETRIC DETERMINATION OF DRUGS, BASED ON MICELLAR-CATALYSED REACTION WITH 1-FLUORO-2,4-DINITROBENZENE

CONSTANTINOS A. GEORGIU, MICHAEL A. KOUPPARIS*
and THEMISTOCLES P. HADJIIOANNOU

Laboratory of Analytical Chemistry, Department of Chemistry, University of Athens, Panepistimiopolis,
Kouponia, Athens 15771, Greece

(Received 10 October 1990. Accepted 18 December 1990)

Summary—A flow-injection stopped-flow kinetic spectrophotometric method for the determination of hydrazines, hydrazides, amines and amino-acids, based on the cetyltrimethylammonium bromide catalysed reaction with 1-fluoro-2,4-dinitrobenzene is described. With the proposed method dihydralazine, isoniazid, levodopa and aspartame can be determined at concentrations of $0.1-6 \times 10^{-4}M$. The calibration ranges can be varied by adjusting the pH and surfactant concentration. The determination of amphetamine, cysteine, *s*-carboxymethylcysteine, cephalixin, tobramycin and gentamicin is also feasible. The method has been applied to the determination of levodopa, isoniazid and aspartame in commercial pharmaceutical formulations. The determination of isoniazid in formulations containing the highly coloured antibiotic rifamycin, and of aspartame in coloured beverages was also accomplished. The results were in good agreement with those obtained by reference methods and the throughput was 40 measurements per hour with 0.4-3.9% RSD.

1-Fluoro-2,4-dinitrobenzene (FDNB), the so-called Sanger reagent, has been used as a chromogenic reagent for the spectrophotometric determination of amino-acids and primary and secondary amines,¹⁻⁷ amino-acid nitrogen in plasma and urine (Goodwin's method),^{8,9} isoniazid,¹⁰ various aminoglycoside antibiotics (gentamicin, tobramycin, amikacin),¹¹ phenols,¹² and the enzyme amidase.¹³ It has also been used in high-performance liquid chromatography for the determination of amines and aminoglycosides and in thin-layer chromatography.¹⁴⁻¹⁶

These methods have inherent disadvantages, however, *e.g.*, a long reaction time is needed, or heating to speed up the reaction, and additional steps for hydrolysis of the excess of FDNB and extraction of the dinitrobenzene product for measurement. The methods cannot be applied to coloured samples. Kinetic methods overcome such problems associated with equilibrium methods. Recently a kinetic potentiometric method has been developed for the determination of amines,¹⁷ amino-acids,¹⁸ hydrazines, hydrazides and azides¹⁹ and phenols,²⁰ in which

the reaction with FDNB is monitored with a fluoride-selective electrode.

The suitability of FDNB as a general reagent for routine determinations, especially in pharmaceutical analysis, renders automation of the kinetic procedures using FDNB highly desirable. This is more imperative since the FDNB reagent is rather difficult to handle and use (it is vesicatory and hydrolyses in alkaline solutions). Flow-injection (FI) is a very attractive technique for automated manipulation of reagent and sample solutions, with data collection during measurements. The classical FI technique is a kinetic one-point (fixed time) procedure, and can be used with FDNB methods, provided that the reaction rate is adequate. Multipoint kinetic procedures can also be achieved by using the combination of flow injection and stopped flow (FI-SF).²¹ This approach provides more precise kinetic measurements and is suitable for use with coloured sample solutions.

Kinetic studies of FDNB reactions in aqueous media have shown that they can be accelerated considerably by micellar catalysis, with various surfactants. This catalytic action has been used to speed up equilibrium spectrophotometric^{22,23} and kinetic potentiometric methods.^{20,24}

*Author for correspondence.

The development of an automated FI-SF kinetic method, described in this work, increases the measurement throughput and the precision of the determinations (multipoint measurements), allows reduction of the number of steps before measurement (in-line pH adjustment and reagent addition, no need to extract the final dinitrobenzene product), provides safe manipulation of the FDNB reagent, and permits the analysis of coloured sample solutions (background signals do not interfere in the FI-SF technique).²⁵

EXPERIMENTAL

Apparatus

A laboratory made automated FI-SF spectrophotometric analyser was used. It consists of a remote controlled multichannel pump (Ismatec MPN-8), an injection valve (Rheodyne 5001) equipped with a pneumatic actuator controlled by the microcomputer through solenoid valves, Teflon mixing coils (0.8 mm i.d.), a spectrophotometer (Bausch & Lomb, Spectronic 21) equipped with an 18- μ l flow-through cell (Hellma), an AIM 65 microcomputer (Rockwell) with the appropriate home-made control interface and a 12-bit ADC card (Rockwell RM65-5302E). It provides automated sampling, mixing with reagent and buffer solutions, stopping the reaction mixture in the cell, multipoint reaction rate (absorbance) measurement, and data reduction and evaluation. The data-logging routine, written in assembly, permits fast (up to 7.5 kHz) data acquisition and is called by the SLOP.BAS program that is used for routine assays. Two other utility programs were developed for use during the development of a new FI-SF method. The PEAK.BAS program determines the residence time in the FI manifold and the INVQ.BAS program determines the linear segment of the reaction curve for each standard. These parameters are then used by the SLOP.BAS program in routine measurements.

The FI manifold designed and optimized for the proposed method is shown in Fig. 1. A stable acidified aqueous ethanolic solution of FDNB reagent is premixed with an alkaline micellar solution at the optimum pH and then merged with the injected sample zone. After adequate mixing, the reaction mixture is stopped in the flow cell for the reaction rate measurement.

The preliminary spectrophotometric study of the reaction was performed with a double-beam spectrophotometer capable of successive scans (Perkin-Elmer Lambda 7).

Reagents

All reagents were of analytical reagent grade and demineralized distilled water was used throughout.

The FDNB stock solution (0.168M) was prepared by dissolving 3.13 g of FDNB (Sigma) in acetone and dilution to 100.0 ml. This solution was stored in a sealed amber glass vial in the refrigerator and was opened only when used. It should be handled carefully as it is vesicatory. The FDNB working solution ($8.40 \times 10^{-3}M$) was prepared daily by 20-fold dilution of the stock solution with 0.001M hydrochloric acid in 20% v/v ethanol solution in water.

Borate buffer (0.10M adjusted to pH 9.5) was prepared according to usual practice, and contained cetyltrimethylammonium bromide (CTAB, Sigma) at a concentration of $3.5 \times 10^{-3}M$ (for isoniazid and dihydralazine) or $1.5 \times 10^{-3}M$ (for levodopa and aspartame). During the optimization studies, the following buffers were used: (a) pH 8.0 and 8.5 (TRIS 0.10M), (b) pH 9.0 and 9.5 (boric acid 0.10M) and (c) pH 10.0 and 10.5 (borate 0.060M), containing various (0.00, 0.75, 1.50, 3.50, 5.50 and 7.50mM) concentrations of CTAB.

Stock $1.000 \times 10^{-2}M$ solutions of isoniazid, levodopa and aspartame and a $2.000 \times 10^{-3}M$ solution of dihydralazine hydrochloride were prepared from the pure substances (Sigma), the purity of which was determined by the U.S. Pharmacopeia (USP) XXI and National

Fig. 1. Manifold used in the automated kinetic determinations. Sample volume 200 μ l.

Formulary (NF) XVI methods. Working standard solutions in the ranges shown later in Table 3, were prepared by appropriate dilution of the stock solutions. Other substances tested for possible determination by the method were amphetamine, cysteine, cystine, *s*-carboxymethylcysteine, cephalixin, tobramycin, gentamicin, propranolol, isoxsuprine, amoxicillin and acetaminophen (paracetamol).

Kinetic study of the reaction

Appropriate volumes of a working solution of each substance studied, the FDNB reagent and the borate buffer (pH 9–10) were mixed and transferred into the observation cell of the scanning spectrophotometer. Successive scans were made (at 1 scan/min) with a scanning rate of 980 nm/min in the range 300–600 nm. From the spectra obtained the λ_{\max} values for the 2,4-dinitrobenzene derivatives were found.

Measurements with the FI-SF analyser

The spectrophotometer of the FI-SF analyser was set at the λ_{\max} of the corresponding 2,4-dinitrobenzene derivative (428 nm for isoniazid and dihydralazine, 342 nm for aspartame and 352 nm for levodopa), then the residence time and the time interval (measurement time) during which the $A = f(t)$ reaction curve is linear were determined by using the working standard solutions of the substance and the appropriate investigative program (PEAK.BAS and INVQ.BAS, respectively). Subsequently, the SLOP.BAS program was loaded and the timing parameters for the determination and information for the number of standards, samples and runs per standard and sample were provided to the program.

When the optimized manifold (Fig. 1) was used with 200 μ l of sample or standard, the flow was stopped for 16 sec (residence time), followed by a time interval of 2 sec for mechanical equilibration of the stopped mixture, then multiple (40–256) absorbance readings, equally spaced on the time axis, were taken during a measurement time of 15–40 sec, as estimated by the INVQ.BAS program for each determination. The pump was then restarted and a time interval of 40 sec was allowed for washing the measured sample from the manifold and loading the next sample into the sample loop. Subsequently, the experimental reaction rate ($\Delta A/\Delta t$) was calculated by linear regression of the absorbance readings, and was used for construction of the calibration curve or

determination of the analyte concentration in the samples.

Sample preparation

For solid formulations the official USP sampling procedures were followed. From the final fine powder an accurately weighed portion was dissolved in water, so that the concentration of the drug was in the range of the corresponding calibration curve (Table 3). An ultrasonic bath or a mechanical shaker was used to ensure complete disintegration of the powder, and any insoluble matter was allowed to settle or was filtered off or centrifuged. For the analysis of beverages containing aspartame, carbon dioxide was expelled by purging with nitrogen and the sample was diluted tenfold with the buffer used.

All measurements were performed in an air-conditioned laboratory maintained at a nominal temperature of about 25°.

RESULTS AND DISCUSSION

Preliminary kinetic investigation

To find λ_{\max} for the coloured 2,4-dinitrobenzene (DNB) derivative of each analyte and obtain a rough estimate of the reaction rate, a kinetic spectrophotometric study was performed as described above. Figure 2 shows successive spectra obtained from the reaction of FDNB with isoniazid. The DNB-isoniazid derivative, with $\lambda_{\max} = 428$ nm, is formed rather slowly, so the reaction must be accelerated for use in an FI-SF method with sufficient sensitivity and short analysis time. Micellar catalysis with CTAB was chosen to accelerate the reaction. The λ_{\max} values for the DNB derivatives of the other substances studied were 346 nm for amphetamine, 342 nm for aspartame, 352 nm for levodopa, 340 nm for cysteine, 342 nm for cephalixin, 344 nm for tobramycin, and 350 nm for gentamicin and *s*-carboxymethylcysteine. Several substances (phenols and cystine) form water-insoluble DNB derivatives which render spectrophotometric measurements impossible because of the cloudy solutions obtained.

The λ_{\max} of FDNB is 240 nm, that of its ethanolysis product is 283 nm and that of its hydrolysis product (2,4-dinitrophenol) is 360 nm.

Design and optimization of the FI-SF method

In an FI procedure using FDNB, the problem of stabilizing the reagent solution has to be solved. FDNB is only slightly soluble in water, and undergoes base-catalysed solvolysis

Fig. 2. Kinetic study of the FDNB-isoniazid reaction. [Isoniazid] $1.25 \times 10^{-4} M$, [FDNB] $1.4 \times 10^{-3} M$, in $0.33 M$ borate buffer adjusted to pH 9.5. Ten successive scans at 1 scan/min.

in solvents that contain active hydrogen atoms, such as ethanol and water. A very stable FDNB stock solution can be prepared in acetone, but solutions containing more than 5% v/v acetone cannot be pumped through the conventional silicone rubber tubing used in peristaltic pumps. Therefore, the working FDNB solution was prepared daily in 20% v/v ethanol solution acidified with hydrochloric acid. A spectrophotometric stability study of working FDNB solution containing ethanol at concentrations of 20, 30, 40 and 50% v/v revealed 4, 6.5, 8 and 8% solvolysis of FDNB, respectively in a period of

8 hr. Therefore, a 20% content of ethanol in the working FDNB solution provides a reagent stable enough for an 8-hr routine operation of the analyser.

The effect of pH and surfactant concentration on the analytical reaction was studied. Table 1 shows the characteristics of the calibration curves for isoniazid, constructed by measuring the reaction rate of standards over the pH range 9.0–10.5. The sensitivity increases with pH but so does the blank value (due to base-catalysed FDNB solvolysis), whereas the linear concentration range decreases. A pH of 9.5 was chosen

Table 1. Effect of pH on the calibration graph for isoniazid ([CTAB] $1.5 \times 10^{-3} M$)

pH	Slope, $mA \cdot sec^{-1} \cdot l. \cdot mole^{-1}$	Intercept, $mA \cdot sec^{-1}$	DL*, $10^{-3} M$	r	Range, $10^{-4} M$	Blank $\pm SD (n = 6),$ $mA \cdot sec^{-1}$
9.0	$(2.73_6 \pm 0.02_7) \times 10^3$	0.03 ± 0.03	19	0.9996	2–50	0.06 ± 0.17

*Detection limit: concentration corresponding to a net analytical signal equal to three times the standard deviation of the blank.

as a compromise between sufficient sensitivity, wide linear response range, low blank value, good linearity and precision. The effect of the surfactant concentration on the characteristics of the calibration curve for isoniazid is shown in Table 2. The sensitivity and the blank value increase with the surfactant concentration, but the linear concentration range decreases at $[CTAB] \geq 0.0015M$. A CTAB concentration of $0.0035M$ was chosen as a compromise between sensitivity and low blank value. The same optimum pH and CTAB concentration were found for dihydralazine, while for the determination of aspartame and levodopa the optimum CTAB concentration was $0.0015M$. The linear range and the sensitivity of the determinations can be varied by changing the reaction pH and/or the CTAB concentration.

Evaluation of the method

Typical calibration data for aspartame, levodopa, dihydralazine hydrochloride and isoniazid under the optimized conditions are shown in Table 3. The linearity of calibration was excellent and the precision (relative standard deviation, RSD) of the measurements

§Contains 150 mg of rifamycin.

||Contains 300 mg of rifamycin.

To examine the applicability of the proposed FI-SF method to routine pharmaceutical analyses, the effect of various excipients and the antibiotic rifamycin, which is present in mixed formulations with isoniazid, was studied. Recovery results for mixed solutions of isoniazid and the substances studied are shown in Table 4. Common excipients do not interfere, except sodium lauryl sulphate and carboxypolyethylene (carbopol), which give negative errors (possibly by formation of mixed micellar solutions or partial saturation of the surfactant micelles, and a consequent change in catalytic

action). Experiments with these two excipients and a surfactant-free buffer solution gave recoveries of 97.2–101.4%, so formulations containing these two excipients can be analysed by use of a surfactant-free buffer but with lower sensitivity and decreased measurement throughput. This also applies to mixed isoniazid–rifamycin formulations.

Applications

The proposed FI-SF method was applied to the determination of isoniazid, aspartame and levodopa in commercial formulations and of

Fig. 3. FI-SF recordings for the determination of isoniazid (INH) in (a) standard solutions and in tablet solutions containing (b) 300 mg and (c) 150 mg of rifamycin per tablet. 	Nominal	Found \pm SD	
		FI-SF*	Reference method†
Sprite	0.50	0.43 ± 0.01	0.41
Coca Cola	0.50	0.51 ± 0.02	0.48

*Three samples each measured in triplicate.

†HPLC method.²⁶

aspartame in diet ("light") beverages. It compares favourably with reference methods (Table 5) and permits the determination of isoniazid in mixed isoniazid-rifamycin formulations. Typical FI-SF recordings for this otherwise tedious determination are given in Fig. 3. The FI-SF technique is based on measurement of the slope of the rising part of the curve, eliminating interferences due to coloured substances in the sample.

For the determination of aspartame in beverages (Table 6), the results obtained by the proposed FI-SF method were higher than those obtained by the HPLC²⁶ reference method. This may be due to small amounts of amino-compounds or phenols present in the beverages. The time required for a single measurement with the HPLC method is 15–20 min, discouraging its use in routine analysis, whereas the FI-SF method requires only 1.5 min per measurement, allowing a high sample throughput in routine analysis. Typical FI-SF recordings for aspartame determinations are shown in Fig. 4. The

advantage of the FI-SF methods of avoiding interferences due to background signals is utilized in the determination of aspartame in Coca Cola, which contains highly coloured caramel colouring.

The method can also be applied for the determination of other substances which give soluble 2,4-dinitrobenzene derivatives, such as cephalixin, tobramycin and gentamicin.

CONCLUSIONS

The proposed FI-SF kinetic method overcomes problems associated with (a) incompleteness of analytical reactions which require high temperatures and long reaction times when used in equilibrium spectrophotometric methods, and (b) the need to hydrolyse the surplus reagent and then extract the reaction product from the mixture. The method permits analysis in highly coloured samples and features a measurement throughput of 40 per hour. As stated above, the proposed method (with spectrophotometric detection) is not suitable for the determination of phenols. The applicability of the method can be extended to phenols of pharmaceutical interest by use of a fluoride-selective flow-through electrode as detector in the FI-SF system.

MACROSCOPIC AND MICROSCOPIC ACID DISSOCIATION CONSTANTS OF DIPROTIC ACIDS—A POTENTIOMETRIC AND SPECTROPHOTOMETRIC STUDY

PAOLO UGUAGLIATI* and LUCIANO CANOVESE

Dipartimento di Chimica, Facoltà di Scienze, Università di Venezia, S. Marta, Venezia, Italy

(Received 1 October 1990. Accepted 24 January 1991)

Summary—A state-of-the-art survey of the determination of acid dissociation microconstants of diprotic acids is presented. It is shown that potentiometric and spectrophotometric titration data can yield *macroscopic* constants but are not sufficient to completely resolve the *microconstant* system unless some sort of assumption is made, which may not always be warranted. Such an estimative deduction procedure is applied to 2,6-di(methylthiomethyl)-3-hydroxypyridine chloride.

The acid dissociation equilibria of polyprotic acids are characterized by the so-called *macroscopic* constants which are unrelated to the specific protonation sites of the various species present in solution. Such macroscopic constants are a composite of the *microscopic* constants which are related to the dissociation equilibria of the individual species. As will be shown in this report, potentiometric or spectrophotometric techniques can only provide the values of macroscopic constants. Assessment of the microscopic constants is based on further assumptions which may not always be justified.

A wealth of research efforts have been devoted to determining microconstants by a variety of spectral methods.^{1,2} The aim of the present paper is to outline the state-of-the-art of the subject in order to clarify matters and describe the application of potentiometric and spectrophotometric techniques to a novel 3-hydroxypyridine derivative to be studied as a chelating ligand for transition metal complexes.

Theory

Consider the diprotic acid derived from a substituted 3-hydroxypyridine (I; Scheme 1).

The macroscopic constants K_2 and K_1 , which can be determined by titration of I with a strong base, are related to the microscopic ones by the equations:

$$K_2 = K_{12} + K_{13}$$

$$K_1 = K_{24} \cdot K_{34} / (K_{24} + K_{34})$$

$$= K_{12} \cdot K_{24} / (K_{12} + K_{13})$$

$$K_2 \cdot K_1 = K_{12} \cdot K_{24} = K_{13} \cdot K_{34}$$

$$K_{23} = K_{13} / K_{12} = K_{24} / K_{34} \quad (1)$$

Only three equations relate the four microconstants K_{12} , K_{13} , K_{24} and K_{34} , so that at least one piece of additional information is required for a complete determination.

Let's now express the concentrations of species involved in the above equilibria in terms of pH and system variables.

Let:

$$S = K_{12} + K_{13}; \quad pS = -\log S \quad (2)$$

$$P = K_{12} \cdot K_{24}; \quad pP = -\log P \quad (3)$$

so that

$$pK_2 = pS$$

$$pK_1 = pP - pS$$

If a volume V_0 of a solution of I at analytical concentration $c_0 M$ is titrated with a volume V of a solution of strong base at concentration c , we have from equation (1):

$$V_T = V_0 + V$$

$$a_0 = 1 / (1 + 10^{pP - pS - pH} + 10^{pP - 2pH})$$

$$[\text{I}] = (c_0 V_0 / V_T) a_0 10^{pP - 2pH}$$

$$[\text{II}] = (c_0 V_0 / V_T) a_0 10^{pK_{24} - pH}$$

$$[\text{III}] = (c_0 V_0 / V_T) a_0 K_{23} 10^{pK_{24} - pH}$$

$$[\text{IV}] = (c_0 V_0 / V_T) a_0 \quad (4)$$

*Author for correspondence.

The electroneutrality equation is:

$$[\text{H}^+] - [\text{OH}^-] + cV/V_T - (c_0 V_0/V_T) a_0 (2 + 10^{pP - pS - \text{pH}}) = 0 \quad (5)$$

and contains only pP and pS as refinable parameters. Non-linear regression of pH vs. V data will only yield values for $P = K_{12} \cdot K_{24}$ and $S = K_{12} + K_{13}$. There is no way of getting the values of individual microconstants without further assumptions.

Equation (4) can be rewritten as:

$$\begin{aligned} \text{[I]} &= H \cdot R \\ \text{[II]} &= K_{12} \cdot R \end{aligned}$$

$$\text{[III]} = (S - K_{12})R = K_{13} \cdot R$$

$$\text{[IV]} = (P/H)R$$

where

$$H = [\text{H}^+]$$

$$R = (c_0 V_0/V_T)/(H + S + P/H) \quad (6)$$

It is evident that if it were possible to measure the sum $\text{[I]} + \text{[III]}$ (or $\text{[II]} + \text{[IV]}$) then non-linear fitting of such sums to pH data would open the way to S , P and K_{13} (or K_{12}) and thus to the complete microconstant set according to equations 1, 2 and 3.

Equation (5) can be recast as

$$V = V_0[c_0(R' - 1) + H - OH]/(OH - H - c) \quad (7)$$

where

$$H = [H^+]$$

$$OH = [OH^-]$$

$$R' = (H/K_{13} - K_{34}/H)/(1 + H/K_{13} + 1/K_{23} + K_{34}/H)$$

from which, again, only R' values can be obtained. These, combined with equations (2) and (3), are still one equation less than the four independent ones that are required to solve for the four unknowns K_{12} , K_{24} , K_{13} and K_{34} . Now, one way out of the circle would be the knowledge of the constant for the equilibrium between the zwitterion II and the neutral species III ($K_{23} = [III]/[II]$), which is not affected by changes in pH.

If we resort to spectrophotometric titrations, then the absorbance of a solution of I at concentration c_0 vs. pH is expressed by

$$\begin{aligned} A_{\lambda, \text{pH}} &= c_0 R [H\epsilon_1 + K_{12}\epsilon_{II} \\ &\quad + K_{13}\epsilon_{III} + (P/H)\epsilon_{IV}] \\ &= c_0 R [H\epsilon_1 + \Sigma_K + (P/H)\epsilon_{IV}] \end{aligned} \quad (8)$$

where

$$R = 1/(H + S + P/H)$$

$$\Sigma_K = K_{12}\epsilon_{II} + K_{13}\epsilon_{III}$$

The apparent extinction coefficient of monoprotonated species is therefore the sum of constant fractions of the extinction coefficients of II and III, so that the latter behave spectrally as though they were one single component. Thus, the condition for observing a global isobestic point is

$$\epsilon_1 = \epsilon_{IV} = \Sigma_K/S$$

Fulfillment of such a condition can be expected to be rather uncommon. In the pH range where one of the species does not contribute to the absorbance, partial isobestic points may be observed. However, their presence cannot be exploited to deduce the presence of only two spectral components.

Non-linear regression of absorbance vs. pH [equation (8)] will only give the parameters S and P , and the sum Σ_K , from which the single microconstants K_{12} and K_{13} could be extracted if

both extinction coefficients ϵ_{II} and ϵ_{III} were known independently; this again requires additional pieces of information not available from the titration data alone (the extinction coefficients of I and IV can be deduced from limiting absorbance data taken at low and high pH, respectively, or allowed to float in the optimization process as further parameters to be refined while S and P can be taken from the potentiometric titration or included in the refinement for consistency).

Summing up, fitting models corresponding to equations (5), (7) and (8) are overparameterized and attempts at refining (in the least-squares sense) all microconstants imbedded in the models, will eventually lead to singular normal equations, extremely sluggish convergence rates and parameter partial correlation coefficients with absolute values virtually equal to unity. All these symptoms indicate the need for reducing the dimensionality of parameter space by only refining proper combinations of some of the parameters, as we have shown above.^{3,4}

The mathematical formulation and the arguments outlined so far can be easily extended, without loss of generality, to acid-base equilibria involving other polyprotic systems, such as aminoacids, catecholamines, catechols, aminophenols, etc.^{1,2}

The earliest attempts at determining microscopic constants in equilibria of the type of **Scheme 1** were based on the assumption that blocking one of the active groups (e.g., by esterification or alkylation) would leave the acid-base properties of the other unaltered.^{1,2,5-7} For instance, if one assumes that K_{13} in **Scheme 1** is virtually identical to the acid dissociation constant for the ester

then it is possible to resolve the whole microconstant equilibrium system. In an analogous way, N -alkylation in the pyridinium derivative

would provide a breakthrough to the K_{12} value. Such an assumption may be justified for specific systems, depending on the particular molecular

structure of the species involved, but its generalized use is not warranted.⁸

Another approach is based on the fact that, if the two acidic groups can be associated with characteristic spectral features, then dissociation of one group can be followed independently of the other. In other words, it is assumed that the spectral properties of one group are independent of whether the other group is protonated or not. In this way, it is possible to assess the microconstants from the fractional deprotonation of one of the two groups as a function of pH. This approach, earlier introduced by Edsall *et al.*,⁷ allows the experimental measurement of the sums [II + IV] or [I + III] in equation (6), from which K_{12} or K_{13} can be evaluated, respectively. In practice, it is assumed that in equation (8) $\epsilon_I \cong \epsilon_{III}$ and $\epsilon_{II} \cong \epsilon_{IV}$ at suitable wavelengths, so that the absorbance data can be successfully fitted in terms of parameters S , P and K_{12} (or K_{13}).^{5,9-13}

A similar approach has been adopted for IR¹⁴ and Raman¹⁵ spectral data pertaining to related systems. However, the validity of results is often limited by lack of precision.

Nuclear magnetic resonance spectrometry has also been widely employed for the determination of microconstants, based on the calculation of the fractional deprotonation of one of the acidic groups as a function of pH from the chemical shift of a unique resonance, on the premise that the substrate contains an NMR-active nucleus whose chemical shift effects depend on dissociation of only one dissociable group.¹⁶⁻¹⁹ However, in some cases reliable values of microconstants cannot be obtained due to the high correlation between the parameters and the poor conditioning of equations involved.

Summing up, all the methods devised so far entail some sort of assumption that may not always be warranted. As a consequence, the results from different experimental approaches often disagree seriously.¹³ Any attempt at determining all microconstants from spectral data based on the equation²⁰

$$\alpha_{OH} = H \cdot S / (H^2 + H \cdot S + P)$$

(where α_{OH} is the mole fraction of singly dissociated phenolate anions in catechol derivatives) through subsequent mathematical reworking is an exercise in self-delusion.

EXPERIMENTAL

The substrates **A** and **B** ($X = \text{CH}_2\text{SCH}_3$) were prepared by a route to be described in a forth-

coming paper. All other chemicals were of reagent grade purity.

Potentiometric titrations

Potentiometric titrations were carried out with a Metrohm 654 pH-meter at 25° under a nitrogen stream. The glass electrode was calibrated with the standard Metrohm buffer (pH 4 and 7). A 50-ml volume of a 0.001M solution of the chlorhydrate $A \cdot \text{HCl}$ (prepared *in situ* by adding the stoichiometric amount of standard hydrochloric acid to a weighted amount of **A**) was titrated with a freshly prepared CO₂-free solution of 0.01M sodium hydroxide. The ionic strength was maintained by using a 0.1M solution of sodium chloride in doubly distilled and degassed water as the solvent for all solutions.

Spectrophotometric titrations

These were carried out with a Perkin-Elmer Lambda 5 spectrophotometer equipped with a cell compartment kept at 25° at constant ionic strength (0.1M sodium chloride) in doubly distilled and degassed water. To 5-ml aliquots of a 5.01×10^{-4} M solution of **A** were added 5-ml aliquots of standard hydrochloric acid or sodium hydroxide solutions. The pH (1-13) and the UV-VIS spectra (220-380 nm) of the resulting solutions were recorded.

Data analysis

Mathematical and statistical analysis and graphical display of experimental titration data were carried out on an IBM PS/2 70 personal computer equipped with an Intel 80387 maths coprocessor by use of locally adapted non-linear regression and plotting algorithms written in TurboBasic (Borland).

RESULTS AND DISCUSSION

Potentiometric titrations

Potentiometric titration data for the system in **Scheme 1** ($X = \text{CH}_2\text{SCH}_3$) were analysed according to models in equations (4-6) to determine the *macroscopic* dissociation constants K_2 and K_1 [equation (1)] in the following way. A weighted non-linear least-squares fitting of pH *vs.* V data was carried out by use of Marquardt's algorithm^{21,22} with pS and pP as the refinable parameters. During each iterative cycle, equation (5) was solved numerically for pH at each data point by a modified iterative bisection equation solver.^{23,24} Partial derivatives of the object function with respect to the parameters

were approximated by a numerically efficient forward differentiation scheme.²⁵ The function minimized was $\sum w_i (\text{pH}_{\text{obs}} - \text{pH}_{\text{calcd}})^2$ with the weighting scheme²⁶ $w_i = 1/(\text{pH}_{i+1} - \text{pH}_{i-1})^2$ to avoid lending too much influence to the less accurate pH values in the steeply-rising portion of the titration curve. Convergence to the optimized parameter vector was rapidly reached to yield the values of $\text{p}S = 3.90 \pm 0.02$ and $\text{p}P = 12.30 \pm 0.02$. Uncertainties quoted throughout are one standard error of estimate from the inverse covariance matrix. The parameter correlation coefficient was 0.79. At convergence, the experimental pH values agreed with those calculated from equations (4–5) and the optimized parameters to within 0.06 of a pH unit (weighted standard error of fit = 1.3). Residuals were randomly scattered and approximated a normal distribution.

The macroscopic dissociation constants are therefore $\text{p}K_2 = 3.90 \pm 0.02$ and $\text{p}K_1 = 8.40 \pm 0.04$. These values are sufficiently far apart to allow the mixture of monoprotinated species II + III to be predominant around pH 6.

Spectrophotometric titrations

The dependence of the absorbance of solutions of A on wavelength and pH from spectrophotometric titration is shown in Fig. 1. in which spectra at some selected experimental pH values were omitted for the sake of clarity.

An *a priori* parameter identifiability analysis of the model in equation (8) indicated that only *three* parameters could be uniquely determined by non-linear regression, *i.e.*, S , P and Σ_K .²⁷ The extinction coefficients ϵ_I and ϵ_{IV} were determined

directly from absorbances at low and high pH, respectively. Further, the parameter vector in equation (8) could be reduced to the single parameter Σ_K by fixing S and P at the values derived from potentiometric analysis (see earlier). This may serve to check the consistency of data and the overall experimental layout.

Non-linear least-squares fits of absorbance to pH for the 3-parameter model at different wavelengths gave S and P values virtually independent of wavelength and in very good agreement with those determined potentiometrically ($\text{p}S = 3.97 \pm 0.05$, $\text{p}P = 12.31 \pm 0.03$ as averages of values at five selected wavelengths). The standard error of estimate was about 5 absorbance units. Parameter correlation coefficients are fairly high (0.7–0.9, in absolute value), probably due to an intrinsic feature of the model and of the instrumental method. Figure 2 shows a 3-D representation of the 2-variable function $A_{\lambda, \text{pH}}$ in equation (8), using the optimized parameters.

As can be seen from Figs. 1 and 2, a global isosbestic point is present at 339 nm, where the condition $\epsilon_I = \epsilon_{IV} = \Sigma_K/S$ appears to be verified. Figures 3(a) and (b) show the results of spectrophotometric titration at two wavelengths and the corresponding contributions of the species I, II + III, IV to the observed overall absorbance as a function of pH.

Up to this point, all the information we could gather is embodied in the following 4-unknown 2-equation system:

$$\begin{cases} K_{12} \cdot \epsilon_{II} + K_{13} \cdot \epsilon_{III} = \Sigma_K \\ K_{12} + K_{13} = S \end{cases} \quad (9)$$

Fig. 1. Spectra of a $2.505 \times 10^{-4} M$ solution of A as a function of pH. (a) pH 1.05; (b) 3.65; (c) 4.79; (d) 6.12; (e) 7.72; (f) 12.71.

Fig. 2. 3-D representation of the dependence of absorbance of a $2.505 \times 10^{-4}M$ solution of A on pH and wavelength as in equation (8).

(the equations $P = K_{12} \cdot K_{24} = K_{13} \cdot K_{34}$ would introduce the additional unknowns K_{24} and K_{34} , respectively). Our inadequacy in solving system (9) stems from the fact that we ignore both the individual concentration of II and III and their extinction coefficients. Therefore, we have squeezed the last drop of information from all combined experimental data at hand. From now on, we must resort to some kind of assumption or approximation if we are to completely resolve the microconstant scheme.

The microconstant system

As noted earlier, there may be a wavelength range in the spectra of Fig. 1 in which it may be justifiable to make the assumptions

$$\epsilon_1 \cong \epsilon_{III}; \quad \epsilon_{II} \cong \epsilon_{IV} \quad (10)$$

Let's now surmise that equations (10) apply to the spectra around 260 nm, which is tantamount to assuming that loss of the proton from the nitrogen group does not affect the spectrum of the ionized phenolic group. Analogous assumptions were first advocated by Edsall *et al.*⁷ in their pioneering studies of protonation equilibria of related polyprotic systems. Then equation (8) becomes

$$A = c_0 R [(H + S)\epsilon_1 + K_{12}(\epsilon_{IV} - \epsilon_1) + (P/H)\epsilon_{IV}] \quad (11)$$

A least-squares fit of absorbance to pH data in equation (11) at 260 nm with S and P fixed at the potentiometric values yields $pK_{12} = 4.71$, from which the whole set of microconstants is calculated as:

$$pK_{12} = 4.71; \quad pK_{13} = 3.97$$

$$pK_{34} = 8.33; \quad pK_{24} = 7.59$$

$$pK_{23} = -0.74 \quad \text{whence} \quad [II]/[III] = 0.18$$

The same results are of course arrived at if system (9) is solved with the aid of equation (10) and the Σ_K value corresponding to the appropriate wavelength.

Attempts at applying equations (10) and (11) outside the range 260–270 nm will lead to absurd (negative) values for either K_{12} or K_{13} .

Support for this approach can be gathered from the pK_A value for compound V as the chloride,

which we established to be 4.04 ± 0.02 by potentiometric and spectrophotometric titrations. The higher acidity of the NH^+ group in I and

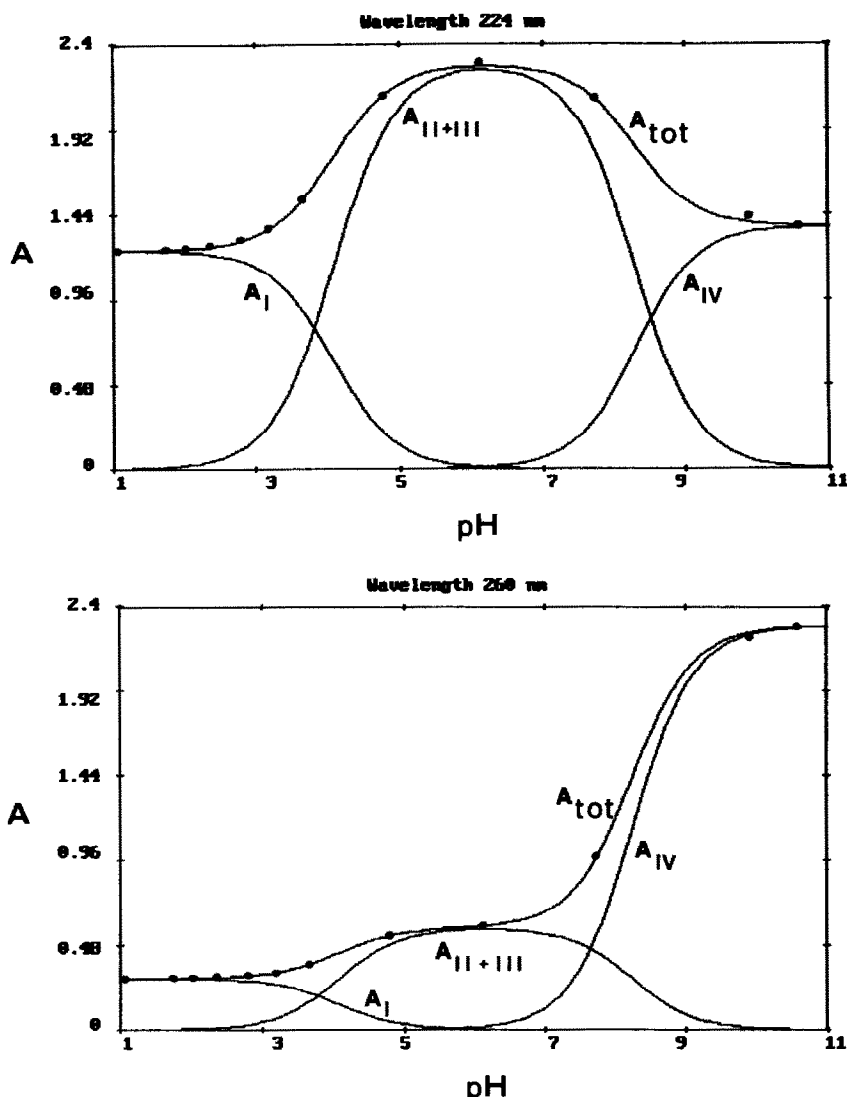

Fig. 3. Spectrophotometric titration of A at (a) 224 nm and (b) 260 nm. Solid line A_{tot} is the fitting curve of equation (8). The circles are observed data points ($c_0 = 2.505 \times 10^{-4} M$). Solid lines A_I , A_{II+III} , and A_{IV} are the relative contributions of I, (II + III), and IV, respectively, to the total absorbance as a function of pH from equation (8).

V as compared to that in pyridinium ion (pK_A 5.25) is likely to be caused by the presence of the two electron-withdrawing methylthiomethyl (CH_2SCH_3) substituents [the electron-attracting character of these groups is reflected by the pK_A value of 4.64 for 2-(methylthiomethyl)pyridine²⁸]. The higher acidity of the OH group in III relative to phenol is comparable to that in *m*-nitrophenol (pK_{34} 8.33 *vs.* pK_A 8.38) and stems from the presence of the heterocyclic nitrogen which has been suggested to be roughly equivalent to a nitro-group.⁵ This is consistent with the very large increase in acidity of the phenolic proton relative to phenol in I (pK_{12} 4.71 *vs.* pK_A 9.9), due to the presence of

the additional positive charge (*cf.* pK_A 4.96 for *N*-methyl-3-hydroxypyridinium iodide²⁹). Finally, the negative charge of the phenolate group in zwitterion II renders its NH^+ proton much less acidic than its counterpart in the cationic phenol I (pK_{24} 7.59 *vs.* pK_{13} 3.97).

It appears from our scheme that the neutral hydroxypyridine III predominates over the phenolate-pyridinium zwitterion II. This is in contrast with Lunn and Morton's assumption about related 3-hydroxypyridines for which the zwitterion was claimed to be the only monoprotonated species present in the pH range midway between the two macroscopic pK_2 and pK_1 values.³⁰ Based on the analysis of the problem

that we have presented in this paper and on the spectral changes reported,³⁰ we cannot see how such a claim could be sustained.

SPECTROPHOTOMETRIC EXAMINATION OF REDOX EQUILIBRIA BY USE OF LOGARITHMIC TRANSFORMATIONS

S. KOCH and G. ACKERMANN

Bergakademie Freiberg, Sektion Chemie, Freiberg-9200, Germany

(Received 12 February 1990. Accepted 21 January 1991)

Summary—For the spectrophotometric characterization of redox reactions, a logarithmic transformation is proposed by which it is possible to analyse indirectly the functions $E = f(\text{pH})$ and $E = f(C)$ derived from experimental data. Besides the mechanism of the reaction the equilibrium constant can also be calculated. The method is generally usable for equimolar redox systems and also for non-equimolar ones if a single equilibrium exists in the range under examination. References to the evaluation are given and the practicability is demonstrated with the system $\text{Fe}^{3+}/\text{SO}_3^{2-}$.

Spectrophotometric methods of examining redox equilibria are rarely published because the potentials of the half-cells are known and therefore the reactions can be formulated. In the examination of unknown redox reactions, however, experimental methods must be used. When the components are coloured, spectrophotometric methods are applicable, such as Job's method¹ or the molar ratio method.² In the case of equimolar systems it is disadvantageous that these methods give only the possibility of finding the relative molar coefficients (m/n). It is not always possible to characterize complicated redox systems unequivocally with these coefficients. Moreover, with these methods only reactions with high equilibrium constants can be tested. By applying special kinds of transformations containing the equilibrium constants, the absolute coefficients (m, n) can be determined. The transformation proposed by Ceba *et al.*³ can be used for the determination of the molar coefficients and equilibrium constants, but a statement of the number of protons exchanged is not possible.

This paper reports a generally applicable logarithmic transformation with which it is possible to find the stoichiometry of the reaction, including the number of protons exchanged and the equilibrium constant.

EXPERIMENTAL

The spectrophotometric measurements were made with a Beckman DU spectrophotometer and 1-cm cells. All samples were prepared by

adding the reagents in the following sequence: iron solution, perchloric acid, sodium sulphite and sodium chloride. Measurements were made immediately after mixing (pH curve) or after 2 months (C_R curve). The iron(III) standard solution was prepared by dissolving the sulphate in 0.1M sulphuric acid. The concentration of the sodium sulphite solution was determined iodometrically.

General aspects

A general redox reaction between A_q and B_r to yield A'_s and B'_t can formally be written, including polynuclear species, as

where charges are omitted for simplicity. At equilibrium

$$mq = m's \quad (2)$$

and

$$nr = n't \quad (3)$$

Equation (1) can therefore be written as

The species A'_s and B'_t are in this case in the stoichiometric relation

$$[A'_s]:[B'_t] = m':n' = \frac{mq}{s} : \frac{nr}{t} \quad (5)$$

Also, the total concentrations of A and B (C_A and C_B) are given by

$$C_A = q[A_q] + s[A'_s] \quad (6)$$

$$C_B = r[B_r] + t[B'_t] \quad (7)$$

If the ionic strength (I) is practically constant, the law of mass action is valid, and

$$K^* = \frac{[A'_s]^{m'} [B'_t]^{n'} [H]^x}{[A_q]^m [B_r]^n} \quad (8)$$

$(m, n, m', n') = 1, 2, \dots; x = 0, \pm 1, \pm 2, \dots$

For proton-free equilibria, the corresponding constant K , resulting from (8) with $x = 0$, is

$$K = \frac{[A'_s]^{m'} [B'_t]^{n'}}{[A_q]^m [B_r]^n} \quad (9)$$

Fundamentals of the transformation

As extended examination has shown, because of the exponential form of (8) and (9), linear relationships can only be established if logarithmic functions are used. From equation (8),

$$\log \frac{[A'_s]^{m'} [B'_t]^{n'}}{[A_q]^m [B_r]^n} = x\text{pH} + \log K^* \quad (10)$$

If the concentration term is called Z then

$$\log Z = x\text{pH} + \log K^* \quad (11)$$

which is the equation of a straight line with slope x and intercept $\log K^*$. An indirect analysis with a simple assumption of linearity cannot be performed, since because of the use of a logarithmic function linearity would result even if x , m or n' were wrong. In the case of the true molar coefficients a straight line results:

$$\log Z = f(x\text{pH})_{(K^* = \text{const.})} \quad (12)$$

and x is the value of the slope in the correct mathematical equation. The calculation of the equilibrium constant is first demonstrated for a general model with coloured components. For further convenience, A_q , B_r , etc. are simplified and written as A, B, ...

According to the Lambert-Beer law, for a path-length d , the absorbance A is given by

$$A/d = \epsilon_A[A] + \epsilon_{A'}[A'] + \epsilon_B[B] + \epsilon_{B'}[B'] \quad (13)$$

By combination of equations (5), (6) and (7), the values of the concentrations are

$$[A'] = \frac{m'(qrA/d - r\epsilon_A C_A - q\epsilon_B C_B)}{m'r(q\epsilon_{A'} - s\epsilon_A) + n'q(r\epsilon_{B'} - t\epsilon_B)} \quad (14)$$

$$[B'] = \frac{n'[A']}{m'} \quad (15)$$

$$[A] = \frac{C_A - s[A']}{q} \quad (16)$$

$$[B] = \frac{C_B - t[B']}{r} \quad (17)$$

Since $m' = mq/s$ and $n' = nr/t$, m' and n' can be replaced in the logarithmic function (10) to give

$$\log Z = \frac{mq}{s} \log [A'] + \frac{nr}{t} \log [B'] - m \log [A] - n \log [B] \quad (18)$$

Equilibria involving protons

To solve this problem it is necessary to analyse the curve $A = f(\text{pH})$ resulting from experiments with constant C_A , C_B , I and λ , after use of transformation (11), equations (14)–(17) or (18) and a plot of the results. The parameters (x, m, n) used are only the correct values if the straight line function $\log Z = f(x\text{pH})$ meets the criterion

$$\frac{\Delta \log Z}{\Delta(x\text{pH})} = x \quad (19)$$

Both m and n can have only a positive sign, but the values of x can be either positive or negative, positive for systems in which protons are released.

Extrapolation of the straight line resulting from use of the correct values of the molar coefficients gives $\log K^*$ from the intercept on the ordinate: since this results from extrapolation to $x = 0$ or $\text{pH} = 0$, all values of x give the correct value for the equilibrium constant.

Proton-free equilibria

Redox equilibria that are independent of pH are relatively few. For systems with $A = f(\text{pH}) = \text{constant}$, the function $A = f(C_B)$ is obtained from a set of experiments with C_A , I and λ all constant. For the evaluation, equations (18) and (14)–(17) with varying (m, n) , are again used.

For the correct parameters, the criterion $\log Z(C_B) = \text{const.}$ must be fulfilled. By applying this formulation with C_A , pH, I and λ constant, equilibria involving protons can also be handled. In this case, only (m, n) results. An apparent constant $K' = K^*/[H]^x$ is obtained, defined by

$$\log K' = \log Z \quad (20)$$

Table 1. Transformation $Z = f(\text{pH}, C)$; absorption by only one component

Condition	Concentration [A']
$\epsilon_A > 0$	$\frac{\epsilon_A C_A - qA/d}{s\epsilon_A}$
$\epsilon_A' > 0$	$A/d\epsilon_A'$
$\epsilon_B > 0$	$\frac{m'(\epsilon_B C_B - rA/d)}{n'\epsilon_B}$
$\epsilon_B' > 0$	$m'A/dn'\epsilon_B'$

In the case of proton-free equilibria, the equilibrium constant K for expression (9) is easily obtained with correct coefficients from $\log K = \log Z$.

Application of the transformations

The logarithmic transformations give the possibility of analysing the functions $A = f(\text{pH})$ and $A = f(C)$ resulting from spectrophotometric measurements. Before starting the experiments it must be known that the mechanism and species involved will always be the same. Only under these conditions will the transformations work.

For application of the mathematical equations, the molar absorptivities ϵ_A , ϵ_B , etc., must be known. Generally, a wavelength can be found at which only some of the components absorb. If 1, 2 or 3 of the species are coloured, equation (14) will give [A']. As equations (15), (16) and (17) show, the functions for [B'], [A] and [B] are not affected. The necessary relationships are compiled in Tables 1, 2 and 3.

To characterize colourless systems, it is necessary either to use the ultraviolet region or to change one component into a coloured compound. In the latter case, this derivatization must not noticeably influence the primary redox

Table 2. Transformation $\log Z = f(\text{pH}, C)$ (absorption by two components)

Condition	Concentration [A']
$(\epsilon_A, \epsilon_A') > 0$	$\frac{qA/d - \epsilon_A C_A}{q\epsilon_A' - s\epsilon_A}$
$(\epsilon_A, \epsilon_B') > 0$	$\frac{m'(qA/d - \epsilon_A C_A)}{n'q\epsilon_B' - m's\epsilon_A}$
$(\epsilon_A', \epsilon_B') > 0$	$\frac{m'A}{d(m'\epsilon_A' + n'\epsilon_B')}$
$(\epsilon_B, \epsilon_A) > 0$	$\frac{m'(r\epsilon_A C_A + q\epsilon_B C_B - qrA/d)}{m'rs\epsilon_A + n'q\epsilon_B}$
$(\epsilon_B, \epsilon_A') > 0$	$\frac{m'(rA/d - \epsilon_B C_B)}{m'r\epsilon_A' - m'\epsilon_B}$
$(\epsilon_B, \epsilon_B') > 0$	$\frac{m'(rA/d - \epsilon_B C_B)}{n'(r\epsilon_B' - t\epsilon_B)}$

Table 3. Transformation $\log Z = f(\text{pH}, C)$ (absorption by three components)

Condition	Concentration [A']
$(\epsilon_A, \epsilon_A', \epsilon_B') > 0$	$\frac{m'(qA/d - \epsilon_A C_A)}{m'(q\epsilon_A' - s\epsilon_A) + n'q\epsilon_B'}$
$(\epsilon_A, \epsilon_A', \epsilon_B) > 0$	$\frac{m'(qrA/d - r\epsilon_A C_A - q\epsilon_B C_B)}{m'r(q\epsilon_A' - s\epsilon_A) - n'q\epsilon_B}$
$(\epsilon_A, \epsilon_B, \epsilon_B') > 0$	$\frac{m'(r\epsilon_A C_A + q\epsilon_B C_B - qrA/d)}{m'rs\epsilon_A - n'q(r\epsilon_B' - t\epsilon_B)}$
$(\epsilon_A', \epsilon_B, \epsilon_B') > 0$	$\frac{m'(rA/d - \epsilon_B C_B)}{m'r\epsilon_A' + n'(r\epsilon_B' - t\epsilon_B)}$

mechanism. It is therefore best to use a reaction in which weak co-ordination complexes are formed. In this case it is not recommended to determine the equilibrium constant.

In performing the experiments, there are some conditions which must be kept constant by using a suitable salt. Because of side-reactions, buffer solutions are not recommended. The timing of the procedure must be very carefully regulated, in case kinetic effects interfere. Besides this, it has to be taken into account that the equilibrium must not be fully shifted to the right, since the mathematical model would then not be valid, because $[A_r] \rightarrow 0$ and $[B_r] \rightarrow 0$. Partial reaction can often be achieved by suitable selection of the pH and reactant concentrations. It is advantageous that there are no approximations in the transformation, i.e., that there is no restriction concerning the total concentrations C_A and C_B .

Though it is not possible to give general instructions for application of this transformation, some remarks can be made.

It can first be supposed that the quantities q , r , s and t are known. Otherwise, besides

Fig. 1. pH function of the system $\text{Fe}^{3+}/\text{SO}_3^{2-}$ ($C_{\text{Fe}} = 2 \times 10^{-3} M$, $C_{\text{SO}_2} = 2 \times 10^{-2} M$, $1 M \text{ NaCl}$, $\lambda = 380 \text{ nm}$).

variation of x , m and n , the variation of s and/or t is also necessary. The criteria $\log Z(C_B) = \text{constant } \Delta \log Z / \Delta(x\text{pH}) = x$ are also valid in this case. In this connection the relative molar coefficients $V = n/m$ (determined by the Job method or photometric or potentiometric titration) are valuable, since by using these quantities it becomes possible to predict m and n .

Thereafter the reaction processes can be formulated. In the case of oxyanion oxidants the role of water must be considered. Here, an exact assignment of the general and particular equations of the reactions is of importance.

Example

We have examined the stoichiometry of the system $\text{Fe}^{3+}/\text{SO}_3^{2-}$ in a strong acid medium. From the properties of SO_2 and SO_4^{2-} the following reaction can be formulated:

Comparison of the general and particular reactions shows that the reaction equation is unequivocally determined by x , m and n . The shape of the function $A = f(\text{pH})$ (Fig. 1) indicates a positive number of protons is involved.

Iron(III) is measured as its chloro-complex, for which the Lambert-Beer law, with $\epsilon_{\text{Fe(III)}} = 550 \text{ l. mole}^{-1} \cdot \text{cm}^{-1}$ holds in the pH range from 0.18 to 0.58. The pH values used for the evaluation are given by the concentration of perchloric acid used, with due regard to the reaction

For evaluation under the conditions $\epsilon_A > 0$ and $q = r = s = t = 1$, the cases to be applied (Table 1) are

$$[A'] = \frac{\epsilon_A C_A - A/d}{\epsilon_A}$$

$$[B'] = \frac{n}{m} [A']$$

$$[A] = C_A - [A']$$

$$[B] = C_B - [B']$$

$$\log Z = m \log [A'] + n \log [B']$$

$$-m \log [A] - n \log [B].$$

By use of these equations, transformations according to equation (11) are possible. From

a graph of $\log Z$ vs. $x\text{pH}$ the value of x can be found. The results are compiled in Table 4. The coefficients $m = 2$, $n = 1$ and $x = 3$ necessary for $\Delta \log Z / \Delta(x\text{pH}) = x$ to be fulfilled, are in agreement with the known equation. This example shows the value of the proposed method. Finally, in Fig. 2 some typical straight lines for $m = 2$, $n = 1$ and $x = 1 \dots 5$ are shown. The straight line with $x = 3$ represents the case with the correct parameters.

The mechanism is confirmed by the analysis of a C_B -function with $\epsilon_{\text{Fe(III)}} = 820$, over the

DIRECT SPECTROPHOTOMETRIC DETERMINATION OF Nd IN MIXED RARE EARTHS WITH SEMI-XYLENOL ORANGE AND CETYLPYRIDINIUM CHLORIDE

NAI-XING WANG

Department of Chemistry, Shandong University, Jinan, Shandong, 250100, People's Republic of China

(Received 17 August 1990. Revised 20 November 1990. Accepted 14 December 1990)

Summary—The derivative absorption spectra of the neodymium complex with Semi-Xylenol Orange and cetylpyridinium chloride has been investigated. The characteristic absorption of the complex is ~ 350 times that of neodymium chloride. The fourth-order derivative spectrum has been used to eliminate the interference of the other lanthanides, and to increase the sensitivity by a further factor of 6. Beer's law is obeyed for 0–7.5 μg of Nd in 25 ml of solution. The relative standard deviation for 7 determinations of 1.8 $\mu\text{g}/25$ ml neodymium was 1.3%. The detection limits were 5.8 ng/ml in the absence of lanthanum and 11.2 ng/ml in the presence of 44 ng/ml lanthanum (or 36 ng/ml yttrium). The method has been used for the determination of neodymium in mixed rare earths, with satisfactory results.

There has always been interest in determination of individual lanthanides in their mixtures, on the basis of the absorption bands of their 4f electron transitions.¹⁻⁷ Various complexing agent/surfactant systems have been reported for determination of the lanthanides but few of them are useful for the determination of individual elements in the group.⁸⁻¹⁰

Semi-Xylenol Orange has been used in the presence of cetylpyridinium bromide for the spectrophotometric determination of the lanthanides¹¹ and we have now found that use of cetylpyridinium chloride as the surfactant, and the fourth-order derivative spectra, eliminates the interference of the other lanthanides in the determination of neodymium and increases the sensitivity, with Semi-Xylenol Orange as the chromophore.

EXPERIMENTAL

Apparatus

A Shimadzu UV-3000 double-beam spectrophotometer with 4.0-cm path-length cells was used.

Reagents

Standard solutions of the lanthanides were prepared from the pure oxides (Johnson Matthey), ignited before use.

Standard solutions of Semi-Xylenol Orange (SXO, $5.00 \times 10^{-4}M$) and cetylpyridinium chloride (CPC, $2.00 \times 10^{-2}M$) were prepared by

dissolving 0.1369 g of SXO (Shanghai Reagent Three Plant, China) in 500 ml of water and 1.790 g of CPC (Fluka) in 250 ml of water, respectively.

Buffer solutions were prepared by mixing 1.0M hexamine solution with suitable volumes of 0.1M hydrochloric acid or 0.1M sodium hydroxide. Analytical-reagent grade chemicals were used wherever possible.

Procedure

Transfer a known volume of lanthanide solution to a 25-ml standard flask, add 0.75 ml of $5.00 \times 10^{-4}M$ SXO, 5.0 ml of pH-8.2 hexamine buffer solution and 1.0 ml of $2.00 \times 10^{-2}M$ CPC. Dilute to the mark with distilled water and after 15 min record the fourth-order derivative spectrum against a reagent blank (or suitable amounts of a corresponding lanthanum complex solution) as reference, using 4.0-cm cells.

RESULTS AND DISCUSSION

Absorption spectra

The absorption spectra of the neodymium and representative lanthanide complexes and of the neodymium ion are shown in Fig. 1.

From Fig. 1a it is evident that the absorption maximum for all the lanthanide-SXO-CPC complexes is in the region of 585–607 nm, so it is not possible to determine neodymium directly in the presence of other lanthanides, especially

Fig. 1. Absorption spectra of neodymium and lanthanide (Ln) complexes. (a): $[Ln] = 1.0 \times 10^{-6} M$; $[SXO] = 1.5 \times 10^{-5} M$; $[CPC] = 8.0 \times 10^{-4} M$; pH = 8.2; 4.0-cm cells; 1, La; 2, Nd; 3, Y; 4, Ho. Reagent blank as reference. (b): 5, Nd^{3+} ($[Nd] = 1.0 \times 10^{-4} M$) against water as reference; 6, Nd-SXO-CPC against La-SXO-CPC as reference. Other conditions as for (a).

lanthanum, which has almost the same absorption pattern. However, there is a slight difference at 586 nm between the absorption spectra of the neodymium complex and the other lanthanide complexes. The absorption spectrum of the neodymium complex, measured against the lanthanum complex as reference is shown in Fig. 1b, along with that of neodymium measured against water. It is clear that the amplitude of the neodymium absorption band is red-shifted and remarkably increased by the complexation. The molar absorptivity calculated for the neodymium complex was $2.3 \times 10^3 \text{ l. mole}^{-1} \cdot \text{cm}^{-1}$, which is ~ 350 times that for neodymium chloride.

To eliminate the interference of the other lanthanides in the determination of neodymium, we investigated the 1st–4th order derivative spectra of the complexes. The optimal conditions proved to be use of the fourth-order derivative with $\Delta\lambda = 1.8 \text{ nm}$, band-pass = 1.0 nm and scan rate = 50 nm/min. Figure 2 shows the fourth-order derivative spectra of the lanthanide complexes, from which it is clear that the derivative spectrum of the neodymium complex is very different from the spectra of the other complexes. The amplitudes at 585 and 587 nm are significant for neodymium, and negligible for the other lanthanides.

Optimization of reaction conditions

The pH and the concentrations of SXO and CPC were optimized by varying one of

them at a time (Figs. 3–5), and the values selected are those given in the procedure. To allow for consumption of the reagents by other lanthanides present in analysis of mixtures, the amounts recommended in the procedure are about 10 times greater for SXO and 650 times greater for CPC than necessary for the sum of the lanthanides present.

Fig. 2. Fourth-order derivative spectra of lanthanide complexes. $\Delta\lambda = 1.8 \text{ nm}$; band-pass = 1.0 nm; scan-rate = 50 nm/min. Other conditions as for Fig. 1(a).

Fig. 3. Effect of pH on the fourth derivative absorption of the neodymium complex. $[\text{Nd}] = 1.0 \times 10^{-6} \text{ M}$; $[\text{SXO}] = 1.5 \times 10^{-3} \text{ M}$; $[\text{CPC}] = 8.0 \times 10^{-4} \text{ M}$; 4.0-cm cells; $\Delta\lambda = 1.8 \text{ nm}$; band-pass = 1.0 nm; scan-rate = 50 nm/min; peak to trough amplitude at 585 and 587 nm.

The complex takes 15 min to form completely and is stable for at least 24 hr.

Calibration graph and detection limits

A linear calibration graph was obtained by plotting the peak to trough amplitudes at 585 and 587 nm for neodymium in the concentration range 0–7.5 $\mu\text{g}/25 \text{ ml}$ and the derivative molar absorptivity was found to be $1.38 \times 10^4 \text{ l. mole}^{-1} \cdot \text{cm}^{-1}$, ~ 2000 times greater than for neodymium chloride. The calibration spectra are shown in Fig. 6. The relative standard deviation for 7 determinations of 1.8 $\mu\text{g}/25 \text{ ml}$ neodymium was 1.3%. The detection limits were 5.8 ng/ml in absence of lanthanum and 11.2 ng/ml in the presence of 44 ng/ml lanthanum (or 36 ng/ml yttrium).

To test the utility of the method, a synthetic lanthanide sample was prepared with composition (%) La_2O_3 24.10, CeO_2 52.30, Pr_6O_{11} 5.28, Nd_2O_3 15.32, Sm_2O_3 1.12, Eu_2O_3 0.15, Gd_2O_3 0.10, Ho_2O_3 0.20, Er_2O_3 0.20, Y_2O_3

Fig. 4. Effect of $[\text{SXO}]$ on the fourth derivative absorption of the neodymium complex: pH = 8.2; other conditions as for Fig. 3, except for $[\text{SXO}]$.

Fig. 5. Effect of $[\text{CPC}]$ on the fourth derivative absorption of the neodymium complex: pH = 8.2; other conditions as for Fig. 3, except for $[\text{CPC}]$.

1.23. The result obtained for Nd_2O_3 was 15.62% (relative error 2.0%). The relative standard deviation (6 determinations) was 1.8%. In addition, the amount of neodymium in a reference

Fig. 6. Calibration spectra. $[\text{Nd}]$ ($\mu\text{g}/25 \text{ ml}$): 1, 1.08; 2, 2.16; 3, 3.24; 4, 4.32; 5, 5.40; 6, 6.48; 7, 7.56; pH 8.2, $\Delta\lambda = 1.8 \text{ nm}$; band-pass 1.0 nm; scan-rate 50 nm/min.

material* was determined. The value found was 17.05% and the certified value was 16.75% (relative error 1.8%). The relative standard deviation (5 determinations) was 1.7%. This shows that the accuracy and precision of the method are quite satisfactory.

A PC-BASED GENERAL PROGRAM FOR THE SIMULATION AND ANALYSIS OF CYCLIC VOLTAMMETRIC EXPERIMENTS

DAVID K. GOSSER JR.* and FENG ZHANG

Department of Chemistry, The City College of the City University of New York, New York, NY 10031 U.S.A.

(Received 19 September 1990. Revised 9 January 1991. Accepted 15 January 1991)

Summary—A PC-based program, a General Program for Simulation of Cyclic Voltammetric Experiments (GPS-CV), is described. GPS-CV, written in Turbo Pascal 5.5, utilizes advances in simulation methodology that increase efficiency, allow for generality of mechanism, and include *IR* drop and capacitive current effects. An accessible user interface is used, and a graphical analysis program is provided. Cyclic voltammograms for nearly any mechanism can be simulated by the user. A companion program, CVFIT, combines the GPS-CV program with a least-squares fit by simplex minimization to give the best-fit parameters, with error estimates. The use of CVFIT is demonstrated with a three-parameter fit of experimental cyclic voltammograms.

Computer simulation by the explicit finite difference method has proven to be a powerful tool for the analysis of cyclic voltammetric experiments. The shape of a cyclic voltammetric curve reflects both electron transfer at the electrode and the solution chemical reactions that are coupled to the electron transfer. Thus, through a cyclic voltammetric study, a great deal of information can often be deduced regarding electrode processes and chemical reactions in solution that are initiated by electron transfer at the electrode. Simulations are often helpful in the preliminary stages of a cyclic voltammetric study, assisting in predicting mechanism(s) that can give rise to the cyclic voltammograms observed. Once a particular mechanism is decided upon, experimental results can be compared with successive simulations in order to extract rate and equilibrium parameters of the chosen mechanism. Because of the recognized importance of simulation, much attention has been focused on improving the original method proposed by Feldberg.¹ Among notable advances are the description of an expanding space grid to save computation time,² the inclusion of the mutually interrelated effects of *IR* drop and capacitive current,³ and the development of general methods for treatment of solution chemical reactions in the context of the explicit finite difference method.^{4,5}

This work describes a PC-based program which enables the experimentalist to simulate the cyclic voltammetry (CV) for almost any desired mechanism, and compare the result with experiment. The desired mechanism is entered in a simple manner with a full screen display, with options for varying the diffusion coefficients of individual species. In addition, the fitting program which is included finds a best fit for the experimental data. The value of such an approach lies in the elimination of the need to solve by analytical or numerical means the partial differential equation that models each new mechanism. Thus, more time is available for the consideration of problems of a chemical nature, and a large amount of repetitious work is avoided. In addition, the increased computational power now available in personal computers has meant that a generalized program can be an accessible tool for the mechanistic analysis of cyclic voltammograms.

Five main objectives were considered in the construction of a generalized program.

1. Mechanistic generality. The program uses a modular structure with a general solution of the homogeneous chemical kinetics. This means that virtually any electrochemical mechanism that can be formulated as a combination of electron transfers at the electrode and homogeneous chemical reactions can be simulated.

2. Speed of computation. An expanding space grid is used to minimize computation time. In

*Author for correspondence.

addition, the program is written in Turbo Pascal 5.5, which can take advantage of the gain in speed offered by the 8087, 80287 or 80387 math co-processors commonly used in personal computers.

3. Ease of use. A full screen display for input of mechanistic and experimental parameters, with options for corrections and changes, is utilized. The parameters are entered for the most part in common experimental units, not in dimensionless units. A graphic analysis program is provided for on-screen view of simulated or experimental files. Input is "error corrected"; that is, if a "fatal" error is made in the input (such as entry of a real number instead of an integer), the program will re-request the information.

4. Inclusion of non-ideal factors. A recently described method³ for including the effects of *IR* drop and capacitive current is incorporated in the simulation.

5. Quantitative comparison of experimental and simulated data. A simplex routine is used to optimize the fit between experimental and simulated cyclic voltammograms.

IMPLEMENTATION OF THE PROGRAM

The partial differential equation for linear diffusion and solution chemical kinetics is:

$$\frac{\partial C_q}{\partial t} = D_q \frac{\partial^2 C_q}{\partial x^2} \pm \sum k_g C_{g,1} C_{g,2} \quad (1)$$

where C = concentration, D = diffusion coefficient, x = distance, t = time, k = chemical rate constant, q = species subscript, and g = reaction subscript.

A discrete form of the diffusion term on the right-hand side of equation (1) is:

$$C_{i,j+1} = C_{i,j} + \frac{D\Delta t}{\Delta x^2} [C_{i-1,j} - 2C_{i,j} + C_{i+1,j}] \quad (2)$$

where i is a spatial subscript and j is a time subscript.

Equation (2) is equivalent to the creation of a space and time grid (see Fig. 1). Computation time can be decreased by utilizing an expanding space grid or an expanding space-time grid. Here, an expanding spatial grid was utilized: an expanding time grid can cause inaccurate calculations of the solution chemical kinetics.⁵ The expanding grid was constructed with the spatial increment doubled in size every fourth grid-point, after the method of Seeber and Stefani.⁶

Fig. 1. A time and space grid utilized by the finite difference method. The program described in this work uses an expanding spatial grid to save computation time.

Near to the electrode, the concentrations will be determined by the potential (*i.e.*, through the equations of electrochemical kinetics) and diffusion, and at "infinite" distance the concentrations will be the same as the initial conditions. These facts constitute the boundary conditions for equation (1). In this work, the flux at the electrode was calculated according to a previously described method, which takes into account the flux of species at the surface of the electrode due to both the heterogeneous kinetics as described by the Butler-Volmer equation [equation (3)] and diffusion.⁷ The potential, E , in the Butler-Volmer equation can be corrected for *IR* drop in a number of ways. In this work, following the method of Boyer *et al.*,³ the *IR* term is included by reading an experimental current file and using a measured (or estimated) resistance to calculate *IR*.

$$\frac{i}{nFa} = k^0 [C_{ox} e^{-\alpha nF[E - E^0]} - C_{red} e^{(1-\alpha)nF[E - E^0]}] \quad (3)$$

The capacitive current is also calculated as in Boyer *et al.*,³ by using the potential corrected for *IR* drop in calculating the capacitive charging current at each time step in the simulation.

Although diffusion and chemical reaction are concurrent processes, in the explicit finite difference method they are calculated separately. This procedure, which is valid if the time increments are small enough, leads to the possibility of very general treatments of the chemical kinetic term in equation (1). In particular, it has been shown that simple numerical methods such as an iterative modified Euler method⁵ or a Runge-Kutta method⁴ can be used to provide general solutions for the differential equations that model chemical kinetics. Thus, a simple algorithm

based on equation (4) has been used to solve chemical reaction kinetics:

$$C_{q,n} = C_{q,0} + \frac{\Delta t}{2} \left[\frac{\Delta C_{q,0}}{\Delta t} + \frac{\Delta C_{q,n-1}}{\Delta t} \right] \quad (4)$$

where the changes in concentrations are obtained from a differential approximation for the kinetics, based on the initial concentration and the n th concentration. For example, for the kinetic scheme

the n th concentrations $C_{a,n}$ and $C_{b,n}$ for A and B respectively are calculated as:

$$C_{a,n} \equiv C_{a,0} - \frac{k_1 \Delta t}{2} [C_{a,0} + C_{a,n-1}] \quad (5)$$

$$C_{b,n} \equiv C_{b,0} + \frac{k_1 \Delta t}{2} [C_{a,0} + C_{a,n-1}] - \frac{k_2 \Delta t}{2} [C_{a,0} + C_{b,n-1}] \quad (6)$$

The inclusion of all of these features in a General Program for Simulation of Cyclic Voltammetric experiments (GPS-CV) results in a rather complex program structure. Index numbers are assigned to each species in the mechanism, to each electrode reaction, and to each solution chemical reaction. Program loops are used to include all reactions for all species within the usual scheme for simulation by explicit finite differences. This is illustrated by Table 1.

The use of the GPS-CV program is nearly self-evident for those familiar with cyclic voltammetry. However, to give a clear idea of its capabilities and the conventions utilized, a brief summary of the interactive input procedure follows.

Input/output for GPS-CV

Number of species in the mechanism. An integer equal to the total number of species in the mechanism is entered. Although the screen input is designed for up to 8 species more can be entered if necessary.

Concentrations of the species. The initial concentration of each species is entered in normalized units. That is, the concentration of each species is divided by a chosen normalizing concentration (C_{norm}), typically that of the primary

electroactive species. Each species is now associated with an integer, in the order of entry. Later entries, which describe electrode reactions and chemical reactions, utilize these number identifications.

Redox couples. The integer indexes of the oxidized and reduced forms of each redox couple are entered, followed by the reduction potential (in volts), the heterogeneous rate constant (in cm/sec), and the transfer coefficient. For an electron transfer that is considered to be reversible, a value of 10 cm/sec will ensure reversibility under most circumstances. If a two-electron transfer (where one of the redox species is shared by two couples) is among the electrode reactions, these should be entered in sequence when written as reductions. For instance:

Solution chemical reactions. Each chemical reaction (first- or second-order) is described by entering two indexes for the reactants and two for the products (if the reaction is first order, 0 is entered in the space reserved for the second species of a second order reaction). First-order rate constants are entered in units of sec^{-1} . Second-order rate constants are entered in units of $1. \text{mole}^{-1} \cdot \text{sec}^{-1} \times C_{\text{norm}}$.

Experimental parameters. The number of half cycles (1, 2 or 3), the initial potential, switching potential(s), final potential (V) and scan rate (V/sec) are entered. Asymmetric potential waveforms, which are often useful, are possible in this scheme.

Changes in input. At this point, the user can inspect the entire input screen and change selected parameters. It is also possible to change the default temperature (298.15°) or the default diffusion coefficient for each species ($1.00 \times 10^{-5} \text{ cm}^2/\text{sec}$). The diffusion coefficients are changed by entering a multiplier of the default value (for instance, enter 0.5 for a diffusion coefficient of $5.00 \times 10^{-6} \text{ cm}^2/\text{sec}$). If it is desired to simulate a mechanism with a diffusion coefficient larger than the default coefficient, the default diffusion coefficient must be changed in the source code.

Option for capacitive current. If it is desired to include a capacitive current in the simulation, then the electrode area (cm^2), double-layer capacitance ($\mu\text{F}/\text{cm}^2$), solution resistance ($\text{k}\Omega$), and the normalizing concentration ($\text{mole}/\text{l.}$) are requested.

Option for IR drop. The effect of the IR drop can also be included. It is necessary to provide an experimental data file of current-potential values (1 point per mV), and to enter the resistance, area, and normalizing concentration. The experimental current is read and the simulation potentials are corrected accordingly.

Names of data and graphic output files. The user selects the names of the output files which are to contain the simulated current and potential values. The graphics file contains data to be used in the graphics routine, and the data file contains the simulation data and record of parameters. The data file can also be used as input for commercial graphics programs for high-quality print output.

Stimulated current. The simulated current and potential values are displayed on the

screen during the simulation so that progress can be monitored. The simulated current (I_{sim}) displayed and saved in the output files is related to the actual current (I_{amps}) according to $I_{sim} = I_{amps} / (Area \times C_{norm} \times 100 \times \nu)$, where $Area$ = electrode area and C_{norm} = the normalizing concentration, and ν = scan rate. Generally, the program sets the time increments used in the simulation so as to achieve less than 0.1% error.

If the option for capacitive current and/or IR drop was selected, then the simulation current is output directly in amperes.

Graphics. An on-screen graphics representation of the simulation output can be obtained for CGA or Hercules graphics screens. The initial and final potentials of the desired graph are input, a scale factor for the y (current) axis is selected, and the name of the graphics file is

Fig. 2. The appearance of the screen after the input procedure for the following mechanism and experimental parameters. Six chemical species with the following initial concentrations (in normalized units): 1.0, 0.0, 1.0, 0.0, 0.0, 0.0; two redox reactions: $1 + e \rightleftharpoons 2$, $E^0 = -0.20$ V, $k = 10.0$ cm sec⁻¹, $\alpha = 0.5$; $5 + e \rightleftharpoons 6$, $E^0 = -0.35$ V, $k = 10$ cm sec⁻¹, $\alpha = 0.5$; one chemical reaction: $2 + 3 \rightleftharpoons 4 + 5$, $k_1 = 1.00$ sec⁻¹/Cnorm, $k_{-1} = 25$ sec⁻¹/Cnorm; experimental parameters: scan rate = 1 V/sec, initial potential = 0.0 V, switching potential = -0.5 V, final potential = 0.0 V.

requested. A cursor is scrolled across the screen by pressing of arrow keys and the corresponding current/potential values are shown.

Sample input and graphics. The appearance of the input screen for the simulation of a specified mechanism is shown in Fig. 2. It is difficult to indicate the nature of the input procedure, since the input is highly interactive, and the final input screen does not fairly represent the "friendliness" of the program. A hardcopy of the screen graphics for the same simulation is shown in Fig. 3 and that with a capacitive current contribution in Fig. 4.

Sample computation times for fast chemical reactions

Typical computation times for the simulation of an EC mechanism for an experiment (scan rate, 1 V/sec; scan range, 1 V, with increasing values of the rate constant (k) on a Gateway 386 PC (20 MHz) with an 80387 math co-processor are as follows: 1 min ($k = 100$ sec⁻¹), 15 min ($k = 10,000$ sec⁻¹), 2.5 hr ($k = 100,000$ sec⁻¹). Simulations on a 286 PC (with co-processor) took about 4 times as long. Because second-order rate constants are entered as k in $l \cdot mole^{-1} \cdot sec^{-1} \times C_{norm}$, mechanisms involving rates that are nearly diffusion-controlled can be simulated in a reasonable amount of time. In digital simulation, since the computation time is related to the total time of the experiment, the simulation times will be much shorter for

Fig. 4. Screen plot for the same mechanism as in Fig. 3, but with a capacitive current contribution according to the following parameters. Scan rate = 20.0 V/sec, electrode area = 0.02 cm², double layer capacitance = 50 μ F/cm², solution resistance = 3 k Ω .

experiments with faster scan rates, such as might be employed when ultramicroelectrodes are used. For instance, the simulation of the mechanism with $k = 100,000 \text{ sec}^{-1}$ and scan rate = 1000 V/sec is equivalent to the simulation where $k = 100 \text{ sec}^{-1}$ and scan rate = 1 V/sec, and takes only one minute.

CVFIT: GPS-CV WITH SIMPLEX OPTIMIZATION

In order to exploit the power of digital simulation fully for the analysis of cyclic voltammograms, it is necessary to have a quantitative method for comparison of experimental and simulated results. A method that lends itself to a general treatment is nonlinear least-squares fitting,⁸ in which the parameters of interest (*e.g.*, reduction potentials, heterogenous or homogeneous rate constants) are varied in a systematic way until a simulation is found that minimizes the least-squares difference between the experimental result and the simulation. Here, we have utilized the simplex method, a robust algorithm for function minimization.⁹ In curve fitting by least squares, it is desirable to obtain an estimate of the errors in the fitted parameters. We use the procedure of Phillips

and Eyring,¹⁰ in which the error estimate is obtained from a quadratic approximation of the error surface obtained from a simplex minimization. The program CVFIT is a program which couples a simplex fitting routine to the GPS-CV program. The CVFIT program calls the interactive GPS-CV once at the beginning, so that the user can provide a first guess for the simulation parameters. The initial simplex is based on a uniform random distribution centered on the input guesses. It subsequently repeatedly calls an automated version of GPS-CV with new guesses that are provided from the simplex until a best fit is reached within a set tolerance. For the operation of CVFIT it is necessary to identify the parameters to be fitted in the source code. Thus, for the operation of CVFIT, it is necessary to have a Turbo-Pascal Compiler (version 5.5 or higher).

APPLICATION OF CVFIT TO THE ANALYSIS OF THE CYCLIC VOLTAMMETRIC DATA

Experiments were performed with a BAS-100A electrochemical analyzer. The data sets were transferred to a fixed disk on an IBM-compatible computer. The electrochemical cell

Fig. 5. The best fit simulation (line) compared with selected experimental data (circles) for cyclic voltammetry of ferricyanide at 5 V/sec.

utilized a 3-mm diameter glassy-carbon working electrode and a silver/silver chloride reference electrode. Solutions were 1.5mM ferricyanide with 0.10M potassium chloride, adjusted to a pH of 2.0. The uncompensated resistance was estimated to be 115 Ω with the BAS-100A. The BAS-100A does this by assuming an $R_u C_{dl}$ circuit (where R_u stands for uncompensated resistance and C_{dl} for double-layer capacitance) and the zero-time current for a potential step is extrapolated for the current decay.

As a preliminary test of the efficacy of the overall approach, CVFIT was used to optimize the formal reduction potential (E^0), and the heterogeneous rate parameters (k^0 and α) to give the best fit to cyclic voltammograms of $\text{Fe}(\text{CN})_6^{3-}$ at scan rates of 5.0 and 10.0 V/sec. Literature values¹¹ for the diffusion coefficients of ferricyanide ($7.6 \times 10^{-6} \text{ cm}^2/\text{sec}$) and ferrocyanide ($6.3 \times 10^{-6} \text{ cm}^2/\text{sec}$) were used in the simulation. A linearly extrapolated faradaic background current was subtracted before the

Table 2. Summary of best-fit parameters found by the CVFIT program, with and without inclusion of correction for the IR drop

With IR drop simulation		
v , V/sec	5	10
E^0 , V	0.3020 ± 0.0025	0.3035 ± 0.0005
k^0 , cm/sec	0.0115 ± 0.0021	0.0124 ± 0.0013
α	0.5425 ± 0.0022	0.5448 ± 0.0032
Without IR drop simulation		
v , V/sec	5	10
E^0 , V	0.2941 ± 0.0005	0.2925 ± 0.0026
k^0 , cm/sec	0.0114 ± 0.0011	0.0125 ± 0.0012
α	0.4851 ± 0.0022	0.4851 ± 0.0026

fitting procedure. The double-layer capacitance was estimated to be 17 $\mu\text{F}/\text{cm}^2$ by using a preliminary four-parameter fit. The best-fit simulations are compared with experimental data in Figs. 5 and 6, and the best fits with and without inclusion of the IR drop calculation are summarized in Table 2. When IR drop is included, the results are in line with previous estimates of k^0 and α .¹² Our results indicate that IR drop has more effect on the value determined for α than on that for k^0 . Also, as expected, IR drop causes systematic errors in determinations of the reduction potential. The total time for each three-parameter fit was about 1 hr on the Gateway 386 PC.

Work is underway on the application of CVFIT to analysis of electrode mechanisms involving coupled chemical reactions.

Availability of the program—The compiled and source code of the programs GPS-CV and CVFIT (with detailed instructions) are available on request. If possible, please include \$15 to cover the cost of disks, mailing, and to receive upgrades of the programs. The GPS-CV program is a revised and extended version of another program written in FORTRAN and designed for mainframe use. This program is also available by computer mail (Gosser@CCNY).

Acknowledgements—This research was supported in part by grant number 669270 from the PSC-CUNY Research Award Program of the City University of New York. We thank Dr. Edward M. Eyring for kindly providing us with the FORTRAN source code of the error-estimation procedure.

Laboratory of Chemical Analysis, Department of Chemical Technology, Twente University of Technology, P.O. Box 217, 7500AE Enschede, The Netherlands

(Received 1 October 1990. Accepted 22 January 1991)

Summary—A method for extracting single peaks from complex linear sweep and cyclic voltamperograms is presented. Voltamperograms are transformed by means of semidifferentiation, then all undesired peaks are removed from the semiderivative curve and replaced by calculated baselines. The resulting curve is semiintegrated back, giving a voltamperogram with one peak only. Baselines in the semiderivative domain are determined by the least-squares curve-fitting of datapoints from peak border regions, using the equation that describes the semiderivative peak of a reversible electrode process. With this procedure peaks can be removed without assumptions about the mechanism of the underlying electrode reaction. Due to its design, the algorithm presented is suitable for the fully automatic processing of cyclic and linear sweep voltamperograms. Performance of the procedure was checked with generated reversible voltamperograms as well as in real experiments with both reversible and irreversible systems. The smallest distance between two peaks of equal height, for which the described method can yield correct results, has been found to be 110 mV for a reversible one-electron process at 298 K. This procedure can also be applied to the elimination of the cathodic current from the cyclic voltamperogram of a single component in order to get a pure anodic current value, free from cathodic contribution, or vice versa.

Linear sweep voltammetry (LSV) and cyclic voltammetry (CV) are simple and relatively fast electroanalytical techniques used mainly for qualitative studies. Their experimental simplicity and well-established theoretical background also make them attractive for automated electrochemical investigations to be implemented in an expert system for the elucidation of electrode mechanisms, and this is under study. However, applicability of LSV and CV to quantitative studies is restricted by the shape of the signal: a broad, asymmetric, "tailing" peak. As a consequence of this feature, in composite voltamperograms peaks often overlap and measurement of their parameters (peak current and peak potential) is significantly hindered. Influence of the cathodic current on the anodic part of the voltamperogram makes measurement of the anodic peak current difficult, or even impossible if several cathodic peaks exist. Therefore, a good method for the separation of overlapping peaks is desired, if one wants to use these techniques to obtain quantitative results. For

our purposes, we would demand the method to have additional features: the ability to separate peaks without any special assumptions about the electrode reaction mechanism and the capability to resolve peaks originating from a multistep reaction of one compound as well as from signals obtained from the mixture of the electroactive species.

The separation of cyclic voltammetric peaks has been an objective of extensive studies.¹⁻⁴ However, most popular methods have some restrictions: direct curve fitting of overlapping peaks¹ requires parameters describing the peak shapes before fitting can start, knowledge of what excludes its application to unknown (or unidentified) mixtures and to peaks resulting from multistep reactions. The deviation-pattern recognition method² needs knowledge about the underlying electrode reaction mechanism. The approach of Perone *et al.*³ works only under supervision of the experimenter, relying on his decision. Interrupt-scan method, as proposed by Boudreau and Perone,⁴ while profitable for qualitative measurements, according to the authors doesn't give satisfactory quantitative results for staircase voltammetry. An extension of work¹ with another, more general approxi-

*On leave from University of Warsaw, Chemistry Department. Author for correspondence.

mate function⁴ to fit overlapping peaks retains the restrictions of the original work, *i.e.*, the necessity of delivering peak-shape parameters prior to the fitting; moreover, the paper⁴ presents results of this method for square-wave voltammetry only.

Problems with overlapping peaks can be partially overcome by combining LSV with a mathematical transformation like semidifferentiation or semiintegration.^{5,6} The transformed voltamperograms reveal attractive features for both analytical and mechanistic studies, such as the independence of the signal on the potential change function,⁷ higher symmetry and small peak widths,^{5,8} a linear relationship between semiintegrated current and the surface concentration of the reactant at the electrode⁹⁻¹¹ and simpler analytical equations describing the peak shapes.

The increasing number of applications of semidifferentiation and semiintegration coupled to linear sweep voltammetry (also called semi-differential/semiintegral electroanalysis or convolution potential sweep voltammetry) is reflected by the fact, that recently commercially available instrumentation is equipped with these possibilities (*e.g.*, Bioanalytical Systems Inc, PARC EG & G Corp.). However, the number of electrode processes, for which a full theoretical description of the signals is available is rather small. As far as semiintegration is concerned, Saveant and co-workers published a series of papers,¹²⁻¹⁷ in which a number of equations has been derived. These equations, employing both current and its semiintegral cannot be used, however, for the direct interpretation of semiintegrated curves. For semidifferentiated voltamperograms, Goto and Ishii⁵ reported an equation describing the peak of the reversible process, while Dalrymple-Alford *et al.*^{6,18} gave the result for the irreversible case. Goto and Ishii⁸ also investigated the influence of the use of staircase instead of linear sweep voltammetry.

In contrast to semiderivative voltammetry, the theory of cyclic voltammetry is well developed. For mechanistic investigations, voltammetric curves can be studied according to the standard procedures if the necessary parameters are available. These procedures, most employing variations of peak potential, E_p , peak current, i_p , and anodic to cathodic current ratio with scan rate and concentration, often require values of currents which cannot always be directly measured from the recorded curve.

In this paper an approach is proposed, which combines the benefits of the easy interpretation of voltamperograms and the enhanced resolution characteristics of semidifferentiated linear sweep and cyclic voltammetry curves. This goal is achieved by semidifferentiation of a complex voltamperogram, separation of the semiderivative signals, removal of the undesired peaks by replacing them with the appropriate fragments of the baseline and semiintegration back to the $i(E)$ form, that will now contain peaks of interest only. Moreover, the proposed method is relatively universal and can be applied to electrochemical processes with different kinetics.

THEORY

The current in a linear sweep voltamperogram with two overlapping peaks can be described as the sum of two independent current functions, $i(t) = i_1(t) + i_2(t)$. Due to the linear and homogeneous character of the semidifferential operator,^{9,19} this additivity remains valid also in the semiderivative domain:

$$\frac{d^{1/2}}{dt^{1/2}} i(t) = \frac{d^{1/2}}{dt^{1/2}} i_1(t) + \frac{d^{1/2}}{dt^{1/2}} i_2(t) \quad (1)$$

After subtracting the contribution of one of the components from the total semidifferentiated signal, the remaining curve can be semiintegrated yielding the original current peak of this component due to the relationship:

$$\frac{d^{-1/2}}{dt^{-1/2}} \left(\frac{d^{1/2}}{dt^{1/2}} i(t) \right) = i(t) \quad (2)$$

Semidifferentiation and semiintegration can easily be performed with standard algorithms. The problem of removing unwanted peaks from a semiderivative curve and reconstruction of the baseline in these regions must be solved now. Voltammetric peaks which are not very close to each other are sometimes fully separated in the semiderivative domain. This results from the fact that semiderivative peaks are much narrower than voltammetric ones and that the value of the semiderivative drops rapidly to zero at the descending part of the peak, in contrast to the long "diffusional tail" of the original signal (see for example^{20,21}). This case is shown in Fig. 1A. To remove peak 1, baseline values at points marked A and B must be estimated. Then all datapoints between A and B are replaced by new values calculated under the assumption, that the baseline is linear in this range. Additionally, for the purpose explained later it is

assumed, that its slope is fairly small. These assumptions are generally valid, if the original voltamperogram is background-corrected.

The situation is more complicated when the semiderivative peaks also overlap (Fig. 1B). The dashed line marks the baseline for peak 1. The part marked as B is a sum of two contributions: a linear one, corresponding to what was previously called baseline and a non-linear one, being the descending branch of peak 0 in the region where peaks overlap. To be able to remove peak 1, the curve between C and A must be replaced by the sum of these two components, so it is necessary to estimate both of them separately.

The equation that describes the semiderivative peak of a reversible process is:^{5,18}

$$\frac{d^{1/2}}{dt^{1/2}} i = (n^2 F^2 A \nu c D^{1/2} / 4RT) \cosh^{-2} \times [(nF/2RT)(E - E_{1/2})] \quad (3)$$

and it was found, that it can be used for fitting data from irreversible electrode processes,^{22,23} too. For the present purpose, it is also assumed that a function of this type can describe the part of the peak far away from its top, irrespective of the reaction mechanism.

In the considered fragment of the semiderivative voltamperogram, equation (3) can be rewritten in the simplified form

$$\frac{d^{1/2}}{dt^{1/2}} i = h \cosh^{-2} [k(E - E_p)] \quad (4)$$

where h , k and E_p denote parameters related to the peak height, to peak width and to the

Fig. 1. A—two non-overlapping semiderivative peaks. Small filled circles mark peak borders. B—two overlapping semiderivative peaks.

position of peak top, respectively. It must be noted that the above parameters need not necessarily describe the whole peak, but only the relevant fragment.

To characterize the shape of the non-linear component of the baseline, h , k , and E_p must be found by curve fitting. Additionally, if datapoints used for fitting are selected from a rather small part of the curve lying, for example, around point B in Fig. 1B, the linear component can be considered constant there. It allows for a reduction in the number of parameters and for the equation for the complete baseline to be written as follows:

$$y = y_B + h_0 \cosh^{-2} [k_0(E - E_{p0})] \quad (5)$$

where the first term represents the value of the linear component at point B and the second one the descending branch of peak 0. It should be noted that the slope of the linear component determines the range over which equation (5) is valid.

The overall semi-differentiated signal in the range of selected datapoints can be finally written by adding the function describing the ascending branch of peak 1 to equation (4) resulting in:

$$y = y_B + h_0 \cosh^{-2} [k_0(E - E_{p0})] + h_1 \cosh^{-2} [k_1(E - E_{p1})] \quad (6)$$

from which the parameters required have to be obtained by curve fitting (indexes indicate peak number). Once y_B is found, the linear component of the baseline fragment necessary for the replacement of peak 1 can be obtained by using the value of y_A at the point A. Calculation of the y_A value at the free end of the overlapping peak can be done in the same manner as calculations at the border points of the non-overlapping peak from Fig. 1A. For these purposes, however, another procedure was used. The method often used of taking the datapoint(s) value(s) at an arbitrary distance from the peak top (far enough to ensure, that the peak contribution is zero) was not employed, because it is subjective and can give wrong results in the case where noise or another peak appears in that region. Instead, an approach was used based on the fitting of datapoints around the peak border point to equation (5) (border point is selected on the basis of peak derivative). In this situation, however, the interpretation of the parameters in equation (5) is slightly different: now y_B denotes the wanted value of the baseline at the peak

border, while the second term is a contribution of the residual of the peak branch. Again, if datapoints are chosen in a narrow range, or if the baseline slope is small, the method yields the baseline value at the border point even if the position of this point was selected not very precisely.

When all necessary baseline parameters are calculated at both peak borders, the unwanted peak can be removed. In case of non-overlapping peaks, it is done just by drawing the straight line between points A and B in Fig. 1A. If the peak overlaps, then the dashed line from Fig. 1B is calculated with the equation

$$y = y_0 + sE + h_0 \cosh^{-2}[k_0(E - E_{p0})] \quad (7)$$

in which y_0 and s are terms describing the offset and the slope of the linear baseline component (obtained from values of y_A and y_B) and the third term is identical to the second term on equation (5), *i.e.*, the descending branch of peak 0. The procedure proposed can also be used for removing peak 1 instead of peak 0. In this case, h_0 , k_0 and E_{p0} in equations (5) and (7) have to be replaced by h_1 , k_1 and E_{p1} , respectively.

EXPERIMENTAL

Reagents

Solutions (0.1M) of In^{3+} , Tl^+ , Co^{2+} and Zn^{2+} were prepared from indium nitrate, thallium sulphate, cobalt perchlorate (Merck, *p.a.*) and zinc sulphate (Fluka, *p.a.*). Potassium chloride (1M) (Suprapur, Merck) was used as the supporting electrolyte in all experiments. All substances were dissolved in demineralized water filtered through a Millipore Q-II installation. Oxygen was expelled with specially pure (polarographic grade) nitrogen (Hoekloos).

Equipment

Experiments were carried out with the Autolab-100 fully computer-controlled electrochemical system (Eco Chemie, Utrecht, The Netherlands) connected to a Metrohm 663 VA static mercury drop electrode. An Ag/AgCl electrode (3M potassium chloride) was used as the reference electrode. In all experiments. All calculations were done with an Olivetti M24 personal computer (IBM PC/XT compatible).

Recording procedure

Voltamperograms were recorded with 50 ml of supporting electrolyte. The solution was deaerated for 15–20 min before the experiments.

Two series of measurements for each pair of A and B compounds were done. In the first series, a blank voltamperogram, a voltamperogram of A and a voltamperogram of A + B were recorded by subsequently adding solutions of the respective ions into the cell. The peak of compound A, obtained via processing of the A + B voltamperogram were compared to the original voltamperogram of A. In the second series, the order of additions was reversed: voltamperograms of a blank, of B and of B + A were recorded. The peak of B separated from the voltamperogram of B + A was compared to the peak of B alone. No correction for the volume change was made, because the total volume change did not exceed 0.2%.

All voltamperograms were stored on disk before further calculations.

Procedure

The whole procedure for peak separation was implemented in the form of a menu-driven program written in C (Microsoft-C version). In the development of the program, standard assembler routines from the Autolab-100 analyzer package were used for experimental set-up control.

General scheme. Depending on the kind of studies, voltamperograms were recorded or generated (see below). After completing this step, semidifferentiation was carried out, and baselines of all semiderivative peaks were calculated by curve fitting. All undesired peaks were then removed and replaced by their baselines. The cycle was completed by semiintegration of the processed semiderivative curves yielding the voltamperogram that contains only the peaks(s) of interest.

Data acquisition. Voltamperograms were recorded by varying the potential according to a staircase function and measuring the current in the last 20% of each step (but no longer than 20 msec). To reduce the noise, voltamperograms were digitally filtered (Savitzky–Golay procedure²⁴) or several voltamperograms recorded at subsequent mercury drops were averaged. In the standard procedure, background voltamperograms were always subtracted.

Data generation for simulation purposes. Voltamperograms of reversible systems were generated by use of equation (3). First, the semiderivative peaks for the cathodic and the anodic part were generated, then the whole curve was semiintegrated giving the artificial reversible voltamperogram. Different peak com-

binations were obtained by changing heights and potentials. The program was capable of generating them for different temperature values as well.

Semidifferentiation/semiintegration. A Grünwald definition of these operations (discrete differintegration)²⁵ was used in a modified first-order algorithm (G0 according to Oldham²⁶). This algorithm possesses very attractive features: it is fast, simple and can be used for both semidifferentiation and semiintegration (details can be found in the Appendix). There was no significant change in results when the higher order (G1) algorithm was used. In the implementation presented here, the operation on a curve containing 400 data points took approx. 2.8 sec (IBM PC/XT 8 MHz with coprocessor).

Detection of peak overlapping. The program recognized overlapping and non-overlapping peaks automatically. Test for peak overlapping was based on the check, whether two ranges of datapoints for fitting, as calculated for non-overlapping peaks (see below), overlap or not.

Fitting of non-overlapping peak border zones. This procedure was used at the free (non-overlapping) ends of peaks. Datapoints for fitting to equation (5) were selected around the peak border within a distance equal to 1/6 of the distance between peak border and peak top. The border of a peak, used in datapoints range selection, was defined as a point, in which the derivative is equal to 0.1% of its maximal value in the corresponding inflection point. The derivative calculations were carried out with Savitzky-Golay's "smooth derivative" method;²⁴ this enables typical noise enhancement caused by differentiation to be overridden. This definition of peak border has several advantages. It is independent of the presence of a baseline with a constant value; due to the very low value of the derivative (practically equal to zero in most situations), if peaks overlap, the border point is placed in the minimum at the curve between them. In case of real voltamperograms containing noise, the border point is selected at the place where noise becomes comparable to the signal. The situation, when the method doesn't give good results is a combination of a very low noise level and a baseline with a large slope.

As initial guesses of the parameters to be fitted, the peak height measured from the curve was used for h_0 , 0.1% of this value as y_B , E_{p0} was set to the value of the peak potential read from the curve and k_0 was calculated from the

datapoint with highest absolute value, using equation (5).

Fitting of data in the overlap zone. All datapoints constituting the middle 1/3 of the range between peak tops (minimum of 15 points) were fitted to equation (6). This choice was a compromise between requirements of the curve fitting (large number of points spread over the range) and assumptions, under which equation (6) was derived (small range covered by datapoints). Five parameters in this equation (y_B , h_0 , k_0 , h_1 and k_1) were fitted, while the other two (E_{p0} and E_{p1}) were directly estimated from the curve by using simple correction because their changes due to overlapping are relatively small. In the first generation of initial guesses, peak potentials (as read from the curve) were used for E_{p0} and E_{p1} , for h_0 and h_1 —directly measured peak heights, y_B was set to 0.1% of the highest value of h_0 or h_1 and k_0 and k_1 were calculated from the last datapoints at borders of the fitting range assuming, that curve there follows a pure \cosh^{-2} function. In the next step, the appropriate corrections for the positions of peak tops, due to overlapping, were calculated with guesses from the first generation. The second generation was then created consisting of corrected E_{p0} and E_{p1} values and new k_0 and k_1 values re-evaluated with new peak potentials. Finally, y_B , h_0 , k_0 , h_1 and k_1 were used in the curve-fitting procedure for refinement, while E_{p0} and E_{p1} were not corrected further.

The procedure used for curve-fitting was a least-squares one according to Wentworth.²⁷ Fitting was performed until corrections to h_0 , h_1 , k_0 and k_1 were smaller than 0.1%.

Removal of undesired peaks. After calculating all the necessary parameters, the baseline was drawn as a straight line, or, baseline points were calculated by using equation (7), depending on whether the removed peak overlaps or not. This procedure covered all points, for which the difference between the original and the new value exceeded 3%.

RESULTS AND DISCUSSION

The method presented can be applied to the separation of voltammetric peaks in two situations. The first one occurs when both overlapping peaks are present in the same branch, either cathodic or anodic, and the second one occurs when they lie in different branches of the voltamperogram. This latter application deals with the separation of cathodic and anodic

peaks. It is well known, that in studies of reduction of substances, the anodic peak appears at the "tail" of the cathodic one and consequently the measured anodic current is a sum of the cathodic and anodic contributions (this can easily be seen when the voltamperogram is plotted in $i-t$ coordinates instead of $i-E$). From the point of view of peak separation, this situation is similar to the first case, where the latter cathodic peak rises from the "tail" of the previous one. Application of the presented method allows the anodic peak current (an important parameter in mechanistic investigations) to be read directly from the processed voltamperogram.

In the practical part both applications were checked with generated voltammetric curves. To check if the shape of the remaining peak is not influenced by the procedure, four peak parameters were tested: peak potential, peak current and potentials of inflection points. Inflection points were chosen for characterization, because in contrast to the half-peak potentials, their positions are not influenced by a constant or linearly varying background. In order to check the method in reality, two experiments with real electrochemical systems were also performed.

The developed program worked relatively fast: a separation of the voltamperogram of two systems took typically 20–80 sec, depending on the noise (which slowed down curvefitting) and the total number of points (increasing differentiation time). In comparison to the method described by Perone *et al.*,³ a high number of decisions is done by the program, so no special skill, experience or extensive knowledge about the algorithm principles is demanded from the operator.

Calculations with generated data

For artificially generated cyclic voltamperograms two series of tests were carried out. In the first, a pair of peaks (cathodic and anodic), simulated for a reversible electrode reaction was separated giving the anodic peak. Because in the process of semidifferentiation only points preceding the investigated one are included in calculations of the semiderivative value, removal of the anodic peak does not influence the cathodic one. The error in the peak current (i_{pa}) in separated voltamperograms can be expected to depend on the difference between the peak potential and the potential of the turning point ($E_{pc}-E_{turn}$).

An example of this separation is shown in Fig. 2. Errors in the anodic peak current, i_{pa} , and the anodic peak potential, E_{pa} , as a function of the difference between cathodic peak potential (E_{pc}), and the potential turning point (E_{turn}) are collected in Table 1. It can be seen, that for $E_{pc}-E_{turn} > \sim 75$ mV, the error in peak current was less than 1%, but for very small distances it grew rapidly.

As far as the potential of the anodic peak is concerned, its shift was less than 1 mV if the distance, $E_{pc}-E_{turn}$, was 80 mV or more (data points were generated with an interval of 0.98 mV). It is not clear, why two values of errors in E_{pa} , for $E_{pc}-E_{turn}$ in range of 200–300 mV, deviate from the general trend.

The second test with generated data was carried out in order to find a separation limit for peaks occurring in one branch of the voltamperogram and to study errors in their parameters obtained with the proposed procedure. For this purpose, artificial voltamperograms of two reversible systems were first added up and then separated (heights of cathodic peaks were equal). The parameters obtained were compared with their initial values (an example of the results is presented in Fig. 3, where the voltamperogram containing 2 anodic and 2 cathodic peaks is drawn together with the results obtained—two separated voltamperograms of each system). All results of this test (errors in i_p , E_p and potentials of inflection points, E_{asc}^{inf} and E_{desc}^{inf}) for all four peaks are collected in Tables 2–5. It can be seen, that errors are small and have a random character with increasing absolute values for smaller peak distances. Single values deviating from the general trend are due to the discontinuities of the peak function at points where replacement stops. If such discontinuity appears very close to, for example, the inflection point, the obtained respective parameter will be influenced more strongly. The limit of separation, 110 mV for a one-electron process, was determined by the convergence of the curve-fitting. Below this value, real potentials of semiderivative peaks differ significantly from values estimated from the overlapped curve, and fitting doesn't converge. This separation limit appears to be smaller than the one presented in a comparable method.³

Experimental data

The method was checked with real electrochemical systems as well. In two series, a couple of reversible + reversible systems and a couple

Fig. 2. Generated voltamperogram of one-electron reversible system. Peak potential $E_{pc} = -0.329$ V, potential of turning point $E_{turn} \approx -0.6$ V, scan rate 0.1 V/sec, potential step 4 mV, temperature 298 K (solid line) and result of removing the cathodic peak (dashed line).

of non-reversible + non-reversible systems were separated. As an example of the first case, a solution of $\text{In}^{3+} + \text{Tl}^{+}$ ions (ΔE^0 approx. 115 mV) was prepared with concentrations of 2×10^{-5} and $6 \times 10^{-5} M$, respectively (voltammetric peaks with approximately equal heights). Voltamperograms were recorded with a scan rate of 0.66 V/sec with a potential step of 1.6 mV. Figure 4 presents one of these voltamperograms and two curves obtained as a result of the processing. From the procedure outlined above it could be expected that no baseline remains. However, for the In^{3+} peak a small potential-dependent baseline is observed, which

can be attributed to the small number of points. This number is determined by the lowest potential step height that can be realized with the 12-bits D/A converter of the measuring system.

In the second experiment, a mixture of Zn^{2+} and Co^{2+} ions (both concentrations $10^{-4} M$) in 1M potassium chloride was examined with a scan rate of 1.0 V and a potential step of 3.6 mV. Results of the experiments and experimental conditions are collected in Tables 6 and 7.

In both cases, only cathodic peaks are reported, because with the experimental set-up (relatively small mercury drop) and the potential sweep rate limited by keeping potential step height small, a strong accumulation effect for $\text{In}^{3+} + \text{Tl}^{+}$ couple occurred, significantly changing the shape of anodic peaks. This change was large enough to set the convergence limit of curve-fitting above 115 mV. In case of the reduction of Co^{2+} ions, no anodic peak was observed.

All voltamperograms had to be smoothed before processing, because in case of a high S/N ratio, the determination of the peaks borders as described and the curve fitting do not give good results. However, in the authors' experience problem of high noise was encountered very seldom and it was always possible to overcome it by the averaging of several voltamperograms. It should be noted that background subtraction is very important for good performance of the

CONCLUSIONS

The method presented here can be applied to the resolution of overlapping LSV or CV peaks originating from both reversible and non-reversible systems with reliable results. When used for the separation of peaks in one branch (cathodic or anodic), a resolution limit of 110 mV (reversible case, one electron transfers) could be obtained.

When resolving peaks lying in different branches of the cyclic voltammetric curve, the anodic and cathodic peak of the investigated system, free from a cathodic or anodic peak influence, respectively, can be obtained. Precision of the calculated peak parameters depends in this case on the distance between peak top and the turning point of the voltamperogram.

Accumulation in the mercury drop influences the shape of the semiderivative peaks in the anodic segment and increases the minimal distance between the two peaks that can be resolved. When two voltammetric peaks strongly

overlap and the accumulation effect occurs, the anodic part of the voltamperogram sometimes cannot be separated even though the cathodic part can.

The algorithm needs hardly any decisions by the operator, which is an attractive feature when

the automatic processing of voltamperograms is concerned. This implies that the program can be used by personnel having little experience in using electrochemical methods.

APPENDIX

The Grünwald definition of discrete differintegration is:

$$\frac{d^u f(t_j)}{dt^u} = \lim_{N \rightarrow \infty} \left[\frac{(N/t')^u}{\Gamma(-u)} \sum_{j=1}^N \frac{\Gamma(N-j-u)}{\Gamma(N-j+1)} f(t_j) \right]$$

where $f(t_j)$ is a value of the function to be differintegrated at time t_j , N is the number of evenly spaced points preceding the point t_j , t' is the time interval between points, u is the instance of differintegration (1/2 for semidifferentiation and -1/2 for semiintegration). This equation can be rewritten in the convolutional form

$$\begin{aligned} \frac{d^u f(t_j)}{dt^u} &= \lim_{N \rightarrow \infty} \left[(N/t')^u \sum_{j=1}^N \frac{\Gamma(N-j-u)}{\Gamma(-u)\Gamma(N-j+1)} f(t_j) \right] \\ &= \lim_{N \rightarrow \infty} \left[(N/t')^u \sum_{j=1}^N w_j f(t_j) \right] \end{aligned}$$

where w_j are values of a weighting function depending only on u and N . This reformulation gives an approach equivalent to the G0 algorithm described by Oldham.²⁶

Inspection of the last w_j values gives:

$$W_N = \frac{\Gamma(N-N-u)}{\Gamma(-u)\Gamma(N-N+1)} = 1$$

$$w_{N-k} = \frac{\Gamma(N-N+k-u)}{\Gamma(-u)\Gamma(N-N+k+1)} = \frac{\Gamma(k-u)}{\Gamma(-u)\Gamma(k+1)}$$

$$\begin{aligned} W_{N-k-1} &= \frac{\Gamma(N-N+k+1-u)}{\Gamma(-u)\Gamma(N-N+k+2)} \\ &= \frac{(k-u)\Gamma(k-u)}{(k+1)\Gamma(-u)\Gamma(k+1)} = \frac{k-u}{k+1} W_{N-k} \end{aligned}$$

and leads to the general recursive formula

$$W_j = \frac{k-u}{k+1} W_{j+1}, \quad W_N = 1$$

where k is an index counting from the end, $k = N - j - 1$.

This definition makes the weighting function independent of the value of N . It can be found, that for differintegration of a set of N points it is enough to calculate the set of N weights only once at the beginning and then differintegration becomes a summation of weighted point values. This approach allows one to make a very compact and simple algorithm for differintegration, in which, after calculation of weights, only n multiplications and $n-1$ additions (plus one multiplication by a normalizing factor) are to be done in order to calculate the differintegral value in j -th point.

GLOSSARY

A	electrode surface area
c	concentration
D	diffusion coefficient
E	actual electrode potential
$E_{1/2}$	potential of polarographic halfwave of the compound
E_{p0}, E_{p1}	parameters related to potential at which semiderivative peak # 0 and # 1 appear
F	Faraday constant
h	semiderivative peak height
h_0, h_1	parameters related to height of respectively semiderivative peak # 0 and # 1
$i, i(t)$	current
k	parameter describing width of the semiderivative peak
k_0, k_1	parameters related to width of respectively semiderivative peak # 0 and # 1
n	number of electrons involved in electrode process
N	actual number of the point, counting from the lower limit of the semiderivative
s	slope of the baseline in semiderivative domain
T	absolute temperature

t'	time interval between two subsequent points
u	instance of differintegration
v	scan rate
w_j	weight for point j
y	value of semiderivative of the current in respect to time
y_A, y_B	baseline value at semiderivative peak border
y_0	constant term in linear baseline equation, obtained from combination of baseline values at both peak borders.

ELIMINATION OF THE COPPER-ZINC INTERFERENCE IN ANODIC STRIPPING VOLTAMMETRY BY ADDITION OF A COMPLEXING AGENT

ALDALEA LOPES BRANDES MARQUES (Dep. Tecnologia Quimica/UFMA) and
GILBERTO ORIVALDO CHIERICE* (IFQSC/USP/Sao Carlos)
Caixa Postal 369, CEP 13560, Sao Carlos/SP, Brazil

(Received 24 September 1990. Revised 22 December 1990. Accepted 14 January 1991)

Summary—The addition of cyanide and Triton X-100 suppress the formation of the Cu-Zn intermetallic compound in ASV making it possible to determine traces of zinc(II) in the presence of an excess of copper ions. The precision of the method (5%) and the accuracy (error of 1.4%) in sea water are satisfactory.

The formation of Cu-Zn intermetallic compounds causes interferences in the analysis of either element by anodic stripping voltammetry (ASV), particularly when working with a mercury film electrode (MFE).¹ The addition of gallium can successfully displace copper to form a much more stable copper-gallium compound.² However, the method does not give good recovery for solutions in which the copper content is higher than that of zinc.³ Other methods which may be used include the use of a twin-electrode thin-layer cell in which copper and zinc are deposited at two different working electrodes⁴ and a method where the generalized standard addition technique is applied to eliminate the interference.⁵ However, neither of these methods is simple or universally applicable.

Although a complexing agent to eliminate the Cu-Zn interference in ASV has not yet been suggested, the use of such reagents to solve other metallic interferences in ASV has been studied.⁶⁻⁸ The present work investigates the possibility of using the known reaction between cyanide and the cupric ion to prevent the formation of Cu-Zn intermetallic compounds in ASV. The strong $\text{Cu}(\text{CN})_4^{2-}$ complex does not show a d.c. polarographic reduction wave because its half-wave potential is very negative.⁹ On this basis we have extended the use of cyanide as a masking agent for copper in a supporting electrolyte in the determination of zinc by ASV. The results obtained show a recovery of 100% for the zinc peak in the presence of an excess of copper. A procedure is

described for the determination of zinc in standard solutions and sea water samples.

EXPERIMENTAL

Apparatus

Voltammetric measurements were made with a hanging mercury drop electrode (HMDE) and a MFE in a PAR Model 174A polarographic analyser connected with a PAR model 303 electrode and a PAR model 0089 X-Y recorder. A 0.6-cm diameter glassy-carbon disk electrode was used as a substrate for the mercury film. The MFE was adapted to a PAR system model 303 (Fig. 1). The glassy-carbon disk was inserted into a Pyrex glass tube, which was attached to the glass capillary tube of the HMDE. The electric contact was obtained with the mercury inside the glass tube and the mercury from the capillary. Such a system is very easily constructed and can be extended to other solid electrodes.

The electrode was polished with 0.3 μm of alumina powder each day. Preformed MFE was plated with mercury in a 40-mg/l. $\text{Hg}(\text{II})$ -1M sodium nitrate solution at pH 2, acidified with nitric acid.

All glassware, plastic containers, utensils, etc., were soaked for several days in 7M nitric acid and then rinsed with Millipore Milli-Q water before use. The addition of reagents and the dilutions were done with automatic micropipettes.

Reagents

The metals standard solutions were prepared by diluting A.A.S. standard (1000 mg/l.). Nitric

Fig. 1. Adaptation scheme of the glassy-carbon electrode to PAR model 303 electrode. (1) pyrex tube (\varnothing , 6 mm); (2) glassy-carbon disk (\varnothing , 5 mm); (3) compartment filled with mercury; (4) glass capillary referent to the hanging mercury drop electrode.

acid was of suprapure grade (Merck). All the solutions were prepared with Millipore Milli-Q water. Super dry nitrogen was used to remove dissolved oxygen.

The sodium perchlorate and phosphate buffer solutions were purified with liquid-liquid extraction with sodium diethyldithiocarbamate in tetrachloride media. A sea water sample was collected, filtered (0.45- μm pore size) and stored naturally and in acidic media (nitric acid) at 1°.

Procedures

After the electrode^{1,3} was prepared it was removed from the plating solution, rinsed carefully with ultrapure water and then transferred to the cell for measurements. A freshly prepared deposit was used in each experiment.

The measurements were performed in a cell, with a suitable aliquot (limited to 10 ml) of standard or sample solution. The pH was adjusted to 8.5 with 100 μl of a 1M phosphate buffer. In this medium, Triton X-100 (10⁻⁴% *v/v*) and cyanide were added for the copper complexation reaction. The solution was then purged with nitrogen for 20 min. The preconcentration potential was applied to the working electrode in the stirred solution and after a 30-sec rest period a positive-going scan was initiated and the resulting voltamperogram recorded. Aliquots of the zinc(II) standard solution were then added and the precon-

centration/oxidation cycle was repeated with a MFE or a new mercury drop.

For the determination of zinc the $\text{CN}^-/\text{Cu(II)}$ ratio must be high to eliminate the copper peak. The zinc peak, in a solution containing 40 $\mu\text{g/l}$. zinc ions and 40 $\mu\text{g/l}$. copper ions, has previously been found to tolerate a large excess of cyanide, up to 4.600 $\mu\text{g/l}$., but here a different response was evident. A decrease in the slope of the calibration curve was observed leading to an increase in the recovery from 96 to 150%. A $\text{CN}^-/\text{Cu(II)}$ ratio between 20 and 50 alters the background curve but does not change the slope; ratio values close to 20 are generally sufficient. On the other hand, the $\text{CN}^-/\text{Cu(II)}$ ratio also depends on the $\text{Cu(II)}/\text{Zn(II)}$ ratio. Therefore, a $\text{CN}^-/\text{Cu(II)}$ ratio range of 15–50 was considered ideal.

The polarographic parameters were as follows: accumulation potential (E_a), -0.9V or -1.3V; scan direction, positive; pre-electrolysis time, 1–10 min; rest time, 30 sec; DPASV/HMDE: scan rate, 5 mV/sec; pulse amplitude, 50 mV; drop time, 0.5 sec; DCASV/MFE: scan rate, 20 or 50 mV/sec.

RESULTS AND DISCUSSION

Copper-zinc interference

Previous reports have described that inter-metallic interferences are more pronounced at MFE's, which has been detected whenever the MFE has been used, regardless of the experimental conditions.^{1,3} To provide a direct observation of the severity of the problem the MFE was used for this study.

To establish the effect of the Cu-Zn interference on stripping voltammetry zinc ions from a 200 $\mu\text{g/l}$. solution were deposited at a preformed MFE for 2 min at -1.3V and stripped with the subsequent positive scan which produced a well defined zinc wave (Fig. 2, curve 2). When the same experiment was repeated with 100 $\mu\text{g/l}$. Cu(II) in the sample, a 50% depressed zinc wave was recorded along with an enhanced copper wave (Fig. 2, curve 3). Curve 4 shows the same experiment but the electrode was plated at -0.9V (where zinc is not reduced) and the copper wave is smaller. This fact provides evidence that the Cu-Zn compound is oxidized at the same potential as copper inducing two errors, positive and negative, for both copper and zinc respectively, when the electrode is plated at -1.3V.

Elimination of Cu-Zn interference

Five different complexing agents were tested, based on the stability of the formed complex, disodium ethylenediaminetetracetate, azide, thiocyanate, diethanoldithiocarbamate and cyanide; the last presented the best applicability and experimental results. This is confirmed by the stability constants of the $\text{Cu}^{\text{I}}(\text{CN})_4^{3-}$ ($\log \beta_4 = 30$) and $\text{Zn}^{\text{II}}(\text{CN})_4^{2-}$ ($\log \beta_4 = 19$) complexes.¹⁰

The magnitude of the error due to Cu-Zn interference and its elimination by cyanide addition on the working electrolyte is illustrated in Fig. 3. Curve 1 shows a zinc peak depression due to the addition of copper and curve 2 shows the zinc peak recovery in the same sample, obtained by addition of cyanide at pH 8.5.

Figure 4 shows the zinc(II) calibration curves between 20 and 210 $\mu\text{g}/\text{l}$. in a solution containing 20 $\mu\text{g}/\text{l}$. Cu(II) in the absence (curve 1) and presence (curve 2) of cyanide. Curve 1 is not linear while the curve 2 is linear in the 20–170 $\mu\text{g}/\text{l}$. concentration range. This suggests that in the absence of cyanide there is a formation of successive complexes of Cu-Zn intermetallic compounds.

Fig. 2. Effect of the Cu-Zn interference on stripping voltammetry. Deposition potential of (1–3), -1.3 V; (4), -0.9 V; deposition time, 2 min. Scan (1), $0.02M$ NaClO_4 ; scan (2), (1) + 200 $\mu\text{g}/\text{l}$. $\text{Zn}(\text{II})$; scan (3), (2) + 100 $\mu\text{g}/\text{l}$. $\text{Cu}(\text{II})$; scan (4), replicate scan (3).

Fig. 3. Occurrence and elimination of Cu-Zn interference. Deposition potential, -1.3 V; deposition time, 1 min; pH 8.5; $0.02M$ NaClO_4 ; 200 $\mu\text{g}/\text{l}$. $\text{Zn}(\text{II})$. Curve 1, zinc peak depression (current, %) vs. copper(II) concentration; Curve 2, zinc peak recovery (current, %) vs. cyanide concentration.

These satisfactory results obtained when the copper concentration in the solution is higher than that of zinc (Fig. 3) confirm the applicability of the proposed method, in contrast to the gallium addition method where, under the same conditions, the magnitude of interference is only lowered.³

The observed behaviour can be explained by the fact that the strong complexation of copper(I) by cyanide shifts its reduction potential to a more cathodic region than that where zinc(II) reduction occurs. In fact, the calculated potential shift is about $-0.94V$ for the $\text{Cu}(\text{I})/\text{Cu}(\text{Hg})$

Fig. 4. Calibration curves of zinc(II) in the absence (Curve 1) and presence (Curve 2) of cyanide. Deposition potential, -1.3 V; deposition time, 2 min; pH 8.5; $0.02M$ NaClO_4 ; 20 $\mu\text{g}/\text{l}$. $\text{Cu}(\text{II})$; 400 $\mu\text{g}/\text{l}$. CN^- .

system and only -0.15V for the Zn(II)/Zn(Hg) system:

$$\Delta E_{\text{Cu(II)}}^0 = -0.059 \log \beta_4[\text{CN}^-]^4 = -0.94\text{V}$$

$$\Delta E_{\text{Zn(II)}}^0 = -0.029 \log \beta_4[\text{CN}^-]^4 = -0.15\text{V}$$

It has been found that the presence of $10^{-4}\%$ (v/v) of Triton X-100, as suggested in the literature,^{6,7} gave a better definition of the anodic peak of zinc. Thus all working solutions contain this non-ionic surfactant.

Influence of pH

The effect of pH was studied by measurement at a fixed concentration of $50 \mu\text{g/l}$. zinc(II), $25 \mu\text{g/l}$. copper(II) and $500 \mu\text{g/l}$. CN^- over the pH range 7–10. The experiments showed that zinc peak height was affected by pH variations in the presence of phosphate buffer and that the peak-height for zinc was greatest at pH 8–9.

Practical application

Voltammetric methods are most suitable for the analysis of saline water because it is an ideal electrolyte for voltammetry.¹¹

The proposed method was tested by zinc determination in a standard solution and a sea water sample. The determination of zinc in the presence of copper in standard solution, showed good recovery (95%) at low concentrations ($2 \mu\text{g/l}$), which indicates that the method can be used in sea water. The same procedure was applied in a sea water sample (Fig. 5): Curves 1–2, in Fig. 2, shows the occurrence of the interference, in sea water; Curve (3), its elimination; Curves (4–6), the reproducibility of the measurements and curves (7–9), the standard additions of zinc(II). Before, copper was determined at -0.9V (where the zinc is not deposited) and the necessary cyanide concentration was calculated according to copper concentration. After, an aliquot with a 10-fold excess of cyanide over copper was added to mask copper (curve 3). In this way zinc was determined at -1.3V with a collection period of 10 min. In both cases the two metals were determined by the standard addition method without prior decomposition of the organic matter because in preliminary tests it had been found that wave form was not influenced by dissolved organic matter. This means that the determination corresponds only to the free zinc species.

A comparison of the zinc content found by DPASV/HMDE and DCASV/MFE was used

Fig. 5. DCASV/MFE scans of sea water after 10 min collection. Scan rate, 20 mV/sec ; pH 8.5; deposition potentials of (1) and (4–9), -1.3 V ; (2–3), -0.9 V ; scans (1–2), sea water; scan (3), (2) + $100 \mu\text{g/l}$. CN^- ; scans (4–6), 3 replicates of the scan (3); scan (7), (6) + $19.42 \mu\text{g/l}$. Zn(II) ; scan (8), (6) + $38.83 \mu\text{g/l}$. Zn(II) ; scan (9), (6) + $58.25 \mu\text{g/l}$. Zn(II) .

to evaluate the relative accuracy of the proposed method, based on the fact that the copper–zinc interference was not observed in the HMDE at this concentration. A sea water sample was analysed 3 times in succession and the results showed good agreement between the obtained results by DCASV/MFE [$7.1 \mu\text{g/l}$. Zn(II)] and DPASV/HMDE [$7.2 \mu\text{g/l}$. Zn(II)].

The precision was evaluated by means of 3 replicate analysis of a sea water sample. The relative standard deviation for zinc, when CN^- ions were present, was 5%.

CONCLUSION

The present work shows a new manner to eliminate the interference of copper on the determination of zinc by ASV. The method involves additions of cyanide, which avoid the formation of the Cu–Zn intermetallic compounds because the $\text{Cu}^{(II)}(\text{CN})_4^{3-}$ complex is not reduced, consequently there is no diffusion of copper ions to the drop.

VOLTAMMETRIC MEASUREMENT OF HALOPERIDOL FOLLOWING ADSORPTIVE ACCUMULATION AT GLASSY-CARBON ELECTRODES

PENG TUZHI,* YANG ZHONGPING and LU RONGSHAN

Department of Chemistry, Hangzhou University, Hangzhou 310028, People's Republic of China

(Received 17 October 1990. Revised 9 December 1990. Accepted 31 December 1990)

Summary—A sensitive stripping voltammetric method is reported for trace measurement of the psychotherapeutic drug haloperidol. The method is based on adsorptive preconcentration of haloperidol on the glassy-carbon electrode in an open circuit, followed by medium exchange and voltammetric determination of surface species. Cyclic voltammetry was used to explore the adsorptive behaviour and the results obtained suggest that the adsorption of haloperidol corresponds to the Frumkin-type isotherm. The adsorptive stripping response was evaluated with respect to stripping mode, electrolyte, pH, preconcentration time, concentration dependence, possible interference and other variables. The detection limit was $1.3 \times 10^{-9}M$ (10 min preconcentration) and the response was linear. The relative standard deviation (at the $1.3 \times 10^{-6}M$ level) was 2.3%. Applicability to a patient's urine sample is illustrated.

Haloperidol is an important psychotherapeutic drug and has been widely used as a tranquiliser in recent years. This long-acting neuroleptic is particularly useful in the treatment of schizophrenia and in the prevention of psychotic relapse. Usually, UV spectrophotometry¹ is used for routine analysis of the drug although other methods, such as GC,² TLC,³ fluorimetry⁴ and radioimmunoassay,⁵ have been reported. The sensitivities for most of these methods are not high and more sensitive techniques are required for assaying the drug in body fluids after therapeutic doses.

Bishop and Hussein⁶ studied anodic voltammetry of butyrophenone neuroleptics at platinum and gold electrodes and found that haloperidol shows neither anodic nor cathodic activity in 0.1M sulphuric acid.

The present study reports an extremely sensitive stripping voltammetric procedure for measuring trace amounts of haloperidol. The drug can be adsorbed on the surface of glassy-carbon electrodes, and then shows anodic activity in linear scan voltammetry. The adsorptive characteristic, which usually prevents voltammetry from being a useful analytical method, is exploited for obtaining effective preconcentration. It is demonstrated that immersing the glassy-carbon electrode in the haloperidol solution for short time periods allows convenient

measurements at the $10^{-8}M$ concentration level. Cyclic voltammetry is employed to examine adsorptive and electrochemical behaviour on the electrode surface. The scheme of open circuit accumulation/medium exchange/stripping voltammetry⁷ is used to minimize interference resulting from macro solution constituents. Trace amounts of haloperidol in urine have been measured without pre-isolation.

EXPERIMENTAL

Apparatus and reagents

Stripping and cyclic voltammetric data were collected with a BAS-100A electrochemical analyzer. The working electrode was a BAS glassy-carbon voltammetry electrode. The 10-ml sample cell was fitted with an Ag/AgCl reference electrode (BAS RE-1B) and a platinum wire auxiliary electrode, on the BAS C-1A cell stand which provided magnetic stirring during preconcentration. A BAS PL-10 digital plotter was used for obtaining voltamperograms.

Pure haloperidol was supplied by Shanghai No. 19 pharmaceutical laboratory; a stock solution ($2.7 \times 10^{-3}M$) was prepared by dissolving appropriate weights in ethanol. All other solutions were prepared with demineralized water and analytical grade reagents. Unless specified otherwise, the supporting electrolyte was Britton-Robinson buffer (pH 9.0). Urine samples were obtained from patients in Hangzhou No. 7 hospital.

*Author for correspondence.

Procedure

A fresh working electrode surface was utilized for each experiment. The surface was hand-polished for 30 sec with 0.05 μm of alumina slurry (BAS PK-3). The electrode was then rinsed with demineralized water to remove residual polishing material from the surface. The polished electrode was immersed into a sample solution, and adsorptive accumulation was begun in an open circuit for a selected time, while the solution was stirred at 400 rpm. Following this, the electrode was transferred into a "clean" supporting electrolyte solution. The linear scan or differential pulse voltamperograms were recorded by applying a positive-going potential. The scan was initiated at +0.4 V, terminated at +0.9 V. No nitrogen was needed to remove oxygen during the experiment.

RESULTS AND DISCUSSION

Figure 1 shows repetitive cyclic voltamperograms for $4.3 \times 10^{-7} M$ haloperidol at the glassy-carbon electrode in Britton-Robinson buffer (pH 9.0). Stirring the solution for 2 min in an open circuit resulted in a large anodic peak in the first scan (designated as 1), with a peak potential of 0.53 V. No peaks were observed in the cathodic branch. Subsequent repetitive scans yielded significantly smaller peaks, indicating rapid desorption of the product from the electrode surface or formation of a non-electroactive product. Repetitive scans without prior preconcentration did not yield any peak. There were no peaks obtained at platinum and gold electrodes for $1 \times 10^{-4} M$ concentration with 2 min preconcentration (not shown), meaning no adsorption on these metallic surfaces. It is obvi-

Fig. 1. Repetitive cyclic voltamperograms for $4.3 \times 10^{-7} M$ haloperidol in a Britton-Robinson buffer solution (pH 9.0), after 2 min stirring (400 rpm in an open circuit). Scan rate 25 mV/sec.

Fig. 2. Influence of the concentration on the linear scan stripping peak current (a) and on the fraction of covered surface (b) for haloperidol after an 8-min accumulation period. Other conditions as in Fig. 1.

ous that the anodic peak is caused by adsorptive haloperidol on the glassy-carbon surface.

Adsorption of haloperidol at glassy-carbon electrodes can be estimated by using linear scan voltammetry. The fraction of covered surface (θ) can be obtained from the ratio of peak area to maximum peak area. Logarithm forms for Langmuir and Frumkin adsorption isotherms are expressed as follows:

$$\log \frac{\theta}{(1-\theta)C} = \log \beta \quad (1)$$

$$\log \frac{\theta}{(1-\theta)C} = 2\alpha\theta \log e + \log \beta \quad (2)$$

If $\log[\theta/(1-\theta)C]$ is a constant [equation (1)], or a function of θ [equation (2)], the adsorption obeys the Langmuir or Frumkin isotherm respectively.⁸ Figure 2 shows the influence of the concentration (8 min accumulation time) on the peak current and the fraction of covered surface (θ). The plots are linear up to $1.5 \times 10^{-7} M$, and then they level off, indicating the electrode surface is saturated subsequently. The relationship of $\log[\theta/(1-\theta)C]$ and θ can be obtained from the data of Fig. 2 (see Fig. 3). The plot is linear (slope 0.95, intercept 6.48 and correlation coefficient 0.991) indicating that haloperidol adsorption on the glassy-carbon surface corresponds to the Frumkin isotherm. On the basis of the plot, the adsorption coefficient (β) is determined as 3.0×10^6 l./mole, and the attraction factor (α) is 1.09.

Fig. 3. Plot of $\log [\theta / (1 - \theta) C]$ vs. θ for haloperidol adsorption. All data are from Fig. 2.

The adsorbed haloperidol can be measured by using different voltammetric waveforms. Well-defined peaks after accumulation were obtained by both linear scan (Fig. 1) and differential pulse voltammetry (Fig. 4). The latter technique was preferred because it is almost three times more sensitive than linear scan voltammetry, *e.g.*, for $1.3 \times 10^{-6} M$ haloperidol after a 1-min accumulation time, the peak current in differential pulse voltammetry (scan rate 10 mV/sec, pulse amplitude 50 mV and pulse period 0.5 sec) is 2.3 times higher than that obtained in linear scan voltammetry (scan rate 25 mV/sec).

The adsorption properties of the drug can vary with the composition of the supporting electrolyte. Various electrolytes *e.g.*, phosphate buffer, borate buffer, ammonium acetate buffer and Britton–Robinson buffer, were evaluated as suitable media for the adsorptive stripping measurement of haloperidol. Best results (with

Fig. 4. Differential pulse stripping voltamperograms for $1.3 \times 10^{-6} M$ haloperidol after different accumulation periods: a, 0; b, 1 min. Scan rate, 10 mV/sec; pulse amplitude, 50 mV; pulse period, 0.5 sec. Other conditions as in Fig. 1.

Fig. 5. Influence of the solution pH on the stripping peak potential (a) and on the peak current (b). Other conditions as in Fig. 4.

respect to signal enhancement and peak shape) were obtained with the Britton–Robinson buffer and therefore this electrolyte solution was used. The adsorptive stripping signal of haloperidol depends on the buffer pH. Figure 5(b) shows the dependence of the peak enhancement on the solution acidity. Almost no response to haloperidol was observed in solutions more acidic than pH 5.0. Increasing the pH from 5.0 to 9.0 resulted in a rapid increase in peak enhancement. The peak current decreased at higher pH. Accordingly pH 9.0 was used throughout to satisfy the sensitivity. The effect of the solution pH on the peak potential was also evaluated [Fig. 5(a)]. The peak potential shifted negatively, from 0.73 to 0.45 V, upon increasing pH from 5 to 10. The plot of peak potential vs. the solution pH was linear, with a slope of 53 mV per pH unit and a correlation coefficient of 0.998.

The effect of instrument conditions on the haloperidol adsorptive stripping response is examined. As expected, the peak height increased rapidly upon increasing the scan rate. However, as both the peak current and background current must be considered, more than a 10 mV/sec scan rate is not recommended. The stripping current also increased with both pulse amplitude and period. But increasing these two pulse parameters increased peak width and background current. In order to obtain an adequate analytical

response, the following parameters were chosen: pulse amplitude 50 mV and pulse period 0.5 sec.

It is difficult to obtain good reproducibility for the adsorptive stripping response of haloperidol on the glassy-carbon surface. Repetitive measurements on the same electrode surface caused the peak current to decrease rapidly. In order to obtain a reproducible surface, polishing with alumina for 30 sec was employed. The precision of this method was estimated by nine repeated measurements of $1.3 \times 10^{-6} M$ haloperidol (conditions as in Fig. 4). The mean peak current was 585 nA with a range of 570–595 nA and a relative standard deviation of 2.3%. It is obvious that the reproducibility of the results is attributed to the use of a fresh electrode surface in each run.

The adsorptive behaviour of haloperidol is affected by the mass-transport conditions during the preconcentration step. For example, a stirring rate of 400 rpm resulted in a 6-fold enhancement of the response, compared to that obtained in a quiescent solution ($1.3 \times 10^{-6} M$ haloperidol, 1 min preconcentration). Figure 6 shows the dependence of the adsorptive stripping peak current on the preconcentration time at two concentration levels. It is clear that the adsorptive accumulation is effective. The longer the preconcentration time, the more haloperidol adsorbed and the larger the peak current. Delahay and Fike⁹ have shown that for diffusing-controlled adsorption, the quantity of adsorbed material is proportional to the square root of the adsorption time, on the condition that the fraction of the surface covered is far from its equilibrium value. For haloperidol adsorption, the peak current is almost linear with the accumulation time. The deviation from linearity is observed only for solution of higher concentra-

tions. Similar results were reported for adsorptive stripping measurements of *cis*-dichlorodiammineplatinum(II).¹⁰ Such behaviour indicates that the adsorption is not controlled solely by the diffusion toward the surface.

The adsorptive stripping current increased with the concentration of haloperidol. The response was linear over 5.3×10^{-9} – $2.6 \times 10^{-8} M$ concentration range with 5 min accumulation (slope 4.2 nA/ $10^{-9} M$, correlation coefficient 0.999), and over 5.3×10^{-8} – $2.6 \times 10^{-7} M$ concentration range with 2 min accumulation (slope 10 nA/ $10^{-8} M$, correlation coefficient 0.998). The detectability was estimated from measurements of $5 \times 10^{-9} M$ haloperidol after 10 min preconcentration. The limit of detection, calculated from 3 times the noise, was found to be $1.3 \times 10^{-9} M$.

Because of open circuit accumulation and medium exchange in this method, most of the common metal ions did not interfere during the measurements. The following metal ions were tested at the 100 ppm level and found not to affect the $1.3 \times 10^{-6} M$ haloperidol peaks: Cu(II), Pb(II), Ni(II), Zn(II), Cd(II) and Fe(III). However, the stripping measurements based on adsorption are subject to interference from organic surfactants, which may also compete with haloperidol for space on the electrode surface. It is important to demonstrate susceptibility of this procedure to the presence of these materials for the direct voltammetric measurements of haloperidol in biological samples. Ascorbic acid and uric acid (100 ppm) did not affect the haloperidol peaks ($1.3 \times 10^{-6} M$, 1 min accumulation) but 100 ppm glucose, 40 ppm cholesterol and 5 ppm gelatin resulted in depression of the peak current to 11, 12 and 14% respectively.

In complex samples, such as body fluids, the advantages of the open circuit adsorption preconcentration/medium exchange/stripping voltammetric measurement are apparent. Such samples contain lots of chemicals, some at major component concentration; direct voltammetric measurements of analytes in such samples at trace levels are often impossible. Figure 7 shows the determination of haloperidol in a patient's urine sample (20 mg per day) diluted (1:10) with Britton–Robinson buffer. The drug peak in the voltamperogram was observed at +0.5 V [Fig. 7(a)]. A standard addition of $2.7 \times 10^{-7} M$ haloperidol caused this peak to rise [Fig. 7(b)]. A haloperidol concentration of $2.4 \times 10^{-6} M$ was found in the patient's urine. The

Fig. 6. Influence of accumulation time on different concentrations of haloperidol: a, $1.3 \times 10^{-8} M$; b, $1.3 \times 10^{-7} M$. Other conditions as in Fig. 4.

Fig. 7. Voltamperograms for the diluted (1:10) patient's urine sample with Britton-Robinson buffer solution (a), and the sample solution spiked with $2.7 \times 10^{-7}M$ haloperidol (b). Other conditions as in Fig. 4.

measurement is simple and convenient. No sample pretreatment was used other than 1:10 dilution with supporting electrolyte.

In conclusion, haloperidol does not show electroactivity at platinum and gold electrodes; the oxidation takes place only after adsorption at glassy-carbon electrodes which means that adsorption plays an important role in electrode reactions and may be the cause of reaction to some degree. Thus, a study of some non-electroactive organic compounds by use of adsorptive stripping voltammetry is expected.

DETERMINATION OF MOLYBDENUM BY ATOMIC-ABSORPTION SPECTROMETRY AFTER SEPARATION BY 5,5'-METHYLENEDISALICYLOHYDROXAMIC ACID EXTRACTION AND FURTHER REACTION WITH THIOCYANATE AND TIN (II)

MERCEDES SANCHEZ,* DOMINGO GAZQUEZ and PALOMA GARCIA

Department of Analytical Chemistry, Faculty of Sciences, University of Granada, Granada, Spain

(Received 24 November 1989. Revised 31 January 1991. Accepted 7 February 1991)

Summary—A method is described for the determination of molybdenum down to the microgram level, in samples of soil, steels, fertilizers and pharmaceuticals. After attack with acids, this element is separated from matrix elements by extraction of its 5,5'-methylenedisalicylohydroxamic acid (MEDSHA) complex from 4*M* hydrochloric acid, into methyl isobutyl ketone. Molybdenum is determined by atomic-absorption spectrometry (AAS), after conversion of the Mo-MEDSHA complex into the Mo-SCN⁻ complex in the organic phase. The detection limit is 0.03 µg/ml, with a relative standard deviation not exceeding 1.5% at a level of 2 µg/ml. The method is highly selective and suffers only from interference by tungsten.

Application of flame atomic-absorption spectrometry (AAS) for determination of molybdenum has been studied by many workers. Because the determination is subject to many interferences and low sensitivity,¹⁻³ preconcentration of very small amounts of molybdenum, as in geological samples or biological materials, is necessary before its AAS determination. The analytical aspects of the most commonly used extraction methods are summarized in Table 1.

α -Benzoinoxime is very widely used for extraction of molybdenum into various solvents,^{7,10,11} and Aliquat 336 has been used for the extraction of Mo together with Sb, As, Bi, Cd, Cu, Pb, Ag and Zn.^{12,13}

Hydroxamic acids such as *N*-benzoyl-*N*-phenylhydroxylamine¹⁶ and benzohydroxamic acid¹⁸ have also been utilized. The chelate formed with the first is extracted into toluene, while the benzohydroxamate complex is extracted into ethyl acetate as an ion-pair with Adogen 464.

The reaction between molybdenum(VI), SCN⁻ and Sn(II) in hydrochloric acid medium is probably the most used system. Kim and co-workers have described several methods in which the thiocyanate complex is extracted into methyl isobutyl ketone (MIBK)⁵ or as an

ion-pair with Amberlite LA1⁶ or Aliquat 336⁸ into chloroform. Aliquat 336 gives a very selective procedure but before the AAS measurement the chloroform must be evaporated and the residue dissolved in MIBK.

This paper describes the successful determination of Mo in several steels, a soil, a fertilizer and a pharmaceutical, based on extraction into MIBK with MEDSHA, followed by change of the Mo-MEDSHA complex into the Mo-SCN⁻ species. The method presents high sensitivity and satisfactory precision, and is practically free from interferences, so we think that it is more advantageous than the direct Mo-SCN⁻ extraction procedure.⁵

EXPERIMENTAL

Reagents

Stock molybdenum solution, 1000 µg/ml. Prepared by dissolving 1.84 g of analytical grade ammonium heptamolybdate tetrahydrate in distilled water and diluting to 1000 ml. Working solutions were prepared from this stock solution by appropriate dilution.

Stannous chloride solution, ~100 g/l. Prepared by warming analytical grade SnCl₂·2H₂O (20 g) and a small piece of analytical grade tin metal in 10*M* hydrochloric acid (20 ml), until a clear solution was obtained. After cooling, the

solution was diluted to 200 ml with distilled water and a small piece of tin metal was placed in it.

Potassium thiocyanate solution, ~100 g/l.

5,5'-Methylenedisalicylohydroxamic acid. The synthesis has been reported previously.²⁰ A 0.02M solution was prepared by dissolving 0.6360 g of MEDSHA in 100 ml of dilute ammonia solution.

All other reagents and organic solvents used were of analytical grade.

Instrumentation

A Perkin-Elmer 2380 atomic-absorption spectrometer with a nitrous oxide-acetylene (6-5) cm single-slot burner head (N₂O flow-rate 12 l./min, C₂H₂ flow-rate 3.9 l./min) and a molybdenum hollow-cathode lamp were used. The 313.3 nm line was used with a 0.7-nm spectral band-pass. The burner was positioned so that the light-beam was about 0.8 cm above the slot.

Procedure

Transfer a measured sample containing less than 50 µg of molybdenum into a 100-ml separating funnel. Add 7.1 ml of concentrated hydrochloric acid (to provide an acid concentration of 4M), 5 ml of MEDSHA solution and distilled water to 20 ml. Shake for 1 min with 5 ml of methyl isobutyl ketone (MIBK). Discard the aqueous phase and add to the organic phase 1.8 ml of concentrated hydrochloric acid, 1 ml of thiocyanate solution, 2 ml of tin chloride solution and distilled water to 20 ml. Shake for 2 min and let the phases separate. Centrifuge the organic phase and aspirate it into the flame. A blank is prepared in the same way. In the analysis of samples containing titanium and tungsten, add enough sodium fluoride to give a 1M concentration in the sample solution to mask these ions.

Preparation of sample solutions

Steel samples. Dissolve a suitable weight of steel sample in 12M hydrochloric acid in a 50-ml Kjeldahl flask by warming gently until the whole reaction has ceased, adding more acid if necessary. Add concentrated nitric acid dropwise to oxidize iron(II) and carbides. Evaporate the solution to dryness, dissolve the residue in 12M hydrochloric acid and dilute to volume in a standard flask of suitable size.

Fertilizers. Place 50 ml of fertilizer in a 250-ml beaker and add 40 ml of 20% v/v hydrochloric acid. Heat for 30 min, reducing the volume to

about 20 ml. Add 50 ml of distilled water, heat to boiling, cool and filter the solution (Whatman No. 40 paper) into a 100-ml standard flask. Wash down the sides of the beaker with water and filter into the flask, diluting to volume with water. The composition of the liquid fertilizer analysed was: total nitrogen 6%, P₂O₅ 4%, K₂O 6%, Mg 0.5%, Mn 0.05%, B 0.029%, Zn 0.05%, Mo 0.0006% and Co 0.0006% (values given by the manufacturer).

Soils.⁵ Moisten 1 g of soil sample with water in a 100-ml Teflon beaker, add 4 ml of 70% perchloric acid and 10 ml of concentrated hydrofluoric acid. Evaporate the solution on a hot-plate at about 200° until white fumes of perchloric acid appear, add another 10 ml of hydrofluoric acid and evaporate to dryness. Wash down the walls of the beaker with 4M hydrochloric acid and add about 20 ml more, cover with a watch-glass and boil gently for a short time to dissolve the residue. Cool and transfer the solution into a 100-ml separating funnel, washing the cover and the beaker with 4M hydrochloric acid to give a final volume of 40-50 ml.

Pharmaceuticals. Weigh 2 ml of sample, e.g., a vitamin complex, into a 100-ml beaker, add 10 ml of concentrated nitric acid and heat, with care to avoid a violent reaction, until a tranquil solution is produced. Cool it, slowly add 5 ml of 60-70% perchloric acid, and heat until brown fumes of nitrogen dioxide appear. If the solution has a dark colour, add 2 ml of concentrated nitric acid and continue the heating until white fumes of perchloric acid appear. Cool the solution and dilute to a final volume of 50 ml with 2M hydrochloric acid. The composition of the liquid vitamin complex analysed was (per ml): vitamin A 8333 IU, vitamin D 1667 IU, thiamine hydrochloride 2.5 mg, riboflavin 2 mg, pyridoxine hydrochloride 0.83 mg, nicotinamide 16.67 mg, ascorbic acid 83.33 mg, MnSO₄ 1.53 mg, K₂SO₄ 5.58 mg, ZnSO₄·7H₂O, 1.75 mg, Na₂MoO₄·2H₂O 0.63 mg, Fe 3.33 mg, saccharin 1.05 mg.

RESULTS AND DISCUSSION

In acidic media molybdenum forms an insoluble yellow complex with MEDSHA (RH₂) according to the reaction²¹⁻²³

The precipitate formed, the composition of which is MoO₂(C₁₅H₁₂N₂O₆)·3H₂O, is fairly

easily extracted into MIBK. Several experimental factors influencing the efficiency of extraction were investigated in detail.

Effects of the acidity and reagent concentration

Figure 1 shows the absorbance values for Mo, after a single extraction of its MEDSHA complex with 10 ml of MIBK from various concentrations of hydrochloric acid and between pH 1 and 8. When the concentration of hydrochloric acid is increased the volume of the organic phase decreases because of the solubility of MIBK in the aqueous phase. For that reason a volume-change correction has been made for the organic phase, taking as reference a volume of 10 ml.

It can be seen that the absorbance of the organic phase is constant in the range from 5M hydrochloric acid to pH 2, although it is lower than expected, and that at pH above 2 it diminishes gradually as the pH is increased. The increase in absorbance of the aqueous phase at pH above 5 indicates a decrease of the extraction efficiency. On the other hand, the absorbance of both the aqueous and organic phases increases when the hydrochloric acid concentration is higher than 5M. This effect may be due to destruction of the Mo-MEDSHA complex and the formation of a chloride complex which is partially extractable into MIBK.²⁴ The logical conclusion, confirmed later, is that the Mo-MEDSHA complex precludes complete atomization of molybdenum in the flame.

The results obtained for the effect of the reagent concentration on the extraction efficiency from 4M and 2M hydrochloric acid and on the molybdenum absorbance are shown in Fig. 2. The extraction percentages have been calculated from measurement of the

Fig. 1. Extraction of molybdenum with MEDSHA into MIBK, as a function of hydrochloric acid concentration and pH. Molybdenum(VI) 10 $\mu\text{g}/\text{ml}$; MEDSHA, $1.0 \times 10^{-3}\text{M}$; MIBK, 10 ml. The absorbances of the organic phases were corrected for volume change (see text).

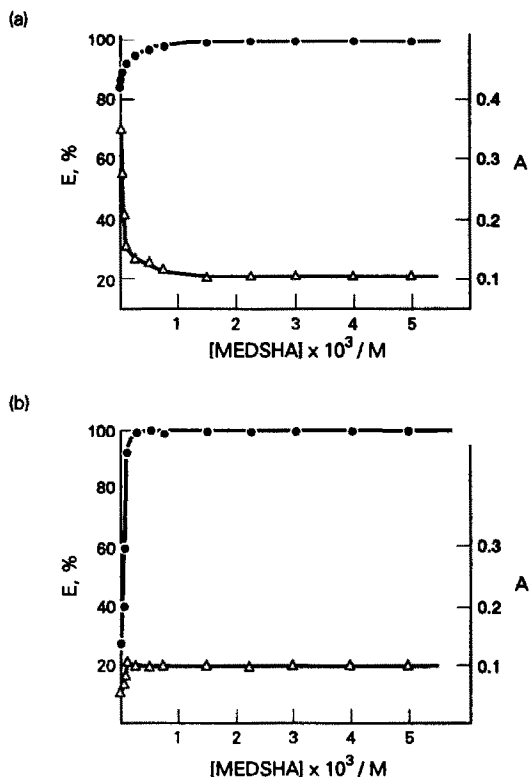

Fig. 2. Dependence of absorbance (Δ) and degree of extraction (\bullet) of molybdenum(VI), on the concentration of MEDSHA in the aqueous phase. Molybdenum(VI), 0.2 mg/20 ml; MIBK, 10 ml; [HCl], (a) 4M, (b) 2M.

molybdenum that remains in the aqueous phase, by the method of Kim *et al.*⁵

It is observed that at both acidities the extraction efficiency improves when the reagent concentration is increased. With a reagent concentration of 5×10^{-4} and $1.5 \times 10^{-3}\text{M}$, for the 2 and 4M hydrochloric acid media respectively, the extraction is quantitative and the absorbance does not change.

The large decrease of the absorbance in the 4M hydrochloric acid phase as the reagent concentration is increased, suggests that at low MEDSHA concentrations a chloride complex of molybdenum is extracted, which is confirmed by the absence of this phenomenon for the 2M hydrochloric acid medium, where the degree of formation and extraction of the chloride complex is lower.

These facts, together with the results obtained in the study of the effect of acidity, show that the atomization efficiency of Mo in the flame, when present as the Mo-MEDSHA complex, is low. Several experiments were done on transformation of that species, after its extraction from 4M hydrochloric acid (this medium was selected in order to obtain as selective a procedure as

Table 2. Comparison of the calibration graphs corresponding to extraction of molybdenum into MIBK by the SCN^- -Sn(II) method and by MEDSHA and further reaction with SCN^- -Sn(II)

‡MEDSHA, 0.003M; HCl, 4M.

possible), into a non-refractory one. The best results were obtained by shaking the organic phase (containing the Mo-MEDSHA complex) for 2 min with a fresh solution of 0.05M potassium thiocyanate and 0.045M stannous chloride in 1M hydrochloric acid.⁵ In this way the Mo-MEDSHA complex is quantitatively transformed into an Mo- SCN^- species, which remains in the organic phase. This fact was checked by preparing two calibration curves for a molybdenum concentration range from 1 to 4 $\mu\text{g/ml}$, the first corresponding to extraction with the SCN^- -Sn(II) system and the second to the MEDSHA extraction and further transformation with SCN^- and Sn(II). The results summarized in Table 2 make evident the effectiveness of the reaction.

Effect of other variables

Shaking for 30 sec is enough to complete the extraction of the Mo-MEDSHA complex under the conditions described.

The effect of the volume ratio of the aqueous and organic phases in the next step was studied, with 10 ml of MIBK for the extraction of molybdenum from various volumes of aqueous phase containing between 10 and 40 μg of

†In the presence of 1M sodium fluoride.

molybdenum. Linear calibration graphs were obtained even when the aqueous phase volume was increased to 200 ml, which shows that 50 $\mu\text{g/l}$ molybdenum can be determined.

Calibration graph

The atomic-absorption signal was linear up to 6 $\mu\text{g/ml}$ molybdenum in the aqueous solution, and the equation for the calibration graph was $A = 0.104C + 0.006$, for C in $\mu\text{g/ml}$, with $r^2 = 0.9998$. A detection limit of 0.03 $\mu\text{g/ml}$ molybdenum was obtained^{25,28} (from ten blanks measured against MIBK), and the precision (RSD) for seven replicate determinations of 2 $\mu\text{g/ml}$ molybdenum was 1.1%.

Interference studies

A detailed study of interference effects was made for cations and anions, in amounts ranging up to $2 \times 10^4 \mu\text{g}$, with 20 μg of molybdenum. Ions were considered as not interfering, if they produced an error in absorbance

of less than twice the coefficient of variation. The tolerance limits are summarized in Table 3.

Among the ions tested, the only major interferences were from Ti(IV) and W(VI), which form bulky precipitates that adsorb or occlude the molybdenum(VI) complex. However, these interferences can be eliminated or minimized, respectively, by adding sodium fluoride before the MEDSHA.

Applications

The proposed method was applied to the determination of the molybdenum content of three certified reference steel samples and a molybdenum-deficient soil. It was also applied to the analysis of a pharmaceutical preparation and a liquid fertilizer, for which approximate molybdenum values were available.

In the samples with a molybdenum content that was not exactly known, the results were compared with those obtained by the direct Sn-SCN⁻ method.

As shown in Table 4, the proposed method shows reasonably good agreement with other values and its accuracy (certified samples) and precision are satisfactory.

CONCLUSIONS

Among the different solvent extraction methods that have been proposed for the determination of molybdenum by flame atomic-absorption spectrometry, the one based on the extraction of this element into MIBK with SCN⁻ and Sn(II),⁵ from hydrochloric acid medium, is perhaps the most useful. We propose a method that makes indirect use of this system and offers some advantages over it: it has a lower detection limit and suffers interference only from W(VI).

DETERMINATION OF COPPER AT ng LEVELS BY IN-LINE PRECONCENTRATION AND FLOW-INJECTION ANALYSIS COUPLED WITH FLAME ATOMIC-ABSORPTION SPECTROMETRY

RAJESH PUROHIT and SUREKHA DEVI*

Department of Chemistry, Faculty of Science, M.S. University of Baroda, Baroda 390002, India

(Received 2 May 1989. Revised 19 December 1990. Accepted 7 February 1991)

Summary—Oxine/formaldehyde/resorcinol and oxine/formaldehyde/hydroquinone resins have been synthesized and their physicochemical properties studied. Conditions were optimized for the preconcentration of copper by batch extraction and column chromatography with the resins. A flow-injection analysis (FIA) manifold was constructed for the determination of copper at ng levels by preconcentration on microcolumns containing the resins, stripping, and atomic-absorption spectrometry. For batch preconcentration a pH of about 2.5–3 was optimal whereas in the FIA system a broader pH range (~2–3.5) could be used. Separations of binary mixtures of Cu(II) with Ni(II) or Pb(II) at $\mu\text{g/ml}$ level did not show any cross-contamination. In the FIA, a 2 cm long column and 2 ml/min flow-rate were adequate for quantitative uptake of copper; 50 μl of 0.1M hydrochloric acid quantitatively eluted the copper.

There is a need for improved automatic/semiautomatic methods for the determination of heavy metal ions in water. Flame atomic-absorption spectrometry (AAS) lacks sensitivity in detection at $\mu\text{g/l}$. levels. Electrothermal-atomization and hydride-generation AAS *etc.* are sensitive but suffer from matrix interferences. Flow-injection analysis (FIA) has contributed¹⁻⁵ to the development of several semiautomatic methods of preconcentration and determination of metal ions. These have employed activated alumina,⁴ oxine immobilized on silica gel,^{3,6,7} Chelex 100,^{2,5} resin 122,⁶ and tri(pyridylmethyl)ethylenediamine.⁸

Chelating resins containing oxine groups are synthesized either from oxine, formaldehyde and resorcinol by condensation^{9,10} or by diazotization of a poly(aminostyrene) resin followed by coupling to oxine.¹¹ The resins have low metal-exchange capacities and slow exchange rates. Their properties were improved by Pennington and Williams¹² and by Parrish and Stevenson¹³ by controlling the water regain and the curing conditions, but the samples required storage in moist conditions. Vernon and Nyo,¹⁴ and Parrish,¹⁵ have reported that the resins are unstable in $>2M$ hydrochloric acid at room temperature. We have attempted to improve the

kinetics of metal exchange and the stabilities of the oxine-containing resins by using hydroquinone in place of resorcinol in the condensation reaction. A new synthetic route has also been established for the synthesis of oxine/resorcinol/formaldehyde resins. Both resins are useful in the semiautomatic FIA method for the determination of copper at ng levels. Conditions have been optimized for determination of copper by (i) flow injection, (ii) a batch method and (iii) column chromatography.

EXPERIMENTAL

Synthesis of resins

Oxine/formaldehyde/resorcinol (8HOQFR) resin was made by refluxing 0.1 mole of oxine in 50 ml of dimethylformamide (DMF) with 0.25 mole of formaldehyde for 20 min. A further 0.1 mole of resorcinol in 50 ml of DMF was added to the refluxing mixture. A reddish gel was formed within 10 min. Refluxing was continued for a further 30 min. The gel was collected, washed with DMF and methanol, and cured at 80° (open cure). The resin to be used for further studies was ground to 60–80 mesh size. Oxine/formaldehyde/hydroquinone (8HOQFHQ) resin could not be synthesized by this method, so a base-catalysed process was used instead. Oxine (0.1 mole) in finely powdered form was stirred into 20 ml of 2M sodium hydroxide. To this

*Author for correspondence.

suspension, 0.25 mole of formaldehyde was added with stirring and heating in a water-bath. Hydroquinone (0.1 mole) in 20 ml of 2M sodium hydroxide was added to the oxine-formaldehyde mixture with stirring. The condensation reaction was continued until a black gel was formed, and this was open cured at 80°. The 60–80 mesh resin was washed thoroughly with water, converted into H⁺-form and used for further studies.

The resins were characterized, and used for batch and column chromatographic studies of copper exchange. The optimal pH for copper uptake was found by following the literature procedure¹⁶ and the copper left in solution was determined complexometrically.¹⁷ The copper taken up by the resin was eluted and similarly determined. The rate constant and activation energy for formation of the chelate were obtained by observing the exchange kinetics at various temperatures. The mode of diffusion of metal ions through the solution towards the resin was determined by the interruption test^{16,18} and was confirmed by the method reported by Nativ *et al.*¹⁹ During the kinetics study by the interruption test the resin beads were removed from the solution for a brief period of time (10 min) and were then re-immersed. The plots of % exchange *vs.* time give the nature of diffusion of the ions.¹⁶ The efficiency of the eluents was tested by the batch method.

Chromatographic separations

Chromatographic columns, 19 cm long, i.d. 7 mm, were prepared with the synthesized resins. Binary and ternary mixtures (25 ml) of copper, cobalt, lead and nickel (each 400 µg/ml) were passed through columns of 8HOQFR and 8HOQFHQ at pH 2 or 3 and a flow-rate of 1 ml/min, followed by washing with water. The

Fig. 1. FIA manifold: 1, two-way stopcock; 2, peristaltic pump; 3, injection valve; 4, column containing resin; 5, detector (AAS).

metal ions were eluted with 3M hydrochloric acid, 0.1M hydrochloric acid, 1M acetic acid and 0.1M hydrochloric acid respectively.

Characterization of the columns

The void volume of the columns was determined by the method given by Helfferich.¹⁶ The break-through capacities and column capacities were determined as described by Inczedy.²⁰

Determination of copper at ng level

A Varian model AA 775 atomic-absorption spectrometer with a chart recorder was used for determination of copper at 324.8 nm. The operating conditions were monochromator band-pass 1 nm, lamp current 2.5 mA, sample uptake rate 1 ml/min, air pressure 39 psig, acetylene pressure 9.8 psig.

The FIA manifold was constructed as shown in Fig. 1. A Gilson Minipuls peristaltic pump was used along with a rotary injection valve (Rheodyne RH 5020). Microcolumns (4 cm long, 2 mm bore) containing an oxine resin were connected in the manifold with 0.5 mm bore Teflon tubing. Acetate solutions (0.2M) adjusted to pH 2 and 3 with a small amount of hydrochloric acid were used as carrier streams. Standard copper solutions were passed through the column at 1 ml/min flow-rate. Copper was eluted from the column by injection of 50 µl of 0.5M hydrochloric acid and determined by flame AAS. The column was further washed

with two 50 μ l injections of acid and passage of buffer solution through the system. A three-way stopcock was used to control the flow of standard solution and buffer.

RESULTS AND DISCUSSION

The physicochemical properties of the resins synthesized (8HOQFHQ and 8HOQFR) are listed in Table 1. The resins are insoluble in most organic solvents, and in acids and alkalis of higher concentrations. They are thermally stable up to 300°. The infrared spectra show a broad band at 3400–3200 cm^{-1} for polymeric —OH stretching, a sharp but weak band for the aromatic tertiary C—N vibration at 1370 cm^{-1} , a methylene group bending vibration at 1400 cm^{-1} and a stretch at 1500 cm^{-1} indicating aromaticity. A weak band at 1600 cm^{-1} indicates the presence of C=N stretching. Unlike the resins reported earlier,^{14,15} our 8HOQFR resin did not show instability in 2–4M acids, and although it had the same resorcinol/oxine/formaldehyde ratio as the earlier resins, its

water content was lower. The exchange capacity for copper was higher (1.72 mmole/g at pH 3, against¹⁴ 0.7 at pH 5). The copper capacity of our 8HOQFHQ was also high, 1.74 mmole/g at pH 3.

The $t_{1/2}$ values for exchange of Cu(II), Ni(II), Zn(II) and Pb(II) are quite low, except for Zn(II) on 8HOQFR (Table 1). Our resins also showed greater stability towards acids and faster equilibration rates than the resins reported earlier (Table 2). The interruption test¹⁶ indicated that the exchange of metal ions with these resins is governed by diffusion within the particles. The interruption gives time for the concentration gradients in the beads to level out, and in particle-controlled diffusion, the rate immediately after re-immersion is greater than that prior to the interruption. In film-controlled diffusion, there is no concentration gradient within the bead, and the diffusion rate depends on the concentration gradient in the film. The interruption does not affect the gradient and hence has no effect on the rate.

Fig. 2. Effect of pH on metal exchange (batch method): ● Cu(II), □ Ni(II), ○ Pb(II), ○ Zn(II); 0.1M metal ion.

Fig. 3. Effect of metal ion concentration on exchange capacity: ● Cu(II), □ Ni(II), ○ Pb(II), ○ Zn(II).

The effect of pH on the metal exchange capacities is shown in Fig. 2. The selectivity, based on the distribution coefficients, was observed to be $\text{Cu} > \text{Zn} > \text{Ni} > \text{Pb}$ at 0.1M metal concentration, for both the resins. The uptake of metal ions by the resins increases (Fig. 3) and the distribution coefficient decreases with increasing metal ion concentration.

For elution of the chelated metal ions, 0.1–5M acids, sodium chloride, sodium citrate, sodium tartrate, potassium thiocyanate, thiourea and 5–50% w/w perchloric acid were tested. Copper, zinc and nickel were quantitatively eluted with 3, 0.2 and 0.1M hydrochloric acid respectively, and Pb(II) with 1M acetic acid. Conditions for separations of Cu–Ni, Cu–Pb, and Cu–Ni–Co can be predicted from the pH and elution studies.

Column chromatographic separations

Mixtures (25 ml) of Cu–Ni, Cu–Pb and Cu–Ni–Co in 1:1 and 1:1:1 proportions, prepared from 400 $\mu\text{g}/\text{ml}$ metal ion solutions and adjusted to pH 3, were passed through the column at a flow-rate of 1 ml/min. The column was washed with water, then the metal ions were eluted with appropriate reagents. As shown in Fig. 4, separation of copper from nickel with 8HOQFR is incomplete, but is satisfactory with 8HOQFHQ. The kinetics in column processes is faster than for the batch process, because the resin surface is constantly coming into contact with fresh mobile phase. This also indicates that the mechanism of the column process is different from that of the batch process.

When the ternary mixture of Cu–Ni–Co is adjusted to pH 2 and passed through the column, nickel and cobalt are detected in the effluent, but copper is retained, and can then be eluted with 3M hydrochloric acid. However, if the mixture is at pH 3, the cobalt and part of the nickel pass through the column; the copper and the rest of nickel are retained on the column and can then be eluted by gradient elution. The separation shows cross-contamination to some extent. Lead and copper can be completely separated by consecutive elution with 2M acetic acid and 3M hydrochloric acid respectively.

Thermodynamics and rate of copper exchange

The rates for uptake of copper by the resins at three different temperatures were calculated from the equations for a first order reaction

$$-\frac{dc}{dt} = kc; \quad -\log(a-f) = \frac{kt}{2.303}$$

where a is the initial concentration of metal ion and f is the concentration left in solution after time t . Therefore $(a-f)$ gives the uptake of metal ion by the resin. A plot of $\log(a-f)$ vs. t gave straight lines passing through the origin, for 8HOQFR, the slopes giving the values of k . However, the plots for 8HOQFHQ were not linear, and a mirror method^{21,22} was used. The rate constant was calculated from the initial rate of the reaction, the appropriate part of the plot being identified by placing a mirror normal to the curve, and moving it until the reflection was a smooth continuation of the plot. The tangent was then drawn perpendicular to the mirror and

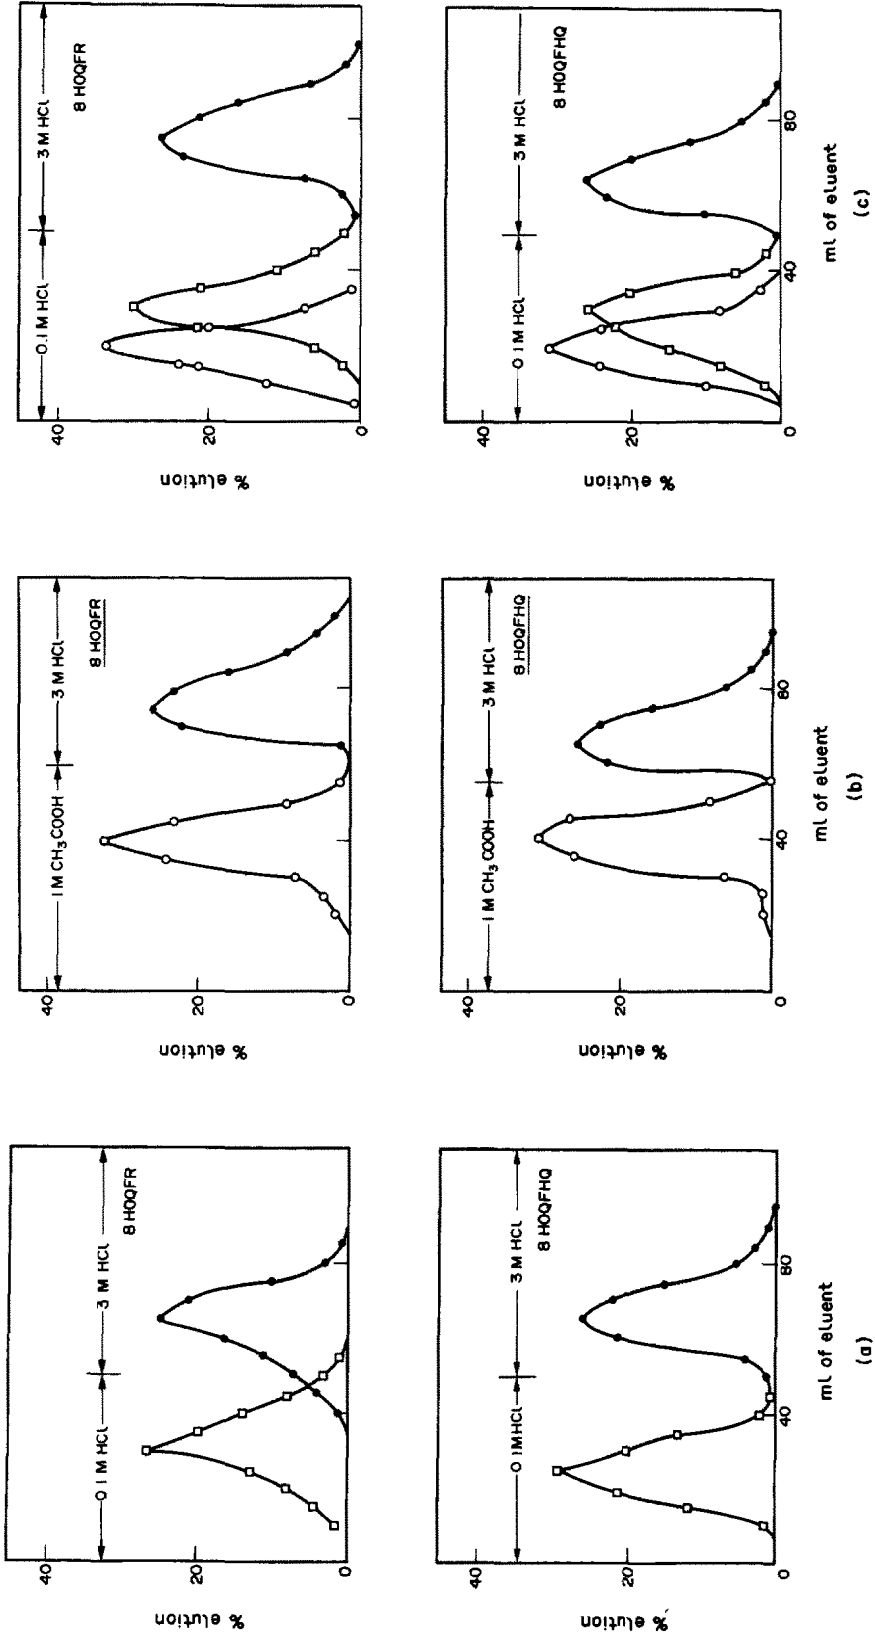

Fig. 4. Chromatographic separations. (a) ● Cu(II) and □ Ni(II), (b) ● Cu(II) and ○ Pb(II), (c) ● Cu(II), □ Ni(II) and ○ Co(II). Concentration of each metal ion in mixture, 400 μg/ml, flow-rate 1 ml/min, pH 3, total volume of mixture 25 ml.

Table 3. Rate constant and activation energy data

Temperature °C	Rate constant k , sec^{-1}	
	8HOQFR	8HOQFHQ
30	1.8	1.2
40	2.8	2.0
50	4.6	3.6
Activation energy, kcal/mole	9.15	9.86

from the slope of the line the rate constant (k) was calculated. The activation energy of complex formation was determined by using the Arrhenius equation

$$k = Ae^{-\Delta E/RT}$$

and a plot of $\log k$ vs. $1/T$ is given in Table 3. The activation energy is higher for 8HOQFHQ than for 8HOQFR, which indicates a slower exchange rate for copper on the former and is in agreement with the $t_{1/2}$ values (Table 1).

Flow-injection system

Copper at ng level was determined with the FIA manifold shown in Fig. 1. When copper was preconcentrated on the chelating-resin microcolumn by passage of 5 ml of $1 \times 10^{-7}M$ copper solution, the column effluent did not show the presence of copper when continuously analysed by AAS, indicating quantitative chelation of copper on the microcolumn. The column was then washed with buffer, and the chelated copper was eluted by injection of 50 μl of 0.5M hydrochloric acid to ensure quantitative elution. The dispersion due to the FIA system was calculated from the AAS signals for direct nebulization of a 50 $\mu\text{g}/\text{ml}$ copper solution and for 50 μl of the same solution injected into the FIA system, with and without introduction of the present microcolumn. It was found that use of the microcolumn did not affect the peak height.

Fig. 5. Effect of pH in FIA method: flow-rate 2 ml/min, column length 2 cm, Cu(II) 5 ml, $10^{-7}M$.

Fig. 6. Effect of flow-rate in FIA analysis: pH 3, column length 2 cm, Cu(II) 5 ml, $10^{-6}M$.

The dispersion was found to be 1.5. The sharp peak for the elution of copper from the microcolumn indicates faster kinetics. Continuous elution of copper with 0.5M hydrochloric acid also gives a narrow peak, of comparable height, indicating that the analyte is concentrated in a relatively narrow zone of the eluent. The dispersion of the system depends on the volume of sample injected. Conventional flame AAS gives $\mu\text{g}/\text{ml}$ detection levels whereas the FIA system with a microcolumn for preconcentration gives ng/ml levels.

The FIA system was optimized by varying the pH of the copper solution (Fig. 5). The optimum pH was lower than that for the batch system (Fig. 2). Tris, phosphate and acetate

Fig. 7. Calibration peaks: 10 ml of 20, 40, 60, 80 and 100 ng/ml Cu solution, 20 μl of 0.5M HCl injected.

buffers (0.2M) were tested as carriers in the FIA system. With phosphate buffer the system was less critically sensitive to variation in pH.

The effect of column length was studied with a carrier stream flow-rate of 2 ml/min. A 2 cm column (i.d. 2 mm) is sufficient for preconcentration. A column length greater than 6 cm increases the dispersion coefficient to ~15%. Increasing the flow-rate decreases the peak height and broadens the width of the peak (Fig. 6). A 2 ml/min flow-rate is recommended.

Elution of copper was quantitative with 20 μ l of $\geq 0.1M$ hydrochloric acid, but lower concentrations gave only 20–30% elution. To ensure complete elution 50 μ l of 0.5M acid is recommended.

A calibration graph for copper was obtained by passing 10 ml of each standard solution through the FI system and eluting the copper with 50 μ l of 0.5M hydrochloric acid. Each data point was measured in triplicate. The regression coefficients for the 8HOQFR and 8HOQFHQ plots were 0.9917 and 0.9940 respectively. The lower limit of detection, based on the copper concentration equivalent to three times the standard deviation of the blank signal for the carrier stream, was 5 ng/ml with preconcentration from 15 ml of solution.

ASCORBIC ACID AS A MATRIX MODIFIER FOR DETERMINATION OF TIN IN CONCENTRATED BORIC ACID SOLUTIONS BY ELECTROTHERMAL ATOMIC-ABSORPTION SPECTROMETRY

ANATOLY B. VOLYNSKY,* EVELINE M. SEDYKH and LIDIYA N. BANNYKH

V. I. Vernadsky Institute of Geochemistry and Analytical Chemistry, USSR Academy of Sciences, Moscow, 117975, USSR

(Received 26 February 1990. Revised 27 October 1990. Accepted 21 January 1991)

Summary—It has been found that the atomic-absorption signal for tin is reduced in the presence of 5 μ l of 0.05–0.30M boric acid at STPF-conditions. It has been proposed that the reason for the boron interferences is the formation of SnB(g) at the atomization stage. In the presence of palladium chloride the interferences from 0.2M boric acid are reduced by a factor of 1.3. The interferences are reduced most effectively when the sample is atomized from a polycrystalline graphite platform or in the presence of ascorbic acid. The interference of up to 0.2M boric acid can be suppressed and the area of the tin signal doubled. It is proposed that the observed phenomenon is connected with the bonding of boron as non-volatile B₄C. Ascorbic acid is the most effective matrix modifier for the determination of different trace elements in boron compounds.

Boron compounds at high concentrations are reported to reduce the atomic-absorption signals for Cr, Fe, Ga and other elements.^{1,2} To diminish or compensate for this, the volatilization of boron as boric acid esters,³ the method of standard additions¹ and addition of boric acid to the standard solutions² have been used. For the determination of tin in solutions prepared by fusing geological reference materials with lithium metaborate and dissolution in acid, various matrix modifiers have been used, such as an ascorbic acid/iron(III) nitrate mixture, ammonia solution, and diammonium hydrogen phosphate.⁴

To elucidate the mechanism of formation of tin ore deposits, the solubility of cassiterite in boric acid solutions at high temperatures and pressures has been studied.⁵ In development of the method of analysis of the solutions obtained, the influence of high concentrations of boric acid (up to 0.3M) on the tin determination was investigated. It was shown that ascorbic acid is the most effective matrix modifier, and a mechanism for its action has been postulated.

EXPERIMENTAL

Reagents

Analytical-grade reagents and distilled water were used. A standard tin solution was prepared by dissolving 100 mg of tin in 2.5 ml of a 1:3 v/v mixture of concentrated hydrochloric and nitric acids. The solution was diluted to 100 ml with 3M hydrochloric acid. To obtain boron and silicon solutions appropriate weights of boric acid and sodium metasilicate nonahydrate were dissolved in demineralized water. Only freshly made ascorbic acid solutions in water were used.

Apparatus

A Perkin-Elmer Zeeman/3030 atomic-absorption spectrophotometer equipped with an HGA-600 electrothermal atomizer and "Intensitron" hollow-cathode lamps was used. The analytical lines used were 286.3 nm (band-width 0.7 nm) for tin, 249.7 nm (band-width 0.7 nm) for boron and 251.6 nm (band-width 0.2 nm) for silicon. The sample solutions (5 or 10 μ l) were injected manually. Pyrolytic graphite platforms (Perkin-Elmer) and platforms home-made from polycrystalline graphite MPG-6 (USSR) were used. Graphite tubes without pyrolytic graphite coating were used as a rule.

*Present address: Laboratory of Organic Analysis, Department of Chemistry, Moscow State University, 119899, Moscow, USSR.

Fig. 1. Effect of boric acid on tin determination in the graphite tube with pyrolytic graphite coating (1) and without coating (2-5). 1, 2, Evaporation from the wall; 3, evaporation from the pyrolytic graphite platform; 4, evaporation from the pyrolytic graphite platform in the presence of 50 mg/ml solution of ascorbic acid; 5, evaporation from the polycrystalline graphite platform.

Procedure

For study of the matrix interferences 10 μ l of 0.15 μ g/ml tin solution in 0.5M hydrochloric acid, and 5 μ l of boric acid solution and/or modifier solution were successively injected into the atomizer. The temperature/time programme optimized for tin determination in the presence of 0.2M boric acid (atomization from the pyrolytic graphite platform) was: drying, temperature 120°/ramp time 5 sec/hold time 25 sec; ashing, 750°/5 sec/15 sec; atomization, 2200°/0

sec/3 sec (gas-stop mode); cleaning, 2600°/1 sec/2 sec. The same temperature/time programme was used for tin determination without the graphite platform, and for the determination of silicon. The temperature/time programme for boron determination (atomization from the wall of a graphite tube with pyrolytic graphite coating) was: drying, 110°/5 sec/25 sec; ashing, 400°/5 sec/12 sec; atomization, 2750°/0 sec/3 sec (gas-stop mode); cleaning, 2800°/1 sec/2 sec.

RESULTS AND DISCUSSION

Tin determination in pure solutions

The lowest response in tin determination in 0.5M hydrochloric acid is observed for atomization of the sample from the wall of a graphite tube with pyrolytic graphite coating. A higher signal is obtained with the graphite tube without coating (Fig. 1), since the partial pressure of free oxygen (p_{O_2}) in the atomizer gas phase is lower because the chemical activity of the polycrystalline graphite is higher than that of the pyrolytic graphite.^{6,7}

The signal is also increased when the sample is atomized from the platform (Fig. 1), owing to the shift of the signal to higher temperatures, where p_{O_2} is minimal. The platform material influences the tin signal area negligibly, but markedly affects the shapes of the signals (Fig. 2a). When

Fig. 2. Signals for tin (1.5 ng) in the absence of the matrix (a) and in the presence of 0.2M H_3BO_3 (b). 1, Evaporation from the polycrystalline graphite platform; 2-4, evaporation from the pyrolytic graphite platform; 3, in the presence of 50 mg/ml solution of ascorbic acid; 4, in the presence of 1 μ g of palladium.

the polycrystalline graphite platform is used, the tin signal appears at higher temperatures. The reason for this is that the tendency of tin to form lamellar compounds with graphite⁸ is reduced when pyrolytic graphite is used, owing to the relatively low chemical activity and smaller specific surface area of this material.

When tin is atomized from the pyrolytic graphite platform in the presence of ascorbic acid the appearance time of the signal significantly increases (Fig. 2). In this case the amorphous carbon formed as a result of thermal decomposition of the ascorbic acid may favour formation of the lamellar compounds. According to the signal shapes (Fig. 2a) the thermal stability of these compounds is lower than that of palladium-tin alloys and the corresponding intermetallic compounds formed when palladium is used as the matrix modifier.⁹

Tin determination in the presence of boric acid

The mutual solubility of tin oxides and boron oxides is very low; the corresponding chemical compounds are not formed.¹⁰ In our experiments the shape of the curves for tin signal *vs.* ashing temperature (Fig. 3) and *vs.* atomization temperature is not changed significantly by the presence of boric acid, and boric acid also does not greatly influence the appearance times of the tin signals (Fig. 2b). Hence atomization of the tin depends only slightly on the interaction of boric acid and tin compounds on the atomizer surface. The most likely causes of suppression of the tin signals in the presence of boric acid are the gas-phase processes. This assumption is corroborated by the decrease in interference when the sample is atomized from the graphite

Fig. 3. Effect of the ashing temperature on signal for tin (1.5 ng); evaporation from the pyrolytic graphite platform. 1, Tin solution in 0.5M HCl; 2-4, determination in the presence of 0.2M H₃BO₃; 3, in the presence of 50 mg/ml solution of ascorbic acid; 4, in the presence of 1 μg of palladium.

platform. The dissociation of the molecules in the gas phase is more complete in this atomizer.¹¹

The interferences from boric acid are lower if the analyte is atomized from the polycrystalline graphite platform (Fig. 1), but such platforms are not commercially produced and have relatively short lifetimes. All other experiments were done with the pyrolytic graphite platforms. Atomization of the sample from these platforms in the absence of the matrix modifier does not effectively suppress the influence of boric acid (Fig. 1).

According to Havezov¹² the molecular absorption lines for BO are split in the magnetic field and may overlap with the analytical lines of tin, but in our experiments (atomization from the graphite platform, $\lambda = 286.3$ nm, bandwidth 0.7 nm) the signals from solutions of boric acid did not differ from the background.

Comparison of different matrix modifiers

The influence of the atomization temperature on the tin signal in the presence of 0.2M boric acid and 1 μg of palladium was studied. Increase in the atomization temperature to >2200° increases the peak height but has practically no effect on the peak area, so an atomization temperature of 2200° is recommended when palladium is used as matrix modifier. For the maximal effectivity of this matrix modifier the palladium solution is added to the platform, then dried and ashed at 750° for 15 sec. The temperature/time programme is then interrupted, the solutions of tin and boron are added to the atomizer, and the programme is restarted.¹³ We do not use a mixture of the solutions of ascorbic acid and palladium as was used previously,¹³ since in that case a significant complication of the processes in the graphite furnace is possible because of the interaction of the reductant and/or its thermal decomposition products with the analyte.

In the presence of boric acid and palladium the maximum ashing temperature is increased and the tin signal shifts to higher temperature (Figs. 2b and 3). Hence boric acid does not interfere in the formation of the tin-palladium compounds⁹ on the atomizer surface, but palladium does not eliminate the boron interferences completely (Fig. 3).

Some water-soluble organic compounds have also been studied as matrix modifiers. When 5 μl of 0.2M boric acid is used, the tin peak area is increased by 20, 20 or 10% if 5 μl of a 50

mg/ml solution of glucose, oxalic or citric acids respectively is also used. Under these conditions the presence of ascorbic acid (5 μ l of a 50 mg/ml solution) more than doubles the tin peak area. This quantity of ascorbic acid is optimal: increasing the concentration and/or the volume used causes rapid build-up of carbon-rich residue on the platform, which sharply decreases the reproducibility of the determination. The relative standard deviation of tin determination (10 μ l of a 0.15 μ g/ml solution) in the presence of 5 μ l of 0.2M boric acid solution is 7.8% ($n = 8$, $P = 0.95$). In the presence of ascorbic acid the reproducibility is improved to 5.0% ($n = 7$, $P = 0.95$). The corresponding value for a pure tin solution is 4.3%. This method was used for the determination of 0.005–0.100 μ g/ml tin in 0.002–0.2M boric acid solutions.⁵

Proposed mechanism of ascorbic acid action

The most probable reason for the decrease of the tin signal in the presence of boron compounds is the formation of SnB(g). The equilibrium $\text{Sn(g)} + \text{B(g)} \rightleftharpoons \text{SnB(g)}$ is defined partly by the quantity of boron in the graphite furnace and partly by the degree of boron atomization at the atomization stage.

It is known that in the presence of ascorbic acid the concentrations of carbon monoxide and hydrogen significantly increase in the ETA gas phase at 100–1200 $^{\circ}$,¹⁴ but the formation of boranes B_xH_y ,¹⁵ which would remove boron from the graphite furnace at the ashing step, is also slightly possible under such conditions. The sensitivity of boron determination is increased

Fig. 4. Effect of 10 μ l of ascorbic acid solution on the signal for boron (1 μ g). 1, Integrated signal, absorbance·sec; 2, absorbance.

Fig. 5. Effect of ascorbic acid on determination of tin (1.5 ng) in the presence of 0.2M H_3BO_3 .

in the presence of ascorbic acid (Fig. 4), which confirms the data of Goyal *et al.*¹⁶ It is known that the concentration of B(g) increases with decrease in the free oxygen concentration in the gas phase of the graphite furnace.¹⁷ In the presence of ascorbic acid p_{O_2} decreases as a result of the interaction of oxygen with amorphous carbon.⁷

At a relatively low tin atomization temperature (2200 $^{\circ}$) boron may exist in the graphite furnace as $\text{B}_4\text{C(s)}$ and B(g); formation of BO(g) is also possible.¹⁷ Evidently, the formation of $\text{B}_4\text{C(s)}$ will favour reduction of the negative boron interferences. The tin signal obtained in the presence of boric acid increases in proportion to the ascorbic acid concentration in the solution (Fig. 5). Apparently, in the presence of the chemically active carbon formed as a result of the thermal decomposition of ascorbic acid, the kinetics of $\text{B}_4\text{C(s)}$ formation is improved. When the polycrystalline graphite platform is used, boron is more effectively bound as $\text{B}_4\text{C(s)}$ because the chemical activity of this graphite is higher than that of pyrolytic graphite.

We could not check experimentally the hypothesis concerning the decrease of B(g) concentration in the presence of ascorbic acid at the atomization temperature of tin (2200 $^{\circ}$), because of the low sensitivity of boron determination at this temperature. However, it is well-known that the behaviour of silicon in the graphite furnace is to a large extent analogous to the behaviour of boron. At high temperatures silicon is also susceptible to the formation of carbide $\text{SiC}_2\text{(g)}$ and oxide SiO(g) .¹⁸ The sensitivity of silicon determination by ETAAS is significantly higher than that for boron. Under the conditions of tin determination the silicon signal decreases with increasing ascorbic acid concentration (Fig. 6). We propose that the concentration of free boron atoms in the gas phase in the graphite tube at 2200 $^{\circ}$ also decreases in the presence of ascorbic

Fig. 6. Effect of 10 μ l of ascorbic acid solution on the signal for silicon (40 ng); evaporation from the pyrolytic graphite platform.

acid. Silicon by itself, up to a concentration of 0.2M, does not influence the tin signal.

CONCLUSION

The most effective matrix modifier for the ETAAS determination of tin in the presence of high concentrations of boric acid is ascorbic acid. The amorphous carbon formed as a result of thermal destruction of ascorbic acid favours the bonding of boron in $B_4C(s)$, which is rather stable at the atomization temperature of tin (2200°). On the basis of the data obtained, ascorbic acid may be recommended as matrix modifier for the determination of other elements as impurities in the presence of high concentrations of boron compounds. Palladium chloride is less effective as the modifier in this case.

(Received 8 January 1991. Accepted 14 January 1991)

Summary—A method is presented for the determination of 2–10M nitric acid based on the fact that the presence of high nitric acid concentration causes an enhancement of the intensity of some bands in the fluorescence spectra of rare earth ions in solution. The 616-nm band of Eu^{3+} shows the most dramatic intensity enhancement with increasing nitric acid concentration. The present method, based on the measurement of the ratio of Eu^{3+} fluorescent band intensities is shown to be independent of Eu^{3+} concentration and relatively free of interference. This robust method allows the presence of an interferent to be determined from the experimental data.

There are a number of processing environments that require a high nitric acid concentration for proper operation. Perhaps the most significant of these is in nuclear fuel reprocessing where the free acid content must be determined to ensure that the fuel samples are appropriately decontaminated or that loss of recoverable fuel is minimized.¹⁻³ Further, the free acid content must be known to enable the waste solutions to be appropriately neutralized before disposal.

In a review of the methods which may be used to measure nitric acid concentrations, Gallagher and Johnson⁴ presented the requirements for a successful measurement technique and critiqued the potential methods. The requirements for successful determination of the mineral acid concentration of nuclear processing streams are rather severe. First, the method has to measure acid concentrations with a precision of $\pm 5\%$ over the concentration range 1–10M. The method must be able to operate in the presence of heavy metal salts, and the processing environment can be rather harsh. This is especially true of a nuclear fuel reprocessing environment where corrosivity and high levels of radiation must be expected. Thus, any method that can operate with all major pieces of equipment and all electronic components remote to the actual measurement site will be desirable. Spectroscopic methods have the potential of utilizing optical fibers to enable isolation of all instrumentation from the measurement site and are thus worthy of investigation.

We propose here a method of measurement of high nitric acid concentrations based on a fluorescence process. The measurement depends on the enhancement of a hypersensitive transition of Eu^{3+} owing to the formation of an inner-sphere co-ordination complex with nitrate ion in highly acidic solutions. This method potentially meets all the requirements of a method capable of determining nitric acid concentration over the concentration range of interest in a harsh processing environment. The Eu^{3+} probe must be present or added to the solution but the Eu^{3+} concentration does not affect the measurement.

EXPERIMENTAL

Instrumentation

Fluorescence measurements were carried out with an LS-5 Luminescence Spectrometer (Perkin-Elmer) with quartz cells (1 cm, Fisher). Instrument settings and data acquisition were carried out through an RS-232C interface between the LS-5 and a Zenith 159 microcomputer. Fluorescence spectra and intensity *vs.* concentration data were acquired with software developed in-house for these experiments. Fluorescence spectra were obtained with the following instrument parameters: excitation/emission slit apertures set to nominal 10/5 nm bandpass; scan speed, 120 nm/min; RC filter response, 4; excitation wavelengths (5–7), $\text{Eu}^{3+}/392$ nm, $\text{Sm}^{3+}/402$ nm, $\text{Dy}^{3+}/350$ nm and $\text{Tb}^{3+}/372$ nm. Spectral data were acquired every 0.5 nm. Intensity *vs.* concentration data were obtained at the

*Author for correspondence.

same excitation wavelengths. In these experiments, excitation/emission slits were set at a nominal 10-nm bandpass, and the RC filter response had a value of 4. Software used in these experiments acquired 250 data points at fixed emission/excitation wavelengths, the data were averaged, and the standard deviation was obtained. Final intensity data were obtained by subtracting the blank from the analyte signal, and the standard deviation was determined by error propagation.⁸

Chemicals and solutions

All reagents (ACS reagent grade) were used as obtained. Lanthanum(III) oxides and the disodium salt of EDTA were purchased from Alfa Products. Acetic acid, sodium acetate, nitric acid, sulfuric acid and hydrochloric acid were obtained from Fisher. Xylenol Orange (95% dye) and sodium carbonate were purchased from Aldrich.

All solutions were prepared from triply-distilled water passed through cation exchange, anion exchange and activated carbon columns. Lanthanum(III) 0.01M stock solutions were prepared by dissolving the corresponding oxide in the minimum amount of 20% (v/v) hydrochloric acid. Excess of acid was removed by evaporation and the remaining chloride salt was then dissolved in the required amount of water. Lanthanum(III) stock solutions were standardized versus EDTA (0.01M) in an acetate buffer medium with Xylenol Orange as indicator.⁹ Stock solutions of acid (12.5M) were prepared by diluting the appropriate amount of con-

centrated acid to one liter with water. Fresh solutions were made weekly. Nitric acid stock solutions were standardized by titration against sodium carbonate with Bromocresol Green as indicator.

Procedure

Blank solutions consisted of purified water for all measurements. The solutions of different Ln^{3+} /acid ratios were prepared by mixing appropriate amounts of the corresponding stock solutions and diluting to a volume of 50 ml with water. All solutions were allowed to stand for a period of at least one hour to reach room temperature and ensure complexation, and were then filtered through a sintered glass filter prior to use. The quartz cell was always kept in place inside the cell container of the LS-5 to avoid any errors caused by changing the cell walls facing the emission and/or excitation monochromators. Before any new solution was placed in the cell, the cell was thoroughly rinsed with water and the new solution with a micropipette.

RESULTS AND DISCUSSION

There are several bands in the fluorescence spectrum of aqueous Eu^{3+} when the solution is excited at 394 nm. Of these, the most intense bands are those observed at 591, 616 and 694 nm.^{5,6} The emission bands at 616 nm ($^5\text{D}_0 \rightarrow ^7\text{F}_2$, $\Delta J = 2$) and 694 nm ($^5\text{D}_0 \rightarrow ^7\text{F}_4$, $\Delta J = 4$) are "forbidden" according to the Laporte selection rule. This accounts for their low emission intensity when compared to that of

Fig. 1. Fluorescence spectra of Eu^{3+} ions in solutions of varying nitric acid concentration. A: 10M HNO_3 . B: 5.0M HNO_3 . C: Triply distilled water.

the "allowed" 591 nm ($^5D_0 \rightarrow ^7F_1$, $\Delta J = 1$) band.¹⁰ The 616 nm band has been designated as a "Hypersensitive Transition" (HT).⁶ This term conveys the effect of the environment surrounding the ion has on the emission intensity of this band.¹⁰ HT or $\Delta J = 2$ transitions have also been observed in the fluorescence emission spectra of other lanthanides in aqueous media such as Sm^{3+} (640 nm, $^4G_{5/2} \rightarrow ^6H_{9/2}$), Tb^{3+} (491 nm, $^5D_4 \rightarrow ^7F_6$) and Dy^{3+} (577 nm, $^4F_{9/2} \rightarrow ^6H_{13/2}$).⁵

Shown in Fig. 1 are the fluorescence emission spectra of aqueous Eu^{3+} ions in water (C), 5M nitric acid (B) and 10M nitric acid (A). The HT at 616 nm shows a six-fold increase when the solvent is changed from water to 10M nitric acid. This enhancement has been extensively discussed in the literature¹⁰⁻¹⁵ and is generally attributed to the inner sphere complexation of the nitrate ion with Eu^{3+} . In a study of the fluorescence behavior of the $\text{Eu}^{3+}/\text{HNO}_3$ system, Piriou and Svoronos¹³ suggested that the composition of the aquanitrate complex of Eu^{3+} has the formula $[\text{Eu}(\text{NO}_3)_m(\text{H}_2\text{O})_n]^{(3-m)+}$ where the value of m is dependent upon the concentration of nitric acid. This dependence might suggest that the intensity of the HT is a direct function of the number of NO_3^- ions complexed with Eu^{3+} . When compared to the HT transition, the other Eu^{3+} transitions do not show dramatic intensity shifts with changes in nitric acid concentration. The 591 and 694 nm bands show only a slight increase in intensity *ca.* 5%, when the solvent changes from water to 10M nitric acid. This slight intensity change was previously reported by Gallagher¹⁰ and is attributed to a near-linear increase in the observed fluorescence lifetime of the 5D_0 state due to $\text{Eu}^{3+}/\text{NO}_3^-$ complexation. Although a small shift in the wavelength of maximum intensity is observed in the band between 680 and 705 nm, the strongest emission remains at 694 ± 2 nm in nitric acid concentrations above 2M.

Fig. 2. Intensity of the Eu^{3+} ion bands as a function of nitric acid concentration. A: 616 nm. B: 591 nm. C: 694 nm.

As mentioned above, the fluorescence emission spectra of Sm^{3+} , Tb^{3+} and Dy^{3+} also contain HT bands. Complementary fluorescence studies of these ions in the 1–10M nitric acid range have shown that, like Eu^{3+} , an increase in the intensity of the respective HT is observed. However, unlike Eu^{3+} , the $\Delta J = 1$ bands of these ions (Sm^{3+} , 596 nm; Tb^{3+} , 479 nm and Dy^{3+} , 479 nm) show a considerable increase in intensity as well. The fact that the $\Delta J = 1$ transition of Eu^{3+} stays relatively constant presents the possibility of using it as an "internal standard."

A plot of emission intensity versus nitric acid concentration of the 591, 616 and 694-nm Eu^{3+} bands is shown in Fig. 2. The intensity of the 616-nm band increases linearly with nitric acid concentration over the range 2–10M. As discussed above, the bands at 591 and 694 nm increase only slightly with nitric acid concentration, $\sim 5\%$. All three plots in Fig. 2 are linear at nitric acid concentrations above 2M. The features illustrated in Fig. 2 allow for the development of a technique to measure high nitric acid concentrations based on Eu^{3+} ion fluorescence. We have used various spectral features to investigate the calibration of nitric acid concentration: (I) the intensity of the band at 616 nm; (II) the ratio of the intensity of the band at 616 nm to the intensity of the band at 591 nm; (III) the ratio of the intensity of the band at 616 nm to the intensity of the band at 694 nm and (IV) the ratio of the intensity of the band at 616 nm band to the intensity of the band at 591 nm minus the intensity of the band at 694 nm.

For the method to be useful, the measurement should not depend upon the concentration of Eu^{3+} and should be insensitive to the presence of potential interferents. As would be expected, the intensity of any individual band is directly proportional to the Eu^{3+} concentration. The use of a ratio of intensities should result in a measurement that does not depend upon the Eu^{3+} concentration. This is analogous to the use of an internal standard. Further, many potential interferents would be expected to affect the entire Eu^{3+} spectrum, thus the ratio of peak intensities should be constant. The various calibration procedures have been tested under varying conditions, and the results of these tests are outlined below.

Although the intensity of the Eu^{3+} band at 616 nm varies dramatically with the nitric acid concentration, results obtained by using the

Fig. 3. Intensity ratios as a function of nitric acid concentration. A. I_{616}/I_{694} . B. I_{616}/I_{591} .

intensity of this band as a measure of nitric acid concentration proved highly unreliable. The band intensity varies significantly with excitation intensity fluctuations, the presence of particulate matter and the presence of other metals. The use of ratios of Eu^{3+} band intensities results in freedom from most of these effects (Fig. 3). All three ratios produce linear plots over the range 2–10M nitric acid. The plots of $I_{616}/(I_{591} - I_{694})$ and I_{616}/I_{694} vs. nitric acid concentration are nearly identical and somewhat more sensitive than that of I_{616}/I_{591} vs. nitric acid concentration. All data discussed above were obtained with a Eu^{3+} concentration of 150 ppm. Figure 4 shows the plots of the I_{616}/I_{694} intensity ratios at 0, 2.5, 5.0, 7.5 and 10M nitric acid as a function of Eu^{3+} concentration over the range 50–250 ppm. The ratio remains constant between 100 and 250 ppm Eu^{3+} . Europium(III) concentrations below 100 ppm show a slight decrease in the intensity ratio. Although not shown here, the plot of I_{616}/I_{591} vs. Eu^{3+} concentration follows the same trend as that of Fig. 4. These data suggest that the concentration of the Eu^{3+} ion employed in the fluorescence determination of nitric acid can be in the range 150–250 ppm Eu^{3+} , but the exact concentration of Eu^{3+} is not important.

Fig. 4. Plot of the intensity ratio, I_{616}/I_{694} , versus Eu^{3+} concentration for various nitric acid concentrations.

Table 1. Concentration of nitric acid as determined from the Eu^{3+} probe fluorescence. The nitric acid concentration was 6.20M in all solutions. The concomitants were all present at 150 ppm, except as noted

Solution	Nitric acid concentration, M		
	I_{616}	I_{616}/I_{591}	I_{616}/I_{694}
Water	6.26 ± 0.07	6.06 ± 0.03	6.26 ± 0.06
SM	6.33 ± 0.07	5.78 ± 0.03	6.09 ± 0.07
Tb	6.23 ± 0.07	6.30 ± 0.03	6.13 ± 0.07
Dy	6.25 ± 0.07	6.01 ± 0.03	6.08 ± 0.08
SM/Tb/Dy	6.40 ± 0.07	5.57 ± 0.03	6.10 ± 0.08
Al	6.28 ± 0.07	6.33 ± 0.03	6.20 ± 0.08
Fe (50 ppm)	4.32 ± 0.11	6.55 ± 0.03	6.62 ± 0.06
Fe	2.15 ± 0.19	6.39 ± 0.03	6.77 ± 0.06
Al/Fe	2.15 ± 0.19	6.44 ± 0.03	6.00 ± 0.06
UO_2^{2+} (560 ppm)	6.41 ± 0.03	4.92 ± 0.02	6.05 ± 0.03
Ru (Satd. RuCl_3)	1.09 ± 0.02	6.62 ± 0.02	5.93 ± 0.03

As stated above the method must be relatively insensitive to the presence of other metals to be generally useful. This point was tested by preparing a set of test solutions containing 150 ppm Eu^{3+} , 6.20M nitric acid and a selection of potential interferents. The rare earth ions were tested because they have fluorescent properties similar to Eu^{3+} , their fluorescence spectra are affected by nitric acid and they are present in raffinate solutions.¹⁶ Iron(III) and Al^{3+} have been found to interfere in other nitric acid determinations due to hydrolysis,^{2,3} but the interference is only noted at concentrations higher than those typically found in raffinate solutions.

The results of the interference studies are summarized in Table 1. All determinations are made by comparing the data obtained in these studies to calibration data obtained in pure water (i.e., the data presented in Fig. 3). The standard deviations included in the Table are the result of three or more independent determinations of each solution. The differences in the results for pure water and the expected results represent day-to-day variations and changing the cell.

As can be seen from the data presented in Table 1, the most significant interference appears to be the presence of Fe^{3+} in the sample solution. The Eu^{3+} fluorescence is quenched by Fe^{3+} , hence the large error in the nitric acid measurement based solely on the intensity of the band at 616 nm. However, the Eu^{3+} fluorescence is uniformly quenched, and the results based on ratio determinations remain fairly accurate. Using a desired accuracy of 5% (the ratio of determinations), suitable results are produced when Fe^{3+} is present when using the intensity of the band at 616 nm divided by the

intensity of the band at 591 nm. The alternative ratio, I_{616}/I_{694} , produces results that are approximately 9% high when Fe^{3+} is present.

The presence of both UO_2^{2+} and Ru^{3+} had an effect on the measurement. When present at 150 ppm UO_2^{2+} caused little interference but at 560 ppm (selected as this was a concentration measured in a raffinate solution¹⁶) it did affect the I_{616}/I_{591} ratio. Ru^{3+} causes a significant baseline shift. A baseline subtraction (linear baseline) yielded the results in Table 1.

The data in Table 1 show that there is obviously some interference due to Sm^{3+} . We believe this to be a spectral interference as Sm^{3+} has a broad excitation peak centered at 402 nm. This peak certainly overlaps the excitation band, centered at 396 nm used to excite the Eu^{3+} fluorescence. Samarium(III) has an emission band at 596 nm that is enhanced by high nitric acid concentration. This band contributes some intensity to the measurement made at 591 nm, and the I_{616}/I_{591} ratio is lowered. Thus, the result of the nitric acid determination with I_{616}/I_{591} is 6.7% too low. There is no Sm^{3+} emission near the Eu^{3+} band at 694 nm and thus the ratio I_{616}/I_{694} produces acceptable results when Sm^{3+} is present.

In one set of experiments, the solutions were run without filtering. A new set of plastic bottles were used to store the solutions, and the bottles were either not washed properly or the high nitric acid concentrations contributed to some reaction with the vessel walls, so that the solutions had significant particle concentrations. The particle suspensions were easily visible and caused a noticeable increase in scattering. The fluorescence spectra of these solutions were measured and compared to the calibration data. The scattering produced by these solutions were manifest by an increase in background signal, especially at low wavelengths. At the low wavelength end, 525 nm, the background signal was increased by 50% compared to filtered solutions, whereas the high wavelength end was increased only slightly. The nitric acid concentrations, as determined from the I_{616}/I_{591} ratio, were identical to those determined with filtered solutions within the deviations seen in Table 1. The I_{616}/I_{694} ratio produced results that were consistently low, ~10%, when compared to the filtered results. The fact that the I_{616}/I_{591} ratio is unaffected by the presence of particulates is explained by the observation that the background increases nearly identically at 616 nm and 591 nm when particulates are present. Thus,

the method can be used without interference from particulate matter when the I_{616}/I_{591} ratio is used.

CONCLUSION

The Eu^{3+} probe method presented here produces results (<5% error) for the determination of high nitric acid concentrations for most situations tested. The method is not ideal in that the probe, the Eu^{3+} , must be added or be present in the analyte solution. While the addition of a reagent is easily accomplished in a laboratory setting, it might not be so straightforward in a processing environment. However, the fact that the Eu^{3+} concentration can vary significantly and not affect the measurement accuracy somewhat alleviates this constraint. Further, the fact that the measurement can be made with a fiber optic system to separate the measurement instrumentation from the sample site might be a real advantage in some situations.

A totally interference-free measurement would be highly desirable. The results presented here were based on the measurement of the fluorescent intensity at three fixed wavelengths. In the case of the Sm^{3+} interference (*i.e.*, one that is spectral), it is highly likely that the interference could be allowed for by utilizing more of the spectral information available. This would be accomplished at some expense in instrumentation relative to the simplest systems envisioned for a fixed three wavelength measurement.

The data in Table 1 clearly shows that the use of an internal standard, *i.e.*, the Eu^{3+} fluorescence at 591 or 694 nm, makes the measurement much less susceptible to interferents. The I_{616}/I_{694} ratio in general produces somewhat better results than does the I_{616}/I_{591} data. The only significant deviation is produced by high Fe^{3+} concentration, a 9.1% error. Again, use of more of the spectral data might diminish the effects of Fe^{3+} on the measurement.

An important point that can be seen in the data presented here is that an interference is noted when the three measurement results do not agree. Thus, the method produces the correct result, or in the situation where an interferent is present, the potential failure of the method is indicated by the lack of agreement of the various calibration methods.

It might be possible to immobilize the Eu^{3+} probe in a manner that would still allow the

required nitrate ion interaction to produce the intensity enhancement of the band at 616 nm. If this were possible, the complication of adding the probe ion to the analyte solution would be eliminated. The measurement could then be accomplished by placing a fiber optic probe with the immobilized reagent into the process stream or sample whose nitric acid concentration was to be determined.

COMPARISONS OF INTEGRATION *vs.* RATE MEASUREMENTS FOR OXIDASE ENZYMATIC ANALYSES

LAWRENCE C. THOMAS* and RASHID AL OTHMAN

Department of Chemistry, Seattle University, Seattle, Washington 98122, U.S.A.

(Received 6 June 1990. Revised 31 October 1990. Accepted 4 November 1990)

Summary—Results obtained by integration of net indicator-substance signals during the progress of a reaction are compared to those concurrently achieved by rate estimation with the time *vs.* signal data, for glucose oxidase assays and enzymatic glucose determinations. Computer-simulated integration results typically exhibit data quality superior to that of rate measurements, for the entire very wide ranges of oxidase activities and concentrations studied. Only at extreme instrument-noise levels and low analyte values did any of the rate procedures (the variable-time method) show some advantage over integration. The data quality, expressed as relative uncertainties, of the simulated results obtained by use of the integration method was typically up to 120 times better than that obtained by rate methods, with greater enhancement at higher enzyme activities or substrate concentrations. Experimental results spanning physiological concentrations showed similar trends, but the advantage was not as great as that shown in the simulations.

Integration of the net indicator-substance response over a specified time interval can be used for kinetic analyses.¹⁻⁷ Other methods of kinetic analysis include rate-estimation⁸⁻¹⁰ and curve-fitting.¹⁰⁻¹³ Some of the rate-estimation methods employ integration of signals over two time intervals, which can be consecutive¹⁴⁻¹⁶ or separated by a delay interval.¹⁴ The difference between the two integrals (which are equivalent to time-averaged responses) can then be used to mimic the two-point differential methods. The curve-fitting methods calculate the "best-fit" to response *vs.* data. The curve is then either compared with a well-known set of data to establish analytical results,¹⁰⁻¹² or is extrapolated to predict a value such as an equilibrium concentration.^{10,13}

Integration over an interval has distinct advantages over the methods based on rate estimation by the fixed-time, variable-time and continuous derivative methods.⁸ Often, a limiting requirement for rate measurements is that changes in transducer response should be directly proportional to time during the measurement interval. Differential methods are usually used with zero-order, first-order or pseudo first-order reactions, but only seldom with second- and higher-order reactions, and may sometimes be mistakenly used in cases for which their theoretical basis is not met

or is otherwise invalid. Thus, rate-estimating methods are sometimes beset with difficulties which cause determinate errors or excessive uncertainties,^{9,14-16} or are restricted to only a narrow range of conditions.

The integration method sums a large number of data over a fairly long period and thereby reduces the relative noise, by signal averaging. This may result in better detection limits, sensitivity, precision and accuracy.⁷ Also, the integration method may often be used for complicated reactions for which rate estimates may fail, *e.g.*, those showing maxima, minima or inflections.^{3,7} Moreover, it does not require well-known kinetic data^{1,3} nor does it require calculations to be made after the experimental run is completed.⁷

In this study, the integration method is directly compared with the fixed-time, variable-time and continuous derivative methods, by use of identical time *vs.* response data from oxygen-consuming enzymatic reactions. Replicate results for the various methods are collected for many variations of the main parameters. These data are characterized statistically as relative uncertainties and compared for the variations explored.

EXPERIMENTAL

Reagents

For laboratory comparisons, enzyme solutions were made from glucose oxidase (130

*Author for correspondence.

I.U./mg) purchased from Sigma Biochemical Co. Buffered solutions (0.1M phosphate, pH 5.5) were prepared with reagent grade chemicals, including *d*-glucose. Distilled water was used for all dilutions.

mole l⁻¹.min⁻¹. No oxygen-consuming or oxygen-depleting interferences were considered in this theoretical work. The enzymatic rate of reaction was assumed to be directly proportional to the concentration of glucose:

$$\left(\frac{dC_{O_2}}{dt}\right)_{\text{overall}} = \frac{-\text{const. [G.O.A.][Glucose]}(1 - 10^3 [H_2O_2])(C_{O_2,eq} - C_{O_2,t})}{C_{O_2,eq}}$$

Instrumentation

The amperometry cell for reactions was an open 30-ml beaker with a 1-cm Teflon-coated magnetic stirring bar and an immersed Beckman oxygen sensor. The electrode system was monitored by a Princeton Applied Research (PAR) 174 potentiostat with the working electrode maintained at -0.55 V *vs.* an Ag/AgCl reference electrode. A typical current from the sensor was 16 nA for solution at equilibrium with air, with white noise approximating 0.15 nA. The beaker was set on a 2-cm thick styrofoam insulator above a magnetic stirring motor.

For theoretical mathematical modeling, an Epon Equity II+ computer was used. Computer programs were written with Microsoft's QuickBasic 4.0 (listings available from the senior author on request).

Procedures

Theoretically-derived current *vs.* time relations were calculated with mathematical models and kinetic data from other work.¹⁶⁻¹⁸ The sensitivity of the amperometric response to oxygen was assumed to be 10⁵ nA.l.mole⁻¹, yielding a current of 25 nA at 2.5 × 10⁻⁴M equilibrium oxygen concentration when a stirred analysis solution with a volume of 1.0 ml was used. On the basis of the oxygen-electrode performance, the constant white noise was assigned a standard deviation of 0.01 nA and the proportional white noise a standard deviation of 0.001*i*_t*n* where *i*_t is the measured current (in nA) and *n* is selected from the set *n* = 1.00, 1.78, 3.16, 5.624, 10, 17.8, 32.6, 56.24 and 100.

Inhibition by peroxide was assumed to diminish the initial glucose oxidase activity (G.O.A.) by 0.1*x*% where *x* is the hydrogen peroxide concentration in μmole/l. Incorporation of oxygen from the atmosphere by the stirring and diffusion (SD) was assumed to be proportional to the degree of oxygen depletion of the test solution,³ and its rate was taken as (dC_{O₂}/d*t*)_{SD} = 0.01 (C_{O₂,eq} - C_{O₂,t})/(C_{O₂,eq})

where [H₂O₂] is in μmole/l. and the constant includes the factor 0.01 from the equation for the rate of incorporation of oxygen from the atmosphere.

For glucose determinations, the G.O.A. concentration used was 10⁻¹¹ I.U./l. and added glucose concentrations were varied between 0 and 0.075M in eight steps (1.00, 1.335, 1.78, 2.372, 3.16, 4.217, 5.624 and 7.5) within each decade. For glucose oxidase assays, the initial concentration of glucose was set at 10⁻³M, consistent with the values used in routine work.^{3,6} The added glucose oxidase activity was either zero or varied in eight steps (again 1.00, 1.335, 1.78, 2.372, 3.16, 4.217, 5.624 and 7.5) within each decade from 10⁻¹³ to 10⁻⁹ I.U./l.

For optimizations, 10⁻¹¹ I.U./l. glucose oxidase was used, with glucose spanning the concentration ranges specified above. Integration time increments of 0.1, 0.25, 0.5, 1.0 and 2.5 sec were used for each entire set of glucose concentrations. The calculations described below were done with 25 replications for each combination. The relative precisions were compared, to select the optimal integration time increment, integration duration and fixed-time intervals used for subsequent studies of relative precisions.

After optimization for each replication within a set of conditions, the time *vs.* oxygen concentration relation was simulated with 0.1-sec time increments and the time-dependent rates for that set of conditions. The corresponding current *vs.* time relations were also generated concurrently with rate estimates and integrations performed continuously as the *i*_t *vs.* time relations developed. Fixed-time estimates were calculated as the difference between the current at 10 sec after addition of the analyte, and the average (over 30 sec) of that at equilibrium before initiation of the catalytic reaction; this procedure is consistent with that typically used for fixed-time measurements.⁸ Variable-time estimates were calculated similarly by using the time required to change *i*_t by 0.3 nA from its equilibrium value; the effects of time-averaging of the non-equilibrium data used for fixed-time

and variable-time measurements are being evaluated in other work, and the results should help to improve data quality for those methods. Maximum rates of change of i_t with respect to time were estimated as the greatest value of $\Delta i/\Delta t$ for any 1-sec time interval. Integrations were summed as shown in Fig. 1(c).

For each set of 25 replications for each variation in conditions, the average (\bar{x}) and standard deviation (s) were calculated. The data quality was defined as \bar{x}/s , for each set, and the values obtained were used in log-log plots against variations in conditions spanning several orders of magnitude.

RESULTS AND DISCUSSION

Results from simulations

Short time increments, e.g., 0.1 sec, produced the best relative uncertainty (s/\bar{x}) values for the procedures investigated. Overall, the data quality for integrations was best with 90-sec integrations, and somewhat inferior for 15-, 30-, 60- and 120-sec integrations, but each integration time gave superior precision for some particular enzymatic activity range. The fixed-

time method had its best overall precision for a measurement time of 10 sec. Consequently, data discussed below are for 10-sec fixed-time intervals, 90-sec integration duration and 0.1-sec data intervals, i.e., 10 Hz sampling frequency.

The current vs. time relations were similar to those found for routine analyses and other research (see Fig. 1).^{3,6} Averaged results changed as expected, with the variable-time method showing high values at low catalysis rates and low values at high rates, the reverse of the behavior of other rate estimates and the integrations. At higher noise levels, all the results exhibit worse precision, as evidenced by less consistent averages (Fig. 2) and lower \bar{x}/s values (Figs. 3 and 4).

The relative uncertainties for glucose oxidase assays by the integration procedure were much better than those obtained with any of the rate-estimating methods, over all catalytic rates when the noise levels were low to moderate, as would be expected for good to poor current-measuring instruments. Similarly, the integration method was substantially better than the fixed-time and continuous derivative methods over all catalytic rates and noise levels

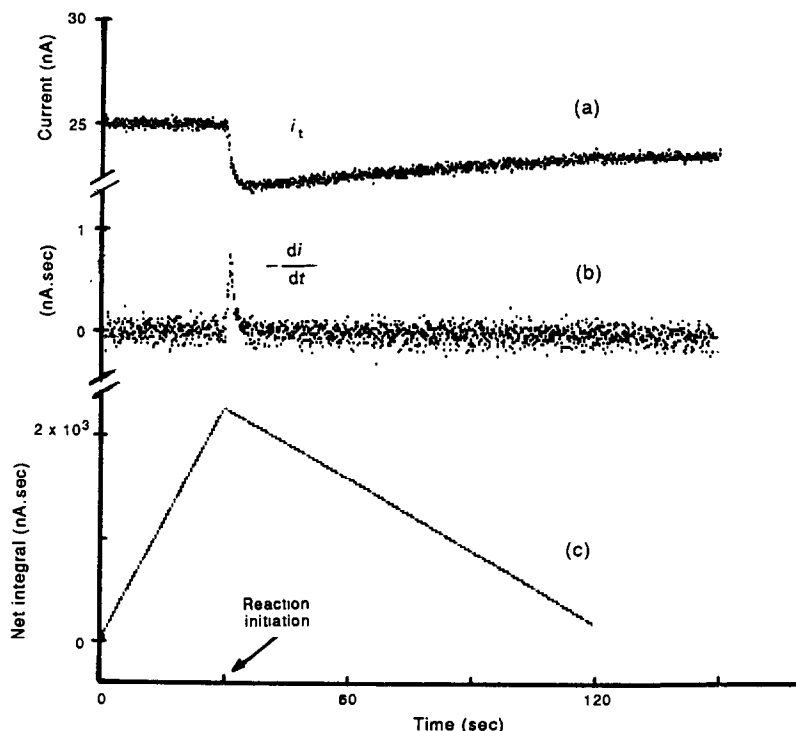

Fig. 1. Time-dependence of (a) response-current for oxygen (i_t), (b) $-di/dt$, and (c) integration data, for 10^{-11} I.U./l. glucose oxidase activity = $3.16 \times 10^{-3} M$ glucose and $\sigma_{\text{noise}} = (0.0056i + 0.01)$ nA. The integration data were obtained by summing the pre-reaction current (multiplied by 3) at 0.1-sec intervals for 30 sec, then subtracting the reaction current at 0.1-sec intervals over the next 90 sec.

Fig. 2. Average results ($n = 25$) vs. C_{glucose} for integrations (+), variable-time (\square), fixed-time (\times) and maximum continuous derivatives (\blacksquare) for glucose oxidase activity of 10^{-11} I.U./l. and $\sigma_{\text{noise}} = (0.00316i + 0.01)$ nA.

Fig. 3. Data quality estimates ($n = 25$) vs. glucose oxidase analyte activity for integrations (+), variable-time (\square), fixed-time (\times) and maximum continuous derivatives (\blacksquare) for $10^{-3}M = C_{\text{glucose}}$ and $\sigma_{\text{noise}} = (0.0056i + 0.01)$ nA.

Fig. 4. Data quality estimates ($n = 25$) vs. glucose concentrations for integrations (+), variable-time (\square), fixed-time (\diamond) and maximum continuous derivatives (\blacksquare) for glucose oxidase activity of 10^{-11} I.U./l. and $\sigma_{\text{noise}} = (0.0178i + 0.01)$ nA.

evaluated. However, at very high current uncertainties [$> \pm(0.0056i + 0.01)$ nA], its variable-time data quality was not degraded as dramatically as that of the other methods, showing higher x/s values at low catalytic rates than did other rate-measuring procedures. Also, with extreme noise levels, e.g., ± 10 nA for 15–25 nA total current, the integration method gave better results than all the other methods at all catalytic rates investigated.

Enzymatic determinations of glucose by monitoring the current in glucose oxidase reaction systems showed overall results similar to those achieved for oxidase assays (Fig. 4). For low to moderate noise levels, $< \pm(0.0316i + 0.01)$ nA, the integration method gave higher x/s values than did any of the rate-estimating methods, for all glucose concentrations used, which spanned a much wider range than that of typical routine analyses. However, as observed for the G.O.A. assays, at high and extreme noise levels the variable-time method had better relative uncertainties than did the integration method, for low concentrations of glucose. For high glucose concentrations, however, the integrations showed better data quality than the rate-estimates, over all the noise levels explored.

Experimental results

Determinations of glucose concentrations between 0.0025 and 0.010M (0.46–1.86 mg/ml) were done concurrently by the three rate-estimate methods and the integration method. Within this narrow range of physiological concentrations, the integration data quality (x/s for $n = 10$) was better by a factor of 2–10 than the variable-time results and 2–50 than the fixed-time and continuous derivative methods. This superiority of data quality was slightly lower than that predicted by theory (see Fig. 4). Extreme concentrations and noise levels were not examined in these laboratory experiments.

Relative calculations, of x/s , indicated that the integration method generally, but not always, gave better results than concurrently made rate-estimates did. Comparisons between integration and fixed-time results typically showed 5–10-fold enhancement of x/s when integration was used for glucose determinations and 2–20-fold enhancement for oxidase assays. Integration gave up to 120-fold improvement in x/s in comparison with the maximum continuous-derivative method. In comparison with variable-time results, integration was usually several times better at normal noise levels, but at very high noise levels the variable-time data quality

was nearly the same as that for integration, and sometimes somewhat better.

CONCLUSIONS

Overall, the integration method gives much better results than do rate-estimation procedures, over broad variations of oxidase reaction conditions, for both simulated and experimental data. This is evident even when minima occur in the current *vs.* time relations during the integration period. The improved data quality offered by integration may therefore improve the reliability of measurements made on non-equilibrium systems during progress of the reaction.

(Received 17 October 1990. Revised 19 November 1990. Accepted 27 December 1990)

Summary—The uricase-like catalytic activity of the ion-exchange resins modified with metalloporphyrins has been investigated through the oxidation of uric acid. The anion-exchange resins modified with Mn^{3+} -tetrakis(sulfophenyl)porphine and the cation-exchange resin modified with Mn^{3+} -tetrakis(1-methylpyridinium-4-yl)porphine exhibited the highest uricase-like activity among the modified resins tested. The fact that these resins accelerated the oxidation of uric acid even after ten cycles of use indicates that the modified resins act as catalysts in the reaction catalyzed by uricase. Some of the modified resins may be effectively used for the determination of uric acid in place of uricase.

Previously, we have demonstrated that the ion-exchange resins modified with metalloporphyrins (M-P_r) exhibit catalase-like^{1,2} and peroxidase-like^{3,4} activities, and are useful for the determination of hydrogen peroxide in clinical assays as a mimesis of the enzymes.^{5,6} We have reported briefly that some M-P_r exhibit enzyme-like catalytic activity in the oxidation of uric acid.⁷ As uricase is one of the important enzymes in the clinical analysis,⁸ the development of its effective artificial mimesis has been attempted. In this paper, we deal with the results of a detailed study on the uricase-like catalytic activity of M-P_r, and its application to the determination of uric acid.

EXPERIMENTAL

Materials

Tetrakis(sulfophenyl)porphine (H₂-TPPS), tetrakis(4-carboxyphenyl)porphine (H₂-TCPP), protoporphyrin (H₂-PP) and tetrakis-

(1-methylpyridinium-4-yl)porphine (H₂-TMPyP) were purchased from Tokyo Kasei Company and Dojin Chemical Laboratories, and were used without further purification for the preparation of metalloporphyrins. Other reagents were of analytical or reagent grade.

Preparation of the modified resins

Aqueous solutions of metalloporphyrins were prepared and used to modify an anion-exchange resin (Amberlite IRA 900, 24-42 mesh) and a cation-exchange resin (Dowex MSC-1, 20-50 mesh) as described previously.¹⁻⁴ The absorption spectra of the solutions of metalloporphyrins agreed with those reported in the literature.^{9,10} All the modified resins contained 25 μmoles of metalloporphyrin per 1 g (dry resin).

Apparatus

Absorption spectra and absorbances were measured on a Shimadzu UV-180 double-beam spectrophotometer and a Shimadzu UV-100 spectrophotometer, respectively, with a 10-mm fused-silica cell.

*Author for correspondence.

Fig. 1. Structures of metalloporphyrins.

Aqueous solution of uric acid

A 100-mg amount of uric acid (Sigma Co., No. 21F-5062) was dissolved in about 80 ml of water containing 60 mg of lithium carbonate and the solution was diluted to exactly 100 ml with water. This stock solution (1 mg/ml) was diluted to the desired concentration with water.

Evaluation of the uricase-like activity

A modified resin (100 mg) was added to a mixture of the uric acid solution (300 $\mu\text{g}/\text{ml}$, 0.5 ml) and 0.05M borate buffer (pH 8.0, 4.0 ml), and the mixture was incubated at 35° for 30 min. The absorbance of the supernatant was measured at 293 nm against water and the control absorbance was obtained by using IRA 900 in place of the modified resin. The activities of the resins were evaluated by the decrease in absorbance of the control. In the case of M-TMPyP, 0.2M carbonate buffer (pH 11.0) and the cation-exchange resin MSC-1 were used as the buffer and the control, respectively.

RESULTS AND DISCUSSION

Metalloporphyrins

The metalloporphyrins used in this study are shown in Fig. 1. All of them are water-soluble. The complexes were immobilized easily and firmly on the ion-exchange resins as discussed previously, by ion-exchange reaction and physical adsorption.¹⁻⁴

Reaction catalyzed by the modified resins

Uricase catalyzes the following reaction (1), and uric acid is oxidized to allantoin.

To confirm that M-P, catalyzed reaction (1), the formation of allantoin and hydrogen peroxide were investigated by using Mn^{3+} -TPPS. To detect allantoin, the supernatant of the reaction mixture was dried and the residue obtained gave relatively strong IR bands around 1770, 1650, 1515, 1180, 810 and 754 cm^{-1} , coinciding with those of standard allantoin, and gave mass peaks (FAB⁺) in glycerol matrix at 159 and 251, which could be attributed to [allantoin + H]⁺ and [allantoin + glycerol + H]⁺, respectively. However, only trace amounts of hydrogen peroxide were detected in the reaction mixture by the colour reaction with peroxidase, phenol and 4-aminoantipyrine.¹¹ Hydrogen peroxide formed from uric acid was decomposed immediately by the catalase-like activity of Mn^{3+} -TPPS, which has been reported previously. When air was replaced by nitrogen, the reaction hardly proceeded even in the presence of catalysis. We concluded from these results that the modified resins catalyze reaction (1).

Reaction conditions

The following examinations were carried out to obtain optimum conditions. A considerable amount of uric acid is adsorbed by the anion-exchange resin. Accordingly, the control by the use of IRA 900 should be referred to in each examination, except for the cases of M-TMPyP_r.

Effect of pH. The amount of unchanged uric acid (%) in reaction mixtures of various pH values are presented in Figs. 2-4. As seen in Fig. 4, Mn^{3+} -TMPyP_r decomposed most of the uric acid at pH 11, but not when the pH was below 9.

On the other hand, the adsorption of uric acid by the anion-exchange resin IRA 900 increases at higher pH. Accordingly, we chose pH 8 for the resins prepared from IRA 900 and pH 11 for the resins prepared from MSC-1.

Effect of buffer. The decomposition of uric acid was found to be affected by the composition of the buffer solutions such as 0.05M borate, 0.2M borate, 0.2M phosphate, 0.033M phosphate and 0.2M tris buffers. Among these buffers used, 0.05M borate, 0.033M phosphate and 0.2M tris buffers give good results. This effect may be attributed to the coordination of a component of the buffer to metalloporphyrins as an axial ligand. However, in the case of

Fig. 4. Effect of pH (3) in acetate (pH 6) and borate (pH 7-11) buffer. ○ Fe^{3+} -TMPyP; ● Mn^{3+} -TMPyP; Δ Co^{3+} -TMPyP; \square Zn^{2+} -TMPyP.

Fig. 5. Effect of incubation temperature. (A): ○ Cu^{2+} -TPPS; ● Mn^{3+} -TPPS; \blacksquare H_2 -TPPS. (B): ○ Fe^{3+} -TMPyP; ● Mn^{3+} -TMPyP; \square Zn^{2+} -TMPyP; \blacksquare H_2 -TMPyP.

M-TMPyP_r, 0.2M carbonate and 0.05M borate buffers (pH 11) gave almost the same result. In this study, we used 0.2M carbonate buffer (pH 11) for M-TMPyP_r and 0.05M borate buffer (pH 8) for other modified resins.

Effect of temperature. Unchanged uric acid (%) decreased with increasing incubation temperature in all cases of M-P_r tested, except for Zn^{2+} -TMPyP_r. (Fig. 5). In particular, for Mn^{3+} -TPPS_r and Mn^{3+} -TMPyP_r, the increase in activity with increasing temperature was remarkable and the maximum activity was observed above 35°. In the case of Mn^{3+} -TMPyP_r, the resin crumbled to pieces at 45°. H_2 -TMPyP_r and H_2 -TPPS_r, which contain no metal, decomposed uric acid only slightly in all the temperature ranges tested, indicating that the central metal is essential for the activity.

Time courses

A 30-min incubation period was sufficient as shown in Figs. 6 and 7. It is of interest that the time needed to attain equilibrium depended on the type of central metal in M-P_r, which indicates that the metal influences not only the activity but also the reaction rate. For example, in the case of Co^{3+} -TPPS_r, the reaction came to equilibrium after about 10 min of reaction. However, the reaction by Fe^{3+} -TMPyP_r was

Fig. 6. Time courses (1). ○ Zn^{2+} -TPPS; ● Mn^{3+} -TPPS; Δ Co^{3+} -TPPS; \blacktriangle Cu^{2+} -TPPS; \square Fe^{3+} -TPPS.

Fig. 7. Time courses (2). ○ Fe³⁺-TMPyP_r; ○ Mn³⁺-TMPyP_r; △ Zn²⁺-TMPyP_r; ▲ Fe³⁺-TCPP_r; □ Zn²⁺-PP_r.

found to be slow and equilibrium was attained after 1 hour of the reaction. As far as the reaction rate is concerned, Co³⁺-TPPS_r gives the best catalysis. For the evaluation of the activity, incubation was carried out for 30 min.

Uricase-like activity

Table 1 shows the unchanged uric acid (%) after treatment with the modified resins. Some of the resins modified with manganese complexes gave relatively high uricase-like activity compared to the other resins tested, similar to peroxidase- and catalase-like activities.¹⁻⁴ It is of interest that Mn³⁺-TMPyP_r, which did not show both the peroxidase- and catalase-like activities,^{2,4} exhibited the highest uricase-like activity among the modified resins tested. The resins modified with Co³⁺-porphyrins showed less activity than Mn³⁺-complexes. These results indicate that the enzyme-like activities of the modified resins depend not only on the kind of porphyrins but also the central metals.

Repeated uses

The effect of repeated use on the activity was examined to confirm its catalytic nature. The results are shown in Fig. 8. Mn³⁺-TMPyP_r and Mn³⁺-TPPS_r maintained their uricase-like activity even after ten cycles of use, although a slight decrease in the activity was observed. The activity of Co³⁺-TPPS_r

Fig. 8. Effect of repeated uses. ○ Mn³⁺-TMPyP_r (pH 11); ● Mn³⁺-TPPS_r (pH 8); ▲ Co³⁺-TCPP_r (pH 8).

decreased when used a second time. This result indicates that Mn³⁺-TMPyP_r and Mn³⁺-TPPS_r are superior to Co³⁺-TPPS_r as a mimesis of uricase.

Analytical application

The reaction (1), catalyzed by uricase, has been used for the clinical assay of uric acid,⁸ by measuring the decrease of absorbance at 293 nm, where uric acid has an absorption maximum. For the application of the modified resins in place of uricase to the determination of uric acid, Mn³⁺-TMPyP_r is more suitable than Mn³⁺-TPPS_r, because the adsorption of uric acid upon the ion-exchange resin does not take place for Mn³⁺-TMPyP_r, which is prepared from the cation-exchange resin. According to the procedure described above, the decrease of absorbance at 293 nm was measured. The calibration curve obtained with the standard solutions gave good linearity in the range 25–300 μg of uric acid. The sensitivity was comparable to that of the method with uricase. This result indicates that Mn³⁺-TMPyP_r can be used in place of uricase for the determination of uric acid.

In conclusion, some of the ion-exchange resins modified with metalloporphyrins exhibit uricase-like activity. In particular, Mn³⁺-TMPyP_r is useful for the determination of uric acid as an artificial mimesis of uricase.

Table 1. Unchanged uric acid (%)*

M =	Mn ³⁺	Co ³⁺	Fe ³⁺	Cu ²⁺	Zn ²⁺	H ₂

(Received 31 August 1990. Revised 27 January 1991. Accepted 4 February 1991)

Summary—Two methods are reported for the indirect determination of thiosulphate down to *ca.* 0.02 $\mu\text{g/ml}$ by differential-pulse polarography. Both methods involve prior oxidation of thiosulphate with iodine, either in acidic medium to tetrathionate or in alkaline medium to sulphate, whereby ultimately one and eight equivalents of iodate are obtained, respectively. The concentration of iodate in the resulting solution is then measured by differential-pulse polarography under optimum conditions. The average recovery for each method amounted to 100.1%, and the relative standard deviations were 1.3 and 1.4% for the two methods.

Thiosulphate is used as a fixing salt in photography, as a detoxicating agent (through thiocyanate formation) in treatment of cyanide poisoning, and as a titrant of universal application in various methods involving iodine. However, like other sulphur compounds,² thiosulphate is considered an environmental pollutant, being susceptible to bacterial attack³ yielding sulphuric acid, which is known to cause serious damage in many industries, particularly corrosion of concrete sewers. Most of the conventional methods for thiosulphate determination, *e.g.*, volumetric, amperometric, coulometric and potentiometric titrations⁴⁻⁶ are designed for macro- or micro-scale levels. Use of 6-fold,⁷ 48-fold^{7,8} and 24-fold⁹ iodometric amplification methods has succeeded in the determination of micro and submicro amounts of thiosulphate, down to about 4.5 μg .⁸

With the advent of modern polarographic and voltammetric techniques,¹⁰ the reducing and complex-forming properties of thiosulphate have been exploited in developing more sensitive and selective methods.^{1-3,11-13} Knittel *et al.*³ developed a differential-pulse anodic stripping

voltammetric method specific for thiosulphate determination from 5 ng/ml to 3 $\mu\text{g/ml}$ in aqueous media, though the calibration graph reported (0-5 $\mu\text{g/ml}$) was linear only from 1.5 to 5 $\mu\text{g/ml}$.

The present work offers an alternative method for the indirect determination of traces of thiosulphate by differential-pulse polarography (DPP), enabling accurate measurement down to *ca.* 0.02 $\mu\text{g/ml}$ in aqueous media.

EXPERIMENTAL

Apparatus

All differential-pulse polarograms were obtained with a Princeton Applied Research (PAR) Model 264A Polarographic Analyzer/Stripping Voltammeter equipped with a PAR Model 303A three-electrode system composed of a static mercury dropping electrode (SMDE) as the working electrode, a silver/silver chloride (0.1M KCl) reference electrode,[†] and a platinum wire as counter-electrode, a 10-ml electrode cell, a Model RE0089 X-Y recorder, and a Model 305 stirrer.

A "WTW" microprocessor pH-meter Model 95 (Germany), having a combined glass electrode with integral temperature sensor and

*Author for correspondence.

†The potential differs by +0.049 V from that *vs.* SCE (*cf.* Henze and Neeb,¹⁰ p. 152).

precise to ± 0.01 , was used and calibrated for the pH range 2–8.

An Eppendorf microlitre pipette accurate to $\pm 0.1 \mu\text{l}$ was used to measure 10–100 μl volumes and a Brand (Germany) microlitre pipette accurate to $\pm 0.5 \mu\text{l}$ for volumes of 200–1000 μl .

Reagents

Except where otherwise mentioned, all reagents were of high analytical grade (Merck Titrisol and Suprapur) and doubly-distilled demineralized water was always used.

Sodium thiosulphate. A $2 \times 10^{-3} M$ solution was prepared and stabilized by addition of 0.02 g of sodium carbonate per 200 ml. This solution was stable for two weeks and was frequently standardized against potassium iodate solution.

Potassium iodate. A 0.1N solution was prepared from standard ampoules and diluted to 0.01 or 0.001N as required for standardization and for the polarographic calibration curves.

Other reagents were a 1.2 mg/ml iodine solution in chloroform, 2M sodium acetate, 50% v/v formic acid solution, saturated bromine water, 1 and 5M sodium hydroxide and 2M sulphuric acid.

Procedures

Tetrathionate procedure. Transfer an aliquot of test solution containing between 3.5 and 60 μg of thiosulphate into a 100-ml separating funnel, add 0.4 ml of the iodine solution, dilute to ca. 5 ml with water and add 5 ml of chloroform. Shake well for 2 min and allow to stand for 1 min.

Discard the chloroform layer and remove the last minute traces of iodine suspended in the aqueous layer, by extraction with five 5-ml portions of chloroform, with vigorous shaking for 1 min each time. Transfer the aqueous layer quantitatively into a 100-ml conical flask, add 1.5 ml of 2M sodium acetate, 1 ml of saturated bromine water and stir the mixture for 3 min. Destroy the excess of bromine by dropwise addition of formic acid (0.25 ml) and adjust the pH to 3.5. Transfer into a 25-ml standard flask and dilute with water to the mark.

Rinse the electrodes and the clean cell with a few ml of the test solution, then pipette ca. 10 ml of it into the electrode cell. Deaerate by passage of pure nitrogen for 4 min and record the differential-pulse polarogram of the iodate at room temperature, using a drop time of 1 sec, a pulse amplitude of 50 mV, a potential scan-rate of 2 mV/sec within the potential range

from -0.20 to -0.75 V, and 20 μA full-scale deflection.

Prepare a calibration curve for 4.0–96 μg of by applying the same procedure, plotting peak current (μA) vs. weight (μg) of iodate or thiosulphate (100 μg of $\text{IO}_3^- \equiv 64.1 \mu\text{g}$ of $\text{S}_2\text{O}_3^{2-}$).

Sulphate procedure. Mix 5 ml of 1M sodium hydroxide and 0.5 ml of iodine solution in a 100-ml separating funnel, add an aliquot of the test solution containing between 2.8 and 45 μg of thiosulphate and shake well for 2 min. After 5 min, add 3.5 ml of 2M sulphuric acid and 8.5 ml of chloroform, shake for 1 min and leave standing for 1 min more to allow separation.

Discard the chloroform layer and remove the remaining traces of iodine by extraction with five 8.5-ml portions of chloroform, shaking vigorously for 1 min each time. Transfer the aqueous layer quantitatively into a 100-ml conical flask, add 1.5 ml of 5N sodium hydroxide followed by 3 ml of 2M sodium acetate to give a pH of about 8. Add 1 ml of saturated bromine water and stir the mixture for 5 min. Add formic acid (0.8 ml) dropwise to destroy the excess of bromine and to adjust the solution to pH 3.5. Transfer the solution quantitatively into a 100 ml-standard flask and dilute with water to the mark.

Record the differential-pulse polarogram of the iodate under the conditions given for the tetrathionate procedure, but use a lower sensitivity of 100 μA full-scale deflection.

Prepare a calibration curve for 30–600 μg of iodate by the same procedure, plotting peak current (μA) vs. weight of iodate (μg) (100 μg of $\text{IO}_3^- \equiv 8.02 \mu\text{g}$ of $\text{S}_2\text{O}_3^{2-}$).

RESULTS AND DISCUSSION

The tetrathionate procedure

This method makes use of the iodine–thiosulphate reaction yielding tetrathionate and iodide, which is then quantitatively oxidized with bromine water to iodate:

In earlier work,⁷ the Leipter reaction was applied to the iodate, but despite the 6-fold amplification, less than 0.1 mg of thiosulphate could not be determined. When the iodate was measured by d.c. polarography, by means of the irreversible cathodic reduction of iodate at the dropping mercury electrode: $\text{IO}_3^- + 6\text{H}^+ + 6e^- \rightarrow \text{I}^- + 3\text{H}_2\text{O}$, only mg amounts of thiosulphate could be determined.¹⁴ However, d.c.

Fig. 1. Representative DP polarograms for the iodate calibration graph (tetrathionate method). Iodate ($\mu\text{g}/25\text{ ml}$): a, 96; b, 48; c, 16; d, 8; e, 4; f, blank.

Fig. 2. Representative DP polarograms for the thiosulphate calibration graph (tetrathionate method). Thiosulphate ($\mu\text{g}/25\text{ ml}$): a, 56.5; b, 42.6; c, 21.3; d, 10.6; e, 7.04; f, 3.52; g, blank.

polarography has been reported¹⁵ to enable determination of inorganic ions only down to $10^{-4}M$, whereas the more sensitive DPP technique has been reported¹⁶ to measure iodate concentrations down to *ca.* $2.4 \times 10^{-6}M$ at pH 3.

Accordingly, the present work is based on combination of the iodometric oxidation of thiosulphate to yield ultimately an equivalent amount of iodate, with measurement of the iodate by DPP.

Since the half-wave potential and the peak height of the iodate wave are pH-dependent,^{14,16} differential pulse polarograms were initially recorded for a solution containing $10\ \mu\text{g}$ of iodate and at pH 2–4, with different polarographic settings. The most precise results were those obtained at pH 3.5, with the peak maximum occurring at -0.42 V .

Experiments were then performed with the tetrathionate procedure cited elsewhere⁷ until a

modified scaled-down version has been developed and proved suitable for the quantitative oxidation of thiosulphate in amounts ranging between 3.5 and $60\ \mu\text{g}$ in a final volume of 25 ml. At first, recoveries consistently high by about 2–3% were obtained, which was thought to be due to contamination from one or more of the reagents used. A series of blank determinations revealed that 5-fold extraction with chloroform, instead of the 3-fold extraction prescribed earlier,⁷ is necessary to eliminate the last traces of iodine completely, and this procedure gave correct results. The tetrathionate produced has no effect on the results, and calibration graphs for iodate standards and thiosulphate standards were identical. Representative differential pulse polarograms from both sets are shown in Figs. 1 and 2.

Excellent results were achieved for 3.5–56.5 μg of thiosulphate (Table 1).

Table 1. Results obtained by the tetrathionate method

	Taken	3.52	7.04	10.6	21.3	42.6	56.5

Peak height of iodate, μA		3.8	7.5	15	30	50	60
Relative standard deviation, %		1.5	1.1	1.2	1.6	1.3	1.8

The sulphate method

The sulphate method depends upon the disproportionation of iodine in strongly alkaline medium (pH 12) to form equimolar amounts of hypoiodite and iodide [reaction (2)]. Thiosulphate is oxidized to sulphate by hypoiodite [reaction (3)] which is itself reduced to iodide, leading to an overall stoichiometry [reaction (4)] of one mole of thiosulphate being equivalent to eight moles of iodide and to eight moles of iodate on oxidation with bromine water [reaction (1)].

Thus slight modifications of the iodometric procedures described in previous works,^{7,8} and adjustment of the pH of the iodate-containing solution to 3.5 as before but dilution to a larger final volume of 100 ml, allowed DPP measurement of the resulting iodate by use of the lowest sensitivity value of 100 μA full-scale deflection under polarographic conditions otherwise the same as for the tetrathionate method. The iodate peak maximum again occurred at -0.42 V, as expected.

The lowest sensitivity and the dilution to 100 ml final volume were selected to compensate for the 8-fold amplification in the sulphate method, as only in this way could the complete DPP peak be recorded on the chart (which was 25 cm wide).

Amounts of thiosulphate in the range 2.8–45 μg were determined and quite reproducible results (Table 2) were obtained.

Unfortunately the instability of lower concentrations of thiosulphate and/or their non-stoichiometric oxidation resulted in inconsistent and erroneous values. However, thiosulphate concentrations as low as 0.14 and 0.02 $\mu\text{g}/\text{ml}$ could be accurately determined by the two indirect methods developed, corresponding to 0.22 and 0.35 $\mu\text{g}/\text{ml}$ iodate, which compares

favourably with the 0.42 $\mu\text{g}/\text{ml}$ limit reported for pure iodate solution.¹⁶

The calibration graphs prepared with thiosulphate and iodate standards were again identical.

All anions and cations that undergo redox reactions with iodine, liberating iodide, interfere in the determination (*cf.* Belcher *et al.*⁸) but sulphate (the reaction product in this variant) does not interfere. The pulse polarograms for the reagent blank showed slight curvature above the baseline, corresponding to not more than 0.04 μg of iodate or 0.025 μg of thiosulphate, which is within acceptable limits; all results were corrected accordingly.

EXTRACTIVE-CHROMATOGRAPHIC SEPARATION OF BISMUTH WITH ALIQUAT 336S FROM CITRATE SOLUTIONS

S. K. SAHOO

Department of Metallurgical Engineering, Indian Institute of Technology,
Bombay 400 076, India

(Received 7 August 1990. Revised 14 January 1991. Accepted 1 February 1991)

Summary—Bismuth is extracted from 0.01M citric acid at pH 3.0 with Aliquat 336S coated on a silica gel column, by extraction chromatography. It was then stripped with 0.1M sulphuric acid and determined spectrophotometrically at 460 nm as the iodide complex. Bismuth was effectively separated from binary as well as ternary mixtures by taking advantage of the difference in the stability of the citrate complexes with metal ions in mineral acids. The method was extended to the analysis of bismuth from low fusible alloys.

The extractive-chromatographic methods for the separation of bismuth involve use of solvating solvents and liquid ion exchangers as the stationary phase. The separation of bismuth from mineral acid media, using liquid anion exchangers has been studied, but such studies from organic acid media are few. Tributylphosphate was used for the extractive-chromatographic separation of bismuth from lead, thallium and silver.^{1,2} Bismuth was separated from transition elements with trioctylphosphine oxide³ and bis(2-ethylhexyl)phosphoric acid⁴ as the stationary phase. The separation of bismuth from silver, cadmium and zinc by extraction chromatography was done with trioctylamine.^{5,6} However, these methods failed to separate bismuth from elements which are associated with fission products.

This paper described the systematic investigation of the extractive-chromatographic studies of bismuth with Aliquat 336S from citric acid solutions. Novel methods are developed to separate bismuth from associated elements. The method is applied to the determination of bismuth in low fusible alloys.

EXPERIMENTAL

Apparatus

A GS 866C spectrophotometer (ECIL, India), provided with corex glass cuvettes with an optical path length of 10 mm and a LI 120 pH meter (ELICO, India) were used.

Reagents

Aliquat 336S (methyltri-n-alkylammonium chloride) (Fluka AG, Switzerland) was used without further purification.

A stock solution of bismuth was prepared by dissolving 2.94 g of bismuth nitrate pentahydrate in 250 ml of distilled water containing 1% nitric acid. The solution was standardized complexometrically.⁷ It contained 4.7 mg/ml of bismuth. A diluted solution containing 100 µg/ml was prepared by appropriate dilution.

The silica gel (100–200 mesh) was dried at 120° for 2 hr and then packed into a U-tube. A stream of dry nitrogen was passed for 2–3 hr through a small Drechsel bottle containing 25 ml of dimethyldichlorosilane, and then through a U-tube containing the silica gel to convert the surface silanol groups to silyl ether groups. The silica gel was then washed with anhydrous methanol to convert the unreacted hydroxyl groups to methoxy groups, as well as to remove hydrochloric acid from the silica gel. The treated silica gel was then dried at 100°. In routine work 1 ml of dimethyldichlorosilane is adequate to render 10 g of silica gel hydrophobic.

A solution containing 1 ml of Aliquat 336S in benzene was prepared and transferred into a flask containing 4 g of the hydrophobic silica gel. The benzene was slowly removed from the suspension with a rotary vacuum evaporator until dry silica gel was obtained; a low vacuum was applied to remove air from the micropores

and to accelerate evaporation of benzene. The silica gel coated with Aliquat 336S was then slurried with citric acid solution and poured into a column (10×0.8 cm). A 4-g amount of the coated silica gel was sufficient to give a bed height of 8 cm and was used for the column studies.⁸

General procedure

An aliquot of solution containing $100 \mu\text{g}$ of bismuth was mixed with 5 ml of $0.01M$ citric acid. The pH of the solution was adjusted to 3.0 with $0.01M$ citric acid or $0.01M$ sodium hydroxide. The solution was passed through the column and bismuth was extracted with Aliquat 336S as the stationary phase. Bismuth was stripped with various mineral acids. Ten 5-ml fractions were collected and bismuth from each fraction was determined spectrophotometrically as the iodide complex at 460 nm .⁹

RESULTS AND DISCUSSION

Effect of pH

The extraction studies of bismuth as a function of pH were carried out in the pH range 1.0–6.0. The extraction commenced at pH 1.0 (45.4%) and it was quantitative from pH 3.0 to 5.0. On increasing the pH further, there was a decrease in the extraction of bismuth, this may be due to hydrolytic precipitation of bismuth. The optimum pH for the quantitative extraction of bismuth was 3.0 (Fig. 1).

Effect of citric acid concentration

The extraction of bismuth was carried out by varying the concentration of citric acid from 1×10^{-4} to $1 \times 10^{-1}M$. The optimum concentration for complete extraction was $1 \times 10^{-2}M$.

Fig. 1. Effect of pH on extraction of bismuth from citric acid.

Fig. 2. Effect of citric acid concentration on extraction of bismuth.

At higher concentration there was a decrease in extraction perhaps because of competitive equilibria between the anionic bismuth citrate complex and the citrate anion itself, for the liquid anion exchanger. At lower citric acid concentration, however, there was a decrease in extraction and an increase in turbidity due to the formation of bismuth oxysalt (Fig. 2).

Effect of stripping agent

The stripping of bismuth was affected by various mineral acids (Table 1). The stripping was quantitative with $4M$ hydrochloric, $0.1M$ sulphuric or $2M$ nitric acid. It was interesting to note that at lower concentration *i.e.*, less than

Table 1. Effect of stripping agents

3.0	100.0	

2M hydrochloric acid, stripping was not quantitative as bismuth formed an anionic chloro complex, which in turn was re-extracted by Aliquat 336S on the column. Similarly, less than 2M nitric acid could not strip effectively. Alkali hydroxides were not useful as they caused either precipitation or solid phase formation. The lower concentrations of sulphuric acid were preferred because of the formation of sulphato complexes. Thus, for all practical purposes, 0.1M sulphuric acid was utilised as the stripping agent for bismuth.

Separation of bismuth from binary mixtures

Bismuth was separated from several elements in binary mixtures by making use of the differences in their ability to form anionic complexes (Table 2). Thus, since alkali and alkaline earths, iron(II), zinc, cadmium, lead, cobalt, aluminium and manganese could not form anionic citrate complexes, they were not extracted and hence

were separated from bismuth. The differences in stability of citrato complexes of various elements were exploited to devise some separations. Zirconium, thorium, uranium and molybdenum formed relatively stable citrato complexes in comparison with the citrato complex of bismuth. Therefore, bismuth was first stripped with 0.1M sulphuric acid and subsequently all those elements which formed stable complexes were stripped with 2M sulphuric acid.

Separation of bismuth from multicomponent mixtures

A mixture of lead/nickel, bismuth and tin(IV) were passed on the column at pH 3.0 and citrato complexes of bismuth and tin(IV) were extracted while lead/nickel passed through the column unextracted. Then bismuth was stripped with 4M hydrochloric acid and finally tin(IV) was stripped with 1M sulphuric acid.

Arsenic, bismuth and antimony were separated by passing the mixture on the column; arsenic was not extracted and was washed with water. Then bismuth was stripped with 4M hydrochloric acid and antimony with 1M nitric acid.

The separation of zinc, bismuth, thorium and zirconium was carried out by passing the mixture through the column; zinc passed through, as it did not form an extractable citrato complex, while the extracted bismuth was stripped with 0.1M sulphuric acid, thorium with 0.25M

*SD—Standard deviation.

sulphuric acid and zirconium with 2M hydrochloric acid.

The separation of lead, bismuth, thorium and molybdenum was effected by washing lead with water, bismuth was stripped with 0.1M sulphuric acid, thorium with 0.25M sulphuric acid and molybdenum with 2M nitric acid.

Aluminium, bismuth, iron(III) and thallium(III) were separated by passing the mixture on the column when aluminium was not extracted; extracted bismuth was stripped with 4M hydrochloric acid, iron(III) with 0.25M hydrochloric acid and thallium with 1M perchloric acid. These analyses were carried out in triplicate and standard deviations are shown in Table 3. In all these cases, the elements were determined spectrophotometrically by the use of appropriate chromogenic ligands.

Determination of bismuth from bismuth based alloys

The method was extended to the separation of bismuth from white metal, sealing alloys and bismuth solder.

About 0.1 g of an alloy was dissolved in *aqua regia*. The filtrate was evaporated to dryness, to remove excess acid, and then leached with dilute hydrochloric acid and made up to a known volume. An aliquot of solution containing lead, bismuth, antimony and tin was passed on the column from 0.01M citric acid buffered at pH 3.0 when all elements except

lead were extracted. Then bismuth was stripped with 4M hydrochloric acid, tin with 1M sulphuric acid and antimony with 1M nitric acid (Table 4).

The separation of bismuth from zinc, lead, tin, antimony, aluminium and thallium was important as they are associated in various low fusible alloys and the separation of bismuth from zirconium, molybdenum and thorium was significant as these are associated in fission products. The proposed method is simple, rapid with the time required less than 2 hr.

SPECIFICATION OF COLOUR CHANGES OF METALLOCHROMIC INDICATORS IN THE TITRATION OF BISMUTH WITH EDTA

K. M. M. KRISHNA PRASAD* and S. RAHEEM

School of Chemistry, Andhra University, Visakhapatnam 530 003, India

(Received 4 September 1990. Revised 9 January 1991. Accepted 25 January 1991)

Summary—The quality of the colour changes at the end-point in the complexometric titration of bismuth(III) with EDTA, using the indicators Hemotoxylin, PAN [1-(2-Pyridylazo)-Naphthol-2], PAR [4-(2-Pyridylazo)-Resorcinol], Xylenol Orange and Thoran is studied by means of the CIE 1931 trichromatic system, using specific colour discrimination (SCD) and colour difference (ΔE^*). The indicators are arranged in order of colour change quality. Of the indicators studied, Hemotoxylin is recommended as the most suitable for this titration.

The detection of the end-point in a titration is based on the colour transition of the indicator at the equivalence point of the reaction between titrant and titrand. Evaluation of this colour transition, by tristimulus colorimetry,¹ allows determination of the most adequate indicator for a specific determination.

Reilley and co-workers^{2,3} stated that for specification of the colour transition of visual indicators, the logical choice is to employ the chromaticity values of the International Commission on Illumination which suggested the use of absorbance values instead of transmittance values in conventional tristimulus colorimetry calculations to determine complementary chromaticity co-ordinates. An expression was derived to relate these co-ordinates to the true colour coordinates by the following expression

$$P_r = G_r - J(Q_r - G_r) - J^2(Q_r - G_r + Q_r^d)$$

where P_r is the true colour point, G_r the grey point, Q_r the complementary colour point, J the colour concentration and Q_r^d the dichromatistic deviation. Breckenridge and Schaub⁴ proposed RUCS (rectangular uniform chromaticity scale) co-ordinates, U and V , for representing the colour, where equidistant colour points represent an equal colour discrimination which are calculated from the

following equations:

$$U = 0.075 - \frac{0.823(x + y - 1)}{x - 7.05336y - 1.64023}$$

$$V = \frac{3.697 - 5.07713y - 1.36896}{x - 7.05336y - 1.64023} - 0.5$$

where (x, y) is the colour point on the chromaticity diagram for a given colour. Using the values of (U, V) , Bhuchar *et al.*⁵ determined a parameter, the specific colour discrimination (SCD), which is a measure of the quality of colour change and is given by,

$$\text{SCD} = \frac{1}{2}(1000) \frac{\Delta\sigma}{\Delta(C_L/C_M)}$$

where $\Delta\sigma = [(U_2 - U_1)^2 + (V_2 - V_1)^2]^{1/2}$, (C_L/C_M) is the ratio of the concentration of ligand to that of the metal ion.

In 1976, the CIE committee on colorimetry recommended the chromaticity co-ordinates L^* , a^* and b^* for the specification of colours.^{6,7} The equations for calculation of these parameters are presented as

$$L^* = 116 \left(\frac{Y}{Y_n} \right)^{1/3} - 16$$

$$a^* = 500 \left[\left(\frac{X}{X_n} \right)^{1/3} - \left(\frac{Y}{Y_n} \right)^{1/3} \right]$$

$$b^* = 200 \left[\left(\frac{Y}{Y_n} \right)^{1/3} - \left(\frac{Z}{Z_n} \right)^{1/3} \right]$$

*Author for correspondence.

where $X_n = 98041$, $Y_n = 100,000$ and $Z_n = 118,103$ are colour stimuli for white light for a light source C , where X , Y and Z are tristimuli for an indicator solution.

The chromaticity difference between two colours is given by the equation,

$$\Delta E^* = [(\Delta L^*)^2 + (\Delta a^*)^2 + (\Delta b^*)^2]^{1/2}$$

Cacho *et al.*⁸ proposed a parameter

$$\Delta J / \Delta(C_L / C_M)$$

to assess the quality of colour change. But Calatayud *et al.*¹ who stated that values of ΔJ show a non-uniform behaviour, preferred the parameter ΔS , standard deviation of colour matching, given by

$$\Delta S = g_{11} \Delta x^2 + 2g_{12} \Delta x \Delta y + g_{22} \Delta y^2$$

where Δx and Δy are changes in CIE coordinates and g_{11} , g_{12} and g_{22} are the values of constants of MacAdam⁹ ellipses corresponding to colour points.

Kotrly and Vytras¹⁰ studied the suitability of six indicators in the titration of Pb(II) with EDTA. Calatayud *et al.*¹¹ carried out investigations on Arsenazo(III) as indicator in the titrations of Ca(II), Pb(II), Bi(III), Fe(III) and La(III) with EDTA. Similar studies have been carried out in the complexometric titrations of the metal ions Pb(II),¹² Ca(II)^{12,13} and Zn(II).¹⁴

In this paper, the results of a detailed investigation of the specification of colour changes of indicators in the titration of bismuth(III) with EDTA are presented and a screened indicator is proposed to improve the quality of colour change.

EXPERIMENTAL

A Shimadzu U.V. Visible double-beam recording spectrophotometer with temperature control attachment was used. An OMC OMEGA-58000 minicomputer was used for calculating the parameters, by running the program in FORTRAN-77 for the weighted ordinate algorithm.

Reagents

Appropriate amounts of bismuth nitrate and the sodium salt of ethylenediaminetetraacetic acid, both analytical-reagent grade from Sarabai M. Chemicals, were dissolved in triply distilled water to give 0.01M solutions.

Indicators

Solutions ($1 \times 10^{-5}M$) of the indicators Hemotoxylin (Sigma), PAN (BDH-LR) and Xylenol Orange (BDH-LR) in ethanol, PAR (BDH-LR) and Thorn (BDH-LR) in water, were prepared.

Determination of chromatic parameters

A 10-ml portion of 0.01M Bi(III) solution and 0.1 ml of indicator solution are taken in a clean, dry beaker and the total volume is adjusted to 50 ml with varying volumes of EDTA and water after adjusting the pH with dilute ammonia.

The spectrum in each case is recorded on a Shimadzu spectrophotometer in the wavelength range 380–770 nm at 10 nm intervals. The absorbance values are treated with a computer program written in FORTRAN-77 and compiled on an OMEGA-58000 computer system. The algorithm adapted for the calculation of chromaticity parameters is the weighted ordinate method with $\Delta\lambda = 10$ nm, using the coefficients of the standard illuminant C and "10° standard observer".¹⁵

RESULTS AND DISCUSSION

The pH of the solution at the beginning of the titration, when using Hemotoxylin as indicator, is adjusted to 1.5 with dilute ammonia solution, while for the other indicators the pH is adjusted to the following ranges for each indicator: PAN: 1–3; PAR: 1–2; Xylenol Orange: 1–3 and Thoran: 2–3.

From the spectra of the indicators at different values of (C_L / C_M) (Fig. 1a–e), the tristimulus values X , Y and Z are determined by using the expressions:

$$X = \sum \bar{x} E T \Delta\lambda$$

$$Y = \sum \bar{y} E T \Delta\lambda$$

$$Z = \sum \bar{z} E T \Delta\lambda$$

where $\bar{x}E$, $\bar{y}E$ and $\bar{z}E$ (the product of the energy distribution values and tristimulus of pure spectrum colours) are values at different wavelengths in the range 380–770 nm with intervals of 10 nm, and are taken for standard illuminant C , where T is transmittance. The true colour co-ordinates of any coloured solution are given by

$$x = \frac{X}{X + Y + Z} \quad \text{and} \quad y = \frac{Y}{X + Y + Z}$$

Fig. 1. Spectra of different indicators at different (C_L/C_M) ratios. (a) Hemotoxylin; (1) 0.92, (2) 0.94, (3) 0.96, (4) 0.98, (5) 1.0, (6) 1.02, (7) 1.04. (e) Thoran; (1) 0.92, (2) 0.94, (3) 0.96, (4) 0.98, (5) 1.0.

These values for all the studied indicators during the course of transition are tabulated in Table 1, along with the complementary colour co-ordinates (Q_x, Q_y) which are calculated by using absorbance values instead of transmittance values. The tristimulus value, Y , represents the brightness of the colour of the solution, whereas the purity of the colour of the solution is the ratio of the distance between the sample point and the illuminant point to the distance between the corresponding pure spectrum point and illuminant point. These two values, along with dominant wavelength (λ_d), which is the wavelength of the pure spectrum colour to be mixed with standard illuminant C to achieve the colour of the solution, are also included in Table 1, since these three parameters correspond closely to the three psychological attributes, brilliance (Y), saturation (pe) and hue (λ_d). The parameter J ,

known as the colour concentration, calculated from the expression

$$J = \frac{X + Y + Z}{X_n + Y_n + Z_n}$$

enables calculation of the volume ratio of the indicator with one or two inert dyes to obtain a screened indicator involving a colour transition at the end-point between complementary colours through greyness (colourlessness), and thereby enhance the quality of colour change.

The colour transition curves of all the indicators studied in the titration of bismuth(III) with EDTA are presented in Fig. 2. According to Reilley *et al.*,^{2,3} in comparing the quality of colour changes of different indicators at the equivalence point, apart from the fact that the distance between the colour points at the equivalence point should be large, the location of the

	1.06	0.4455	40072.5781	0.1534	0.2845	0.1349	0.1430	598.5274	0.6738

points and their relative positioning with regard to greyness (illuminant point) are also important. The colour transition curve of Hemotoxylin shows a long separation between the colour points at the equivalence point, and the curve passes very near to that of the illuminant point, clearly showing that this indicator is exhibiting the qualities of a good indicator. In the case of PAN and PAR, the colour transition curves show similar behaviour with comparable distances, and are present in the same location of the colour diagram. Even though Thoran has a longer distance between the points at the equivalence point, the colour change is not sharp and a gradual decrease in saturation of the colour is observed.

Since the co-ordinates of the colour diagram are non-uniform, CIE has recommended new parameters defined by CIE $L^*a^*b^*$ 1976.^{6,7} The curves drawn (Fig. 3) between a^* and b^* exhibit clearly the superiority of the indicator Hemo-

toxylin over all the other indicators studied, since its (a^* , b^*) curve passes very near to the grey point and requires no further screening.

PAN and PAR exhibit behaviour similar to each other, whereas Xylenol Orange and Thoran have a colour transition in a single quadrant of the (a^* , b^*) graph which indicates a decrease in saturation as the colour changes at the equivalence point.

A more quantitative method for the measurement of the quality of colour change of chemical indicators in visual titrations is suggested by Bhuchar *et al.*,⁵ and involves the calculation of the average number of colour discrimination steps for one (C_L/C_M) unit, which is known as the 'specific colour discrimination' (SCD). The SCD *vs.* (C_L/C_M) curves represented in Fig. 4 clearly show that Hemotoxylin, the indicator with the maximum SCD value, is the most suitable indicator in this titration among the indicators studied. The half band-width pertains-

Fig. 3. Change of colour co-ordinates a^* and b^* (Index as in Fig. 2).

Fig. 4. Specific colour discrimination versus (C_L/C_M) (Index as in Fig. 2).

ing to this indicator is very low, which indicates the higher rapidity of colour change. (The rapidity of colour change is inversely proportional to the half band-width of (SCD) *vs.* (C_L/C_M) peak.) From the absolute values of SCD at $C_L/C_M = 1.0$ (Table 2), the order of increasing quality of colour change of the studied indicators is:

Thoran < Xylenol Orange < PAR
< PAN < Hemotoxylin

Even though the value of the half band-width of the SCD curve of Xylenol Orange indicates that this indicator has a better rapidity of colour change in comparison with PAR, the colour change of the former indicator at the end-point consists of only a decrease of intensity and hence the latter is considered to be the superior of the two. The absolute values of SCD shown in Table 2 also support this argument. A large number of visual titrations with all these indi-

Fig. 5. E^* versus (C_L/C_M) (Index as in Fig. 2).

cators confirms the above mentioned order of quality of colour change.

In their search for the most uniform parameter (against ΔS) for evaluation of the colour break point of the chemical indicators, Calatayud *et al.*¹ reported that the 'total colour difference', ΔE^* , is the most suitable parameter in this regard. The total colour difference values calculated for these indicators also exhibit the same order of decrease as observed in the case of SCD values (Table 2), indicating ΔE^* is also a good parameter. The curves of ΔE^* *vs.* (C_L/C_M) (Fig. 5) confirm the adequacy of the parameter ΔE^* in evaluating the quality of colour change of chemical indicators.

Screening

The quality of colour change of the indicator PAN in this titration is improved by mixing this indicator with Methylene Blue in the concentration ratio of 6:1. The colour change at the equivalence point for the screened indicator is found to be from violet to green through grey-ness ($a^* = -0.06$; $b^* = -0.25$ at equivalence point). The results obtained with screened and

Table 2. SCD values, ΔE^* colour difference at maximum colour change of some metallochromic indicators for bismuth

Indicator	SCD at max. colour change	Half band width of SCD	ΔE^* at max. colour change
Hematoxylin	3001.1	1.7	65.21
PAN	2161.1	2.6	62.99
Xylenol Orange	1677.9	2.5	51.33
PAR	1958.3	3.4	34.09
Thoran	1669.5	2.4	18.42

Table 3. Results obtained with PAN (single) as indicator and PAN + Methylene Blue (6:1) screened indicator in the titration of Bi(III) with EDTA

Bi(III) taken, mg		Bi(III) found, mg	Relative standard deviation, %	Relative error, %
2.42	Single	2.48	0.66	2.48
	Screened	2.44	0.41	0.82
4.85	Single	4.93	0.16	1.64
	Screened	4.88	0.20	0.61
7.27	Single	7.35	0.13	1.10
	Screened	7.31	0.12	0.55
9.70	Single	9.77	0.10	0.72
	Screened	9.73	0.09	0.31
12.12	Single	12.21	0.07	0.74
	Screened	12.14	0.09	0.16

unscreened indicators, presented in Table 3, shows the higher accuracy achievable while using the screened indicator due to the distinctive colour change at the end-point which passes through colourlessness.

CONCLUSION

The quality of colour change of the indicators in the titration of bismuth(III) with EDTA is measured quantitatively with the help of tri-chromatic colorimetry, using the parameters SCD (specific colour discrimination) and ΔE^* (total colour difference) and it is found that Hemotoxylin is the best indicator out of those

studied in this titration. The application of the screened indicator PAN–Methylene Blue (6:1) yields improved accuracy over that using just PAN in this titrimetric determination.

A HIGHLY SENSITIVE COLOUR REACTION FOR CHROMIUM(VI) WITH THE IODIDE-BASIC XANTHENE DYE-PVA SYSTEM

LIU SHAOPU and WANG FUCHANG

Department of Chemistry, South West China Normal University, Beibei, Chongqing, Sichuan, People's Republic of China

(Received 28 June 1990. Revised 26 November 1990. Accepted 14 December 1991)

Summary—A highly sensitive spectrophotometric method has been developed for determination of chromium(VI), based on oxidation of I^- to I_3^- in acid medium, then formation of a 1:1 ion-association compound of I_3^- with a basic xanthene dye in the presence of poly(vinyl alcohol). The molar absorptivity is 1.79×10^5 l.mole $^{-1}$.cm $^{-1}$ at 600 nm for the Rhodamine B system, 1.56×10^5 l.mole $^{-1}$.cm $^{-1}$ at 600 nm with Ethylrhodamine B, 1.56×10^5 l.mole $^{-1}$.cm $^{-1}$ at 570 nm with Rhodamine 6G and 2.01×10^5 l.mole $^{-1}$.cm $^{-1}$ at 590 nm with Butylrhodamine B, respectively. Preconcentration of chromium(VI) by an improved trioctylamine extraction procedure greatly increases the selectivity of the method and can be applied in the spectrophotometric determination of trace amounts of chromium(VI) in tap water, hot-spring water and river water.

For the spectrophotometric determination of chromium(VI), the diphenylcarbazide (DPC) method is most commonly used.¹ The method has good selectivity, but the sensitivity is not very high, the molar absorptivity being only 4.3×10^4 l.mole $^{-1}$.cm $^{-1}$.

In recent years, some highly sensitive spectrophotometric methods for determination of chromium(VI) have been developed, for example, the *o*-hydroxyhydroquinone-phthalein-cetyltrimethylammonium chloride,² *o*-nitrophenylfluorone-cetyltrimethylammonium bromide³ and *p*-chlorophenylfluorone-CTAB-sodium laurylsulphonate method,⁴ with molar absorptivities of about 1×10^5 l.mole $^{-1}$.cm $^{-1}$, but lengthy heating is needed and the selectivity is rather poor.

Spectrophotometric determination of selenium(VI) by its oxidation of iodide to triiodide, and extraction of the tri-iodide ion-association complex with a basic dye in the presence of a surfactant has been reported,⁵ and the same principle is now applied for determination of chromium(VI). Poly(vinyl alcohol), PVA, is used as the surfactant and Rhodamine B (RhB), Rhodamine 6G (Rh6G), and the ethyl and butyl esters of Rhodamine B (ERhB and BRhB respectively) are used as the counter-ion. The colour reactions have high sensitivities, with molar absorptivities between 1.56×10^5 and 2.01×10^5 l.mole $^{-1}$.cm $^{-1}$.

EXPERIMENTAL

Reagents

Standard chromium(VI) solution. A stock solution containing 100 μ g/ml chromium was prepared by dissolving 282.9 mg of pure potassium dichromate in 1000 ml of distilled water, and diluted further as required.

Phosphoric acid, 4M.

Potassium iodide solution, 100 mg/ml.

PVA solution, 1%,

RhB solution, 0.2 mg/ml.

ERhB solution, 0.2 mg/ml.

BRhB solution, 0.1 mg/ml.

Rh6G solution, 0.1 mg/ml.

Trioctylamine (TOA) solution, 5% in chloroform.

Saturated sodium sulphate solution.

Saturated sodium chloride solution.

Apparatus

A Hitachi U-3400 spectrophotometer and a 721 spectrophotometer were employed for absorbance measurement.

Procedure

Place a sample (≤ 5 ml) containing up to 5 μ g of chromium(VI) in a 25-ml standard flask, add 1 ml of 4M phosphoric acid and 2 ml of potassium iodide solution and dilute to 10 ml with water. Set aside for 5 min, then add 5 ml

Fig. 1. Absorption spectra of the ion-associates: 1, RhB *vs.* water; 2, Cr(VI)-KI-RhB *vs.* RhB [Cr(VI), 4 μ g]; 3, Rh6G *vs.* water; 4, Cr(VI)-KI-Rh6G *vs.* Rh6G [Cr(VI) 3 μ g]; 5, ERhB *vs.* water; 6, Cr(VI)-KI-ERhB *vs.* ERhB [Cr(VI) 3 μ g]; 7, BRhB *vs.* water; 8, Cr(VI)-KI-BRhB *vs.* BRhB [Cr(VI) 2 μ g].

of basic dye solution and 2 ml of PVA solution. Dilute to the mark with water and mix. Measure the absorbance in a 1-cm cell at the wave-length of maximum absorbance against a reagent blank.

RESULTS AND DISCUSSION

Absorption spectra

Figure 1 shows the absorption spectra of the ion-associates of the I_3^- ion with four basic xanthene dyes. The absorption maxima are at 600 nm for the RhB and ERhB systems, 570 nm for the Rh6G system and 590 nm for the BRhB system; a bathochromic shift of 20–40 nm from the absorption maxima of the reagent blanks.

Effect of acidity

Figure 2 shows the dependence of the absorbance of the ion-associate on acidity. All the reactions are carried out in dilute phosphoric acid medium, but the optimum acidity ranges vary according to the system.

Effect of reagent concentrations

The optimum concentrations of potassium iodide are 0.024–0.048M for the RhB and BRhB systems, 0.036–0.060M for the Rh6G system, and 0.048–0.072M for the ERhB system, respectively.

The optimum concentrations of the basic dyes are as follows: $(0.76\text{--}1.35) \times 10^{-4}$ M RhB, $(0.84\text{--}1.01) \times 10^{-4}$ M Rh6G, $(0.70\text{--}0.94) \times 10^{-4}$ M ERhB and $(0.76\text{--}1.06) \times 10^{-4}$ M BRhB.

Effect of PVA and β -cyclodextrin

In the presence of PVA or β -cyclodextrin (β -CD), the solution remains clear and the absorbance has good stability. The optimum amounts of 10 mg/ml PVA or β -CD solution are between 0.5 and 4.0 ml. With PVA the absorbance is stable for 60 min for the RhB, Rh6G and ERhB systems, and 30 min for the BRhB system. In the absence of PVA or β -CD, the ion-associates are precipitated and the solutions are turbid.

Composition of the ion-associates

The reacting ratio of chromium(VI) to RhB was found to be 2:3 by the Job method and the

Fig. 2. Effect of acidity on determination of 5 μ g of Cr(VI): 1, Cr(VI)-KI-RhB system; 2, Cr(VI)-KI-ERhB system; 3, Cr(VI)-KI-Rh6G system; 4, Cr(VI)-KI-BRhB system.

Table 1. Interference of foreign ions in the determination of 5 μg of chromium(VI) with the RhB system

Ion	Amount added, μg	Cr(VI) found, μg	Ion	Amount added, μg	Cr(VI) found, μg
Ca^{2+}	10000	5.0	Br^-	10000	4.7
Zn^{2+}	10000	4.7	HCO_3^-	10000	5.0
Ni^{2+}	10000	4.8	F^-	5000	5.0
Mn^{2+}	10000	5.2	Ac^-	5000	5.0
Mg^{2+}	5000	5.0	NO_3^-	5000	5.2
Al^{3+}	20	5.2	BO_3^-	5000	5.0
Cu^{2+}	10	5.1	ClO_4^-	500	5.3
Hg^{2+}	10	4.8	AsO_4^-	500	5.2
Co^{2+}	10	4.8	$\text{S}_2\text{O}_3^{2-}$	5	5.0
Sb(V)	5	5.1	HSO_3^-	5	5.0
Fe^{3+}	5	5.0	NO_2^-	1	5.0
Pb^{2+}	5	4.8		1	5.1
Cd^{2+}	2	5.2			
Ag^+	2	5.0			

equilibrium shift method, indicating that the colour system is based on the equations

Sensitivity and selectivity

The molar absorptivities were found to be $2.01 \times 10^5 \text{ l. mole}^{-1} \cdot \text{cm}^{-1}$ for the BRhB system, $1.79 \times 10^5 \text{ l. mole}^{-1} \cdot \text{cm}^{-1}$ with RhB, and $1.56 \times 10^5 \text{ l. mole}^{-1} \cdot \text{cm}^{-1}$ with Rh6G and ERhB. Beer's law is obeyed over the range 0–0.2 $\mu\text{g/ml}$ chromium (but 0–0.08 $\mu\text{g/ml}$ for the BRhB system).

The selectivity of the RhB system was investigated in the determination of 5 μg of chromium(VI) in the presence of a series of other ions. Table 1 shows the results. The main interfering ions are Hg(II), Pb(II), Sb(III, V), Fe(III), Ag(I), Cu(II), Se(VI) and some strong oxidants

or reductants. Se(IV) interferes when present in amounts $> 2 \mu\text{g}$.

The interference of MnO_4^- can be eliminated by added dropwise suitable amounts of sodium nitrite solution, and the effect of nitrite can be eliminated by adding urea.

Adam and Přibil⁶ have reported a procedure for extraction of chromium(VI) with trioctylamine, which very effectively separates it from large amounts of iron, aluminium, copper, cobalt, zinc, uranium, vanadium, *etc.* We have improved the procedure, extracting chromium(VI) with a chloroform solution of trioctylamine from 0.1–0.2M sulphuric acid, then stripping the chromium(VI) with 0.3M sodium hydroxide. The chromium(VI) is then determined as already described. The interference of many common metal ions and strong oxidants or reductants is eliminated. Thus the method has very high sensitivity and selectivity, and can be applied to the spectrophotometric determination of trace amounts of chromium(VI) in environmental water samples *etc.* Se(IV) can then be tolerated in amounts up to 5 μg .

Extraction of Cr(VI)

Concentrate 250 ml of water sample to 25 ml by heating, add 1 ml of saturated sodium sulphate solution, 10 ml of saturated sodium chloride solution. 10 ml of 1M sulphuric acid and dilute with water to about 50 ml. Shake with 5 ml of TOA solution in chloroform for 2 min, and discard the aqueous layer. Add 5 ml of 0.3M sodium hydroxide to the organic layer, shake the mixture for 2 min, and transfer the aqueous layer to a 25-ml standard flask. Complete the determination as above.

Table 2. Determination of chromium(VI) in synthetic water samples

No.	Cr(VI) added, mg/l.	Sample composition, mg/l.	Cr(VI) found, mg/l.
1	0.200	Fe^{3+} 200, Al^{3+} 200, Ca^{2+} 200, Zn^{2+} 200, Cu^{2+} 200, Co^{2+} 20, U(VI) 20, V(V) 20, Ti(VI) 10, Mo(VI) 10	0.210

ANNOTATION

IS NITRATE REALLY AN INERT ELECTROLYTE?

A BRIEF REVIEW

MADELEINE ŠTULÍKOVÁ

Lečkova 1521, 149 00 Prague 4, Czechoslovakia

(Received 16 November 1990. Accepted 5 February 1991)

Summary—It has been common practice to use sodium or potassium nitrate as a supposedly inert background electrolyte or for adjustment of ionic strength, but nitrate forms sufficiently stable complexes with many metals for its use to result in erroneous values for stability constants. This note surveys the effects.

It is generally accepted that voltammetric, and indeed all, electrochemical methods for determining low concentrations of a test substance (ion) must be applied in the presence of a large excess of a supporting (background) electrolyte, *i.e.*, that a constant and fairly high ionic strength (I) must be maintained in the test solution. The reasons for this requirement are so well known that it is not necessary to examine this subject here. It is obvious that this supporting electrolyte should in no way affect the test system or the electrode and hence the results obtained.

Fifteen or twenty or even more years ago, when the nature of electrochemical processes was not fully understood, considerable effort was expended to elucidate the mechanisms of electrochemical reactions. Consequently, the supporting electrolyte and other components of the solution were not taken for granted and consequently ignored in investigation of the main reaction of interest, as has often happened in more recent work, but were considered as potential participants in the overall electrochemical processes. As will be seen below, considerable information has been obtained on the role that the supporting electrolyte can play in these reactions. In recent years, the shift of interest away from theoretical study of voltammetric and polarographic processes and greater concern with the applications of these methods has led to a tendency to ignore the literature on the potential participation of "inert" electrolytes in electrode processes. There is a general

impression that perchlorates are always "inert" as background electrolytes and that nitrates are very similar, and that no great error is incurred in assuming them to have no effect on electrochemical processes occurring in the solution. These assumptions ignore the fact that the supporting electrolyte solution always contains ions that can interact in some manner with the test ions and/or the electrode surface and thus affect the reactions (properties) being studied. Unless there is a fairly detailed understanding of the types and magnitudes of these interactions, no assumptions can be made about the degree of inertness of a given electrolyte, and when these assumptions are made blindly, there is a very real danger (as will be pointed out below) that the whole set of measured data may be seriously in error. These considerations hold for all types of supporting electrolytes and buffer solutions, but only the case of nitrates in this context will be examined more closely here, as they provide particularly good example of the pitfalls in wait for the unwary.

The possible interactions of nitrates with the electrode/electrolyte/test substance system fall into a number of categories. These will be considered separately, but of course more than one type may be operative (and not necessarily independently) in a particular system. The cation in the supporting electrolyte will be neglected, not because it is not also a potential participant, but as being beyond the scope of this discussion.

Complex formation

The likelihood of formation of complexes of the test ion (usually a metal cation) with nitrate¹⁻⁵ is by far the greatest danger in the use of nitrates as "inert" electrolytes, but tends to be frequently ignored. In addition, mixed complexes can be formed with the participation of other anions or cations present in the solution.^{6,7} Neglecting such complexes can lead to serious errors when stability constants of weak complexes are measured, especially when the metal ion is present in excess and the change in free ligand is measured. A high nitrate concentration can then significantly decrease the concentration of free metal ion. When mixed nitrate/test anion/test cation complexes are formed, the results can be even more misleading. A large number of original papers on nitrate complexes have been published, and the stability constants have been tabulated in various compilations. Although this danger has been repeatedly pointed out in the literature,^{4,5} subsequent papers have consistently ignored earlier warnings, although it is obvious that doing so can at the very least lead to doubt as to the reliability of the results obtained. For example, nitrate was employed as the supporting electrolyte anion¹⁴ in a study of the stability constants of fluoride and chloride complexes of a number of metal ions, although an earlier work⁵ had specifically pointed out that this approach must necessarily lead to errors in these results.

The tendency for mixed complexes, including nitrate ions from the supporting electrolyte, to be formed and the effect that this can have on electrochemical studies have been discussed in a number of papers. For example, mixed cadmium–azide–nitrate complexes can be formed and their formation constants have been determined.⁶ The effect of these complexes on the electrochemical behaviour led the authors to suggest perchlorate as a replacement for nitrate in these systems, although this exchange may not be without its own dangers; a detailed discussion was given of the effect of mixed complexes on the electrochemical system.⁶ No attempt will be made here to give a detailed survey of the determination of the stability constants of nitrate complexes with various ions (see, for example, references 1–13) or of papers that have consistently ignored this danger. Rather, it will be pointed out that this factor should always be considered when employing nitrate and mixed electrolytes and that a careful

literature survey is the only basis for reliable results.

Electrode effects

So far, we have considered only the effects that can arise from interactions in the electrolyte solution. However, the effect that the solution components can have on the processes occurring at the electrode surface is obviously a factor that cannot (or at least should not) be ignored.

Nitrate ions can affect the electrode surface and reactions in a number of ways. For example, it has been found for certain solutions (where there was no evidence for complex formation between the test ion and nitrate) that nitrate ions were nonetheless specifically adsorbed on the electrode surface.¹⁵ This adsorption hindered the charge-transfer reaction of interest and was especially pronounced for the Cu^+/Cu reaction at mercury electrodes.¹⁵ In an apparently far more complicated interaction, nitrate has been found to enhance the adsorption of 2,2'-bipyridyl cadmium(II) complexes, through a complex equilibrium.¹⁶ A number of other papers have been published considering these specific adsorption effects (*e.g.*, by Fawcett and Solomon,¹⁷ and by Cachet *et al.*¹⁸). The effect of adsorption on the stability constants determined by polarographic methods of complexes of metal ions with adsorbable ligands was considered in a comprehensive work some twenty years ago.¹⁹

The effect of the adsorption of electrolyte species on the electrode surface is not, of course, limited to simple physical occupation of active electrode sites. These species must also necessarily affect the properties of the electrode double layer, as was pointed out a quarter of a century ago²⁰ but is now often forgotten. Double-layer effects in the absence of specific adsorption can also be significant (see, for example, references 21–23).

An effect that is not often considered is the catalytic influence that the test ion can have on reduction of nitrate. Such processes can lead to electrode responses that would be absent in the base electrolyte alone and could erroneously be attributed to the electrode reaction(s) of the test ion(s). For example, lanthanum has been found to catalyse nitrate reduction through the formation of at least two types of complexes,²⁴ which also affect the concentration of lanthanum available for electrode reactions. The underpotential deposition of cadmium has also been found to catalyse the reduction of nitrate

ions^{25,26} and lead reduced on the surface of a gold electrode has a similar effect.²⁷ Studies have been carried out (see, for example, references 28–30) to elucidate the mechanisms of these effects, which have even been utilized in the development of methods for nitrate determination, for example by Boese *et al.*³¹ and by Gómez-Nieto *et al.*³²

CONCLUSIONS

The list of ways in which the electrolyte ions can affect the test ions (through complexation, changes in the hydration,¹¹ solubility effects,³³ changes in the diffusion coefficients and solution viscosity³⁴) and the electrode surface^{35,36} (double-layer effects, changes in the number and type of active sites, specific adsorption of simple and complex ions, changes in the zero-charge potentials,³⁷ effects on the electrode kinetics³⁸) is far longer than is generally acknowledged in most practical applications (and even in some theoretical studies). Obviously, a detailed description of these effects for all types of test systems is more suited to a book than to such a short review. Here, it will only be emphasized again that a thorough literature survey including all the pertinent papers (*e.g.*, for possible effects on the determination of stability constants³⁹ and formation constants^{40,41}) is essential before beginning any experimental work with an "inert" electrolyte.

Acknowledgements—The author wishes to thank Dr. R. A. Chalmers of the University of Aberdeen for suggesting the subject of this review and for stimulating discussions, and the University of Aberdeen, Scotland, for providing facilities.

BOOK REVIEWS

Advances in Spectroscopy, Volume 18—Time Resolved Spectroscopy: R.J.H. CLARK and R. E. HESTER (editors), Wiley, Chichester, 1989. Pages xxi + 406. £100.00.

It is only fairly recently that experimental techniques and fundamental theory have progressed sufficiently to allow the probing of a rate process directly at the microscopic, molecular level. This achievement has required a major international scientific effort in the development of time-resolved spectroscopic methods to monitor both reaction kinetics and the molecular dynamic changes which occur during chemical and biological reactions. This book is, therefore, a timely contribution to the considerable progress made in this field and provides a detailed account of the state of some optically based techniques at the time of publication. A series of nine chapters by an international team of authors from the U.S.A., U.S.S.R., Canada, France and Japan provides a comprehensive review of the field, with all chapters quoting references up to 1988 and most up to 1989. The book is technique-based and all chapters provide a basic outline of the theoretical principles underlying a specific technique, a detailed experimental description and, finally, a discussion of some chemical systems to illustrate the type of information generated. A valuable feature of all the articles is the summary outline, by the authors, of future applications and development.

Chapter 1 introduces the novel technique of picosecond transient-phase grating spectroscopy which derives information on non-radiative energy relaxation processes in optically excited molecules by monitoring the changes in the index of refraction induced in the material by these processes. A substantial part of the book (Chapters 2, 3, 4, 6 and 7) is dedicated to developments in time-resolved Raman spectroscopy. Chapter 2 discusses the use of resonance rotational Raman spectroscopy to yield sub-picosecond dephasing of resonant electronic states of gases with rotational and vibrational specificity, and Chapter 3 discusses the monitoring of sub-picosecond vibrational dephasing in the condensed phase by coherent Raman scattering and libration relaxation by degenerate four-wave mixing using temporally incoherent light. Time-resolved resonance Raman spectroscopy is reviewed in Chapter 4, with a focus on transient radical intermediates produced in radiation and photochemical reactions in solution. A valuable discussion on time-resolved Fourier-transform infrared spectroscopy is given in Chapter 5, demonstrating the use of continuous-scan and step-and-sample (SAS) techniques to overcome a natural disadvantage of Fourier transform instruments, namely the requirement of a complete scan of the moving mirror in the Michelson interferometer to generate an interferogram from which spectral information is obtained. At the time of publication, microsecond time resolution had been achieved, with new instruments being developed capable of nanosecond time resolution. The application of time-resolved spectroscopy to biochemical systems is tackled in Chapters 6, 7 and 8 which demonstrate the use of resonance Raman and FTIR spectroscopy in obtaining vibrational information on the transient states in photosynthetic bacterial reaction centres and in obtaining sub-picosecond resonance Raman spectra of heme proteins. The final chapter in the book provides an exciting review of the current state-of-the-art in the generation of ultrashort optical pulses to realize femtosecond time-resolved spectroscopy.

This text represents another excellent addition to the "Advances in Infrared and Raman Spectroscopy" series and is an extremely worthwhile contribution to the field of time-resolved spectroscopy.

R. RAVAL

Electroanalysis of Biologically Important Compounds: J. P. HART, Ellis Horwood, Chichester, 1990. Pages 213. £42.50.

This book surveys amperometric electrochemical methods of estimating clinical and biochemical analytes. The techniques covered are voltammetry, polarography, stripping voltammetry and the use of amperometric detectors in liquid chromatography.

After a brief chapter on theory which serves to survey the various techniques, there follows the bulk of the book, which reviews recent work on a wide variety of analytes. There are separate chapters on pyrimidines and purines, amino-acids, peptides and proteins, vitamins, and coenzymes. Each chapter has sections on electroanalysis and liquid chromatography. New apparatus and techniques, and improvements to old methods, are all included. There is a very useful index of chemical substances and a rather short general index.

The book contains a great deal of useful information about the electrochemistry of the analytes discussed and experimental detail about possible methods of estimation. This information should be useful to an analytical expert when deciding which techniques are applicable to the solution of a particular problem.

This is an excellent book for an expert in either electrochemistry or biochemical or clinical analysis, but is not suitable for the novice, as it assumes considerable background knowledge and experience.

B. G. COOKSEY

Field Desorption Mass Spectrometry, L. PROKAI, Dekker, New York, 1990, Pages vi + 291. \$99.75 (U.S.A. and Canada), \$119.50 (elsewhere).

The aim of this volume 9 in the "Practical Spectroscopy Series" is a relatively complete description of fundamentals, recent developments in instrumentation and experimental techniques. The text is written for specialists working in the field of organic mass spectrometry. The book contains four chapters, each with 100–150 references.

The first part discusses the mechanisms of ion formation. The fundamentals of field desorption and ionization are treated only briefly but there is an excellent book by Beckey on this subject. Consequently, attention is directed primarily to the description of ion emission from the analyte on the emitter. Aspects such as transport along the emitter, the volatility of sample, and field-included extraction from electrolytic solutions and salts are dealt with.

The second chapter is devoted to experimental techniques and represents a major strength of the book. The different approaches for preparation and activation of the emitters are extensively treated, with many practical details and illustrations, showing the experimental set-up as well as micrographs of the resulting emitters. The operational procedures (*e.g.*, temperature selection) are discussed. Concerning instrumentation, many data and observations are packed into rather long sections. A better structure with more headings would have improved the readability of this part of the book. Additional topics such as high resolution, negative ions, tandem instruments and kinetics of the FD method are included. The chapter fulfils the two objectives of the book: an excellent source for practice and a valuable starting point for further reading.

A major part of the third chapter concentrates on the chemistry at the emitter surface. The principal processes and the possibilities to exploit additives and matrices are highlighted in a concise and very accessible way. A good coverage of typical fragmentations and their use for structural analysis is given. The problems related to quantification, and the precautions required, are presented with abundant references. Finally, field desorption is evaluated within the context of other methods for the analysis of thermolabile, high molecular-weight compounds and polymers. The discussion is primarily based on a table of representative papers. It would have been desirable to extend this section substantially and to give more adequate comments on the respective advantages and disadvantages of the techniques mentioned. The selection of the most appropriate technique for a practical problem remains the most important and frequently encountered task of a modern chemist and the specialists should share all their expertise on this aspect.

Part of this criticism is answered indirectly by the last chapter, dealing with selected applications in the field of pharmaceutical research and biosciences, environmental studies, characterization of fossil fuel and petrochemicals, study of inorganic and organometallic compounds and polymer applications. These topics give a well balanced view of the merits of field desorption for qualitative purposes as well as for quantification. Sometimes, the use of other techniques is mentioned, but little comparison is made.

In conclusion, this book provides excellent coverage of the practical aspects and fulfils its scope as a starting point for further reading on most aspects of the method. The major criticisms concerns the somewhat long sections, which could be better structured, and the lack of comparative discussion of field desorption in relation to other recent ionization techniques in organic mass spectrometry.

R. GIJBELS

Principles and Practice of Analytical Chemistry, 3rd Edition: F. W. FIFIELD and D. KEALEY, Blackie, Glasgow, 1990. Pages xii + 521. £19.95 (softback only).

The fact that this is the third edition of this book indicates both the success of earlier editions and the changing nature of the broad subject area, which necessitates frequent updating of material.

Following a short introduction which incorporates a glossary of terms, there is a short but useful chapter on the assessment of analytical data. The labelling of Fig. 2 can be construed as being deliberately vague as the section heading is "The Nature and Origin of Errors". A few worked examples on statistics are included but in general the problem exercises in the text are, unfortunately, not supplied with answers. Chapter 3 covers pH, complexation and solubility equilibria. These topics are dealt with at a very basic level, requiring no previous knowledge in these subject areas.

The amount of space devoted to each analytical technique is based upon its application in industry and Chapter 4 on separation techniques is the largest in the book. Solvent extraction, chromatography and zone electrophoresis are covered. More detail on HPLC instrumentation has been included and GC-mass spectrometry and GC-IR are mentioned. Chapter 5 introduces titrimetry and gravimetry and Chapter 6 covers electrochemical techniques.

Analytical spectrometry is introduced in Chapter 7 and dealt with at the atomic level (absorption and emission) and at the molecular level in subsequent chapters. Both qualitative and quantitative aspects of analysis are covered. Mass fragmentation analysis (strictly not a spectroscopic technique), NMR and IR are included along with visible and ultraviolet spectrometry. I would like to have seen some mention of spectrofluorimetry in this section.

A separate chapter on radiochemical methods is very basic and attempts to cover this entire field in less than thirty pages. The chapter on thermal methods (new for the 3rd edition) is an essential addition for a general text on analytical chemistry.

The penultimate chapter includes very useful examples of real analytical problems and discusses how the analyst selects relevant procedures to determine analytes present in a sample. The excellent examples could be supplemented with one involving the use of HPLC. The book concludes with a very competent chapter on the role of computers in analytical chemistry.

Overall this book is to be recommended for the undergraduate student because all the important analytical techniques are covered at an elementary level. It is also a very useful book for the analyst to have in the laboratory as a convenient

The excellent examples could be supplemented with one involving the use of HPLC. The book concludes with a very competent chapter on the role of computers in analytical chemistry.

Overall this book is to be recommended for the undergraduate student because all the important analytical techniques are covered at an elementary level. It is also a very useful book for the analyst to have in the laboratory as a convenient

reference source for most available techniques. (Some minor techniques are omitted and others such as flow-injection analysis are mentioned only briefly.) If more detail of techniques is required the reader can refer to the lists of recommended books, which are given at the end of each chapter. The book compares favourably with "Fundamentals of Analytical Chemistry" by Skoog and West.

P. J. COX

TrAC—Trends in Analytical Chemistry, Reference Edition Vol. 7: Elsevier, Amsterdam, 1988, Pages xii + 404. US\$200.0, Dfl. 380.00.

This book is the current volume in a series presenting a compilation of the archival material reprinted from the regular monthly edition of Trends in Analytical Chemistry (TrAC) 1988.

The regular monthly topics of *feature, trends, computer corner, interface, meeting reports, book reviews* and *in the news* are all reprinted. The page numbers are common to both editions.

The stated scope of TrAC is to provide broadly-based, easy-to-read scientific reviews of current developments in the analytical sciences, backed up by news and other features of interest to analytical chemists. Particular attention is paid to the impact of computers and biotechnology on analytical chemistry.

In all of the articles this remit has been fulfilled: the items are relatively short and very readable. However, there are only two items listed under biotechnology focus: chemiluminescence immunoassays and flow-through microfluorometry of immobilized enzymes—more might have been hoped for. The effect of computers is much more evident, with a regular monthly article *computer corner* and the four articles on interfacing; some of the trend items are also computer-orientated.

This book is well produced but at \$200 (£100 +) it is costly.

W. BRYCE

Silent Spring Revisited: G. J. MARCO, R. M. HOLLINGWORTH and W. DURHAM (editors), ACS, Washington, 1987. Pages xxiii + 214. U.S.A. and Canada: \$17.95 (softback), \$29.95 (hardback). Elsewhere: \$21.95 (softback), \$35.95 (hardback).

The focal point of *Silent Spring Revisited*, Rachel Carson's *Silent Spring*, has always been a seminal work. This 12-chapter symposium is an appraisal of recent knowledge and thinking on the application of pesticides in relation to the 1962 publication. As such it is difficult to categorize, but it would seem to have a role as a general and specialized source. The two main sections, Regulations and Overviews, include areas of concern which have been expanded since Carson, particularly the contamination of ground water, its effect on aquatics and also the analysis of toxic residues. If Carson's major contribution was to alert the authorities to the dangers of organochlorine insecticides, which resulted in their withdrawal in the U.S.A., then the preoccupation of the nineties may well be whether the replacement organophosphates and carbamates are really safe. The controversial question of carcinogenesis is also discussed. Some useful tables of data illustrate the effects of pesticides on both wildlife and human populations. Each chapter includes references and a glossary, but there are some overlaps and slightly confusing synonyms. A comprehensive index helps to weld together a rather disparate work.

H. J. FLETCHER

Fourier Transforms in N.M.R., Optical and Mass Spectrometry, A User's Handbook: A. G. MARSHALL and F. R. VERDUN, Elsevier, Amsterdam, 1990. Pages xvi + 450. U.S. \$107.25, Dfl. 220.00 (hardback), U.S. \$46.25, Dfl. 95.00 (softback).

The commercial availability of computer-controlled, pulsed, generating and detecting equipment is presently stimulating a renaissance in nearly all branches of spectroscopy. Applications of pulse techniques are continuously being developed and extended, and not only are they causing enormous changes in physics, chemistry, biochemistry, biology and medicine, they are also enormously influencing the training of spectroscopists. It is now crucially important that spectroscopists understand Fourier transform methods and be able to apply them.

This very interesting book has arrived at just the right time. It provides a self-contained unified mathematical treatment of Fourier transform methods and their applications to several branches of spectroscopy. It is aimed at practising spectroscopists, so non-ideal effects are treated in some detail. Noise, non-linear response, limits to spectrometer performance arising from finite detection periods, finite data size, misphasing, etc., are all considered. The use of complex variables to represent physically real quantities, the interpretation of negative-frequency signals, chirping, on-resonance vs. off-resonance responses, Hadamard codes, multiplex advantages and disadvantages, are just examples of topics that are explained.

The fundamental line shapes that are encountered in all branches of spectroscopy are introduced in Chapter 1. Chapters 2 and 3 summarize the basic mathematics of continuous (analogue) and discrete (digital) Fourier transforms, and their practical implications. Chapter 4 discusses common experimental aspects of *signals* encountered in spectroscopy. Chapter 5 similarly discusses *noise*. In Chapter 6, non-Fourier transform methods, including autoregression and maximum entropy methods, are introduced and critically compared with Fourier transform techniques. Chapters 7 and 8 discuss aspects of Fourier transform spectroscopy that are unique to ion cyclotron mass spectroscopy and nuclear magnetic resonance

reference source for most available techniques. (Some minor techniques are omitted and others such as flow-injection analysis are mentioned only briefly.) If more detail of techniques is required the reader can refer to the lists of recommended books, which are given at the end of each chapter. The book compares favourably with "Fundamentals of Analytical Chemistry" by Skoog and West.

H. J. FLETCHER

Fourier Transforms in N.M.R., Optical and Mass Spectrometry, A User's Handbook: A. G. MARSHALL and F. R. VERDUN, Elsevier, Amsterdam, 1990. Pages xvi + 450. U.S. \$107.25, Dfl. 220.00 (hardback), U.S. \$46.25, Dfl. 95.00 (softback).

The commercial availability of computer-controlled, pulsed, generating and detecting equipment is presently stimulating a renaissance in nearly all branches of spectroscopy. Applications of pulse techniques are continuously being developed and extended, and not only are they causing enormous changes in physics, chemistry, biochemistry, biology and medicine, they are also enormously influencing the training of spectroscopists. It is now crucially important that spectroscopists understand Fourier transform methods and be able to apply them.

This very interesting book has arrived at just the right time. It provides a self-contained unified mathematical treatment of Fourier transform methods and their applications to several branches of spectroscopy. It is aimed at practising spectroscopists, so non-ideal effects are treated in some detail. Noise, non-linear response, limits to spectrometer performance arising from finite detection periods, finite data size, misphasing, etc., are all considered. The use of complex variables to represent physically real quantities, the interpretation of negative-frequency signals, chirping, on-resonance vs. off-resonance responses, Hadamard codes, multiplex advantages and disadvantages, are just examples of topics that are explained.

The fundamental line shapes that are encountered in all branches of spectroscopy are introduced in Chapter 1. Chapters 2 and 3 summarize the basic mathematics of continuous (analogue) and discrete (digital) Fourier transforms, and their practical implications. Chapter 4 discusses common experimental aspects of *signals* encountered in spectroscopy. Chapter 5 similarly discusses *noise*. In Chapter 6, non-Fourier transform methods, including autoregression and maximum entropy methods, are introduced and critically compared with Fourier transform techniques. Chapters 7 and 8 discuss aspects of Fourier transform spectroscopy that are unique to ion cyclotron mass spectroscopy and nuclear magnetic resonance

spectroscopy. Chapter 9 briefly considers Fourier transform/interferometry applications in other regions of the spectrum, particularly in infrared and Raman spectroscopy.

This is a timely, well-written, well-indexed book. Each chapter has a set of well-constructed examples, and their solutions. The lists of references include historically important key articles and reviews. The appendices include integrals and theorems for Fourier transform applications, Fast Fourier Transform program listings in both Fortran and Basic, and a pictorial atlas of Fourier transform pairs.

This is a book that deserves to be carefully read by all modern serious spectroscopists, of all kinds.

A. L. PORTE

An Introduction to Surface Analysis by Electron Spectroscopy: J. F. WATTS, OUP, Oxford, 1990. Pages x + 85. £9.95 (softback).

This book provides a short but excellent and comprehensive overview of the theory, practice, and application of X-ray photoelectron and Auger electron spectroscopy in surface analysis. The basic concepts, spectrometer design, and interpretation of spectra are described in clear and simple terms with an ample supply of illustrations. The sections on compositional depth profiling, applications to material science, and comparisons with other analytical techniques indicate clearly that this is now one of the principal methods of qualitative and quantitative analysis, and potential users of this and related techniques will find this book to be one of the best on the subject and exceedingly good value for money.

J. B. CRAIG

Practical Surface Analysis, Volume 1—Auger and X-Ray Photoelectron Spectroscopy: D. BRIGGS and M. P. SEAH (editors), 2nd Edition, Wiley, Chichester, 1990. Pages xiv + 657. £85.00.

The first edition of this book was published in 1983 and quickly achieved a very high reputation among surface spectroscopists. As in other fields, information and developments have expanded to such an extent that a new edition became necessary.

The book opens with a perspective by the principal authors on the analysis of surfaces and interfaces: this is followed by chapters on instrumentation, spectral interpretation, and depth profiling and quantification by Auger electron and X-ray photoelectron spectroscopy. The remaining chapters deal with the applications of AES in microelectronics, metallurgy, and heterogeneous catalysis, with the application of XPS in polymer technology, and with the applications of both techniques in corrosion science. There are nine appendices dealing comprehensively with scale calibration, charge referencing techniques, data analysis, chemical shifts, photoelectron and Auger energies, sensitivity factors, line positions, and kinetic energies.

Each chapter is well written, well illustrated and well documented, and the book is remarkably inexpensive; the reviewer has no hesitation in recommending this edition to practical and theoretical surface spectroscopists and to those in industry who desire better qualitative and quantitative surface characterization of their products. It is to be hoped that the covers of this edition are strong enough to withstand the constant usage that it is likely to encounter.

J. B. CRAIG

Understanding Insulin Action—Principles and Molecular Mechanisms: J. ESPINAL, Ellis Horwood, Chichester, 1989. Pages 129. £26.00.

There is a large amount of work currently published annually on insulin and this compact text presents primarily the recent facts and ideas. Details of metabolism and its control are only included when they relate directly to insulin, and relevant background knowledge is required.

The initial chapter attempts to convey the significance of the discovery of insulin by outlining the history of diabetes mellitus. This brief review covers the period from the description of the disease in the first century AD to the production of genetically engineered insulin in 1979. This is followed by a chapter on the chemistry, synthesis and secretion of insulin, and incorporates a section on the insulin gene. A chapter on the pathophysiology of insulin covers the effect of the hormone on muscle, adipose tissue and the liver. The metabolism of these tissues is examined in relation to the action of insulin and within this limitation it provides a useful review of the control of carbohydrate and fat metabolism. The latter part of this chapter discusses diabetes mellitus, its classification, diagnosis, symptoms, aetiology, complications and treatment. Under the heading of molecular mechanisms involved in insulin action consideration is given to the effects of insulin on proteins through enzyme phosphorylation/dephosphorylation and the movement of target proteins within the cell. Further chapters consider the insulin receptor and a number of compounds which have been proposed as possible secondary messengers within the cell. Finally the author attempts to summarize the data and provide a current molecular mechanism for the mode of action of insulin.

As a user of such texts I found this book valuable and a good source of references to review articles on insulin and related topics.

J. E. ATKINSON

spectroscopy. Chapter 9 briefly considers Fourier transform/interferometry applications in other regions of the spectrum, particularly in infrared and Raman spectroscopy.

This is a timely, well-written, well-indexed book. Each chapter has a set of well-constructed examples, and their solutions. The lists of references include historically important key articles and reviews. The appendices include integrals and theorems for Fourier transform applications, Fast Fourier Transform program listings in both Fortran and Basic, and a pictorial atlas of Fourier transform pairs.

This is a book that deserves to be carefully read by all modern serious spectroscopists, of all kinds.

It is to be hoped that the covers of this edition are strong enough to withstand the constant usage that it is likely to encounter.

Understanding Insulin Action—Principles and Molecular Mechanisms: J. ESPINAL, Ellis Horwood, Chichester, 1989. Pages 129. £26.00.

There is a large amount of work currently published annually on insulin and this compact text presents primarily the recent facts and ideas. Details of metabolism and its control are only included when they relate directly to insulin, and relevant background knowledge is required.

The initial chapter attempts to convey the significance of the discovery of insulin by outlining the history of diabetes mellitus. This brief review covers the period from the description of the disease in the first century AD to the production of genetically engineered insulin in 1979. This is followed by a chapter on the chemistry, synthesis and secretion of insulin, and incorporates a section on the insulin gene. A chapter on the pathophysiology of insulin covers the effect of the hormone on muscle, adipose tissue and the liver. The metabolism of these tissues is examined in relation to the action of insulin and within this limitation it provides a useful review of the control of carbohydrate and fat metabolism. The latter part of this chapter discusses diabetes mellitus, its classification, diagnosis, symptoms, aetiology, complications and treatment. Under the heading of molecular mechanisms involved in insulin action consideration is given to the effects of insulin on proteins through enzyme phosphorylation/dephosphorylation and the movement of target proteins within the cell. Further chapters consider the insulin receptor and a number of compounds which have been proposed as possible secondary messengers within the cell. Finally the author attempts to summarize the data and provide a current molecular mechanism for the mode of action of insulin.

As a user of such texts I found this book valuable and a good source of references to review articles on insulin and related topics.

J. E. ATKINSON

Chiral Separations by HPLC—Applications to Pharmaceutical Compounds: A. M. KRSTULOVIĆ (editor), Ellis Horwood, Chichester, 1989. Pages 548. £78.45.

This book fully achieves the aim set out by the editor in the preface, namely to present the state of the art in chiral HPLC separations. The editor is to be complimented on achieving a consistently high standard of content and presentation from many different international experts.

Part I consists of four chapters dealing with chirality in nature, the unacceptability of data on racemates, enzymes, and enantiomer separation by crystallization. To some extent, Part I is remote from the main thrust of the book but Chapters 2 and 3 do serve to point out forcefully (and accurately) the limitations of drug investigations which ignore the existence of chirality. Part II covers, in three chapters, the main types of mobile phase additives; metal ions, chiral counter-ions; and the cyclodextrins. Part III forms the majority of the volume and begins with two chapters which give an introduction to the use of chromatography for chiral separations, and some pharmacokinetic and metabolism applications. Subsequent chapters deal with the diverse types of chiral stationary phases in current use. All of the chapters in Parts I and II incorporate good coverage of the principles of interaction and examples of separations achieved.

The content of the book as a whole is broad enough to provide the reader with a useful overview. Each chapter, however, is sufficiently detailed and well enough referenced to be useful to chromatographers practically engaged in chiral separation and analysis.

R. B. TAYLOR

Flow Injection Atomic Spectroscopy: J. L. BURGUERA (editor), Dekker, New York, 1989. Pages xii + 353. \$125 (U.S.A. and Canada), \$150 (elsewhere).

The development of flow injection analysis (FIA) has seen probably the most remarkable increase in research activity, as evidenced by publications, of any of the recent advances in instrumental analytical chemistry. This text breaks new ground in that it is the first on FIA to deal with a specific aspect, FIA as a sample introduction system for atomic spectrometry. The various aspects of the subject are covered, including theoretical aspects, instrumentation, applications and current trends. There are a large number of contributors, which leads to a certain amount of repetition and even conflicting view-points so the book is stimulating in this regard. It is thus not a text book presenting material in a logical sequence of steps but rather it sets out to serve both as a practical handbook on experimental aspects and also to bring the reader up to date with recent developments. It certainly succeeds with the latter objective, being a most comprehensive account of the state of the subject. I would criticize the book in that FIA is essentially a practical subject and more information could have been given on building systems from standard laboratory components. Much is left vague, requiring consultation with the literature to investigate whether any more detailed experimental information is available, particularly with regard to the flow-injection-spectrometer interface. In this regard the book is insufficient to let experimenters see for themselves the potential of such systems prior to purchasing commercial equipment. This book will be of most use to those analytical chemists who need to be rapidly acquainted with potential applications of FIA-atomic spectrometry or those who are already users and wish to extend the application to new samples.

A. R. MORRISON

Atomic Spectroscopy: J. W. ROBINSON, Dekker, New York, 1990. Pages vi + 299. \$55.00 (on orders of 5 or more copies, for classroom use only). \$99.75 (U.S.A. and Canada). \$119.50 (all other countries).

There are some good points about this book, but overall I was disappointed by Professor Robinson's introductory text on atomic spectroscopy.

Chapter 1 provides a brief but comprehensive background to the subject with useful sections on atomic structure and atomic spectra. Those new to the subject (*e.g.*, undergraduates) will find the comments on significant figures, reliability of results and sampling of particular interest. Chapter 2 is devoted to atomic-absorption spectrometry (AAS). The basics of AAS instrumentation are described, but there is little information on atomization and interference mechanisms in both flame and electrothermal atomization (ETA). Indeed, of the fourteen pages on ETA, only two pages describe modern developments. Unfortunately, Chapter 2 is dated in many respects. Most commercial AAS instruments only permit operation with premixed air/acetylene and nitrous oxide/acetylene flames, so details about total consumption burners and the use of air/hydrogen or air/coal gas flames are unnecessary. Contrary to the author's comments, oxy-acetylene and oxy-hydrogen flames are not routinely used in AAS.

Chapter 3 covers the basics of atomic-fluorescence spectrometry (AFS) and gives balanced comments on the advantages and limitations of the technique. Unfortunately, little information is given about the main commercial AFS system, which uses an inductively coupled plasma (ICP) as the atomizer. Also, there is no mention of the benefits of laser AFS with an electrothermal atomizer.

I am not sure why a separate chapter was devoted to flame atomic-emission spectrometry (FAES), or Flame Photometry as Chapter 4 is titled, as few analysts now use this technique. I suppose the table of FAES wavelengths will be useful to some readers who may perform occasional analyses by FAES, with commercial FAAS instruments.

Also, there is no mention of the benefits of laser AFS with an electrothermal atomizer.

I am not sure why a separate chapter was devoted to flame atomic-emission spectrometry (FAES), or Flame Photometry as Chapter 4 is titled, as few analysts now use this technique. I suppose the table of FAES wavelengths will be useful to some readers who may perform occasional analyses by FAES, with commercial FAAS instruments.

Chapter 5 provides an introduction to arc and spark atomic-emission spectrometry. The latter technique is still widely used in the metallurgical industry, but arc AES is rarely used in modern laboratories. The chapter has an instrumental bias and is of historical interest. The tables of arc and spark detection limits provide a good basis for comparison of the techniques.

Chapter 6 describes the newer developments in emission spectrometry, with emphasis on inductively coupled plasma (ICP) and direct current plasma (DCP) sources. The instrumentation required for both techniques is discussed but the fundamental processes of plasma spectroscopy are not covered in any detail. A few pages on ICP-mass spectrometry are included at the end of the chapter.

At the reduced bulk purchase price, this book may be an attractive introductory text for undergraduate courses on atomic spectrometry, but it would need to be supplemented by more detailed information on recent developments if such a course was to be truly up-to-date. Its most useful features are the tables of wavelengths for AAS, AFS and AES, the comparative data on detection limits and the information on instrumental systems. However, at the full-cost price, I suspect that the book will not be considered great value by analytical chemists looking for a fundamental text or an up-to-date reference text on analytical methodology.

D. LITTLEJOHN

Chemometrics—Applications of Mathematics and Statistics to Laboratory Systems: R. G. BRERETON, Ellis Horwood, Chichester, 1990. Pages 307. £45.00.

Chemometrics (the design and analysis of laboratory experiments) is of undoubted importance—it does not need much more than a brief scan through the scientific literature to see how poorly many experiments are planned, and how inadequately their data are processed. In many ways the wide availability of the laboratory microcomputer-controlled experiment makes the need for a good understanding of design even more important, yet it is scarcely even mentioned at undergraduate level. Richard Brereton's book will help: it gives good explanations, is readily understood with a minimum of mathematics and covers a wide range of topics. It is very much a "how to do it" publication, although necessarily within the confines of 307 pages the detail may not always be sufficient to enable readers to carry out such procedures for themselves without further information. However, the background obtained from this book will be invaluable when moving to more advanced references.

The topics include factorial design, principal component analysis, univariate and multivariate analysis, and pattern recognition. Interestingly, the maximum entropy method is included with an example involving NMR spectroscopy.

I have one criticism. In its natural handling of prior knowledge and its modification through experiment, Bayesian statistics is the obvious way to proceed in chemometrics rather than use of classical, frequentist statistics. Throughout the book the author uses the language of Bayesian statistics; his approach is also Bayesian. Why then is his mathematical formalism based on classical approaches with not even a mention of the Bayes theorem?

Nonetheless, this is a book to be welcomed—I know I shall be using it.

REVIEW: POLYANILINE—A NOVEL POLYMERIC MATERIAL

AKHEEL A. SYED* and MARAVATTICKAL K. DINESAN

Department of Studies in Chemistry, University of Mysore, Mysore, 570 006, India

(Received 23 July 1990. Revised 13 December 1990. Accepted 14 January 1991)

Summary—Polyaniline synthesis by chemical and electrochemical methods is reviewed. The considerable progress which has been made in characterizing and understanding the properties of polyaniline derived from aniline is discussed. Finally, the progress towards technological applications is evaluated.

The evolution of conducting polymers began in 1975, with the discovery that polysulphur nitride, [(SN)_x], becomes superconducting at low temperatures.¹ Two years later, a linear, conjugated organic polymer, polyacetylene, was shown to have metallic properties.^{2,3} This gave rise to a surge of activity directed towards the exploration, synthesis and characterization of the members of this class of material. Polyaniline is one such organic polymer, which has been rediscovered as a result of this exploration.⁴

Polyaniline (PANI) is now establishing itself as a novel material in the field of conducting polymers. The proposed and anticipated technological potential of PANI is due to its remarkable stability and processibility.

The variety and complexity of the behaviour of PANI—which is assumed to be a reflection of its complicated structure—is clearly manifested in the literature, wherein divergent views have been put forth by different schools of research working on several basic aspects, such as polymerization and redox mechanisms, electronic and ionic conductance, role of protons and water, importance of capacity effects and electrostatic interactions, and stability and solubility, to mention just a few. Therefore, it is not surprising that much of the work on PANI has been, up until now, rudimentary and exploratory in nature. The purpose of this article is to provide an overview of the status and understanding of this complex and interesting polymer.

HISTORICAL BACKGROUND

Polyaniline was first known in 1835 as "aniline black", a term used for any product obtained by the oxidation of aniline. A few years later,

Fritzche^{5,6} carried out the tentative analysis of the products obtained by the chemical oxidation of this aromatic amine. Thereafter, Letheby⁷ discovered that the final product of anodic oxidation of aniline at a platinum electrode, in aqueous sulphuric acid solution, is a dark brown precipitate. Subsequent investigators⁸⁻¹¹ have verified these results, and similar observations have been made during the oxidation of aqueous hydrochloric acid solutions of aniline.¹² Bucherer^{13,14} proposed a phenazene type structure which is more complex, contrary to the present day understanding. Green and co-workers¹⁵⁻²⁰ proposed a linear octameric structure, of the quinone-imine type in the *para*-position, for the product obtained by the chemical oxidation of aniline. The base of the octamer is leuco-emeraldine which exhibits four distinct states of oxidation. They are: protoemeraldine, emeraldine, nigraniline and pernigraniline (Fig. 1). In 1935, Yasui²¹ suggested a reaction scheme for the anodic oxidation of aniline at a carbon electrode. No further research was carried out until the middle of this century when Khomutov and Gorbachev^{22,23} re-examined the results of Yasui, and verified Letheby's original observation about the green precipitate. In addition, on the basis of current-time curves, two different mechanisms for the electrode reaction were proposed. It seems that pursuit of the earlier lines of research on oxidative condensation of aniline, will help us obtain a better understanding of aniline polymerization and the structure of PANI which are currently of interest.

CONSTITUTION AND NOMENCLATURE

Since the resurgence of PANI, there has been considerable confusion regarding its constitution. Studies since then have resulted in the

*Author for correspondence.

Fig. 1. Four oxidation states of leucoemeraldine.

formulation of a proposed structure for the polyanilines, together with a modification of the nomenclature based on the older concepts. As mentioned earlier, Green and Woodhead¹⁵ gave various trivial names to PANI, but they did not know the structure of the polymer at that time, believing it to be an octameric molecule.

PANI may be described as a combination of any desired relative ratio of the idealized repeating units depending on the experimental conditions to which the polymer is subjected. Different names have been proposed in the literature. For the sake of simplicity, we may summarize them as follows. PANI contains two

Fig. 2. Chemical structures of polyaniline.

principal units: (i) the completely reduced form of a repeat unit containing two benzenoid rings (Fig. 2a) and (ii) the completely oxidized form of a repeat unit containing one benzenoid ring and one quinonoid ring (Fig. 2b). In both cases, either one or both, of the nitrogen atoms in a repeat unit may be protonated, depending on the pH of the solution to which the polymer has been exposed. The base and protonated forms are referred to as the amine (A) and the salt (S) forms respectively²⁴ (Figs 2a and 2b). Proto-emeraldine, emeraldine and nigaraniline are the intermediate oxidation states of the above mentioned forms of PANI. Older nomenclature is also still in use; the only difference now being that 'poly' is prefixed to the earlier names. For example, the older term, 'emeraldine', is now replaced by 'polyemeraldine'. However, it is interesting to note that the smallest number of reduced and/or oxidized repeat units which can be used, and which will permit interconversion between the above five compositions, is eight—a finding which is in full agreement with the structure proposed by Green and co-workers¹⁵⁻²⁰ for polyaniline. The conversion of the completely reduced form to the completely oxidized state involves a loss of electrons and protons, as illustrated in Fig. 2c. The reversibility of the reaction opens up technological applications which will be discussed later.

Of the five oxidation states of PANI, polyemeraldine, with the structure shown in Fig. 1 has been most widely studied. For the convenience of readers, the term 'emeraldine' or 'polyemeraldine' will henceforth be used for the emeraldine oxidation state of polyaniline, and the term 'polyaniline' (PANI) for the polymer skeleton containing any one or more oxidation states of polyaniline.

SYNTHESIS

Polyaniline may be synthesized by two principal methods: the direct oxidation of aniline by chemical oxidants, or by anodic oxidation on an inert electrode. (Henceforth, the term PANIC will be used to represent chemically synthesized polyaniline, and PANIE for electrochemically polymerized polyanilines.)

Chemical synthesis

PANIC is a precipitated product from an aqueous solution containing typical reagents: ammonium peroxydisulphate (persulphate),

acids like hydrochloric, sulphuric, nitric or perchloric, and aniline. This direct route represents the classical approach to polyaniline synthesis in which, aniline, the monomer, is converted directly to a conjugated polymer by a condensation process. One of the disadvantages of this direct approach stems from the experimental observation that an excess of the oxidant and higher ionic strength of the medium lead to materials^{25,26,27} that are essentially intractable.

It is not possible to polymerize the *ortho*- and *meta*-substituted aniline derivatives, due to the steric and weak inductance effects of the substituents. The *para*-position should be kept free for radical coupling. During oxidative condensation of aniline, the solution progressively becomes coloured and yields a black precipitate. The colouration of the solvent is probably due to the soluble oligomers. The intensity of colouration depends on the nature of the medium and the concentration of the oxidant.

Many variations of the synthesis of PANIC have appeared in the literature. Four major parameters affect the course of the reaction, and the nature of the final product. These are: (1) nature of the medium, (2) concentration of the oxidant, (3) duration of the reaction and (4) temperature of the medium. Besides these, we have studied the combined effect of the concentration of ammonium persulphate (oxidant), and of duration of the polymerization reaction on the percentage yield of insoluble precipitate (polyaniline). The results are displayed in a three-dimensional diagram (Fig. 3).

Fig. 3. Chemical synthesis of polyaniline. Three-dimensional diagram.

Medium. While choosing a medium for the synthesis of PANIC the following factors have to be kept in mind to obtain desirable results: (1) low ionic strength, (2) volatility and (3) non-corrosive nature of the medium. No medium satisfies all of the above requirements. Sulphuric acid is dependable, but due to low volatility, a thin film of acid is left on the polyaniline powder after drying (to remove water) under dynamic vacuum. Hydrochloric acid and a novel anhydrous medium²⁷—a eutectic mixture of HF and NH_4F with an average formula of $\text{NH}_4\text{F} \cdot 2.3\text{HF}$ (henceforth referred to as NF) are both corrosive, even though they are more volatile than sulphuric acid. The demonstrated advantage of the NF medium is that the percentage yield of PANIC is maximum, when compared to any other medium.²⁷ Thus, the oligomers formed in the reaction are at a minimum, and one can expect an ordered material. We have employed²⁷ sulphuric acid containing 0.5M sodium sulphate (pH = 1) as a medium for the synthesis of PANIC. A low sulphuric acid concentration avoids undesirable cations^{25,26} While the presence of appreciable amounts of sulphate ions enhances the growth rate of the polymer chain.²⁸ It is generally admitted that the faster growth rate of nucleation yields better results. The unwanted thin film of sulphuric acid remaining on the particles of the powder could be eliminated by simple equilibration of the powder with 1M HCl.²⁹ This treatment imposes the chloride ions on the polymer, and eliminates sulphate ions. This has been demonstrated in many polyanilines prepared under various conditions, and thus, can be regarded as a general feature of polyanilines. Elimination of sulphate ions assumes importance if PANI is used as a battery material in non-aqueous solvents such as propylene carbonate—1M lithium perchlorate medium, because the presence of sulphate ions in the polymer matrix leads to undesirable precipitation of lithium sulphate.²⁹ The use of salts, such as sodium sulphate or sodium chloride, in sulphuric or hydrochloric acid, may probably contribute to the buffer effect and conductivity of the medium. Thus, the net effect results in augmentation of percentage yield of the insoluble precipitate, and of the 'quality' of the polymer obtained.

Concentration of the oxidant. Ammonium persulphate, potassium dichromate, ceric sulphate, sodium vanadate, potassium ferricyanide, potassium iodate and hydrogen peroxide have been employed as oxidants for the polymerization of aniline in acidic media. Ammonium persulphate

is most extensively used and the yield, elemental composition, conductivity and degree of oxidation of the resulting polymer are essentially independent of the value of the initial aniline/persulphate mole ratio (r), when $r \leq 1.15$.^{30,31} However, an $r > 1.15$ results in over-oxidation of the polyaniline, with a concomitant decrease in the conductivity³¹ and yield of the polymer.³² A marked change in morphology is also observed.³² In the case of higher concentrations ($r > 1.15$) of the oxidants, such as cerium(IV) sulphate, potassium dichromate, sodium vanadate and potassium ferricyanide, a complexation reaction probably occurs which results in products containing a large percentage of the metal,³² as is indicated by elemental composition data. This supposition may be further confirmed by igniting the sample, and analyzing the residue which must indicate the presence of the metal.³²

Duration of the reaction. The percentage yield of the polyaniline increases with time (0–2 hr), when $r \leq 1.15$. Thereafter, the duration of the reaction has only a limited influence on the yield, conductivity and elemental composition of the polymer.^{31,32}

Effect of temperature. The process of chemical oxidation of aniline consists of a slow endothermic step, which is dependent on the pH, temperature and the concentration of the reactants, and in which the dissolved oxygen in the solvent does not have any influence (in contrast to oxidation–reduction reagents which reduce the induction time); and a fast exothermic step which depends on the temperature and varies with the concentration of the oxidant. Furthermore, the rate of the polymerization reaction varies with temperature in the range 0–80°, whereas, the total enthalpy of the reaction ($H = 372$ kJ/mole) remains almost constant.³³

Apart from the major parameters discussed above, we have studied the effect of the standard reduction potential (SRP) of the chemical oxidant on the nature and yield of the final product, the polyaniline. The results of our preliminary studies along with the conclusions drawn by Pron *et al.*³⁴ are summarized below:

We have employed^{27,32} five oxidants, namely: ammonium persulphate, cerium(IV) sulphate, potassium dichromate, sodium vanadate and potassium ferricyanide. These oxidants have their SRP in the range 2.01–0.36 V *vs.* NHE. Pron *et al.*³⁴ have employed potassium iodate and hydrogen peroxide, as well as ammonium persulphate and potassium dichromate. The major conclusions we draw from these studies

Table 1. Chemical synthesis of PANI using different oxidants and varied reaction conditions

Oxidant	Time of reaction, hr	Temperature, °C	Reaction medium	Normalized aniline/oxidant ratio	Yield, %
*KIO ₃	15	Zero	2M HCl	0.61	100.0
*KIO ₃	3	Zero	2M HCl	0.61	48.5
*(NH ₄) ₂ S ₂ O ₈	1.5	Zero	2M HCl	0.61	82.4
*H ₂ O ₂	15	Room temp.	4M HCl	0.61	60.0
(NH ₄) ₂ S ₂ O ₈	1	Room temp.	1M H ₂ SO ₄	1.00	99.0
Ce(SO ₄) ₂	1	Room temp.	1M H ₂ SO ₄	1.00	75.4
K ₂ Cr ₂ O ₇	1	Room temp.	1M H ₂ SO ₄	1.00	96.0
Na VO ₃	1	Room temp.	1M H ₂ SO ₂	1.00	94.4
K ₃ [Fe(CN) ₆]	1	Room temp.	1M H ₂ SO ₄	1.00	2.1

*Data from Pron *et al.*³⁴

are: (1) the SRP of the oxidant greatly affects the yield of polyaniline and (2) ammonium persulphate is a better oxidant for the polymerization of aniline, because of (i) high SRP, (ii) non-metallic oxidizing species and (iii) non-interference of the reduction product, namely the sulphate ion. On the other hand, Pron *et al.* are of the opinion that: (1) the process of polymerization of aniline is probably much less dependent on the redox potential than on the degradation process; (2) degradation is significantly slowed down in the case of chemical preparation; (3) hydrogen peroxide is ruled out as a reagent in the synthesis of PANIC; and (4) potassium iodate is the most convenient, since it gives good quality samples in a wide range of synthesis parameters. However, it is desirable to mention that the latter employed different temperatures and reaction times for different oxidizing agents (Table 1). Hence, the conclusion drawn that potassium iodate is a better oxidant for the synthesis of PANIC appears to be arbitrary. Nevertheless, another recent communication reports³⁵ that potassium iodate has been used as the oxidant for the preparation of colloidal polyaniline.

Summing up the procedure, one may state that polyaniline was obtained as an insoluble residue during the oxidative condensation of aniline; it was then separated by filtration, washed with a copious amount of the acidic solution of desired ionic strength to remove oligomers, and dried under dynamic vacuum for *ca.* 48 hr. The resulting dark powder was generally transferred to a soxhlet apparatus to remove low-molecular-weight species, and extracted with CH₃CN until the extract was colourless. The material was dried under dynamic vacuum.

Chemical synthesis of emeraldine hydrochloride and emeraldine base

The method³⁶ used for the synthesis of emer-

aldine hydrochloride is summarized as follows. An aqueous solution of ammonium persulphate was added slowly to a solution of aniline in 1.0 mole/dm³ aqueous hydrochloric acid (both solutions precooled to 1°). The reaction mixture was stirred for about an hour (~5°). The precipitate formed was removed by filtration, and washed repeatedly with 1.0M hydrochloric acid, and dried under dynamic vacuum for 48 hr. The material thus obtained was identified as emeraldine hydrochloride.²⁴

The moist emeraldine hydrochloride precipitate cake was suspended in ammonium hydroxide solution for ~15 hr. The separated powder was washed and dried under dynamic vacuum, as described earlier. The powder obtained was analyzed as emeraldine base.³⁷ In conclusion, the chemical preparation of polyaniline is a good method, and at present, electrochemical methods also provide a satisfactory route.

Electrochemical polymerization

There is at present a two-fold interest in the electrochemical polymerization (ECP) process. First, ECP reactions provide a new method of polymerization with a fine control of the initiation and termination steps. Second, ECP have technological potential. Besides, one of the important features found in ECP reactions of conducting polymers is that they proceed with electrochemical stoichiometry. This is because electrochemical reactions are often much cleaner, with respect to possible pollutants, than chemical reactions. Moreover, electrons, as a reagent, are inherently pollution-free, at least, at the point of use.

Electrochemical methods generally employed for ECP of aniline are: (1) constant current or galvanostatic; (2) constant potential or potentiostatic and (3) potential scanning/cycling or sweeping methods. The first essentially consists of a two-electrode assembly dipped in an electro-

lyte solution containing the monomer. Passing a current density of *ca.* 1 mA/cm² will lead to the deposition of a PANIE film on the surface of a platinum foil electrode. Polymerization of aniline at constant potential produces a powder which adheres poorly to the electrode.⁴ On the other hand, electrooxidation of aniline by continuous cycling between the predetermined potentials produces an even polymeric film which adheres strongly to the electrode surface.^{4,38-40} This thin film can be cycled between oxidized and reduced states which are conducting. Thicker films can be produced and can be peeled off from the electrode surface to yield a free-standing, electrically conducting film. As these films are in the oxidized state, they represent polyaniline cations, and their overall charge balance is achieved by incorporation of counter anions from the electrolyte of the solution. The counter anions reported in the literature are F⁻,³⁸⁻⁴⁰ Cl⁻,²⁴ ClO₄⁻,²⁸ SO₄²⁻,^{28,29} and BF₄⁻.^{24,41}

The anodic oxidation of aniline is generally carried out on an inert electrode. Though the usual anode material would be platinum, or conducting glass, many metals such as Fe,⁴²⁻⁴⁴ Cu⁴⁵ and Au⁴⁶ have been employed. Graphite,⁴⁷ vitreous carbon,^{48,49} stainless steel³² and n-type silicon⁵⁰ have been used. Metals such as Ag or Al, which get oxidized more readily than aniline monomer, would obviously not be a good choice for the anode. Until recently, it was believed that PANIE deposited from aprotic solutions such as CH₃CN is electro-inactive, and, therefore, it was thought that electroactive polyaniline could be formed only from acidic aqueous solutions. However, it has been demonstrated that electroactive polyaniline can be synthesized in an aprotic solvent, such as a propylene carbonate solution containing an organic acid (CF₃COOH) and an electrolyte, lithium perchlorate.⁵¹

The ECP of aniline is described as a bimolecular reaction involving a radical cation intermediate. The reaction has a ΔH equal to 121 kJ/mole⁻³, αn equal to 1.2-1.3,⁵² where $n = 2$.⁵³ Here, n is the number of electrons consumed during the electrochemical polymerization and α is the transfer coefficient. The values reported in the literature for the number of electrons (n) consumed during ECP of aniline are 2.60-2.70,^{39,40} 2.16,⁴ and 2.25-2.29.²⁸ In summary, electrochemical methods have definite advantages over chemical methods of synthesis of polyaniline, mostly because of the reliability of the techniques. Moreover, the results show that the stoichiometric electropolymerization reaction

can be a general procedure for the preparation of organic polymer films, with electroactive properties and good electrode behaviour, polyaniline is one such example.

MECHANISMS OF POLYANILINE FORMATION

The numerous methods employed to synthesize PANI have produced several products which differ in their nature and properties and must represent the results of a multitude of polymerization mechanisms of aniline. In general, polymerization proceeds via the radical cation of the monomer, which then reacts with a second radical cation of the monomer to give a dimer by eliminating two protons. At the potential required to oxidize the monomer, the dimer or higher oligomer would also be oxidized, and thus could react further with the radical cation of the monomer to build up the aniline chain.

Mohilner *et al.*,⁵² Breitenbach and Heckner,⁵⁴⁻⁵⁶ Hand and Nelson,^{48,49} and Genies and co-workers^{38,39} have proposed mechanisms for electropolymerization of aniline. The point of agreement in the proposed mechanisms is the first step of oxidation of aniline, *i.e.*, formation of the radical cation. This radical cation gives three different resonance forms as shown in Fig. 4. Two mechanisms for the anodic oxidation of aniline in acidic and alkaline media have been reported.^{52,54-56} The mechanism in acidic media was proposed by Mohilner *et al.*⁵² based upon measurement of the kinetic parameters for the initial charge transfer step, and upon direct comparison of the properties, including infrared studies of the precipitate formed on the anode. On the basis of their experimental evidence, it was suggested that *p*-aminodiphenylamine is one of the intermediates in the electrochemical oxidation of aniline. They also demonstrated *p*-aminodiphenylamine undergoing electrochemical oxidation with greater facility than aniline. The mechanism of polymerization of aniline in a basic medium, like acetonitrile-pyridine, proceeds in a way essentially similar to that proposed earlier in the acid medium.

The anodic oxidation of aniline stipulates only the dimerization process.^{48,49} The formation of oligomers with the n value > 2 is ruled out in case the resulting product is a linear chain. Furthermore, it was concluded that the electrolysis product of aniline earlier characterized as "aniline black", emeraldine, *etc.*, is largely, if

not completely, composed of quinone–hydroquinone mixtures with a small amount of benzdine salt, and composition contingent upon the parent molecule. This is contradictory to our present understanding where the n value determined by gel permeation studies is shown to be greater than 800 repeat units.³⁸

The mechanism proposed by Genies and

co-workers^{38,39} for the electropolymerization of aniline in acidic media is based on detailed studies.^{57–59} Nevertheless, the results concerning the chronoamperometric plots during potential scanning, and potential step methods of electrodeposition of PANI have been taken into account.^{38–40} The mechanism is displayed in Fig. 5.

CHARACTERIZATION

General considerations of "Doping" in conjugated polymers

The treatment of a conjugated polymer with ionizing agents (charge-transfer agents) leads to a concomitant increase in conductivity. This process was named "doping", by analogy with the treatment of silicon with such elements as arsenic, boron and phosphorus. In crystalline silicon, which is tetravalent, the tri- or penta-valent element replaces silicon at a lattice site to produce a "hole" or "electron", respectively. These dopants as they are called are only added at ppm level as the mobility of the carriers is so high, whereas, the charge carriers of the polymers under discussion have lower mobility. Hence, the dopant concentration is increased considerably to attain desired mobility. The polymers derived from organic compounds, with π -electron conjugation and high "dopant" concentration, are termed conducting organic polymers. The nature of the dopant decides the type of conduction in the resulting conducting polymer chain. For example, positive charge carriers in an acceptor-doped polymer results in p-type conduction, while, negative charge carriers in a donor-doped polymer show n-type conduction.

The name "doping" has raised some controversy among scientists for the following reasons: (1) the presence of the "dopant" in conducting polymers is to balance the charge created either by electron removal or addition in the polymer chain, by a redox process unlike that in inorganic semiconductors; (2) the dopants are added at ppm levels to an inorganic material to make it semiconducting, while the amount of counterions in conducting polymers are in the range 10–50% by weight of the material composition; and (3) in inorganic semiconductors the dopants are metals, whereas in organic polymers they are generally non-metallic species. However, the word "doping" is still in use, probably because: (1) it helps to demonstrate similarities between conducting polymers and inorganic semiconductors; (2) in both cases doping changes the state of oxidation without changing the structure (in conducting polymers, doping changes only packing order, whereas the 1-dimensional properties exhibit only along the chains); and (3) the higher concentration of dopants in conducting polymers is to attain desired mobility of the charge carriers on par with inorganic semiconductors. For intrinsic conductivity the carrier concentration decreases exponentially with increasing band gap

(roughly equivalent to the optical absorption threshold), whereas, in conjugated polymers, due to relatively large band gaps, (the conductivity is not intrinsic) the concentration of free carriers is very low at normal temperatures. Therefore, even though conjugated polymers have backbone structures well suited to conduction (*i.e.*, high carrier mobilities), the low carrier concentration results in negligible conductivity. The other question, which remains unclear, is whether doping of polymers is also at random, as it is in a classical semiconductor. Here it is assumed that the dopant "dissolves" in the polymer matrix, unless the doping level exceeds a certain limit of solubility, which is perhaps in the vicinity of a few per cent. This assumption does not contradict the available structural data and is supported by the experimental results on the temperature-dependence of the electrical conductivity in the low doping regime.

Doping in polyaniline: A new concept

The novelty of the polyaniline is that it has a symmetrical conjugated structure, having extensive charge delocalization, resulting from a new type of doping of an organic-polymer salt formation rather than oxidation which occurs in the p-doping of all other conducting polymer systems. PANI differs from earlier studied conducting polymers such as polyacetylene and polypyrrole in that the electronic state of PANI can be controlled through both variation in the number of electrons and in the number of protons per repeat unit (Fig. 6).

The redox activity of PANI is pH-dependent in aqueous medium. It has been established that the electroactivity of PANI ceases in aqueous media of $\text{pH} > 4$.^{27,28} On the other hand, the electrochemical behaviour of PANI, investigated in an aprotic solvent, such as propylene carbonate, in the presence of 1M lithium perchlorate as supporting electrolyte demonstrates two purely electronic processes.²⁹ However, these redox processes also vanish, if a small amount of 2,4,6-trimethyl pyridine (a strong base) is added to the system.^{39,40} Furthermore, the dramatic effect of conductivity of PANI upon variation of pH (changing pH from 0 to 6 decreases electrical conductivity, σ , by six orders of magnitude)⁶⁰ clearly demonstrates that besides, the dopants (counterions), the presence of protons invariably has a pronounced effect on the conductivity. In a recent study,⁶¹ evidence is provided which proves that the emeraldine base form of polyaniline is doped by protonic acids to the metallic

conducting regime by a process involving neither oxidation nor reduction of the polymer, thereby introducing a new concept of doping to the conducting polymer field. In brief, proton-induced conductivity in polyaniline is a remarkable physical phenomenon demanding explanation.

Conductivity measurements

The electrical conductivity (σ) of a polymer may be defined as the ratio of net charge motion, J (or current density), brought about by an electric field, E .

$$\sigma = J/E$$

Poor solubility of polyaniline in commonly known solvents is the prime factor for the solid-state conductivity measurements. Both DC and AC conductivity experiments on polyaniline are reported in the literature. In DC conductivity studies, only the net charge which traverses the entire polymer is measured. In contrast, for AC

conductivity experiments, the electrical conductivity is measured as a function of the frequency of an alternating electric field.

The DC conductivity measurements of chemically synthesized polyaniline were first carried out by French scientists.^{25,26,62,63} A thin 13-mm diameter pellet previously compressed was placed between two mercury conductors and its conductivity was measured. The technique that is generally used now for measuring the solid-state conductivity of pressed pellets, or films of polyaniline, was developed by van der Pauw.⁶⁴ Here, four points of contact, almost equally spaced on the periphery of the sample, are made with a conductive paste such as electrodag. Alternatively, four wires can be embedded into the periphery of the sample. Current (i) is passed through two adjacent contacts while the voltage drop (V) is measured across the other two as shown in Fig. 7. The van der Pauw technique takes into account the sample thickness (d) and thus it must be measured along with the current-voltage characteristics of the sample. The formula employed for the measurement of conductivity, σ , is:

$$\sigma = \frac{\ln 2}{\pi d} \frac{i}{V}$$

A configuration based on the models of Fan *et al.*⁶⁵ and Paul *et al.*⁶⁶ for the *in situ* resistance measurement of polyaniline is reported in the literature.⁶⁶ The authors claim that this configuration is simpler than the one used earlier. The problems usually encountered in conductivity measurements are degradation of the physical form of the polyaniline pellet or film, such as cracking, exfoliation, and loss of electrical contact, to mention just a few. In summary, the electrical conductivity measured by any of

Fig. 6. Electroactive molecular structures in polyaniline.

Fig. 7. van der Pauw configuration for the measurement of conductivity.

the above techniques represents a lower limit for the inherent doped polyaniline.

Factors affecting the conductivity of polyaniline

The DC conductivity (henceforth referred to as conductivity) of chemically and electrochemically synthesized PANI is dependent on a number of parameters. For example, temperature,^{60,67-69} protonation/pH,^{41,60,61,70-79} humidity,^{70,71,79-81} oxidation state^{70,74,75,78,82-84} and counterion⁷⁰ exert major influences on the conductivity of PANI. Besides, temperature of synthesis,⁸⁵ pressure, and duration of compression of PANI powders^{25,26,30,32} also have a considerable influence on the conductivity of PANI.

Temperature. It is well known that the effect of temperature on the conductivity of metallic conductors and on semiconductors is quite different. In metals, or metal-like substances an increase in temperature causes a gradual decrease in conductivity, while the heating of a semiconductor results in a sharp increase in conductivity. The conductivity of PANI has been studied over a wide range of temperatures, *viz.* 5–300 K,⁶⁰ 20–340 K⁶⁸ and 80–300 K.⁶⁷ The data reveal the metallic character of the polymer. Besides temperature dependence, thermopower⁷² and wide range frequency (dc, 10^1 – 10^5 Hz, 6.5×10^9 Hz)⁶⁸ the effect on conductivity has also been reported in the literature. The temperature dependence of the dielectric constant indicates an increase of the coherence length with increasing temperature.⁶⁸ The details are beyond the scope of this article. Hence, the readers are requested to refer to the original papers cited under reference.

Protonation. Insulator-to-metal transition in polyaniline, effected via protonation, was first reported in 1985.^{41,60} Since then, extensive investigations have been carried out to establish proton induced insulator-to-metal transition phenomenon through magnetic,^{69,73,77} optical,^{83,86-90} photoinduced optical,^{91,92} transport,^{60,68,73} thermopower⁶⁰ and ESR studies.⁹³ The earlier studies led to the proposal that the electronic structure of insulator polyaniline (also referred to as emeraldine base) is transformed to that of a granular polaron metal upon protonation (also referred to as emeraldine salt form). Recent studies on protonic acid doping of the emeraldine salt form of polyaniline lend support to the idea that the distribution of protons between polymer and bathing solution is in thermodynamic equilibrium.⁹⁴

In brief, the conductivity of polyaniline is a function of protonation. The proton induced insulator-to-metal ($\sigma \cong 10^{-10}$ ohm⁻¹ cm⁻¹– $\sim 10^0$ ohm⁻¹ cm⁻¹) transition is an interesting phenomenon in polyaniline. This is not observed in other conducting polymers such as polythiophene and polypyrrole. This unique behaviour of polyaniline is due to three important causes. First of all, polyaniline does not have symmetric charge conjugation. That is, the Fermi level and band gap are not formed in the centre of the band, so that valence and conduction bands are quite asymmetric. Secondly, both carbon rings and nitrogen atoms lie within the conjugation path. This configuration differs, for example, from polypyrrole, whose heteroatoms do not contribute significantly to the π -band formation. Thirdly, the electronic state of the polymer can be changed through variation of either the number of electrons or the number of protons.

Humidity. This is an important parameter which greatly affects the conductivity of polyaniline. As indicated earlier, it was reported in 1971^{62,63} which led to the important conclusion that electronic conductivity is associated with the ionic state of the polymer. This information has aroused a great deal of interest. Extensive studies in recent years have demonstrated the importance of moisture content in understanding the behaviour and conduction mechanism of polyaniline. The details will be discussed later. In brief, the conductivity of polyaniline increases extremely rapidly upon exposure to water vapour in contrast to the slow decrease in conductivity under dynamic vacuum.⁸⁰

Oxidation state. PANI exists in many forms classified as follows: fully reduced and neutralized PANI (NH); the protonated species (NH₂⁺); the first oxidized, neutral and/or protonated forms, N= and NH⁺; and the fully oxidized state, N⁺. These forms are in thermodynamic relation to each other according to a classical "square scheme". Based on the hypothesis concerning the relative thermodynamic potential and pK-values for electron transfer, some interesting potential *vs.* pH diagrams are reported in the literature.^{74,75,78} These diagrams have contributed to a better understanding of that fact that quinonic imine is more basic than the corresponding aromatic amine in the polymer chain. These particulars are in conformity with the earlier observations.

A novel method of representing "state" of polyaniline in a three dimensional diagram was first reported by Salaneck *et al.*⁷⁴ Later Genies

and Vieil⁷⁸ proposed a three-dimensional surface diagram for the charge and conductivity to enable convenient and unambiguous description of the electrically conducting state of polyaniline-based polymers. These diagrams are useful, for example, in battery applications and electromagnetic interference (EMI) shielding.⁷⁸

Counterion. The dependence of resistivity of electrochemically synthesized polyaniline (PANIE) on the nature of the counterion was first observed by Paul, Ricco and Wrighton.⁴⁶ This resistivity shows typical U-type functional dependence on the electrochemical potential. The experiment was repeated by Fock and co-workers^{70,71} who used different anions [hydron buffer, paratoluene sulphonate ($\text{CH}_3\text{-C}_6\text{H}_4\text{-SO}_3^-$), tetrafluoroborate (BF_4^-), trifluoroacetate (CF_3COO^-) and chloride (Cl^-)] at pH 2. They also observed a similar U-type functional dependence.

In summary, proton assisted doping-induced conductivity in PANI is a remarkable physical phenomenon, greatly in need of explanation.

CONDUCTION MECHANISMS

The charge transfer in the "emeraldine" form of polyaniline has become the subject of increased study because of the interesting discovery of insulator-to-metal transition as a function of protonation. The proposal of the transition from the electronic structure for insulator PANI (base form of emeraldine) to a polaronic, metal-electronic structure of PANI (salt form of emeraldine) upon protonation is supported by a series of optical, magnetic and band structure studies (references cited in the preceding section). Much of the work on conduction mechanisms of polyaniline is centred around French^{81,95,96} and American^{68,70,71,79} groups. The only point of agreement between the two groups is that the conductivity of the metallic emeraldine salt polymer is sensitive to environmental humidity. The French group of researchers have proposed the presence of a conduction mechanism based on electron hopping between localized states, with a proton-exchange-assisted conduction of electrons, which they enthusiastically refer to

as PEACE. On the other hand, the American group, after extensive studies, have concluded that a charging-energy-limited-tunneling theory is most suitable for the explanation of transport phenomena in the emeraldine form of polyaniline.

The PEACE mechanism⁸¹ is based on room temperature studies of the frequency dependence of conductivity in the range 10^1 Hz– 10^{10} Hz. The French scientists' observation is that the conduction of protonated emeraldine is independent of frequency in this range. But an American group has disputed the choice of this range, and maintained that the measurement should have been conducted at frequencies above and below the aforesaid range also. Their argument is that the hopping mechanism proposed by the French group is not the most suitable for the transport phenomena in the usually existing emeraldine form of PANI.

The American group has carried out an extensive set of optical, photoinduced optical, magnetic, transport, electrochemical and mechanical studies on the polyaniline systems. Their study focuses on the essential role of molecular excitons* and polarons†. Photoexcitation of the exciton absorption in the insulator form leads to the occurrence of polaron absorption features. Insulator-to-metal transition causes a transformation of the electronic structure of the chain into a polaron lattice. These results are in agreement with the charging-energy-limited tunnelling theory. The presence of metallic islands of about 100–200 Å size and average charging energy, E , of about 20 meV and the presence of structural defects, broken bonds, chain links, excess protonation *etc.*, is responsible for sizable barriers between metallic islands. For want of space, this description must necessarily remain incomplete; the reader is requested to refer to the cited original papers, for a more detailed analysis.

In summary, the broad range of optical, magnetic and transport studies show that polyaniline is a system with physics substantially different from polyacetylene and polypyrrole. The present theories certainly account for conduction mechanisms which are interesting, but not conclusive. There is great need to further elucidate the various phenomena in this novel conducting polymer.

ELECTROCHEMICAL STUDIES

As indicated in the preceding sections, polymerization of aniline can be effected by electro-

*An exciton is a non-conduction, non-localized, excited electron state as in a semiconductor.

†A polaron is an excitation in a solid consisting of polar molecules, resulting from the interaction between an electron and its strain field. The presence of a polaron can be detected by irregularities in the shape of the conduction band.

Fig. 8. Electrochemical behaviour of PANI showing two redox systems.

chemical and chemical methods. In the former case, by choosing a suitable medium, polyaniline is obtained which adheres strongly to the electrode. In certain cases a regular growth with almost 100% polymerization yield is seen.³⁸⁻⁴⁰ The strong adherence to the inert electrode has been the basis of detailed electrochemical studies. In contrast, the polyaniline obtained by chemical methods is a dark green, violet, or black amorphous powder which does not adhere to any electrode material. This property has been a serious limitation for extensive electrochemical investigations.

Polyaniline deposited on an inert electrode is conducting in both anodic and cathodic regions. The observations on the electrochemical behaviour of PANI suggest a redox mechanism.³⁸⁻⁴⁰ Notably, the cyclic voltamperogram shows well-defined electroactive regions with at least two rapidly reversible and clearly defined electrochemical systems (Fig. 8).

Electrochemical synthesis of polyaniline

Effect of anodic potential. The cyclic voltamperograms recorded during the electropolymerization of aniline are shown in Fig. 9. At the first cycle, a distant peak corresponding to

Fig. 9. Cyclic voltamperograms showing the growth of polyaniline film.

the oxidation of aniline is observed at 0.7 V vs. $\text{Ag}/\text{Ag}^+ 10^{-2}M$ ($\text{Ag}/\text{Ag}^+ 10^{-2}M$ refers to silver wire dipped in $10^{-2}M$ silver nitrate solution).

Fig. 10. Cyclic voltamperograms showing the appearance of the third redox system 2,2', when the anodic potential is increased.

New peaks, which are ascribed to the electrochemical response of PANI deposits formed during the oxidation process of aniline, appear after the first cycle. The following cycles indicate a regular growth of polymer deposits. In Fig. 8 the polyaniline shows two redox systems. If the higher potential is applied (up to 0.9 V), the third redox system, 2,2' having its redox potential between 1,1' and 3,3' is seen (Fig. 10). The shape, the redox potentials and the electrochemical behaviour of systems 1,1' and 3,3' remain identical in the presence and in the absence of system 2,2'. Therefore, it is suggested that system 2,2' which shows a redox mechanism independent of the mechanism attributed to system 1,1' and 3,3', probably corresponds to a different polymeric structure.^{39,40} Genies *et al.* in their recent study have attributed the redox system 2,2' to the presence of a polymer containing phenazine rings, which is correlated to the formation of cross-linked polyaniline chains by a direct reaction of nitrenium aniline cation ($C_6H_5NH^+$) and the nitrenium of the polyaniline polymer ($-C_6H_4N^+$).⁹⁷ We²⁷ have carried out similar studies on chemically synthesized polyanilines, and drawn some different conclusions which will be discussed later.

If the anodic potential exceeds a certain limit, degradation of the polyaniline results. This

Fig. 11. Cyclic voltamperograms showing the loss of electroactive sites, as the anodic potential is increased after a certain limit (----) cyclic voltamperogram recorded after deterioration of the PANI film.

behaviour has been observed by a number of researchers.^{27,39,40,48,49,52,82,98-102} The degradation products of the polymer depend on the applied anodic potential during electropolymerization, and thereafter. Oxidative degradation of polyaniline refers to the loss of electroactive sites as illustrated in Fig. 11. In most of the cases, degradation occurs in two steps: (1) broadening of the peaks and (2) gradual disappearance of the electroactive sites (redox peaks). High potentials *ca.* 1.8 V in CH_3CN medium, or 1.9 V in aqueous medium, result in the cracking of the film. This is more likely in the case of aqueous media.³² However, it is reported that the redox potential of the 3,3' redox peak is sufficient for the degradation of polyaniline. Quinone and hydroquinone are generally believed to be the products of the oxidative degradation of polyaniline.⁹⁸⁻¹⁰⁰ the mechanism of which has been reported in the literature.⁹⁸⁻¹⁰⁰

Effect of anions. It has been indicated in the preceding section that anions have a limited influence on the conductivity of polyaniline. In contrast, the counterions derived from the supporting electrolyte have considerable influence on the rate of polymerization of aniline, and on the properties of the resulting products.^{28,103,104} The growth rate of a PANI film is 2.7–2.8 times faster in sulphuric acid than in perchloric, nitric, or hydrochloric acids.²⁸ This behaviour has been shown to be due to porous and granular structures of PANI, when synthesized in a sulphuric acid medium, as against smooth morphology of PANI synthesized in hydrochloric or perchloric acid medium.^{103,104} This property is explained on the assumption that the polymerization process proceeds in two stages. The first stage is the polymerization on the bare platinum electrode, or partially blocked electrode, by polyaniline. The second stage is polymerization on the platinum electrode completely covered by polyaniline. In the first stage the Pt-electrode surface is expected to be one of the determining factors of the polymerization rate. When the deposited polyaniline film blocks the platinum electrode surface, the aniline polymerization becomes more difficult, so the polymerization rate decreases. Consequently, further polymerization of aniline (second stage), would depend to some extent, on the morphology of films formed. At this juncture, a pore-rich structure is preferable to a smooth one. Hence, the growth-rate of polyaniline is more pronounced in sulphuric acid solution than in hydrochloric or perchloric acid solution. Similarly, use of HBF_4 , H_3PO_4 or HF results in

net morphological structure. This morphology like granular or porous structure helps for "higher rate", of polymerization of aniline than perchloric or hydrochloric acid medium.^{103,104}

In an interesting study, it is demonstrated that polyaniline has a selectivity for high molecular weight dopants.¹⁰⁵ The electrochemical polymerization of aniline was done in an aqueous solution containing 1M perchloric acid and 1×10^{-2} M sodium salt of polystyrene sulphonic acid, or polyvinyl sulphonic acids, or poly-(2-acrylamide-2-methyl-1-propane) sulphonic acid. The resulting PANI film was subjected to wide-scan electron spectroscopy which revealed the association of polymer electrolyte with the PANI chain. Although, the concentration of polymer electrolyte was one hundredth to that of perchloric acid, it is surprising that polymer electrolyte was selectively incorporated into the polyaniline matrix. This incorporation is explained in terms of a polymer effect, whereby incorporation proceeds just like the closing of a zipper.¹⁰⁵

Effect of the solvent and pH. The solvent has a pronounced effect on the shape of the cyclic voltamperogram of PANI. Discrete and well-defined peaks are observed in the case when polyaniline is synthesized in a eutectic mixture of HF and NH_3 ,^{39,40} while in the case of other media, comparatively broader peaks are observed. Furthermore, the electroactivity of polyaniline is not seen in solvents such as DMF, DMSO, methanol and ethanol. This probably results from the increase in nucleophilicity of the solvent. This conclusion is further supported by the fact that polyaniline does not exhibit electroactivity in a solution with pH greater than 4.²⁸

Electroanalytical techniques

Chronoamperometry and chronocoulometry methods have also been employed for the characterization of PANI. The former technique necessarily derives from the potential step, and the response is measured in terms of $I = f(t)$. From the type of curves, it is possible to distinguish the "quality" of the PANI synthesized in different media and supporting electrolytes. For example, it is shown that polyaniline synthesized in a eutectic mixture of NH_3 and HF medium has better utility for rechargeable batteries than that synthesized in other media.³⁸ The latter technique, also known as potential step chronocoulometric method (PSE), has been employed to determine the number of electrons involved in the redox mechanism of PANI.³⁸⁻⁴⁰ It has

been shown that the number of electrons in the redox mechanism is independent of the thickness of the PANI layer, but is influenced by anions in the solution.^{39,40}

Investigations on the conducting properties and the charge transfer during the redox process of PANI, and measurement of the electron transfer reaction rate at the polymer/solution interface have been carried out with Levich's direct and inverse criteria.¹⁰⁶ This technique is generally used for the study of electrochemical behaviour of the polymer-coated electrodes. The method consists of following the evolution of the current potential curves, corresponding to the electrolysis of redox species in solution, with respect to the rotation rate of the rotating disk electrode (RDE).¹⁰⁷ The evolution of these curves, during the reactions on naked platinum and Pt/PANI RDE allows us to estimate the conducting properties of PANI and helps in the measurement of the electron transfer rate at the polymer/solution interface.¹⁰⁷ It is reported that the charge transfer is a rapid phenomenon^{39,40} at the polymer/solution interface, and in the polymeric bulk.

Cyclic voltammetry studies of chemically synthesized polyaniline

Electrochemical characterization of chemically synthesized polyanilines presents a real challenge, because of their insolubility in solvents commonly employed for electrochemical investigations. Furthermore, they do not adhere to any electrode material, which makes electrochemical investigations extremely difficult. Nevertheless, four methods for the cyclic voltammetric (CV) study of chemically synthesized polyanilines have been reported in the literature. Two of the four methods were developed by American scientists,²⁴ and the other two by ourselves.^{27,29} The details of the first two methods are as follows: (1) The polymer was ground to a fine powder and ca. 1 mg was impregnated into glass filter paper (ca. 1 cm²), either with a spatula or a finger covered with a rubber glove. The filter paper was then shaken to remove the excess of polyaniline powder and placed on a platinum mesh which was folded so as to encase the filter paper on both sides. (2) Finely ground polyaniline powder was suspended in acetone or chloroform, and a few drops of suspension were poured on to a platinum foil (ca. 1 cm²) electrode and allowed to dry in air. The authors claim that these methods yield identical cyclic voltamperograms. However, a preconditioning of chemically prepared polyaniline is necessary to obtain reproducible results.

The methods developed by us are as follows: (1) 2–3 mg of chemically synthesized PANI were pressed on a thin inox grid which acts as a working electrode; an aluminum disc was used as counter electrode, and Ag/Ag^+ $10^{-2}M$ in propylene carbonate as reference electrode. The specially designed electrochemical cell was developed by French scientists.¹⁰⁸ The diagram and details of the components are published elsewhere.¹⁰⁹ The working electrode is mechanically maintained between the current collector and a plastic grid. On most occasions, $1M$ lithium perchlorate in propylene carbonate was used as electrolyte. One of the limitations of the above method is that the cell is unsuitable for use in aqueous media such as $1M$ hydrochloric or sulphuric acid. (2) In the other method,²⁷ we employed a mixture of chemically synthesized polyaniline (an amorphous powder), furnace black (a non-electroactive conductor), and polyvinylidene fluoride, $(-\text{CH}_2\text{CF}_2-)_n$ (slightly ionic conductor and binder) in the ratio 2:5:5 by weight. The mixture was made into a paste by the addition of one or two drops of DMSO solvent. The previously washed platinum wire (area 0.03 cm^2) of the Taccussel electrode was pushed back into the teflon. The paste was smeared and the excess of the DMSO solvent was evaporated by placing the electrode in a vacuum desiccator for about 15 min. This procedure leaves a thin layer adhering to the platinum. The advantage of this method is that the modified electrode can be employed in aqueous and non-aqueous media. Both methods yield encouraging results. We have studied²⁷ the influence of sweep rate on the i_{pa} and i_{pc} values, using our above-mentioned methods. The values rise linearly with the sweep rate as is expected for the redox reaction involving surface attached species. This experiment demonstrates the validity and dependency of our proposed methods. All the four methods involve permeation of electrolyte into the polymer powder particles.

A great deal of information concerning the reversibility and the nature of electron transfer steps can be obtained from cyclic voltamperograms. The characteristics of each scan, in most cases, can be determined by the way peak current and potentials vary with sweep rate. In our studies on PANIC, we have found the values of the slope of $\log i_p$ vs. $\log \nu$ curves for the two anodic and cathodic waves in the range 0.9–1.0. These values demonstrate that i_p tends to be proportional to ν for anodic and cathodic waves.²⁷

Voltammetric peak currents are proportional to ν in the case of thin-layer geometries only when electron-transfer is rapid (“reversible” systems). When electron-transfer begins to exert rate control, the dependence of peak current on ν becomes less than one. Currents observed at polymer-modified electrodes which are first-order in ν are indicative of rapid interfacial electron transfer as well as of facile charge transport through the film.

We²⁹ have demonstrated a very large capacitance background “current” associated with the cyclic voltamperogram of chemically synthesized PANI. From our results we have shown that 40% of the total charge stored in the polymer is the “capacitive” charge which is not related to any chemical redox reactions. The “non-capacitive” currents, representing the current due to the charges involved in the redox process, are too slow to follow, and thus contribute to the a.c. signal. Thus, two kinds of doping sites which are characterized by a long relaxation time ($T_1 > 1000$ sec) and a short relaxation ($T_2 > 10$ sec) are present in polyanilines. The total “capacitive” and “non-capacitive” charges can be deduced by integration of the voltamperograms. They are of the same order of magnitude, and represent about 40 and 60%, respectively, of the total charge stored in the polymer.

Another interesting feature associated with chemically synthesized polyanilines is reported by us. From our cyclic voltammetric studies we have shown that chemically synthesized PANI are 1-dimensional conducting polymers. The first scan of the CV of PANI reveals two well-defined redox systems 1,1' and 3,3'. Subsequent increase in the anodic potential, and/or repeated cycling, results in the 2,2' redox system which is an outcome of a higher oxidation level of PANI than that for the system 1,1' and 3,3'. Supporting evidence has come from solid-state ^{13}C NMR studies of PANI.^{110,111} The spectra obtained for PANI synthesized at a higher anodic potential is quite complex, which reveals the possibility of *ortho*-coupling, or a 3-dimensional matrix.³²

In summary, electroanalytical techniques such as chronoamperometry, chronocoulometry and cyclic voltammetry have been used for the characterization of polyaniline. The latter has played a yeoman role in solving some bewildering problems, such as effect of pH, ionic and electronic processes, *ortho*-coupling and cross linking, capacitance effects and degradation phenomena, to mention a few. Though CV is fundamentally a characterization technique, it does provide a

procedure for the polymerization of aniline-like monomers. Today it is also employed as a powerful electroanalytical tool by scientists working on "conducting polymers".

SOLUBILITY AND MOLECULAR WEIGHT DETERMINATION

The solubilization of polyaniline is of paramount importance, both scientifically and commercially. Scientifically, it provides a medium more conducive to the production of well-resolved analytical data, especially in the determination of molecular weight which helps in elucidating molecular configuration and structure in the conducting and insulator states. In commercial applications, polyaniline solutions would provide a form more amenable to conventional plastics processing technology.

There are conflicting reports on the solubility of polyaniline, contradictory views being advanced as early as 1910. Willstatter and Dorgi^{112,113} reported that an oligomeric (eight-monomer chain compound) aniline was largely insoluble. Green and Woodhead¹⁵ repeated their experiments and claimed solubility of this material in 80% acetic acid, 60% formic acid, pyridine and concentrated sulphuric acid. Later DMF was added to the list of solvents for electrochemically synthesized polyaniline.⁵² Partial solubility of polyanilines in its emeraldine base form in N-methylpyrrolidone,⁸⁰ THF,^{114,115} benzene, DMSO,¹¹⁶⁻¹²¹ chloroform,^{80,114,119,120} and methanol^{119,120} was also reported. As a result, it has become common practice to remove insoluble material⁸⁰ and use the soluble, possibly lower-molecular-weight, fraction for the preparations of films. Such cast films are predominantly amorphous and, generally, they have been categorized as intractable and amorphous material.

Routes towards soluble polyaniline include the preparation of graft polymers,¹²¹ copolymers¹²² and polyaniline derivatives.¹¹⁴ Unfortunately these species invariably show significantly reduced conductivities in comparison with the unmodified homopolymer. In a recent communication,¹²³ the feasibility of solution processing of crystalline, electrically conductive, polyaniline fibres and films was demonstrated. The authors claim that dissolution in sulphuric acid provides a simple means of processing polyaniline into films, fibre *etc.* In a separate communication, solubility of conducting polymers in organic acids (polar solvents) has been attributed to

hydrogen-bonding.¹¹⁸ In brief, solubility data of polyanilines makes possible systematic studies directed towards the understanding of this interesting polymer.

A preliminary investigation on the molecular weight of the soluble fraction of PANI in DMF was first reported in 1985.³⁸ An interesting facet of the reported data, pertinent to the present discussion, is that polyaniline is a macromolecule, and not an octomer, as believed earlier.^{15-20,52} These results were further confirmed by different workers. It is claimed¹¹⁵ that electrochemically synthesized polyaniline has a fraction whose molecular weight is at least 9000. Yet, another report mentions the molecular weight of 4300, measured by the GPC method.¹¹⁷ The viscosity measurements of polyaniline solution in sulphuric acid give an estimate of 12,000 molecular weight (rigid chain limit) and 40,000 molecular weight (flexible chain limit).¹²³ Since the conformation of polyaniline in the liquid state is not yet established, the viscosity data appear to be more of an approximation.

The procedure of dissolving polyaniline and determining its molecular weight has generated much activity among those interested in the commercialization of this novel material. Many new studies have been made in recent years, and continued research will undoubtedly lead to new discoveries and technology.

SPECTROSCOPIC STUDIES

Structural characterization of polyaniline with spectroscopic techniques presents a real challenge. Because of the amorphous nature of this material, information obtained from X-ray and neutron diffraction is quite limited, while its limited solubility restricts the use of standard characterization techniques for classical polymers. (Only recently was polyaniline, in the form of its emeraldine salt, recovered in crystalline form from a solution in sulphuric acid, by precipitation with water or methanol.)¹²³ Furthermore, the optical properties of PANI vary considerably, when it is doped, and when its state of oxidation is altered. New spectroscopic transitions induced by doping offer clues on the identity of the charged species: Spectroelectrochemical,^{1,37,74,75,85,87,88,124-129} UV-visible,^{69,89,116,130-136,139} IR,^{37,90,91,92,116,131-135,137,138,140,141} Raman,^{86,87,88,142-144} ESR,^{91-93,126,127,145} and XPS¹⁴⁶⁻¹⁴⁹ methods have been employed to this end. Solid-state NMR spectroscopy^{110,111,150,151,155,156} is found useful for the characterization of

insulator forms of PANI. The results of these studies are summarized briefly below.

Electrochemical spectroscopy

Spectroelectrochemical techniques are the combination of optical and electrochemical techniques. These techniques are a convenient means for obtaining the spectra and electrochemical potentials, and for observing subsequent chemical reactions during polymerization of aniline, and the doping/undoping of the resultant polymer. UV-visible-, IR-,³⁷ ESR-^{126,127} and Raman-spectroelectrochemical^{87,88} techniques have been employed to this end. Some of the salient features of the studies are: (1) doping/undoping of the polymer has a profound influence on the chromatic behaviour of PANI; (2) using the aforesaid techniques, four forms of PANI can be distinguished;^{74,75} (3) existence of two polaron-bipolaron states in the polymer has been established¹²⁷ and (4) presence of more quinonoid rings in the oxidized state of PANI has been demonstrated.^{87,88}

UV-visible spectroscopy

UV-visible absorption spectra of the electrochemically deposited polyaniline on substrates, such as (i) polyester plastic film coated with a thin layer of gold,¹²⁸ (ii) ITO-covered glass slides,^{87,88} and (iii) gold sputtered on a glass substrate,^{87,88} have been reported in the literature. Attempts have also been made to record spectra of thin free standing film but with limited success,³² probably due to strong absorptions in the optical range. Of late, most of the UV-visible studies are centred around a soluble emeraldine base.¹³⁹ The data derived from the studies demonstrate a red shift in both 2.0 eV and 3.8 eV absorption peaks, comparable to the shifts observed for emeraldine films and powders. The narrow strong absorption peak without the free electron absorption tail was explained as due to strong localization of polarons in solution form.

Infrared spectroscopy

Infrared spectra can yield valuable evidence concerning the electronic structure (and thus the geometry) of the PANI. A systematic IR study of chemically synthesized polyaniline powders, and of the anode precipitate prepared by constant potential electrolysis of aniline in sulphuric acid with platinum anode was first reported by Mohilner *et al.*⁵² The data from the IR spectra indicated the structural similarity of the anodic

precipitate with the chemically synthesized emeraldine and even more so with nigraniline (polyemeraldine and polynigraniline are the names commonly used in the present day literature). The fact that the spectrum of the anodic precipitate is not identical in every detail with either of the chemically synthesized compounds may imply that the electrochemically produced material is not a single substance, but rather a mixture of nigraniline and emeraldine.⁵² The marked similarities in the other properties of the anode precipitate and emeraldine—in particular, solubility in 80% acetic acid—strongly support the hypothesis that the anodically formed material is principally emeraldine. These results were confirmed by Ohira *et al.*¹⁴⁰ However, they note that polyaniline produced by the electrochemical method in neutral or basic media, essentially have 1- and 3-substituted benzene structures which are electroinactive even in acidic solutions. Fourier transform infrared studies on polyaniline analogues such as phenyl-capped octaaniline,¹³¹ aniline oligomers ($n = 2-4$),¹⁴¹ the electropolymerization product of *para*-amino diphenylamine⁵⁷⁻⁵⁹ and polyaniline/zeolite hybrids¹³³ are also reported in the literature.

Resonance Raman spectroscopy

The Resonance Raman Scattering (RRS) of PANI offers valuable information on the structure of the polymers. Moreover, it provides definite structural characterization because of the characteristic dependence of the Raman spectral pattern on the disposition of the ring substituents of aromatic compounds.¹⁴² Furthermore, one of the distinct advantages of RRS over other optical techniques is the possibility of studying the optical transitions even of powdered material. The first study of RRS on PANI powders was carried out by us⁸⁶ and the results are in full agreement with the optical absorption studies of electrochemically synthesized PANI films. Resonance raman scattering studies with electrochemically synthesized PANI¹⁴⁰ and its derivatives,¹⁴³ and with polyaniline-metalloporphyrin¹⁴⁴ are also to be found in the literature. Nevertheless, *in situ* Raman-spectroelectrochemical experiments appear to have resolved the complicated behaviour of the spectra for the various forms of PANI.^{87,88} In brief, RRS is useful in the structural study of complex multichromophore materials like PANI. Information on each chromophore can be obtained separately by a proper choice of exciting wavelength. The results indicate that: (1) the chemically, or

electrochemically, synthesized PANI chain consists of a mixture of benzenoid and quinonoid rings, the relative proportions of which depend on the reduced or oxidized state of the polymer; (2) *para*-substituted benzene and quinone diimine moieties are present in the base form of emeraldine; and (3) there is some evidence in favour of head-to-tail polymerization of aniline, with no *ortho* incorporation of phenylene diimine groups,¹⁴³ especially when combined with other evidence from IR studies.

X-ray photoelectron spectroscopy (XPS)

X-ray photoelectron spectroscopy (XPS) is capable of providing information with respect to the surface elemental composition and dopant level in PANI¹⁴⁶⁻¹⁴⁹ and its derivatives.^{150,151} The data regarding binding energies and surface composition offer some clues on the identity of a desired element present in a complex chemical environment. This information is particularly important in the determination of surface ele-

for this are: (1) compositional defects; (2) a distribution of torsion angles between adjacent rings; (3) variations in *syn* and *anticonformational* arrangements about the benzenoid rings, or *cis* and *trans* configurations about the quinonoid rings; (4) variation in the sequencing of benzenoid and quinonoid units; (5) thermally induced molecular motions; (6) the possibility of rotations or flips of benzenoid rings about their 1,4 axes and (7) a non-uniform charge, and/or spin distribution, for the conducting salts.

Despite broad lines, ¹³C crosspolarization magic angle spinning nuclear magnetic resonance (CPMAS NMR) spectra of deprotonated PANI (insulator form) resolve localized benzenoid and quinonoid ring structures, indicating that extensive electron delocalization along the backbone does not occur.¹⁵²⁻¹⁵⁴ Recent ¹³C NMR studies^{110,111,155,156} have determined that the emeraldine base consists primarily of a well-defined microstructure of alternating 1A and 2A units as shown below:

mental stoichiometry. Interestingly, XPS data of Cl-doped PANI has indicated the presence of covalent chlorine along with the two different ionic chlorine environments in PANI.¹⁴⁹ The relative contribution to the total chlorine signal was observed to be dependent on the applied potential.¹⁴⁹

¹³C NMR spectroscopy

The exact nature of the oxidized form of polyaniline is still unclear. As discussed earlier, the chemical and electrochemical evidence suggests that increasing the oxidation level of polyaniline results in creation of an increasing number of quinone-imine or other type of oxidized polymer sub-units. It is not yet known whether the perturbation in the polymer π -system, induced by an oxidized site, is localized or extensively delocalized.

The chemical shift data of PANI, derived from solid-state ¹³C NMR spectroscopy provides valuable information on the chemical structure of the polymer¹⁵²⁻¹⁵⁷ and its derivatives.¹⁵⁷ However, sequence distributions and chain conformations result in low spectroscopic resolutions, because of broad line-width. Possible reasons

The ¹³C NMR spectra of polyaniline in non-aqueous solvents are also reported in the literature.^{141,145} Recently solid-state ¹⁵N NMR spectroscopy has been utilized as a structural probe for the emeraldine base forms of PANI.¹⁵⁸

MORPHOLOGY

Studies on morphology of chemically and electrochemically synthesized PANI are important for investigating the intrinsic characteristics of the polymer. Many of the studies^{24,103,104,159-162} conducted up till now are rudimentary and exploratory in nature. The dependence of morphology upon variables such as different anions employed in the synthesis, the nature of the electrodes, and/or differences in chemical and electrochemical procedures need to be investigated in detail.

APPLICATIONS

Rechargeable batteries

For the last few years intense activity has been generated in the construction of a polyaniline-metal battery. This is because polyaniline has

certain advantages over other conducting polymers, such as simplicity and rapidity of preparation of the polymer by the chemical or electrochemical method, and chemical durability against aerial oxidation and moisture. Furthermore, the ability of polyaniline to store a considerable charge through the redox process has led to proposals for both non-aqueous^{38,163-167} and aqueous batteries.^{25,26,168-171}

In a non-aqueous medium, lithium is usually employed as the anode material in rechargeable batteries. But the use of a non-aqueous solvent in polyaniline-lithium batteries is beset with a serious problem: on charging, there is a tendency for dendrites to form when lithium is plated on the lithium electrodes, particularly at high charging rates. These dendrites can grow to considerable lengths, and shortcircuit a cell internally. Also, the high cathodic potential of the Li/Li⁺ couple often causes decomposition of the solvent, the mechanism of which has not yet been fully elucidated.¹⁷⁰

The use of polyaniline as cathode material, in conjunction with lithium-doped aluminium as anode material, in propylene carbonate containing 1M lithium perchlorate, results in an open circuit voltage of 3.7 V.³⁸ The massic capacity of 145 Ah/kg, and the self discharge (with separator) rate of about 8% after 90 days make the polyaniline-lithium battery more attractive for new types of technological applications.

In a recent communication,¹⁶⁷ PANIE was shown to have a maximum discharge capacity of 164 Ah/kg, a low rate of self-discharge, and a long life, as a positive active material in a secondary lithium battery. The larger massic capacity of PANIE is attributed to its fibrous structure which is produced galvanostatically, in an aqueous 1M perchloric acid solution containing 0.5M aniline at room temperature, when using the current density of 5 mA/cm². In our experiments, we have observed that PANI synthesized in sulphuric acid media has a granular structure, which is in accordance with the observation made by the aforesaid authors.¹⁶⁷ Propylene carbonate is a good electrolyte solvent, extensively employed in secondary lithium batteries, to ensure longer life and lower self-discharge for PANI. Further research efforts are required to find a new electrolyte system that is compatible with lithium and PANI.

The development of a practical Li/PANI battery is not a simple task. Apart from the technical shortcomings mentioned earlier, there remains the problem of 'safety' from the stand-

point of pollution. As Li is evidently a serious pollutant, it seems realistic to exploit aqueous batteries rather than non-aqueous Li-PANI cells. Also, the use of a water-based electrolyte in rechargeable batteries has certain advantages—an important one being that the ionic conductivity of aqueous electrolytes is greater than that of non-aqueous electrolytes; and hence, other factors being equal, cells employing aqueous electrolytes might be expected to deliver a higher output current.

French scientists^{25,26} were the first to employ two different oxidation states of PANI (now commonly known as 1S and 2S forms) as anode and cathode in a rechargeable battery cell in aqueous 1N sulphuric acid. These cells exhibited an open circuit voltage of ~0.40 volts. Very few data are available concerning the recyclability of either the anode material or the cathode material, in any aqueous electrolyte.

There were renewed efforts to employ polyaniline in conjunction with zinc¹⁶⁸⁻¹⁷¹ or lead oxide^{170,171} as the counter electrode. Polyaniline acts as the negative pole when combined with zinc, while it acts as the positive pole when combined with lead oxide. A difficulty, experienced with zinc as the counter electrode, is its spontaneous dissolution in acidic media, while polyaniline is electroactive only in the lower pH region. An advantage of using lead oxide as counter electrode is that no special caution is needed to avoid over-charging.

In brief, polyaniline is a promising material for both aqueous and non-aqueous storage batteries.

The question whether non-aqueous or aqueous electrolytes would be preferable for a specific purpose cannot be answered until much more information has become available. The use of aqueous electrolytes will, in general, be accepted to result in cells having a smaller potential, and hence, a smaller energy density than batteries employing a non-aqueous electrolyte. Real long-term advances in the field can only be accomplished by detailed studies on chemical and electrochemical reactions, occurring during storage and recycling, under a wide variety of experimental conditions.

Electrochromic devices

The optical characteristics of the PANI films undergo changes with the corresponding changes in the conductivity.^{98-100,172-174} In the oxidized state, PANI films are coloured and highly conductive; while in the reduced state, they are

optically transparent with low conductivity. In fact, colouration and conductivity are associated with the doping of the films.

Kobayashi *et al.*⁹⁸⁻¹⁰⁰ were the first to report the mechanism of the electrochromic reactions of PANI films and its applications to practical electrochromic display devices with liquid electrolytes. The colour of PANI films is reversibly changed to green by oxidation; and to transparent yellow by reduction in 1M hydrochloric acid, in the potential range from -0.2 V to $+0.6$ V *vs.* SCE. The reversibility of the colour change can be observed more than 10^6 times in the aforesaid potential range, with rapid response of less than 100 msec. However, Akhtar *et al.*¹⁷² are of the opinion that the problems of longrange stability, and of encapsulating devices with liquid electrolytes are many, so that the use of a solid-state electrolyte appears to be an attractive alternative. The advantages claimed in their report are protection from atmospheric oxidation and easy control of solid-state electrolyte composition.

In an interesting study, it has been demonstrated that the surface of an oxidized PANI electrochromic film, in contact with pure water, is more hydrophilic than that of a reduced surface. Furthermore, hydrophilicity is directly related to the conductivity of the film: the higher the conductivity, the greater the hydrophilicity of the surface.¹⁷³

Photoelectrochemical cells

The conversion of solar energy to chemical or electrical energy by photoelectrochemical cells (PECs) has attracted considerable attention during the last decade.^{175,176} This is because of their inherent simplicity of manufacture and consequently reduced cost. However, the susceptibility of narrow band-gap semiconductors to photodegradation has been a serious limitation on its wide popularity.

Two applications of PANI in PECs have been studied to date: protection against photo-corrosion of inorganic semiconductors,³⁰ and photoresponse of junction PANI film.¹⁷⁷ In the former case, the polyaniline-coated semiconducting electrodes (Cd-chalcogenides, Si, GaAs, GaP) exhibited enhanced stability of the photocurrent when compared to the current of the naked electrodes; while in the latter case, the photocurrent is induced when visible light from a 500 W xenon lamp is allowed to fall on a PANI film coated on platinum.¹⁷⁷ The authors mention a slow current photo-response of the order of

minutes for PANI in aqueous solution. Subsequent development in this field has resulted in a fast photoresponse of junction polyaniline film.¹⁷⁸

Electronic devices

A large change in electronic conductivity of PANI with a change in electrochemical potential is the basis for the development of PANI-based electronic devices. In practice, PANI deposited on to a gold microelectrode array has been shown to behave like electronic devices such as a diode and a transistor.⁴⁶ These polymer-based, transistor-like devices can be turned 'on' and 'off' by electrical or chemical signals that oxidize and reduce the polymer. For example, redox reagents such as $\text{Fe}(\text{CN})_6^{3-}$ and $\text{Ru}(\text{NH}_3)_6^{3+}$ can be used to turn a polyaniline-based transistor⁴⁶ on and off. In a separate communication, the design and operation of a PANI-transistor sensitive to moisture have been described.¹⁷⁹

Catalysis

Polyaniline and modified polyaniline have been shown to exhibit catalytic activity.^{180, 183} During oxidation of formic acid, using polyaniline-coated electrodes,¹⁸⁰ it was observed that oxidation rates of polyaniline electrodes are comparable to the oxidation rate at a platinumized platinum electrode at low overpotentials. This behaviour is the basis for evaluation of modified PANI as a fuel cell electrode.¹⁸⁰ The electrolytic reduction of oxygen and protons with modified polyaniline films has been reported in the literature.¹⁸²

In an interesting study, electrodeposition of platinum microparticles onto polyaniline film has been demonstrated.¹⁸³ The resultant film exhibits catalytic activity for hydrogen evolution and methanol oxidation. In another communication, polyaniline-nafion composite films have been shown to display better reversibility than the polyaniline alone.¹⁸¹ In brief, catalytic and electrocatalytic activity of polyaniline is of great importance and further research will certainly lead to newer technological applications of polyaniline.

Indicators

The multiple colour changes of polyaniline films^{145,184} on electrodes and chromatic reactions of polyaniline solutions in different pH ranges¹¹⁷ are the bases for development of PANI as an indicator. Recently, Jiang and Dong¹⁸⁴ have developed a PANI/Pt electrode as a redox

colour indicator in the titration of iron(II) with cerium(IV) solution. We¹⁸⁵ have developed soluble polyaniline solution as an acid–base indicator in the titration of 0.05–0.5M sodium hydroxide × sulphuric, hydrochloric, perchloric or nitric acid. The use of polyaniline solution as redox indicator is also investigated.³²

Ion exchange chromatography

Unlike other conducting polymers such as polypyrrole and polythiophene, PANI has a unique feature that the equilibration by acid solution imposes the anion in the polymer. This has been the basis for the use of PANI as an anion exchange polymer.¹⁸⁵ We¹⁸⁵ have shown that mixtures of halide ions can be separated on polyaniline.

CONCLUSIONS

The rediscovered polymer, the polyaniline, in less than a decade's time has travelled the arduous route from laboratory benches to commercial markets. This concise review has attempted to describe the synthesis and the physicochemical properties of polyaniline and to point out its potential in technology. The possibilities disclosed by its unique characteristics are, nevertheless, challenging. The newer applications of polyaniline in diversified technologies will attract increasing attention and interest from industrial and academic laboratories.

QUANTITATIVE INVESTIGATION OF MATRICES FOR DIFFUSE REFLECTANCE INFRARED FOURIER TRANSFORM SPECTROMETRY

MOLLIE L. E. TEVRUCHT

Department of Chemistry, University of Alaska, Anchorage, AK

PETER R. GRIFFITHS*

Department of Chemistry, University of Idaho, Moscow, ID 83843, USSR

(Received 5 December 1990. Revised 11 February 1991. Accepted 19 February 1991)

Summary—Five materials were investigated for use as diluent matrices for diffuse reflectance infrared Fourier transform (DRIFT) spectrometry of powdered samples. DRIFT spectra of powdered carbazole dispersed in germanium, silicon, diamond, potassium chloride and a chalcogenide glass were compared. Three particle size ranges were investigated for five concentrations of carbazole ranging from 0.1–10%. The effects of particle size and refractive index of the matrix are discussed.

Diffuse reflectance infrared Fourier transform (DRIFT) spectrometry has been used to study such varied samples as coals,^{1,2} polymers,³⁻⁵ silanes in glass fibers,^{6,7} silicon dioxide in silicon carbide⁸ and silanes in silica gel.⁹ DRIFT spectra have been acquired of neat, unground samples,^{4,6} of neat, ground samples,^{1,2} of samples with a thin potassium chloride overlayer,^{3,7} and of samples abraded onto silicon-carbide-coated paper.⁵ As most commonly practiced, however, the analyte is dispersed in a non-absorbing matrix and the diffusely reflected radiation is collected to obtain the spectrum.⁸⁻¹¹ DRIFT spectra of samples prepared in this manner most closely resemble transmission spectra of samples pressed in alkali halide pellets.¹² The diluent matrix for DR spectrometry is often an alkali halide such as potassium chloride, favored because of its transparency throughout the mid-infrared, its ease of grinding and its non-toxicity. Drawbacks include its hydrophilicity and ionic nature. Water adsorbs quickly and tenaciously on potassium chloride and the resulting bands in the DRIFT spectra can interfere with the absorptions due to the analyte. Analyte spectra can also be altered by ionic exchange between the analyte and the alkali halide matrix.¹³ A further complication arises when alkali halides are left in a powdered state for several hours before use, as they show a proclivity to adsorb air-borne organic compounds leading to the

appearance of bands around 3000–2800 cm⁻¹.

It would be advantageous to employ a matrix which was non-absorbing, non-hygroscopic, non-reactive, non-toxic and easily ground. Kaihara *et al.*¹¹ proposed a matrix composed of a mixture of cesium iodide and potassium bromide but such a matrix has no advantage over potassium bromide or potassium chloride alone.¹⁴ Azarraga and co-workers investigated several possible matrices,¹⁵ including calcium and magnesium fluoride, sulfur and silver halides. The spectra of calcium fluoride and magnesium fluoride have too many bands that would interfere with the bands in the DRIFT spectrum of the analyte at long wavelengths. Sulfur suffered the same problem and was deemed too reactive for use in some situations, while the silver halides were too soft to grind well. Diamond powder appeared to be the most promising material of those studied. However, the specific effect of a change in matrix on the infrared spectrum of a sample was not studied.

An important application of DRIFT spectroscopy has been for detection and identification in high-performance liquid chromatography (HPLC)¹⁶⁻¹⁸ and thin layer chromatography (TLC).^{19,20} With a direct deposition interface, the chromatographic effluent is sprayed onto the diluent matrix. The presence of water in the effluent can be disastrous if a water-soluble matrix such as an alkali halide is used.¹⁸ A TLC/DRIFT interface, originally developed in our laboratory²¹ and now marketed

*Author for correspondence.

commercially by Laser Precision Analytical (Irvine, CA) uses a chalcogenide glass²² for the matrix. This interface is currently used in our laboratory to study the extracts of coals separated with TLC.²⁰ The chalcogenide glass possesses many of the properties of an ideal matrix: it is nonhygroscopic, inert, easily ground and insoluble in common chromatographic solvents. It is composed of germanium, antimony and selenium with the approximate formula $\text{Ge}_{28}\text{Sb}_{12}\text{Se}_{60}$, and has a refractive index of 2.7. How the spectra obtained with the chalcogenide matrix differ from those acquired with a potassium chloride matrix or a diluent of higher refractive index has never been reported.

Silicon^{12,13} and germanium^{12,13,24} have also been suggested for use as matrix materials. Like the chalcogenide glass, both elements are hydrophobic, easy to grind, have relatively featureless infrared spectra, and are inert. They possess rather high refractive indices of 3.4 and 4.0, respectively. The refractive index of potassium chloride in comparison, is only 1.5 while that of diamond is 2.4. Most organic compounds have refractive indices of around 1.5. It is known that a high refractive index matrix reduces the intensity of the analyte bands,¹² but the effect of the matrix on band intensities and linearity with respect to concentration is unknown. A matrix with a higher refractive index will have higher front surface reflection, which should lead to more scattering. Since the scattering coefficient varies with wavenumber, the effect will not be uniform over the entire spectrum. Also, the penetration depth of the infrared radiation decreases dramatically as the scattering coefficient is increased,²⁵ which would lead to less intense bands. The decrease in effective penetration depth has been postulated to explain the significantly decreased band intensities in spectra of compounds diluted in matrices of high refractive index.^{12,25,26}

A second parameter which should affect band intensities in DRIFT spectra is the particle size of the matrix. With potassium chloride as the matrix, it has been shown^{9,10,12,14,24} that bands become stronger and sharper with decreasing particle size. In one study, particles 5–10 μm in diameter were found to give spectra of higher contrast than larger particles,¹⁰ although another report showed little difference in the spectra of weakly absorbing compounds as long as the particles were less than 75 μm in size.¹² For diamond powder, the optimal particle diameter was reported to be 6 μm .¹⁵ However,

whether this size is appropriate for matrices with a higher refractive index has not been studied. Since the scattering properties of a powder are dependent upon both particle size and refractive index, it is difficult to determine the ideal particle size for germanium and silicon *a priori*.

The effective penetration depth of radiation into a powdered sample is controlled by several factors. For a given matrix and concentration of analyte, the particle sizes of the analyte^{12,26,27} and its diluent matrix govern the effective penetration depth. As the particle size of the sample increases, the beam is increasingly attenuated on transmission through a sample particle. It can be calculated that the absorbance of most fundamentals in the transmission spectrum of a carbazole particle 20 μm in diameter would exceed 2.0 for all but the weakest bands, and particles over 50 μm would completely attenuate the radiation across essentially all spectral features. Assuming some of the radiation reaching the detector has not passed through one analyte particle, the result will be an apparent broadening of all bands in the spectrum.

The effect of particle size can be counteracted through a change in the refractive index of the surrounding matrix. Depending on how the sample is packed prior to spectral acquisition, bands in the DR spectrum of carbazole diluted in potassium chloride can be up to two orders of magnitude greater in intensity than those of carbazole in silicon.¹² When the single beam spectrum of germanium powder is ratioed against that of potassium chloride, the resulting reflectance is less than 50%. The single beam spectra of all four matrices were ratioed against that of potassium chloride, and the resulting reflectance spectra are shown in Fig. 1(A–D). Reflectance spectra of small (5–10 μm diameter) particles of diamond, chalcogenide glass, silicon and germanium are shown in Fig. 1(A), (B), (C) and (D), respectively. Upward-going features in the four spectra arise from the uncompensated bands in the reference spectrum due to adsorbates on the potassium chloride. The inverted bands at 3400 and 1640 cm^{-1} result from the presence of water in the potassium chloride, while that at 2900 cm^{-1} is due to adsorbed organic compounds. The small, sharp feature at 1390 cm^{-1} is from a nitrate contaminant in the potassium chloride. The Si-O stretching band seen in Fig. 1(C) occurs around 1200 cm^{-1} , while the Ge-O stretching band of crystalline Ge is found near 900 cm^{-1} in Fig. 1(D). The broad,

Fig. 1. The single beam spectra of (A) diamond, (B) chalcogenide glass, (C) silicon and (D) germanium ratioed against that of potassium chloride. None of the spectra have been offset, and all are plotted from 0–110% transmittance.

downward-going band near 810 cm^{-1} in Fig. 1(B) is presumably attributable to the stretching mode of Ge-O, shifted by the presence of Se and Sb in the glass.

For a non-absorbing material, the dependence of the reflectance, R , upon the refractive index, n , is described by the Fresnel equations. When the matrix is changed from potassium chloride to germanium, the refractive index increases from 1.5 to 4.0, and the front surface reflectance increases from 0.04 to 0.36 at normal incidence. The increased reflectance of the Ge matrix increases the scattering coefficient and therefore prevents radiation from penetrating into the sample. A significant fraction of the incident radiation does not interrogate analyte particles located more than a few micrometers below the surface.²⁵ The competing effects of refractive index and particle size control the effective penetration depth for DRIFT spectrometry.

In this paper we report the qualitative and quantitative effects of different refractive index and particle size matrices and DRIFT spectra. Spectra obtained with diluent matrices of silicon, germanium, diamond powder, a chalcogenide glass and potassium chloride were analyzed with a typical organic compound, carbazole, as the test analyte. Carbazole has an

infrared spectrum with a number of isolated bands of different intensities, and strong bands at both high and low frequencies. The effect of the matrix on both weak and strong bands can be analyzed, along with the effect of scattering of the radiation by the matrix. Three particle size ranges of carbazole and each matrix were used, as well as a range of concentrations of carbazole in each matrix.

EXPERIMENTAL

Diamond powder (Graves Co., Pompano Beach, FL) was obtained in three particle sizes: $6\text{ }\mu\text{m}$, $30\text{ }\mu\text{m}$ and $45\text{ }\mu\text{m}$. Germanium and silicon (-325 mesh; Alfa Products, Danvers, MA) were ground separately in a stainless steel capsule in a Wig-L-Bug ball-mill grinder (Crescent Manufacturing Company, Lyons, IL). The chalcogenide glass ($\text{Ge}_{28}\text{Sb}_{12}\text{Se}_{60}$, TI Glass No. 1173, Texas Instruments, Dallas, TX) and potassium chloride ("random cuttings", Harshaw, Solon, OH) were broken into small chunks with a mortar and pestle, then ground in the same way as the silicon and germanium. Except for diamond, each matrix was sieved to three particle size ranges in a Sonic Sifter (ATM Corporation, Milwaukee, WI). Carbazole (Eastman Kodak Co., Rochester,

NY) was ground and sieved in a similar manner. The particle size ranges used were 5–10 μm , 20–30 μm and 53–75 μm . These particle sizes were chosen to be approximately equal to the wavelength, slightly larger than the wavelength and several times larger than the wavelength of mid-infrared radiation (2.5–15 μm), respectively.

After the required particle size range had been obtained, carbazole was diluted in each matrix to concentrations of 0.1%, 0.33%, 1.0%, 3.3% and 10% (by weight). The carbazole and matrix material were mixed without further grinding, and were packed into 4.5-mm diameter, 5-mm deep sample cups with a modified Parr pellet press (Moline, IL).²⁸ Although each matrix exhibited very distinct packing characteristics, the amount of sample and the duration and amount of pressure were controlled to achieve consistent and reproducible packing for each sample. Since some materials (KCl, $\text{Ge}_{28}\text{Sb}_{17}\text{Se}_{60}$) were more easily compressed for all particle size ranges than others, samples diluted in them were pressed more compactly than those in the other matrices.

Spectra were measured at 4 cm^{-1} resolution with a Digilab Model FTS-20 spectrometer (Bio-Rad, Digilab Division, Cambridge, MA) equipped with diffuse reflectance optics of the type described by Fuller and Griffiths¹⁰ and an intermediate-range mercury-cadmium-telluride (MCT) detector (Infrared Associated, New Brunswick, NJ). Typically, 256 scans were co-added for each spectrum, and the reference spectrum for each sample was that of its pure matrix. Each experiment was performed three times, and the results averaged.

After taking the ratio of the single beam spectrum of each sample and the appropriate reference spectrum, the reflectance spectrum was converted to $\log(1/R)$, baseline-corrected, converted back to reflectance and then to the Kubelka–Munk format. Baseline correction was required when the pure matrix reflected less radiation than the diluted carbazole, leading to reflectance values greater than 100% in the ratioed spectrum. The baseline correction fitted line segments between four points of the spectrum, then leveled them and added to or subtracted for the flattened baseline to bring it to a $\log(1/R)$ value of zero across the spectrum. The four points selected (3700, 2700, 2100 and 660 cm^{-1}) fell in baseline regions. All spectral manipulations were performed with Spectra-Calc software (Galactic Industries, Salem, NH).

Transmission spectra of 1 wt. % carbazole pressed in a potassium bromide (Harshaw, Solon, OH) pellet were acquired on a Nicolet 740 spectrometer (Nicolet Instrument Company, Madison, WI) equipped with an MCT detector and operated under conditions where the response is linear. Compressed pellets ranged in thickness from 130–280 μm . The spectra were taken at 4 cm^{-1} resolution, and 256 scans were co-added.

RESULTS AND DISCUSSION

The transmission spectrum of 1% carbazole compressed in a potassium bromide pellet of 280 μm thickness is shown in Fig. 2, along with the structure of carbazole. DRIFT spectra of carbazole diluted to 1 weight percent in potassium chloride, diamond, the chalcogenide glass, silicon and germanium of 5–10 μm particle size are shown in Fig. 3(A), (B), (C), (D) and (E). The spectra are plotted in Kubelka–Munk units, and all have been ordinate-expanded to full-scale. Several differences in relative band intensities between the six spectra in Figs. 2 and 3 are readily apparent. The broad feature near 900 cm^{-1} in the germanium spectrum arises from incomplete compensation of a Ge-O band, shown in Fig. 1(D), present in both the sample and the reference spectra. As shown in Fig. 1(C), the spectrum of pure silicon ratioed against that of potassium chloride has bands near 1200 cm^{-1} attributable to Si-O stretching modes, but they are not visible in the spectrum of carbazole diluted in silicon.

The transmission spectrum of the potassium bromide disk most closely matches that of carbazole diluted in silicon or germanium. As the refractive index of the diluent matrix increases, so do the relative intensities of the bands above 3000 cm^{-1} , attributable to the N-H (3420 cm^{-1}) and C-H (3050 cm^{-1}) stretching absorptions of carbazole. In the transmission spectrum, the intensities of the N-H stretching band at 3420 cm^{-1} and the C-H out-of-plane deformation bands between 775 and 700 cm^{-1} have roughly the same intensity, whereas in the potassium chloride DRIFT spectrum the low frequency bands are much more intense. Since both the N-H and C-H stretching modes exhibit the same trends, and since no such suppression is seen in the potassium bromide pellet transmission spectrum, the effect cannot be ascribed to the formation of an amine salt. The spectral features below 2000 cm^{-1} exhibit less dramatic

Fig. 2. Transmission spectrum of 1 wt. % carbazole pressed in a potassium bromide pellet. The structure of carbazole is given above the spectrum.

differences. In this region, as the refractive index of the matrix is increased from 1.5 (KCl) to 4.0 (Ge) the analyte bands become sharper and better resolved. This is especially obvious for the C-H out-of-plane deformation bands, as well as the doublet at 1625/1602 cm^{-1} due to C=C

aromatic ring breathing modes. One possible cause for the broadening of the bands in the spectra of carbazole in potassium chloride, diamond, the $\text{Ge}_{28}\text{Sb}_{12}\text{Se}_{60}$ glass is attenuated total reflectance in the matrix particles. When the refractive indices of the sample and the matrix

Fig. 3. DRIFT spectra of 1 wt. % carbazole in (A) potassium chloride, (B) diamond, (C) chalcogenide glass, (D) silicon, and (E) germanium. Particles of carbazole and all matrices were between 5 and 10 μm in size. Scale expansions for B through E are indicated on the spectra.

Table 1. Bands in carbazole spectrum chosen for analysis

Frequency, cm^{-1}	Assignment	Absorption coefficient, cm^{-1}
3419	N—H stretching mode	12200
3051	C—H stretching mode	2050
1602	C=C aromatic ring breathing mode	3300
1450	C—C bending mode	10500
1240	C—N stretching mode	5650
727	C—H out-of-plane deformation mode	18200

are similar, there is increased penetration into the analyte particles from adjacent matrix particles. This could result in increased absorption of the impinging radiation and saturation-like effects in the spectrum. Although this explanation is not very plausible, no other causes are evident at this time.

To compare the spectra of carbazole in each of the five matrices quantitatively, the six bands listed in Table 1 were analyzed. The assignment and absorption coefficient calculated from the transmission spectrum of carbazole pressed in a potassium bromide pellet are also listed. The Kubelka–Munk function, $f(R_\infty)$, gives the ratio of the absorption coefficient, k , to the scattering coefficient, s .²⁹ The absorption coefficient was calculated from the potassium bromide disk spectrum as

$$k = \frac{\ln T}{cx} \quad [1]$$

where T is the transmittance of a given band, c is the weight percent concentration of carbazole in the pellet (weight:weight) and x is the pellet thickness in cm.

The selected six bands encompass both high and low frequency absorptions and range from medium-weak to strong intensities. The values for these six bands for small (5–10 μm), medium (20–30 μm) and large (53–75 μm) particle sizes are plotted against weight percent carbazole in potassium chloride, diamond, $\text{Ge}_{28}\text{Sb}_{12}\text{Se}_{60}$, silicon and germanium in Figs. 4–8, respectively. At least three variables control the differences in the spectra, since particle size, index of refraction and packing density all affect the intensities of bands in a given spectrum. Increased pressure applied to the sample results in more intense bands in the resulting spectrum.³⁰

The variation in band intensities with particle size for each matrix will be considered first. The particle sizes of both analyte and diluent were the same for every mixture of carbazole in each matrix. As shown in Fig. 4, for both the small (5–10 μm) and medium (20–30 μm) particle sizes of carbazole dispersed in potassium chlor-

ide ($\text{C}_{12}\text{H}_9\text{N}:\text{KCl}$) the intensities of corresponding bands are roughly equal. The band intensities in the DRIFT spectrum of carbazole diluted in the large (53–74 μm) particles of potassium chloride are weaker; this is particularly evident for the strong feature at 727 cm^{-1} .

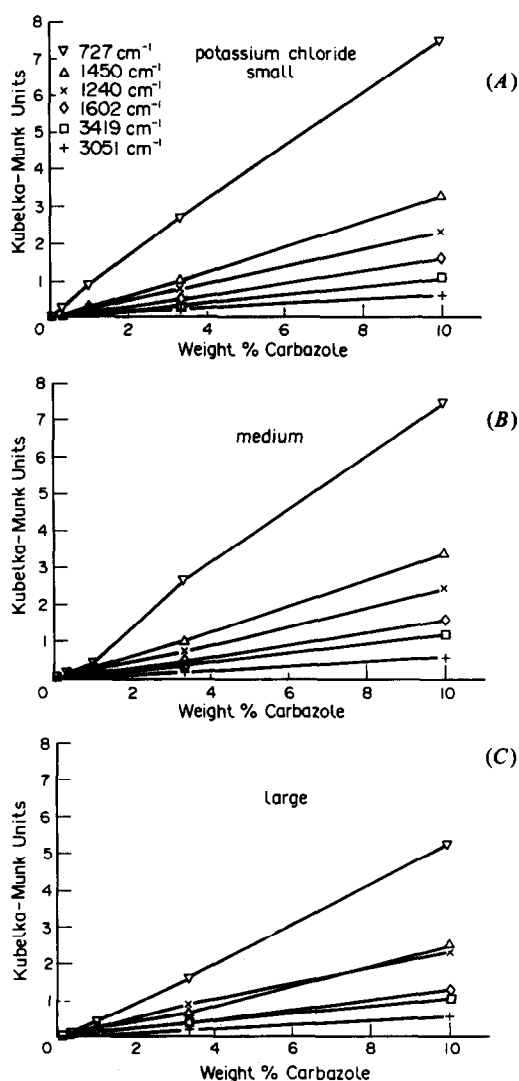

Fig. 4. The Kubelka–Munk intensity of six bands in the DRIFT spectrum of carbazole diluted in potassium chloride. Particles of carbazole and potassium chloride were (A) between 5 and 10 μm , (B) between 20 and 30 μm , and (C) between 53 and 75 μm in size. The key for all three graphs is given in (A).

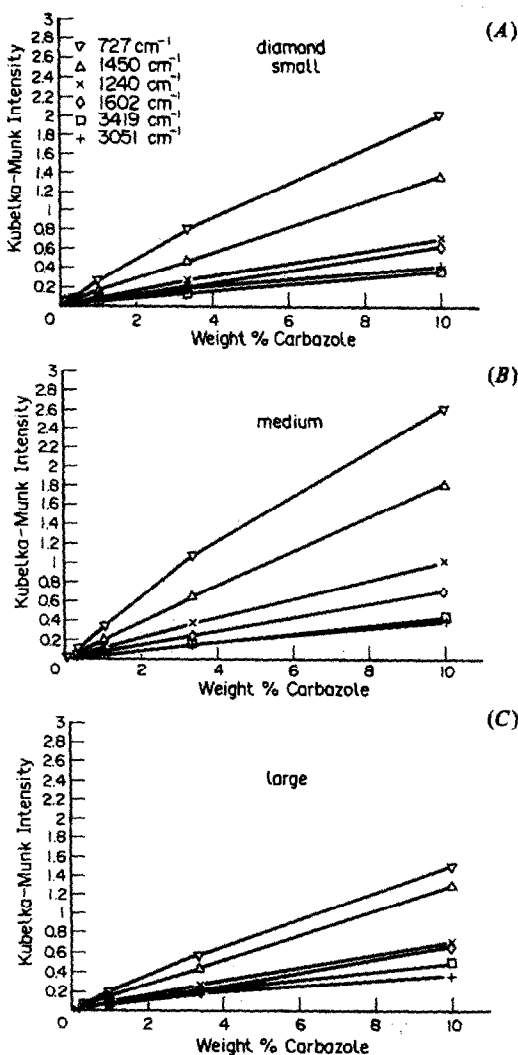

Fig. 5. The Kubelka-Munk intensity of six bands in the DRIFT spectrum of carbazole diluted in diamond powder. Particles of carbazole and diamond were (A) between 5 and 10 μm , (B) between 20 and 30 μm , and (C) between 53 and 75 μm in size. The key for all three graphs is given in (A).

These results are in accord with other published results,^{12,24} and are easily explained since in the Kubelka-Munk equation, $f(R_\infty)$ increases as s decreases. Thus, larger particles, with their lower scattering coefficient, would give rise to more intense spectral features. This will hold only in the absence of front-surface reflection leading to anomalous dispersion or *reststrahlen* features in the spectrum. Chalmers *et al.*²⁴ have demonstrated that for an increase in particle diameter from 2 to 5 to 10 μm , the Kubelka-Munk band intensity increases with increasing particle diameter for all but the strongest bands in the spectrum. The same workers²⁴ showed that for silica spheres dispersed in potassium bromide there is an increase

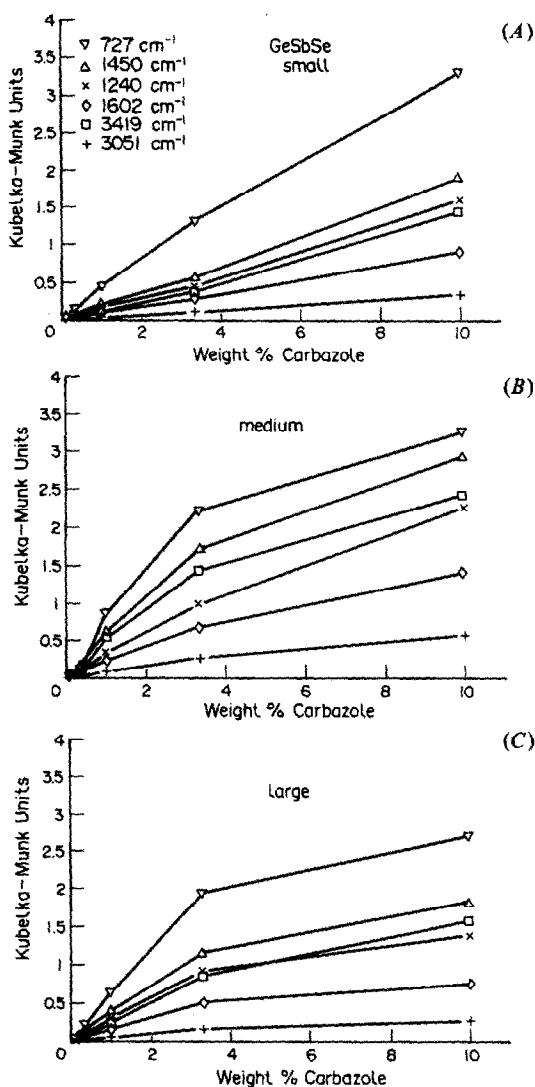

Fig. 6. The Kubelka-Munk intensity of six bands in the DRIFT spectrum of carbazole diluted in $\text{Ge}_{28}\text{Sb}_{12}\text{Se}_{60}$. Particles of carbazole and $\text{Ge}_{28}\text{Sb}_{12}\text{Se}_{60}$ were (A) between 5 and 10 μm , (B) between 20 and 30 μm , and (C) between 53 and 75 μm in size. The key for all three graphs is given in (A).

in bandwidth and decrease in intensity as the diameter of the spheres is increased from 2 to 32 μm . They state that the bands decrease in intensity because the "absorption constants" decrease as the particle diameter increases, but the cause of this effect is not discussed. The particle size dependence of both the scattering and absorption coefficients means that for weak bands, or very small particles, the intensity of bands will increase with increasing particle size. In the DRIFT spectra of an analyte, *reststrahlen* effects will be observed first with very strong bands. Thus, larger particles of analyte or strongly absorbing analytes, the spectra of

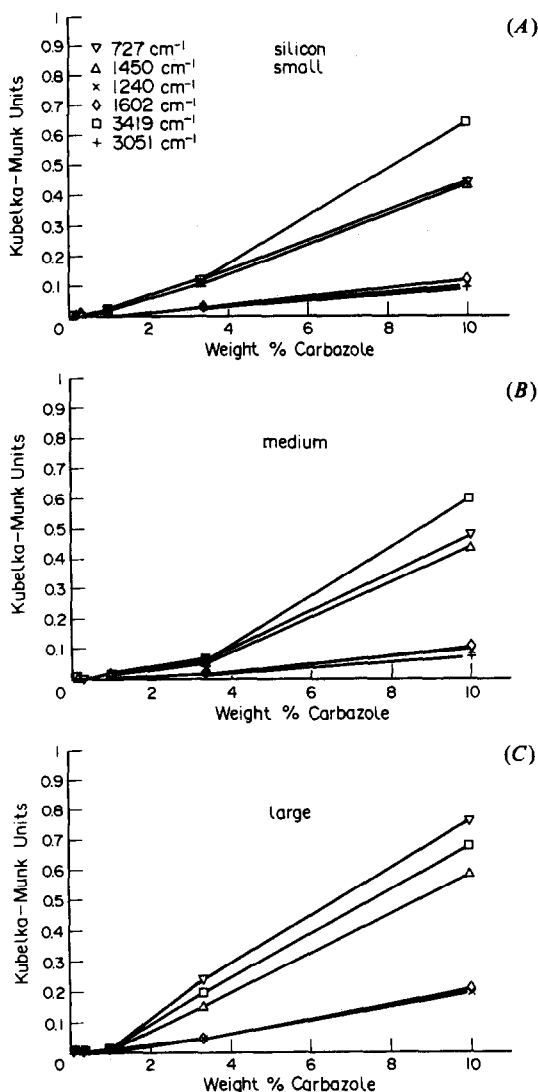

Fig. 7. The Kubelka-Munk intensity of six bands in the DRIFT spectrum of carbazole diluted in silicon. Particles of carbazole and silicon were (A) between 5 and 10 μm , (B) between 20 and 30 μm , and (C) between 53 and 75 μm in size. The key for all three graphs is given in (A).

which would contain relatively strong bands, would be more prone to anomalous dispersion and its attendant diminution of strong spectral features. Chalmers and MacKenzie caution that, since the particle diameter at which the changeover occurs will be different for bands of different intensity, ratios of weak and strong bands will not remain constant as the particle size is altered. Thus, for $\text{C}_{12}\text{H}_9\text{H}:\text{KCl}$ the largest particles give rise to weaker bands than the smaller two particle size ranges of the same mixture; this is most evident for the strongest bands in the spectrum, which as mentioned above are the most susceptible to *reststrahlen* effects.

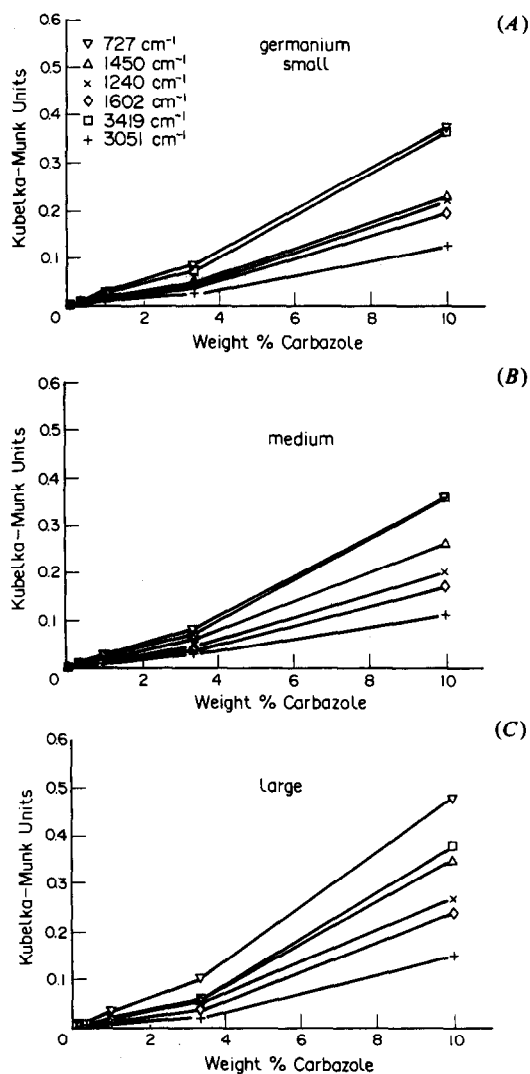

Fig. 8. The Kubelka-Munk intensity of six bands in the DRIFT spectrum of carbazole diluted in germanium. Particles of carbazole and germanium were (A) between 5 and 10 μm , (B) between 20 and 30 μm and (C) between 53 and 75 μm in size. The key for all three graphs is given in (A).

Plots of intensity with respect to the concentration of carbazole in potassium chloride are fairly linear. To measure the linearity of the data, the log of the intensity was plotted against the log of the concentration of carbazole. If the relationship between $f(R_\infty)$ and c were perfectly linear, the slope of the log-log plot would be 1, and for all matrices other than silicon the slope is within 5% of this value, independent of the particle size. The resulting slopes of the log of the intensity *vs.* the log of the weight percent of carbazole in all five matrices are given in Table 2 and shown schematically in Fig. 9.

The slopes of such plots in the small particle size range of potassium chloride for the six

Table 2. Slopes of plot of log(intensity) *vs.* log(concentration)

Matrix	Particle size	Band position, cm^{-1}					
		3419	3051	1602	1450	1240	727
Potassium chloride	5–10 μm	1.04	1.13	1.00	1.05	1.00	1.02
	20–30 μm	1.00	1.12	1.02	1.06	0.96	1.09
	53–75 μm	1.01	0.97	1.05	1.00	0.98	1.07
Diamond	5–10 μm	0.92	0.91	1.03	0.95	0.94	0.96
	20–30 μm	0.99	1.07	0.99	1.01	1.02	0.96
	53–75 μm	1.03	1.05	1.03	0.99	1.04	0.95
$Ge_{28}Sb_{12}Se_{60}$	5–10 μm	1.01	1.00	0.94	0.94	0.95	0.95
	20–30 μm	1.04	0.83	0.86	0.86	0.89	1.05
	53–75 μm	1.33	0.85	0.92	0.98	0.95	1.17
Silicon	5–10 μm	1.44	1.42	1.38	1.51	1.30	1.64
	20–30 μm	1.43	1.29	1.27	1.46	1.35	1.54
	53–75 μm	1.42	1.49	1.59	1.33	1.31	1.17
Germanium	5–10 μm	1.02	1.06	1.06	0.99	1.12	0.97
	20–30 μm	1.11	0.99	1.05	1.07	1.06	0.97
	53–75 μm	1.11	1.09	1.08	1.00	1.12	1.14

bands of carbazole listed in Table 1 ranged from 1.00 to 1.13; for the medium and large particle size potassium chloride corresponding ranges are 0.96 to 1.09 and 0.97 to 1.07, respectively. Overall, the slopes indicate a minor positive deviation from linearity, but the more intense bands display slight negative non-linearity due to saturation at the higher concentrations of carbazole. For carbazole mixed with diamond, which has a refractive index of 2.4, the graphs of band intensity *vs.* concentration are shown in Fig. 5. The difference in the maximum ordinate of the plots in Figs. 4 and 5 immediately indicates that the analyte bands are more than twice as weak when diamond is used as a matrix instead of potassium chloride. The medium sized particles yield slightly more intense bands than the small ones, with the large particles giving the weakest absorptions.

The same trend is shown in Fig. 6 for the data with $Ge_{28}Sb_{12}Se_{60}$ as the diluent matrix. For the chalcogenide glass diluent, there is a pronounced negative deviation in the plot of intensity *vs.* concentration, exceeding that seen for any other matrix used in this study. For the smaller particle size range, linearity is maintained quite well for all bands. For the larger two particle size ranges however, significant non-linearity is shown for concentrations of carbazole of 3 wt. % and above. The $Ge_{28}Sb_{12}Se_{60}$ glass is exceedingly brittle, and it is possible that sample morphology effects are the cause of this non-linearity.

The corresponding plots for carbazole diluted in silicon and germanium are shown in Figs. 7 and 8, respectively. The band intensities are

approximately equal for all particle sizes for both matrices. Unlike the three matrices of lower refractive index, the intensity of bands in the spectra deviate strongly in a positive direction with increasing concentration. The stronger bands exhibit an increased intensity with increasing particle size, probably because of the effect of anomalous dispersion. As the fraction of carbazole grows, the overall refractive index of the sample decreases. By the time the concentration of carbazole is 10 weight percent, there are enough analyte particles on the surface of the sample that a significant fraction of the incident radiation will penetrate into the sample, and hence be absorbed more strongly by the analyte. With a greater proportion of carbazole particles in the sample, there is a greatly increased probability of the infrared radiation interacting with a carbazole particle rather than being reflected out of the sample by a germanium or silicon particle. This effect is important for concentrations of carbazole as low as 3 weight percent for particle diameters between 53 and 75 μm .

Band intensities of carbazole in four of the five matrices decrease with increasing refractive index of the matrix. The exception to this trend is diamond, for which the band intensities are between that of $Ge_{28}Sb_{12}Se_{60}$ and silicon. The anomaly is best explained by considering the packing characteristics of potassium chloride, diamond and $Ge_{28}Sb_{12}Se_{60}$. Unlike diamond, both potassium chloride and $Ge_{28}Sb_{12}Se_{60}$ compress easily and compactly, forming a cohesive mass in the sample cup. Diamond particles show little affinity for one another, and do not

pack well; this is especially true for the medium and large particle size ranges used in this study. Yeboah *et al.* have demonstrated that increased compactness of DRIFT sample leads to increased band intensities in the resulting spectrum.³⁰ Since both potassium chloride and $\text{Ge}_{28}\text{Sb}_{12}\text{Se}_{60}$ are so easily compressed, carbazole dispersed in these materials will be at a higher packing density, leading to more intense bands for those two matrices. Thus, the effect on the scattering coefficient of the decrease in refractive index from $\text{Ge}_{28}\text{Sb}_{12}\text{Se}_{60}$ to diamond is offset by the result of a greater packing density.

CONCLUSION

The choice of the ideal matrix for use in diffuse reflectance infrared Fourier transform spectroscopic measurements depends upon the samples to be studied. If samples can be made with the analyte at concentrations of about 1 weight percent, or if only qualitative information is sought, all five matrices can yield good results. If the analyte is only weakly absorbing or if the concentration is too low, the use of silicon and germanium should be avoided since band intensities may fall below the level of noise in the spectrum. For working over a wide range of concentrations of analyte, potassium chloride, diamond or chalcogenide glass of small particle size is the best selection. From concentrations of 0.1 to 10 weight percent of carbazole in these three matrices of small particle size, the intensity of all but the strongest bands increased linearly with increasing concentration. If potassium chloride is employed as a diluent, small particles (less than 30 μm in diameter) yield optimal spectra, but particles up to 75 μm in diameter provide acceptable results. Diamond of only the smallest particle size range is suitable for use, since the larger particle sizes are extremely difficult to pack reproducibly. Large particles of chalcogenide glass are not recommended because of the highly non-linear relationship between concentration and intensity for particles greater than 20 μm in diameter. If a wide range of analyte particle sizes will be encountered, the choice is narrowed to powdered alkali halides, such as potassium chloride. Band intensity changes between the three different particle size ranges of carbazole and diamond preclude the use of diamond as a matrix. The chalcogenide glass is a suitable matrix for use in the TLC/DRIFT accessory since analyte bands are not severely attenuated in comparison

to spectra acquired with potassium chloride as the matrix, band intensities vary linearly with the low concentrations encountered in such an application, and the material is nonhygroscopic.

DETERMINATION OF TRACE AMOUNTS OF A PROTEOLYTIC ENZYME BY FIA WITH A STOPPED-FLOW AND AN ON-LINE PRECONCENTRATION TECHNIQUE

THOMAS GÜBELI,* JAROMIR RŮŽIČKA† and GARY D. CHRISTIAN

Department of Chemistry, BG-10, University of Washington, Seattle, Washington 98195, U.S.A.

(Received 9 January 1991. Revised 19 February 1991. Accepted 20 February 1991)

Summary—An automated method for the determination of small amounts of proteolytic enzymes has been developed, by combining a stopped-flow and an on-line preconcentration technique, using sorbent extraction. It is based on the hydrolysis of a synthetic chromogenic substrate during the stopped-flow period, yielding *p*-nitroaniline, which is then preconcentrated on a C-18 column. The *p*-nitroaniline is then eluted from the column to the spectrophotometer flow cell with methanol. In operation, the substrate solution (500 μ l) is injected into 0.1M tris-HCl buffer carrier and merged with the sample stream. The mixed plug is stopped in a waterbath, kept at constant temperature, for reaction. The operation of the manifold, including data acquisition, is controlled by a personal computer. Optimal parameters were 40°C, pH 8.3, a substrate concentration of 5 mM and wavelength 400 nm. The detection limit, using a 30 min stopped-flow reaction time, is 0.1 μ U protease/ml. The method is intended to be used in combination with portable low volume air samplers for monitoring workplace enzyme dusts in the detergent industry.

Proteolytic enzymes are widely used in the detergent industry. They are added to washing products to remove protein-based stains. These enzymes belong to the group of the subtilisins that are alkaline serine proteases originating from various strains of *Bacillus*.¹ Today only detergent enzyme granulates with a very low enzyme dust content are marketed and it is essential that sensitive analytical methods are developed to control the low enzyme dust levels under operating conditions. The American Conference of Governmental Industrial Hygienists (ACGIH) has established a ceiling limit of 0.06 μ g/m³ for pure airborne enzyme dust,² a level presently not satisfactorily measured by any analytical method. The aim of this work was to develop a flow-injection preconcentration technique for the enhancement of an existing spectrophotometric method applicable for monitoring enzyme dust at the workplace.

The described method is sensitive enough to allow the use of low air sampling volumes and short sampling times. The investigated enzyme is an endoproteinase of the serine type (Savinase™, Novo-Nordisk, Denmark). The

method relies on the proteolytic hydrolysis of a *p*-nitroanilide substrate (N-succinyl-L-alanyl-L-alanyl-L-propyl-L-phenylalanyl-*p*-nitroanilide), yielding the yellow chromophore *p*-nitroaniline (Fig. 1). This substrate has already been used for the determination of various enzymes such as chymotrypsin,³ human leukocyte elastase and cathepsin G,⁴ and detergent enzymes.⁵ The last report proved the suitability of the substrate for the analysis of small quantities of detergent proteases in the presence of high levels of surfactants. In order to achieve the highest sensitivity in the present study, important parameters such as temperature, pH, kinetic constants and wavelength were studied and optimized.

Flow-injection analysis (FIA) has proved its versatility and suitability for automation since its development by Růžička and Hansen in the mid-1970s in several hundred publications.⁶ The novel manifold described here is based on reversed FIA, stopped-flow and preconcentration by means of sorbent extraction; the substrate solution is injected into a buffer carrier solution and then merged with the sample stream. The flow is stopped for 5–30 min to allow reaction, and then the *p*-nitroaniline product is preconcentrated on a C-18 column. It is eluted with methanol to a spectrophotometric detector. The control of all devices by a computer allows

automated performance of the analysis. Column preconcentration techniques have been used for the analysis of trace amounts of metals^{7,8} as well as anionic species.⁹

EXPERIMENTAL

Reagents

All chemicals were of analytical-reagent grade and demineralized water was used throughout. Methanol (HPLC grade), calcium chloride dihydrate and dimethylsulfoxide were obtained from Baker, Phillipsburg, NJ. N-Succinyl-L-alanyl-L-alanyl-L-propyl-L-phenylalanyl-*p*-nitroanilide, *p*-nitroaniline, and tris[hydroxymethyl]aminomethane were obtained from the Sigma Chemical Company, St Louis, MO. The protease (SavinaseTM), with an activity of 3.46 U/g, was provided by Novo-Nordisk, Denmark. The activity units are Novo internal units (kilo Novo protease unit) expressed as units per gram of enzyme powder and are measured relative to a Novo-Nordisk enzyme standard by a procedure with N,N-dimethylcasein (DMC) substrate and trinitrobenzenesulfonic acid (TNBSA) reagent that reacts with the product.^{10,11} The enzyme powder contained 1% of pure active enzyme.

All FIA and other assays were conducted by using a Tris buffer solution containing 0.1M Tris in 0.01M calcium chloride, adjusted to pH 8.3 at room temperature with 1N hydrochloric acid, unless otherwise stated. The sample, the carrier stream and the substrate solution were prepared in the same buffer and filtered through a Whatman filter No. 5 (2.7- μ m pore size) prior to use. A 12.5mM stock solution of the substrate was prepared by dissolving it in DMSO. Substrate working solutions were produced by appropriate dilution of the stock solution with Tris-hydrochloric acid buffer. Enzyme solutions in the range 0.1–10 μ U/ml were prepared by a two-step dilution of a 5-mU/ml buffered stock

solution, using Tris-HCl buffer for dilution. All solutions were stored at 4° when not in use.

Apparatus

A schematic diagram of the flow-injection manifold is shown in Fig. 2(a). The peristaltic pumps, model C-6V (P1, P2), were obtained from Alitea USA, Medina, WA, and were equipped with PVC pump tubing (0.89 mm i.d., Cole-Parmer, Chicago, IL). Teflon tubing (0.81 mm i.d.) was used for the rest of the system. All streams (sample, carrier and eluent) were propelled at 1 ml/min. Fittings were purchased from Upchurch Scientific (Oak Harbor, WA). The valves (V1, V2) were integrated into a single unit by using an electrically actuated 10-port rotary valve (Valco Instruments, Houston, TX) configured as shown in Fig. 2(b). A Milton-Roy Mini 20 spectrophotometer (Cole-Parmer, Chicago, IL) was used as the detector. The pumps and the valve were controlled by an IBM Data Acquisition and Control Adapter and an IBM PC/AT compatible computer with EGA graphics. The analog signal of the photometer was amplified from 500 mV to 5 V full scale and

digitized with a 12 bit A/D converter of the IBM board. A menu-driven program written in house based on Microsoft Fortran version 4.1 and 5.0 and Microsoft Macro Assembler version 5.1 allowed the precise control of the pumps and valve, and the collection and treatment of data.¹² Batch spectrophotometric and spectral measurements were made with a Hewlett-Packard 8452A Diode Array Detector.

Procedures

Enzyme activity determination. Batch enzymatic reactions for determining activities were initiated by adding 0.25 ml of substrate working solution to 1 ml of buffered enzyme solution with thorough mixing. Relative reaction rates under different operating conditions for a fixed concentration of enzyme are simply expressed as absorbance units per minute (AU/min) at a pathlength of 10 mm. The absorbance of the *p*-nitroaniline produced was measured continuously, except where otherwise noted.

Temperature influence. A 1.5- μ U/ml enzyme solution in the Tris-HCl buffer, pH 8.0 was used for temperature studies. The reaction rate was determined by recording the absorbance between 1 and 30 min. At 44°, a three point measurement was made (10, 20 and 30 min).

Wavelength and pH value dependence. Absorbance spectra at different pH values were obtained with the diode array detector. Readings were taken at two minute intervals from 2.5 to 28.5 min.

Kinetic constants. The determination of the Michaelis constant, K_m , was conducted at 30° and pH 8.3, with duplicate measurements of the initial reaction velocity at four different substrate levels between 0.25 and 2mM, using a conventional batch technique. The concentration of the enzyme solution was 1 μ U/ml.

Preconcentration of *p*-nitroaniline. A manifold with a peristaltic pump operated at a flow-rate of 1 ml/min, a Perspex column (7 mm \times 2 mm i.d.) filled with 10 mg of C-18 material (40 μ m particle size, Analytichem International, Harbor City, CA) and the diode array detector were used to measure the retention efficiency. Prior to the loading of the *p*-nitroaniline solution (2.5 μ g/ml in Tris-HCl buffer, pH 8.3) the column was activated with approximately 200 μ l of methanol and rinsed with the same volume of Tris-HCl buffer. The *p*-nitroaniline solution was pumped continuously and the unretained amount was measured as it passed through the detector. Absorbance data acquisition was

started 19 seconds after the *p*-nitroaniline solution reached the column.

Operation of the FIA system. The FIA system employed is shown in Fig. 2(a). It has the following functions: inject, mix, incubate, pre-concentrate, elute and monitor. Two peristaltic pumps (P1 and P2) were used to propel the sample (S), buffer (C) and methanol (E) streams as well as to fill the injection loop of valve V1 with reagent (R). The reagent (500 μ l, 5mM substrate) was injected into a carrier stream (Tris-hydrochloric acid buffer), merged with the sample stream (enzyme solution), mixed in a knotted reactor (100 cm \times 0.81 mm i.d.) and subsequently propelled into a reaction coil (240 cm \times 0.81 mm i.d.) placed in a waterbath (T) held at 40°. The mixed zone was stopped there for an incubation time of 5–30 min. Next, the pump (P1) was started again, the hydrolysis product (*p*-nitroaniline) was initially monitored while passing through the detector D (peak A, Fig. 3), and then it was retained on the column packed with C-18. The spent stream left the system through waste line W1. When the retention step (PR) was completed, pump P1 was stopped, and the valve (V1) turned to the load position [see Fig. 2(b)], thereby also opening valve V2 and the waste line W2. Pump P2 was activated and the preconcentrated *p*-nitroaniline eluted (EL) with methanol in a countercurrent mode and subsequently detected (peak B, Fig. 3), leaving at W2. Simultaneous with the elution, the reagent loop was filled again.

Construction of the column and the detector flow cell is shown in Fig. 4. The C-18 cartridges as designed for the Varian Advanced Auto-

mated Sample Processor [AASP (13)] cleanup system are available as cassettes consisting of 10 items. For the present use, an individual cartridge was cut off this assembly and mounted in the flow-injection system as shown in Fig. 4.

RESULTS AND DISCUSSION

In order to achieve the required sensitivity for the method, the most important parameters influencing the proteolytic activity were investigated and optimized. The effect of temperature is shown in Fig. 5. At a reaction time of 30 min the reaction rate, expressed in absorbance units per minute, was increased by a factor of 1.44

Fig. 5. Effect of temperature on the activity of the proteolytic enzyme. The reaction rate, expressed in absorbance units per minute (AU/min) is based on a reaction time of 30 minutes and an enzyme activity of $1.5 \mu\text{U/ml}$.

Fig. 6(a). Spectrum of the substrate at pH 8.3. Absorbance maximum is at 315 nm.

Fig. 6(b). Spectrum of *p*-nitroaniline at pH 8.3. Absorbance maximum is at 382 nm.

when the temperature was changed from 23 to 44° . Higher temperatures can be chosen with this enzyme but this increases the probability of building air bubbles in the FIA-system.

Absorption maxima for the substrate and the *p*-nitroaniline at pH 8.3 are at 315 nm and 382 nm, respectively, as seen in Fig. 6. The dependence of the reaction rates on pH is shown in Fig. 7. From this (curve fitted) figure it can be

Fig. 7. Wavelength and pH value dependence of the measured reaction rate (AU/min) of a $1 \mu\text{U/ml}$ enzyme solution at 22°C . Readings were taken every two minutes during a reaction time of 28.5 minutes.

seen that the optimum pH is near 8.3 and a wavelength of 400 nm is superior to higher wavelengths while still having sufficiently low blank values [see Fig. 6(a)]. The molar absorptivity of *p*-nitroaniline at 400 nm was determined to be 1.18×10^4 l. mole⁻¹ cm⁻¹ ($n = 3$, pH 8.3). The significant changes of the apparent reaction rates with pH are due to changes in enzyme activity and changes in the molar absorptivity of *p*-nitroaniline. The absorptivity increases by 1.2% from pH 8.0 to 8.3 and by 3.5% from pH 8.3 to 8.6.

The determination of the Michaelis constant K_m was performed at 4 different substrate levels. Using a Lineweaver-Burk plot, K_m was calculated to be 0.53 mM and V_{max} (maximum reaction velocity) for a $1\text{-}\mu\text{U/ml}$ enzyme activity to be 5.2×10^{-3} AU/min ($R = 0.992$). Since the substrate has a limited solubility of approximately 10 mM in Tris-hydrochloric acid buffer³ and the blank value (see Fig. 8) from overlap with the *p*-nitroaniline spectrum should be as low as possible, a concentration of 5 mM was chosen for the experiments.

The preconcentration experiment (Fig. 9) showed that the capacity of C-18 for *p*-nitroaniline is about 0.5 μg (3.6 nmol) for a sorbent mass of 10 mg, with a loss of $<2\%$. However, the retention efficiency diminishes at higher quantities of *p*-nitroaniline, which results in a non-linear calibration curve (Fig. 8). The capacity for the co-retained substrate is about 475 nmole for a loss of $<2\%$. The retention of the *p*-nitroaniline did not appear to be affected by the presence of the substrate.

A typical recording using the described manifold with an incubation time of 5 minutes is shown in Fig. 3. The peak obtained with preconcentration (peak B) is much narrower and more

Fig. 8. Plot of the peak height of the preconcentrated reaction products vs. enzyme activity. Stop time: 5 min at 40° .

Fig. 9. Retention efficiency of a C-18 column (10 mg, 7×2 mm i.d.) for *p*-nitroaniline. The flowrate was 1 ml/min and the pNA concentration 2.5 $\mu\text{g/ml}$ (Tris-HCl buffer pH 8.3).

than a factor of seven higher than the peak obtained without preconcentration (peak A), thus yielding a sensitivity increase of at least the same magnitude. As seen from this recording, obtained with an enzyme activity of 5 $\mu\text{U/ml}$, a direct measurement without preconcentration would be sufficient. For low activities of 0.1 $\mu\text{U/ml}$, corresponding to the desired sensitivity, a preconcentration step is necessary to achieve a satisfactory signal-to-noise ratio. The calibration graph (Fig. 8) shows that the response curve is not linear. However, by increasing the amount of C-18 to increase the retention capacity, an extended linear relationship can be obtained if desired. Relative standard deviations of net sample signals of the typical two to three repetitive injections were 2.8 – 17% . The sampling frequency is dependent upon the selected incubation time and ranges from 1.7 to 6 samples/hr (incubation time: 5 to 30 min). More than 60 injections were performed without having to change the pump tubings or the column. The detection limit for the protease, with a reaction time of 30 min (40°), is about 0.1 $\mu\text{U/ml}$. Since the Novo-Nordisk protease standard used in this work has an activity of 3.46 U/g and contains 1% of pure active enzyme, this value corresponds to 0.29 ng enzyme/ml. Therefore to achieve the ACGIH limit of 0.06 μg pure enzyme/ m^3 air, the enzyme dust contained in 4.8 litres of air has to be trapped quantitatively in 1 ml of aqueous solution. Battery operated low volume air samplers with Midget impingers¹⁴ may fulfill this purpose.

CONCLUSIONS

The proposed method allows an automated and sensitive determination of extremely low

activities of detergent proteases in solution, and has the potential for continuous monitoring of enzyme dust in the industrial environment. Future work is intended to enhance the performance of the system by implementing double injection and syringe based pumps^{15,16} which will allow interrupted operation of the flow injection system for several thousands of measurements. However, the low sampling frequency of the method will be difficult to overcome due to the necessity of long incubation times. To circumvent this problem and to enhance the sensitivity of the method even more, studies will be made to preconcentrate not only the products of the enzymatic reaction but the enzyme as well on a suitable solid support.

INDIRECT DETERMINATION OF THE PESTICIDE DIMETHOXYDITHIOPHOSPHATE IN AN FIA-AAS SYSTEM WITH LIQUID-LIQUID BACK-EXTRACTION

ORONCIO JIMENEZ DE BLAS, JOSE LUIS PEREDA DE PAZ and JESUS HERNANDEZ MENDEZ
Department of Analytical Chemistry, Nutrition and Food Science, University of Salamanca,
37008 Salamanca, Spain

(Received 14 November 1989. Revised 14 February 1991. Accepted 19 February 1991)

Summary—A method has been developed for the determination of dimethoxydithiophosphate (DDTP) by liquid-liquid extraction in a flow-injection analysis (FIA) system with detection by atomic-absorption spectrometry (AAS). It is based on the formation of the Cu(DDTP)_2 complex and its extraction into chloroform, and back-extraction of the copper with an ammonia buffer (pH 10). The method uses small amounts of samples, avoids handling errors and is fast and highly reproducible. It features a detection limit of 0.39 ppm DDTP ($2.45 \times 10^{-6} M$ in the organic phase) and a relative standard deviation of 1.6%. The method has been applied to the determination of the organophosphorus pesticide malathion in an agricultural formulation.

The development of sensitive, selective and fast methods for the determination of pesticides is mandatory nowadays on account of the broad use of these compounds. A major group consists of the organophosphorus pesticides derived from dimethoxydithiophosphate (DDTP). The methods developed for determination of DDTP can equally be applied to the determination of these pesticides once the optimum hydrolysis conditions for yielding DDTP from them have been found. There are several methods in the literature for the determination of DDTP, including titrimetric,¹ chromatographic,²⁻⁴ spectrophotometric⁵⁻¹¹ and atomic-absorption spectrometric techniques.^{12,13}

The spectrophotometric method reported by Norris *et al.*¹⁴ is imprecise owing to the instability of the Cu(DDTP)_2 complex. An internal reaction occurs, resulting in a reversible equilibrium with colourless copper(I) dimethyldithiophosphate and bis(dimethoxyphosphothiorone) disulphide.¹⁵ Extracting the complex increases its stability and this was exploited in earlier work for the indirect determination of DDTP. However, the extract had to be mineralized¹⁶ or the copper back-extracted into an aqueous phase.¹⁷

This paper reports the use of a continuous extraction FIA-AAS system for determination of DDTP, on the basis of the earlier work mentioned above. The use of back-extraction offers substantial advantages over the batch-

extraction and mineralization methods, namely ease of operation, limited need for laboratory ware, lower sample consumption, good stability in time, immediate phase separation, possibility of automation and avoidance of kinetic problems and various manipulative errors, *etc.*

EXPERIMENTAL

Apparatus

A Varian Techtron AA 1475 atomic-absorption spectrometer furnished with a conventional copper hollow-cathode lamp was used.

Reagents

All reagents were of analytical grade and doubly distilled water was used for dilutions. Methanol solutions of DDTP were prepared from the technical liquid product (82.8% pure). The standard copper solutions were prepared from a 0.020M solution made with electrolytic copper.

Malathion was determined in the agricultural formulation Exathion-4, a spraying powder from Cónдор S.A. Standard malathion solutions in methanol were made from the technical liquid product (91.3% pure) and titrated after alcoholic hydrolysis.¹⁶

FIA-AAS ancillary equipment

The manifolds used are depicted schematically in Fig. 1. The ancillary equipment used

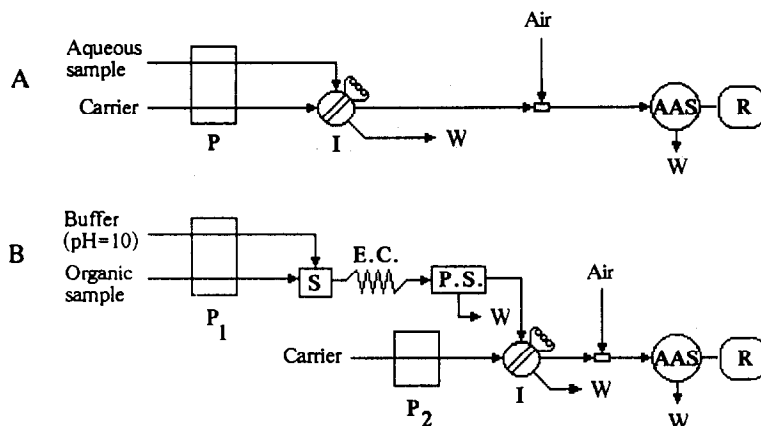

Fig. 1. Flow-injection manifolds used in (A) the determination of copper, and (B) its back-extraction. P, P₁ and P₂, peristaltic pumps; I, injection valve; W, waste; S, segmenter; E.C., extraction coil; P.S., phase separator; R, recorder. Air denotes air compensation.

comprised the following elements; Gilson Minipuls-2 (HP-4) peristaltic pumps fitted with PVC tubes of 0.89 mm i.d. for aqueous phases and Isoversinic fluorinated-plastic tubes of 1 mm i.d. for the organic phase; a Rheodyne 2050 injection valve; a Teflon segmenter, designed and constructed by the authors according to a model reported by Cantwell and Sweileh;¹⁸ a nylon membrane phase-separator, also home-made (Fig. 2); a Millipore HA hydrophilic membrane (0.45 μm pore size).

Measurement of copper standards in the FIA-AAS system

Measurements were made with the manifold depicted in Fig. 1A. Aqueous copper solutions were injected into a carrier stream of doubly distilled water, and the copper was determined by AAS under suitable instrumental conditions. The flow-rate of the carrier and the aspiration rate of the nebulizer of the atomic-absorption spectrometer were air-compensated.^{19,20}

Fig. 2. Detailed view of the phase separator. F_s, segmented flow; F_o, organic stream; F_a, aqueous stream. 1, 3 and 4, Teflon membranes; 2 hydrophilic membrane of 0.45 μm pore size (Millipore HA).

Continuous extraction in the FIA-AAS system

This was studied with the aid of the manifold shown in Fig. 1B. The samples were prepared by extracting the Cu(DDTP)₂ complex into chloroform according to a procedure reported elsewhere.¹⁶ The continuous back-extraction was accomplished with 0.2M NH₄⁺/NH₃ buffer solution (pH 10).¹⁷ The sample and buffer were propelled to the segmenter (S) by a peristaltic pump. The segmented flow was then driven to the extraction coil (EC), where mass transfer took place, and then on to the phase separator (PS). The aqueous phase from the separator filled the injection loop (I), the contents of which were subsequently inserted into a carrier stream (doubly distilled water) which was led to the AA spectrometer nebulizer. The injection of previously separated samples offers the advantage of decreasing their dispersion and hence increasing the sensitivity, notwithstanding the somewhat larger sample volumes required.

The instrumental conditions for the AAS measurements of copper were the same in every case, *viz.* wavelength 324.8 nm, band-pass 0.5 nm, lamp current 3 mA, observation height 11 mm above the burner, air flow-rate 12 l./min and acetylene flow-rate 1.7 l./min.

Procedure

An appropriate amount of DDTP, 3.0 ml of 0.01M nitric acid, 4 ml of chloroform and a small stoichiometric excess of copper were placed in a separatory funnel, which was then shaken for 2 min, and the organic extract was decanted. A further two extractions with 3 ml of chloroform were made.¹⁶ The copper was back-extracted with the 0.2M NH₄⁺/NH₃ buffer

from the samples thus obtained, in the manifold shown in Fig. 1B.¹⁷ The extraction flow-rate was 2 ml/min and a 100-cm knotted reactor was used. The injected volume was 160 μ l and the carrier flow-rate 5 ml/min. The copper was determined under the instrumental conditions described.

RESULTS AND DISCUSSION

Optimization of the measurement of copper in the FIA-AAS system

The FIA-AAS combination is somewhat peculiar as regards dispersion,²¹ as a result of the effect of the nebulizer parameters on the amount of sample aspirated. The flow-rate and the injected volume are the variables which most significantly affect the dispersion;^{22,23} the length and inner diameter of the tubing are less influential, and are frequently overlooked in this type of work. On the other hand, the flow-rates commonly used in continuous extractions (≈ 1 ml/min)²⁴⁻²⁶ must be compatible with the aspiration rates required in atomic-absorption work (5-6 ml/min).

To study the influence of the injected volume on the dispersion volumes of 40, 160 and 245 μ l were used (void volumes not considered). The dispersion decreased with increasing injection volume from 40 to 160 μ l, above which it remained virtually constant. A volume of 160 μ l was therefore chosen for all subsequent experiments.

The influence of the carrier flow-rate on absorbance is illustrated in Fig. 3. The sensitivity

Fig. 3. Influence of the carrier flow-rate on the absorbance of copper: (□) 1.27 ppm Cu (0.125 A with conventional aspiration); (■) 2.54 ppm, Cu (0.256 A with conventional aspiration). The injected volume was 160 μ l in all instances. One carrier stream was used up to 2.75 ml/min, two between 2.75 and 5.0 ml/min, and three between 5.0 and 7.75 ml/min.

†Three carrier lines.

increases with increasing flow-rate, although rates above 5 ml/min result in pulse problems arising from the peristaltic pump. Table 1 reflects these problems derived from the use of three carrier lines and also shows the variation of the precision with the flow-rate. The carrier flow-rate used to avoid these problems and ensure good precision was 5 ml/min (Fig. 3 and Table 1).

Optimization of the continuous extraction in the FIA-AAS system

The study of the extraction process involved three variables: the type and length of the extraction reactor and the flow-rate. Coiled and knotted reactors were used, and as can be seen in Fig. 4, the extraction yield increased with increasing reactor length. In addition, for a given reactor length, the knotted reactor proved to be more efficient than its coiled counterpart. These results are accounted for by the greater turbulence within knotted reactors, which favours contact between the phases and therefore gives rise to greater mass transfer. Also, the flow-rate appears to affect only the shorter reactors, particularly the 50-cm long coiled reactor. The 100-cm knotted reactor was chosen because although the 300-cm coiled reactor provided higher sensitivity, this did not compensate for the disadvantages of larger amounts of sample and longer determination times

Fig. 4. Influence of the type and length of extraction coil and the flow-rate on the extraction yield: (□) coiled; (■) knotted. The injected volume was 160 μ l and the carrier flow-rate was 4 ml/min in all instances.

required. The flow-rate selected, 2 ml/min, resulted in a good sampling rate.

Analytical features

By use of the proposed procedure a calibration graph for DDTP was prepared. Figure 5 shows a typical FIA recording obtained from

three injections of each standard. The study of the precision involved 9 injections of a sample obtained by extracting 1.65 μmole of DDTP into 25.0 ml of chloroform ($8.0 \times 10^{-5} M$ in the chloroform solution). The relative standard deviation (rsd) was 1.6%. The detection limit, obtained by applying the 3 s/m criterion,²⁷ was 0.39 ppm DDTP, equivalent to a concentration of $2.45 \times 10^{-6} M$ in the chloroform solution. Table 2 compares the results obtained by the proposed method with those provided by other methods for determination of DDTP^{14,16,17} on the basis of the $\text{Cu}(\text{DDTP})_2$ complex. The proposed method has better analytical features than the standard procedure¹⁴ and although its precision is poorer than that of the back-extraction procedure,¹⁷ the FIA-AAS method is much faster and requires smaller amounts of sample.

Interferences

In previous work¹⁷ interferences with the extraction of the $\text{Cu}(\text{DDTP})_2$ complex were studied. The first group of species considered consisted of some metal ions [$\text{Zn}(\text{II})$, $\text{Fe}(\text{III})$, $\text{Pb}(\text{II})$, $\text{Cu}(\text{II})$ and $\text{Bi}(\text{III})$] which form complexes with DDTP. The serious interference from iron and bismuth can be overcome, although addition of an excess of copper is required.

The second group of species considered comprised certain organophosphorus compounds from different groups of pesticides. Malathion, belonging to the DDTP group, does not interfere as it is not hydrolysed in the acidic medium from which the extraction takes place and hence

does not yield DDTP. Some thiophosphate pesticides interfere negatively, which may be due to interferences in the extraction of the complex.¹⁶

Applications

The proposed procedure was applied to the determination of malathion in an agricultural formulation. The optimum hydrolysis conditions to yield DDTP had already been studied,¹⁶ and it was clear that other DDTP group pesticides would interfere with the extraction.¹⁶ The C3ndor S.A. formulation Exathion-4 was used, with a malathion content of about 4%. As preliminary treatment, the active matter was separated by dispersing a known weight (a few grams) of the sample in methanol, filtering, and making up to a given volume with the same solvent. The FIA recordings provided by the malathion standards and the sample are shown in Fig. 6. The results were compared with those obtained by the procedures mentioned above (Table 3). As can be seen, the more precise procedures give malathion contents slightly lower than that stated by the manufacturer. The standard procedure is apparently more accurate, although is not very representative because of its imprecision.

Fig. 6. Recordings obtained for malathion standards and sample. The numbers above the peaks have the same meaning as in Fig. 5.

(Received 20 December 1990. Accepted 12 February 1991)

Summary—Microwave induced plasmas, sustained in a Beenakker resonator and a surfatron, respectively, are used to excite vapours released by electrothermal evaporation of solutions from a tungsten coil. The analytical figures of merit of AES for two easily volatilized elements (Cu, Cd) are compared for argon MIP operated in the two resonators under optimized conditions. In the Beenakker resonator a 1-filament plasma was produced at an argon flow of 0.45 l./min and a forward power of 50 W. In the surfatron a 2-filament plasma with 2.44 l./min argon and a forward power of 130 W was used. The detection limits for Cu and Cd with the surfatron are lower than those obtained with the Beenakker resonator and are in the range 10–20 ng/ml. Also interferences arising from an easily ionized element such as Na are lower with the surfatron than with the Beenakker resonator. The linear dynamic ranges in the case of the surfatron are also superior and extend over three decades of concentration.

Microwave induced plasmas (MIPs) are prominent sources for performing optical emission spectrometric multielement determinations. They are produced without electrodes in a resonator where the microwave energy is coupled to a gas (argon or helium) flowing in a quartz capillary. Microwave induced plasmas for atomic spectrometry were first operated in resonators at reduced pressure, as in the case of the so-called Evenson $\frac{1}{4} \lambda$ resonator.¹ They became of real interest for atomic spectrometric analysis since it was possible to operate them at atmospheric pressure. This could be realized with the TM₀₁₀ resonator, developed by Beenakker² and later improved by van Dalen *et al.*³ In addition, other microwave cavities for use at atmospheric pressure have become available during the last few years. The so-called surfatron⁴ is operated

at atmospheric pressure and was described by Hubert *et al.*⁵ Spectroscopic investigations of argon plasmas⁶ and investigations of the working parameters by use of helium or argon plasmas operated in a surfatron followed.⁷

Since the MIPs are operated at low power, as compared to the inductively coupled plasma (ICP), restrictions for the introduction of samples in MIPs exist. Generally large amounts of matter cannot be brought into MIPs without disturbing their discharge stability. Also, due to the low gas kinetic temperatures⁸ matrix effects are high.

Various methods of sample introduction have been used in combination with MIPs. Pneumatic nebulization of solutions, as it is known from ICP spectrometry, is hampered by the low power of the MIP. Nevertheless, Kollotzek *et al.*^{9,10} could produce a toroidal plasma, into which wet aerosols produced by a Meinhard nebulizer could be taken up. They used a quartz

*Author for correspondence.

capillary with 4 mm i.d. in a TM_{010} resonator and 150 W forward power. Yet a desolvation of a wet aerosol improves the analytical performance.¹¹

Further electrothermal evaporation (ETV) of dry solution residues can be used. Here, solution aliquots are brought into a graphite furnace or put on a metal filament, dried, and subsequently the analyte is released as vapour during a heating stage.¹² The advantage of this approach is the separation of evaporation and excitation. The sample is volatilized in the graphite furnace or on the metal filament, so that the whole energy of the plasma is used for the excitation.

In the case of the MIP, Aziz *et al.*¹³ used a graphite furnace. The sample was evaporated and the solvent vapour was removed through the sampling aperture by an argon flow entering from both sides of the furnace so as to avoid condensation in the treatment line. Heltai *et al.*¹⁴ showed that the toroidal argon MIP could be operated also reliably in combination with electrothermal evaporation.

The use of a metal filament was described by Runnels and Gibson.¹⁵ They used a 0.4-mm platinum filament placed in an evaporation chamber and an argon-MIP for the determination of volatile metal chelates. Other papers on the application of metal filaments included the use of tungsten and tantalum filaments. Aldous *et al.*¹⁶ employed platinum and tungsten filaments, on which a reproducible amount of sample could be collected as a surface film by dipping them into the solution. When using a rapid electronic amplifier/integrator, a linear dynamic range of three decades for Cd was achieved. Kawaguchi *et al.* determined picograms of metals in metal enzymes by using evaporation from a tantalum filament and excitation in a helium-MIP under reduced pressure.¹⁷ They also investigated the interelement effects and the mechanism of excitation of the He-MIP.¹⁸

Van Dalen *et al.*¹⁹ determined halogen and sulphur by using a tantalum filament and a He-plasma produced in a TM_{010} resonator at atmospheric pressure. A special sampling unit which uses a tungsten filament has been described by Brooks and Timmins.²⁰

The aim of this work is to compare under optimized conditions the analytical performance of a Beenakker resonator and a surfatron, respectively, in MIP-AES in combination with the same electrothermal evaporation unit. An objective evaluation of both plasmas is obtained

as the same signal recording equipment is used.

In both cases, a tungsten coil, as described by Berndt *et al.*²¹ for AAS, is employed for analyte evaporation. The detection limits and the linear dynamic ranges for a volatile element (Cd) and a less volatile element (Cu), are determined. Also the influence of an easily ionized element such as Na on the Cd and Cu signals is studied.

EXPERIMENTAL

MIP equipment

For the measurements with the Beenakker resonator a 200 W microwave generator (EMS, Mikroton 200 Mark III) was used. In the case of the surfatron, which requires a higher forward power, a generator with 300 W maximal forward power (AF, GMW 24-301 DR) was used. The TM_{010} resonator used in this work is a modified version² of that described by Beenakker.¹ The surfatron was built after a description given by Selby and Hieftje⁷ (Fig. 1).

Evaporation unit

The tungsten coils used for electrothermal evaporation were produced for halogen lamps (Osram GmbH, Munich, FRG). They consist of 12 turns with dimensions of 3 mm × 7 mm × 1 mm and can be used up to a voltage of 24 V and a power of 250 W. The high melting point of tungsten (3410°) permits it to achieve the temperature of up to 2000° required for the sample volatilization by applying a voltage of 9 V.

For drying sample aliquots of 20–50 μ l within 1 min, a voltage of 0.35 V was selected. Then the coil did not glow at the end of the evaporation time, by which a loss of volatile elements and compounds was prevented. The water vapour produced during the solvent evaporation was released through the side-arm of a three-way valve, placed between the quartz evaporation unit and the argon flow 2 inlet. A PTFE plug was used, which makes greasing superfluous and prevents contaminations. The experimental facilities and operating conditions are given in Table 1.

Measurement

For analysis 20 μ l of the solution was dispensed on the coil with the aid of a micropipette and during this procedure the MIP was operated with the argon flow 2 only. After closing the sample aperture, the sample was dried and

the analyte solvent vapour was released through the three-way valve.

Subsequent to the drying stage, the argon flow was switched from 2 to argon flow 1. After waiting 30 sec for stabilization, the sample was evaporated and transported into the plasma. After recording the signal, the flow was switched back to argon flow 2 and the next sample could be brought onto the coil.

This procedure was used both with the Beenakker resonator and with the surfatron. In the case of the latter we partly worked with argon flow 1 and argon flow 2 together (see Table 2). In all other experiments the argon flow 2 was turned off prior to the analyte evaporation stage.

RESULTS AND DISCUSSION

Measurements with the Beenakker resonator

Stability area of the MIP. In the TM_{010} resonator a 1-filament plasma can be produced by using a clamping device with 4 narrow cuts. The capillaries used may have diameters from 1 to several mm. In the case of a capillary with an internal diameter of 2 mm, the plasma cannot be ignited reproducibly as it changes its burning position. This effect could not be completely eliminated by asymmetrically positioning the capillary in the resonator. As the reproducibility of the signals finally was insufficient, the 2-mm capillary was not used for analytical measurements.

Table 2. Optimal working conditions for the different plasma forms obtained in a surfatron

Plasma form	Chamber depth, mm	Gap length, mm	Forward power, W	Refl. power, W	Argon flow 1, l./min	Argon flow 2, l./min	Signal to background ratio for 3 µg/ml Cu
tor. I	45.5	14.6	100	2.4	0.35	—	18
tor. II	44.4	12.3*	130	2.5	0.38	—	20
1-filament	37.3	10.0	110	1.7	0.90	0.38	22
2-filament	43.0	13.0*	130	2.6	2.44†	—	110

*As low as possible.

†As high as possible.

With a capillary diameter of 1.5 mm and 1 mm, respectively, the plasma filament lied stable at one position and was not disturbed when the coil was heated for evaporating the sample. With gas flows below 0.6 l./min Ar, the signals were found to be reproducible. All further determinations, therefore, were performed with a quartz capillary having an internal diameter of 1 mm.

For a one-filament MIP in a quartz capillary with 1-mm inner diameter the microwave forward power, the gas flow and the selection of the observation zone of the plasma were optimized (Table 3). It was found that a forward power of 50 W and an argon flow 1 of 0.46 l./min gave optimum line to background ratios for the elements studied.

Calibration curves. The linear dynamic ranges for Cd and Cu are different but, as shown for Cd, they also depend on the analyte species present (Fig. 2).

The evaporation temperatures *e.g.* of cadmium chloride and cadmium sulphate are very different, namely 490° and *ca.* 1000°, respectively. The calibration curve of the cadmium chloride bends off at low concentrations, which might be related to the higher volatility as compared to cadmium sulphate where no losses were observed. Therefore, all further measurements are performed with cadmium sulphate.

When measuring peak heights, the linear range of the calibration of Cu is limited. This is due to an increase of the signal duration, which was found to be proportional to the concentration. With Cd the linear dynamic range is

Table 3. Optimized working parameters for the 1-filament plasma in the TM₀₁₀ resonator

Parameter	Range	Optimum
Forward power	40–60 W	50 W†
Position observed*	0–0.5 mm	0.35 mm

*0 mm means the edge of the capillary and 0.5 mm is the center of the plasma.

†As low as possible for a stable plasma.

higher than with Cu. It is only limited by a decrease of the temperature and the stability of the plasma with an increase of the amount of analyte introduced. The increase of the signal duration in the case of Cu can be due to effects in the plasma and/or during the evaporation.

The addition of Na generally leads to an increase of the Cu and Cd signals (Fig. 3 and Table 4), which is proportional to the Na concentration. This can be explained by a shift in the ionization equilibrium or by an increased excitation of the low energy Cu and Cd levels at the lower plasma temperature resulting from ionization of the Na added.

Measurements with the surfatron

Stability area of different types of MIPs. After adjusting the coupling plunger until a minimum of reflected power was obtained, various plasma forms could be produced depending on the gap length, the chamber depth, the gas flows and also on the axial position of the capillary in the surfatron. As a result of variations of these parameters four different plasma forms were found, namely, a 1-filament plasma, a 2-filament plasma and two toroidal plasmas, marked as I and II. The latter mainly differ by the conditions under which they were achieved, but also by their stability area and performance (Table 3).

Fig. 2. Calibration curves: 50 W forward power and 0.46 l./min argon. Cd (line Cd I 228.8 nm): + CdCl₂; *CdSO₄, Cu (line Cu I 324.8 nm): ■ CuCl₂.

Fig. 3. Influence of Na on the determination of Cd and Cu with MIP-AES using a Beenakker resonator and ETV. \times Cd; \square Cu; \bullet Cd + 20 $\mu\text{g/ml}$ Na (line Cd I 228.8 nm); \circ Cu + 10 $\mu\text{g/ml}$ Na (line Cu I 324.8 nm).

All plasma forms were produced in a capillary with an internal diameter of 4 mm and an outer diameter of 6 mm. Experiments with a capillary having 2 mm i.d. and 6 mm o.d. did not lead to a stable plasma. At the conditions investigated only an unstable 1-filament plasma was obtained.

The toroidal plasma I was obtained at a gas flow between 0.3 and 0.5 l./min and a forward power of 90–120 W. Its reflected power depends on the chamber depth and the gap length [Fig. 4(a) and (b)]. The capillary should not protrude out of the surfatron. At this position the reflected power was minimum (2.4 W).

The toroidal plasma II could be operated stably at a forward power of 130–160 W and a gas flow of 0.3–0.6 l./min. In contrast to the toroidal plasma I, the reflected power here was minimal, when the capillary protruded 10 mm out of the surfatron. The values of the chamber depth and the gap length for minimal reflected power are given in Table 3.

A 1-filament plasma could be obtained at a forward power of 105–115 W and a gas flow between ca. 0.5 and 1.5 l./min. Thus the plasma was stable only within a small range of forward power, whereas the gas flow could be largely

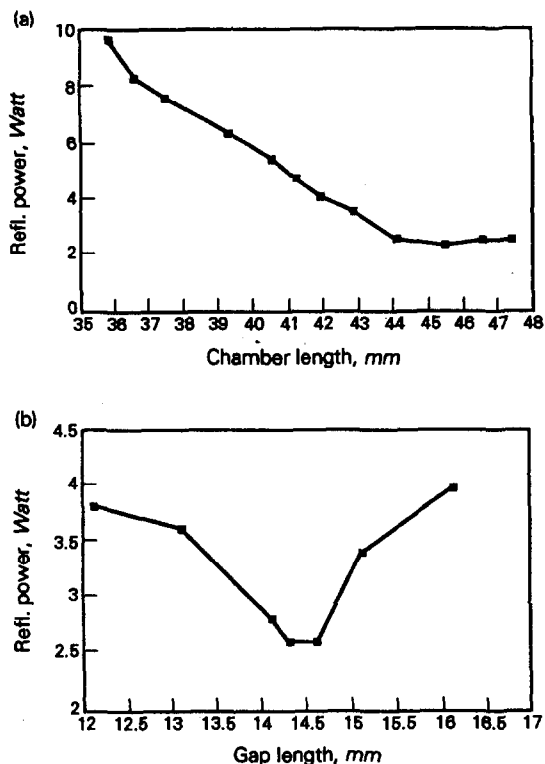

Fig. 4. Optimization of the chamber depth (a) and the gap length (b) of the surfatron (toroidal plasma I). Forward power: 100 W; argon flow 1: 0.35 l./min; (a) with gap length: 14.6 mm; (b) with chamber depth: 45.5 mm.

variated. The reflected power was at a minimum, when the capillary protruded ca. 20 mm out of the surfatron. A 2-filament plasma could be produced at a gas flow of 1.8–2.5 l./min and a forward power of 120–170 W, provided the capillary does not protrude out of the surfatron. Both plasma filaments came together in front of the surfatron and outside the capillary. The position of the two plasma filaments depended on the gas rate. At an argon flow > 2.3 l./min the plasma filaments lay stably above each other. At a gas flow < 2 l./min they lay horizontally side by side, whereas at gas flows between these values the filaments were not stable in either of these positions over a longer time.

The gas flows and the microwave forward powers for the four plasma forms described above were optimized with regard to their analytical performance. The observed region was selected in the center of the capillary, as for all plasma forms the best signal to underground ratio was found here (Table 1).

Calibration curves. Of the four plasmas the 2-filament plasma was selected, because for the elements determined (Cd and Cu) the signal to

background ratios and the linear dynamic ranges are superior. Already at low concentrations the calibration curve of Cu tails off when peak heights were measured. The effect, however, is stronger in the case of the surfatron as compared to the TM_{010} resonator. When using peak areas the linear dynamic range increased (Fig. 5). In the case of Cd this has hardly any effect, as the signal duration is not spread out, as already discussed in the case of the Beenakker resonator.

When adding different amounts of Na to the Cu and Cd solutions and measuring peak areas, the calibration curves shift. At lower concentrations the curves with added Na were found to lie above the pure solutions (Fig. 6).

CONCLUSIONS

In this work a 1-filament MIP obtained in a Beenakker resonator and the optimized 2-filament plasma in the surfatron have been studied. The latter plasma form is the most stable. Its detection limits (Table 5), based on the 3σ concept, are in the range 10–20 ng/ml

Fig. 6. Influence of Na on the determination of Cd and Cu by MIP-AES, using a surfatron and ETV. × Cd; + Cd + 10 µg/ml Na (line Cd I 228.8 nm). ■ Cu; * Cu + 10 µg/ml Na (line Cu I 324.8 nm).

Table 5. Comparison of the linear dynamic ranges and detection limits

	Beenakker 50 W 1-filament 0.46 l./min		Surfatron 130 W 2-filament 2.44 l./min	
	Cu	Cd	Cu	Cd
Dynamic range	$2 \cdot 10^2$	$1 \cdot 10^3$	$1 \cdot 10^3$	$2 \cdot 10^3$
Detection limit µg/ml (20 µl sample aliquot)	0.05	0.09	0.01	0.02

and thereby come near to those of ETV-ICP spectrometry. They are lower by a factor of 4 to 5 than those obtained with the 1-filament MIP in the Beenakker resonator.

The linear dynamic ranges for Cu and Cd with the surfatron and with peak area are considerably larger than those of the Beenakker resonator (Table 5).

In MIP-AES the matrix effects are higher than those of ICP spectrometry. This is due to the small amounts of material which can be taken up by the plasma without disturbing it and to the influence of elements such as Na. With the surfatron, the influence of Na on the signals of Cu and Cd is lower than with the Beenakker resonator, where especially for the case of Cu the effect is high (see Table 4). This comparison between both resonators is difficult to interpret, because in the case of the surfatron the calibration curves with added Na are not parallel to those of the pure solutions. Due to the high matrix effects, ETV/MIP-AES especially is of use in multistage procedures, where the matrix is separated from the elements to be determined.

Within the linear range the relative standard deviation (RSD) is 3–5% with both resonators. It is similar to the one obtained with graphite furnace AAS or MIP-AES using graphite furnace evaporation.¹³ The RSDs increase as the Na content goes up.

In the case of the 2-filament plasma a side-on observation at the point before the plasma filaments come together, *e.g.*, with an optical fiber, could improve the signal to background ratio, considerably.

ELECTROTHERMAL ATOMIZATION ATOMIC ABSORPTION SPECTROMETRY OF CADMIUM WITH A PLATINUM TUBE ATOMIZER

KIYOHISA OHTA,* SYN-ICHI ITOH and TAKAYUKI MIZUNO

Department of Chemistry for Materials, Faculty of Engineering, Mie University, Mie, Tsu, 514, Japan

(Received 4 January 1991. Revised 18 February 1991. Accepted 26 February 1991)

Summary—The determination of cadmium by electrothermal atomization atomic absorption spectrometry with a platinum tube atomizer in the presence of air has been investigated. The detection limit of cadmium was 0.09 pg (9 pg/ml for a 10- μ l volume). The relative standard deviation of the measurement was 2.9%. For 2.5 pg of cadmium, Cu, Pb, Zn, Al, Ca, Fe, K, Mg and Na (10^4 – 10^5 -fold) did not interfere with the absorption signal. The method has been applied to the determination of cadmium in some biological materials. The average analytical value found for the standards lay within the limits of the certified values. The remarkable merits of the platinum atomizer are its stability in air and long life-time (able to withstand more than 1000 heating cycles in air).

The toxic effects of cadmium are now well recognized and many researchers have reported the determination of cadmium in biological materials by electrothermal atomization atomic absorption spectrometry (ETA–AAS).^{1–9} However, in most cases there is the problem of matrix interference and pre-separation techniques and matrix modifier methods have therefore been performed before analysis.^{1–9}

Metal tubes and wires^{10–14} have recently been developed as atomizers in ETA–AAS and have been found to be excellent in comparison with graphite atomizers. However, there is a limitation for routine *in situ* analysis. For protection from oxidation, both graphite and metal atomizers need a purge gas in a large cylinder, which occupies a relatively large space. The purge gas disturbs the design of a compact AA system with routine analysis. Maeda *et al.* reported that oxygen gas came into play as a stabilizer and background reducer in the determination of cadmium in biological samples by graphite furnace AAS.⁷ In view of these points, platinum metal is the most suitable atomizer. An ETA–AAS system with a platinum wire in an argon atmosphere has been reported.¹² The sensitivities and detection limits were improved over those obtained from conventional flame measurements. Fragale and Bruno¹⁵ described a simple flame emission device for use in teaching laboratories which incorporates a platinum wire

atomizer. Berndt and co-workers^{16–18} reviewed the utilization of metal loops (Pt, Pt/Ir or Ir) for discrete sample introduction into flames. They have reported the benefits of using platinum wires in flames. There is, however, no report of ETA–AAS with a platinum tube atomizer.

In this study, we report the determination of cadmium in biological materials by ETA–AAS with a novel platinum tube atomizer in air. Interference studies with the atomizer were performed. A simple, precise and convenient method for determination of cadmium is shown.

EXPERIMENTAL

Apparatus

The platinum tube atomizer (33 mm long, 2.0 mm i.d. and 0.03 mm wall) was made from a high purity platinum foil (99.98% Koch Chemicals Ltd.). A 0.3-mm diameter hole was drilled at the midpoint of the tube to inject a sample. The atomizer was hung from two electrodes modified from conventional style electrodes, as shown in Fig. 1. The electric power for the atomizer was supplied with a transformer (YAMABISHI, S-130-5, Cap. 500 VA). Two pinhole apertures were placed in front of and in the rear of the atomizer to provide a narrow beam of light about 1.0 mm in diameter and to remove background emission from the atomizer surface. A monochromator (Nippon Jarrell-Ash 0.5 m Ebert-type), an amplifier, a memoriscope (Iwatsu MS-5021),

and a microcomputer (Sord M223) were used for the atomic-absorption measurements in this study. The light source was a hollow cathode lamp (Hamamatsu photonics Co.) with a Cd-resonance line of 228.8 nm. Background molecular absorption was checked with a deuterium lamp (Original Hanau D200F). The absorption signal from the amplifier and the output signal from a photodiode for the measurement of atomizer temperatures were simultaneously fed into the microcomputer. The calibration of the temperature of the atomizer was done against the photodiode voltage with an optical pyrometer (Chino Works).

Reagents

A standard stock solution (1 mg/ml) of cadmium was prepared as the nitrate by dissolving high purity metal (optical grade) in 7M nitric acid and diluting the solution with demineralized distilled water. Solutions of the matrix compounds for the interference study were prepared as nitrates or chlorides in 0.1–6M acid. The working solutions for measuring atomic-absorption were diluted from the stock solutions with water just before use. All chemicals used were of analytical grade purity.

Procedures

For the interference study, a 1- μ l aliquot of the sample solution containing Cd (2.5 ng/ml) and interferent (25–250 μ g/ml) was pipetted into the platinum tube atomizer. The sample was dried at 350 K for 10 sec and heated to atomization at 1720 K for 3 sec in air. The atomizing temperature corresponded to 1.0 K/msec heating rate. After the atomization of cadmium, the suspended atomizer was immersed into 6M hydrochloric acid in a

small beaker and washed with demineralized distilled water for the removal of the matrix residue.

An accurately weighed biological sample (about 0.1 g) was digested with 8 ml of 14M nitric acid and 2 ml of hydrogen peroxide (30%) in a Uni-seal decomposition vessel by placing it into a preheated 390 K electric oven for 3 hr. After digestion, the solution was transferred to a Teflon beaker and evaporated to dryness in a polyethylene glycol bath (380 K). The residue was dissolved in about 2 ml of 1M nitric acid. The solution was transferred into a 10 ml standard flask and made up to volume with water. The prepared solution was further diluted with demineralized distilled water if required. The ETA-AAS measurement was performed in the same manner as described for the interference studies.

RESULTS AND DISCUSSION

For a sensitive analysis of cadmium with the platinum tube atomizer by ETA-AAS, it is important to investigate the effect of the atomization rate on the cadmium-AA profile. Accordingly, the signal was measured at various heating rates of the atomizer in air. A heating rate greater than 1.24 K/msec was impossible because of the low melting point (2047 K) of platinum metal. Therefore, the following measurements were consequently carried out at 1.0 K/msec heating rate.

Interference study

In general, biological materials contain large amounts of Al, Ca, Fe, K, Mg, Na and Zn. Accordingly, the effects of these elements and of Cu and Pb (of which interferent effects are known¹⁹) on the cadmium (2.5 μ g) absorption signal (peak height and peak area) were investigated with the platinum tube atomizer under the experimental conditions. The use of the peak area was not suitable for the study as shown in Table 1. A typical atomization profile is shown in Fig. 2.

Aluminum, iron, potassium, magnesium and sodium (250 ng) did not interfere with the cadmium signal, as shown in Table 1. However, interferences of 250 ng of copper, lead and zinc on the cadmium were observed; copper particularly depressed the cadmium signal. However, as illustrated in Fig. 2, 25 ng of copper did not influence the cadmium signal, and similar results were found for lead and zinc

Fig. 2. Atomic absorption signals in the platinum tube atomizer in air: (a) 2.5 pg of cadmium, (b) Cd and 25 ng of copper (c) 25 ng of copper, (d) temperature trace.

as well. The cadmium signal in the presence of 2500 ng of calcium was also investigated, because calcium is one of the most abundant elements in biological materials. Although the cadmium signal was depressed by this amount of calcium, a 250 ng amount did not affect the signal.

In air, as can be seen from the above results, the normal amounts of the matrix elements did not influence the cadmium signal. Maeda *et al.*⁷ reported that the addition of oxygen gas to the graphite furnace in the determination of cadmium greatly decreased the background absorption arising from sample matrices such as milk, orange juice and blood, and that the addition of oxygen gas prevented the cadmium signal depression. These samples contain large amounts of Al, Ca, Fe, K, Mg, Na and Zn, which were also studied by the use of the platinum tube atomizer. The results support the use of oxygen as a matrix modifier in the platinum tube atomizer.

Detection limit, characteristic mass and reproducibility

The detection limit, which was the weight of analyte which gave an atomic-absorption signal equal to three times the standard deviation of the background (obtained from the measurement of a solution blank), was calculated from the height of the cadmium absorption signal. The detection limit of cadmium by use of the platinum tube atomizer was 0.09 pg (corresponding to 9 pg/ml, if 10 μ l is used). The value was better than for carbon atomizers.²⁰

The characteristic mass of cadmium, which was defined as the mass of element giving an absorption of 1% (0.0044 abs), by the atomizer was 0.099 pg, which is comparable to that for carbon atomizers.²⁰

The reproducibility by the use of the platinum atomizer was estimated. The r.s.d. for 2.5 pg of cadmium was 2.9% for 7 measurements. Furthermore, the atomizer could withstand more than 1000 heating cycles in air.

Determination of cadmium

In order to test the applicability of the proposed method to the analysis of real samples, some reference biological materials were analyzed. The biological materials in this study were digested with an acid mixture of concentrated nitric acid and hydrogen peroxide.⁴ The dynamic range of the calibration curve was 0–15 pg. Table 2 shows the results obtained for some biological materials, compared with certified values. The relative standard deviations for the method were 3.7–27% at 3 or 4 replicate analyses. The average value found for the standards lies within the limits of the certified values. The method can be considered satisfactory for the determination of cadmium in biological materials.

Table 1. Interferences on the atomic absorption signal of cadmium

Interferent added, ng	Peak height/Abs	Peak area/rel. Abs*Time	Number of measurements
(Cd 2.5 pg)	0.144 \pm 0.007	21.5 \pm 1.6	5
Al 250	0.141 \pm 0.007	17.8 \pm 0.6	3
Ca 2500	0.118 \pm 0.009	18.9 \pm 1.9	4
250	0.144 \pm 0.004	20.6 \pm 1.8	5
Cu 250	0.085 \pm 0.007	14.6 \pm 0.9	4
25	0.146 \pm 0.005	22.1 \pm 1.2	5
Fe 250	0.144 \pm 0.004	16.1 \pm 2.1	4
K 250	0.140 \pm 0.005	20.5 \pm 1.3	5

Orchard leaves*SRM1571	0.11 ± 0.03 ($n = 3$)	0.11 ± 0.01
Oyster tissue*SRM1566a	3.6 ± 0.2 ($n = 3$)	3.5 ± 0.4

*NIST standard.

Number of analyses in parentheses.

As described above, the large benefit of the platinum atomizer is inertia and long lifetime in air. In addition, most elements (10^4 – 10^5 -fold for cadmium) did not affect the cadmium absorption signal. These remarkable performance characteristics of the platinum tube served for an accurate determination of cadmium in biological materials. The disadvantages of the use of a platinum atomizer are the low melting point of the metal and a clean-out step. However, the platinum tube atomizer can be used with simple, "low-tec" electrothermal atomization atomic-absorption spectrometry. The atomizer may serve as a tool for the accurate determination of other volatile elements at low cost.

THE RAMESES ALGORITHM FOR MULTIPLE EQUILIBRIA—IV. STRATEGIES FOR IMPROVEMENT (RAMESES III)

B. W. DARVELL and V. W.-H. LEUNG

Dental Materials Science Unit, University of Hong Kong, Prince Philip Dental Hospital,
34 Hospital Road, Hong Kong

(Received 22 May 1990. Revised 28 January 1991. Accepted 6 February 1991)

Summary—The algorithm RAMESES has been enhanced by the improvement of the forward extrapolation procedure to give more accurate estimates with a smoothed polynomial function in a dynamically adaptive scheme, ADEPT. A class of problems exhibiting chaotic behaviour due to exaggerated feedback has been controlled by limiting the correction factors. Improved execution speed has also been obtained through indirect addressing of sparse array elements. Some illustrative examples are given.

Previously, the principal structure of an efficient algorithm for solving the equations of multiple equilibria,¹ some developments of the programming thereof,² and a modification which led to a substantial increase in the execution speed³ have been reported.* Some further improvements are now presented which (i) reduce execution time (ii) increase the precision of forward extrapolation and (iii) enable the handling of a class of problems previously not anticipated. Some illustrative test results are presented.

NEWTON-RAPHSON

A number of other reported procedures have employed Newton-Raphson (NR) methods of solution, some of which have been acknowledged (principally by their authors) to have limitations,^{1,4} although these are of known origin.⁴ It might be thought that such NR methods ought to be applicable in RAMESES as well and this was explored. The adaptive procedures for adjusting the estimates in RAMESES work through the gain matrix, G [equation (2.4)]. The sensitivity of the system to perturbation of component estimates is allowed for here to some extent. Theoretically,^{5,6} however, it might be thought better to express these procedures in NR terms (with the previous notation^{1,3}), *i.e.*,

$$\mathbf{P}_{A(n+1)} = \mathbf{P}_{A(n)} + (\mathbf{M}^T \mathbf{X}^D \mathbf{M})^{-1} (\mathbf{T} - \mathbf{S}) \quad (1)$$

$$\mathbf{X}_{A(n+1)} = \mathbf{X}_{A(n)} + (\mathbf{M}^T \mathbf{X}^D \mathbf{M})^{-1} \mathbf{X}_{A(n)}^D (\mathbf{T} - \mathbf{S}) \quad (2)$$

*In referring to the earlier reports, equation numbers will be identified by prefix, *e.g.*, 1.5 refers to equation (5) in reference 1.

depending on whether the corrections were to be in concentration or logarithmic concentration. (The superscript D is used here to mean the 'diagonalized' vector, *i.e.*,

$$X_{ii}^D = X_i; \quad X_{ij}^D = 0, \quad i \neq j \quad (3)$$

in order that the algebra be correct.)

Despite the neatness of such statements, and the formal principle upon which they are based (in theory, taking into account all contributions to the sensitivity of the sums, S^j), in attempts to implement either of them [*i.e.*, equations (1) and (2)] we failed to achieve convergence in any of a number of test systems previously used.² That this is a common problem is illustrated by the sophisticated protection against divergence employed in SUPERQUAD,⁷ which can only handle four components,⁷ and itself one of a series of successors to MINQUAD,⁸ developed to overcome deficiencies in that program.^{5,7} The explanation was found to be that in general the multidimensional response surface is not monotonic over a sufficiently large region, and the gross simplification represented by the differentiation implicit in equations (1) and (2) fails to recognise this. The problem is exacerbated by increasing the number of components and equations. The system becomes chaotic, showing extreme sensitivity to changes in values. The attempt was therefore abandoned. Evidently, under limited conditions and convoluted protection procedures, or modified approaches, the NR approach can be made to work.^{1,4,5,7} However, NR and related methods depend on the inversion of $(\mathbf{M}^T \mathbf{X}^D \mathbf{M})$, or some

similar matrix, at each iteration to generate the next vector of concentration shifts.^{5,6} This is itself very time-consuming, but it also involves a considerably greater number of arithmetic operations to form that matrix than the procedure represented by equation (2.4). All of this suggested that little benefit over existing (NR and similar) procedures was likely to be obtained from pursuing the approach now, in view of the considerable developments that have already been made in this area, but especially since the existing RAMESES algorithm appears to be quite efficient.² It is nevertheless pertinent to observe that the difficulties arise simply from the inappropriateness of NR to this general class of problem. One known and serious limitation is that initial estimates must be "sufficiently close" or within the "convergence range", for which no useful measure exists before the event.⁴ In addition, there are recognized difficulties with inverting such matrices in this context, such as loss of precision and the risk of singularities or near-singularities arising. RAMESES cannot ever suffer from singularity in any sense as this term has no relevance in the context of its algebra, there being only the one inversion of the coefficient matrix C_b [equation (1.7)], and this cannot be singular if formed correctly.

FORWARD EXTRAPOLATION

In an earlier paper, we discussed the use of polynomial estimation of the elements of the input vector X_A based on the previous points of a scan.² The coefficients then were derived directly and represented the exact fitting of the polynomial curve of degree $b - 1$ to b points; b was termed the order of the extrapolation.

Noticing that, at each point in the scan, each X_{Ai} has an associated error of a maximum size given by the calculation tolerance, ϵ , some improvement in the accuracy of the prediction might be obtained by smoothing over more points, that is, for a given degree of polynomial, $d < b - 1$. In other words, by fitting a polynomial curve in the least-squares sense, the standard error of the prediction for the next point may be reduced. The direct implementation of this idea would involve much further calculation, including the inversion of the matrix of sums of squares and cross-products of rank $d + 1$ for each of the species' concentrations to be predicted, and for each degree that was to be tested in searching for a 'best fit', a very time consuming procedure. However, for

uniformly spaced points in the independent (scanning) variable, considerable computational simplification is possible, and the weights previously given² emerge as the special case when the degrees of freedom for the curve fit are zero.

The coefficients and theory of such curve fitting are well worked out,^{9,10} and the coefficients have integral values when an overall 'weight' division is taken out.^{9,10} The values of the coefficients and weights for the next point in a series have been tabulated for degrees 1-5, and for up to 25 points in the known sequence, along with the standard errors (σ) of predicted points.⁹ These errors are summarised in Fig. 1. It can be seen that, for a given degree, the values of σ are asymptotically proportional to $b^{-0.5}$, as would ordinarily be expected. More importantly, the error increases substantially with an increase in d . However, one or two points more than the minimum are expected to reduce the error to near that expected for the next lower degree, *i.e.*, the loss of accuracy arising from the use of a higher degree polynomial may be offset by using more points in the prediction.

Fig. 1. Log-log plot of the standard error (σ) of polynomial extrapolation to the next evenly-spaced point in a series as a function of the number of points (b) used in the fitted curve, for polynomial degree (d) 1-5. The circled points are for minimum $b (= d + 1)$; the dashed line shows b for each d at near-constant σ . Data taken from reference 10.

The number of extra points so required increases rapidly as b is increased. The questions then arise as to whether any practical predictive improvement can be obtained with $b > d + 1$ and, if so, how far this idea can be taken. Given the many degree and number of points combinations possible, a good many strategies are conceivable. To avoid a too detailed description of the route, the conclusion only of an extensive series of comparisons over several test systems (see EXAMPLES Section) will be given.

The optimum performance, on average, was obtained by the conditions giving as near uniform an expected error, σ , in the predicted point as possible. The number of points to be used can be read off as corresponding to the points nearest below the horizontal dashed line of Fig. 1, viz $b = 2, 5, 9, 14$ and 20 for degrees 1–5, respectively. This expected nearly constant error is on the supposition that the true curve is of the same degree as the line fitted. As the species' log(concentrations) are not polynomial functions in the present sense; there remains the need for a search for the degree of curve giving a 'best fit'. The method used as most effective was in part based on the fact that n , the number of points available for the curve fitting, ranges from zero at the start to an indefinitely large value (depending on the range of the scan and the step interval, h). There is thus constraint initially as $d \leq b - 1$ must hold. Table 1 shows the variation in b used for each d as the number of fitted points increases. After the first point, there is no (real) choice but to use this as the next guess (using $b = 0$ is, on average, rather worse than any reasonable approximation). With two points, no test is possible, but $d = 1$ is on average by far the best choice and was used by default. At $n = 3$, a choice of $d = 1$ and $d = 2$ is possible, and $d = 3$ is not so clearly advantageous in general. After that, the scheme is straightforward, with b increasing towards the general optimum for each d as n increases, and then stopping at that value. The coefficients c , and associated weights, w , used are given in Table 2, and their use is summarized in the following equation, where, to minimize subscripts, we write p_{-j} to represent the log(concentration) for the (i)th species of interest in P_{Ai} at the j th prior point:

$$\hat{P}_{Ai}(d) = \sum_{j=1}^b p_{-j} c_{-j}(d, b) / w(d, b) \quad (4)$$

There is at present no known simple function which can be used to generate these coefficients,

and the most effective way of using them in a program is entered as a set of DATA statements to be read into an array as required.

Knowledge about the goodness of fit of a given degree of curve can only be based on a test of the immediately prior point. That is, to decide how best to predict p_0 , the goodness of prediction of p_{-1} must be tested with p_{-2}, p_{-3}, \dots . Thus, in equation (4), p_{-j} is replaced by p_{-j-1} . Then, given the expectation of continuity that no jump in best fit d of greater than ± 1 will be required, at most only three values need be tested: $d_i - 1, d_i, d_i + 1$, where d_i is the last chosen degree, subject to $0 \leq d \leq 5$. The test is then of the magnitude of the error of prediction of the previous point:

$$\text{error}(d) = |P_{Ai} - \hat{P}_{Ai}(d)| \quad (5)$$

where the circumflex implies the estimate at degree d , although (of course) P_{Ai} itself has error, the maximum of which is equal to ϵ . The optimisation of the degree of curve used is done for each independent species, independently. The more stable concentrations thus engender less calculation than do the more rapidly varying ones.

When the previous guess is 'exact' to the required tolerance, i.e., requiring zero iterations for a solution, the entire search procedure is skipped, the last prevailing d being used until iteration occurs again.

The Adaptive Extrapolation Procedure written to embody the above ideas is now termed ADEPT for convenience. In the tests described below, this will be described as either

on or off, depending on whether it is invoked or not; the latter case corresponds to $b = 0$ under RAMESES II.²

OSCILLATION

Despite earlier optimism concerning the assuredness of convergence,¹ and the pattern-breaking introduced to cause convergence when a certain kind of oscillation occurred, exploration of the behaviour of the algorithm and its implementation has revealed a class of problems that fails to give convergence for the general worst case of no prior information.²

To reiterate, the initial guesses (that is, for the first point of a scan or with $b = 0$) for the concentrations of the independent species will in general be far removed from the actual solution

values; RAMESES adopts a very low initial concentration for all such species as this is, on average, better than other possible starting points.² Further, the algebra of the problem permits (in principle) any meaningful subset of the species present to be defined as the independent species.^{1,3} For simplicity, this subset may be chosen to represent the 'minimal' notional building blocks required to form every species with only positive coefficients. However, this necessarily results in highly charged independent species when, for example, polybasic acids or high oxidation state metals are present. If one of these is used as the 'free' species, that is the one being used to adjust for charge balance, then the feedback may be so extreme that the system oscillates wildly and uncontrollably, especially when that species is present in very

Table 2. Coefficients and weights, $w(d, b)$, for the polynomial extrapolation functions of ADEPT for each degree up to 5 and the number of points used, b . The coefficients, $c(d, b, -j)$, are given in order of distance from the point to be predicted, and correspond to p_{-1}, p_{-2}, \dots [see equation (4)]

low concentration. This lack of control arises essentially from the nature of the oscillation in that it has a period of greater than two iterations, which the adaptive gain procedure² was not designed to handle. In fact, it turns out to be rather difficult to identify oscillation of that kind reliably, so that corrective action can be taken, without severely compromising the present efficiency for other systems. The problem could be avoided by choosing a low charge number (complexed) free species, but this would seriously weaken the principle upon which RAMESES has been designed, namely, to handle any starting conditions reliably without the use of prior knowledge or exploration. Accordingly, a procedure has been designed to handle such situations.

Previously,² no upper limit was found necessary for the elements of F , the (diagonal) matrix of correction factors; this enables rapid convergence in many cases, as does the setting of a rather small lower limit.² It was found, however, that in cases of the uncontrolled oscillation, setting much closer limits permitted the commencement of a convergent series of iterations. Thus, a limit should be adjusted towards unity whenever a calculated F_{ii} lies outside that bound. However, very great changes in the value of F_{ii} may occur under ordinary circumstances in the early iterations (indeed, this is one reason for the algorithm's usual efficiency), and the limit adjustment needs to be held off until it is likely that uncontrolled oscillation is the cause. A slight relaxation of the limits can also be used during convergence to prevent untoward constraint arising spuriously.

A possible implementation of the procedure in BASIC is given in the Appendix as the procedure FLIMIT. After testing the effects of this procedure it was found that the best balance was obtained with the following values for the relevant constants:

- switch%: 4
- dec #: there is a shallow optimum in the region 0.3–0.6; 0.5 was chosen.
- inc #: 1.1; this value is not critical.
- limit #: 25; this was found to be best matched to the factor used in setting the initial guesses for the vector X_A ,² as this then ensured little influence, if any, on the more well-behaved systems. Thus a at equation (2.15) is now 10^{-25} .

INDEXING

Even though RAMESES II achieved lower storage requirements and execution time by eliminating a sparse matrix multiplication, there are still multiplications of matrices containing a large number of zeros, *viz*: at equation (1.12) and (3.6), and other calculations that might be considered redundant. In this latter group are all operations involving components with zero concentration² and fixed partial pressures. There are two main strategies that may be employed in these circumstances: testing for the presence of the zero before doing the multiplication or using an address matrix to indicate the non-zero elements. There is necessarily some execution time required for such schemes, and their benefits must outweigh that loss of speed for them to be worthwhile implementing. Effectively, the trade-off to be considered is the difference in the time to execute an "IF $x = 0$ THEN . . ." test as compared to a location index assignment such as " $i = A(j)$ ", both with respect also to " $y = x * 0$ ". A number of trials served to show that an address matrix was the more efficient, becoming more so as the size of the system increased, particularly the numbers of components, r . Thus, considering as an example the indexing of the matrix C'_A [equation (3.17)] for the calculation of equation (3.6), the zeros are eliminated by row. A BASIC procedure, ROWINDEX, to achieve this is given in the Appendix, as is the code for the implementation of the addressing procedure used in the evaluation of equation (3.6), EQUATION36.

Further indexing for the processing of the independent vector, X_A , to skip zero concentrations, fixed partial pressures and the like, is trivial and need not be elaborated upon.

LOWER BOUND

A potential problem, although as yet not encountered in practice, is that of an independent species' concentration falling below that value corresponding to the smallest positive machine number, EPS, or perhaps more to the point, to less than $\epsilon^{-1} \cdot \text{EPS}$. In contrast to the previously discussed handling of zero or vanishing calculated concentration,² no default condition can be employed. This type of fault is not related to the algorithm employed for solution, but to the system under study, the choice of independent species, and the dynamic range of the machine/language combination in use.

As, again, reliance on prior knowledge is inappropriate, a test for this condition can be built into the tolerance test subroutine. For example, if

$$P_{Ai} < \log_{10}(\text{EPS}/\text{TOL}) \quad (6)$$

holds, at any time after (say) 10 iterations, where $\text{TOL} = \epsilon$, the program should branch to an error handling routine. This could indicate the nature of the problem, permit the choice of a substitute independent species, and then proceed with the column exchange between C_A and C_B , and the corresponding element exchanges between X_A and X_B , and within Q [equation (2.12)], before proceeding to the inversion of the replacement C_B and the second attempt at a solution. This violates the principle of the RAMESES design in that user-intervention is required, but in view of the fact that it is a simple choice and also that the problem has yet to arise, it may not be too much of a burden, and the violation is not considered too serious. Equally, this is essentially a machine-dependent problem and so must apply to any algorithm dealing with this kind of system.

It is worth pointing out at this juncture that, even if a calculated concentration falls well below N_0^{-1} , the 'Avogadro dilution', both the algebraic solution of the system of equations and the existence of the species, in the statistical sense of only rarely occurring for a (very) short duration, remain valid, as does the model. The chemical implications of such species are a matter for a different forum; non-existence depends on interpretation.

EXAMPLES

The program incorporating ADEPT, the extreme oscillatory control and the indexing

refinements is referred to as RAMESES III. The opportunity has been taken to fix up some bugs and inefficiencies that have been found in the code. The testing was done in the same language and on the same machine as before.² RAMESES graphics screen images were printed directly on a dot-matrix printer (P5, NEC Corporation, Tokyo, Japan) with an EGA Screen Dump program (P5DUMP, Imago Software, Sydney, Australia).

The direct comparison of RAMESES II ($b = 0$) and III (ADEPT off), is shown in the left hand part of Table 3. Regardless of other considerations, such a test is essential to ensure freedom from starting-condition constraints.² The test systems that were previously employed were used (despite some doubts about their usefulness otherwise²) to allow ready comparison with previous results. We now refer to the artificial system called ESTIME as System V. Some substantial improvement in all except Systems I and III were obtained. Even in System III, despite nearly doubling the mean iterations (due to detuning, *v.i.*), the indexing gave a net decrease in execution time. The deterioration in System I is proportionately large, but in real terms quite irrelevant. This illustrates essentially the overhead in execution time due to indexing in a very small system.

With ADEPT on the results (Table 3) show an entirely satisfactory improvement in performance. In particular, the number of 'zero iteration' points is a very large proportion of the total for Systems I and IV, and not insignificant in Systems II and III. Only System V proved resistant under these conditions, but even here the minimum number of iterations is, for each set of starting conditions, equal to one.

Table 3. Some illustrative results for the test systems to show the effect on timing of the current implementation of RAMESES III (pH 0–14, $h = 0.25$ [57 points]; $-\log \epsilon = 3$)

Fig. 2. Log(τ) vs. $-\log(h)$ for System I for $-\log \epsilon = 3-10$.

Fig. 4. Log(total Itn.) vs. $-\log(h)$ for System II for $-\log \epsilon = 3-10$.

The 'zero' iterations should perhaps be explained. If the elements of S , the component total vector [equation (1.12)], are each within tolerance with only the extrapolated values of X_A to find X_B , then no refinement of X_A whatsoever is necessary, and the routine skips to the calculation for the next point. Thus no iteration with equation (2.4) has been performed, and the iteration number recorded is zero. The number of zero iterations is therefore a further measure of the effectiveness of the extrapolation, because no calculation beyond that of the polynomial was required. Previously, iterations were counted on entry to the core routine, but this gives a false picture of what the algorithm has actually done. Earlier reported iteration values² (maximum, minimum and mean) should therefore each be reduced by one for proper interpretation (the iteration values for RAMESES II in Table 3 have been so adjusted). This definition of the number of iterations also accounts for the mean falling below one in some case in the present report.

An interaction was expected between the stepping interval and the accuracy of forward extrapolation, depending on the tolerance permitted and the preselected degree of the fitted polynomial under RAMESES II.² Although the latter factor is irrelevant in ADEPT, the interrelationships of run-time (τ), total number of iterations and number of zeros with tolerance (ϵ) and step size (h) were examined for all five test systems for a scan over the range pH 0-14; $h = 1, 0.5, 0.2, 0.1, 0.05, 0.02, 0.01$; $-\log \epsilon = 3-10$. Some representative results are given in Figs. 2-10.

For the simple Systems, I, III and IV, $\log \tau$ increased in fairly uniform steps with $-\log \epsilon$, and was also more or less linearly dependent on the number of steps taken (Fig. 2). For Systems II and V the picture is more complicated (Fig. 3), showing local optima, presumably due to some tuning effect, which optima shifted to smaller h at tighter tolerances.

Fig. 3. Log(τ) vs. $-\log(h)$ for System II for $-\log \epsilon = 3-10$.

Fig. 5. Log(no. of zero iterations) vs. $-\log(h)$ for System IV for $-\log \epsilon = 3-10$. The vertical line segments indicate zero iteration steps.

Fig. 8. Number of iterations vs. pH for System III under RAMESES III with ADEPT, $-\log \epsilon = 10$. pH step sizes a : 1, b : 0.1, c : 0.01.

Fig. 9. Number of iterations *vs.* pH for System IV under RAMESES III with ADEPT, $-\log \epsilon = 10$. pH step sizes *a*: 1, *b*: 0.1, *c*: 0.01.

The only differences between plots within these groups were essentially of the scale factors applied to the ordinate. These effects are mirrored in the number of iterations (Fig. 4), more or less uniformly for all systems. The relative differences arise only because of the overhead arising from the size of the system rather than variation in the behaviour of the system or the algorithm. The number of zeros observed increased steadily with a decrease in h , the absolute slope of the log-log plot approaching unity once zeros become possible (Fig. 5). It is nevertheless more difficult to be accurate at tighter tolerances.

We have argued² that, because of condition-sensitivity, algorithm performance should be

demonstrated in part by the variation in number of iterations per point over a scan. Thus, for the five test systems used, we give some such results for the above pH scans for three values of h , namely 1 (*a*), 0.1 (*b*) and 0.01 pH (*c*) (Figs. 6–10). The tolerance was set to 10^{-10} in order to avoid the plots having large and overlapping sections running along the abscissa, *i.e.*, zero iterations, but also to show more clearly the relative effects of changing h and pH. For example, System I at $\epsilon = 10^{-3}$ has respectively 7/15, 105/141 and 1226/1401 (zeros/no. of points) for the three step sizes.

For Systems II and V the difficulty of solution increases markedly for $\text{pH} \geq 3$. It is speculated that 'difficulty' is a property of the system and

Fig. 10. Number of iterations *vs.* pH for System V (condition *d*) under RAMESES III with ADEPT, $-\log \epsilon = 10$. pH step sizes *a*: 1, *b*: 0.1, *c*: 0.01.

Table 4. Some run results for the system H_3PO_4 in water, using the stated ion as the free (charge balance) species, employing the procedure FLIMIT in RAMESES III (pH 2–6.9, $h = 0.1$ [50 points]; $-\log \epsilon = 3$)

Free Species	ADEPT off iterations				ADEPT on iterations				zeros
	τ , sec	max	min	mean	τ , sec	max	min	mean	
$H_2PO_4^-$	4.8	3	1	2.06	4.6	3	0	0.60	31
HPO_4^{2-}	32.5	30	3	23.60	4.1	23	0	0.46	49
PO_4^{3-}	33.6	28	20	24.30	5.9	64	0	1.78	48

conditions, and not the algorithm, as the same pattern appeared under all the many strategies investigated.

One curiosity that may be detected by inspection of Figs. 6–10, most easily for the lines (b) corresponding to $h = 0.1$ pH, is of an oscillation in the number of iterations taken from point to point superimposed on the general trend. The period is generally equal to 2 or a little greater. Close inspection of the elements of the error matrix E [equation (1.15)] showed the following general explanation. When a solution is delayed because a small number of the X_{Ai} have not settled, the remaining elements of X_A necessarily continue to improve in precision, sometimes to many digits better than the preset tolerance would suggest. This means that the estimates for the next point are good and fewer iterations are required to achieve the required precision because the error of prediction is proportionately smaller. However, in that time, the stable elements will not have achieved the same high precision. This continues for a small number of points but eventually the accumulated errors become large enough to require more iterations. As can be seen, the effect is not large enough to cause concern, but the amplitude is in some sense a measure of the perturbation sensitivity of the system. The larger oscillations occur in regions of greater difficulty, as measured by the (local) average number of iterations.

Phosphoric acid in water provides a good example of the kind of uncontrolled oscillatory behaviour occurring during attempted solution. For a scan in pH from 2 to 7, using either HPO_4^{2-} or PO_4^{3-} as the free species, the calculation fails ever to converge, although for $H_2PO_4^-$ the solution is obtained very rapidly.

Introducing the FLIMIT procedure, all three free species choices can be used successfully in satisfactorily short calculation times and few iterations even with ADEPT off (Table 4). The entry for $H_2PO_4^-$ (ADEPT off) is unaffected by the use of FLIMIT. With ADEPT on, the results were somewhat improved (Table 4). In the case HPO_4^{2-} , only the first point of the 50 in the scan is calculated iteratively, because this species has a constant concentration, while for PO_4^{3-} only the first two points are found by iteration as its $\log(\text{concentration})$ changes linearly.

An example has been given of a system (now labelled System VI) that fails in an established program, GEOCHEM, and of a method of avoiding that difficulty.⁴ It was reported that at pH 7.3 the revised produce took 82 iterations to $\epsilon = 10^{-6}$ (their definition of tolerance appears to be similar to that of RAMESES): no timing was given.⁴ Using the published information (which has some errors*) and adding a background 'NaCl' for charge balance, and scanning over pH 0–14, $h = 0.1$, the results shown in Figs. 11 and 12 and Table 5 were obtained. It can be seen that while there is some more difficulty in the pH range 5–9, RAMESES encountered no particular problem, even with ADEPT off: at pH 7.3, the single calculation required 45 iterations for $\epsilon = 10^{-6}$.

DISCUSSION

The use of smoothing polynomial functions to provide the independent species' concentration estimates for the calculation of the next

Table 5. Some run results for System VI with RAMESES III; pH 0–14, $h = 0.1$. (Dashes under 'zeros' mean 'not applicable'.)

*We have dealt with the typographical errors in the report⁴ as follows: corrected the sign of the $\log(\text{formation constants})$; assumed that (a) total concentrations are given as $-\log(\text{conc.})$, not $\log(\text{conc.})$; (b) "DTPA" complexes are "CaDTPA"; (c) the second "CaDTPA" complex with stoichiometry "110" is in fact "210". The carbonate said to be present, but not defined, was ignored.

Fig. 11. Distribution diagram for System VI. Species: 3 Ca^{2+} , 4 Fe^{3+} , 5 H_5DTPA^- , 9 DTPA^{5-} , 10 HDTPA^{4-} , 11 $\text{H}_2\text{DTPA}^{3-}$, 12 $\text{H}_3\text{DTPA}^{2-}$, 13 H_4DTPA^- , 14 CaDTPA^{3-} , 15 CaHDTPA^{2-} , 16 Ca_2DTPA^- , 17 CaOH^+ , 18 FeDTPA^{2-} , 19 FeHDTPA^{2-} , 20 FeOHDTPA^{3-} . The 'background' species are omitted, and the Fe-OH species are at very low concentrations.

point in a scan provides the most efficient use of the information available at prior points, given that these functions are approximations. The rapid deterioration of prediction accuracy with degree for the minimum number of points (Fig. 1) can be seen to provide a limitation to the effectiveness of the simple procedure suggested earlier,² but of course then the choice of degree was arbitrary.

It is unfortunate that direct comparison of these results with the theoretically attractive⁵ analytical differentiation for extrapolation, as used for example in PSEQUAD,¹¹ cannot presently be made as no documented examples

are known. We speculate however that since it is essentially based on a form like equation (1), the method will be successful in systems or regions with many straight lines in the plots of $\log(\text{concentration})$ vs. pH for example (such as are seen in Systems II and III, Figs. 7 and 10 in Reference 2). But in more complex regions, such as typifies System V (Fig. 1²), we would expect less efficiency. ADEPT is more flexible.

With the incorporation of ADEPT, any further substantial improvement in speed or efficiency seems unlikely. This remark needs qualification. In the tests that have been done, many combinations of strategies and values for

Fig. 12. Number of iterations vs. pH for System VI under RAMESES III with ADEPT (a) off, (b) on; $-\log \epsilon = 3, 6$; $h = 0.1$.

the few arbitrary factors used exist, and for some systems and conditions quite remarkable results can be obtained. However, this has been found to be to the detriment of performance with other systems or conditions, sometimes badly so. Some consequences of this kind of effect are to be seen in the results for Systems I and III (Table 3). Quite clearly, there can be no universal optimum strategy. So, relying on the principle that we have taken as a guide the development of RAMESES, *i.e.*, that prior knowledge should not be needed, we are obliged to concede that the results presented are not by any means the best possible for each system, because we avoid the provision of user-adjustable parameters or switches. Simply put, the user should not need to be concerned with tuning before starting work. In this sense, the production of dedicated programs for particular problems,¹² or more elaborate but still limited generalised solutions to a class of problems,¹³ has required system-specific analysis. But, although this serves immediate purposes, it does not help other users who must tailor such programs to their individual needs. These other approaches are therefore redundant in the face of the existence of algorithms such as RAMESES. We believe that we have come close to an overall optimum tuning of the present program, and that it will be of wide applicability. We shall therefore turn our attention to

handling other aspects of the general problem within the framework of RAMESES. Whether it is the fastest possible program is another matter and is a question we see no point in attempting to address. A speed claim has been made for another program,¹⁴ but this is with a routine that relies on a weak tolerance test.² Such claims are dangerous and not very helpful. Even so, RAMESES III can be seen to compare at least favourably despite the handicap of a rigorous tolerance test.

The oscillation problem now handled represents the same kind of difficulty as defeats some NR techniques inasmuch as the initial estimates are outside of the region of convergence.⁴ However, whether it is capable of being controlled as easily as at present in the NR context cannot be said as, on the one hand, we are unaware of any other treatment of this type of problem, and, on the other, charge balance itself is rarely considered.² It remains noteworthy that the revised algorithm for the NR method only had an "increased" convergence range, *i.e.*, of input estimate values that would lead to a solution; RAMESES only requires each $X_i > 0$, with no sensible upper bound.

Experience to date leads to the confidence that RAMESES can continue to be developed as a robust, efficient algorithm with effective implementation. It is hoped to make the program available for testing shortly.

A COMPUTER MODEL OF STRUVITE SOLUTION CHEMISTRY

W. D. SCOTT, T. J. WRIGLEY and K. M. WEBB

Environmental Science, School of Biological and Environmental Sciences, Murdoch University,
Murdoch 6150, Western Australia

(Received 9 March 1990. Revised 18 February 1991. Accepted 26 February 1991)

Summary—A computer model is developed to describe struvite solution chemistry; this includes the electroneutrality equation and allows greater variability in the input components. Relationships between the major ions are retained without approximation. The model results fit data derived both in our laboratory and from the literature. Equilibrium constants which markedly affect the output are identified and solubility constants are derived. Applications of the model include studies of waste-water treatment and of the formation of kidney stones.

The solubility product (K_{sp}) for struvite ($MgNH_4PO_4 \cdot 6H_2O$) has been derived by several authors (e.g., Johnson,¹ Taylor *et al.*,² and Burns and Finlayson³). However, these solubility product values are based on only some of the complex ionic equilibria and various approximations are made which limit their applicability. For instance, Linder and Little⁴ developed a computer model for equilibrium speciation of urine. Good predictions were obtained for the precipitation of calcium oxalate monohydrate, dicalcium phosphate dihydrate, calcium hydroxyapatite and uric acid, but not for struvite.

A more complete understanding of struvite solution chemistry is necessary to solve applied problems such as its formation in waste-water treatment systems and in urinary and kidney stones (uroliths). In the removal of phosphorus in waste-water treatment systems struvite deposition has attracted considerable attention, and is a major precursor of the eutrophication of water bodies.⁵⁻⁷ Struvite is the most common type of urolith deposited in cats and dogs, and forms 15% of all uroliths found in humans. All these depositions occur as a result of increased concentrations of less soluble crystallites at raised pH.⁶⁻¹⁰ Also struvite formation is important after the application of phosphate fertilizers to soils¹¹ and after the canning of seafoods.¹²

There is a need for an algorithm that treats the general problem of struvite equilibria. The aim of this study is to specify mathematically the solubility of struvite, by using the known ionic equilibria. The intention is to compare theoretical solubility data derived from the

model with available data and provide a basis for the development of a predictive model for use in waste-water treatment and medical research.

Chemical equilibria

The appropriate literature values of the solubility constants and dissociation constants are listed in Table 1. The equilibria listed in the first column include only the simplest forms and are presented in the way they are used in the final algorithm (Table 2). The constants in Table 1 are for a standard temperature of 25° and were used to form Figs. 1(a) and 1(b). The second column shows a range of pK values from the references as noted; the third column consists of selected values as used. Note that the literature values are derived from experiments and are dependent on the model used to interpret the experimental results.

The model was developed to understand the optimal conditions for struvite formation and is limited to the range of minimum solubility. It allows for variations of components formed from ammonia, phosphate, magnesium and water. A separate term may be included to account for the addition of an excess of non-reacting ions.

Three assumptions are made, as follows:

(1) No species are present other than those derived from the independently variable components, water, magnesium, ammonia and phosphate. Ionic and molecular species included are Mg^{2+} , $Mg(OH)^+$, NH_3 , NH_4^+ , PO_4^{3-} ,

Table 1. Equilibrium solubility constants relevant to struvite formation

	Range of log <i>K</i> values from literature ^{13,14}	Value of log <i>K</i> used in calculations ¹⁵
$H^+ + NH_3 = NH_4^+$	9.2–9.3 ^{a,b}	9.3
$H^+ + H_2PO_4^- = H_3PO_4$	2.1–2.2 ^{c,d}	2.1
$H^+ + HPO_4^{2-} = H_2PO_4^-$	7.1–7.2 ^{e,f}	7.2
$H^+ + PO_4^{3-} = HPO_4^{2-}$	12.0–12.4 ^g	12.0
$Mg^{2+} + OH^- = MgOH^+$	2.6 ^{h,i}	2.6
$Mg^{2+} + 2OH^- + 6H_2O = Mg(OH)_2 \cdot 6H_2O$	10.5–11.3 ^j	10.9
$Mg^{2+} + HPO_4^{2-} = MgHPO_4$	5.8 ^{k,l}	5.8
$Mg^{2+} + PO_4^{3-} + 8H_2O = Mg_3(PO_4)_2 \cdot 8H_2O$	25.2 ^{k,l}	25.2
$Mg^{2+} + PO_4^{3-} + 22H_2O = Mg_3(PO_4)_2 \cdot 22H_2O$	23.1 ^{k,l}	23.1
$Mg^{2+} + NH_4^+ + PO_4^{3-} + 6H_2O = MgNH_4PO_4 \cdot 6H_2O$	13.2 ^{k,l}	13.2
$H^+ + OH^- = H_2O$	13.9–14.0 ^{m,n}	14.0

HPO_4^{2-} , $H_2PO_4^-$, H_3PO_4 , OH^- , H^+ , H_2O and an excess of non-reactive positive and negative ions. In contrast to the work of Verplaetse *et al.*¹⁶ and Stumm and Morgan,¹⁷ this assumption considers the possibility of an excess of acid, ammonium or magnesium ions; it not only applies to the case of dissolution of pure struvite but allows for formation of struvite from its pure components when these are in non-stoichiometric portions.

(2) The effects of ionic strength on activity coefficients can be neglected; it is assumed that the activities of individual ions are equivalent to their concentrations. Currently we have assumed the ionic strength of around 0.1 to be relevant to urine and waste-water treatment. Note that it is possible by repeated calculations to estimate activity coefficients by using the Debye-Hückel or Davies approximations. These calculations are more time-consuming and are to be considered in a follow-up paper. This approximation is already widely used and is unlikely to change the structure of the results.

(3) Only one insoluble solid phase is formed and the mole fractions in the solid are identical to the component activities.

Computational methods

Extensive calculations were made with version 4.2 of the Maple symbolic manipulator¹⁸

run on a Commodore Amiga 2000 with a 20 Mbyte hard disc and 3 Mbytes of RAM. Initially a series of equations describing the variations of the species in the system were found. These equations are derived from the equations of conservation of mass and conservation of charge in solution as presented below. The network of equations is expressed as an input file to Maple in Table 2. This algorithm presents assignments for the equilibria and the equations in a structured form that produces outputs in Fortran code.

First to be considered are the mass-balance equations:

$$Plqd = [H_3PO_4] + [H_2PO_4^-] + HPO_4^{2-}] \\ + [PO_4^{3-}]$$

$$Nlqd = [NH_4^+] + [NH_3]$$

$$Mlqd = [Mg^{2+}] + [MgOH^+]$$

where each is simply a total sum of molarities and where square brackets represent molar concentrations.

Secondly, we recognize the equation of electrical neutrality:

$$[H^+] + [NH_4^+] + 2[Mg^{2+}] + [MgOH^+] \\ = [OH^-] + [H_2PO_4^-] + 2[HPO_4^{2-}] + 3[PO_4^{3-}]$$

fortran(c,optimized,filename = 'df1:c.for');	

Notes

:= signifies an assignment; # separates out comments and ^ signifies a power. Other operations should be self-evident with special functions, e.g., "solve" being used to perform operations.¹⁸

Extra terms for the excess of non-reactive ions are added as appropriate. Lastly we include an overall mass balance of the constituents in the solid phase (see Table 2).

Two input variables are specified in the input Maple file, namely the total molar concentration of magnesium in the liquid phase (Mlqd) and the concentration of hydrogen ions in solution (H). It is necessary in this fully flexible system to specify two concentrations to determine the equilibria. These degrees of freedom are expected from the Gibbs phase rule¹⁹ for the case of four independently variable components and two phases. The temperature is held constant at 25° and the pressure is 1 atmosphere; two degrees of freedom remain, which we

choose conveniently as the pH and the total molar concentration of magnesium in the liquid (Mlqd). The output from Maple is a series of Fortran codes, which are algebraic and relate all variables to the equilibrium constants; these algebraic expressions fill several pages.

The technique produces an 11th order polynomial in H, so H is used as an argument, one of the input variables. The other argument, Mlqd, then gives an explicit quadratic equation for the total molar concentration of phosphorus in solution (Plqd). The output algebraic code is integrated into a Fortran program which solves for Plqd, then back-substitutes to obtain values for the other 18 variables, producing a data file containing the values of all 20 variables. From

these data, groups of variables are selected for graphical presentation and numerical comparisons.

EXPERIMENTAL

Solutions of the salts magnesium chloride, potassium dihydrogen phosphate and ammonium chloride in distilled water were made up in 200-ml lots in 250-ml Erlenmeyer flasks, and were initially adjusted in pH with 0.4M sodium hydroxide for use in experiments at approximate pH values of 6.5, 7.2, 7.5 and 8.1. Sets of four flasks were prepared for each pH value. The initial flask concentration of magnesium was 7.0mM, of phosphorus 3.1mM and ammonium 130.6mM. The flasks were sealed with parafilm, then placed in a water-bath set at 30°, and rotated at 70 cycles/min. Each flask contained 1 g of borosilicate glass grindings for enhanced nucleation of crystals from solution. Sampling took place at approximately 0.5, 2, 40, 60 and 200 hr. The total number of data points collected was 66.

Samples (5 ml) were drawn from the solutions with a syringe. Each sample was drawn through a Whatman glass fibre filter paper and a 0.45 μm membrane filter to remove solid and glass particles. Magnesium, ammonia and phosphorus were measured according to APHA methods;²⁰ pH was measured in the flask just prior to sample extraction.

RESULTS AND DISCUSSION

Calculated concentration contours

The structure of the system at equilibrium, as derived from the theory above, is presented in Figs. 1(a) and 1(b). These represent three-dimensional surfaces for dissolved phosphorus [Fig. 1(a)] and nitrogen [Fig. 1(b)] in the solution. These calculated concentrations are for a temperature of 25° and are total values at equilibrium in the presence of a precipitate. Figure 1(a) presents contours at constant values of total dissolved phosphorus; Fig. 1(b) gives contours at constant values of total dissolved ammonia (or nitrogen species). The equilibrium constants used are estimated from Högfeldt¹⁵ and are listed in Table 1, column 3.

The contours in Fig. 1(a) indicate that at a given total magnesium concentration in solution, the total phosphorus in solution decreases with increasing pH, *e.g.*, at $10^{-5}M$ magnesium, phosphorus decreases from $10^{-0.5}M$ at

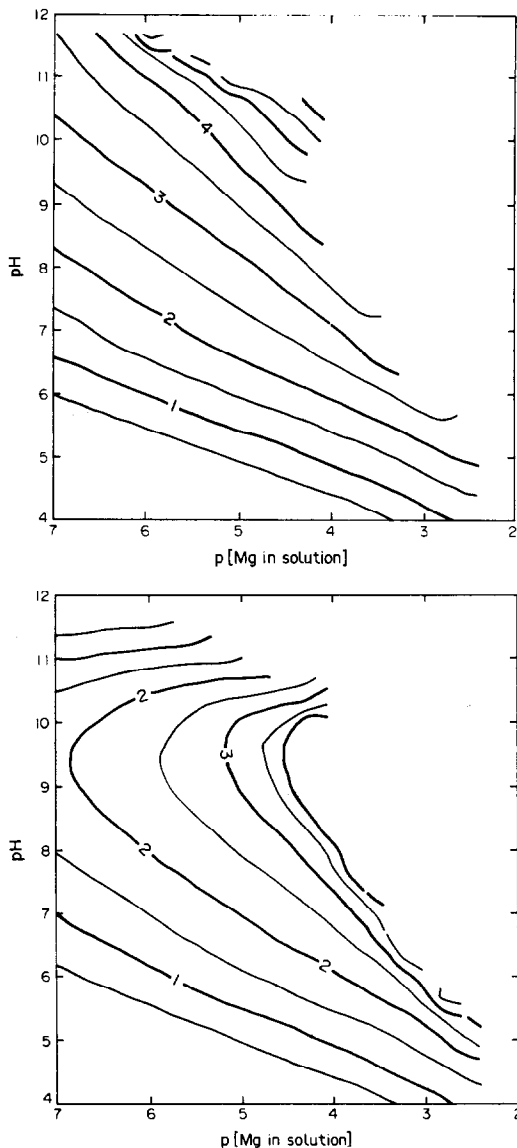

Fig. 1. Plots relating concentration of (a) phosphorus species in solution and (b) nitrogen species in solution to pH and p (magnesium in solution). The numbers on the contours are $-\log[\text{species in solution}]$, at 25°C.

approximately pH 5 to $10^{-4.3}M$ at pH 10. Similarly, in Fig. 1(b) the concentration curve for the solubility of nitrogen at a fixed magnesium value of $10^{-5}M$ indicates that nitrogen in solution decreases from $10^{-0.5}M$ at pH 5 to a minimum concentration of $10^{-3.2}M$ at pH 9.5, then increases in concentration to $10^{-1.5}M$ at pH 11.

The concentration of phosphorus in solution decreases rapidly with an increase in either magnesium or pH; the nitrogen in solution decreases with a increase in magnesium with the smallest rate of change occurring at pH near to 9 [Figs. 1(a) and 1(b)].

Note that these curves have 2 degrees of freedom and require contours to simulate the three-dimensional nature of the equilibria. In contrast, Verplaetse *et al.*¹⁶ show the system as being only a function of pH, a single independent variable. It is clear that their calculations do not require two degrees of freedom. Careful examination of their algorithm shows that they have not directly considered the necessity to consider electrical neutrality. This means that some form of internal adjustment must be expected to bring the system to an electrically neutral state. Perhaps this can be attributed to the complexing agents, but in the general case this is unrealistic.

Our results are difficult to compare with those of Verplaetse *et al.*¹⁶ as their formulation is for the dissolution of struvite in its entirety. That means that if $M_{lqd} = P_{lqd} = N_{lqd}$ our calculated results should be similar to theirs. From Figs. 1(a) and 1(b), $M_{lqd} = P_{lqd} = N_{lqd} = 10^{-3.5} M$ at about pH 7 at 25°. The data of Verplaetse *et al.*¹⁶ indicate that at 37° and pH 7 the corresponding concentrations would be about $10^{-2.5} M$. This is satisfactory agreement, considering the restricted nature of the calculations. The salient point is that though Verplaetse *et al.* used the activity coefficients, they seem to have ignored the electroneutrality equation, so the Gibbs phase rule would have been violated except in special cases.

Our model incorporates all the mass balances as well as the electroneutrality equation. The plots in Fig. 1 are just two examples of contours out of at least 400 curves which can be derived from the model.

Comparison of theoretical model predictions with laboratory and literature data

Laboratory data. Figure 2(a) presents a comparison between the measured and calculated phosphorus concentrations (P_{lqd}); which are significantly correlated ($r^2 = 0.77$ with 66 data points from equilibration times up to 200 hr). For data points derived from times greater than 50 hr this correlation increases in significance [$r^2 = 0.91$, $n = 32$, Figure 2(b)]. The measured nitrogen (N_{lqd}) values are correlated with model-derived values for equilibration times up to 200 hr ($r^2 = 0.85$, $n = 66$) and even more so for times greater than 50 hr ($r^2 = 0.97$, $n = 32$). Note that the nitrogen is in excess and has a limited range in concentration, and that the statistics are not very useful. Figures 3(a) and 3(b) show that the correlation of the P_s values

Fig. 2. Phosphorus concentrations in solution at 30°C calculated by the model, compared with laboratory results (a) 0–200 hr and (b) 50–200 hr equilibration.

derived from the model and laboratory data is significant for times up to 200 hr ($r^2 = 0.72$, $n = 66$) and much more so for times greater than 50 hr ($r^2 = 0.96$, $n = 32$); P_s is the conditional solubility product, which is both concentration- and pH-dependent.

Two major conclusions drawn from the comparison of the model data with the laboratory data are (1) the model is successful in predicting struvite solution chemistry and (2) improved correlations are found for equilibration times greater than 50 hr. It appears that true equilibrium exists after 50 hr, in agreement with Taylor *et al.*²

Literature data. A correlation ($r^2 = 0.46$, $n = 20$) exists (Fig. 4) between the model P_{lqd} values and the only other data set available² for an equilibrium struvite solution, that completely specifies the mass and charge balances. The

Fig. 3. P_5 values at 30°C calculated by the model, compared with laboratory results for (a) 0–200 hr and (b) 50–200 hr equilibration.

correlation improves if the two outlying points are removed ($r^2 = 0.85$, $n = 18$). These authors used combinations of specific chemicals and

Fig. 4. Phosphorus concentrations in solution at 25°C calculated by the model, compared with the experimental data of Taylor *et al.*² The line has a slope of 1.

have specified the amount of excess ions. The scatter of points may be partly due to a disparity between their quoted values and our estimates of their excess ion values. The relationship between NIqd generated from the model and that derived from the data of Taylor *et al.*² is not highly significant. We believe a major factor in this discrepancy may be difficulty in measuring the nitrogen concentrations.

Derivation of best-fit solubility constants. Literature values of solubility constants have inherent limitations because they have been derived by using approximate solution equilibria. Hence, K values were derived from the present model by applying a least-squares program to laboratory and literature data. This enabled modification of the solubility constants to yield the best fit, as well as allowing an estimate of some of the constants. The second column of Table 3 shows the values derived for the experimental temperature of 30° from some literature values. Six solubility constants

Table 3. A comparison of literature solubility constants with values derived for ionic equilibrium during model calibration

*Selected 30°C value—Sillén and Martell¹³ quote $\log K$ 9.08, but Högfeldt¹⁵ quotes 8.38.

†Literature value from Table 1.

‡Selected 30°C value—Sillén and Martell¹³ quote $\log K$ 13.833, but Högfeldt¹⁵ quotes 13.851.

listed in Table 3 were found to have a marked effect on the least-squares comparison. The literature K values often vary by more than one order of magnitude and some of this disparity may be resolved with more information about species. The standard values given by Högfeldt¹⁵ are usually used, but these constants do not take account of all interfering species. We think the present algorithms allow for all known species and should give a "best" set of equilibrium constants.

In conclusion, we have developed a model which considers the known reactions for the formation of a mixed precipitate in a pure solution. The model of struvite formation considers ionic reactions in the solution and reactions in the solid precipitate, without the need for bold approximations. The model allows for all combinations of the three chemical components as well as extra ionic species. Previous workers have only considered the solution of struvite directly, or with specific chemicals added to form known combinations of species. The model has been validated with both laboratory and literature data and several equilibrium constants have been redetermined.

The model still has some deficiencies, in that it does not use activity coefficients, or include other dissolved species, e.g., dissolved MgHPO_4 , MgPO_4^- and $\text{MgH}_2\text{PO}_4^+$, and the effects of organic complexing agents. This work is continuing and a following paper will address some of these points.

The model in its present form is primarily qualitative. That is, the curves simply present the structure of the equilibria and the various deficiencies of the model do not allow precise interpretation. Its real use is in the design of systems that allow a known amount of struvite to be precipitated. When all the appropriate constants are known, this is an inversion problem and not easily solved analytically. Consider the problem of calculating the precipitation of struvite in waste-water, knowing the amounts of ammonia, phosphate and magnesium in the input stream. The present algorithm produces a table of struvite concentrations in the solid for various pH values and amounts of magnesium.

One way of completing the inversion is simply to interpolate in this table while maintaining the appropriate concentrations and amounts of the three inputs. The final outcome is the amount of struvite in the total mix, expressed in g/l., in the stream.

Acknowledgement—We gratefully acknowledge the excellent positive review of our paper by Dr R. A. Chalmers. His efforts have greatly improved the quality of the manuscript.

(Received 17 August 1990. Revised 5 November 1990. Accepted 17 December 1990)

Summary—A novel computer-assisted ^{13}C NMR spectroscopic method for the identification and determination of chlorohydrins in reaction mixtures formed during the manufacture of glycerol, is described. It utilizes the unique features of quantitative and edited ^{13}C NMR spectrometry and avoids chromatographic separation for identification and quantification of the mixture components. It is simple, specific and quicker than the GC-MS and GC-IR methods.

1,2,3-Trihydroxypropane (glycerol) is an important intermediate in the manufacture of alkyd resins, ester gums, urethane foams, drugs, cosmetics and toothpastes. It is synthetically produced in large quantities.¹⁻³ The product generally contains chlorohydrins, glycerol, glycidol and their hydrolysis products in different proportions, and complete analysis of the mixture is of great importance not only to determine the extent of reaction but also to optimize the processing conditions. Several methods based on chromatography, spectroscopy and combined techniques such as GC-MS and GC-IR have been reported.⁴⁻¹¹ These methods generally involve a two-step procedure involving isolation of the components, followed by identification and quantification, but they suffer from a number of shortcomings due to lack of selectivity in chromatographic separation.

The present paper describes a simple, specific and single-step procedure using computer-assisted ^{13}C NMR spectrometry. It is based on comparing edited ^{13}C NMR spectra with multiplicity data derived directly from the chemical structures. It does not require a chromatographic separation. The results obtained are comparable with those obtained by GC-MS.

EXPERIMENTAL

Apparatus

A JNM Model FX-90Q FT-NMR spectrometer (JEOL, Tokyo) with a C/H dual probe

containing a quadrature detection system was used.

Reagents

All reagents were of analytical grade unless otherwise specified. Deuterium oxide (minimum isotope purity 99.8%) was obtained from Stohler Isotope Chemicals, U.S.A. Reaction mixtures containing chlorohydrins, glycerol and glycidol were obtained from pilot plants in our laboratory.

Procedures

Determination of quantitative ^{13}C NMR data. Quantitative ^{13}C NMR spectra were obtained by a gated decoupling pulse technique to ensure suppression of the nuclear overhauser effect (NOE). Spin-lattice relaxation was shortened by addition of chromium triacetylacetonate [$\text{Cr}(\text{acac})_3$] at 0.05M concentration. A recycle time of 10 sec between scans was found suitable for quantitative measurements. The spectrometer was operated at a resonance frequency of 22.5 MHz with 8 K (8192) data points and the probe temperature was maintained at 27°. The spectral width was 5 kHz and the pulse width was 28 μsec which was a 90° pulse for the spectrometer. About 100 pulses were needed to obtain a spectrum with a good signal to noise (S/N) ratio. Chemical shifts were measured with TMS as internal reference. The samples were undiluted and were examined in 10 mm o.d. tubes. The internal lock was maintained by means of D_2O in a capillary concentric with the NMR tube.

*Gives the number of carbon atoms of type $-\text{CH}_3$, $-\text{CH}_2$ and $-\text{CH}$ contributing to a particular resonance for each compound.

[×], ⁺ and [°] indicate carbon atoms bonded to Cl, OH and O respectively, and ^d indicates a double bond.

Determination of edited ^{13}C NMR data. Multiplicity data were obtained from edited spectra acquired by the distortionless enhanced polarization transfer pulse technique (DEPT) at $\theta = 3\pi/4$ and $\pi/2$. At $\theta = 3\pi/4$, the CH_3 and CH resonance signals are positive, those for CH_2 are negative and those for quaternary carbon atoms are suppressed. At $\theta = \pi/2$, all resonances except those of CH are suppressed. Assignments were based on coincidence of appearance of signals in both the quantitative and edited ^{13}C NMR spectra.

RESULTS AND DISCUSSION

Optimization of operating conditions for quantitative ^{13}C NMR spectrometry

^{13}C NMR spectrometry is used for obtaining both qualitative and reliable¹²⁻¹⁴ quantitative information, but requires close attention to be paid to many experimental parameters.^{15,16} These were considered during design of the present experiments. The spin-lattice relaxation times (T_1) of all the carbon resonances of the compounds to be found in the reaction mixtures were measured by the inversion recovery technique¹⁷ and were used for selecting appropriate recycling times between pulses.

Generally, three methods have been employed in efforts to obtain quantitative results by ^{13}C NMR spectrometry. They are based on

use of long pulse delays ($5T_1$), gated decoupling, and the addition of paramagnetic relaxation reagents such as $\text{Cr}(\text{acac})_3$ and $\text{Fe}(\text{acac})_3$. Shoolery,¹⁵ and Levy and Edlund,¹⁸ studied extensively the limitations and problems associated with use of the relaxation reagents and pointed out that the use of $\text{Cr}(\text{acac})_3$ alone will not ensure complete suppression of the NOE that is due to ^{13}C - ^1H dipole-dipole interaction. They suggested that the NOE may be quenched more effectively by using $\text{Cr}(\text{acac})_3$ and a gated decoupling technique simultaneously, and this approach was therefore used in the present investigation to ensure complete suppression of the NOE in order to obtain reproducible results.

Simulated data base

A data base containing chemical shifts, multiplicities, degeneracy and type of bonding was derived from the molecular structures of all the components to be found in the reaction mixtures. It is presented in Table 1. The multiplicity data for each compound are described effectively by using line notation ($\text{CH}_3/\text{CH}_2/\text{CH}$) and distinguishing the bond-types appropriately. They give the actual number of methyl, methylene and methine group carbon atoms contributing to a particular resonance. These data are used in identifying reaction mixture components by a reverse search procedure¹⁹.

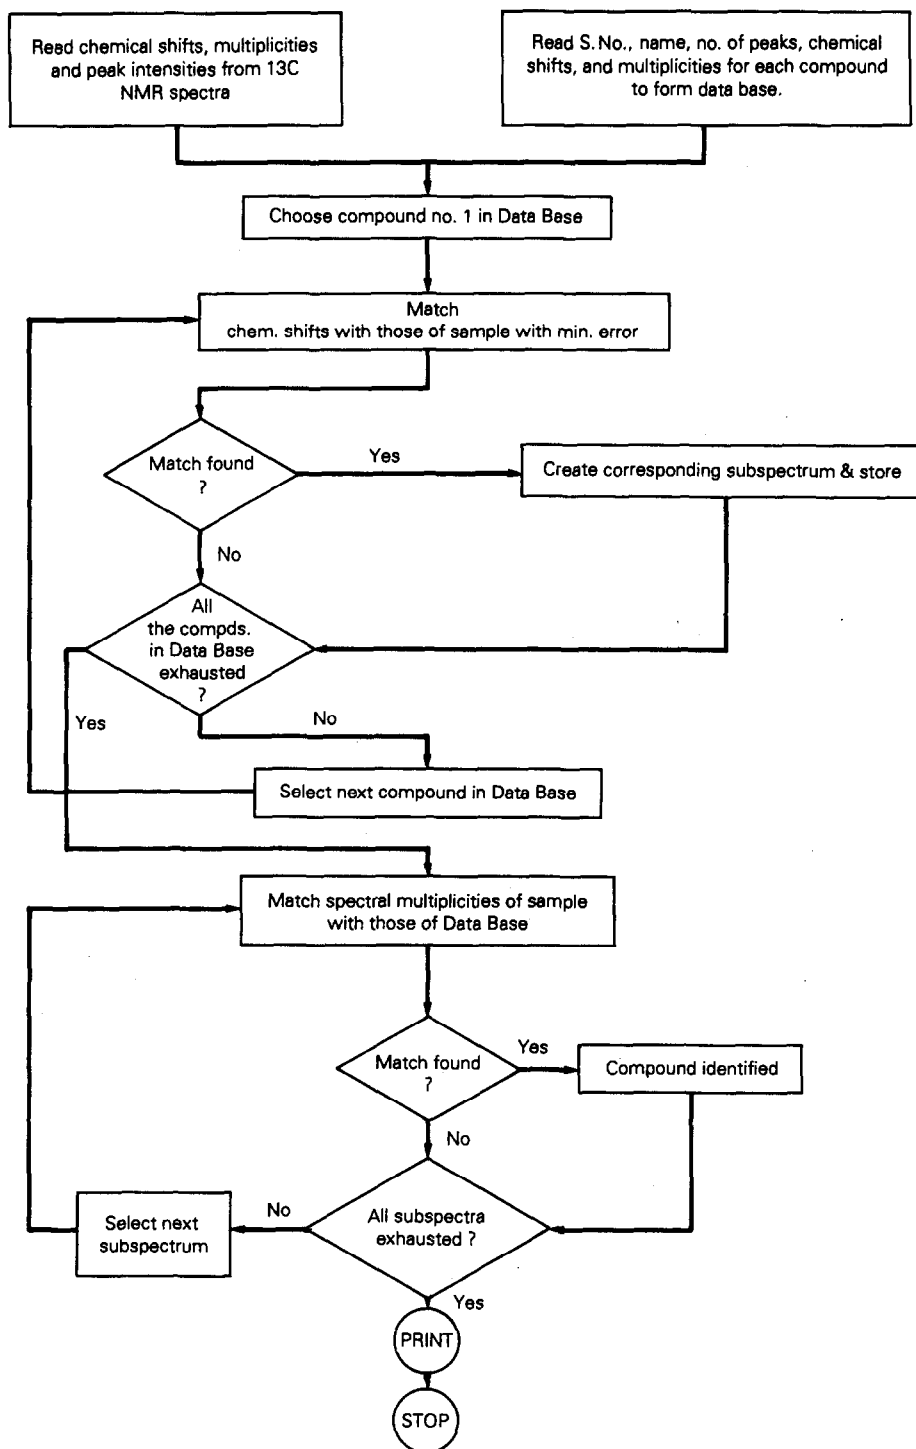

Fig. 1. Flow chart of logic for ^{13}C NMR analysis of reaction mixtures formed in the manufacture of glycerol.

Search algorithm

A flow chart for ^{13}C NMR analysis of a reaction mixture is given in Fig. 1. It involves the processing of quantitative and edited ^{13}C

NMR data to determine relative peak areas and multiplicities arising from hydrogen coupling. In the first step separation of carbon resonances by compound is performed by using chemical shift data. In the second step the simulated

Fig. 2. Quantitative and edited ^{13}C NMR spectra of a three-component mixture containing MCH, DCH and ECH.

library is subjected to a reverse search procedure in which all possible subsets of the library multiplicity data matching with spectral multiplicities are determined. If a suitable match is not found, the tolerance limit is increased and the process is repeated. Thus a unique group of compounds is found in the simulated library, that matches the quantitative and multiplicity data of the reaction mixtures.

Standard mixtures

The method was evaluated by determining the content of a three-component mixture containing 25% monochlorohydrin (MCH), 34% dichlorohydrin (DCH) and 41% epichlorohydrin (ECH), compounds 5, 8 and 10 in

Table 1. The quantitative and edited ^{13}C NMR spectra are shown in Fig. 2. The quantitative spectrum contains a total of 7 resonances, including 1 methyl, 5 methylene and 3 methine carbon atoms. It can be seen from the edited spectrum with $\theta = 3\pi/4$ (Fig. 2) that the peak at 45.57 ppm is actually due to overlap of the two resonances of methyl and methylene carbons. The positive and negative signals at this resonance not only confirm this but also give the relative contributions to the resonance calculated by the distortionless enhanced polarization transfer technique. Table 2 summarizes these results along with the allocations of the resonances in accordance with the algorithm described in Fig. 1.

Table 2. Computer-assisted ^{13}C NMR analysis of a three-component mixture containing 25% MCH, 34% DCH and 41% ECH

Fig. 3. Typical ^{13}C NMR spectra of reaction mixture from the manufacture of glycerol.

Reaction mixtures

Typical ^{13}C NMR spectra for the reaction mixtures under investigation are shown in Fig. 3. Table 3 gives the computer analysis of ^{13}C NMR data obtained for a typical reaction mixture in the process of manufacturing glycerol. Five compounds, *viz.* glycerol, glycidol, monochlorohydrin, dichlorohydrin and epichlorohydrin are identified in the reaction mixtures. The quantitative ^{13}C NMR spectrum contains a total of 10 resonances. For example the peaks 1, 3 and 4 in Table 3 are initially

matched and identified as belonging to ECH, by use of chemical shift and multiplicity data respectively. The ECH content is subsequently determined from the peak areas. Similarly, the content of each compound is determined by using the areas of the corresponding peaks matched for identification. Three different reaction mixtures were then analysed by the proposed method. Table 4 gives a comparison of these results with those obtained by GC-MS. The time required to complete an analysis was 1 hr by NMR and $\frac{1}{2}$ hr by GC-MS. The results show that the ^{13}C NMR method is not only

simple and rapid but also reasonably accurate and precise.

CONCLUSION

A simple, specific and rapid method for identification and determination of chlorohydrins in reaction mixtures formed during the manufacture of glycerol has been developed, based on use of computer-assisted ^{13}C NMR spectroscopy. The lowest limit of detection for any of the components in the reaction mixture was 50 $\mu\text{g/g}$, but this could be improved by increasing the number of quantitative spectra collected.

FUNCTIONAL GROUP EFFECTS IN LASER-EXCITED MULTI-PHOTON PHOTOIONIZATION OF ORGANICS IN LIQUID SOLUTIONS

P. A. SNYDER* and E. VOIGTMAN†

Department of Chemistry, University of Massachusetts at Amherst, Amherst,
Massachusetts, 01003, U.S.A.

(Received 8 January 1991. Revised 13 February 1991. Accepted 21 February 1991)

Summary—Of the organic compounds examined for possible two-photon photoionization behavior, 43% were found to yield analytically useful photoionization with excitation at 308 nm. Fifty-five per cent produced greater photoionization responses than aniline, the *de facto* photoionization standard. Additionally, 16 of the surveyed compounds were more *photoionization efficient* (i.e., exhibit higher photoionization per unit absorption cross-section) than aniline. It was found that photoionization is relatively easily achieved with primary amines, anilines and diamines. Less readily photoionized were primary and tertiary amides, esters, alkyl ethers, and most halogenated compounds, the main exceptions being the halogenated anilines. Tertiary amines and fluorinated compounds gave poor photoionization results.

Photoionization occurs when a molecule absorbs one or more photons, causing ejection of an electron. The direct photoionization of a molecule from the ground state generally requires ultraviolet (UV) light.¹ Photoionization (PI) techniques have been used, with considerable effectiveness and high sensitivity, for the gas phase detection of both molecules and atoms. Consecutive multiphoton photoionization (MPPI) of molecules may also be carried out in solution.² The photoionization process is much more complex in the condensed phase than in the gas phase because photoionization produces a cation and either an electron in a solvent cage or an anionic species. Molecular MPPI is analytically useful, in the condensed phase, because the ionization potential is lower due to the solvation stabilization of the photo-generated charge carriers.

In the gas phase, organic molecules typically have ionization potentials of ≈ 9 eV. In solutions, effective ionization potentials are as much as several electron volts less than those observed in the gas phase. Although gas phase photoionization can be an extremely sensitive and practical technique, high energy sources are necessary to photoionize molecules in the gas phase.³ Condensed phase photoionization does

not need as energetic a source due to the lower ionization potentials.

Several studies of photoionization of solutions have been conducted in the past two decades. The photoionization of pyrene has been studied in detail.^{2,4-7} The quantitative determination of aromatic molecules has also been achieved.⁸⁻¹¹ The compounds that have been studied thus far consist mainly of polycyclic aromatic hydrocarbons (PAHs). There is almost no information available on the photoionization of the majority of organic compounds. Langhorst's studies of PI detection of organic compounds in the gas phase suggested that PI sensitivity depends upon carbon number, functional group, and bond type.¹² A survey of several organic compounds in the liquid phase was therefore conducted to determine if correlations between functional group and ease of photoionization could be made as has been done in the gas phase.

EXPERIMENTAL

The experimental instrumentation is illustrated in Fig. 1. Two-photon photoionization was induced by a Questek 2210 xenon chloride excimer laser. Its wavelength of emission was 308 nm (4.03 eV) and the laser was operated at a 20-Hz repetition rate. A windowless flow cell, shown in Fig. 2, was utilized. A -900 V bias voltage was applied to a stainless steel solution

*Present Address: Merck & Co., P.O. Box 2000, RY 71-22,
Rahway, N.J., 07065, U.S.A.

†Author for correspondence.

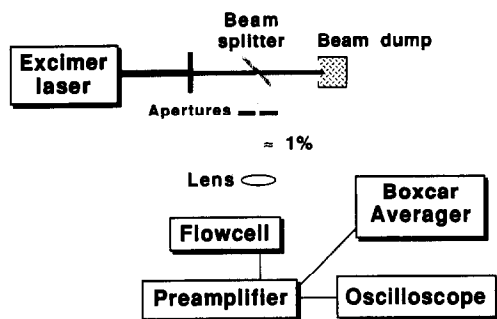

Fig. 1. The experimental apparatus for a laser induced photoionization study.

reservoir. The (negative) photocurrent produced upon two-photon photoionization was detected at the stainless steel pedestal. A voltage-mode preamplifier, capacitively coupled (50 nF, 1600 WV, silvermica) was utilized to convert the photocurrent to a voltage. The gain of the preamplifier was $\sim 3.0 \times 10^6$ V/A. A Tektronix 2465A 350-MHz oscilloscope was used to observe and monitor the waveform magnitude. The SR250 Gated Integrator and Boxcar Averager (Stanford Research Systems) was used to acquire the PI signal from the preamplifier. The oscilloscope was used to monitor setting of the gate width and delay of the boxcar system. The optimum gate width was $\sim 1 \mu\text{sec}$ and the optimum delay $\sim 3\text{--}4 \mu\text{sec}$ after the laser firing. The SR265 software package, for the SR250 Boxcar, was used to select a non-time scan and collect and average four runs of 1024 points. The SR265 program was also used to calculate the average signal and standard deviation, in volts.

Stock solutions of the organic compounds, each at 120 $\mu\text{g/ml}$, were prepared in HPLC-grade methanol (Fisher). Methanol was used because most organic compounds, of preliminary interest, were at least sparingly soluble in it. The purity of the compounds was checked, by melting point determinations, and were found to be in agreement with literature values. Ten-fold methanol dilutions of the stock solutions resulted in 12 $\mu\text{g/ml}$ solutions which were used for the PI detection survey. This concentration is approximately the upper limit concentration for photoionization studies. For several compounds, further dilutions were necessary to avoid saturation of the preamplifier output.

The mean blank (methanol) signal was subtracted from the PI signal produced by each organic compound. The standard deviation of the methanol blank was 23 nA. The blank-subtracted PI signal voltage was divided by 3×10^6

Fig. 2. Schematic of the three mode windowless flow cell.

V/A to produce a nominal photocurrent signal, in nA. The molar absorptivity of each compound, in methanol solution at $\sim 12 \mu\text{g/ml}$, 1.00-cm pathlength and 308 nm, was measured with the Perkin—Elmer Lambda 3B UV-Visible spectrometer.

RESULTS AND DISCUSSION

The tabular results of the photoionization studies are given in Tables 1 and 2, which list the 111 organic compounds examined in this survey. The photocurrent magnitude (I_{ph}) and molar absorptivity at 308 nm (ϵ) are also listed for each compound in Table 2. The 63 compounds in Table 1 either exhibit negligible absorbance at 308 nm, thereby precluding MPPI at the excimer laser wavelength, or they produce photocurrents less than three standard deviations of the blank, *i.e.*, less than ~ 70 nA. Thus, the test solutions were already at or below the detection limit.

Analysis of the results in Tables 1 and 2 indicate that 48 of 111 compounds (43%) yield useful PI detection response with 308-nm excitation. Aniline, which is readily photoionized, may serve as a *de facto* 'photoionization standard', rather like quinine in molecular fluorescence studies and sodium vapor in atomic fluorescence studies. It is seen that 34 of 47 compounds (72%) in Table 2 absorb 308-nm light more strongly than aniline does, while 26 of 47 (55%) produce higher PI signals than aniline, *ceteris paribus*. Accordingly, more than half of the compounds listed in Table 2 should yield lower detection limits than aniline does.

To demonstrate the sensitivity and linearity of MPPI detection, consider the detection limit determination of 1,5-diaminonaphthalene, the

second most readily photoionized compound listed in Table 2. A methanol stock solution of 15 $\mu\text{g/ml}$ of 1,5-diaminonaphthalene was prepared. Thirteen binary serial dilutions, in methanol, were performed, with the most dilute solution having a concentration of 1.8 ng/ml. Solutions more concentrated than 1.8 $\mu\text{g/ml}$ produced photoionization signals too large for the boxcar to process. The photoionization signals of the remaining solutions were measured and a log-log plot of photocurrent versus concentration is illustrated in Fig. 3.

The limit of detection ($S/N \equiv 3$) for 1,5-diaminonaphthalene in methanol was found to be 7 ng/ml. This is an extremely good detection limit taking into consideration the noise produced by polar solvents.¹³ Note that detection limits in non-polar solvents are as much as 1000 times better.¹³ The slope of the log-log calibration curve is 0.9989, indicating excellent linearity.

Returning to the analysis, Table 2 also shows the photocurrent magnitudes normalized by respective molar absorptivities. The results are therefore corrected for absorption cross-section. It was found that 16 of 47 (34%) of the surveyed compounds yield normalized photoionization responses that exceed that of aniline. Accordingly, $\sim 1/3$ of the surveyed compounds are more photoionization efficient than aniline.

Photoionization ease

Analysis of the results for compounds in Tables 1 and 2 suggest that photoionization is relatively easily achieved with primary amines, anilines and diamines. Polycyclic aromatic hy-

drocarbons also tend to work well, especially in non-polar solvents. Less readily photoionized, under present experimental conditions, are primary and tertiary amides, esters, alkyl ethers, and most halogenated compounds, the main exceptions being the halogenated anilines. Compounds which exhibit poor photoionization include tertiary amines and fluorinated compounds. Notice that 1,9-diaminononane gives poor PI detection even though it is a diamine. It was hoped that it would yield good performance so that its use as a possible photoionization tag could be explored. The goal was to attach the diamine by utilizing one of its amino groups for bonding to a desired moiety, leaving the other 'end' free for PI detection. Unfortunately, this appears out of the question with 1,9-diaminononane, and the lower molecular weight homologs of it, *e.g.*, cadaverine and putrescine, are too noisome to utilize in this manner.

Photoionization efficiency

Many of the surveyed compounds are readily detected by transmittance measurements, particularly with excitation wavelengths more optimally chosen than 308 nm. Evidently, the best application for laser-excited MPPI is for compounds that are weak absorbers but produce large photoionization signals. These compounds may not be readily detected by transmittance measurements, but are easily detected by MPPI.

Compounds with large ϵ 's and/or small PI signals will have small I_{ph}/ϵ values. Small ϵ 's and/or large PI signals will yield large I_{ph}/ϵ values, so these latter are the compounds best

suiting for PI detection. Examined in this light, the most efficient photoionization is achieved with amines, diamines, anilines and amides.

Functional group dependence

Functional group dependence is difficult to evaluate. In the gas phase, the effects of functional group dependence are considerably better understood, though far from complete. Jaffé¹⁴ comprehensively examined the effects of substituents on the ' σ ' substituent constant in the Hammett equation. Crable and Kearns¹⁵ measured ionization potentials of numerous

substituted benzenes and found linear correlation between measured ionization potentials and the ' σ^+ ' values (similar to the Hammett ' σ ' values) of Brown and Okamoto.¹⁶ More recently, Tembreull *et al.*¹⁷ have examined the effect of functional group type and ring location on the ionization potentials of a variety of substituted benzenes, including halogenated benzenes and substituted anilines. They found that ionization is facilitated by electron releasing groups (*e.g.*, $-\text{NH}_2$, $-\text{OH}$, $-\text{CH}_3$), hindered by electron withdrawing groups (*e.g.*, $-\text{NO}_2$, $-\text{CN}$, $-\text{COOH}$) and helped or hindered by halogen substitution, depending on the substitution pattern and other factors. As an example, dichlorinated aniline exhibits a substantial ionization potential lowering only when the chloro groups are in the *meta* and *para* positions.

For photoionization in liquid solutions, the same general observations are likely to be relevant, but great caution must be exercised in extrapolating from the gas phase. The lowered ionization potentials for analyte moieties in solutions are largely unknown and are strongly dependent on numerous solvent system parameters. Furthermore, the quantitative relationship between the measured photoionization currents in solutions and the actual ionization potentials in the solution environments has not been determined. Accordingly, no attempt will be made, at present, to definitively address the matter, since available data are insufficient to the task.

Of the 11 aniline derivatives in Table 2, 10 have higher molar absorptivities at 308 nm than does aniline, yet only 2 of the derivatives are more PI efficient. Several additional aniline derivatives, listed in Table 1, produced PI signals too small to be considered reliable. It appears that substitution generally degrades PI efficiency (in solution), though detection limits should be comparable to that of aniline because photocurrent magnitudes are not much changed by functional group substitution. Roughly speaking, ring activation, especially in the *para* position, appears to enhance the photoionization of substituted aniline. Similarly, *ortho* substitution,

especially with a ring deactivator, tends to decrease photoionization efficiency. These results are in general agreement with the results of Langhorst¹² and Tembreull *et al.*¹⁷

CONCLUSION

Despite the limited number of surveyed compounds and other experimental limitations (*e.g.*, 308-nm excitation and methanol solvent system), the survey of organic compounds illustrated that there is a definite correlation between functional group and ease of photoionization in solution. Compounds similar to those studied, in structure and/or functional groups, should produce similar photoionization results. The photoionization tag studies are potentially very important and are presently in the planning stage.

COLOUR REACTION OF PLATINUM(II) WITH 5-(4-NITROPHENYLAZO)-8-(*p*-TOLUENESULPHONAMIDO)- QUINOLINE AND ITS ANALYTICAL APPLICATIONS

ZHAO JIANWEI and XU QIHENG*

Department of Chemistry, Yunnan University, Kunming, 650091, People's Republic of China

(Received 30 May 1990. Revised 22 January 1991. Accepted 9 February 1991)

Summary—A simple, rapid and sensitive spectrophotometric method has been developed for the determination of platinum. 5-(4-Nitrophenylazo)-8-(*p*-toluenesulphonamido)quinoline (NPTSQ) reacts with platinum(II) almost instantaneously in alkaline solution to form a violet-red 1:2 complex with an absorption maximum at 640 nm. Beer's law is obeyed over the concentration range 0–1 $\mu\text{g/ml}$ platinum. The molar absorptivity is $1.37 \times 10^5 \text{ l. mole}^{-1} \cdot \text{cm}^{-1}$. The method has been used for the determination of microamounts of platinum in catalysts and anode slime.

Many spectrophotometric methods have been reported for the determination of platinum.^{1–4} Several^{5–14} involve either heating the solution or allowing it to stand for a long time for maximum colour development. Some reagents^{15–17} cannot tolerate interference by heavy-metal or other ions. Recently, several new organic reagents^{18–23} have been suggested for the determination of platinum and have good sensitivity and selectivity. In this paper, we report the colour reaction of platinum(II) with a new reagent, 5-(4-nitrophenylazo)-8-(*p*-toluenesulphonamido)quinoline (NPTSQ),²⁴ and a method for the rapid spectrophotometric determination of microamounts of platinum. The major advantages of this method over existing ones are that maximum colour intensity is attained almost instantaneously at room temperature and the sensitivity is higher than that of other methods.

EXPERIMENTAL

Apparatus

A spectrophotometer (Model 721, Third Analytical Instrument Factory, Shanghai) with stoppered cells of 1-cm optical path was used for all absorbance measurements.

Reagents

Platinum(II) standard solution. Prepared with pure K_2PtCl_4 to give a stock solution containing 100 $\mu\text{g/ml}$ platinum. Diluted further as required.

NPTSQ solution, $2.0 \times 10^{-4}\text{M}$, in 95% ethanol.

NaOH–KCl solution. Dissolve 4.0 g of sodium hydroxide and 7.5 g of potassium chloride in 30 ml of water, and dilute to 500 ml with water.

Tween-80 solution, 20 mg/ml.

All other reagents were of analytical grade.

Procedures

Determination of microamounts of platinum. Take a known volume of solution containing up to 25 μg of platinum(II), in a 25-ml standard flask, add 2.0 ml of NPTSQ solution, 3.0 ml of Tween-80 solution and 3.0 ml of NaOH–KCl solution, dilute to the mark with distilled water, shake and measure the absorbance at 640 nm against a reagent blank prepared in the same manner.

Determination of platinum in anode slime. Dissolve an accurately weighed sample (0.5–1.5 g) of anode slime by heating with 20 ml of *aqua regia*, evaporate the solution to incipient dryness, add 5 ml of concentrated hydrochloric acid and evaporate until nitrogen dioxide ceases to evolve. Let cool to room temperature (18–25°), add 2.5 ml of 3.0M hydrochloric acid to dissolve soluble salts, filter off the residue and wash it with ~20 ml of distilled water, dilute the combined filtrate and washings to ~25 ml, saturate the solution with sodium chloride and extract with two 10-ml portions of tributyl phosphate (TBP). Strip platinum from the organic phase with three 20-ml portions of 25% v/v nitric acid saturated with sodium nitrate. Evaporate the

*Author for correspondence.

combined nitric acid extracts to incipient dryness in a small beaker, and dissolve the soluble salts in 0.3M hydrochloric acid. Transfer the solution to a 25-ml standard flask and dilute to the mark with distilled water. Take 2.0 or 5.0 ml of the solution in a 25-ml standard flask, add 0.5 ml of 20% potassium iodide solution, then 5 min later add a drop of 5.0% ascorbic acid solution,²² adjust to nearly neutral with 0.2M sodium hydroxide, and complete the determination as above.

Determination of platinum in a catalyst. Weigh accurately about 1.0 g of Pt-Al₂O₃ catalyst and dissolve it in 10 ml of *aqua regia*. Evaporate the solution to incipient dryness, add 5 ml of concentrated hydrochloric acid and evaporate until no more nitrogen dioxide is evolved, then let cool to room temperature. Dissolve the soluble salts with distilled water, filter off the residue and wash it with distilled water, collecting the filtrate and washings in a 50-ml standard flask, and dilute to the mark with distilled water. Take 1.0 ml of the solution in a 25-ml standard flask and add 0.5 ml of 20% potassium iodide solution, then 5 min later add a drop of 5.0% ascorbic acid, 0.5 ml of 2.0% sodium fluoride solution, and complete the determination as above.

RESULTS AND DISCUSSION

Absorption spectra

Under the conditions used, platinum(II) forms a violet-red complex with NPTSQ, as

Fig. 1. Absorption spectra of NPTSQ and its platinum(II) complex. (1), NPTSQ (against water as reference); (2), NPTSQ-Pt(II) complex (against reagent blank as reference).

Table 1. Tolerance limits in the determination of 10 μg of platinum(II) with NPTSQ

Ion added	Amount tolerated, μg
I ⁻ , acetate, ascorbate	1000
F ⁻ , Zn(II)	500
Ga(IV)	400

Cu(II)	2
Co(II), Ru(III)	1
Pd(II)	0.5

does platinum(IV), but the molar absorptivity of the platinum(IV) complex is very low. The platinum(II) complex exhibits maximum absorption at 640 nm, whereas that of the reagent is at 515 nm. The absorption spectra of NPTSQ and its platinum(II) complex are shown in Fig. 1.

Reaction conditions

The optimum pH for the NPTSQ-Pt(II)-Tween-80 system is in the strongly alkaline region and addition of 2.0–5.0 ml of the NaOH-KCl solution to an approximately neutral test solution was found to give essentially the same absorbance; addition of 3.0 ml is recommended.

In the absence of surfactant or in the presence of an ionic surfactant a precipitate forms in the colour system, but the presence of a non-ionic surfactant, such as the emulsifying agent OP, poly(vinyl alcohol), Triton X-100 or Tween increases the solubility. Tween-80 was found to be the best additive, 1.0–5.0 ml of 2% Tween-80 solution giving good results; 3.0 ml is recommended.

Maximum and stable absorbance was attained with 1.0–3.0 ml of 2×10^{-4} M NPTSQ, and use of 2.0 ml is selected as optimal.

At room temperature, platinum(II) reacts nearly instantaneously with NPTSQ. The

chelate is stable in solution for at least 24 hr. The order of addition of reagents seriously affects the system, however. Addition in the order Pt(II), NaOH-KCl solution, Tween-80 solution, NPTSQ solution gives the worst results, whereas the order Pt(II), NPTSQ, Tween-80, NaOH-KCl solution gives the best.

Analytical characteristics

A calibration graph was prepared by the procedure described for determination of microamounts of platinum. Beer's law was obeyed over the concentration range 0-25 μg of platinum in 25 ml of final solution; the linear regression equation obtained was

$$A = 0.0282C + 0.00102 \quad (r = 0.998)$$

where C is expressed as $\mu\text{g}/25$ ml. From this equation, the molar absorptivity was calculated to be 1.37×10^5 $l. mole^{-1}. cm^{-1}$.

The composition of the complex was determined by the molar-ratio and continuous-variation methods, and found to be 1:2 (metal:ligand).

Interferences

The influence of 36 diverse ions on the determination was examined. The ions to be tested were added individually to a solution containing 10 μg of platinum. The tolerance limits (error < 2%) listed in Table 1 showed that platinum could be determined in the presence of many foreign ions, but the interference of Ru(III), Co(II), Pd(II) and Cu(II) was serious. Hence, extraction with TBP^{25,26} was used in the

analysis of samples containing these species. The interference of Al(III) was eliminated by masking with sodium fluoride.

Applications

The method has been applied to the determination of microamounts of platinum in a catalyst and an anode slime. The results are shown in Table 2, along with the values found by a reference method.

Conclusion

The comparison (in Table 3) of the NPTSQ method with others shows that NPTSQ is a highly sensitive spectrophotometric reagent for platinum, and that the method is simple and rapid, more selective and with higher sensitivity. It may be used to determine microamounts of platinum in small samples.

(Received 6 July 1990. Revised 18 December 1990. Accepted 27 December 1990)

Summary—The ultraviolet (UV) photolysis of several classes of nitrogenous pesticides was examined with a view to photo-induced fluorescence detection in flow-injection analysis (FIA) and liquid chromatography. The solvents evaluated as typical reversed-phase mobile phases included water, methanol, and 1:1 mixtures of methanol/water and acetonitrile/water, and methanol/acetonitrile/water mixtures. Acetone, acetophenone, the surfactant Triton X-100, and the photocatalyst titanium dioxide were assessed as photosensitizers to enhance the UV photolysis and fluorescence responses. FIA and liquid chromatographic separations of several pesticides were followed by post-column UV photolysis for the fluorescence detection. Ultraviolet photolysis produces some fluorescent products. The type of photolytic solvent seems to play a significant role. The presence of photosensitizers also affects the fluorescence response of some pesticides. The photochemical transformation products of some of the pesticides are suggested. Analytical figures of merit were evaluated for determination of several pesticides in ground water. The post-column UV photolysis approach for fluorescence detection in liquid chromatography was assessed for several nitrogenous pesticides in ground water samples at ng/g concentrations.

A variety of detectors have been developed for liquid chromatographic and gas chromatographic determination of trace levels of pesticides.¹ Although liquid chromatography (LC) with ultraviolet (UV) detection is sensitive for many organic compounds, it lacks selectivity, especially for complex matrices. Fluorometric²⁻⁴ and electrochemical^{5,6} detectors are more selective than UV detection but intrinsically fluorescent and electroactive compounds are relatively few. Recently, it has been shown that the introduction of a UV lamp in-line induces photochemical reactions in several compounds, leading to the formation of active species that respond to electrochemical^{7,8} or fluorescence detection.⁹⁻¹¹

The photochemistry of several classes of pesticides has been reviewed by Crosby,¹² and more recently by Marcheterre *et al.*¹³ Plimmer¹⁴ has summarized the photochemistry of the halogenated pesticides in the light of present knowledge of the mechanism of photochemical loss of chlorine from aromatic systems. A large number of pesticides contain aromatic structures that absorb strongly at some of the shorter wavelengths, resulting in bond fission; intermolecular energy transfer may also occur from

a sensitizer.¹⁵ The effect of UV light on dinitrophenols, phenyl esters, and esters of nitrophenols and pentachlorophenols has been well documented.¹² In the presence of a sensitizer, several compounds that are otherwise inert may undergo photolytic degradation reactions. Addition of acetone as a sensitizer was reported to result in the rapid disappearance of ethylenethiourea under both natural and artificial light.¹⁶ Photolysis was sensitized also by riboflavin, Rhodamine B or Methylene Blue. The production of radicals by photolytic or other homolytic processes may also be an important factor in the biological action of a pesticide.¹⁴

We have constructed a post-column photolysis/fluorescence detector^{10,11} and extensively examined several classes of nitrogenous pesticides for the fluorescence induced by UV photolysis in LC and FIA. Typical reversed-phase mobile phases (methanol, 1:1 mixtures of methanol/water and acetonitrile/water) were evaluated as the photolytic solvents. Acetone, acetophenone, the surfactant Triton X-100 and the photocatalyst titanium dioxide were assessed as potential photosensitizers to enhance photolysis and fluorescence responses. Both flow-injection analysis and liquid chromatographic techniques were employed.

*Author for correspondence.

EXPERIMENTAL

Apparatus

The instrumental system described earlier^{10,11} for LC postcolumn UV photolysis fluorescence detection was used in this work. A schematic diagram of the system is shown in Fig. 1. Briefly, it consisted of a Perkin-Elmer Series 4 liquid chromatograph solvent-delivery system, a Perkin-Elmer ISS-100 autosampler, Milton Roy minipumps, a UV mercury lamp surrounded by an open tubular knitted photolytic reactor, a Kratos FS 970 fluorometer and a Perkin-Elmer LCI-100 laboratory computing integrator. A Kratos Spectroflow 980 programmable fluorescence detector replaced the FS 970 in the later part of the studies. A Tracor Model 965 photoconductivity detector was used with a Soltec Model 261 chart recorder.

Perkin-Elmer 3 × 3 (0.46 × 3.3 cm; 3 μm) and Waters Resolve (0.46 × 15 cm; 5 μm) C18 columns (room temperature) and linear acetonitrile/methanol/water gradients were used for all LC separations. To detect nanogram amounts of pesticides in water, the volume of sample injected in the column was 400 μl, and the solvent program was optimized for the separation of several pesticides in 27 min, as follows: flow-rate 1.0 ml/min; linear gradient from 60:35:5 to 20:55:25 water/acetonitrile/methanol in 11 min; linear gradient to 30:14:56 water/acetonitrile/methanol in 6 min; hold at 30:14:56 for 4 min; linear gradient to 60:35:5 water/acetonitrile/methanol in 4 min; equilibrate for 2 min.

All initial photolysis studies were performed by flow-injection analysis (FIA) to allow rapid screening and to eliminate chromatographic problems. The solvent flow-rate used was 1 ml/min for all solvent/photosensitizer systems.

Fluorescence was measured at wavelengths longer than 418 nm after excitation at 235 nm with a deuterium source. This setting provided maximum response for several pesticides that produced fluorescent species upon photolysis, and had emission and excitation maxima at these wavelengths, but was a compromise for several other analytes. The fluorescence signals were integrated by the LCI-100 and printed on thermal paper. Fluorescence signals were also printed on the Soltec strip-chart recorder. Experimental conditions were optimized by a single univariate optimization method in the following sequence. The Teflon irradiation reactor designs (coiled, or knitted differently in three dimensions), flow-rates through the reactor, residence times, mobile-phase effects on responses, and concentrations were examined and adjusted to provide maximum responses and minimal band broadening on the chromatograms for pesticides.

Reagents

Acetonitrile, acetone and water (all LC grade), methanol (Optima® grade) and Triton X-100 were obtained from Fisher Scientific Company.

Chlorsulfuron, chlorimuron ethyl, metsulfuron methyl and sulfometuron methyl were obtained from Du Pont (Wilmington, DE), and fenoxycarb was from Maag Agrochemicals (Vero Beach, FL). All the other pesticide standards

came from the U.S. Environmental Protection Agency, Pesticides and Industrial Chemicals Repository (Research Triangle Park, NC). The purities ranged from 95 to 100%. The chemical structures of these pesticides (except for avermectin) are shown in Figs. 2 and 3. Solutions of each pesticide (1 mg/ml) were prepared in methanol or water and diluted so that a 1- μ l injection contained between 0.1 and 10 nmole. Injections of 1 μ l were made to minimize the effects of the pesticide solution solvent on the photolysis/fluorescence responses.

Measurement procedure

Relative fluorescence response measurements were initially made without an LC column in place, by FIA for rapid screening. The solvent systems (water, methanol, and 1:1 mixtures of methanol/water and acetonitrile/water) were evaluated for fluorescence response and for use as mobile phases. The solvent systems evaluated with the photosensitizers were water, 1:1 v/v mixtures of methanol/water and acetonitrile/water, each with 0.5% v/v acetone; 1:1 v/v mixtures of methanol/water each with 0.5% v/v acetophenone, 0.02% v/v Triton X-100 or 0.2 mg/ml titanium dioxide. Each of the 37 nitrogenous pesticide solutions (1 μ l) was examined in each of these solvent systems. The fluorescence measurements were performed in two modes of operation: (1) UV lamp off (native fluorescence) and (2) UV lamp on (photo-induced fluorescence). Replicate measurements (at least 3) were made, to evaluate the reproducibility for each analyte. Relative fluorescence intensities, normalized to that of an equimolar amount of quinine sulfate standard, were evaluated after the UV photolysis of each analyte/solvent system combination. The analyte fluorescence response is the difference between the mean of 3–5 measurements (RSD = 5%) with the UV lamp on and the UV lamp off. Fluorescence improvement factors (ratio of fluorescence intensity of photolyzed chemical to fluorescence intensity of untreated chemical) were also evaluated for each analyte. Reversed-phase LC separations were performed and postcolumn UV photolysis and fluorescence measurements were performed for several of those analytes that showed high fluorescence responses in the FIA mode. Analytical figures of merit and recoveries from ground water samples fortified with the analytes at 25–500 ng/ml concentrations were evaluated for several pesticides.

The photosensitizers acetone, acetophenone and Triton X-100 were added directly to the solvents to produce photosensitization, thus eliminating the need for an additional FIA pump.

RESULTS AND DISCUSSION

Fluorescence detection of pesticides

All 37 nitrogenous pesticide chemicals, representing several classes of compounds (see structures in Figs. 2 and 3), were evaluated for fluorescence improvement after UV irradiation and phototransformation. Some of these pesticides are from the EPA Pilot Groundwater Study list because of increasing interest in them.¹⁷ Each of the 9 solvents and photosensitizer systems was employed for screening fluorescence responses and fluorescence improvement following photolysis of each pesticide. The highest fluorescence responses obtained for each compound are listed in Table 1. Also included are the fluorescence improvement factors and the solvent system that produced the highest improvement factor. These results indicate that about 70% of the compounds screened show significant fluorescence improvements upon UV photolysis, with relative fluorescence greater than 1% and/or fluorescence improvement factors larger than 3. It may be noted that the solvent system giving the highest fluorescence response varied from compound to compound. Further, solvent type significantly influenced photolysis efficiencies, fluorescence intensities and relative fluorescences. Scholten *et al.*¹⁸ have reported similar observations. All the compounds in Table 1, except chloramben, gave significant fluorescence responses only after irradiation with UV light, indicating that this fluorescence resulted from some of the phototransformation products. Further, all of these compounds contained an aromatic grouping, suggesting that this fluorescence most likely resulted from phototransformation of this moiety.

Addition of acetone, a photosensitizer, to the 1:1 water/acetonitrile solvent system enhanced the UV photolysis reaction and increased relative fluorescences for the analytes carbetamide, metribuzin, cyromazine and terbacil. These analytes showed lower fluorescence responses in the absence of acetone.

Of all the compounds studied, only two, fluridone and chloramben, showed significant native fluorescence intensity without UV photolysis under the present experimental conditions, and this varied significantly with various solvent

systems. The most intense native fluorescence and the optimal solvent systems for these two pesticides are given in Table 2. It is interesting that the native fluorescence intensity of chloramben is 10.5 times greater in 100% methanol than in 1:1 water/methanol (see Table 1). Further, UV photolysis enhanced the fluorescence intensity of chloramben and produced a high fluorescence improvement (83.5; see Table 1).

For several pesticides the relative fluorescence improvement was very dependent upon the solvents used, indicating that the solute environ-

ment was important in the photolysis mechanism. It has been reported that the presence and/or absence of oxygen affects the rates of photolysis and products formed from some pesticides.^{19,20} Even though the solvents used in this investigation were purged with helium to avoid bubble formation during chromatography, the oxygen permeability of Teflon prevented deoxygenation from being achieved during photolysis. Therefore, the role of oxygen, if any, in the photolysis of these pesticides is not known. Further, it has been reported that UV irradiation of Teflon

produces protons and fluoride ions, which may also affect photolytic pathways.²¹

The effect of the photosensitizers was evaluated by adding them prior to UV photolysis. Table 3 lists acetone photosensitizer-enhanced UV photolysis and fluorescence response for several compounds. No one solvent system produced the highest fluorescence responses for all the pesticides. Fluorescence responses without acetone are also included for comparison. The presence of acetone enhanced the UV photolysis, giving fluorescence improvement factors 5–15 times higher for all the pesticides except 1,1-dimethylhydrazine. In other instances, however, the presence of acetone in the solvent system produced diminished fluorescence signals. The fluorescence improvements are summarized in Table 4.

The use of the photocatalyst titanium dioxide as a photosensitizer was evaluated by using an aqueous suspension. Initial studies were carried out with 0.2 mg/ml titanium dioxide dispersed in LC grade water. This suspension was constantly stirred and dispensed at a flow-rate of 0.5 ml/min into a 1:1 water/methanol solvent system. The five pesticides showing no significant fluorescence responses with UV photolysis and without a photosensitizer were: ethylenethiourea, trifluralin, thiobencarb, dinoseb and chlorsulfuron. Three of these compounds upon UV photolysis in the presence of titanium dioxide gave a relative fluorescence response greater than 1%. The relative fluorescence (photolysis efficiency) values for three pesticides were: dinoseb (1%), thiobencarb (1.3%), and trifluralin (11%). Further work is needed to evaluate the effect of the photocatalyst titanium dioxide on other pesticides.

Photoconductivity and programmed wavelength fluorescence detection

A preliminary study was done with the photoconductivity detector for measurement of responses of several pesticides following UV photolysis. There was very little difference in photolytic efficiency between the UV sources, when used with either the LC fluorescence instrumentation or the photoconductivity detector. The peaks measured with the photoconductivity detector were somewhat broader, probably because of the open tubular design of the reactor. The limits of detection were within an order of magnitude of each other. All subsequent measurements were made by optical detection, because of the selectivity advantage conferred

Fig. 4. Typical FIA traces of the LC-integrator output. A = 0.2 ng of diphenamid; B = 1 ng of diphenamid.

by changing the fluorescence excitation and emission wavelengths.

A new programmable fluorescence detector, an ABI Analytical Kratos Division Spectroflow 980 model, was obtained to replace the Kratos model FS 970 detector and a comparative performance study was carried out for several analytes. The fluorescence signal intensities with the Spectroflow 980 detector were 3–4 times higher for equal amounts of analytes than those with the FS 970 detector. The fluorescence responses for several analytes were more than four times as great when measured with the new detector. Typical traces of the fluorescence signals for diphenamid are shown in Fig. 4.

Analytical figures of merit

Analytical figures of merit for determination of some of the more responsive compounds were evaluated by LC, employing UV photolysis for the generation of fluorophores. Several classes of pesticides in ground water were determined by this approach. Aqueous standard solutions of various pesticides (covering a range of concentrations) were examined individually and as mixtures. LC separation of the analytes was achieved in the reversed-phase mode in 27 min with the water/acetonitrile/methanol gradient solvent program mentioned in the experimental section, on a C18 column at room temperature. The chromatographically separated pesticides were UV photolyzed and their fluorescence responses were measured. Typical LC chromatograms are shown in Fig. 5 for a multi-component pesticide mixture. Analytical figures of merit for determination of several

Fig. 5. Chromatograms of multi-component pesticides in water, obtained by the reversed-phase LC and postcolumn UV photolysis and fluorescence detection technique. Column, Waters Resolve C18 (0.46 × 15 cm; 5 μm); sample injection volume, 400 μl; amount of each pesticide, 50 ng. 1, Carbetamide, retention time 5.45 min; 2, carboxin, retention time 7.77 min; 3, alachlor, retention time 14.09 min; 4, butachlor, retention time 19.80 min.

pesticides are given in Table 5. These analytical figures were determined from at least 6–10 measurements of various concentrations. The calibration equation was calculated by a least-squares program with Lotus software. The limit of detection for the analyte was evaluated from 6 or more fluorescence measurements of the lower concentrations. The standard deviation of measurements was within the range 3–5% RSD. Fluorescence signal peak heights, background noise (peak-to-peak) and blank measurements were recorded and detection limits were evaluated from the lower concentrations for a signal-to-noise ratio of 3. The limits of detection for the pesticides with this technique are in the lower μg/kg range. Typical analytical curves for these analytes were linear over an analyte mass

range of 2–3 orders of magnitude with the low end of the curves in the range of lower nanogram amounts.

Analytical applications

LC postcolumn UV photolysis followed by fluorescence detection was applied to the determination of pesticides in ground water samples. The samples were then fortified with pesticides at various levels and the pesticides were determined again in the same way (four replicates). Least-squares and regression analyses of the data are shown in Table 6. The mean recoveries ranged from 95 to 115% at the lower μg/kg concentrations.

CONCLUSIONS

The postcolumn UV photolysis of 37 pesticide chemicals, followed photoinduced fluorescence detection by FIA and LC, with nine solvent-photosensitizer combinations showed that more

than two-thirds of these compounds produce high fluorescence responses upon UV photolysis. These analytes showed no fluorescence improvement without photolysis, indicating that the fluorescence improvement resulted from some of the phototransformation products. The relative fluorescence response of most analytes was very dependent on the solvent environment and on the presence or absence of photosensitizing agents. Fluorescence response measurements of the analytes after photolysis produced limits of detection in the lower nanogram range. Several pesticides were determined in ground water samples at $\mu\text{g}/\text{kg}$ concentrations with this LC postcolumn UV photolysis fluorescence detection technique. The recoveries for various analytes ranged from 95 to 115% at the lower $\mu\text{g}/\text{kg}$ concentrations.

SEPARATION OF TRACES AND LARGER AMOUNTS OF BISMUTH FROM GRAM AMOUNTS OF THALLIUM, MERCURY, GOLD AND PLATINUM BY CATION-EXCHANGE CHROMATOGRAPHY ON A MACROPOROUS RESIN

F. W. E. STRELOW

Division of Processing and Chemical Manufacturing Technology, C.S.I.R., P.O. Box 395, Pretoria 0001, South Africa

(Received 11 July 1989. Revised 27 August 1990. Accepted 26 February 1991)

Summary—Traces and larger amounts of bismuth (up to 50 mg) can be separated from gram amounts of thallium, mercury, gold and platinum (up to 5 g) by sorption from a mixture of 0.1M hydrochloric acid and 0.4M nitric acid on a column containing just 3 g (8.1 ml) of AGMP-50, a macroporous cation-exchange resin. This resin retains bismuth much more strongly than does the usual microporous resin (styrene-DVB with 8% cross-linkage). Other elements are eluted with the same acid mixture as that used for sorption, and bismuth is finally eluted with 1.0M hydrochloric acid. Separations of bismuth are sharp and recoveries quantitative. Only microgram amounts of the other elements remain in the bismuth fraction. Amounts of bismuth as little as 5 μ g have been separated from 5 g of thallium, and determined (r.s.d. = 2%) by flame atomic-absorption. Only 100- μ g amounts of bismuth have been separated from gram amounts of mercury, gold, and platinum, but there is no reason to believe that smaller or larger amounts of bismuth cannot be separated from these elements and recovered with the same accuracy as that for the separation from thallium. The lower limit of the method is determination of 0.4 μ g of bismuth in 10 ml of solution (0.004 absorbance). An elution curve, the relevant distribution coefficients and the results of analysis of synthetic mixtures and two practical samples [thallium metal and mercury(II) nitrate] are presented.

The separation of bismuth from other elements by ion-exchange chromatography has received considerable attention during the past few decades. Probably the first selective method described was that of Lur'e and Filipova who found that bismuth was eluted by 0.05M sulphuric acid, containing 10 mg/ml potassium iodide, from a cation-exchange column, while copper and lead were retained.¹ Many other elements should also be retained.

One of the most selective and generally applicable methods available originates from the work of Nelson and Kraus² who showed that bismuth is retained by strongly basic anion-exchange resins from hydrochloric acid media over practically the whole acid concentration range. Lead can be eluted with 8M hydrochloric acid, followed by elution of iron(III) and most other elements with 0.5M hydrochloric acid. Bismuth is retained and can be eluted with 1M sulphuric acid. Cadmium, zinc and indium are only partially eluted and thallium(III), mercury(II), gold(III), platinum(IV) and palladium(II) are not eluted at all with 0.5M

hydrochloric acid. They accompany bismuth either partially or completely. Numerous variations of this method have appeared in the literature.

Even more selective is anion-exchange in nitric-hydrobromic acid mixtures.³ As much as gram amounts of cadmium can be separated from traces of bismuth by eluting cadmium with 0.03M hydrobromic acid in 2M nitric acid, from a quite small column. This separation is not possible by anion-exchange in pure hydrochloric or hydrobromic acid (or iodide) media, because both elements are strongly retained even at low acid concentrations and show only minor differences in their anion-exchange behaviour in pure halide solutions.

Some species, such as thallium(III), gold(III), mercury(II) and platinum metals, which form very stable chloride or halide complexes, are retained together with bismuth by anion-exchange resins from halide-containing solutions over practically the whole concentration range. Separations of these elements from bismuth by anion-exchange procedures in

halide solutions are therefore difficult or impossible.

It has been shown that bismuth can be sorbed selectively from 8M ammonium nitrate,² or from nitric acid-methanol mixtures,⁴ but the large salt concentrations in the first case could cause problems, and mercury(II), gold(III) and palladium(II) are also sorbed from nitrate or nitric acid-methanol solutions.

A different approach for separation of bismuth from large amounts of thallium has been described recently.⁵ The bismuth is retained from dilute nitric acid by a cation-exchange resin with a low degree of cross-linkage (Bio-Rad AG50W-X4) and thallium, as Tl(I), is eluted with 0.6M nitric acid. As much as 2 g of thallium can be separated. Unfortunately, mercury(II) is also retained and cannot be cleanly separated from bismuth by this method. Large amounts of gold or platinum could cause problems in chloride-free solutions of dilute nitric acid because such solutions tend to become unstable (with respect to reduction to the metal) when the last traces of chloride are removed by repeated evaporations with nitric acid.

Recent publications^{6,7} indicate that macroporous cation-exchange resins such as Bio-Rad AG MP-50 retain bismuth much more strongly from dilute hydrochloric acid solutions than the usual gel-type resin with 8% divinylbenzene (DVB) cross-linkage does, whereas the sorption of mercury(II), gold(III), thallium(III) and platinum(IV) does not change significantly. This seemed to offer good prospects for the separation of traces and also larger amounts of bismuth from large amounts of these species.

Also, because bismuth forms an oxychloride that is quite insoluble in very dilute hydrochloric acid, but becomes more soluble with increase in chloride as well as hydrogen-ion concentration, and distribution coefficients for bismuth are much larger in nitric than in hydrochloric acid,⁷ the use of nitric-hydrochloric acid mixtures as eluting agents seemed to offer possibilities for separating larger amounts of bismuth and for achieving separations on relatively small columns. Distribution coefficients have been determined for bismuth on a gel-type 8% cross-linked resin in the mixed acids,⁸ but such information does not exist for macroporous resins. This paper therefore presents distribution coefficients for bismuth(III) on a macroporous resin in nitric-hydrochloric acid mixtures. The results are used to develop a method for the quantitative separation of traces and larger

amounts of bismuth from thallium(III), gold(III), mercury(II) and platinum(IV).

EXPERIMENTAL

Reagents

Reagents were of analytical grade purity unless stated otherwise, and distilled water was further purified by passage through an Elgastat demineralizer. A standard solution of bismuth was prepared by dissolving 2.000 g of bismuth metal (99.98% pure) in nitric acid, evaporating to dryness on a water-bath, and making up to 1000 ml with 0.50M nitric acid. Solutions containing lower concentrations of bismuth were prepared by dilution as required. Solutions of thallium(III), gold(III) and platinum(IV) were prepared by dissolving the pure metals in *aqua regia*. After evaporation to dryness on the water-bath, the remaining salts were dissolved in hydrochloric acid and the solutions were diluted to the required volume in 0.1M acid (for thallium) or 0.5M acid (for gold and platinum). The gold(III) solutions contained 40 mg/ml of the metal, platinum(IV) solutions 20 mg/ml, and thallium (III) solutions 100 mg/ml. The thallium solution also contained some free chlorine to ensure that thallium was in the +3 oxidation state. Before the final dilution to volume the solutions were purified from traces of bismuth by passing them (in about 0.1M hydrochloric acid) through columns containing 5 g of AGMP-50 resin, washing with 0.1M hydrochloric acid and making up to volume with the same acid (thallium) or adding the concentrated acid to give a final acid concentration of 0.5M (gold, platinum).

The resin was the Bio-Rad AG MP-50 macroporous sulphonated polystyrene cation-exchanger, 100-200 mesh.

Apparatus

Borosilicate glass tubes of 11.8 mm i.d. and 150 mm length, fitted with a No. 1 porosity sintered-glass plate and a burette tap at the bottom, served as columns. The top was connected to an additional piece of wider tube (20 mm i.d., 100 mm long) fitted with a B19 joint to take a separating funnel as reservoir.

The columns were filled with a slurry of AG MP-50 (100-200 mesh) resin in the hydrogen form until the settled resin reached the 8.1 ml mark (3 g of dry resin). The resulting resin column was 74 mm long in water. Because the resin, as received, was found to contain appreci-

able amounts of calcium (about 1 mg per g of dry resin), it was purified by passage of about 200 ml of 5*M* nitric acid followed by 50 ml of demineralized water.

A Varian-Techtron AAS instrument was used for atomic-absorption spectrometry (AAS) with an air-acetylene flame, for all elements. For the smallest amounts of bismuth (20 and 5 μg) a slotted tube made of transparent fused silica, similar in construction to the slotted stainless-steel tube described by Watling,⁹ and Watling and de Villiers¹⁰ was used. The use of the slotted tube enhanced the absorbance signal by a factor of about 3, stabilized the signal, and made it possible to obtain an absorbance of about 0.2 for 2 ppm of bismuth with only moderate scale expansion ($\times 2$).

Distribution coefficients in nitric acid-hydrochloric acid mixtures

Portions (2.500 g) of AG MP-50 resin (dried at 110°) were equilibrated in a mechanical shaker for 24 hr at 20° with 250 ml of a solution containing 10 mg of bismuth and the concentrations of nitric and hydrochloric acid shown in Table 1 and Fig. 1. After equilibration, the resin was separated from the aqueous phase by filtration through a glass column that was 200 mm long and 23 mm wide (i.d.), with a No. 1 porosity sintered-glass plate at the bottom. The resin was transferred into the columns and washed with demineralized water, and the aqueous phase was retained. The sorbed bismuth was then eluted with $\sim 1M$ hydrochloric acid and also retained. The amounts of bismuth in the two phases were determined by flame atomic-absorption after suitable dilution, and the distribution coefficients calculated from the analytical results. The coefficients are presented in Table 1 and Fig. 1.

Elution curves

A solution containing 5.00 g of thallium(III) and 30 mg of bismuth in about 250 ml of 0.10*M* hydrochloric acid containing 0.40*M* nitric acid

[HNO ₃], M	[HCl], 0.1 <i>M</i>	[HCl], 0.2 <i>M</i>
0.2	4860	243
0.3	1720	120
0.4	790	67
0.5	385	41.0
1.0	41.1	7.6
2.0	3.8	1.7

Fig. 1. Distribution coefficients for bismuth in hydrochloric/nitric acid mixtures, 0.50*M* total acid concentration.

was passed through a clean column of 8.1 ml (3 g) of AG MP-50 resin as described above. The column had been conditioned by passage of about 20 ml of a mixture of 0.10*M* hydrochloric and 0.40*M* nitric acid. The solution was washed onto the resin with a few small portions of the acid mixture, which was also used to elute thallium at a flow-rate of 2.0 ± 0.3 ml/min, a total of 100 ml being used. Finally bismuth was eluted with 1.0*M* hydrochloric acid at the same flow-rate. Ten-ml fractions were collected from the beginning of the sorption step, with an automatic fraction collector. The concentrations of thallium and bismuth in the fractions were determined, after suitable dilution, by flame AAS (standard conditions). The experimental elution curve is shown in Fig. 2.

In another experiment, the elution of thallium was continued to establish how strongly 30 mg of bismuth was retained; no bismuth appeared in the first 500 ml of effluent. Elution curves for Au(III), Hg(II) and Pt(IV) were very similar to the curve shown for thallium in Fig. 2.

Fig. 2. Elution curve for Tl(III)-Bi(III) mixture, sorbed from 0.10M HCl + 0.40M HNO₃ on 8.1 ml (3 g) of AG MP-50 resin (100-200 mesh). Flow-rate 2.0 ± 0.3 ml/min.

Quantitative separation of synthetic mixtures

Five-ml volumes of a standard solution containing 1.00 μg/ml bismuth in 0.5M nitric acid were added to five bismuth-free solutions, each containing 5.00 g of thallium. Enough 1M hydrochloric and 5M nitric acid were added to give 0.1 and 0.4M concentrations, respectively, when the solutions were diluted to 250 ml. The solutions were then passed through columns containing 3 g of AG MP-50 resin as described earlier. Each was washed onto the resin quantitatively with a few small portions of a mixture of 0.10M hydrochloric and 0.40M nitric acid, then the thallium was eluted with 100 ml of the same reagent at a flow-rate of 2.0 ± 0.3 ml/min. Finally bismuth was eluted with 80 ml of 1.0M hydrochloric acid at the same flow-rate. The bismuth fractions were evaporated to about 1 ml, finally in a 25-ml beaker, and then transferred into 10-ml standard flasks. Triplicate blanks were treated in the same way.

Bismuth was determined in both samples and blanks by flame AAS with the slotted transparent fused-silica tube as already described. The mean blank value was used to correct the recoveries obtained for the synthetic mixtures. The amounts of thallium remaining in the bismuth fraction were also determined by AAS. The experiment was repeated with 20 μg, 100 μg, 500 μg, 2000 μg, 20.00 mg and 50.0 mg amounts of bismuth, more concentrated standard solutions being used for the larger amounts.

The 20-μg amounts were determined by flame AAS with the slotted tube, but direct AAS

without the tube was used for the 100-μg, 500-μg and 2.000-mg amounts. The 500-μg amounts were determined in a volume of 25 ml and the 2.000-mg amounts in 100 ml. The 20.00 and 50.00-mg amounts were determined by titration with EDTA, (Xylenol Orange as indicator). Next, the separation was tried for 100-μg amounts of bismuth and 5.00-g amounts of mercury(II). Then the same amounts of bismuth were separated from 2.00 g of gold(III) and from 1.00 g of platinum by the same procedure.

Determination of bismuth in thallium metal and mercury(II) nitrate

Thallium metal (5 g) and mercury(II) nitrate (8.09 g ≡ 5.00 g of mercury) were separately weighed out accurately into 400-ml beakers. The thallium was dissolved in *aqua regia* and the solution was evaporated to dryness on the water-bath, after some chlorine water had been added. The dry thallium salts were dissolved in about 250 ml of a mixture of 0.10M hydrochloric and 0.40M nitric acid, again with addition of some chlorine water. The mercury(II) nitrate was dissolved in 250 ml of the acid mixture. The separation was performed as described above for the synthetic mixtures. Three blanks were taken through the whole procedure. Finally the bismuth fractions of the samples and blanks were evaporated to ~1 ml, then accurately made up to 10.0 ml and analysed for bismuth by flame AAS with the slotted silica tube and scale expansion.

Table 2. Determination of bismuth in synthetic mixtures

Bismuth taken	Other element taken	Bismuth found	Amount of other element in Bi fraction
5.00 μg	5.00 g Tl	$5.0 \pm 0.1 \mu\text{g}$	60–125 μg

RESULTS AND DISCUSSION

The results for the analysis of synthetic mixtures are presented in Table 2 and those for the analysis of two practical samples in Table 3. These show that the method provides a sharp and quantitative separation of bismuth from gram amounts of thallium, mercury, gold and platinum. As much as 50 mg of bismuth can be separated from 5 g of thallium, mercury, gold or platinum on a column containing just 3 g of AG MP-50 resin. Such a separation is not possible on a similar column of gel-type AG 50W-X8 resin. The distribution coefficient in 0.10M hydrochloric/0.40M nitric acid mixture is 790 (Table 1) for the macroporous resin, compared with 51 for the microporous resin. A much larger column, with 20 g of resin, would therefore be required if a gel-type resin were used. At lower acid concentrations the coefficients for the gel-type resin do increase, but then the solubility of bismuth oxychloride decreases very sharply. Nevertheless, both resins can be used to separate traces of bismuth from large amounts of the other elements named above. However, at the lower acid concentrations which have to be used, the gel-type resin tends to retain considerably larger amounts of the other element together with bismuth (up to several milligrams out of some grams). As little as 5 μg of bismuth has been separated from 5 g amounts of the

other elements and determined in synthetic and practical samples (Tables 2 and 3) with a coefficient of variation of about 2% for 5- μg amounts and better than 1% for 20- μg amounts, and is much smaller for the largest amounts tested. Only microgram amounts of the other elements, which do not interfere, remain in the bismuth fraction. The lower limit of the method, based on the amount of bismuth in 10 ml of solution that will give an absorbance of 0.004 is about 0.4 μg , or 0.08 ppm in a 5-g sample.

Blank runs gave values which were uncertain and at the limit of detectability, about 0.1 μg or less. Obviously considerably smaller amounts and concentrations of bismuth could be separated and determined with use of electrothermal (furnace) AAS for the determination. This could not be investigated because the instrumentation, though available, was not operational.

It may be of interest that a considerably smaller fraction of the gold is retained by the macroporous resin from the hydrochloric-nitric acid mixture used for this work (7–11 μg out of a total of 2.00 g) than that retained by a gel-type resin, such as AG 50 W-X8, from 0.10M hydrochloric acid (8–17 μg out of a total of 50 mg).¹¹ Also, the relatively large amounts of thallium (about 0.1 mg) and the amounts of the other elements that accompany bismuth can be reduced to a few μg , when required, by use of 0.20M hydrochloric acid/0.30M nitric acid mixture as the sample medium and eluent, even though the distribution coefficient for bismuth is only 120 under these conditions and somewhat larger columns (5 or 6 g of resin) have to be used when the sample volume is 250 ml.

Though palladium, rhodium and iridium have not been investigated, these elements

Table 3. Determination of bismuth in practical samples

Sample	Sample weight, g	Bi found,* ppm
Thallium metal (Fluka, <i>puriss.</i>)	5.00	2.34 ± 0.05
Mercury(II) nitrate (Merck, <i>p.a.</i>)	8.09 (\equiv 5.00 g Hg)	0.18 ± 0.03

*Mean and standard deviation of five analyses.

should also be separated by the method. Some low-level tailing could occur, so it is possible that traces of these elements might remain in the bismuth fraction.

(Received 28 November 1990. Revised 12 February 1991. Accepted 20 February 1991)

Summary—A new polymer matrix based membrane electrode with an ion-exchanger responding to calcium was constructed by dissolving the copolymer ethylene-vinyl-acetate together with the ion-exchanger in chloroform in the presence of a mixture of dioctylphthalate-nitrobenzene as plasticizer. The ion-exchanger used as the electroactive component was calcium didecyl phosphate in di-(*n*-octylphenyl) phosphonate (Orion). This electrode exhibited near-Nernstian response over the concentration range 10^{-1} – 4×10^{-6} M calcium. The pH did not affect the electrode performance within the range 8–11. Response time varied from 15 to 120 sec and the lifetime exceeded six months. The membrane is subject to static charge buildup, but this is avoided by controlling the level of dryness of the membrane. Selectivity coefficients determined for both monovalent and divalent cations showed negligible interference by most of these ions. The electrode was applied successfully to the determination of calcium in commercial mineral waters.

The use of ion-selective membrane electrodes is finding increasing application in pharmaceutical analysis.¹⁻³ The development of sensors that are easy to use and maintain, fast-responding, with low cost materials have boosted the use of potentiometric methods. Traditional methods for analysis utilizing spectrophotometry,⁴ polarography,⁵ chromatography⁶ and enzymatic measurements⁷ that may be characterized in some cases by low detection limits and high selectivity may possess limitations such as toxicity of reagents, high cost and complexity of the apparatus or the procedure.

Ion-selective polymer-membrane electrodes based on ion-pair or chelating ligand complexes entrapped in the polymer, suffer from problems such as interferences and leaching of the active component and the plasticizer⁸⁻¹⁰ from the polymer matrix. The leaching, which causes the deterioration of the response of the electrodes and leads to limited electrode lifetime, depends primarily on the nature (the lipophilicity) of the softener and the membrane active component.¹¹ In order to minimize the problems of interference, the use of alternatives

to poly(vinyl chloride) (PVC) as the polymer matrix have been suggested.⁸ However, depending on the polymer used, the electrodes may exhibit poorer performance. Hence, the use of VAGH copolymer (hydrolyzed vinyl chloride/vinyl acetate) for calcium electrodes offers no advantages,⁸ while poly(vinyl isobutyl ether) exhibits the same behavior as a PVC electrode containing the same sensing ingredients.¹²

In this paper, we describe the use of ethylene-vinyl-acetate copolymer (E/VAC) as the matrix membrane for construction of ion-selective polymer-membrane electrodes. The use of this copolymer in an ISE has not previously been reported. The structure is as follows:

A new method for the assembly of this electrode was developed. This new membrane has been characterized for use in construction of a calcium ion-selective electrode. The proposed electrode exhibits high selectivity for calcium

*Author for correspondence.

over many cations. The main advantages and disadvantages of the electrode are compared with the ISE, previously developed for the determination of calcium.

EXPERIMENTAL

Reagents

All reagents were of analytical-reagent grade and were used without further purification. E/VAC, 40% weight of the vinyl acetate monomer in the copolymer, (LEVAPREN 400, $m < n$) Bayer was kindly supplied by Professor G. Geuskens (ULB). Sources of all other reagents were as follows: tetrahydrofuran, chloroform and dioctyl phthalate from Janssen and nitrobenzene from Merck. All solutions were prepared in Milli-Q water. Stock solutions, $10^{-1}M$, were stored at room temperature and standard solutions were prepared from stock solutions by sequential dilution with Milli-Q water.

Preparation of the electrode

A commercially available solution of Orion 92-20-02 calcium didecyl phosphatate in di-(*n*-octylphenyl) phosphonate was used as the electroactive material for the calcium ISE. Membranes were prepared by dissolving the electroactive material ($100 \mu\text{l}$) and about 350 mg of E/VAC in 4 ml of an appropriate solvent (chloroform) at about 60° in a water bath. To this solution is added 1 ml of both dioctyl phthalate and nitrobenzene as plasticizer and the mixture was exposed to ultrasound to insure good dispersion of electroactive material in the matrix.

Ag/AgCl	$10^{-1}M$ CaCl ₂	Membrane E/VAC	Sample solution Ca ²⁺ (xM), pH (y)	Buffer bridge	KCl saturated	Hg ₂ Cl ₂ /Hg
---------	------------------------------	-------------------	--	------------------	------------------	-------------------------------------

A simplified scheme of the electrode is shown in Fig. 1. A micropipette tip was used as the electrode body. The end of the tip was dipped in the polymer mixture for a few seconds and then it was left in air for three hours. Longer drying times should not be used, in order to minimize static electricity build up. Calcium chloride solution, $10^{-1}M$, was used as the internal reference solution, and the internal reference electrode was an Ag-AgCl electrode. The electrode was activated before use by soaking it overnight in a $10^{-1}M$ solution of calcium chloride and it was stored in the same solution when not in use.

Fig. 1. Schematic diagram of the electrode: (1) coaxial cable; (2) glass tube; (3) cable junction; (4) parafilm; (5) micropipette tip; (6) glass tube; (7) $10^{-1}M$ CaCl₂; (8) Ag/AgCl; (9) E/VAC membrane.

Potential measurements

Potentiometric measurements were carried out at room temperature with a Tacussel Ion processor II. A Tacussel 6000 pH-meter with a Tacussel glass electrode was used to measure pH. A saturated calomel electrode was employed as the reference electrode in both measurements. Electrode response was examined by immersing the membrane electrode in 10 ml of buffered solution together with the double junction saturated calomel reference electrode. The cell used to investigate the characteristics of the electrode may be represented as follows:

The calibration curves were generated by addition of a 0.1-ml aliquot of 10^{-6} – $10^{-1}M$ aqueous primary ion solution to 10 ml of the stirred solution. The potential was recorded when the reading became stable (± 0.1 mV/10 sec) after each addition. The data were plotted as observed potential *vs.* the logarithm of the concentration of the primary ion. Concentration of calcium in commercial mineral water were then determined in a similar manner by means of a calibration graph, and the values obtained were checked by standard addition.

RESULTS AND DISCUSSION

Membrane materials

It has been suggested that polymers with low glass transition temperatures (T_g) are suitable matrices for polymer membrane electrodes.¹³ Our results agree with this hypothesis since polystyrene ($T_g = 100^\circ$) tested in our laboratory resulted in electrodes with no response, while good results have been found for the measurement of both organic (methixene, promethazine and some local anesthetics) and inorganic (calcium) cations by using E/VAC matrix whose glass transition temperature is below room temperature ($T_g = -50^\circ$). This study reports the results for the measurement of calcium ions. An advantage of E/VAC is the wide range of solvents that can be used to dissolve it, which allowed the use of alternatives to tetrahydrofuran and cyclohexanone commonly used with PVC. Six solvents are able to dissolve E/VAC: carbon tetrachloride, chloroform, dichloromethane, *p*-xylene, tetrahydrofuran and toluene. From a response-stability point of view, the use of E/VAC instead of PVC causes an excessive susceptibility of the electrode to static electricity if allowed to become too hard, but this problem can be avoided by controlling the level of dryness of the membrane. Excellent potential stability could be achieved by limiting the dryness to an extent that provides for minimum mechanical strength of the membrane in the ISE, accomplished by allowing to air dry for three hours only.

The technique described for the assembly of the electrode, in which the sensor is inserted into the end of a micropipette tip, demonstrates the use of a simple and inexpensive material for the body of the electrode and insures good protection of the sensor against solution turbulence.

Response characteristics of the electrode

Several parameters were investigated for optimal performance of the electrode. Typical calibration curves obtained for electrodes containing different amounts of calcium ion-exchanger, after one night of conditioning in 0.1M calcium chloride are shown in Fig. 2. The optimal tested amount of the Orion sensor reagent appears to be 0.1 ml per 6 ml of polymer mixture, for maximum potential response to calcium ion. The electrode demonstrates, under these conditions, a linear response in the 10^{-1} – 10^{-5} M range, with a useful range extended to 5×10^{-6} M, a slope of about 26 mV per concen-

Fig. 2. Dependence of the Ca^{2+} E/VAC membrane electrode response on the calcium ion-exchanger content per 6 ml of polymer mixture. (\square) 20 μl (\blacksquare) 50 μl (\circ) 100 μl (\bullet) 200 μl (+) 500 μl (\times) 1 ml. pH 9.4, Beckman Buffer.

tration decade and a correlation coefficient of 0.9996. The range of linear response for the first three electrodes (Orion sensor reagent > 0.1 ml) can be extended to 10^{-1} M by a much longer period of activation or after several uses of the electrode.

An electrode prepared under the condition of 100 μl of sensor reagent without any other softener gives no response at all. Therefore, we selected the mixture dioctylphthalate nitrobenzene as plasticizer for our calcium ISE. The performance of the electrode with time (Fig. 3)

was evaluated from calibration curves obtained over six months. In fact, measurements with this electrode prior to any activation step showed a short range of linear response and long response time. Figure 3 was evaluated from calibration curves obtained over six months. During the first week of conditioning, a large variation in the potential was observed. However, after this stage of stabilization, the change in the potential was about 9 mV over six months of use (Fig. 3, linear portions). After six months of use, the lower limit of linear response was $4 \times 10^{-6}M$. And the detection limit (Fig. 3, lowest curve), taken as the calcium concentration at which the potential deviated by $S \log 2$ from the extrapolation of the linear portions of the calibration curve, was $10^{-6}M$.

The major effect of conditioning was to lower the response time of the electrode. The response time depended on the concentration of the test solution. For electrodes conditioned for one week, fast response (ca. 15 sec for 95% response) was observed with solutions $> 10^{-3}M$ while in more dilute solutions, as much as 2 min or more were required for 95% response.

Table 1 summarizes the characteristics of the E/VAC membrane calcium electrode compared with those of a PVC membrane electrode of similar composition prepared in our laboratory and those reported for PVC membrane calcium electrodes based on the same ion-exchanger. The E/VAC membrane electrode shows more-or-less the same performance as the PVC electrode prepared in this study. The limit of linear response is lower than that of other reported PVC electrodes. The slope found here is less than that reported for PVC based electrodes.^{14–16} While we cannot assume a lifetime as long as the eighteen months of the conventional electrode,¹⁶ the calibration parameters found for our electrode after six months of continuous use

indicate a long durability of this electrode. It is evident from Table 1, when comparison is made between E/VAC and PVC electrodes prepared under the same conditions, that E/VAC is as useful as a PVC like matrix membrane for ion-selective electrode construction.

Effect of pH and foreign cations

The pH dependence of the electrode potential was tested over the range 4–11 for 10^{-4} – $10^{-1}M$ calcium chloride (Fig. 4). The pH values of the solutions, prepared in a Beckman buffer at pH 4.9, were adjusted by addition of small volumes of 10M sodium hydroxide solution. The well known dip in the potential–pH curves which characterizes calcium ISEs based on calcium bis-dialkylphosphate type sensor^{17,18} appears for the present membrane below pH 7. The plots in Fig. 4 indicate that at pH 8–11, the potentials are constant. Potentiometric measurements were therefore done at pH about 9.4. We note that at this pH, the electrode exhibits the same

Fig. 4. pH-effect on the Ca^{2+} E/VAC membrane electrode response at four different concentrations of calcium chloride.

characteristics by changing the buffer from a Beckmann buffer to an acetate buffer.

In order to investigate the selectivity of this new membrane, the response of the electrode was examined in the presence of various foreign cations. Potentiometric selectivity coefficients $K_{Ca^{2+}, X^{z+}}$ given in Table 1 were evaluated by both the separate solution method and the mixed solution method following the equation

$$K_{Ca^{2+}, X^{z+}} = [Ca^{2+}]/[X^{z+}]^{2/z}$$

where z is the charge on the foreign ion, $[X^{z+}]$ is its concentration and $[Ca^{2+}]$ is the concentration of calcium that provides equal response to that of the interfering ion under investigation. According to the separate solution method, the electrode potentials were measured for solutions containing only interfering ion. Then the calcium ion concentration that produced the same potential as the foreign ion at $[X^{z+}]$ was determined graphically from the calibration curve established in the absence of any foreign ion. In the mixed solution case, calibration curves were established by measuring potentials of the solutions containing a constant concentration of interfering ion and varying the concentration of calcium from 10^{-6} – $10^{-1}M$. The concentration at which the potential deviates by S log 2 from the extrapolation of the linear

portion of the curve was considered as $[Ca^{2+}]$. If such deviation caused by the presence of the interfering ion did not begin at a concentration of calcium above $4 \times 10^{-6}M$ for the E/VAC electrode and $3 \times 10^{-6}M$ for the PVC electrode, which are the Nernstian limits in a pure solution of calcium, we have considered $K_{Ca^{2+}, X^{z+}}$ as $<10^{-4}$. The cations investigated with the concentrations stated in Table 2 are completely soluble in water at the working pH (9.4) of the electrode.

The selectivity coefficients listed in Table 2 show that the E/VAC membrane calcium electrode has a high selectivity for calcium over many cations, especially relative to Na^+ , K^+ and Mg^{2+} , which are usually present in real samples. Only Mn^{2+} ions interfere significantly. Despite the small selectivity coefficient for Hg^{2+} , the calibration curve obtained in the presence of $10^{-3}M$ Hg^{2+} shows a strong deviation from linearity between 10^{-1} and $10^{-2}M$ calcium. However, the electrode is not affected by immersing it in a solution of Hg^{2+} since complete recovery of the calcium response is observed after washing the electrode, without a need for reconditioning. Generally speaking there is good agreement between the selectivity coefficient values of our E/VAC electrode and those published¹⁴⁻¹⁷ for PVC electrodes, especially when the mixed solution method was applied.

	Nominal	Nominal	Found \pm S.D. (n = 5)	Percent accuracy
1	1.3	3.5	3.62 ± 0.07	103
2	0	20	20.2 ± 0.8	101
3	22	23	22.9 ± 0.4	99.6
4	18	65	68 ± 2	105
5	24	78	78 ± 1	100
6	4.2	101	102 ± 4	101
7	36	202	201 ± 2	99.5
8	84	467	468 ± 9	100.2

The comparison is significant here since selectivity coefficients were each determined by the same procedure and under the same conditions. The main difference occurs with Cu^{2+} and Zn^{2+} ions. In contrast to the reported PVC membrane Ca^{2+} electrodes,^{15,16} the presence of Zn^{2+} ions does not alter the response characteristics of the E/VAC membrane towards Ca^{2+} . On the other hand, Cu^{2+} ions cause greater interference with the PVC electrode. Extending this comparison between the E/VAC and reported PVC membrane electrodes to the same membrane composition based PVC membrane electrode prepared in our laboratory allowed us to attribute the improvement of the E/VAC Ca^{2+} electrode parameters concerning interferences with Zn^{2+} and Cu^{2+} to the polymer E/VAC itself. In fact a PVC electrode plasticized with the mixture dioctylphthalate-nitrobenzene exhibits the same behavior in the presence of Zn^{2+} and Cu^{2+} ions as conventional PVC membrane electrodes plasticized with di-(*n*-octylphenyl)phosphonate.

Analytical application

With $10^{-6}M$ detection limit, the electrode described can be used for the determination of calcium in various samples by direct potentiometry. To investigate the applicability of this electrode, the calcium content of samples from different sources of commercially available mineral water was determined by simple immersion of the electrode in the diluted or undiluted sample adjusted to pH 9.4 by addition of a small quantity of concentrated acetate buffer. The potentiometric data listed in Table 3 are in good agreement with the nominal values listed on the bottle containers by the manufacturers. It is possible to determine calcium in the range 3–500 p.p.m. The presence of magnesium, even with a concentration equal to that of calcium in the investigated samples, did not affect the measurement. Recovery of calcium between 99 and 104% by standard addition indicates the feasi-

bility of using the E/VAC membrane Ca^{2+} electrode in analytical applications. A mean standard deviation of 2.4% demonstrates the precision of the method.

CONCLUSION

The use of E/VAC copolymer offers promise as an alternative to PVC in polymer membrane electrodes. The proposed calcium ISE is simple to prepare, inexpensive, easy to use and has a long lifetime. In general, the performance of this electrode is similar to that of PVC electrodes but its particular value lies in its stability toward zinc and other foreign inorganic cations. It exhibits improved selectivity for calcium with respect to copper and the alkali metals. This electrode was applied successfully for the potentiometric determination of calcium in mineral water. The new membrane has been successfully applied to construction of electrodes for the measurement of local anesthetic compounds (Tetracaine, Lidocaine and Procaine) based on ion-pair complexes.¹⁹

THALLIMETRIC OXIDATIONS—VI

TITRIMETRIC AND SPECTROPHOTOMETRIC METHODS FOR THE DETERMINATION OF PHOSPHITE AND ANALYSIS OF BINARY MIXTURES OF PHOSPHITE AND OXALATE

M. S. PRASADA RAO, A. RAMA MOHAN RAO, KARRI V. RAMANA and S. R. SAGI
Inorganic Chemistry Laboratories, Andhra University, Waltair 530003, India

(Received 21 June 1990. Revised 29 November 1990. Accepted 14 December 1990)

Summary—Titrimetric and spectrophotometric methods have been developed for the estimation of phosphite at mmole and μ mole levels, respectively. Thallium(III) is used as an oxidant and the thallium(I) produced is determined either oxidimetrically with potassium bromate or by measurement of the absorbance of thallium(III) at 260 nm in the presence of 0.1M hydrochloric acid and 1M perchloric acid. Based on the fact that phosphite and oxalate are oxidized under different conditions, methods are described for the analysis of binary mixtures of phosphite and oxalate. A method is also described for estimation of thallium(III) with phosphite as reductant, and is applied for analysis of mixtures of thallium(I) and thallium(III).

Few redox methods are available for the estimation of phosphite. Rupp and Kroll¹ determined it by treatment with excess of potassium bromate for 1 hr at room temperature or heating at 60° for 30 min in a sulphuric acid medium followed by iodometric titration of the excess. Bernhart² has described a method in which phosphite is oxidized quantitatively to phosphate by heating with cerium(IV) in sulphuric acid solution at 80–100° for 15 min, the excess of cerium(IV) being titrated with iron(II) solution, with ferroin as indicator. Boyer³ developed a method in which excess of iodine slowly oxidizes phosphite to phosphate in bicarbonate solution. The excess of iodine is back-titrated with 0.05M arsenite. Rao and Gowda⁴ oxidized phosphite by heating with vanadate for 20 min in a boiling water-bath in the presence of silver as catalyst, cooling, and titrating the surplus vanadate with 0.05M ammonium iron(II) sulphate with *N*-phenylanthranilic acid as indicator.

There are virtually no methods available for the estimation of phosphite in the μ mole range. We have therefore examined the reaction between thallium(III) and phosphite, and have developed convenient methods for the determination of phosphite in μ mole–mmole amounts.

It has been suggested⁵ that oxalate is likely to occur along with hypophosphite and/or phosphite and must be tested for whenever the purity of these chemicals is determined. We

therefore also examined analysis for phosphite and oxalate in mixtures on the basis of earlier work on the thallium(III)–oxalate system⁶ and the results of the present study.

Most of the thallium(III) complexes with reducing ligands are prone to redox decomposition, at least partially, at relatively high temperatures or in the presence of diffused light, even in the solid state, and some thallium(I) is always found to be present along with thallium(III).⁷ There is a need to analyse such samples and also certain complexes of thallium in mixed oxidation states.⁸ Methods for this have already been developed,^{9,10} and the thallium(III)–phosphite reaction can also be used.

EXPERIMENTAL

Reagents

Thallium(III) solutions in perchloric acid and sulphuric acid were prepared and standardized as reported earlier^{9,11} and their concentrations verified by other methods. An aqueous solution of disodium hydrogen phosphite, (B.D.H. analytical grade) was prepared and standardized by the method of Bernhart.² All other reagents were of analytical grade.

Apparatus

Although the photochemical reactions described take place much faster in direct sunlight,

this has variable intensity, so all the work was done with a Philips high-pressure mercury vapour lamp (200/250 V, 125 W) as the light source, placed 15 cm above the test solutions, which were contained in colourless uncovered glass vessels.

A Shimadzu UV-260 recording spectrophotometer with silica cells of 1-cm path-length was used for the absorbance measurements.

Titrimetric determination of phosphite (mmole range)

Thermal method. To an aliquot of samples containing 0.05–0.5 mmole of phosphite in a 250-ml round-bottomed flask add 20 ml of 5M perchloric acid and 1.5 mmole of thallium(III) and dilute to 100 ml. Reflux for 40 min. Add 15 ml of concentrated hydrochloric acid and cool to 60°. Add 0.1 ml of 1-mg/ml Methyl Orange indicator and titrate the thallium(I) with 0.05N potassium bromate (1.392 g/l.) until the indicator is destroyed. The method is also applicable in sulphuric acid medium.

Photochemical method. To an aliquot of sample, containing 0.05–0.5 mmole of phosphite, in a 200-ml beaker, add 20 ml of 5M perchloric acid, 0.075 mmole of bromide and 1.5 mmole of thallium(III), and dilute to 100 ml. Stir the solution and expose it to the radiation from the high-pressure mercury vapour lamp for 4 hr. Add 15 ml of concentrated hydrochloric acid, 0.1 ml of 0.1 mg/ml Methyl Orange indicator, heat to 60° and titrate with 0.05N potassium bromate (1.392 g/l.) until the indicator is destroyed. The method is also applicable in sulphuric acid medium. Although the method requires prolonged exposure to the mercury vapour lamp, it is useful for the determination of phosphite when heating has to be avoided.

Spectrophotometric determination of phosphite (μ mole range)

To an aliquot of sample, containing 0.5–1.25 μ mole of phosphite, add 1 ml of 5M perchloric acid and 5 ml of 5×10^{-4} M thallium(III). Reflux for 40 min. Transfer the solution to a 25-ml standard flask, add 2.00 ml of 11.6M perchloric acid and 2.5 ml of 1M sodium chloride and dilute to volume (solution I). Prepare a corresponding solution without phosphite (solution II). Mix well, and after 60 min measure the absorbance of solution II against solution I as reference, at 260 nm. The absorbance corresponds to the thallium(III) that has reacted.

Prepare a calibration graph by the same procedure. The amount of phosphite is in 1:1 molar ratio to the amount of thallium(III) that has reacted.

Photochemical method. To an aliquot of sample, containing 0.5–1.25 μ mole of phosphite, add 1 ml of 5M perchloric acid, 0.5 μ mole of sodium bromide, 5 ml of 5×10^{-4} M thallium(III) and expose the solution to the radiation from the mercury vapour lamp for 4 hr. Transfer the solution to a 25-ml standard flask, and complete the determination as above, measuring the absorbance of a reagent blank against the test solution as reference.

Determination of thallium(III) (mmole range)

The methods are the same as for determination of phosphite in the mmole range but a sample containing 0.05–0.5 mmole of thallium(III) is used with 1.5 mmole of phosphite.

RESULTS AND DISCUSSION

The reaction between thallium(III) and phosphite is slow, but is catalysed by light and is also considerably faster at elevated temperature. Separate studies had shown that phosphite does not interfere in the titration of thallium(I) with bromate, with Methyl Orange as indicator, so the reaction was used to monitor the progress of all the reactions described here. The reactions were carried out in sulphuric or perchloric acid medium.

The molar reacting ratio of thallium(III) and phosphite was found to be 1:1, as shown by the equation

A minimum of threefold molar ratio of thallium(III) to phosphite is required for rapid reaction, but higher ratios do not appear to increase the reaction rate very much. The use of halides to catalyse thallimetric oxidations has been reported,^{6,9,10,12–14} so bromide and chloride were tested as catalysts.

It was found that at high temperatures bromide itself reduces thallium(III) to thallium(I), so its effect on the thermal reaction between thallium(III) and phosphite could not be determined. It was found that the photochemical reaction is fastest when the thallium(III) to bromide ratio is in the range between 4:1 and 1:1. Under these conditions, thallium(III) is likely to be present as TlBr^{2+} (by analogy

with the chloride system¹⁵) and to be photochemically active. Chloride, even at low concentrations, retards both the photochemical and thermal reactions between thallium(III) and phosphite.

An increase in acid concentration up to 1*M* accelerates the rate of the photochemical reaction, but higher concentrations have no noticeable effect. Increase in acid concentration up to 3*M* also increases the rate of the thermal reaction, but with acid concentrations above 4*M* the detection of the end-point in the bromatometric titration becomes difficult. The results of these experiments led to development of the procedures described for titrimetric determination of phosphite. The recovery data in Table 1 show that the methods are satisfactory and accurate.

The absorption spectra¹⁶ of thallium(I) and thallium(III) in 1*M* perchloric acid/0.1*M* hydrochloric acid medium show that thallium(III) has considerable absorption at 260 nm (molar absorptivity 9.15×10^3 l.mole⁻¹.cm⁻¹) but thallium(I) does not absorb. The presence of phosphite and phosphate does not affect the absorption spectrum of thallium(III) under these conditions, and the thallium(III) species obeys Beer's law at 260 nm. In the spectrophotometric method for phosphite an excess of thallium(III) is allowed to react with phosphite either photochemically (with bromide as catalyst) or by heating. The amount of phosphite in the test sample corresponds to the amount of thallium(III) reduced to thallium(I), which can be read from the calibration curve. The method is quite accurate (Table 2).

Analysis of binary mixtures of PO_3^{3-} and $C_2O_4^{2-}$

Chloride and bromide ions in small concentrations catalyse the photochemical oxidation of oxalate by thallium(III).⁶ The photochemical reaction between thallium(III) and phosphite is extremely slow and inhibited by the presence of chloride. Hence oxalate can be selectively deter-

0.950	0.960	0.950

mined in the presence of phosphite by titrating bromatometrically the thallium(I) produced.

In the presence of sufficient bromide, both oxalate and phosphite are completely oxidized by thallium(III) either photochemically or by heating. In both cases, the thallium(I) formed can be determined bromatometrically. Hence the phosphite in a mixture with oxalate can be determined by difference. Typical results are shown in Table 3.

Determination of thallium(III)

It was also found that a threefold molar ratio of phosphite to thallium(III) would give a rapid reaction and that higher ratios do not appreciably alter the rate of reaction. The effect of acidity, chloride and bromide was then examined. The photochemical reaction was found to be reasonably rapid when the Tl(III):Br⁻ molar ratio was between 4:1 and 1:3 in 1*M* perchloric or sulphuric acid medium.

The method could therefore be applied to analysis of mixtures of thallium(I) and thallium(III) with two identical aliquots of sample. The first is titrated with potassium bromate (Methyl Orange as indicator). The second is mixed with phosphite and perchloric acid and either refluxed for 30 min or, in the presence of sufficient bromide, exposed to radiation from a mercury vapour lamp for 4 hr, and then titrated with bromate. The first titration gives the

0.500	0.125	0.505	0.120

amount of thallium(I) and the second gives the total amount of thallium, so the amount of thallium(III) is obtained by difference. Table 4 shows that satisfactory results are obtained.

Interferences

Cd(II), Zn(II), Ru(III), Co(II), Ni(II), Hg(II), Al(III), Pb(II), NH_4^+ , Na^+ , K^+ , Ca^{2+} , Ba^{2+} , SO_4^{2-} , CH_3COO^- , PO_4^{3-} , 2,2'-bipyridyl and 1,10-phenanthroline do not interfere even if present in 100-fold molar ratio to phosphite, but even traces of oxalate or hypophosphite interfere by reducing thallium(III) to thallium(I). Arsenite interferes with the bromatometric titration method itself. Cu(II) up to 0.05M and Fe(III) up to 0.01M do not interfere, but at higher concentrations their colours interfere with detection of the end-point in the bromatometric titration. Even traces of chloride retard the reaction, the effect increasing with chloride concentration. Though bromide catalyses the

reaction at concentrations up to a Tl(III):Br⁻ molar ratio of 1:1, further increase in bromide concentration retards the rate of the reaction.

SPECTROPHOTOMETRIC DETERMINATION OF ZIRAM, FERBAM AND ZINEB WITH DIPHENYLCARBAZONE

ASHOK KUMAR MALIK and A. L. J. RAO

Department of Chemistry, Punjabi University, Patiala 147002, India

(Received 9 August 1990. Revised 8 February 1991. Accepted 20 February 1991)

Summary—A procedure has been developed for the determination of ziram (zinc dimethyldithiocarbamate), ferbam (ferric dimethyldithiocarbamate) and zineb (zinc ethylenebisdithiocarbamate) after their decomposition and extraction of the diphenylcarbazone complexes of the zinc or iron into isobutyl methyl ketone. These complexes absorb strongly at 520 nm. The method is rapid, sensitive and selective and can be used for the determination of these dithiocarbamates in commercial and synthetic mixtures.

Dithiocarbamates have found a variety of applications in agriculture as pesticides and in the rubber industry as vulcanization accelerators and anti-oxidants. The toxicity of the dithiocarbamates is increased when they are in the form of heavy metal salts. The dithiocarbamates are generally determined on the basis of their decomposition by hot mineral acid to the amine and carbon disulphide. Most of the analytical methods for their determination are based on the Clarke method¹ in which the dithiocarbamate is decomposed in acidic solution to give carbon disulphide, which is then absorbed in methanolic potassium hydroxide solution, and the potassium methyl xanthate so formed is titrated iodimetrically. Various modifications of this method are reported in the literature.²⁻¹³ Dithiocarbamates have also been determined in vegetables by high-pressure liquid chromatography,¹⁴ titrimetry¹⁵ and extraction voltammetry.¹⁸ Ziram, ferbam and zineb have also been determined by converting these into copper^{17,18} or molybdenum¹⁹ complexes in acidic medium. The extraction of the molybdenum complexes is not rapid; for example, the molybdenum ethylenebisdithiocarbamate complex is extractable only after heating for 5 min. Here we present a new, simple, rapid, sensitive and selective method based on the determination of the zinc(II) and iron(III) present in ziram, zineb and ferbam, respectively, by converting them into diphenylcarbazone complexes.

EXPERIMENTAL

Equipment

A digital ECIL pH-meter and an SP-20 Spectronic spectrophotometer were used.

Reagents

All solvents and reagents were of analytical reagent grade.

Ziram, ferbam and zineb solutions, 1 mg/ml. Pure ziram and zineb were obtained from Wilson Laboratories, Bombay. Ferbam was prepared in the laboratory by the method given in the literature.²⁰ The purity of these samples was checked by elemental analysis and by determining their zinc and iron content by EDTA titrations, with Eriochrome Black T and Xylenol Orange, respectively, as indicators.²¹ Stock solutions of ziram and zineb were prepared by dissolving 0.100 g in 100 ml of 0.1M and 0.5M sodium hydroxide, respectively, and of ferbam by dissolving 0.100 g in 100 ml of acetonitrile. These solutions were standardized²¹ and further diluted with sodium hydroxide solution or acetonitrile as required.

Diphenylcarbazone solution, 3 mg/ml. Diphenylcarbazone (0.300 g) was dissolved in 100 ml of absolute ethanol.

Pyridine solution, 50 mg/ml. Pyridine (5.0 g) was dissolved in 100 ml of water.

Buffer solution. Boric acid and potassium chloride solutions (0.2M, 100 ml of each) were mixed, adjusted to pH 9.0 with 0.2M sodium hydroxide, and diluted to 500 ml.

Other solutions. Stock solutions for interference studies were prepared by dissolving suitable salts in water. Synthetic samples were prepared by mixing solutions of suitable salts to give the required composition.

Isobutyl methyl ketone. The purity of the isobutyl methyl ketone was checked spectrophotometrically before use.

Procedure

To aliquots of sample solutions containing 0.12–1.90 $\mu\text{g/ml}$ ziram, 0.11–1.70 $\mu\text{g/ml}$ zineb or 0.35–4.80 $\mu\text{g/ml}$ ferbam add 2.0 ml of pyridine solution to ziram and zineb samples (but not to ferbam samples), and 3.0 ml of buffer solution, so that the pH after dilution to 25 ml is 9.0. Transfer into separating funnels, and add diphenylcarbazone solution (1.0 ml for ziram and zineb and 1.5 ml for ferbam) and 25 ml of isobutyl methyl ketone. Shake the mixtures for 5 min, separate the organic layers and measure the absorbances at 520 nm, against reagent blanks prepared under similar conditions.

RESULTS AND DISCUSSION

The absorption spectra of the zinc(II)–diphenylcarbazone–pyridine and iron(III)–diphenylcarbazone complexes were recorded against reagent blanks. The complexes absorb strongly at 520 nm. The maximum absorbance was observed when the pH of the aqueous phase was 9.0–10.0 for ziram and zineb, and 9.0–11.0 for ferbam, and when 0.8–1.0 ml of 3 mg/ml diphenylcarbazone solution was used for ziram and zineb, and 1.0–1.5 ml for ferbam. Smaller amounts of diphenylcarbazone gave incomplete complex formation, but larger amounts did not increase the absorbance. Therefore use of 1.0 ml for ziram and zineb and 1.5 ml for ferbam is recommended. The binary zinc–diphenylcarbazone complex is not completely extracted into isobutyl methyl ketone,²² but it has been observed that the complex is completely extractable in one step into isobutyl methyl ketone in the presence of 1–100 mg/ml pyridine in the aqueous phase; the extraction of the iron–diphenylcarbazone complex is unaffected by the presence or absence of pyridine.

Various organic solvents were examined for the extraction of the complexes in the presence of pyridine. Chou *et al.*²³ reported that pyridine enhances the extraction of zinc complexes through adduct formation. We have found that in the presence of pyridine the zinc–diphenyl-

carbazone complex is not extractable into diethyl ether and carbon disulphide but is extracted by benzene, n-butyl acetate, acetylacetone, n-amyl alcohol, n-amyl acetate, chloroform, carbon tetrachloride, toluene, isobutyl methyl ketone and ethyl acetate. Of these isobutyl methyl ketone and ethyl acetate were found to be the most effective. The extraction into isobutyl methyl ketone is slower than that into ethyl acetate, but because of the solubility of water in ethyl acetate isobutyl methyl ketone was selected for use. In isobutyl methyl ketone the complexes are stable for more than 8 hr.

The Job, mole-ratio and logarithmic methods indicated the formation of the 1:2:2 (M:L:Py) complex in the case of zinc and 1:3 (M:L) complex in the case of iron(III).

Analytical characteristics

The calibration curves, for measurement at 520 nm, were linear over wide concentration ranges, given in Table 1 along with other performance characteristics. The limit of detection was calculated by the IUPAC recommended procedure.²⁴

Interferences

Various foreign ions were examined for interference in the determination of 40 μg of ziram and zineb, and 100 μg of ferbam. Of the anions examined, the amounts (mg) shown in parentheses are tolerable: acetate (80), bromide (80), chloride (50), tartrate (50), thiosulphate (5); 100 mg of citrate, nitrate, oxalate, sulphate, sulphite or thiourea did not interfere, but metabisulphite and EDTA interfered strongly. Fluoride up to 100 mg is tolerable in the case of ziram and zineb, but only 2 mg in the determination of ferbam.

Of the cations examined, Cu(II) and Hg(II) interfered but could be masked with 1.0 ml of 50 mg/ml thiourea and potassium iodide solutions, respectively. Pb(II), Sn(IV), As(III), Ca(II), Cr(VI), Mo(VI) and Sb(III) are tolerable up to 1.0 mg and Hg(II), Bi(III) and Mn(II) up to 0.1 mg. Interference by free Zn(II) or Fe(III) is

Table 1. Analytical characteristics of the determination of ziram, ferbam and zineb with diphenylcarbazone at 520 nm

Characteristics	Ziram/zineb	Ferbam
Linear range, $\mu\text{g/ml}$	0.12–1.9/0.1–1.7	0.35–4.8
Detection limit, $\mu\text{g/ml}$	0.08	0.18
Molar absorptivity, $l.\text{mole}^{-1}.\text{cm}^{-1}$	8.36×10^4	5.3×10^4
Precision, RSD, %	0.9	1.0

avoided by prior extraction of ziram, zineb or ferbam into chloroform, followed by evaporation of the organic phase to dryness.

The mutual interference of ziram, zineb and ferbam was studied, along with the interference of some common pesticides such as thiram (tetramethylthiuram disulphide), nabam (disodium ethylenebisdithiocarbamate), maneb (manganese ethylenebisdithiocarbamate), vapam (sodium *N*-methylthiocarbamate) and dibam (sodium dimethylthiocarbamate). Pesticides containing no metal ion did not interfere in the determination of ziram, ferbam and zineb. Determination of ziram and zineb in the presence of ferbam and maneb was possible after masking with 2.0 ml of 50 mg/ml sodium fluoride and sodium citrate solutions, respectively. Ferbam in the presence of maneb was determined in the presence of 2.0 ml of 50 mg/ml sodium citrate solution. Ziram and zineb interfere in the determination of each other.

Simultaneous determination of ziram and ferbam, or zineb and ferbam

Ziram and ferbam or zineb and ferbam were taken in various proportions and dissolved in acetonitrile. Equal aliquots of the solution were analysed in the presence and absence of 2.0 ml of 50 mg/ml sodium fluoride solution. The difference in absorbance corresponded to the amount of ferbam.

Applications

The method is one of the most sensitive available for the determination of ziram, ferbam and zineb. Five dilutions of stock solutions prepared from "Ziram 27% S.C." and "Dithane Z-78" were analysed, with pure samples of ziram and zineb as references, and in all cases the recoveries were between 98 and 100% with a relative standard deviation of 2–3%.

Determination of ziram, ferbam and zineb in grain

The procedure was applied to the determination of ziram, ferbam and zineb in grain. A known amount of ziram, ferbam and zineb was crushed with 20 g of grain and the mixture was shaken mechanically with 100 ml of chloroform for an hour. The mixtures were filtered and the residues were washed with three 10-ml portions of chloroform. The extracts were evaporated to 2.0 ml in a current of dry air at room temperature. The ziram and zineb residues were dissolved in 0.1*M* and 0.5*M* sodium hydroxide,

Table 2. Recovery of ziram, ferbam and zineb from grain

	40	39.0	97.5

*Mean of three determinations.

respectively, and the ferbam in acetonitrile, and analysed by the general procedure. Untreated samples were taken as reference. The results are given in Table 2.

Comparison of sensitivity

The sensitivity of the present method is better than that of the methods of Lowen,¹² Cullen²⁵ and Chmiel,²⁶ which are based on the determination of liberated CS₂. It is also more sensitive than the direct methods reported by Rao *et al.*^{19,28} (5 and 2 $\mu\text{g}/\text{ml}$ ziram and zineb), Rangaswamy *et al.*^{17,18} (1 $\mu\text{g}/\text{ml}$ zineb and 0.8 $\mu\text{g}/\text{ml}$ ziram and ferbam) and Verma *et al.*²⁷ (0.6 $\mu\text{g}/\text{ml}$ ferbam). By the present method it is possible to estimate 0.12, 0.35 and 0.11 $\mu\text{g}/\text{ml}$ ziram, ferbam and zineb, respectively.

SPECTROPHOTOMETRIC DETERMINATION OF THALLIUM AFTER ITS EXTRACTION AS AN ION-PAIR OF THE CHLORO-COMPLEX AND PYRONINE G

K. KRISHNAN NAMBOOTHIRI, N. BALASUBRAMANIAN and T. V. RAMAKRISHNA*

Department of Chemistry, Indian Institute of Technology, Madras 600 036, India

(Received 21 September 1990. Revised 4 December 1990. Accepted 22 January 1991)

Summary—A sensitive and selective procedure for the spectrophotometric determination of thallium is described. The method is based on the formation of an ion-pair between $[TlCl_4]^-$ and the pyronine G cation in chloride-containing acid media. The ion-pair is extracted into benzene and permits the determination of as low as 0.3 μg of thallium in a final volume of 25 ml at 530 nm. The system obeys Beer's law in the concentration range 1–14 μg of thallium in a final volume of 25 ml. Potassium iodate was found to be highly effective for the oxidation of Tl(I) to Tl(III) and the presence of excess oxidant does not interfere. The method can be used for the determination of thallium in high purity cadmium, cadmium sponge and rock samples.

Numerous methods have been proposed for the spectrophotometric determination of thallium,¹ but the most sensitive ones are based on the ability of the anionic chloro- or bromo-complex of thallium(III) to interact with cationic dyes to form ion association complexes. Methods have been described based on the extraction of the ion-pair formed between the anionic bromo-complex and Brilliant Green² or Crystal Violet,³ and the chloro-complex and Methyl Violet,⁴ Rhodamine B⁵ Methylene Blue⁶ or Methylene Green.⁷ Thallium(I), if present, was oxidized to the trivalent state with Ce(IV),² bromine,^{3,5} hydrogen peroxide⁴ or sodium nitrite.⁶ As the presence of excess of oxidants destroyed the cationic dye, they were removed by boiling the solution (for hydrogen peroxide or bromine) or adding hydroxylammonium chloride [for Ce(IV)] or urea (for NO_2^-). Fogg *et al.*⁸ reviewed the methods which used basic dyes for the determination of thallium and other elements and indicated that problems can arise due to the incomplete oxidation of thallium(I) in the determination.

Our studies on the spectrophotometric determination of thallium(I) revealed that potassium iodate in acid medium is highly effective for its oxidation and the resulting thallium(III), as an anionic chloro-complex, can be made to interact with pyronine G and extracted into benzene. The blank absorbance was almost negligible and

was unaffected by the presence of unused potassium iodate. The method was found to be suitable for the determination of thallium(I) down to 0.3 μg in a final volume of 25 ml.

EXPERIMENTAL

Apparatus

A Carl-zeiss PMQ II spectrophotometer was used with 10-mm quartz cells.

Reagents

All reagents were of analytical grade.

Standard thallium (I) solution, 1000 ppm. Dissolve 1.303 g of thallium nitrate in 1 litre of distilled water containing 2 ml of concentrated nitric acid. Dilute an appropriate volume of this stock solution with water to provide a 2 $\mu\text{g}/\text{ml}$ solution.

Pyronine G, 0.025%. Dissolve 0.25 g of pyronine G in 1 litre of distilled water.

Potassium iodate, 0.025%. Dissolve 0.25 g of potassium iodate in 1 litre of distilled water.

Sulphuric acid, 10N.

Sodium chloride, 5%.

Potassium iodide, 2.5%.

Sodium nitrite, 0.5M.

Sulphamic acid, 5%.

Benzene (thiophene free). Used for extraction.

Procedure

Transfer the sample solution containing not more than 14 μg of thallium into a 60-ml separating funnel and add, while mixing, 1 ml

*Author for correspondence.

each of 10*N* sulphuric acid and 2.5% potassium iodide solution to reduce the thallium(III), if any, to thallium(I). Then, add 1 ml of 0.5*M* sodium nitrite solution and extract off the liberated iodine by equilibrating with 5 ml of benzene. Repeat the extraction if necessary and discard the organic layer.

Transfer the aqueous layer containing thallium(I) into a 25-ml standard flask and treat with 2 ml of a 5% solution of sulphamic acid. Add, with mixing, 5 ml of 10*N* sulphuric acid followed by 2 ml each of 5% sodium chloride, 0.025% pyronine G and 0.025% potassium iodate solutions and dilute to the mark with water. Mix well and allow the solution to stand for 20 min. Transfer the solution into a 60-ml separating funnel and equilibrate with 10 ml of benzene for 2 min. Separate the organic layer and treat with 0.5 g of anhydrous sodium sulphate. Measure the absorbance of the benzene extract at 530 nm with 10-mm cells against a reagent blank. Establish the concentration of thallium by reference to a calibration graph prepared for 1–14 μg of thallium, following the procedure described.

RESULTS AND DISCUSSION

Preliminary experiments were carried out in 2*N* sulphuric acid medium containing 10 μg of thallium(I) and 2 ml each of 5% sodium chloride, 0.025% pyronine G and 0.025% potassium iodate in a final volume of 25 ml. The solutions were equilibrated for 5 min with 10 ml of benzene. The results indicated that the extraction of the ion-pair into benzene was selective as the absorbance of the blank at 530 nm, where the ion-pair absorbed maximally, was found to be negligible. The presence or absence of iodate in the medium had no effect on the blank and the intensity of the absorbance of the sample extract was found to increase in

direct proportion to the amount of thallium(I) present.

The effect of various experimental parameters on the thallium(I) reaction was therefore examined in detail. The results are summarized in Table 1. Except for the study of the effect of acidity, the overall acidity was maintained at 2*N* in a final volume of 25 ml. Extractions were conducted with 10 ml of benzene and the absorbances of the extracts were measured at 530 nm in 10-mm cells.

A reaction time of 20 min was found necessary before extracting into benzene. Equilibration of the phases for about 2 min was found to be sufficient for the quantitative extraction of the ion-pair into the organic phase. The intensity of the extract was found to remain stable for at least 3 hr. The order of addition of reagents had no effect on the absorbance of the extract. Similarly the variation of aqueous phase volume from 25–100 ml had no effect provided the overall concentrations of the reactants in the solution were maintained at the optimum level.

Table 2 gives the data on the extraction behaviour of various solvents tested for the extraction of the ion-pair. Benzene gave maximum extraction of the ion-pair and the blank was very low in this solvent. The presence of chloride in excess of 0.08*M* caused an increase in the blank absorbance although the net absorbance of thallium remained unaffected.

The calibration graph was linear in the concentration range 1–14 μg of thallium(I) in a final volume of 25-ml and the molar absorptivity was $1.2 \times 10^5 \text{ l. mole}^{-1} \text{ cm}^{-1}$. The Sandell sensitivity was found to be 0.0007 $\mu\text{g/cm}^2$. The precision of the proposed procedure was checked by establishing the concentration of 10 samples each containing 10 μg of thallium(I). The mean recovery was 10.08 μg and the coefficient of variation was found to be 1.4%.

Composition of the complex

Since treatment of thallium(I) with iodate resulted in the formation of thallium(III), the composition of the extracted complex was established with thallium(III) by Job's continuous variation and molar ratio methods. Both methods indicated that the mole ratio of Tl(III):Cl⁻:Pyronine G in the complex was 1:4:1. However, when identical amounts of thallium(I) and thallium(III) were subjected to extraction under conditions optimal for thallium(I), the absorbances obtained were widely different. Thus for solutions containing 10 μg, the absorbance was found to be 0.580 for thallium(I) and 0.400 for thallium(III). The enhancement observed in the case of Tl(I) determination may be attributed to the formation of an additional ion-pair formed between pyronine G and the anionic species ICl₂⁻ or ICl₄⁻. The formation of ICl₂⁻ species can be explained on the basis of the oxidation of iodine by excess iodate⁹ present in the acidic chloride containing medium in accordance with:

The net reaction being

The species ICl₄⁻, on the other hand, can result from the reduction of iodate by Tl(I) in accordance with the net reaction:

It is evident from the above equations that twice the amount of Tl(I) would be required to produce ICl₂⁻ species equivalent to ICl₄⁻ resulting from the reduction of iodate.

To confirm the nature of the species causing enhancement in the determination of Tl(I), experiments with varying amounts of iodine in benzene were carried out under conditions optimal for Tl(I). Though this experiment would not give direct evidence for the formation of ICl₄⁻, it would provide indirect evidence whether or not the formation of ICl₂⁻ was responsible for the observed enhancement. Experiments with iodine solution showed a linear relationship with increasing amount of iodine and the absorbance produced (0.18) by 2.5 μg of I₂ was identical to the enhancement observed for 10 μg of Tl(I) over Tl(III). Since in accordance with equation (1), 2.48 μg of I₂ would result from 10 μg of Tl(I), it was felt reasonable to conclude that the ICl₂⁻ species [equation (2)] was responsible for the observed enhancement in the case of Tl(I). If ICl₄⁻ had been the species, as evident from equation (4), 5 μg of thallium(I) would have been adequate to cause the observed enhancement.

Interference studies

The interferences of milligram amounts of several ions on the determination of Tl(I) were individually studied and the results are summarised in Table 3.

Iodide, as expected, enhanced the apparent recovery of Tl(I) due to formation of ICl₂⁻ species, but the interference could be overcome by treating the sample with 2 ml of 0.5% sodium nitrite solution and extracting the liberated iodine into benzene. The determination in this instance was completed after adding sulphamic

acid to destroy the unreacted nitrite. The interference of Ce(IV) was overcome by reduction with iodide and determination after removing the excess iodide as described above.

Citrate effectively overcame the interference of WO_4^{2-} , MoO_4^{2-} , Pd^{2+} and Bi^{3+} . The influence of Hg(II) and Sb(III) on the reaction was overcome by displacing them from solution with copper foil.¹⁰

Since nitric acid was found to be totally ineffective in oxidizing Tl(I) to Tl(III), it was used to overcome the interferences due to AsO_3^{3-} , Sn^{2+} , Sb^{3+} and Fe^{2+} in Tl(I) determination. In this instance, the excess nitric acid was fumed off with sulphuric acid before subjecting to determination.

Application

The method developed was applied to the analysis of thallium in cadmium sponge, rock samples and a synthetic solution of high purity cadmium. The rock samples were opened out by repeatedly heating 2 g of the finely ground material with concentrated nitric acid and hydrogen fluoride.¹¹ The mixture was treated with 2 ml of 10N sulphuric acid and evaporated to fumes of sulphur trioxide. Cadmium sponge was brought into solution by heating 1 g of the sample with 20 ml of dilute sulphuric acid (1:9) in the presence of 5 ml of concentrated nitric acid and evaporating the solution almost to dryness.¹¹ As no authentic sample of high purity

cadmium was available, a synthetic mixture containing the various metal ions in appropriate proportions¹² corresponding to 1 g of the sample was made. The mixture was treated with 5 ml of concentrated nitric acid and 2 ml of 10N sulphuric acid and evaporated to fumes of sulphur trioxide. The residue in each instance was dissolved in a minimum volume of water, filtered (rock samples and cadmium sponge) and made up to 100 ml (cadmium sponge and high purity cadmium). The entire filtrate (rock samples) or suitable aliquots of the made-up solution were treated with a copper foil on a hot plate for 10 min. The solutions were allowed to cool, treated with 2 ml of 5% citrate solution and the determination was carried out as described. The results of this along with those obtained from samples spiked with thallium(I) are shown in Table 4. The data show that the method works satisfactorily.

DETERMINATION OF BUTYLTIN, METHYLTIN AND TETRAALKYLTIN IN MARINE FOOD PRODUCTS WITH GAS CHROMATOGRAPHY-ATOMIC ABSORPTION SPECTROMETRY

D S. FORSYTH and C CLEROUX

Food Research Division, Bureau of Chemical Safety, Food Directorate, Health Protection Branch, Health and Welfare Canada, Ottawa, Ontario K1A 0L2, Canada

(Received 15 January 1991 Revised 5 April 1991 Accepted 17 April 1991)

Summary—Extraction methods were developed for the determination of butyltin, methyltin and tetraalkyltin in marine food products. Alkyltins were complexed with either diphenylthiocarbazone (dithizone) or tropolone from enzymatically hydrolyzed samples. Tetraalkyltins were extracted with hexane. Butyl or methyl derivatives of the alkyltins were made by Grignard reaction for analysis by gas chromatography-atomic absorption spectrometry. Many of the examined marine food products contained ppb levels of alkyltins. Tetramethyltin and tetraethyltin levels were less than the method detection limits of 0.8 and 0.7 ng/g (as Sn), respectively.

Organotin compounds are used in a number of commercial applications including biocide formulations, poly(vinyl) chloride stabilizers and homogenous catalysts.¹

Organotins enter the marine environment through various routes. Tributyltin has been extensively used in antifouling ship paint formulations. Tributyltin released from the paint has been found to adversely affect many non-target organisms, particularly molluscs.²⁻⁴ As a result, some countries, beginning with France in 1982, have banned or restricted the use of tin-based antifouling paints.

Methyltin can be produced from the biomethylation of inorganic tin in the presence of estuarine microorganisms^{5,6} and naturally occurring iodomethane.⁷ Methyltin compounds have been isolated from water,^{8,9} sediments^{8,10} and fish.⁹

Previous methods for the analysis of organotins in biological samples include: (a) the extraction of butyltins by solvent¹¹⁻¹³ or tropolone-solvent^{14,15} followed by gas chromatography of the pentyl,^{14,15} ethyl,^{11,13} methyl¹⁶ or hydride¹² derivatives and (b) the formation of methyltin hydrides^{9,17} from tissue homogenates.

The purpose of this study was to evaluate both the efficacy of alkyllead extraction methods developed by our group¹⁸ for butyl- and methyltins and tetraalkyltins in marine food products and to examine current alkyltin levels in these products. Dual element extraction

methods offer the advantages of less sample preparation time per element and greater sample throughput. The methods reported in this paper use a lipase/protease hydrolysis (to prevent acid induced breakdown of organolead analytes and enhance extraction) and require no sample cleanup prior to analysis by gas chromatography coupled to atomic-absorption spectrometry.

EXPERIMENTAL

Reagents

Me₃SnCl, Me₂SnCl₂, Me₄Sn and Et₄Sn were used as received from Alfa Products, Johnson Matthey, Ward Hill, MA, USA. The Bu₃SnBr contained approx. 20% Bu₂SnBr₂ which was removed by crystallization from a methanol solution. The isolated Bu₂SnBr₂ contained no other tin compounds. The remaining Bu₃SnBr was 97% pure.

Butylmethyltins (BuMe₃Sn, Bu₂Me₂Sn and Bu₃MeSn) were synthesized and isolated as previously described¹⁹ with the exception that Bu₃MeSn was prepared from the corresponding butyltin by reaction with methylmagnesium chloride (3.0M in THF, Aldrich Chem. Co., Milwaukee, USA). Distilled-in-glass grade solvents (Caledon Laboratories Ltd., Georgetown, Ontario) and American Chemical Society reagent chemicals were used. Diphenylthiocarbazone (dithizone) was purchased from BDH Inc.

(Toronto, Ontario). Tropolone was obtained from Aldrich Chemical Co., Inc. (Milwaukee, Wisconsin, USA). Lipase (Type VII) and protease (Type XIV) were purchased from Sigma Chemical Co. (St. Louis, USA).

Instrumentation

The gas chromatograph (GC)-atomic absorption spectrometer (AAS) system used was described previously.¹⁸ The GC was fitted with a glass column (2.1 m × 6 mm o.d., 2 mm i.d.) packed with 3% OV-73 on Chromosorb WHP 100/120 mesh (Chromatographic Specialties Ltd.) Operating conditions were: carrier gas, helium, 30 ml/min; transfer line temperature, 225°; injector temperature, 175° (tetraalkyltins), 200° (butylmethyltin); temperature program (tetraalkyltins) 35° initially (1-min hold) with a linear increase (1.0°/min) to 37° (no hold) followed by a linear increase (20°/min) to 175° (1 min hold); temperature program (butylmethyltins), 40° initially (1-min hold) with a linear increase (15°/min) to 275° (2-min hold).

Operating conditions for the AAS were: bandpass, 0.5 nm; Photron Super Sn hollow cathode lamp (Photron Pty., Victoria, Australia) current, 15 mA; boost current 25 mA, wavelength 224.6 nm. Deuterium background correction was used during tetraalkyltin determination.

A VG Analytical 7070EQ interfaced with a Varian VISTA 6000 was used for GC-MS confirmation. The system (conventional magnetic sector only) was operated in the electron impact mode at 30 eV (to conserve high molecular weight ions) and with a mass resolution of 1000. Gas chromatography operating conditions were: column, J&W DB-5 capillary column (30 m × 0.25 mm i.d., 0.25- μ m film); carrier gas, helium (15 psi); injector temperature

program (on column), 80° initially (0.5-min hold) with a linear increase (80°/min) to 250°; column temperature program, 70° initially (1.5-min hold) with a linear increase (5°/min) to 85° (no hold) followed by a linear increase (15°/min) to 200° (no hold) and a final linear increase (20°/min) to 260°.

Selected ion monitoring (m/z 203, 205 and 207 for Me₃BuSn, 245, 247 and 249 for Me₂Bu₂Sn and 287, 289 and 291 for MeBu₃Sn) was conducted on both samples and standards run under the same GC-MS conditions. All MS analyses were qualitative for confirmation of GC-AAS results.

Sample preparation

Consumer marine food items were purchased from local supermarkets and specialty shops. Fish fillet homogenates were prepared with a meat grinder (Moulinex, Model 244) whereas the shellfish and mollusc samples were prepared with a Polytron tissue homogenizer (Brinkmann Instruments). All samples were stored at -20° until analysis.

Extraction procedure

Methyltin. The methyltins were isolated with the same procedure as reported for alkylleads.¹⁸ The samples were enzymatically hydrolyzed for 24 hr, extracted with 0.05% (w/v) dithizone in 20% dichloromethane/hexane and back extracted into dilute nitric acid (removing most coextractives). The nitric acid extract was re-basified and then extracted three times with the dithizone solution. The pooled dithizone extract was reduced to 1 ml and butylated by adding butylmagnesium chloride.

The method detection limits (Table 1), based on a 5-g sample size, were 0.2 and 0.5 ng Sn/g for Me₃BuSn and Me₂Bu₂Sn respectively

#Method Detection Limit, [(LOD/mj vol) × extract vol]/sample wgt] × 10⁻³ (ng Sn/g)

Butyltin. Method 1. The samples (5 g) were enzymatically hydrolyzed for 24 hr.¹⁸ The pH was adjusted to 9 and the samples were extracted (rotary tumbled) once (65 rpm, 5 min) with 10 ml of hexane. The hexane was collected after centrifugation (3000 rpm, 5 min) which hastened phase separation. The samples were then extracted once with 0.05% (w/v) dithizone (10 ml) in 20% dichloromethane/hexane. The pooled organic extracts were derivatized as described in Method 4.

Method 2. Samples (5 g) were extracted with the method described by Ohhira and Matsui¹⁵ with the only difference being that the 0.05% tropolone solution was made up in hexane rather than benzene. The samples were processed with a Polytron homogenizer, 1.5 g of sodium chloride and hydrochloric acid were added (to pH 0.5) followed by two extractions (65 rpm, 20 min) with 0.05% (w/v) tropolone (10 ml) in hexane. The pooled organic extracts were reduced in volume to 1 ml at 40° in precalibrated tubes under a nitrogen stream. Derivatization was as per method 4.

Method 3. The samples (5 g) were enzymatically hydrolyzed for 24 hr.¹⁸ The resulting hydrolysates were then extracted as described in Method 2 (minus the homogenization step) and derivatized as described in method 4.

Method 4. The samples (5 g) were enzymatically hydrolyzed for 24 hr¹⁸ and 500 mg of sodium sulphite were added after the enzymes just prior to incubation. The hydrolysates were extracted as described in method 2 (minus the homogenization step). Derivatization was carried out as follows: tetrahydrofuran (1.0 ml) and methylmagnesium chloride (0.8 ml, 3.0M in THF) were added to the dithizone extract. The sample tube was capped under nitrogen, vortexed for approx. 10 sec and rotary tumbled (25 rpm) for 10 min. The samples were cooled in an ice bath and the volume adjusted to 10 ml with prechilled 0.5M nitric acid, which should be added dropwise initially. Isooctane (0.7 ml) was added, and the sample tumbled (25 rpm) for 2 min. Centrifugation (2000 rpm, 5 min) hastened phase separation. The nitric acid layer was discarded, and the organic phase extracted (25 rpm, 2 min) with 8 ml of distilled water. Sample volume was adjusted to 2.0 ml, dried over sodium sulfate (approx. 50 mg) and stored in an autoinjector vial. The method detection limit (Table 1) was 0.5 ng Sn/g for Bu₃MeSn and Bu₂Me₂Sn.

Tetraalkyltins. The samples were processed as previously reported for tetraalkylleads.¹⁸ Homogenized samples (5 g) were enzymatically hydrolyzed for 48 hr with 2 ml of hexane present. The hydrolysates were cooled, extracted for 10 min and then centrifuged. The organic layer was collected and the sample reextracted once with hexane (1 ml). The pooled extracts were made up to 3.0 ml, dried over sodium sulfate and then stored in an autoinjector vial.

The method detection limits (Table 1) for Me₄Sn and Et₄Sn were 0.8 and 0.7 ng Sn/g respectively.

Recovery experiments

Samples of fresh/frozen marine fish fillet, shellfish and mollusc (5.0 g) were spiked prior to hydrolysis with a mixture containing either two butyltins, methyltins or tetraalkyltins. The percentage recovery of each compound was determined by comparing the mean peak area of the recovered compound with the mean peak area of the compound in a blank hydrolysate extract spiked just prior to alkylation (alkyltins) or by comparing the mean peak area of the recovered compound with the mean peak area of the compound in a spiked blank hydrolysate extract diluted to the expected concentration (tetraalkyltins). Marine food samples were quantitated by comparison of peak area to external standards. Reagent blanks were run concurrently with each set of samples.

RESULTS AND DISCUSSION

All of the alkyltin recoveries were 75% or better, with the majority exceeding 90% (Table 2). Methyltins and tetraalkyltins therefore, can be isolated effectively with extraction procedures originally developed for alkyllead compounds.¹⁸ Initial work, however, indicated that the butyltins were not extracted into the acidic back extraction of the method reported for marine fish fillets¹⁸ so a modified procedure (method 1) was developed.

With method 1, tributyltin was extracted with hexane but recovery of dibutyltin required an additional extraction with 0.05% dithizone solution. Dibutyltin and tributyltin recoveries from a mollusc matrix (Table 2) were 41 and 108% respectively. As recoveries from buffer solutions were high, matrix interference was suspected. The addition of potassium cyanide and/or sodium chloride improved recoveries slightly,

but not enough to make the method practical for mollusc matrices.

Method 2, using tropolone-solvent extraction, was based on the work of Ohhira and Matsui.¹⁵ Hexane was substituted for benzene which was considered an unnecessary health hazard. After preliminary work no difference in extraction efficiency between hexane and benzene was observed. Dibutyltin and tributyltin recoveries from oyster were 87 and 62%, respectively (Table 2). Method 2, therefore, recovered more dibutyltin but less tributyltin than method 1. The differences between the extraction efficiencies of methods 1 and 2 were reflected in the butyltin levels found in contaminated fresh clams (Table 3) but not in the canned oyster and mussel.

Enzymatic hydrolysis was included in method 3 as a technique to decrease matrix interferences. Dibutyltin and tributyltin recoveries were 47 and 95% respectively (Table 2). Tributyltin recoveries therefore, were improved by the enzymatic hydrolysis. The dibutyltin, however,

appeared to be partially converted to monobutyltin, which was detected in the GC-AAS chromatograms of recovery samples but not in the blank hydrolysate extracts spiked just prior to methylation. Tributyltin levels in both the fresh and canned contaminated marine food products (Table 3) increased from those reported for method 2. However, there was no conversion of dibutyltin to monobutyltin in the contaminated marine foods analyzed by method 3, resulting in the dibutyltin levels remaining similar to or greater than those determined with method 2 (Table 3). The higher butyltin levels found with method 3 (Table 3) suggest that there was a bound unextractable form in the sample homogenate prior to enzymatic hydrolysis. Other authors have expressed concern over matrix interferences,^{11,13,17} some of which were irreversible. The enzyme hydrolysis used in methods 3 and 4 appears to be effective in reducing matrix interferences and releasing organotin analytes (Table 3) from a variety of marine food matrices.

§No recovery data obtained

The addition of sodium sulphite to the homogenate prior to hydrolysis (method 4) was found to prevent partial dealkylation of dibutyltin to monobutyltin in cod, clam and lobster during recovery trials. Dibutyl- and tributyltin recoveries averaged 95 and 87% respectively (Table 2). In the contaminated marine foods (Table 3), tributyltin levels in the fresh clam remained similar to those obtained with method 3 (Table 3) but increased considerably in the canned oyster and mussels. Dibutyltin levels dropped slightly with low levels of monobutyltin present in the contaminated canned marine foods (Table 3).

Method 4 was adopted for the analysis of marine food products reported in Table 4 since the butyltin recoveries were consistently high and the dealkylation of dibutyltin was suppressed. Method development should be investigated further as: (a) butyltin levels in the contaminated canned marine food products behaved somewhat differently than predicted from recovery experiments with fresh/frozen products and (b) although the appearance of low monobutyltin levels in the canned marine foods with method 4 probably resulted from increased analyte extractability (as found with tributyltin), artifact formation remains a possibility.

Many of the marine food products contained alkyltins (Table 4). Several of the marine fish

fillets contained low levels (<1.2–2.4 ng/g) of tributyltin. Trimethyltin was found in a turbot sample. Dibutyltin was not detected in any of the fish samples.

Both fresh and canned molluscs contained higher levels of butyltin compounds (ranging from <1.0 to 155.8 ng/g) than the marine fish fillets (Table 4). Tributyltin was the predominant species (Table 4) with much lower levels of dibutyltin and possibly monobutyltin present. Trimethyltin was also found, at a low level (0.7 ng/g) in one of the mollusc samples (Table 4). Tetraalkyltin levels in all samples were less than the reported method detection limits (Table 1).

The presence of alkyltin was confirmed in three samples by comparison with standards, using GC-MS. The canned mussel sample (Fig. 1) contained BuMe₃Sn (*m/z* 207 [M-CH₃]⁺), Bu₂Me₂Sn (*m/z* 249 [M-CH₃]⁺) and Bu₃MeSn (*m/z* 291 [M-CH₃]⁺).

The predominance of tributyltin in the marine food products clearly indicates contamination from commercial usage of butyltin based products. Similar levels (69–170 ng/g) of tributyltin have been found previously in aquacultured salmonids²⁰ exposed to tributyltin treated sea pens. Ishizaka *et al.*¹¹ found Bu₂Sn²⁺ and Bu₃Sn⁺ at levels of 0.02–0.05 and 0.02–1.49 ug/g respectively in purchased marine food products.

*Uncorrected for recovery

The methyltin may originate from environmental methylation of inorganic tin or the use of dimethyl- and monomethyltin compounds as heat and light stabilizers in PVC plastics. Tugrul *et al.*⁹ also found low (0.8–27 ng/g, dry weight basis) levels of methyltin compounds in several marine fish species. Current trends of alkyltin levels in marine food can be assessed only after further analyses are completed.

CONCLUSIONS

Extraction methods originally developed for alkyllead determination can be used to efficiently extract methyltin and tetraalkyltin compounds from marine food products with no or few modifications. A tropolone-solvent extraction procedure proved more effective for butyltin determination than the organolead methods. Recovered butyltin levels in contaminated marine foods increased after enzyme hydrolysis. Many of the consumer marine food items examined contain parts per billion levels of butyltin compounds. Several samples contained low levels of methyltin. The predominance of tributyltin indicates contamination of the marine food supply by commercial

Fig. 1 Selected ion GC-MS of mussel containing (a) BuMe₃Sn, (b) Bu₂Me₂Sn and (c) Bu₃MeSn

usage of the compound in antifouling paint formulations. No tetraalkyltin compounds were detected.

(Received 23 June 1989, Revised 1 March 1991, Accepted 11 March 1991)

Summary—The decomposition of standard leaf samples of varied origin and nature by fusion with sodium hydroxide in an open system has been studied. The use of sodium nitrate as an auxiliary agent facilitated the mineralization of most of the samples. The solutions obtained were analysed for calcium, magnesium and potassium by flame atomic-absorption spectrometry. The method is fast and quite precise, with absolute standard deviations of 0.04–0.13, 0.002–0.03 and 0.04–0.12% for calcium, magnesium and potassium contents of 0.8–5.0, 0.13–0.48 and 0.36–2.2% respectively. The limits of detection ($\mu\text{g/ml}$) in the determination step were 0.10 for calcium, 0.011 for magnesium, and 0.09 for potassium.

Calcium, magnesium and potassium are three major mineral components of plants, their contents in which depend on the particular vegetable species and the soil in which these are grown. Deficiencies of these essential elements can cause serious defects in plants.

Although instrumental measurements are occasionally made directly on such samples without prior destruction of the organic matrix,^{1,2} a prior mineralization is generally used, in which case the risk of losses, contamination and interference effects must be considered.

The AOAC³ recommends dry ashing for the mineralization; this approach has several variants, with different ashing temperatures and subsequent treatment and analysis of the ash.^{4–6} The ashing temperature and the mass of analyte present are factors to be taken into account to avoid losses of these three elements at above 450°. Laser ashing⁸ has also been used for this type of sample.

Wet ashing procedures can be divided according to whether they are implemented in an open or a closed system. Open systems have been used for decomposition with various acids or their mixtures.^{9–15} Mixtures of nitric acid and hydrogen peroxide have been used for decomposition with heating in a microwave oven.¹⁷ Closed systems seem to be less prone to result in analyte losses through volatilization during the heating,^{18,19} and use has been made

not only of concentrated acids, but also of hydrogen peroxide in Teflon pressure vessels to reduce the risk of contamination and acid corrosion.²⁰ Rapid destruction of plant material with nitric acid vapour has also been employed in determination of trace elements.²¹

Fusion with sodium hydroxide can be a useful alternative to the wet and dry methods, but has been relatively little exploited in analysis of organic matrices; in fact, it has only been employed in the determination of F⁻,²² As and Sb,²³ P,²⁴ and S,²⁵ with fusion in open systems, and of Ge with fusion in a closed system.²⁶ Earlier problems such as lack of purity of the reagents have now been overcome with the introduction of commercial reagents with very low metal contents. The hygroscopic nature of alkali-metal hydroxides can sometimes be advantageous, in favouring homogenization between the sample and the flux (we have even found it of use to start the attack by adding a few drops of water).²⁵

Once the organic matrix has been decomposed, calcium, magnesium and potassium are usually determined in plant material by AAS^{2,3,5,13} and ICP.^{12,14–16,27}

Here we report the decomposition of leaf samples by fusion with sodium hydroxide in a silver crucible at comparatively low temperature (350°). The results for calcium, magnesium and potassium in standard samples are in agreement with the certified values.²⁸

EXPERIMENTAL

Apparatus

A Perkin-Elmer model 5000 atomic-absorption spectrophotometer was used with the instrumental parameters recommended in the instrument manual. A flow spoiler was employed as impactor.

A Barnstad II water purifier was used.

Reagents

A 0.2M solution of La(III) was prepared from Probus Analytical grade $\text{LaCl}_3 \cdot 7\text{H}_2\text{O}$. Merck *p.a.* grade sodium hydroxide, sodium chloride and hydrochloric acid were used.

Standard samples

The standard leaf samples were those prepared and certified by the Comité Inter-Institute d'Etude des Techniques Analytiques de Diagnostic Foliaire (C.I.I.)²⁸ Their homogeneity was tested by the laboratory which prepared the standards (Centre de Recherches Rhône-Progil), by the CETAMA method.²⁹

The mineralization procedure used in the intercalibration⁵ involved calcination of 2 g of sample at 450° for 2 hr, and subsequent acid treatment of the ashes. The residue was collected on filter paper, ashed at 550° and treated with hydrofluoric acid. The residue from this was dissolved with concentrated hydrochloric acid. Calcium (in the presence of 30 mg/ml lanthanum chloride) and magnesium were then determined in the combined solution by flame atomic-absorption spectrometry (FAAS) and potassium by flame-emission spectrometry.³⁰

The results were subjected to a full statistical analysis³¹

Alkaline fusion

In a 50-ml silver crucible fuse 4 g of sodium hydroxide and swirl the crucible during cooling until the alkali has solidified on the bottom and walls. Weigh 0.1 g of sample, previously dried at 70–80° for 16 hr, into the crucible and add 0.5–1 ml of water to wet the sample and the alkali. Warm gently in the burner flame and swirl the crucible vigorously to obtain a homogeneous mixture of the alkali and organic matter at a relatively low temperature. Keep warming and swirling the crucible until all the moisture has evaporated. Gradually increase the temperature, with continued swirling, until the mixture has fused. Then heat strongly until all organic matter has been destroyed. If a

charred residue is left (as is usually the case), keep heating and add a small amount of sodium nitrate, not more than 0.1–0.2 g, as auxiliary oxidant and continue heating until oxidation is complete and a transparent melt has been formed.

Once cold, the fusion product can be readily dissolved with successive small volumes of hot water (not more than 5 ml at a time). Combine these extracts in a 250-ml beaker, and acidify by dropwise addition of 3M hydrochloric acid with vigorous stirring to help remove the CO_2 released. Boil the clear solution for a few minutes and then transfer it to a 50-ml standard flask, dilute to the mark and mix.

Prepare blank solutions similarly, including the fusion.

Determination

Pipette 1, 2 or 3 ml of the sample solution (depending on the analyte to be assayed and its content in the sample) into a 25-ml standard flask, add 2 ml of the lanthanum solution, dilute to the mark, mix, and measure by FAAS. Run a corresponding volume of blank solution in the same way, and apply the resulting correction.

RESULTS AND DISCUSSION

First we studied the decomposition of various leaf samples with molten sodium hydroxide. Maize was easily mineralized, leaving no carbon residue, and not needing use of the auxiliary oxidant. Golden apple leaves gave the strongest carbonization, necessitating use of the largest amount of auxiliary agent (about 0.2 g). All the other samples behaved similarly to each other and required less than 0.1 g of sodium nitrate. These small differences can be related to the different texture of the samples, and hence their varying composition. The mineralization was accomplished satisfactorily within 5 min in every case. The highest absorbances yielded by the blanks were 0.011, 0.005 and 0.016 for Ca, Mg and K respectively.

Calibration

We ran three calibrations for standards containing lanthanum chloride and the same amounts of sodium chloride as the unknown samples (0.08, 0.16 or 0.24M, corresponding to 1, 2 or 3 ml subsamples from an overall volume of 25 ml) and covering six analyte concentrations in the ranges 0–4 $\mu\text{g/ml}$ Ca,

0–0.5 $\mu\text{g/ml}$ Mg and 0–2 $\mu\text{g/ml}$ K. The experimental results were fitted by linear regression; Table 1 gives the equations and correlation coefficients. As can be seen, the sensitivity decreased with increasing sodium chloride concentration (*i.e.*, the slope decreased). At the

sodium chloride and lanthanum concentrations used in the calibrations, the sample uptake (flow-rate at the nebulizer) was decreased by a factor similar to that for the decrease in sensitivity in the case of potassium and a slightly larger factor for calcium and magnesium, which may be accounted for by the interaction with Cl^- , Na^+ and La^{3+} ions in the flame.³² The high sodium content (1840–5520 $\mu\text{g/ml}$) acted as an ionization buffer for potassium. The detection limits³³ achieved were 0.10, 0.011 and 0.09 $\mu\text{g/ml}$ for Ca, Mg and K respectively.

†Five separate decompositions

that of K; the lower precision for Ca could be attributed to the well-known tendency of calcium to form refractory compounds. The average values yielded by the proposed method are statistically comparable with the recommended values.

The accuracy of the proposed method was statistically satisfactory and the confidence ranges were encompassed by the standard selection ranges established by the C.I.I., except for the determination of Ca in cotton, where neither the average certified value nor the recommended value was within the confidence range obtained by the proposed method at the 95% probability level, though they would at the 99.9% level. This exception is due to the small standard deviation ($s = 0.045$) of the results and the high Ca content (2.98%) found, which combine to give a very narrow confidence interval. However, the value found lies within the selected range established for the certified sample (2.884–3.274%).²⁸ Therefore, the proposed method has no systematic error at the stated confidence level.

Conclusions

The proposed method is quite accurate and precise for the analysis of leaf samples. This testifies to the efficiency of alkaline fusion with sodium hydroxide for decomposing organic matter, which has so far been little exploited, probably because of formerly serious drawbacks such as reagent impurities and crucible contamination, which have by now been overcome.

(Received 8 March 1991 Accepted 4 April 1991)

Summary—Detecting changes in magneto-optical rotation is useful as a universal on-line detector for high-performance liquid chromatography. Such apparatus is similar to a polarimeter except for the external magnetic field on a flow cell. Two modulation modes suitable for the magneto-optical rotation detector are discussed. Use of a semiconductor laser provides better sensitivity than a He-Ne laser. The detection limit is 0.006% (w/w) for polyethylene glycol 20000 in a 20- μ l injection.

Many laser-based analytical systems have been developed. Some of them have been applied to a flow detector for high-performance liquid chromatography (HPLC) and flow-injection analysis.¹ They are classified by their principle of operation, sensitivity, universality, convenience, detector dimensions and cell volume. A refractive index (RI) detector is popular because of its universality. The detectability of the conventional RI detector is in the order of 10^{-7} RI units which corresponds to μ g-sub- μ g hydrocarbon levels. A refractive index gradient detector based on interferometry could improve the detectability to 4×10^{-9} RI units and sub-ng levels.² Recently, the indirect photometric method has been developed and provides the universal sensitivity with absorption,³ fluorescence⁴ and thermal lens⁵ detection. The detection limit of 10^{-2} – 10^{-3} % (w/w) depends on the displacement scheme. This method can improve the mass detectability in the order of 10 ng with small-volume detection, using lasers. In a previous paper,⁶ we demonstrated another universal flow detector based on magneto-optical rotation (MOR).

Magneto-optical rotation, the so-called Faraday effect, is a general optical property of substances in a magnetic field. When the linearly polarized light propagates through a medium in a magnetic field parallel to the direction of the light beam, the polarized plane of the light rotates.⁷ The rotation angle is proportional to the strength of the magnetic field and the optical path length. The proportionality factor is known as the Verdet constant. A change in composition of a solution modifies its rotatory

power. A small change of MOR can be measured with a technique similar to sensitive polarimetry.⁸⁻¹² In a previous paper,⁶ we used external magnetic field modulation and a He-Ne laser for sensitive detection.

In this paper, we evaluate the modulation modes suitable for the MOR detection and describe the utility of a semiconductor laser. It provides very stable light intensity and allows simple replacement with a He-Ne laser for better sensitivity. The semiconductor laser is the most compact and convenient source of laser light. This feature allows versatility in instrumentation designs.

EXPERIMENTAL

Instrumentation

The experimental set-up is shown in Fig. 1. It is basically similar to the laser-based polarimeter reported by Yeung *et al.*⁸ The light source was a He-Ne laser (Uniphase 1101P; 1 mW of light at 633 nm) or a semiconductor laser (Sharp LT023MC; 3 mW of light at 784 nm). The semiconductor laser was operated in the power control mode with an integrated circuit (Sharp IR3C02N) as specified by the manufacturer. The beam of the He-Ne or semiconductor laser was focused with a 20-cm focal length lens or a 3-lens collimator (Sakai Glass), respectively. Careful optical adjustment is important because the light scattering on the cell wall induces depolarization. A pair of Glan-Thompson prisms served as the polarizer and the analyzer, respectively, and provided an extinction ratio of 10^{-6} .

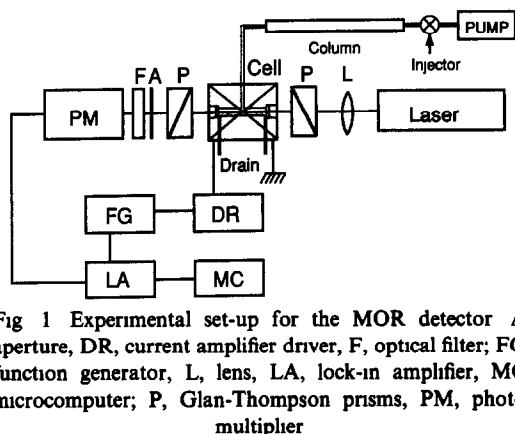

Fig 1 Experimental set-up for the MOR detector A, aperture, DR, current amplifier driver, F, optical filter; FG, function generator, L, lens, LA, lock-in amplifier, MC, microcomputer; P, Glan-Thompson prisms, PM, photomultiplier

The flow cell was made of aluminum with $8\text{-}\mu\text{l}$ volume bores (10-mm long and 1-mm in diameter) and had a central inlet and two side outlets.¹³ This design provided more linear analytical curves than the conventional one with a Z-type inlet and outlet because the laser beam deflection from RI change was small. A coil of 500 turns of 0.8-mm diameter wire was wound round the cell as the modulator of the magnetic field. A 2-A dc current produced a magnetic field strength of 300 G at the flow region. Experiments were carried out at room temperature with no temperature control.

A photomultiplier (Hamamatsu R1333) detected the light traversing the polarizers and an optical filter. The photomultiplier was connected to a lock-in amplifier (NF Circuit 5610B) through a current amplifier (NF Circuit LI-76). The strength of the magnetic field in the flow cell was modulated to a square wave by a bipolar power supply (Metronix BPA182A). A function generator (Kenwood FG273) provided a reference oscillation to the lock-in amplifier and the bipolar power supply. The recovering MOR signal was displayed on a chart recorder. For frequency distribution measurements we calculated fast Fourier transformation (FFT) of the output of the current amplifier with a 12-bit A/D converter (Canopus ANALOG-PRO) and a microcomputer (NEC PC9801).

Chromatography

The chromatography system consisted of an injector with a $20\text{-}\mu\text{l}$ loop (Rheodyne 7413) and a pump (JASCO 880-PU) operated at a flow-rate of 0.5 ml/min. Gel chromatography of polyethylene glycol (PEG) was performed on a 10-cm \times 0.76-cm column (Asahipak GS-310M) with distilled water as the eluent. For part of the measurements the sample was injected directly

into the flow system without a column to eliminate the dilution. All chemicals were of analytical reagent grade.

RESULTS AND DISCUSSION

Modern polarimetry uses an AC modulation technique to improve the signal to noise ratio (S/N).^{8,12} Three typical polarization modulation modes are shown in Fig. 2. The plane of the linearly polarized light is modulated by an angle, α , which is produced through MOR of the solvent itself for the simple and sensitive instrumentation. The amount and direction of the modulation angle, α , can be controlled by the current fed to the coil around the cell. The angle β is MOR due to the solute. Transmitted light intensity is the square of the projection amplitude of an electric vector and is proportional to the square of a rotating angle at $\sin(\text{angle}) \ll 1$. Mode A in Fig. 2 illustrates the simplest operation; the polarization modulates by equal negative and positive angles ($-\alpha$ and $+\alpha$) from the polarizer-analyzer cross alignment. This mode is generally used in optical activity measurements.¹⁰ However, in MOR detection this operation compensates for a MOR change of the solution in the output of the lock-in amplifier. Therefore modes B and C in

Fig. 2 Three typical polarization modulation diagrams for the MOR detector. Solid and dashed vector represents an electric field of polarized light when a sample is present and absent, respectively. α , modulation angle produced through MOR of the solvent itself; β , MOR due to the solute, θ , offset angle. The X and Y axes correspond to polarization planes of the analyzer and polarizer, respectively

Fig. 2 would be more suitable for the MOR detection. In mode B, the polarization modulates in the same manner as in mode A. In addition, an offset angle, θ , is applied; θ is the angle of the analyzer away from the polarizer-analyzer cross alignment. In mode C, the polarization modulates by the positive angle, $+\alpha$, with the offset angle, θ .

The intensity of light transmitted through the optical system, I_T , is given by¹⁴

$$I_T(\theta, \omega) = I_0[\epsilon \cos^2(\theta + \omega) + (1 + \epsilon^2/4) \sin^2(\theta + \omega)] \quad (1)$$

where ϵ is the extinction ratio of the polarizer and analyzer and ω is the amount of rotation caused by a sample. At a low concentration, ω is a simple sum of MOR's due to the solvent and solute.⁶ Fluctuations of I_T determine noise in the MOR measurement. The S/N ratio of the modulation modes B and C may be described by

$$\frac{S/N_{\text{mode B}}}{=} \frac{[I_T(\theta, \alpha + \beta) - I_T(\theta, \alpha)] - [I_T(\theta, -\alpha - \beta) - I_T(\theta, -\alpha)]}{f_{dc} I_T(\theta, 0) + f_{ac} [I_T(\theta, \alpha) - I_T(\theta, -\alpha)]} \quad (2)$$

and

$$\frac{S/N_{\text{mode C}}}{=} \frac{I_T(\theta, \alpha + \beta) - I_T(\theta, \alpha)}{f_{dc} I_T(\theta, 0) + f_{ac} [I_T(\theta, \alpha) - I_T(\theta, 0)]} \quad (3)$$

respectively, where f_{dc} and f_{ac} are the fluctuation of the dc and ac components, respectively, at the detection frequency of the lock-in amplifier. We can calculate S/N for various combinations of ϵ , θ , f_{dc} and f_{ac} .

Figure 3 shows dependencies of S/N on the offset angle and the extinction ratio (10^{-6} and 10^{-9}) for a 0.1% (w/w) phenol solution in modes B and C. Lines are calculated with equations (1)–(3). The dependencies of S/N are determined by the balance between the increases in the signal component, $\sin(\beta + \theta)$ and the leak of light with θ . The fluctuations, f_{dc} and f_{ac} , are parameters for fitting the observed values. Observed values were obtained in direct injection operation with the He-Ne laser and the modulation of the magnetic field at 100 Hz and 300 G. The 0.1% (w/w) phenol aqueous solution provides $\alpha = 0.065^\circ$ and $\beta = 1.5 \times 10^{-4}$ at the optical length of 10 mm and with a magnetic field intensity of 300 G. The Verdet constant of water and phenol is 2.2×10^{-4} and 5.3×10^{-4} deg/G cm,¹⁵ respectively. The opti-

Fig. 3 Dependence of S/N on the offset angle and the extinction ratio for a 0.1% (w/w) phenol solution \circ , observed in mode B and C, respectively, solid line calculated with $\epsilon = 10^{-6}$, dashed line calculated with $\epsilon = 10^{-9}$

imum f_{dc} and f_{ac} is 2.8×10^{-4} and 1.1×10^{-4} , respectively. Both observed and calculated dependencies of S/N on θ agree with each other. The mode B with a modulation by $-\alpha$ and $+\alpha$ requires a certain offset angle to avoid the disappearance of the MOR signal. In mode C, S/N is the largest around the polarizer-analyzer cross alignment ($\theta = 0$). The S/N ratio with the extinction ratio of 10^{-9} is a few times larger than that with 10^{-6} , as shown with dashed lines in Fig. 3. A pair of Glan-Thompson prisms, that serve as the polarizer and analyzer, respectively, with a better extinction ratio should improve the sensitivity. At any conditions, strengthening of the magnetic field increases S/N in a straightforward manner. Since mode C provides a larger S/N at any offset angle than mode B, the following chromatographic measurements were carried out in mode C with an offset angle of 0–0.03°.

The output stability of the light source is important since the fluctuations, f_{dc} and f_{ac} , affect S/N linearly. The frequency distribution of the light intensity fluctuation has been measured to evaluate the optimum modulation frequency, as shown in Fig. 4. Figure 4(a) shows the noise without the laser light and the strength of the magnetic field calibrated by the MOR signal of water in the cell. Peaks at 60 Hz correspond to line noise in the electronics. In Fig. 4(b) and (c), a peak around 300 Hz indicates a MOR signal of water of 0.04° . The longitudinal axis at 0 dB corresponds to the DC component of the light transmitted through the

Fig 4 Frequency distribution of intensity fluctuation of light transmitted through the optical system, (a) no laser, (b) He-Ne laser, (c) semiconductor laser. No offset angle is applied

polarizer and analyzer. The strength of the magnetic field decreases with increasing modulation frequency due to the induction effect of the coil. The noise level of the He-Ne laser is higher than that of the semiconductor laser, especially at less than 200 Hz. Gas discharge lasers such as He-Ne or Ar ion ones have larger noise, a typical drift and flicker component is about 1–5% and 0.1–1%, respectively. On the other hand, the output of the semiconductor laser is very stable, because direct conversion of the electronic energy to light can easily control the output with a simple electronic feedback circuit. Both drift and flicker noise of the semiconductor laser can be reduced by the order of 10^{-5} ^{12,16}. We have chosen a modulation frequency of 300 Hz at which the conflict between the increase in noise and the decrease in the strength of the magnetic field is small.

Figure 5 presents the MOR signal of 0.03% (w/w) and 0.015% (w/w) PEG 20000 (average molecular weight: 18000–25000) aqueous solution with the He-Ne laser and the semiconductor laser, respectively. The 20- μ l sample was injected directly into the flow system. The strength of the magnetic field, the modulation frequency and the time constant of the lock-in amplifier are 200 G, 300 Hz and 300 msec, respectively. The background low frequency noise, the so-called drift, improves dramatically by about one order of magnitude when employing the semiconductor laser, even without temperature stabilization. This corresponds to a

Fig 5 MOR signal from polyethylene glycol 20000 aqueous solution in the flow system; (a) 0.03% (w/w) conc with He-Ne laser, (b) 0.015% (w/w) conc with semiconductor laser. Offset angle is 0.03°.

good S/N of the semiconductor laser at low frequency in the fluctuation distribution measurements; the noise intensity of the semiconductor laser is 15 dB (about 5 times) smaller than that of the He-Ne laser in Fig. 4. The high frequency noise also improves by about two orders of magnitude. The detection limit at $S/N = 3$ is 4 μ g (0.02%) and 1.2 μ g (0.006%) for the use of the He-Ne laser and the semiconductor laser, respectively, for the direct injection operation. The analytical curves are linear up to 3% and increase monotonically up to 10%. Apparent peaks due to the RI change disturb the signal peak in the high concentration region. The μ g-order detectability for the MOR-based detector is comparable to the conventional RI detector.

The gel chromatography for optically transparent samples is an appropriate demonstration of the usefulness of the MOR flow detector. Figure 6 shows a chromatogram of a 20- μ l injection of 1% (w/w) PEG 6000 and 2000 (average molecular weight: 7400–9000 and 1800–2200, respectively) mixture, using the

Fig 6 Gel chromatogram of polyethylene glycol (PEG) 6000 and 2000 aqueous solution. Column, Asahipack GS-310M, mobile phase, water, flow-rate, 0.5 ml/min; sample, 1.0% (w/w) each (20- μ l injection)

semiconductor laser. The strength of the magnetic field, the modulation frequency and the time constant of the lock-in amplifier are 200 G, 300 Hz and 3 sec, respectively. The detection limit of PEG 6000 is 8 μg (0.04%) in our chromatography system.

In conclusion, we have demonstrated a HPLC detector with a new principle based on MOR that provides universal response. It will be an alternative to the RI detector. This apparatus is capable of natural optical activity measurement, which is very important in biological studies. In addition, several essential molecules, such as steroids and fatty acids exhibit limited absorptions in the UV and visible spectrum and hence the application of this detector to clinical and environmental research will be useful.

Acknowledgements—The authors thank Dr. Hizkata and T. Sakane of Sharp Corp for supplying the semiconductor laser chips. This work is partially supported by a Grants-in-Aid for Scientific Research (No. 02855180) from the Ministry of Education of Japan.

Following submission of this paper, a report by Xi and Yeung appeared that described the same principle reported here, with differences in instrumentation and performance.¹⁷

SEPARATION OF NIOBIUM AND TANTALUM BY EXTRACTION CHROMATOGRAPHY WITH BIS(2-ETHYLHEXYL)PHOSPHORIC ACID

YI YU VIN and S. M. KHOPKAR*

Department of Chemistry, Indian Institute of Technology, Bombay 400 076, India

(Received 22 January 1990 Revised 24 February 1991. Accepted 5 March 1991)

Summary—A novel method is developed for the reversed-phase extractive chromatographic separation of niobium and tantalum with bis(2-ethylhexyl)phosphoric acid. Niobium is extracted from 1–10*M* hydrochloric acid and can be stripped with 3*M* sulphuric acid containing 2% hydrogen peroxide. Tantalum is extracted from 0.1–2*M* hydrochloric acid and can be stripped with 0.1*M* hydrochloric acid containing 2*M* tartaric acid. It is possible to separate niobium and tantalum, in different ratios, from multicomponent mixtures.

Tributyl phosphate¹⁻⁴ has been used as the stationary phase for the extractive chromatographic separation of niobium and tantalum, with hydrochloric acid and hydrogen peroxide as stripping agents. Aliquat 336^{5,6} and trioctylamine⁷⁻⁹ have also been used to separate niobium and tantalum, with ammonium fluoride and ammonium chloride as stripping agents. Thenoyltrifluoroacetone¹⁰ and methyl isobutyl ketone¹¹ were found not to be effective as extractants for niobium and tantalum.

Bis(2-ethylhexyl)phosphoric acid (HDEHP) gives quantitative extraction of niobium and tantalum from a tartaric/oxalic acid mixture,¹²⁻¹⁶ but this system has not been applied in extraction chromatography.

The present work investigated the extractive chromatographic separation of niobium and tantalum from each other and from other elements. The method was extended to the determination of these metals in real samples.

EXPERIMENTAL

Apparatus

A borosilicate glass chromatography column packed with silica gel was made as described earlier.¹⁷

Reagents

Bis(2-ethylhexyl)phosphoric acid (Schuchardt, Munich) was used without further purification.

The stock solution of niobium was prepared by fusing 100 mg of niobium pentoxide with 5 g of potassium bisulphate in a platinum crucible. The cooled mass was dissolved in 5 ml of 200 mg/ml tartaric acid solution, made up to 100 ml with distilled water and standardized gravimetrically with *N*-benzoyl-*N*-phenylhydroxylamine;¹⁸ it was found to contain 0.68 mg/ml niobium. A solution containing 40 µg/ml niobium was prepared by appropriate dilution.

The stock solution of tantalum was prepared by fusing 100 mg of tantalum pentoxide (Aldrich) with 5 g of potassium pyrosulphate. The cooled melt was dissolved with 2 ml of 50-mg/ml ammonium oxalate solution, diluted to 100 ml with distilled water and standardized gravimetrically with selenious acid;¹⁹ it was found to contain 0.81 mg/ml tantalum. A solution containing 20 µg/ml was prepared by appropriate dilution.

Procedure

Concentrated hydrochloric acid was added to a known volume of solution containing 40 µg of niobium or 20 µg of tantalum. The solution was passed through the column at a flow-rate of 1 ml/min. The extracted niobium or tantalum was stripped with a suitable stripping agent. Twenty 2-ml fractions were collected and analysed spectrophotometrically, for niobium with 4-(2-thiazolylazo)resorcinol²⁰ and tantalum with Brilliant Green.^{21,22}

RESULTS AND DISCUSSION

Extraction conditions

Niobium and tantalum were found to be quantitatively extracted from 1–10 and 0.1–2M hydrochloric acid respectively (Fig. 1).

Stripping agents

None of the mineral acids in any concentration range was effective for stripping niobium and tantalum. However, niobium can be completely stripped with 3–4M sulphuric acid containing 2–3% hydrogen peroxide, and tantalum completely stripped with 0.1M hydrochloric acid containing 1.5–3M tartaric acid, and partially stripped with 3–4M sulphuric acid containing 2–3% hydrogen peroxide.

Separation from binary mixtures

The different conditions required for stripping niobium or tantalum were exploited to devise several separation methods. When niobium was extracted from 2M hydrochloric acid or tantalum was extracted from 0.1M hydrochloric acid in the presence of one of the other ions listed in Table 1, most accompanying ions were not extracted and so passed through the column. When the accompanying ion, *e.g.*, iron, was co-extracted, it was stripped with mineral acid before niobium was stripped with 3M sulphuric acid containing 2% hydrogen peroxide or tantalum with 0.1M hydrochloric acid containing 2M tartaric acid (Table 1).

Separation of niobium from tantalum

As shown in Fig. 1, niobium and tantalum can both be extracted from 1–2M hydrochloric acid

Fig. 1 Effect of hydrochloric acid concentration on extraction of niobium and tantalum

Table 1 Separation of niobium and tantalum from binary mixtures (Nb 40 μ g, stripped with 3M H₂SO₄ + 2% H₂O₂; Ta 20 μ g, stripped with 0.1M HCl + 2M tartaric acid; most other ions pass unextracted through the column)

*Co-extracted, stripped with 3M hydrochloric acid before Nb or Ta

acid, but Table 2 shows that they can be separated if the tantalum is stripped first, with 0.1M hydrochloric acid/2M tartaric acid mixture, and then the niobium with 3M sulphuric acid containing 2% hydrogen peroxide (Table 2).

Separation of niobium or tantalum from multi-component mixtures

The optimum conditions for the extraction and stripping of various metals are summarized in Table 3. Gallium, indium, iron, tin, antimony, bismuth, vanadium, titanium, beryllium, molybdenum, tantalum and (partially) niobium are extractable from 0.1M hydrochloric acid, whereas only germanium, thorium and niobium are extracted from 10M hydrochloric acid.

Table 2 Extraction and stripping conditions for niobium and tantalum (Nb 40 μ g; Ta 20 μ g)

Conditions		Nb	Ta
		Extracted, %	
Extraction from	0.1M HCl	54.0	99.6
	1M HCl	99.6	100.2
	2M HCl	99.8	99.9
		Recovery, %	
Stripping with	3M H ₂ SO ₄ + 2% H ₂ O ₂	99.9	40.9
	0.1M HCl + 2M tartaric acid	0	100.4

These differences in behaviour can be exploited for multicomponent analyses, provided proper stripping sequences are used. Table 4 gives some examples.

When a mixture of manganese, iron, thorium, niobium and uranium in 2M hydrochloric acid was passed through the column, all except manganese were extracted. They were then stripped in succession, iron with 3M hydrochloric acid, thorium with 3M phosphoric acid, niobium with 3M sulphuric acid containing 2% hydrogen peroxide and uranium with 6M hydrochloric acid containing 0.1M ascorbic acid.

The separation of a mixture of chromium, iron, tantalum and niobium in 2M hydrochloric acid was similarly achieved; chromium was not extracted, iron was stripped with 3M hydrochloric acid, tantalum with 0.1M hydrochloric acid containing 2M tartaric acid and niobium with 3M sulphuric acid containing 2% hydrogen peroxide.

A five-component mixture (in 0.1M hydrochloric acid) containing nickel, bismuth, antimony, tin and tantalum was separated by passing it through the column. All the components except nickel were extracted. Bismuth was then stripped with 0.5M hydrochloric acid,

antimony with 3M nitric acid, tin with 5M hydrochloric acid and tantalum with 0.1M hydrochloric acid containing 2M tartaric acid.

A mixture of vanadium (or lead or bismuth or chromium), tantalum (or molybdenum) and niobium in 2M hydrochloric acid was separated, only the tantalum, molybdenum and niobium being extracted. Molybdenum was stripped first with 0.1M hydrochloric acid containing 0.2M tartaric acid, or tantalum with 0.1M hydrochloric acid containing 2M tartaric acid, and finally niobium with 3M sulphuric acid containing 2% hydrogen peroxide.

The mixture of copper or bismuth or aluminium with vanadium (or iron), tantalum and titanium was resolved by making it 0.1M in hydrochloric acid before passage through the column. The copper or bismuth or aluminium was not extracted. Vanadium or iron was stripped with 3M hydrochloric acid, tantalum with 0.1M hydrochloric acid containing 2M tartaric acid and finally titanium with 2.5M sulphuric acid containing 3% hydrogen peroxide.

Determination of niobium in stainless steel

About 0.5 g of steel was dissolved in a mixture of hydrochloric and hydrofluoric acids (2:1 v/v).

	Fe	50	100.6	3M HCl	20	1,10-Phenanthroline
	Ta	20	98.9	0.1M HCl + 2M tartaric acid	20	Brilliant Green
	Nb	40	100	3M H_2SO_4 + 2% H_2O_2	20	TAR
3	Ni	100	99.2	Not extracted	16	PAR
	Bi	100	100.2	0.5M HCl	18	Iodide
	Sb	50	99.0	3M HNO_3	18	Phenylfluorone
	Sn	60	98.3	5M HCl	22	Pyrocatechol Violet
	Ta	20	99.0	0.1M HCl + 2M tartaric acid	20	Brilliant Green
4	V/Pb/Bi/Cr	150	98.5	Not extracted	18	Hydrogen peroxide/dithizone/iodide/diphenylcarbazide
	Ta or Mo	20	99.5	0.1M HCl + 2M tartaric acid	20	Brilliant Green/Tiron
	Nb	40	99.4	3M H_2SO_4 + 2% H_2O_2	20	TAR
5	Cu/Bi/Al	100	99.4	Not extracted	16	Cupral/iodide/Alizarin Red S
	V/Fe	150	100.3	2M HCl	20	Hydrogen peroxide/1,10-phenanthroline
	Ta	20	99.0	0.1M HCl + 2M tartaric acid	20	Brilliant Green
	Ti	150	98.6	2.5M H_2SO_4 + 3% H_2O_2	20	Hydrogen peroxide

The solution was evaporated almost to dryness, the salts were taken up by addition of 2 ml of 200 mg/ml tartaric acid solution and the solution was made up to volume in a 100-ml standard flask with distilled water. An aliquot was made 2M in hydrochloric acid, and passed through the column. Niobium and iron were extracted, and chromium, nickel and manganese passed through the column. The iron was stripped with 3M hydrochloric acid and niobium with 3M sulphuric acid containing 2% hydrogen peroxide. The niobium content was found to be 1.05, 1.03 and 1.04% (certified value 1.02%).

The proposed method is simple, rapid and selective. The separation of niobium and tantalum from each other and from chromium, molybdenum, iron, vanadium and tin is important, as these are associated in various types of steel. The total time required for separation

and determination of niobium and tantalum is 45 min.

POLAROGRAPHIC DETERMINATION OF FLUORIDE USING THE ADSORPTION WAVE OF THE Ce(III)-ALIZARIN COMPLEXONE-FLUORIDE COMPLEX

LU GUANGHAN, LI XIAOMING, HE ZHIKE and HU SHUANGLONG

Department of Chemistry, Central China Normal University, Wuhan, 430070, People's Republic of China

(Received 3 January 1991. Revised 3 March 1991. Accepted 13 March 1991)

Summary—A very sensitive electrochemical method for trace measurement of fluoride in water is discussed. The complex of cerium(III) with alizarin complexone (ALC) and fluoride ion is adsorbed at the dropping mercury electrode. In cathodic sweeps, the peak height is directly proportional to the concentration of fluoride over the range 8×10^{-8} – $5 \times 10^{-6}M$ (1.5×10^{-9} – 9.5×10^{-8} g/ml), and the detection limit is $5 \times 10^{-8}M$ (9.5×10^{-10} g/ml). The proposed method was applied to the determination of fluoride in water

Fluorine is a very important element in nature. A large number of methods for the determination of fluoride have been reported, principally colorimetric ones.¹⁻⁷ A fluoride-selective electrode was used for the determination of trace fluoride.^{8,9} However, the sensitivity of these methods is not very high and the range of detection is only about 5×10^{-6} – $2 \times 10^{-5}M$. Recently, a polarographic method for determination of fluoride in the presence of La(III) and alizarin complexone (ALC) has been studied.¹⁰ However, reaction equilibration is required for about 2 hr before the potential scan is carried out. The linear range of the method is 1×10^{-7} – $6 \times 10^{-6}M$. In this report, we have investigated the electrochemical behaviour of the Ce(III)-ALC-F⁻ complex in aqueous solution by single-sweep polarography and cyclic voltammetry. The reaction is equilibrated for about 30 min before the potential scan is carried out. The linear range is 8×10^{-8} – $5 \times 10^{-6}M$ (1.5×10^{-9} – 9.5×10^{-8} g/ml), with a detection limit of $5 \times 10^{-8}M$ (9.5×10^{-10} g/ml).

EXPERIMENTAL

Apparatus

A Model JP-2A oscillopolarograph (Chengdu Instrumental Factory, China) was used. A three-electrode system was used with a dropping mercury working electrode (DME). The reference and counter electrodes were saturated calomel and platinum wire electrodes respectively. A Model 82-1 neopolarograph (Lisui

Electronic Factory, China) was used for cyclic voltammetry, with a three-electrode system consisting of a hanging mercury drop electrode as working electrode, a saturated calomel reference electrode and a platinum counter-electrode. A Model pHs-3 meter (Shanghai, China) was used for pH determinations. The electrolytic cell was a 10-ml beaker

Reagents

All solutions were prepared from analytical-reagent grade chemicals and doubly-distilled water.

Stock solutions of F⁻ were prepared by dissolving sodium fluoride in water. Standard solutions were obtained by diluting the stock solutions with water.

A $5 \times 10^{-4}M$ Ce(III) stock solution was prepared by weighing and dissolving 0.1085 g of cerium nitrate [Ce(NO₃)₃.6H₂O] in 450 ml of water. The pH was adjusted to *ca.* 4.8 with 1M nitric acid and the solution was diluted to 500 ml with water.

A $1 \times 10^{-3}M$ stock solution of alizarin complexone (ALC) was prepared by dissolving 0.0964 g of ALC in 2M sodium hydroxide and neutralizing the solution to a yellow colour with 2M nitric acid,¹¹ and then diluting to 250 ml with water.

A 1M hexamethylene tetramine [(CH₂)₆N₄] solution was prepared by weighing and dissolving 70 g of (CH₂)₆N₄ and 50 g of potassium nitrate in 450 ml of hot water. The pH was adjusted to *ca.* 4.8 with 2M nitric acid.

Procedure

To the standard or sample solution (8×10^{-8} – $5 \times 10^{-6} M$ fluoride), add 1.0 ml of $1 M (CH_2)_6N_4$, 0.1 ml of $1 \times 10^{-3} M$ ALC, 1.0 ml of $5 \times 10^{-4} M$ Ce(III) and 1.0 ml of acetone. Allow to stand for about 30 min and then dilute the solution to 10 ml with water. The derivative single-sweep polarogram is then recorded from $-0.3 V$ to $-0.8 V$ (*vs.* SCE) and the height of the peak measured at $-0.64 V$ (Fig. 1).

RESULTS AND DISCUSSION

Selection of experimental conditions

The effects of pH and the concentrations of Ce(III) and ALC on peak height are shown in Fig. 2. The optimum conditions for the determination are $5 \times 10^{-5} M$ Ce(III) and $1 \times 10^{-5} M$ ALC. The optimum pH is about 4.8. It was also found that acetone can reduce the formation time of the Ce(III)–ALC– F^- complex. The optimum concentration of acetone is 10%.

Effect of standing time

In order to obtain a stable peak height, the solution to be analysed was required to stand for some time; a 30-min period was found to be optimum.

Under the optimum conditions, the relationship between peak height and concentration of F^- was linear from $8 \times 10^{-8} M$ to $5 \times 10^{-6} M$ (correlation coefficient = 0.9976). A detection limit of $5 \times 10^{-8} M$ was obtained (concentration

Fig 1 Derivative single sweep polarogram of the Ce(III)–ALC– F^- complex. Curve 1, $0.1 M (CH_2)_6N_4$, 10% acetone, $1 \times 10^{-3} M$ ALC, $5 \times 10^{-5} M$ Ce(III), pH = 4.8. Curve 2, Conditions as for curve 1 plus $3 \times 10^{-6} M F^-$. P₁, ALC; P₂, ALC–Ce(III) complex peak; P₃, Ce(III)–ALC– F^- complex peak.

Fig 2 Effect of supporting electrolyte concentration on peak height of Ce(III)–ALC– F^- complex, $F^- = 3 \times 10^{-6} M$

giving a signal equal to three times the standard deviation of the blank).

Effect of foreign ions

The experimental results show that 2000-fold K^+ , Na^+ , Cl^- , NO_3^- and NO_2^- ; 1000-fold Ca(II) and Mg(II); 600-fold Ni(II); 100-fold Pb(II); 70-fold Zn(II), Cu(II) and Co(II); 50-fold Cr(III) and Mo(VI); 40-fold Fe(III) and PO_4^{3-} and 10-fold Cd(II) have no effect on the determination of F^- (0.05 ppm).

Properties of the polarographic wave

Electrocapillary curves. These curves can give some information about the adsorption of a particular species. A solution containing F^- has an electrocapillary curve lower than that of the supporting electrolyte (Fig. 3) because the adsorption of the Ce(III)–ALC– F^- complex on the surface of the DME changes the surface

Fig 3 Electrocapillary curves. Curve 1, $0.1 M (CH_2)_6N_4$, 10% acetone, $1 \times 10^{-5} M$ ALC, pH = 4.8. Curve 2, Conditions as for curve 1 plus $5 \times 10^{-5} M$ Ce(III). Curve 3, Conditions as for curve 2 plus $3 \times 10^{-6} M F^-$.

Table 1. Analytical results for fluoride in some natural samples

Sample	n*	Mean value, ppm	sd†, ppm	Recovery of added fluoride, %	Fluoride-selective electrode value, ppm
Tap water	4	0.42	0.03	105	0.43
Lake water	4	0.40	0.05	95	0.41
Well water	4	0.18	0.02	95	0.19

*n = number of determinations.

†sd = standard deviation

tension of the mercury drop. This clearly illustrates the adsorption of Ce(III)-ALC-F^- at the DME.

Effect of accumulation time. The effect of accumulation time at a hanging mercury drop electrode was studied with normal adsorptive voltammetry in $0.1M (\text{CH}_2)_6\text{N}_4-5 \times 10^{-5}M \text{Ce(III)}-1 \times 10^{-5}M \text{ALC}-1 \times 10^{-7}M \text{F}^-$. It was found that the peak height increases with accumulation time and maximum increase occurred with a 2-min accumulation time. If the process is diffusion controlled, with no adsorptive accumulation, the peak height will be independent of the accumulation time before scanning. This proves that the polarographic wave is an adsorption wave.

Effect of starting potential. It was found that the more positive the starting potential, the higher the peak was. The peak height for Ce(III)-ALC-F^- increased with sweeps started from more positive potentials, which allowed more complex to be adsorbed at the electrode. This result shows that the Ce(III)-ALC-F^- complex is negatively charged.

Cyclic voltammetry. The cyclic voltammetry of the system was investigated with a Model 82-1 voltammetric analyser with a hanging mercury drop electrode. The Ce(III)-ALC-F^- complex gives a cathodic peak at about $-0.64 \text{ V (vs. SCE)}$. No peak was observed on the anodic branch, indicating irreversibility of the reduction. The cathodic peak in the first scan with an accumulation time of 1 min was much higher than that in the second scan.

In addition, the polarographic wave shows a decrease in peak height down to zero with addition of surface-active agent, such as tetradecylpyridinium bromide. All these phenomena give evidence of the adsorption character of the wave.

Sample analysis

The procedure for the determination of fluoride in water samples was as follows. Aliquots (0.5 ml) of each water sample were transferred into the 10-ml electrolytic cell. A 1.0-ml portion of $1M (\text{CH}_2)_6\text{N}_4$, 0.1 ml of $1 \times 10^{-3}M \text{ALC}$, 1.0 ml of $5 \times 10^{-4}M \text{Ce(III)}$ and 1.0-ml of acetone were added to each solution in sequence. After shaking and allowing to stand for 30 min, the solutions are diluted to 10 ml with water. The determination is made by the procedure described above. The results obtained are given in Table 1, and are compared with those obtained with a potentiometric fluoride selective method¹² Recovery of spiked fluoride is listed also. The method is sensitive, requiring only 1% of the volume of water sample required for the selective electrode method (50 ml of sample mixed with 20 ml of total ionic strength adjustment buffer solutions and diluted to 100 ml).

(Received 24 January 1991 Revised 3 March 1991 Accepted 6 March 1991)

Summary—The amounts of free ions and labile complexes of Pb, Zn and Cd have been determined in a complex organic growth medium by use of anodic stripping staircase voltammetry, ASSV. It was possible to determine the labile fractions of metals and to obtain good correlation with data on the toxicity of the metals to *Tetrahymena* when using a specific reduction potential (E_r) for each element, -600 , -800 and -1200 mV vs SCE for Pb, Zn and Cd, respectively. The labile fractions in the organic growth medium were less than 1% for Pb (Pb precipitated), 15% for Zn (as labile complexes) and 30–40% for Cd (as free ions) for total heavy metal concentrations of 0.5 – 2 mM. The toxicity to *Tetrahymena* decreased in the order Cd \gg Zn \gg Pb. The effect of Pb was greater than predicted by ASSV, probably because *Tetrahymena* additionally ingests the lead-containing precipitate and therefore is exposed to concentrations of Pb exceeding those of the soluble species found in the medium. The results stress the importance of using different specific reduction potentials when different elements are compared, instead of one potential common to all elements. The use of a fixed potential may lead to erroneous conclusions regarding the concentrations of labile species in solution.

The speciation of heavy metals in water has been the subject of many studies, as indicated in the review by Florence.¹ Since speciation is known to affect the toxicity to living organisms^{2–5} and to control metal bioavailability, the total metal concentration, as measured by AAS, for example, has little or no meaning for the assessment of toxicity in nature. The free metal ion concentration may be a more useful parameter in determining metal toxicity, although some chelates may be more available and toxic than their corresponding free ions. The complete resolution of all chemical species would be the ideal, but unrealistic goal. The heavy metals of interest in environmental studies are normally present in low concentrations, and since the aquatic environment is complex with unknown constituents, a direct identification of the species is difficult. A more realistic approach is to determine the amounts of metal with the same degree of chemical availability, *i.e.*, complex-bound with similar strength, regardless of the exact nature of the complexes.

In this study anodic stripping staircase voltammetry, ASV,⁶ is the primary method to distinguish labile and bound species of the heavy metals Pb, Zn and Cd. The reduction potential at a mercury electrode is used to differentiate between “free” or “labile” and “bound” forms of the metals. There are several reasons for not using a direct electrochemical method such as cyclic voltammetry. The sensitivity of cyclic voltammetry is too low for many of the measurements, thus the same method could not be used in all cases, making direct comparisons less accurate. Also the organic growth medium may cause deterioration of the electrode surface and affect the cyclic voltammetric response more than the ASSV-response because the oxidation current is significantly lower in cyclic voltammetry. Finally, we are interested in developing a method which can be employed in environmental studies, *i.e.*, at ultra-trace levels of heavy metals.

Another type of fractionation of metals utilizes the particle size distribution of heavy metals in the solution. The particles may be pure metal precipitates, but metals could also be precipitated with particulate matter of the medium.

*Present address Department of Environmental Technology,
Danish Technological Institute, Gregersensvej P O Box
414, DK-2630 Taastrup, Denmark

Such measurements of speciation were performed in an organic growth medium (PP), where the toxic effects on *Tetrahymena* have been studied. *Tetrahymena* is a common freshwater ciliate, often used in assay with heavy metals, see Nilsson for a review.⁷

Zinc has already been investigated in a simple inorganic medium.⁸ It was found that the calculation of speciation may lead to quite erroneous results, even in solution which are much simpler than the natural aquatic environment. Therefore, the present study was undertaken to identify the toxic fractions of heavy metals in an organic growth medium containing a variety of protein fragments, vitamins, salts, *i.e.*, a quite complex medium.

EXPERIMENTAL

Electrochemical measurements

The electrochemical method and the computer controlled instrumentation have been described previously.⁶ Part of the work was done with a new set-up including a Biodata Microline 4000 waveform capture system connected to an Admiral 20286 Personal Computer, using an IEEE 488 interface and ASYST 2.1 software. The new instrumentation was programmed to emulate the old set-up, thus all experiments were performed in exactly the same way. The working electrode was a 3-mm Metrohm 628-10 rotating glassy-carbon electrode rotated at 2000 rpm, the reference electrode was an Ingold mercury sulphate electrode, and a platinum wire served as the counter electrode. The mercury sulphate reference electrode had a potential of +400 mV relative to the SCE electrode and all potentials are given *vs.* SCE. The glassy carbon was covered with a mercury film formed by reduction of 100 ppm Hg^{2+} in 0.2M potassium nitrate at -1100 mV *vs.* SCE for 65 sec.

Samples (10.0 ml of the medium under investigation) were prepared in 0.2M potassium nitrate, the metal ion was added and the pH was readjusted with sodium hydroxide. The oxidation peak current (I_p) was measured after reduction of the metal ions at a plating potential (E_{pl}) for a plating time (p_t) selected according to the actual concentration. Plating times from 0.1 and 10 sec were used in this study.

The plating potential E_p was varied in steps of 100 mV from a value with zero peak current ($I_p = 0$) to a value where the current was independent of potential ($I_p = I_d$). Because of the very low plating time (0.1 sec) in some measure-

ments the reduction current during the stripping scan cannot be neglected. Therefore, plating time was extended such that plating time including scan time was constant at all plating potentials.

The same film was used for measurement both in the medium and in a reference solution of the same metal in 0.2M potassium nitrate in doubly demineralized water deoxygenated with argon. In the proteose peptone (PP) medium very small effects of dissolved oxygen were observed, and as the PP solutions did form a lot of foam when bubbled with argon, the experiments were run in PP saturated with air. In the organic growth medium the electrode deteriorates with time. Therefore, the electrode was only kept in this medium for the minimum time necessary for one measurement.

Size fractionation

The fractionation procedure was initiated by a separation of particulate species by filtration through a 0.45- μm membrane filter. The filtrate was then introduced into an Amicon ultrafiltration system with YM-5 ultrafilters with a cut-off 5000. The ultrafiltration cell and membrane was flushed with doubly distilled water before a sample was introduced and the system pressurized with nitrogen. After filtration the concentration of the three metals was determined by flame atomic-absorption spectrometry on a Perkin-Elmer 2280 instrument.

Toxicity test with Tetrahymena

Tetrahymena pyriformis GL⁹ was grown axenically at 28° in 2% PP enriched with 0.1% yeast extract and inorganic salts.¹⁰ The 100-ml cultures were shaken and aerated and the cells used were in the exponentially multiplying growth phase (about 5×10^4 cells/ml).

Lead, zinc or cadmium was added to the medium in acetate form. Stock solutions used were 100 and 200mM, kept in polyethylene bottles and at least 0.1M in nitric acid. When addition of the metal salts to the medium caused a decrease of pH, sodium hydroxide was used to readjust the pH to 6.8.

The cell density of the cultures was normally determined in triplicate, using an electronic particle counter, Coulter Counter Model ZB, after fixation in a 1:1 (by volume) mixture of 1% glutaraldehyde in an inorganic salt solution.¹¹ Addition of some metals to the medium gave precipitates. In this case the electronic particle counter could not be used directly be-

cause the presence of precipitate resulted in an excess value of the cell density.¹² However, by adding hydrochloric acid to the fixed cell sample the precipitate was dissolved and a homogeneous sample could be obtained for counting. When a high rate of cell mortality was observed the cell density was determined manually in triplicate with a Fuch-Rosenthals cell chamber, because the electronic particle counter could not differentiate between living and dead cells. No difference in the number of cells of untreated control cultures was found with the two methods.

For growth experiments the original 100-ml culture was divided into two portions, the metal was added to one portion, whereas the other served as control. From both cultures cell samples were withdrawn simultaneously for the determination of cell density.

THEORY

On plotting the electrochemical response with the oxidation peak current (I_p) as a function of the reduction potential (E_{pl}), a pseudo-polarogram is obtained.^{13,14} For a free aqua-ion of the investigated metals the curve (Fig. 1, curve a) is an S-shaped wave given by

$$I_p = I_d / \{1 + e[(nF/RT) * (E_{pl} - E_{1/2})]\} \quad (1)$$

The half-wave potential, $E_{1/2}$, is the potential at which the current is one half the limiting current (I_d). $E_{1/2}$ is characteristic of the free metal ions

Fig 1 Schematic pseudo-polarograms for (a) free ions, (b) all ions in complex form; (c) both free and complexed ions and (d) medium and very strong complexed ions. $E_{1/2}$: plating potential giving peak currents corresponding to labile forms. E_x : plating potential resulting in peak currents including complex bound ions.

and is close to $E_{M^{2+}/M(Hg)}^0$. In the case of complexation of M^{2+} by ligands L

$$K_f = [ML_m^{2+}] / [M^{2+}][L]^m \quad (2)$$

the curve will be shifted cathodically:

$$\begin{aligned} E_{1/2}(\text{complexed}) - E_{1/2}(\text{free ion}) \\ = -(RT \ln 10/nF) \log(1 + K_f[L]^m) \quad (3) \end{aligned}$$

i.e., the curve is observed at a more negative potential (Fig. 1, curve b).

The term $RT \ln 10/nF$ is equal to $59.16/n$ mV at 25° . For $n = 2$ a shift of 29.6 mV is predicted for each decadic increase in K_f or $[L]^m$, when excess L is present. As an example, for $[L] = 3mM$ and $K_f = 10^{13}M^{-1}$ the shift is 310 mV (Fig. 1, curve b).

When L is deficient, the polarogram consists of two waves, the first for the free ions (height proportional to $[M] - [L]$) and the second for the complexed metal (height proportional to $[L]$), this case is shown in Fig. 1, curve c.

If the reduction potential is shifted beyond the reduction potential of the solvent, the metal complex cannot be determined by ASSV. Figure 1 curve d shows the case of partial reduction at -310 mV relative to $E_{1/2}$ but the main part remaining bound in a strong complex, which cannot be reduced within the available potential range.

Plating at the potential E_x will give a response proportional to the amount of free ion and loose complexes with shifts less than about 60 mV (corresponding to $K_f[L]^m = 100$), whereas the response at E_y will represent both free ions and relatively strong complexes ($K_f[L]^m$ equal to 10^{13}).

It must be stressed that the labile fraction includes the ions, and becomes free when the equilibrium in equation (2) is shifted to the right as a result of the depletion of M^{2+} at the electrode. This amount is limited by the kinetics of the dissociation of the complex, *i.e.*, in general, loose complexes dissociate fast and strong complexes slow, but the mechanism is similar to what might occur when M^{2+} is depleted because of transport through a biological membrane. In this respect, the ASSV-labile fraction is similar to the bioavailable fraction.¹ Thus, at the lowest potential, where I_p is close to I_d , free ions and labile complexes of each element will be reduced. Since this potential depends on the half-wave potential for each element (see Figs. 2 and 3 as an example) we shall denote this potential the specific potential, E_s .

Fig 2 Staircase voltamperograms for $10\mu\text{M}$ Pb, Zn and Cd in 0.2M KNO_3 saturated with air. Plating potentials from -1400 (lefthand, lower curve) to -600 mV vs SCE (righthand upper curve); plating time 1 sec, step-length 10 mV, step-time $256\ \mu\text{sec}$ (i.e., scan-rate 156 mV/sec)

The amount of metal, which can be reduced at a given potential is called ASSV-labile, and the concentration is calculated from the proportion of the response in the medium to the limiting response I_d in water, measured at the same film electrode.

RESULTS

Electrochemical response in 0.2M potassium nitrate

The oxidation current as a function of potential for the free aqua-ions of the three metals in 0.2M potassium nitrate in water is shown in Fig. 2 for plating potentials ranging from -1400 to -600 mV. For each metal a peak is observed at a potential characteristic of the metal. It can be seen that the peak currents depend on the plating potential. The experiments were run in 0.2M potassium nitrate saturated with air. Due to the effect of oxygen the limiting current decreased by 8% for Pb, by 25% for Cd and by 52% for Zn, as compared to deoxygenated solution. A plot of the oxidation peak currents, I_p , as a function of the plating potential, E_{pl} , gives pseudo-polarograms for the three free ions, see Fig. 3. From these pseudo-polarograms the specific potentials for the free ions of Pb, Cd and Zn are taken to be -600 , -800 and -1200 mV vs. SCE respectively.

Electrochemical response in growth medium

In the proteose peptone medium, the electrode response of lead was very low, Table 1. Electrode deterioration resulted in a rapid decrease of the response during repetitive measurements. The addition of lead gave a white precipitate, easily visible at concentrations above 0.5mM lead, and the amount of labile lead increased only slightly from a total concentration of 0.5mM – 2mM . In all cases, the

*Potential relative to $E_s(CD)$

concentration of labile lead is less than $10\mu M$. The potential where I_p reaches a constant value is shifted cathodically about 400mV relative to the potential in 0.2M potassium nitrate indicating that Pb is strongly complex bound.

One wave was also observed for Zn and the amount of labile Zn is given in Table 2. The measurements of Zn were also affected by electrode deactivation in PP. Since the response does not reach a constant value corresponding to I_d it is not possible to assess a single potential shift for Zn. The effect of several overlapping shifted waves with different shifts and heights is seen. Thus, the results indicate the presence of many complexes of varying strengths, but also that a significant part of the Zn is labile in PP.

Cadmium gives a strong and very stable response to PP. The current only decreased slightly because of electrode deterioration, and the levels, Table 3, were quite stable. The potentials do not indicate any shift in the curve

relative to that in water. Thus, in PP nearly half of the Cd is present in a very labile form.

Filtration of growth medium

Atomic-absorption spectrometric determinations, after addition of $24\mu M$ Pb, $76\mu M$ Zn and $44\mu M$ Cd (5 ppm of each of the elements) in samples of PP prior to, and after, filtration through a $0.45\text{-}\mu$ filter and finally after additional ultrafiltration, are given in Table 4. For Pb, 90% was found in the particulate fraction and did not pass the $0.45\text{-}\mu$ filter. Zinc and cadmium did not bind to particles larger

than $0.45\mu\text{m}$ and only 20% were removed by ultrafiltration.

Toxicity in PP-medium

The effect of different concentrations of Pb, Zn and Cd on the rate of cell proliferation was tested in the PP medium during 24-hr exposures.

Addition of 0.5 and 1mM Pb had no significant effect on cell proliferation which, however, started after a variable lag period, Fig. 4(a). A normal generation time of less than 3 hr was found after 3 and 4 hr exposure to 0.5 and 1mM Pb, respectively. Both cultures reached maxi-

mum cell density (about 1,000,000 cells/ml) after 24 hr, *i.e.*, comparable to control cells. In 2mM Pb, cells exhibit a lag period of about 4 hr, after which the cells start proliferation, but at a decreased rate; the generation time was prolonged by a factor of 1.25 above the control value, and after 24 hr only about 350,000 cells/ml were seen.

Zinc affects cell proliferation in a way comparable to that described for lead with cell proliferation resumed after a variable lag period [Fig. 4(b)]. Addition of 0.5mM Zn had no significant effect on cell proliferation. In the presence of 1mM a lag period of about 2 hr preceded cell proliferation at a decreased rate; the generation time was prolonged by a factor of 1.2 above the rate of control cells but the same final cell density was reached. Although some cells died during the first 3 hr of exposure to 2mM Zn, the survivors were capable of proliferation; the generation time was prolonged by a factor of 3 above the control value during the following 5 hr. A cell density of about 550,000 cells/ml was seen after 24 hr exposure, indicating a further increase in the rate of cell proliferation.

Addition of Cd to cells caused a high rate of cell mortality, thus all cells died within 30, 20 and 15 min exposure to 0.5, 1 and 2mM Cd respectively, see Fig. 4(c).

In vivo observations revealed that *Tetrahymena* ingest the precipitate formed on addition of Pb (in particular) to the organic growth medium. The ingested precipitate was incorporated into food vacuoles and later defecated from the cells as defecation balls. All exposed cells contain small, refractile granules which are not seen in the control cells. Typically, the number of granules increased with time and metal concentrations. In proliferating cells the number of granules reached a stable level, but in the stationary growth phase, where control cells also form the small refractile granules, the metal-treated cells contain an increased number of these granules.

DISCUSSION

When different elements are to be compared it is important to realise that electrochemical stripping methods may lead to erroneous conclusions, when a fixed reduction potential is used for all elements, because the electrochemical labile fractions would be different for different metals. The reduction potential should therefore be selected for each element.

The effect of oxygen on ASSV of Pb, Cd and Zn can be explained in terms of the reduction product, OH^- , which may precipitate $\text{M}(\text{OH})_2$ near the electrode surface. This effect is greater in 0.2M potassium nitrate than in PP, because of the buffer capacity in PP.¹⁵ This effect is most pronounced for Zn, with the most cathodic plating potentials, since the second reduction step of oxygen occurs at -900 mV vs. SCE . The solubility products for the three hydroxides are similar.¹⁶

The concentration of labile Pb species or free Pb^{2+} ions determined in PP is very low: $0\text{--}10 \mu\text{M}$ even after addition of 2mM lead. Precipitation is directly observed, and this explains the low concentrations in labile Pb. The current increases significantly with negative plating potentials indicating that the residual soluble Pb is bound in several complexes.

The observed response for Zn in PP is smaller than in 0.2M potassium nitrate at low potentials, but at more negative potentials the responses increases rapidly. This indicates that Zn is bound in a variety of complexes, of which a substantial part is very labile. At $E_s(\text{Zn})$ we find a current corresponding to a concentration of free ion or very labile complexes of 84, 149 and $220 \mu\text{M}$ at total concentrations of 0.5, 1 and 2mM, respectively. Because of the cathodic shift of the whole response, it is most likely that the current at E_s corresponds to labile complexes rather than to residual free ions. The ASSV-measurements thus indicate that Zn is distributed among several complexes of which about 15% are very labile.

The current for Cd is about half of that in water, and no shift in reduction potential can be seen in the experimental values. This means that half of the Cd is present as free ions or very labile complexes in PP. The remaining part of the Cd must be bound in quite strong complexes.

The filtration experiments followed by determination of total concentrations by AAS support the above findings. Lead is removed to 90% by $0.45 \mu\text{m}$ filtration with no effect of subsequent ultra-filtration. Cadmium stays in solution as does zinc. Thus, the results of filtration support that Pb is active in building aggregates that may precipitate at higher concentrations.

The high tolerance of *Tetrahymena* towards Pb in the organic growth medium is in agreement with the very low ionic concentration of the metal found by ASSV. The protective property of the organic growth medium towards

toxic effects of Pb is also indicated by an increased toxicity of the metal in diluted medium.¹² Although the toxicity of lead is greater than predicted from the ASSV data the growth rate is only slightly affected by 2mM Pb under the present experimental conditions. The discrepancy between the ASSV data and the toxicity could be that *Tetrahymena* ingests the precipitate formed by addition of Pb and therefore becomes exposed to higher amounts of Pb than measured by ASSV. Electron microscopy has revealed that Pb enters *Tetrahymena* through the membrane of digestive vacuoles and through the cell surface;¹⁷ however, in the digestive vacuoles most of the lead-containing precipitate is converted to refractive debris which is defecated.¹² That *Tetrahymena* is able to proliferate in the presence of 2mM lead agrees well with earlier studies in which the cells were maintained under comparable growth conditions.¹² Liu *et al.*,¹⁸ however, found that $48 \mu\text{M}$ Pb was lethal to *Tetrahymena*. The apparent discrepancy between these results and those obtained in the present study may be explained by the use of different organic growth media with different complexing capacity for Pb.

Zinc is an essential metal required in trace amounts by living cells, but toxic in excess amounts. Addition of Zn to the growth medium causes an inhibition of cell proliferation which resembles that described for Pb but the effect is more pronounced. The toxicity of Zn to *Tetrahymena* seems strongly correlated with the amount of organic materials in the medium, a factor which may partly explain some of the disagreement on the concentration of Zn tolerated by this organism.¹⁹⁻²¹ The toxicity of metals may also change with time of exposure as a result of an adaptation. *Tetrahymena* exhibits a certain lag period before cell proliferation takes place in the presence of Pb and Zn. This lag period may be caused by a change in the medium or an adaptation phase during which a metal-regulating system is activated. In *Tetrahymena* this detoxification system may include both a retention of metal within the digestive vacuole and a reduced entry through the plasma membrane. The small refractile granules found in *Tetrahymena* under unfavorable growth conditions have been shown to accumulate Pb, Zn and Cd, when added externally,^{17,19,20} in agreement with their proposed function as ion-regulators.²²⁻²⁴

The toxic effects of Cd, an industrial pollutant, on *Tetrahymena* have been studied extensively.

In the PP medium all cells die within 30 min in 0.5mM Cd which indicates a very high toxicity. About 0.05mM Cd inhibits cell proliferation and produces a high rate of mortality.²⁵⁻²⁷ However, the effect of a given concentration of Cd depends on the initial cell density of the culture.²⁵ Even though most of the cells die in concentrations of about 0.05mM Cd, the surviving cells resume cell proliferation, as if they became adapted.^{25,26,28} A metallothionein-like protein has been found in *Tetrahymena* after exposure to Cd,²⁹⁻³² it may also play an important role in metal detoxification in this organism. The toxicity of Cd seems also to depend on the amount of organic material in the medium; thus, growth is inhibited at 4μM in 0.2% PP,²¹ whereas it is uninhibited at 18μM Cd in 2% PP medium.²⁵ Even though two different strains of *Tetrahymena* was used, the main difference between these studies may well be explained by the different concentrations of organic material. That Cd inhibits cell proliferation in the PP medium at very low concentrations is in agreement with the ASSV data, which indicate that about two-fifths of the added Cd is ASSV-labile.

CONCLUSION

The electrochemical results suggests that Cd is rather (30–40%) free in the organic growth medium, Zn is complexed, but with a substantial amount of quite labile complexes (15%), and Pb are complexed as well as precipitated (less than 1% free). The toxicity of metals towards *Tetrahymena* decreases in the order Cd ≫ Zn > Pb, in agreement with a decreased amount of labile metal. However, the toxicity of Pb is greater than predicted, presumably because the organisms ingest the precipitate formed by addition of lead, and therefore become exposed to a higher concentration of Pb than measured by ASSV.

In conclusion, ASSV can be used to assess the labile fraction of heavy metals by proper selection of specific reduction potentials (E_r) for each element, and good agreement is obtained with the toxicity data. However, an evaluation of the toxicity of heavy metals to aquatic organisms should not be based on the chemical measurements alone, since some complexes may be more toxic than the corresponding free ions. Furthermore, the effect of metals on living organisms are quite complex e.g., different metal ions may show variable toxicity according to different sites of action.

POTASSIUM SODIUM CHLORIDE INTEGRATED MICROCONDUITS IN A POTENTIOMETRIC ANALYTICAL SYSTEM

CUI HONGBO and SUN JUNYAN

Institute of Applied Ecology, Academia Sinica, Shenyang, China

(Received 6 December 1990 Revised 13 February 1991. Accepted 21 March 1991)

Summary—The preparation and application of a K^+ , Na^+ and Cl^- integrated microconduit potentiometric analytical system with tubular ion-selective electrodes (ISEs), microvalve, chemfold, electrostatic and pulse inhibitors is described. Electrochemical characteristics of the tubular ISEs and integrated microconduit FIA-ISEs were studied. The contents of K^+ , Na^+ and Cl^- in soil, water and serum were determined with the device. The analytical results agreed well with those obtained by flame photometric and silver nitrate volumetric methods.

The contents of potassium, sodium and chloride in soil, water and serum are among the determinations which are routinely most often performed in soil chemistry and clinical analytical chemistry. Although flame photometry and silver nitrate volumetry are used as the standard analytical methods for potassium, sodium and chloride, segregated flow and flow-injection analysis-ion selective electrode (FIA-ISE) analytical systems with automatic devices have been used to replace the flame photometer and its fuel gases and gas exhaust, to simplify experimental procedures, to decrease reagent and sample requirements and to increase sampling rate and analytical precision.¹⁻³

We have constructed a new potassium, sodium and chloride integrated microconduit device with micro tubular ISEs, microvalve, coil, chemifold, electrostatic and pulse inhibitors based on Růžička's work.⁴ The size of the device is about one-third smaller than a cigarette pack and about one-third as thick (normally $10 \times 30 \times 50$ mm). In comparison with the Růžička pH integrated microconduits, its specification is as follows:

(1) The device has all solid structure in order to eliminate separation of the adhesive membrane from the perspex piece and solution leakage, at the same time raising the insulating ability of the device and increasing the service life.

(2) The tubular ISEs are well connected to the integrated main piece with a standard channel

to allow replacement of tubular ISEs very simply and to determine more analytes.

The characteristics of the tubular ISEs and the experimental conditions of the integrated microconduit FIA-ISEs were studied. The conditions of K^+ , Na^+ and Cl^- in soil, water and serum samples were determined. The analytical results agreed well with those obtained by flame photometric and silver nitrate volumetric methods.

EXPERIMENTAL

Apparatus

A schematic diagram of the FIA-ISEs manifold used in this study is shown in Figs. 1 and 2. An Orion 901 ionanalyzer connected to a Dahua recorder is used. A Carlo Erba Instrumentazione model 1512 peristaltic pump with Tygon pump tubes was used to propel the carrier and to aspirate the sample solution. The home-made micro-tubular electrodes, microvalve, coil, electrostatic and pulse inhibitors were integrated into the microconduits which allowed the volume between the valve and the electrodes to be reduced to less than $10 \mu\text{l}$ in order to minimize sample dispersion. The connection between the microvalve and the electrode was made with a 0.5-cm long stainless steel tube which was earthed to prevent interference from static electricity created by the pump roller. The connection between the indicator

(B) Expanded view of tubular flow-through cell I, Ag/AgCl inner reference electrode; M, sensitive membrane; S, internal reference solution, E, epoxy resin

electrode and the reference electrode was made with a micro three-way tube.

Tubular flow-through electrodes

The tubular flow-through potassium, chloride and sodium electrodes were respectively prepared by replacing part of the wall of a small piece of PVC tubing (1.5 cm long, 0.5 mm i.d., 1.5 mm o.d.) with the valinomycin sensing membrane (0.25 mm²), by coating a fine layer of silver chloride onto the inner wall of the silver cylinder (1.0 cm long, 0.5 mm i.d., 0.6 mm o.d.) and by using sensing sodium capillary glass (1.5 cm long, 0.5 mm i.d., 0.7 mm o.d.).⁵⁻⁶ They were placed into the perspex housing respectively as shown in Fig. 1(B). The housings were respectively filled with a suitable inner solution containing the sensing ion and saturated silver chloride into which a Ag/AgCl wire was inserted to serve as the inner reference system. Those pieces of tubing act as potentiometric flow-through detectors with zero dead volume. The dimensions of all the tubular electrodes were 1.5 cm long, 1.0 cm wide and 1.2 cm high.

The prepared tubular electrodes were then integrated into the microconduit with the standard channel (Fig. 2).

Reagents

Doubly distilled water and analytical reagent grade acids and salts were used throughout unless otherwise stated.

The standard solutions and carrier components used for testing the electrode characteristics and calibrating the electrodes prior to K⁺, Na⁺ and Cl⁻ measurements in soil and water are as follows: K⁺: 0.1N hydrochloric acid-triethylamine (1:50) standard solutions, $C_K + = 0.1$ ppm (in carrier). Cl⁻: 0.2M-Cl⁻ standard solutions, $C_{Cl^-} = 10^{-5}M$ (in carrier). Na⁺: 0.25M magnesium acetate-Na⁺ standard solutions, $C_{Na^+} = 10^{-5}M$ (in carrier).

The calibration solutions used for calibrating the electrodes prior to serum K⁺, Na⁺ and Cl⁻ determinations are as follows: (A) 40mM Na⁺-4mM K⁺-136 mM Cl⁻ standard solution. (B) 80mM Na⁺-8mM K⁺-80mM Cl⁻ standard solution.

These solutions are both of pH 7.40 and ionic strength 0.16M.

Sample preparation

Water. K⁺: Pipette 5 ml of water into a 25-ml beaker and add 5 ml of pH 8.5 0.2N HCl-triethanolamine (1:25).

Na⁺: Pipette 5 ml of water into a 25-ml beaker and add 5 ml of 0.4M potassium nitrate.

Cl⁻: Pipette 5 ml of water into a 25-ml beaker and add 5 ml of 0.4M potassium nitrate.

Soil. Weigh 5 g of an air-dried soil sample into a 50-ml flask. Add 25 ml of water and shake for 3 min. Pipette the filtrate and

prepare the sample as above for the water sample.

Serum. The serum tested originated from the Shenyang hospital and was not diluted.

Electrode characteristics

In order to study the response characteristics of the electrodes in different experimental conditions, a rod electrode and a tubular flow-through electrode in the integrated microconduit with the same sensing membrane were made and tested separately in the static state and in the flow state at 25° (Table 1).

According to the data presented in Table 1, the characteristics for the tubular electrode integrated microconduit under flow conditions had rapid response (5-10 sec), high reproducibility (±0.1 mV) and good stability (overall EMF drift of 0.2 mV/hr over at least 8 hr). This is due to the stable experimental conditions with respect to precise sampling volume, reproducible transport, constant flow and washing in the system.

Flow-injection analysis selectivity coefficient values are slightly different than those obtained in the static state. A plausible explanation is that the contact time between the interference solution and the membrane is much shorter under dynamic conditions than in static measurements. Moreover, the flow of the carrier solution between injections of interference samples provides continuous wash and recondi-

tioning of the membrane. Also, adsorption, desorption and response speed of the sensing membrane may be different. By adjusting experimental conditions, changing carrier components or using FIA treatment on line, the effect of interfering ions on the analytical results may be decreased.

The K⁺, Na⁺ and Cl⁻ flow-through micro-electrode integrated microconduits produce less dispersion, increased sampling rate and analytical precision. Addition of a small amount of the sensing ion to carrier appears to improve the dynamic properties of the electrode, enabling narrower peaks and good linearity to be obtained.

Standard and sample measurement

The integrated microconduit manifold was connected as in Fig. 1. The conditions selected were sampling volume $S_v = 100 \mu\text{l}$, the pumping rate for the indicator electrode $Q = 2.0 \text{ ml/min}$, and for the reference electrode $Q = 0.24 \text{ ml/min}$. The system was calibrated with a series of standard solutions and the samples were analysed. The results summarized in Table 2 show excellent agreement between the integrated microconduit method, flame photometry and silver nitrate volumetry. Typical outputs for calibration series are shown in Figs. 3-5.

For the lower sampling volume with the FIA system, the maximum potentials (peak heights)

Na ⁺	proposed method	34	39	72	189	123	61.2	50.1	25.8	30.2	49.5	50.7	48.3	134	131	130	129	132	140	139
	flame photometry	38	41	72	182	123	60.9	50.2	25.7	31.8	48.8	52.0	49.2	133	132	132	130	132	138	141
Cl ⁻	proposed method	24	32	54	164	78	26.1	49.3	18.4	14.2	17.8	11.4	16.4	88	100	97	98	104	101	96
	volumetry	21	28	54	161	74	25.9	49.6	17.6	15.0	18.1	12.1	17.1	88	98	98	98	101	99	95

are lower than those obtained by the steady state mode, revealing the influence of the sample dispersion and response time on the readout. The slope of the calibration curve will be the same as that based in steady-state measurements (Fig. 3). The sampling volume S_v required to reach steady state readouts with the integrated microconduit device is only 1/3 of the volume previously required by conventional FIA-ISE methods.

The determination of K^+ , Na^+ and Cl^- in soil, water and serum was carried out separated with the integrated microconduit device shown in Fig. 1. The analytical results agreed well with those obtained by flame photometric and silver nitrate volumetric methods. The following regression equations were obtained for the results.

$$K^+ : C_{FPM} = 0.991 C_{FLA} + 0.129$$

$$Na^+ : C_{FPM} = 0.987 C_{FIA} + 0.118$$

$$Cl^- : C_{VM} = 1.004 C_{FIA} + 0.088$$

where

FPM = flame photometric method

VM = silver nitrate volumetric method

FIA = integrated microconduit FIA-ISE method

Fig. 3 Response curves obtained by injecting 100 μ l (right, middle) and steady state (left) of standard solutions of different K^+ concentrations into a carrier stream of $C_{K^+} = 0.1$ ppm

Fig 4 Response curves obtained by injecting 100 μ l standard solutions of different Na^+ concentrations into a carrier stream of $C_{Na^+} = 10^{-6}M$

In general, the detection limit of the integrated microconduit FIA-ISE method appears higher than for the static state method due

Fig 5 Response curves obtained by 100 μ l standard solutions of different Cl^- concentrations into a carrier stream of $C_{Cl^-} = 10^{-5}M$

to sampling dispersion and slower response of the electrode at very low concentrations. The sampling rate was related to the sample concentration.⁷ The larger the differential value in the concentrations between the carrier and the sample, the more time required to return to the base line. The sampling rate was about 120–200 per hr at almost equilibrium state with carry over of less than 0.7%. The standard deviation over the linear range with tubular electrodes was about 0.1 mV (N = 11).

THE DETERMINATION OF LEAD IN TOTAL SUSPENDED AIR PARTICULATES BY X-RAY FLUORESCENCE SPECTROSCOPY

THOMAS A. LAFISCA, STUART J. NAGOURNEY and CHARLES PIETARINEN
New Jersey Department of Environmental Protection, 380 Scotch Road, Trenton,
New Jersey 08625, U.S.A

(Received 10 January 1991. Revised 26 March 1991 Accepted 2 April 1991)

Summary—A method has been developed for the measurement of lead in air particulates collected on glass fiber filter paper with wavelength-dispersive x-ray fluorescence spectroscopy (WDXRF). Analyses conducted by both WDXRF and an EPA-approved procedure that employs acid sonication followed by analysis of the extract by atomic-absorption spectroscopy (AAS) shows excellent agreement between the two methods. WDXRF calibration was accomplished with standards prepared from known additions of Pb to unexposed glass fiber filter discs. Method equivalency has also been demonstrated by the analysis of several reference materials and the statistical analysis of quality control data. The WDXRF procedure has also been used to evaluate the distribution of Pb in the particulates across the surface of the filter.

The Clean Air Act of 1970 provided the United States Environmental Protection Agency (EPA) with the authority to establish maximum air concentrations for the most significant pollutants; these are termed National Ambient Air Quality Standards. The pollutants for which standards have been set are particulate matter, carbon monoxide, ozone, nitrogen dioxide, sulfur dioxide and lead. These standards are designed to protect the quality of the environment and provide an adequate margin of safety from adverse impacts on human health.

The New Jersey Air Sampling Network collects samples of either total suspended particulates or only that fraction which is respirable (less than 10 microns in diameter). The total suspended particulate (also known as high volume) filter program collects 24 hour samples of particulates from the air on glass fiber filter paper at least once every six days. There are 28 total suspended particulate samplers in operation at various locations throughout the State. All samples are analyzed for the amount of particulates; selected samples are analyzed for the amounts of benzo-(a)-pyrene, extractable organics, sulfates, nitrates, lead and other metals. Levels of many trace metals are typically in the μm^3 concentration range.

Approved EPA methodology for the analysis of lead on high volume filters involves

sonication of a portion of the filter in dilute *aqua regia*, followed by measurement of Pb in the extract by flame atomic-absorption spectroscopy (AAS). While being sensitive and accurate, the AA method is labour intensive, time consuming and requires the use of large amounts of reagents and glassware. The AA method is also constrained since AA cannot be operated unattended. To overcome these impediments and improve productivity, other methods for the analysis of lead on high volume filters were explored. Analyses of high-volume air filters by wavelength-dispersive x-ray fluorescence (WDXRF) spectroscopy is an attractive alternative, requiring a minimal amount of sample preparation and manpower. There are no reagents or glassware needed and the instrument can be operated unattended to maximize sample throughput.

Application of WDXRF to this media has its own set of analytical problems. This paper describes a procedure for the WDXRF determination of Pb in total particulates collected on glass fiber filters with a direct deposition method for the preparation of calibration standards and the analysis of multiple sections of each sample filter strip. Problems with the application of WDXRF and the remedies that were developed will be presented and comparisons with the EPA-approved sonication-AAS method will be made.

EXPERIMENTAL

Apparatus

Air particulate matter was collected with a General Metal Works Model 2000 high volume sampler. Whatman EPM 2000 glass fiber filter paper (20.24 × 25.40 cm) was used for collection. Filters were weighed with a Torbal Model EA-IAP analytical balance. The acid sonications were made in a L and R Model T28B Sonication bath. AAS analyses were made with a Perkin-Elmer Model 5000 spectrometer equipped with a Model 7500 computer, a Model AS-50 sample changer and a 10.5-cm single-slot burner head for analyses with an air acetylene flame.

WDXRF measurements were made with a Philips Model 1404 wavelength dispersive spectrometer equipped with a Digital Equipment Corporation Model 350 computer and a Herzog Model PW 1500 sample changer. The operating conditions are shown in Table 1.

Reagents

The *aqua regia* for the sonication of the filters was prepared with trace-metal grade nitric and hydrochloric acid (JT Baker Chemical Company). Doubly-demineralized water with a resistivity greater than 18 ohms was used throughout.

A concentration of 10,000 $\mu\text{g/ml}$ lead, obtained from the National Institute for Standards and Technology [Standard Reference Material (SRM) 3128], was used to prepare all calibration standards.

Procedure

Ambient air is drawn into a covered housing and through a glass fiber filter at a flow-rate of (1.13–1.70 m^3/min). Particles within the range of 100–0.1 μm diameter are retained on the filter. An average flow-rate of 1.70 m^3/min for a 24-hr period ensures that a measurable amount of

particulates will be collected. The filters are tared under controlled temperature and humidity before being placed in the field. After exposure, the filter is returned to the laboratory and allowed to stand for 24 hr in the same conditions before being re-weighed and the total mass determined.

Analysis

According to the EPA protocol¹ a 2.54-cm wide by 20.24-cm long strip is cut from each high volume filter with a template and a pizza cutter. The filter strip is folded to fit the inside diameter of a 30-ml glass beaker. Twenty millilitres of dilute *aqua regia* (2.6M nitric acid and 0.9M hydrochloric acid) are added and the beaker is covered with wax paper. The samples are sonicated for 30 min and then filtered through Whatman 41 filter paper into a 100-ml standard flask. Demineralized water is added to cover the filter in the beaker, which is allowed to soak for an additional 30 min before filtration into the standard flask. This soaking procedure is repeated. The flask is brought to volume with demineralized water.

The measurement of Pb in the filter extract by flame atomic-absorption spectroscopy at 217.0 nm has been described elsewhere.²

For our analysis by WDXRF, diameter discs (32 mm) were cut from glass fiber paper with a stainless steel die. The filter discs were placed into aluminum sample cups held in place with a Viton O-ring. A calibration curve was prepared by making known additions of the National Institute for Standards and Technology (NIST) Pb solution at varying concentrations to glass fiber paper discs cut from an unexposed filter. For each filter sample, 5 discs were cut from each filter strip. The concentration of Pb on each filter disc was calculated by comparison of the response to the standard curve. The concentration of Pb on the five discs is summed and a mean calculated. This value is then divided by the area of disc exposed to the x-ray, then multiplied by the area of the original filter and divided by the volume of air sampled to give the concentration of Pb as μm^3 of air sampled. This enables compensation for the inherent inhomogeneous distribution of Pb across the surface of the filter strip.

The calibration curve was generated with spiked filter glass fiber discs prepared by the addition of 50 μl of various concentrations of Pb prepared from serial dilutions of the NIST SRM to blank filter discs. The calibration discs

Table 1 WDXRF instrumental operating conditions

Spectral Line	Pb L-beta
Peak Position	28.235 2-theta, 0.982 nm

Tube Target	Cr
Tube Voltage	60 KV
Tube Current	50 MA
Analyzing Crystal	LiF 200
Detector	Scintillation Counter
Collimator	Coarse
Vacuum Path	1 Pascal
Sample Rotation	Yes
Channel Mask	Small

were dried for 10 min at 75° and then measured under the conditions shown in Table 1. A disc without added Pb was included in the calibration curve. The calibration data were fitted with a linear regression algorithm that also corrects for self-absorption and matrix effects.³ The response of the x-ray to lead on glass fiber filters was linear from 0.22 to 22.0 μg of lead per cm^2 .

RESULTS AND DISCUSSION

Calibration standards preparation

The preparation of calibration standards by depositing known amounts of Pb directly onto discs prepared from unexposed glass fiber filter paper was quite successful. Preparation of 6 individual sets of standards by this method showed a mean difference of 3.27% in the response of standards prepared to contain 10 μg of Pb.

The efficacy of this approach to calibration is further demonstrated by the results of the analysis of a filter disc containing 5 μg of Pb, prepared by this direct deposition method from the NIST source, and analyzed with each group of sample filter discs as an unknown. For 12 separate 5 μg additions analyzed over a 6 month period, the mean value of Pb measured is $101.6 \pm 2.8\%$.

Sample homogeneity

Previous analysis of glass fiber filters by the acid sonication/AA procedure have shown that there can be an uneven distribution of material across the entire filter or even within the 2.54-cm wide strip. The AA method extracts and analyzes the entire filter strip. Other XRF applications to the analysis of metals in air particulates collected on filter media involve analysis of various sections of the filter. In all other cases, only a very small fraction of the entire filter is actually subjected to the XRF analysis, taking only one³ or several⁴ filter discs per filter. For our application, analysis of a single filter disc would mean that only 10% of the filter strip would be analyzed.

Table 2. AA/WDXRF comparison

Thrd Quarter 1989		
Sampling Site	No of Samples	Mean \pm SD AA/WDXRF
Newark	16	1.08 \pm 0.10
Newark Boys Club	15	1.01 \pm 0.13
Deepwater	13	1.18 \pm 0.29
New Brunswick	16	1.12 \pm 0.26
Fourth Quarter 1989		
Sampling Site	No of Samples	Mean \pm SD AA/WDXRF
Newark	15	0.94 \pm 0.12
Newark Boys Club	9	0.76 \pm 0.15
Deepwater	7	1.00 \pm 0.18
New Brunswick	21	0.84 \pm 0.14

To compensate for the uneven distribution of Pb across the surface of the filter strip, 5 discs were cut from each filter strip taken from samples which were collected at different locations in New Jersey. The discs from each filter strip were obtained by taking one cut near each end, two between the center and each end and one from the center. Analysis showed significant inhomogeneity in the distribution of Pb; the average deviation of the mean ranged from 1.82 to 16.25%.

Results

Five high volume sampling locations were selected to compare the results of analysis of lead by the standard sonication/AA and WDXRF methods. The sampling locations ranged from urban areas where there are high air particulate concentrations to rural areas where the particulate air concentrations are much lower.

Filter strips from each site from a six month period in 1989 were first analyzed by WDXRF, and then the entire strip analyzed by the sonication/AA method. The values in Table 2 are the mean AA/WDXRF ratios and standard deviations obtained for each sample at each site. The data shows generally good agreement between results generated by the two methods. The lower ambient amounts of Pb collected at the Newark Boys Club and New Brunswick sites may contribute to the lower AA/WDXRF ratios.

Table 3. Analysis of NIST filters

Filter	NIST Value	AAS Value	WDXRF Value	AA/NIST	WDXRF/NIST
1C	7.47	7.22	7.29	0.97	0.97
2C	14.92	16.30	14.27	1.09	0.96
3C	29.81	29.92	24.05	1.00	0.81

All values in μg filter

Table 4 Analysis of polymer film standards

Date of Analysis	Pb Added to Filter μg	Measured Pb, μg
4-10-90	2.00	2.08
5-10-90	2.00	2.00
6-10-90	2.00	2.04
7-10-90	2.00	2.04
4-10-90	10.00	9.45
5-10-90	10.00	9.28
6-10-90	10.00	9.33
7-10-90	10.00	9.13

This quality of the agreement between the results generated by the AA and WDXRF techniques is reinforced by the analyses of filter media containing known amounts by both techniques as discussed below.

Quality assurance

In our WDXRF method of analysis, glass fiber filter discs containing 5 μg of added Pb (prepared as above from the NIST SRM) are analyzed after every 10 measurements. The criteria for data acceptance has been established as $\pm 10\%$ of the added value. Recoveries ranged from 97.8 to 105.0% over the six-month duration of this study.

Several other types of filter media containing known amounts of Pb were analyzed during the course of this study. Samples of cellulose acetate filter paper impregnated with Pb (as well as with known amounts of Cd, Cr and Ni) were analyzed by both the WDXRF and AA/sonication procedures. As shown in Table 3 the data obtained by both methods agreed well with the NIST-certified values for samples 1C and 2C. For sample 3C the solution containing Pb was applied off the center of the disc; the placement of the disc may have resulted in an incomplete exposure to the x-ray beam, accounting for the lower value.

Mylar polyester film impregnated with known amounts of Pb were obtained from Micro Matter Co. Analysis of the materials over a four month period showed good agreement with the known value (not certified), which is another

indicator of the long-term stability of the instrument calibration (Table 4). These results can also be used to decide when re-calibration is necessary.

As mentioned earlier in the paper, samples of glass fiber filters that are impregnated with lead were obtained from EPA's Research and Monitoring Evaluation branch to evaluate the equivalency between the XRF and AA methods of analysis. The filter strips were cut into sections and analyzed by XRF. The total filter strip was then extracted by sonicating in dilute *aqua regia* and analyzed for lead by AA. The results obtained are shown in Table 5, and again indicate the accuracy of both the WDXRF and the sonication/AA methods.

CONCLUSIONS

We have shown that WDXRF is a viable analytical method for the analysis of Pb in air particulates that are collected on glass fiber filter paper with this method for calibration and analysis. Our QA studies suggest that this procedure can be extrapolated to the measurement of Pb on other filter media. We are currently examining the efficacy of this approach to the analysis of other metals on glass fiber and quartz filter media.

COMPLEXATION OF Eu AND Tb WITH FULVIC ACIDS AS STUDIED BY TIME-RESOLVED LASER-INDUCED FLUORESCENCE

G. BIDOGLIO, I. GRENTHE*, P. QI†, P. ROBOUCH and N. OMENETTO‡

Commission of the European Communities, Joint Research Centre, Environmental Institute,
21020 Ispra (VA), Italy

(Received 14 February 1990. Revised 24 February 1991 Accepted 26 February 1991)

Summary—Complexation of Eu and Tb with fulvic acids (FA) has been studied by time-resolved laser-induced fluorescence. The lanthanide species are excited by a pulsed Xe/Cl excimer laser and the short-lived luminescence of the fulvic acids is eliminated by time gating. The conditional binding constants (K') and the total metal-binding capacities of the fulvic acids have been determined from the equilibrium titration curves. No significant variations of the $\log K'$ values (about 6) have been found in the pH range investigated (2.7, 5.5, 6.5) at ionic strengths of 0.1 and 1M (NaClO₄). An inverse relationship of K' to total metal concentration is observed. Substitution of Eu for Al has been found to depress the fluorescence signal of the Eu-FA complex. The binding constants of Al³⁺ and Eu³⁺, derived from the competition experiments, are of the same order of magnitude. The effect of competition on metal binding and trace-metal transport is discussed.

The importance of humic/fulvic acids for the transport and bioavailability of trace metals in surface-water systems has been recognized for a long time.^{1,2} Extensive experimental studies have been made on the composition of humic/fulvic acid materials,^{1,3} their acid-base properties,⁴⁻¹³ and their metal-binding characteristics.^{7-9,13-16} Humic/fulvic acids are heterogeneous materials with a large range of molecular weights. It is generally recognized that they are polyelectrolytes containing a set of different functional groups, *cf.* Marinsky and co-workers^{10,11} for a recent literature survey. Their metal and hydrogen-ion binding have been described by means of site-specific binding constants,^{5,12,13} and of a continuous distribution of binding constants.⁷ The stoichiometry of the metal-binding reactions, and their equilibria, are in general described by the equation:

where M denotes a metal ion and HFA the humic/fulvic acid in a state of protonation that is dependent on the pH of the solution. M is in

general not the free metal-ion, Mⁿ⁺, but symbolizes all metal species not bound to the fulvic/humic acid. The equilibrium constant for reaction (1) is thus a *conditional* constant. Some authors have used more elaborate models, involving the stepwise binding of several FA to each metal ion (*e.g.*, Bertha and Choppin⁴ and Torres and Choppin¹⁷), and the formation of ternary complexes such as CuOCuFA (Ephraim and Marinsky¹³).

Traditional solution chemical methods, such as potentiometry (*e.g.*, Buffle *et al.*¹⁴) ion-exchange (*e.g.*, Ephraim *et al.*¹⁸), solvent extraction (*e.g.*, Torres and Choppin¹⁷) and spectrophotometry (*e.g.*, Moulin *et al.*¹⁶) have been used to study the chemical equilibria between humic/fulvic acids and metal ions. The potentiometric studies typically involve direct measurement of the free metal-ion concentration with an ion-selective electrode,¹⁴ rather than an indirect measurement through the hydrogen-ion concentration (*cf.* Ephraim *et al.*,¹¹ Figs. 14-19). The potentiometric methods require a total metal-ion concentration larger than, say, 0.1mM. The ion-exchange and solvent extraction techniques can be used at trace level concentrations, say from 10⁻¹⁰ to 10⁻⁷M. The spectrophotometric method is complicated by the strong light-absorption of the humic/fulvic acids and it seems possible to use light-absorption measurements only for systems

where the metal ion has absorption bands at wavelengths longer than 600 nm, *cf.* Moulin *et al.*¹⁶

Methods based on the quenching of ligand fluorescence were introduced ten years ago¹⁹ and have recently been discussed by Cabaniss and Shuman.²⁰ Laser-induced fluorescence (LIF) is a well established technique that has been extensively used to study metal binding to biomolecules,²¹ as well as for the study of metal binding in humic/fulvic acid systems.²²

During the last two years we have used this method in an exploratory study of metal binding to fulvic acids. We have studied the bonding of europium, terbium and aluminium to a fulvic acid from Bersbo, Sweden. This material has been characterized¹² by Allard and his group. Europium and terbium were chosen because of their fluorescence properties, but also because they are good model ions for trivalent actinides. Humic/fulvic acids are efficient transport vectors for trace metals in ground- and surface-water systems. Information on their role in the transport of actinides is relevant for the understanding of the radioecology of these elements, and also for the possible environmental impact caused, for example, by leakage from nuclear installations of various kinds.

The binding of trace metals, (TM), to the humic/fulvic materials present in ground- and surface-water systems is a competitive process which takes place in the presence of relatively large concentrations of Mg(II), Ca(II), Fe(II,III), Al(III), *etc.*, according to the equilibrium:

The ratio $[(\text{TM})\text{FA}]/[\text{MFA}]$ depends on the equilibrium constant of equation (2) and the ratio $[\text{M}]/[(\text{TM})]$. No experimental measurements of equilibria of type (2) have been published, a fact which makes it difficult to quantify trace-metal binding. We have therefore studied the competition between aluminium and europium in a fulvic acid system. Aluminium is one of the most important humic/fulvic acid binding elements in nature. However, it is difficult to study its binding directly. Such information may be obtained by combining experimental information from the binary Eu-FA and the ternary Al-Eu-FA systems.

We were also interested in developing fluorescence spectroscopy as a diagnostic tool in order to determine whether Eu(III)/Tb(III)

and, hence, trivalent actinides can bind to the organic materials in ground- and surface-water samples. Information of this type is obviously of interest in radioactive-waste management.

The points of main interest in the present study were to use the sensitivity of the LIF method as a tool for

- (i) determining whether Eu(III)/Tb(III) can bind to organic material in its form present in ground-water samples;
- (ii) comparing fluorescence methods with other techniques for the determination of metal-fulvic acid binding constants;
- (iii) exploring the use of competition methods, with Eu/Tb as probes, for the study of metal-fulvic acid interactions.

EXPERIMENTAL

Reagents

Sodium perchlorate, sodium acetate, acetic acid, sodium hydroxide, perchloric acid, and europium and terbium chlorides were all of analytical grade. The stock solutions of the reagents were prepared with doubly distilled water. They were analysed by standard analytical procedures and their concentrations were known with an accuracy better than 0.5%. Solutions used in the measurements were prepared from the stock solutions by use of standard flasks and calibrated Eppendorf pipettes. Their concentrations were calculated from the known volumes and concentrations of the stock solutions used. The fulvic acid was obtained from the University of Linköping, Sweden. Its properties have been described extensively:¹² the material has a titratable acid capacity in water of 4.65 ± 0.15 meq/g and contains several different acid sites (20% with $pK = 1.7$; 25% with $pK = 3.3$; 30% with $pK = 5$; 20% with $pK = 6.5$ and 5% with $pK = 7$). A stock solution of FA was prepared by weighing a suitable amount of the solid fulvic material and dissolving it in distilled water. The solution was analysed by spectrophotometry (extinction coefficient 27 ± 1 $\mu\text{g}^{-1} \cdot \text{cm}^{-1}$, at 250 nm).

Instrumentation

A tunable dye laser pumped by an excimer laser, and the excimer laser alone were used throughout the experiments. The excimer laser (Lambda Physik, Model EMG-102, Göttingen, Germany) was operated with an Xe/Cl mixture, delivering a 20 nsec pulse of about 100 mJ (at 308 nm) at a variable repetition frequency

(1–100 Hz). The rectangular beam, which was conveniently filtered and shaped with a circular aperture (5 mm diameter), was folded by a quartz prism and mildly focused by a spherical quartz lens (25 cm focal length) into the fluorescence cuvette. At the cuvette, the energy of the laser was reduced to 3–5 mJ. When the tunable dye laser (Jobin Yvon, Longjumeau, France) was installed in front of the excimer laser, the latter could be used as a pump laser by diverting part of its output with a beam splitter. The dye laser, consisting of an oscillator section plus an amplifier section, provided the necessary tunability for the various experiments. Its output beam was directed and focused in the same fluorescence cuvette by means of two prisms and a spherical lens, both laser beams (dye and excimer) were used alternatively, according to the experiments to be performed. The fluorescence light, collected at right angles by another lens (15 cm focal length) was dispersed by a grating monochromator and measured with a photomultiplier (Hamamatsu, Model R928S, Hamamatsu Corp., Japan) wired for fast response. Two monochromators were used, having 1.29 m and 10 cm focal lengths, respectively. The former instrument provided good resolution and stray-light rejection, and the latter was used for its simplicity and convenience of operation. Both monochromators were equipped with scanning facilities to obtain a fluorescence spectrum, whenever needed. The photomultiplier signal, after suitable amplification obtained with a preamplifier directly attached to the anode, was sent into one channel of a boxcar integrator (Stanford Research Corp., Model SR250, U.S.A.) and a digital storage oscilloscope (Tektronix, Model 2430, U.S.A.), which was directly interfaced to a computer (Hewlett Packard, Model 9816). The measuring gate of the boxcar could be adjusted to reject completely the fast fluorescence component. However, since the photomultiplier was not operated stroboscopically, the fast fluorescence signal of the fulvic acids was so strong that it caused saturation of the tube and/or preamplifier (with consequent ringing). The gate was then opened after complete recovery of linear operating conditions. This obviously limited the resolution of fast-decay components in the signal and the possibility of deconvolution of multicomponent decay. The energy of both lasers was constantly monitored by a pyroelectric detector positioned near the cuvette: its output was fed into the other channel of the

boxcar integrator and continuously displayed on a strip-chart recorder.

Choice of conditions for fluorescence excitation

We use the fluorescence data for the interpretation of chemical equilibria in metal–fulvic acid systems. The technique used is the same as in other spectrophotometric methods, *cf.* Rossotti and Rossotti.²³ It is of great advantage for the interpretation of such data if the experiment can be done in such a way that only one or a few species will contribute to the measured absorptivity (or fluorescence intensity) of the solution. For precise measurements it is of course also desirable to have a large value of the molar absorptivity (or the corresponding emission coefficient) for the absorbing (emitting) species. Europium is often excited by using a dye laser tuned to 394 nm, which corresponds to a resonant absorption transition in the metal ion. The fluorescence observed corresponds to the $^5D_0 \rightarrow ^7F_2$ “hypersensitive” transition at 616 nm, and the $^5D_0 \rightarrow ^7F_1$ transition at 592 nm. With 394 nm excitation the fluorescence spectrum will contain significant contributions from both free Eu and bound Eu, *cf.* Dobbs *et al.*²² The excitation of the *bound* europium occurs much more efficiently through the excitation of the fulvic acid molecule, followed by an energy transfer to the metal. With such an excitation mechanism, there should be a very strong increase in fluorescence of the bound europium when exciting the ligand at shorter wavelengths, where the molar absorptivity is higher. At the same time the excitation of the free Eu ion should be negligible. This is indeed what happens: a direct excitation at 308 nm with the Xe/Cl excimer laser increases the fluorescence of bound europium (EuFA) and it is only this species which contributes to the measured fluorescence intensity. We have evaluated the decay times of the EuFA complex both with 308 and 394 nm excitation and found them to be the same within experimental error ($\sim 10\%$), indicating a similar excitation mechanism in both cases. The same conclusion seems to hold for the terbium–fulvic acid system, on excitation at 308 and 228 nm. Fulvic acids are known to be sensitizers in photoredox reactions.²⁴ We found no clear evidence of decomposition or redox reactions in the solutions used in our experiments, and both the europium and terbium systems behaved in a similar way. In some cases, however, we observed a transient signal, the fluorescence decreasing noticeably and then stabilizing after

20–30 sec, indicating that some kind of photochemical reaction was occurring. We have no conclusive experimental evidence of such a phenomenon, which certainly deserves a more systematic investigation.

Procedure

Most experiments were titrimetric in nature, two solutions of known composition being mixed in a titration vessel. The two solutions had the same hydrogen-ion concentration, in general obtained by use of an acetate buffer. The hydrogen-ion concentrations of the initial solutions and the solution in the titration vessel were measured by using a combined Ross glass-electrode (Orion, Model 810200, U.S.A.) and a pH-meter (Radiometer, Model PHM84, Denmark). The reference solution of the electrode had the same ionic strength as the test solution (0.1 or 1.0M NaClO₄). The electrode was calibrated in concentration units with an acetate buffer of known [H⁺]. The precision of the pH measurements was better than 0.005, and the accuracy about 0.03. The fluorescence was measured in 1 cm fused-silica cuvettes with 3 ml samples withdrawn from the test solutions. At the lowest metal concentrations (10⁻⁸M or less) we measured the blank correction of pure fulvic acid. The blank correction for free Eu(III) was negligible in the Eu(III)–FA titrations carried out with the excitation set at 308 nm. Sorption on the walls, important at concentrations lower than 10⁻⁷M, was found to be fairly slow (a few hours). The sorbed EuFA could be removed by washing with concentrated mineral acid.

The titrations were in general done at constant metal-ion concentration by mixing a solution S containing 2 × 10⁻⁵ or 2 × 10⁻⁷M M(III), 10mM acetate buffer and sodium perchlorate to give an ionic strength *I*, with a solution T of the same composition as S but containing a known quantity of fulvic acid, usually 50 ppm. The titrations were done at three different hydrogen-ion concentrations, -log[H⁺] = 2.7, 5.5 or 6.5, and two ionic strengths, *I* = [Na⁺] = 0.1 or 1.0M.

A few titrations were done by starting with a solution containing fulvic acid (50 ppm) and no metal, and then increasing the metal-ion concentration by adding a titrant containing only the metal-ion.

The competition experiments had to be done in such a way that the ratio [Al]/[Eu] was larger than 10. In order to avoid too high an Al(III) concentration we had to use

[Eu(III)] = 2 × 10⁻⁷M. The experiments were done as titrations at pH 5.5, at constant Eu(III) concentration, by increasing the fulvic acid concentration. After each addition of FA a 3 ml sample was withdrawn from the test solution and its fluorescence intensity measured. Three successive additions of a concentrated Al(III) solution were made to the solution in the cuvette. After each addition the fluorescence intensity was measured. The additions were so small that the Eu(III) and FA concentrations did not change appreciably (the largest change was 3%). To avoid the formation of a precipitate (detectable through light-scattering) we had to keep [Al(III)] < 2 × 10⁻⁵M.

TREATMENT OF DATA

Binary system: M–FA

It is generally assumed that the reactions with humic/fulvic acids are of the type exemplified by equation (1). As most experimental studies are made with buffers at constant pH, it is practical to write this equation as:

with an equilibrium constant

$$K' = [MFA]/[M][FA] \quad (4)$$

where *K'* is a conditional constant which depends on the pH, the ionic strength and the total concentration of the metal ion. Titrations of M and FA often result in titration curves of the type shown in Fig. 1. In all the figures shown, the intensity of the fluorescence signal (FI) is given in arbitrary units. This curve shape, corresponding to 1:1 stoichiometry, shows that only one species is formed. We prefer to consider the binding in humic/fulvic acids as an ion-exchange process and not a process similar to complex formation with small ligands.

We will use equation (3) as a purely phenomenological description of the equilibrium in metal–fulvic acid systems. The following notations will be used:

μ_{FA}	the maximum fluorescence, in arbitrary units
FI	the fluorescence of the test solution (same units as above)
[M] _t	total metal-ion concentration (<i>M</i>)
[M]	concentration of metal-ion not bound to FA (<i>M</i>)
<i>c</i>	total metal-binding capacity of fulvic acid (mole/g)

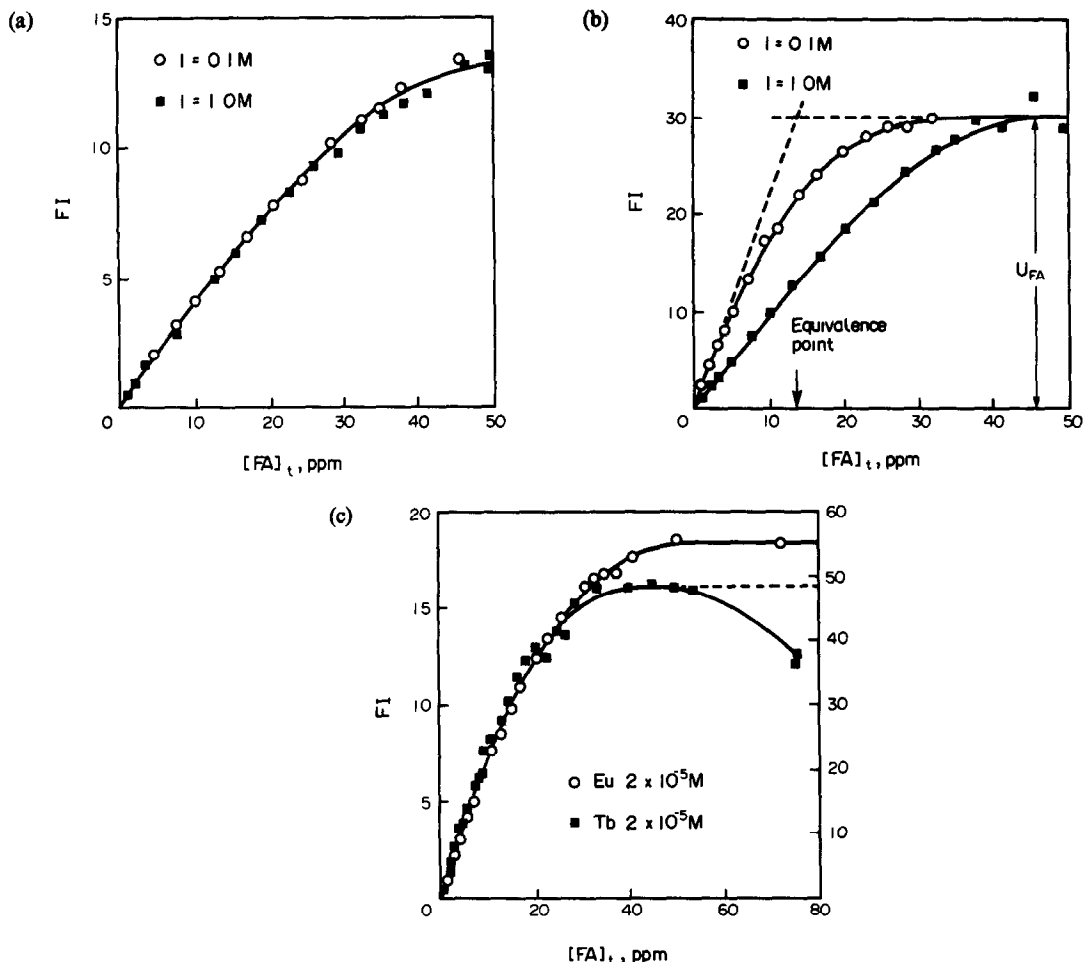

Fig. 1 Equilibrium titration curves of lanthanides with fulvic acids in NaClO_4 solutions at different pH values and ionic strength (I). The fluorescence signal (FI) is given in arbitrary units ($\lambda_{\text{exc}} = 308 \text{ nm}$) (a) $[\text{Eu}]_i = 2 \times 10^{-5} \text{ M}$, pH 2.7, (b) $[\text{Eu}]_i = 2 \times 10^{-5} \text{ M}$, pH 6.5; (c) $I = 0.1 \text{ M}$, pH 5.5.

$[\text{FA}]_t$ total fulvic acid concentration (g/l.)
 $[\text{FA}]$ free fulvic acid concentration (M)
 $[\text{MFA}]$ complex concentration (M).

The following relations can then be written:

$$[\text{MFA}] = [\text{M}]_i \text{FI}/u_{\text{FA}} \quad (5)$$

$$[\text{M}]_i = [\text{M}] + [\text{MFA}] \quad (6)$$

$$c[\text{FA}]_t = [\text{FA}] + [\text{MFA}] \quad (7)$$

By substituting equations (5–7) into (4) we obtain

$$K' = (\text{FI}/u_{\text{FA}})/(1 - \text{FI}/u_{\text{FA}}) \times (c[\text{FA}]_t - [\text{M}]_i \text{FI}/u_{\text{FA}}) \quad (8)$$

Fi and u_{FA} are measured experimentally, and c is measured from the extrapolated equivalence point, as indicated in Fig. 1b. The equilibrium constant K' is then calculated from equation (8). We have in general preferred a curve-fitting method, where a set of curves of FI vs. $[\text{FA}]_t$ is

calculated for given values of the experimental parameters $[\text{M}]_i$, $[\text{FA}]_t$, c , and u_{FA} , with K' as a predictor variable. A set of such curves is shown in Fig. 1b. The results of the experimental studies are shown in Fig. 1 and Table 1 (see later).

Ternary system: competition experiments with Al(III)

Some previous studies of the interaction between aluminium and humic acids were done by using distribution methods such as ion-exchange²⁵ and equilibrium dialysis.²⁶ Laser-induced fluorescence is a convenient non-invasive method to study the competition between Al(III) and Eu(III), i.e., the equilibrium:

The equilibrium constant $K'(\text{Al}/\text{Eu})$ for reaction (9) is also a conditional constant, valid only for the ionic medium and pH investigated.

Table 1 Binding constants and capacities of Eu(III) and Tb(III) for the Bersbo fulvic acid, at various $-\log[H^+]$ values, ionic strengths, I , and total lanthanide concentrations, $[M]$

I	$[M]$	Binding capacity, <i>mmole M(III)/g FA</i>			$\log K'^{\dagger}$		
		2 70*	5 56*	6 51*	2 70*	5 56*	6 51*
0.1 M	Eu, $2 \times 10^{-5} M$	0.60 ± 0.10	0.81 ± 0.08	1.35 ± 0.10	6.20 ± 0.10 (6.20 ± 0.10)	5.95 ± 0.10 (6.3 ± 0.1)	6.00 ± 0.10 (6.5 ± 0.1)
1.0 M	Eu, $2 \times 10^{-5} M$	0.60 ± 0.10	0.91 ± 0.09	0.66 ± 0.06	6.00 ± 0.05 (6.00 ± 0.05)	6.0 ± 0.1 (6.2 ± 0.1)	6.40 ± 0.10 (6.7 ± 0.1)
0.1 M	Eu, $2 \times 10^{-7} M$		0.15 ± 0.09			7.90 ± 0.10 (8.3 ± 0.1)	
0.1 M	Tb, $2 \times 10^{-5} M$		1.04 ± 0.10			5.95 ± 0.10 (6.3 ± 0.1)	

* $-\log[H^+]$

† The values in parentheses are the binding constants corrected for acetate complex formation

However, this is sufficient to obtain information about the relative bonding strengths of Eu(III) and Al(III) to FA, information which is relevant for the transport properties of trace quantities of trivalent lanthanides and actinides in ground- and surface-waters. For the competition experiments, the following additional mass balance and equilibrium conditions have to be considered:

$$[Al]_t = [Al] + [AlFA] \quad (10)$$

$$K'(Al/Eu) = [AlFA][Eu]/[EuFA][Al] \quad (11)$$

It follows that relation (7) must be adapted to give:

$$c[FA]_t = [FA] + [EuFA] + [AlFA] \quad (12)$$

$K'(Al/Eu)$ can be calculated by substituting equations (4)–(6), (10) and (12) in (11); it is then expressed in terms of measurable quantities, as in equation (8). We have calculated theoretical curves for FI *vs.* $[FA]_t$ in given experimental conditions; by comparing the experimental data with such theoretical curves (see Fig. 3, below) we were able to estimate $K'(Al/Eu)$.

RESULTS AND DISCUSSION

Determination of binding constants and binding capacities for Eu(III) and Tb(III) with the Bersbo FA

The binding capacities and binding constants for Eu(III) (and Tb(III)) were determined at different ionic strengths, pH values and total metal-ion concentrations. Some of the experimental results are shown in Fig. 1, and the binding capacities and binding constants are given in Table 1. At high concentrations of fulvic acid, the fluorescence signal of Tb showed a marked decrease in intensity (See Fig. 1c). Since absorption of the fluorescence emission by

the non-complexed FA is stronger at 544 nm (Tb) than at 617 nm (Eu), it is conceivable that an inner-filter effect is responsible for the observed phenomenon.

The experimental conditional equilibrium constants were corrected for acetate complex formation by using the equilibrium constant for the reaction: $Eu^{3+} + Ac^- \rightleftharpoons EuAc^{2+}$, determined in 0.5 M NaClO₄,²⁷ and recalculated to 0.1 and 1.0 M ionic strength by the specific ion interaction theory.²⁸ The following interaction coefficients were used: $\epsilon(Eu^{3+}, ClO_4^-) = 0.49 \pm 0.03$; $\epsilon(Ac^-, Na^+) = 0.08 \pm 0.01$ and $\epsilon(EuAc^{2+}, ClO_4^-) = \epsilon(YHCO_3^{2+}, ClO_4^-) = 0.39 \pm 0.04$. The values corrected in this way are given in Table 1.

In a separate titration we investigated the pH-profile of the fluorescence at $[FA]_t = 50$ ppm and $[Eu]_t = 2 \times 10^{-5} M$. The result is shown in Fig. 2. This curve indicates a pronounced pH-dependence of the fluorescence. However, no further studies have been made in order to

Fig. 2. pH-dependence of the Eu fluorescence signal in a 50 ppm FA solution; $[Eu]_t = 2 \times 10^{-5} M$, $I = 0.1 M$ (NaClO₄); $\lambda_{exc} = 308$ nm

ascribe this effect either to changes in the binding sites of the MFA complex, or to variations in the excited-state number density, caused by collisional quenching.

Competition between Al(III) and Eu(III) for FA

The competition experiments show clearly that the fluorescence intensity of EuFA decreases on addition of Al(III), provided the ratio Al(III)/Eu(III) is larger than 10, *cf.* Fig. 3. This decrease is not due to quenching of the EuFA fluorescence, as the decay-time does not seem to be influenced by the presence of Al(III), but to a chemical competition.

From the experimental data we obtain $\log K'(Al/Eu) = -1.6 \pm 0.2$. It is difficult to obtain a precise value of this exchange constant because of its small value and the experimental difficulties due to the precipitate formation encountered at high $[Al]_t$. By correcting this equilibrium constant for the formation of europium-acetate²⁷ and aluminium-hydroxide²⁹ complexes we obtain $\log K'(Al/Eu)_{corr} = -0.6$, *i.e.*, the binding constants of Al^{3+} and Eu^{3+} are of the same order of magnitude.

Several considerations arising from the matter above are now felt appropriate. First, we consider the technical quality of the binding-constant determinations. A comparison with previously used spectrophotometric methods (*cf.* Moulin *et al.*¹⁶) shows the very obvious advantage that no correction is needed for the light absorption of the ligand, and that the measured fluorescence is dependent only on the concentration of MFA. The change in fluorescence emission throughout the titration is also much larger than the change in light absorption, with a resulting increase in the sensitivity and precision of the fluorescence method. The method is also fast and a complete titration with 15 experimental points takes less than an hour to perform. In our experiments we have used acetate buffers to ensure a good buffer capacity of the chemical system. This is necessary when using low total concentrations of metal ion and ligand. When working at higher total concentrations, it should be quite feasible to use the buffering capacity of the fulvic acid and a much less sophisticated experimental set-up, *e.g.*, a spectrofluorimeter, can then be used. However, a pulsed excitation source and gated detection are necessary to avoid measuring the strong FA fluorescence. The equilibrium constants determined by us are nearly identical with the value for Am(III)-FA obtained by Moulin *et al.*¹⁶

Fig 3. Fluorescence titration curves of $2 \times 10^{-7} M$ Eu in $0.1 M$ $NaClO_4$ at pH 5.5 in the presence of different concentrations of Al: (●) no Al, (○) $3.3 \times 10^{-6} M$; (▲) $10^{-5} M$, (□) $2.3 \times 10^{-5} M$. The solid lines represent the theoretical curves, obtained as described in the text

under similar conditions, with the same FA. Europium, terbium and americium are expected to have similar chemical properties. Many of the other quantitative results also agree well with the known chemical properties of the Bersbo FA. The metal-binding capacity at a given ionic strength increases with pH, in keeping with the presence of functional groups of different acidities. The highest binding capacity, $1.30 \pm 0.10 mM$ Eu/g FA, or 3.90 ± 0.30 meq/g at pH 6.5, is close to the total aqueous titratable exchange capacity, 4.86 ± 0.15 meq/g.

The observation that the binding constant and the binding capacity vary with the total metal concentration, *cf.* Table 1, is also in qualitative agreement with the observations of Ephraim *et al.*¹² The higher the total concentration of metal ion, the greater the number of the protonated functional groups used for metal binding. $[MFA]$ increases more slowly than $[M]_t$, hence the conditional equilibrium constants decrease with increasing $[M]_t$, in agreement with the observations. There is no polyelectrolyte effect at pH 2.7, also in agreement with Ephraim's observations on protonation equilibria.¹² The ionic-strength dependence of the binding constant is small in the pH range investigated, and is largest at pH 6.5, where the degree of dissociation of the ligand is largest.

From the data of Ephraim *et al.*¹² we have estimated that the degree of ionization of the FA at the pH values studied is $\alpha = 0.3, 0.77$ and 0.93 , respectively. However, the binding constants vary fairly little in the same pH range,

Fig 4 Sensitivity curve of EuFA fluorescence pH = 5.5, $I = 0.1M$ (NaClO_4); 3 ppm FA, $\lambda_{\text{exc}} = 308$ nm; $\lambda_{\text{em}} = 617$ nm

from $\log K' = 6.2 \pm 0.1$ at pH 2.70 to $\log K' = 6.5 \pm 0.1$ at pH 6.51. The magnitude of the binding constants and their pH variation in the range $5.5 < \text{pH} < 6.5$ are in fair agreement with observations on the same system studied by using an ion-exchange method.¹⁸ The pH-dependence of the Eu(III)-FA system seems to be smaller than that observed for humic acid.¹⁷ The observed binding constant for Eu(III)-FA is also in good agreement with the observations of other investigators.^{15,16}

Spectrophotometric data can be used to obtain thermodynamic information and may, in addition, provide information about the chromophore. However, we found no, or only very small, changes in the shape, intensity ratios and peak positions in the emission spectra. This is perhaps not surprising, bearing in mind that the same donor (oxygen) is present in all the different functional groups of the ligand.

It should be pointed out that the shape of the titration curves gives no indication of the stoichiometry of the complex, showing only that the ligand at a given pH contains a given number of sites which can be occupied by the metal ion in an ion-exchange reaction. We do not think it proper to use the concept of step-wise complex formation, as used for example by Choppin *et al.*^{15,17} The polyfunctionality could possibly be studied by the method developed by Fronaeus³⁰ for polyfunctional ion-exchangers.

Identification of lanthanide binding sites in humic/fulvic material (under in situ conditions)

The very high sensitivity of the fluorescence methods made it feasible to study europium

binding to organic material present in ground-water samples. In a preliminary experiment we tested the sensitivity of the europium fluorescence method by using test solutions containing 3 ppm FA, a 10mM acetate buffer of pH 5.5, and I 0.1M. The europium concentration varied from 5×10^{-8} to $10^{-6}M$. The resulting experimental curve is shown in Fig. 4. The deviation from linearity may be due to the fact that, with increasing Eu(III) concentrations, the Eu(III)/FA ratios might shift outside the plateau region, with a consequent decrease of the fluorescence signal.

The presence of lanthanide/actinide-binding organic materials in ground-water systems is easily tested for by adding a few μl of 0.01M EuCl_3 solution to 100 ml of the water sample and recording its emission spectrum immediately. An example of such a test on a ground-water from Gorleben (Germany) is shown in Fig. 5. The source and the characteristics of this water are given in the legend of the figure. The concentrations of metal ions which can compete with Eu(III) for the organic material are very low in this water.

An advantage of the technique is that it provides direct information on the lanthanide/actinide bonding under *in situ* conditions, *i.e.*, in the presence of all competing ions, such as Ca(II), Mg(II), Fe(II,III), Al(III), *etc.* The fluorescence method gives only qualitative information. Quantitative data usually require much more idealized systems such as the chemically separated HA/FA materials used in the present work.

Fig 5 Typical emission spectra of various Eu(III) species (a) Eu free ions in 0.1 M NaClO₄, pH = 5.5, [Eu]_i = 10⁻⁵ M, λ_{exc} = 394 nm, (b) EuFA complex in 0.1 M NaClO₄, pH = 5.5, [Eu]_i = 10⁻⁸ M; [FA]_i = 3 ppm; λ_{exc} = 308 nm, (c) EuFA complex in a Gorleben ground-water (pH = 8, total carbonates 2 × 10⁻³ M), λ_{exc} = 308 nm; [Eu]_i ~ 4 × 10⁻⁸ M. The detection sensitivity has been optimized for each spectrum

Competitive metal binding and its consequences for trace metal transport

It is obvious from equation (9) that the binding of trace metals such as Eu(III) to HA/FA is influenced by the presence of other cations (and competing ligands, such as OH⁻). The *relative load* of cations is important for the transport capacity of the humic/fulvic material. We have made a model of this, using a Gorleben type water with 16 ppm Ca(II) as the main HA/FA-binding metal ion. The conditional binding constants at pH 6.5 are: log *K'*(Eu) = 6.5 and¹⁴ log *K'*(Ca) = 2.4. By using these constants and the total concentrations [Ca]_t = 4 × 10⁻⁴ M (16 ppm), [Eu(III)]_t = 10⁻⁹ M and [FA]_t = 1 and 10 ppm, we have calculated the concentrations of EuFA and CaFA, assum-

ing that the HA/FA has a metal-binding capacity of around 10⁻³ M Eu(III)/g. We find that with 1 ppm HA/FA 64% of the Eu(III) is bonded as EuFA; the corresponding quantity at 10 ppm is 95%. Deep ground-water often contains little organic material (from <0.1 to 1 ppm is not uncommon³¹ and high Ca(II) concentrations (3.5–9 × 10⁻⁴ M in several deep granitic waters in Sweden³¹). Under these conditions Ca(II) may be an efficient competitor for binding the organic material, in comparison with trace metals such as Eu(III) and trivalent actinides, despite the larger binding constants of these trace metals.

The Gorleben water contains approximately 3 ppm of organic materials, but small concentrations of Ca(II). Under these circumstances, Eu(III) is expected to be strongly bonded, as is indeed observed experimentally.

Bivalent metal ions such as Mg(II), Ca(II) and Fe(II) form weaker hydroxide complexes than Eu(III) but also weaker complexes with other ligands (presumably also with FA/HA). At pH 5.35 these bivalent metal ions may not compete with Eu³⁺ aquo ions for FA. The situation may be quite different at pH > 7 where europium hydrolysis is much more pronounced than that of M(II). Qualitative titrations of Eu/Ca at pH 5.5 indeed showed that competition between the two metals for FA was much weaker than that found for the Al/Eu system. In a recent investigation,³² a different behaviour was found for natural organic substances of higher molecular weight (humic acids). This matter therefore seems worth more experimental investigation.

Acid rain changes the trace-metal distribution in the soil layer. One reason for this might be that the *relative* binding constant of Al(III) to HA/FA increases in comparison with the binding constant of less hydrolysed trace metals at lower pH.

Fluorescence decay-time

There is no doubt that investigations such as those discussed in this work would greatly benefit from a simultaneous measurement of the fluorescence decay-time. In fact, it is well known³³ that, in addition to a change in the fluorescence intensity, there is also a drastic change in the fluorescence lifetime as a result of complexation.

In general, the fluorescence lifetime of lanthanide complexes is greater than that of the corresponding aquo-ions. This is due to the very

efficient energy transfer from the aquo-complex through hydrogen bonding to the solvent. In our case, the complexation by the FA system should also result in a fluorescence lifetime different from that of the aquo-ion. At present, however, we cannot claim any conclusive evidence for such an effect, since, as reported earlier, the strong organic fluorescence produces undesirable artifacts in our detection system. Work is now in progress to eliminate this problem.

ELECTROGENERATION OF Hg⁺ IN THE PRESENCE OF TRYPTOPHAN

A. RENUKA* and K. SHAKUNTALA

Department of Physical Chemistry, University of Madras, A. C. College of Technology, Guindy, Madras 600 025, India

(Received 14 November 1989 Revised 7 March 1991 Accepted 19 March 1991)

Summary—In the presence of L-tryptophan, a one-electron oxidation of mercury takes place at the dropping mercury electrode at 0.265 V vs SCE in 0.1M potassium nitrate. The electrogeneration of the monomeric Hg⁺ ion has been established by a.c. polarography, cyclic voltammetry and ultraviolet spectroscopy. A paramagnetic Hg-trp compound has been electrochemically synthesized and characterized.

The first report of the existence of the monomeric mercurous ion, Hg⁺, appeared in 1940.¹ It was based on an electrochemical investigation of the anodic oxidation of the dropping mercury electrode in the presence of cysteine, and stated that at mercury(I) concentrations < 10⁻²⁰M practically all the mercurous ions are present as Hg⁺ and not Hg₂²⁺. Thirty years later, other evidence for the existence of Hg⁺ was obtained by γ -irradiation of solid inorganic compounds doped with mercury(II), or radiolysis and photolysis of solutions of mercury compounds. Symons and co-workers²⁻⁴ detected the Hg⁺ ion in γ -irradiated glasses, samples of cadmium carbonate containing Hg²⁺ impurity, cadmium acetate doped with mercury(II) and in pure mercuric acetate, by the EPR technique. They indicated that Hg⁺ is produced in a covalent environment. Dalal and co-workers^{5,6} showed that Hg⁺ can be substituted for K⁺ and NH₄⁺ in KHSO₄ and NH₄H₂PO₄ respectively. Faraggi and Amozig⁷ characterized the ultraviolet spectrum of Hg⁺, with λ_{max} at 272 nm. They produced Hg⁺ ions by the reaction of hydrogen atoms with Hg²⁺ or Hg₂²⁺. Gupta and Kaur,⁸ who investigated the polarography of *o*-mercaptobenzoic acid, showed that the anodic wave in 60% v/v methanol medium is due to the formation of an Hg⁺ complex, RSHg. In earlier work^{9,10} we obtained polarographic data for a one-electron anodic oxidation of a mercury electrode in presence of L-tryptophan (trp). In this paper, evidence obtained by

cyclic voltammetry, constant-potential macroelectrolysis, and structure analysis of the reaction product is presented.

EXPERIMENTAL

The experimental details for the reagents and d.c. polarography are the same as those reported earlier.⁹ An alternating voltage amplitude of 5 mV and a frequency of 60 Hz were used in the fundamental harmonic a.c. polarography. An alternating voltage amplitude of 10 mV and a frequency of 120 Hz were used in the second harmonic a.c. polarography. A thick-walled blunt capillary having the following characteristics was used as the dropping mercury electrode (DME): drop time, $t = 6.2$ sec in 0.1M potassium nitrate; mercury flow-rate, $m = 1.3$ mg/sec. Cyclic voltamperograms were obtained with a PAR model 173 potentiostat/galvanostat, model 176 current to voltage converter, and model RE008 XY recorder. The hanging mercury drop electrode (HMDE) was fabricated by the procedure of Bellamy.¹¹ Ultraviolet spectra were obtained with a Zeiss spectrophotometer and a Hitachi 320 spectrophotometer with 1-cm fused-silica cells. Infrared spectra were obtained with a Shimadzu IR 408 spectrophotometer with KBr cells in the range 5000–600 cm⁻¹ and polythene cells in the range 600–200 cm⁻¹. A Polytech FIR-30 spectrophotometer was used for FT-FIR measurements. The EPR spectrum of the sample in the powdered form was recorded on an E4 Varian X-band spectrometer. Constant-potential macroelectrolysis was performed

Fig. 1 Fundamental harmonic a.c. (a, b) and second harmonic a.c. (c) polarograms for the anodic dissolution of mercury in the presence of 6mM trp (b, c) and absence of trp (a), in 0.1M KNO₃

with a large mercury pool electrode 10 cm in diameter. The solution was thoroughly de-aerated with purified nitrogen before the electrolysis and purging was continued during the electrolysis. The product was isolated from the electrolyte solution under a nitrogen atmosphere to avoid contact with air. All experiments were performed at $25 \pm 1^\circ$.

RESULTS AND DISCUSSION

Alternating current polarography and cyclic voltammetry

A representative fundamental harmonic a.c. polarogram for the anodic dissolution of mercury in the presence of trp in 0.1M is shown in Fig. 1, curve b. Curve a is the corresponding polarogram of the supporting electrolyte.

The peak current for peak A (I_pA) increases linearly with [trp] in the range 0.1–0.8mM,

Fig. 2 Cyclic voltamperograms for the anodic dissolution of mercury in the presence of trp in 0.1M KNO₃ at a sweep rate of 50 mV/sec [trp], mM. (1) 0; (2) 2, (3) 4, (4) 8, (5) 20

above which the increase is only slight. The peak potential (E_pA) does not vary with [trp] (Table 1). The peak width at half height is 110 ± 5 mV. The plot of $\log\{(I_p/I)^{1/2} + [(I_p - I)/I]^{1/2}\}$ vs. E is linear, with a slope of 128 mV. The deviation of these values from the theoretical values for a one-electron process (90 mV and 118.2 mV respectively¹²) indicates that peak A corresponds to a quasi-reversible process. It should be mentioned that even slight departures from the theoretical Nernstian conditions will be exhibited as broadening of the a.c. wave.¹³ That the degree of irreversibility is small is shown by the cyclic voltamperogram (Fig. 2) in which $\Delta E_p (= E_{pa} - E_{pc})$ for peak A is 57.5 ± 2.5 mV. E_{pa} is the potential corresponding to the peak labelled aA, and E_{pc} that for peak cA. The second harmonic a.c. polarogram (Fig. 1, curve c) confirms the 1-electron nature of process A, by its possession of two peaks 70 mV apart, and

Fig 3 Effect of $[\text{trp}]$ on electrocapillary curves in $0.1M$ KNO_3 .

the minimum in current at E_pA for the fundamental harmonic a.c. polarogram.

E_pB and I_pB do not vary appreciably with $[\text{trp}]$, but I_pB is lower and E_pB more positive than in the absence of trp . Peak C is not seen at high trp concentrations, but begins to appear at about $12mM$ trp and increases in height with decrease of $[\text{trp}]$, together with a shift in its peak potential, E_pC , to less positive values. Thus it is evident that peaks B and C represent only the mercury–nitrate interactions of the supporting electrolyte,^{9,14} which are suppressed in the presence of trp .

The electrocapillary curves (Fig. 3) in the presence of trp show a marked depression in the potential region (0.3–0.5 V) of processes X and Y of the supporting electrolyte. This could result if the Hg – trp product, free trp , or both, get adsorbed on the electrode surface, causing inhibition of the mercury–nitrate interactions.

Constant-potential macroelectrolysis

Constant-potential macroelectrolysis of $0.05mM$ trp in $0.1M$ potassium nitrate was performed sequentially at three potentials:

Fig. 4 Difference UV spectra recorded during the macroelectrolysis of $0.05mM$ trp in $0.1M$ KNO_3 at the E_pA potential of 0.265 V. (0) before electrolysis; (1–5) at every 30 min during electrolysis (.. .) is the UV spectrum of the brown solid isolated from macroelectrolysis of trp at E_pA .

Fig 5 Difference UV spectra recorded during the macroelectrolysis of $0.05mM$ trp in $0.1M$ KNO_3 at the E_pB potential of 0.365 V. 303 nm corresponds to λ_{max} for nitrate.

(a) E_pA , 0.265 V; (b) E_pB , 0.365 V; (c) E_pC , 0.485 V. The ultraviolet spectra of the electrolysed solutions were recorded at regular intervals during the electrolysis.

Macroelectrolysis at 0.265 V. The spectra recorded at 30-min intervals during the macroelectrolysis at 0.265 V are shown in Fig. 4. The indole chromophore of trp exhibits three different λ_{max} values (272 , 279 and 283 nm)¹⁵ and as electrolysis proceeds, the spectrum shifts toward shorter wavelengths. A new peak appears at 258 nm and develops as the electrolysis proceeds. This new peak is attributable to mercury. The ultraviolet absorption spectrum of mercury has been well analysed, and the absorption at 230 – 235 nm is attributed^{16–18} to $\text{Hg}^{2+}/\text{Hg}_2^{2+}$, and that at 272 nm is attributed⁷ to Hg^+ . The λ_{max} value of 258 nm observed in the present study is closer to 272 nm than 235 nm and may be taken as evidence that Hg^+ is formed under the experimental conditions. It should be mentioned here that the value of 272 nm for Hg^+ was for aqueous solutions containing no complexing agent or excess salts.⁷ In the present case, the solution contains $0.1M$ potassium nitrate and trp . This difference in background medium may account for the shift in λ_{max} .

Macroelectrolysis at 0.365 V. The nitrate ion has a characteristic ultraviolet absorption spectrum with a λ_{max} of 302.8 nm.¹⁹ When the difference spectra were recorded with the unelectrolysed solution of $0.05mM$ trp in $0.1M$ potassium nitrate in the sample cell and the corresponding electrolysed solution in the reference cell, the change in the nitrate absorbance at 302.8 nm could be followed (Fig. 5). The difference in recorded absorbance increases as the

Fig 6 IR spectra of trp and of the brown compound obtained from the macroelectrolysis of trp in 0.1M KNO_3 at 0.265 V. Inset is the visible-region spectrum of the compound in methanol.

electrolysis proceeds, which indicates a decrease in the concentration of nitrate ions. Thus process B is seen to correspond to the mercury–nitrate interactions characteristic of the supporting electrolyte.¹⁴

Macroelectrolysis at 0.485 V. The spectral results obtained were similar to those obtained for the electrolysis at 0.365 V in that the difference absorbance of nitrate increased during the electrolysis. Thus process C is also due to the mercury–nitrate interactions.

Product analysis

A series of constant-potential macroelectrolyses of 0.05mM trp in 0.1M potassium nitrate was conducted in order to collect the product, as follows. The electrolysed solution was removed from the mercury and slowly evaporated to dryness at 60°. The solid left was repeatedly washed with cold doubly-distilled water to remove potassium nitrate and then with hot

doubly-distilled water to remove unreacted trp. The brown solid left behind was dried under reduced pressure. The ultraviolet absorption spectrum of a solution of this compound in methanol is shown by the dotted line in Fig. 4. The spectrum shows shifts in the λ_{max} values for trp and mercury, indicating that the two are bonded to each other. The visible spectrum of the compound in methanol is shown as the inset in Fig. 6. There are two strong absorption peaks at 333 and 394 nm and a weak absorption at 498 nm.

A comparative study of the infrared spectra of the brown compound and trp (Fig. 6) reveals the following features. The characteristic stretching frequency of the NH group of indole at 3500 cm^{-1} is absent in the spectrum of the compound, indicating strong association of the indolyl nitrogen atom with mercury. The NH stretching frequency of the zwitterionic NH_3^+ group shows a minor shift of 30 cm^{-1}

Fig 7 EPR spectrum of compound obtained from the macroelectrolysis of trp in 0.1M KNO_3 at the E_p , A potential of 0.265 V. Inset is the FT-FIR spectrum of the compound. DPPH is diphenylpicrylhydrazyl

from 3010 cm⁻¹ to 2980 cm⁻¹. The stretching frequency of the carboxylic C=O group at 1730 cm⁻¹ is unaffected. The NH in-plane bending vibrations of the -NH₂ or -NH₃⁺ group at 1610 cm⁻¹ are unchanged. Similarly, the carboxylic OH stretching at 1320 cm⁻¹ is also not affected. These observations indicate that the mercury-trp bond is formed at the indolyl nitrogen atom and that other functional groups are not involved in the compound formation. The fingerprint region of trp between 1200 and 600 cm⁻¹ is structureless in the spectrum of the compound. Aromatic compounds in general show a strong absorption at 800 cm⁻¹. CH rocking mode vibration also occurs at 800 cm⁻¹,^{20,21} and trp does show a strong vibration at 800 cm⁻¹ which is absent in the spectrum of the mercury derivative. This observation and the minor shift of the zwitterionic -NH₃⁺ stretching frequency indicate that the binding of mercury at the indolyl nitrogen atom affects the entire molecule. The compound does not show any absorption in the FT-FIR spectrum (Fig. 7, inset).

The EPR spectrum of the compound is shown in Fig. 7. This spectrum is similar to that reported by Dalal *et al.*⁶ for the Hg⁺ (6s¹) ion in irradiated mercuric acetate. However, in the present case, the multiplicities of the signals on either side of the reference (DPPH) do not coincide, indicating the anisotropic nature of the mercury-trp compound.

The foregoing spectral data support the following mechanism proposed⁹ for the anodic dissolution of mercury in the presence of trp.

The brown compound was analysed for mercury [determined as mercury(II) thionalide]²² and for nitrogen by the Kjeldahl method,²³ and the N:Hg atomic ratio found was 2.001, in agreement with the formula C₁₁H₁₁N₂O₂Hg. The magnetic moment of the compound was measured by the Gouy method,²⁴ and a freshly prepared sample had a magnetic moment (μ_{eff}) of 1.87 BM.

The brown compound decomposed on standing, expelling fine droplets of mercury with decreased paramagnetism (μ_{eff} of the decomposed sample was 0.32 BM). This shows that Hg⁺ is unstable and dimerizes, followed by disproportionation, according to the following scheme.

CONCLUSION

There has been a remarkable development in the chemistry of unusual oxidation states of mercury, leading to the identification of formal oxidation states of +0.67,^{25,26} and +0.35,²⁷ and the study of the electrochemical oxidation of the complex [Hgcyclam]BF₄ in acetonitrile medium by Deming *et al.*²⁸ provided evidence for the existence of the Hg³⁺ ion. Electrochemical techniques have been extremely useful in the unravelling of unusual oxidation states of mercury. The present work is yet another example, and reports a method of electrochemically preparing a paramagnetic compound of mercury containing the Hg⁺ ion. Further investigation is in progress.

PROTONATION AND SOLVENT EXTRACTION OF *N-p*-TOLYLBENZOHYDROXAMIC ACID IN HYDROCHLORIC ACID MEDIUM

RAMA PANDE and S. G. TANDON

Department of Chemistry, Ravishankar University, Raipur 492010, India

(Received 3 April 1989. Revised 10 January 1991 Accepted 26 March 1991)

Summary—The protonation of *N-p*-tolylbenzohydroxamic acid (*p*-TBHA) in aqueous hydrochloric acid has been investigated by determination of its distribution between cyclohexane and hydrochloric acid. The pK_a value found was -2.30 ± 0.02 at 30° . The solubility of *p*-TBHA as a function of hydrochloric acid concentration has also been determined. At lower acid concentrations the solubility decreases owing to a salting-out effect, whereas at higher concentrations it increases because of formation of the more hydrophilic protonated species and a salting-in effect. Intramolecular hydrogen-bonding observed in *p*-TBHA provides evidence for protonation of the nitrogen atom.

Substituted hydroxamic acids (HA), of general formula

have been the subject of a large number of physicochemical studies, because of their wide applications in solvent extraction of metals.¹⁻⁵ Nevertheless, it is not clear how distribution of the hydroxamic acids between the organic and aqueous phases is affected by the acidity of the aqueous phase. These reagents might be expected to differ in solubility in different organic solvents, and in their distribution between these solvents and aqueous phases. Another factor that may affect the solubility and distribution ratio, and also the metal-extracting properties of these reagents in acid solutions is the formation of a protonated species ($HA + H^+ \rightleftharpoons H_2^+ A$).

In the present investigation the distribution ratios of *N-p*-tolylbenzohydroxamic acid (*p*-TBHA)

between various organic solvents and aqueous phases were determined, along with the effect of hydrochloric acid concentration on the solubility of *p*-TBHA. The protonation constant was also determined.

EXPERIMENTAL

Absorption spectra were recorded with a Zeiss Specord recording spectrophotometer, and 1-cm path-length matched fused-silica cells. Fixed wavelength measurements were made on an EC model GS 865 spectrophotometer.

Pure *p*-TBHA was prepared by a procedure reported earlier.⁶ The chloroform used was shaken five or six times with equal volumes of water to remove the ethanol (present as preservative) and then distilled. A saturated solution of analytical grade ammonium metavanadate was prepared in distilled water. Analytical grade hydrochloric acid was used to determine the solubilities and distribution ratios, but for the extraction work C.P. grade acid was adequate because any iron(II) present in it did not interfere. Iron(II) is Fe(II). Normally, HCl contains traces of Fe(II) which interfere in the determination of Vanadium V, but in the reverse determination of *p*-TBHA by vanadium V, Fe(II) does not interfere because vanadium V is taken in large excess.

All other organic solvents (BDH, analytical grade) were used without further purification.

Measurement of solubility

Saturated solutions were prepared in different solvents at the desired temperature, and suitable aliquots were used for determining the reagent content.

Table 1 Effect of solvents on the absorption maximum of *p*-TBHA in the ultraviolet

Solvent	λ_{\max} , nm
Water	245–260
Ethanol, 95%	270
Cyclohexane	278
Carbon tetrachloride	279
Chloroform	273
Dioxan	275

Measurement of distribution ratio

A known quantity of *p*-TBHA was dissolved in a known volume (10–25 ml) of organic solvent and shaken vigorously with a known volume (25–100 ml) of water for 30–60 min. The volumes of the two solvents were chosen according to the magnitude of the distribution ratio. The phases were separated by centrifugation and analysed for *p*-TBHA spectrophotometrically with vanadium(V).⁷

For determining the distribution ratio of *p*-TBHA between cyclohexane and hydrochloric acid, a rapid technique was adopted to avoid errors due to acid hydrolysis of the hydroxamic acid. It was observed that with sufficiently vigorous shaking equilibration between the organic and aqueous phases could be achieved within 5 min.

Analysis of the phases

The determination of *p*-TBHA by its absorbance in the ultraviolet gave unsatisfactory results because of the variation of its spectral characteristics with change in the solvent (Table 1) and with the acidity of its aqueous

Table 2. Solubility and distribution ratio of *p*-TBHA in different solvents at 25°

Solvent	Solubility, g/l	<i>D</i>
Water	0.25	—
n-Hexane	1.0	3.85
Cyclohexane	2.4	7.55
Carbon tetrachloride	18.3	62
Methyl isobutyl ketone	87.6	—
Benzene	109	169
Chlorobenzene	116	188
<i>o</i> -Dichlorobenzene	124	184
Ethyl acetate	140	—
Acetone	260	—
Chloroform	375	665

solutions. The *p*-TBHA concentrations were therefore determined spectrophotometrically with vanadium(V)⁷ which gives reproducible and accurate results.

RESULTS AND DISCUSSION

Spectrophotometric study

The ultraviolet spectral characteristics of *p*-TBHA in various organic solvents are presented in Table 1. It is evident that the position of the absorption band shifts according to the solvent used.

In hydrochloric acid media *p*-TBHA hydrolyses into the parent benzoic acid and *N*-*p*-tolylhydroxylamine, the latter being further changed into a variety of complex compounds. Hence the ultraviolet spectrum changes with time and direct spectrophotometry cannot be used to determine the concentration of *p*-TBHA in hydrochloric acid solutions. Figure 1 shows the effect of hydrochloric acid concentration on the ultraviolet spectrum of *p*-TBHA.

Fig 1 Effect of hydrochloric acid concentration on the ultraviolet spectrum of fresh solutions of *p*-TBHA. [HCl], M: A, 0; B, 0.01; C, 3 and 6; D, 10

Fig. 2 Solubility of *p*-TBHA as a function of [HCl]

Solvent extraction studies

The data presented in Table 2 show that of the solvents tested, chloroform gives the highest solubility of *p*-TBHA and water the lowest. *n*-Hexane and cyclohexane are poor solvents for *p*-TBHA. For purification of the reagent by recrystallization a mixture of benzene and petroleum ether of *n*-hexane has proved very effective.

Solubility and distribution ratio of *p*-TBHA as a function of hydrochloric acid concentration

Figure 2 shows that the solubility of *p*-TBHA increases with increasing hydrochloric acid concentration; this is due to protonation of *p*-TBHA in acidic solutions. The hydrophilic nature of the protonated species is presumably responsible for the enhanced solubility. However, a plot of $\{([HA] + [H_2^+A])/[HA]\} - 1$ vs.

$[H^+]$ is not linear, so protonation alone cannot account for the increased solubility, so other factors such as salting-in may also be involved.

The effect of hydrochloric acid concentration on the distribution into cyclohexane is shown in Table 3. Cyclohexane was chosen for the study because of its favourable physical properties such as adequate difference in density from water, low dielectric constant and vapour pressure, zero dipole moment and very low mutual solubility with water. From Fig. 2 and Table 3 it is inferred that for the system of *p*-TBHA with cyclohexane and hydrochloric acid the solubility and the distribution ratio are constant up to about 2*M* hydrochloric acid concentration and then protonation increases the solubility in aqueous medium and decreases the distribution ratio.

The degree of protonation is only 6.6% in 4*M* hydrochloric acid but 92% in 10*M* hydrochloric acid.

The distribution constant (K_D) for the unprotonated reagent between the aqueous and organic phases is defined by the equation

$$K_D = \frac{[p\text{-TBHA}]_{\text{org}}}{[p\text{-TBHA}]_{\text{aq}}}$$

The distribution between cyclohexane and aqueous hydrochloric acid is affected by the protonation reaction, and the distribution constant (D) is

$$D = \frac{[p\text{-TBHA}]_{\text{org}}}{[p\text{-TBHA}]_{\text{aq}} + [p\text{-TBH}_2^+\text{A}]_{\text{aq}}}$$

The dissociation constant, pK_a , of $p\text{-TBH}_2^+\text{A}$ can be calculated from

$$pK_a = H_0 - \log\left(\frac{K'_D - D}{D}\right)$$

Table 3 Distribution data

where H_0 is the Hammett acidity function; the data are presented in Table 3. K'_D is the distribution constant of *p*-TBHA between the organic layer and aqueous acid in the acidity region where appreciable protonation is occurring, and is estimated by the relation

$$D = K'_D - \frac{Dh_0}{K_a}$$

or from the intercept of a plot of D vs. Dh_0 , where $h_0 = 10^{-H_0}$. In the infrared spectra of *p*-TBHA in nujol both $\nu_{\text{O-H}}$ and $\nu_{\text{C=O}}$ appear at lower wavenumbers than expected, namely at 3180 and 3300 cm^{-1} and 1643 and 1623 cm^{-1} , respectively,⁶ and the positions of these bands remain unaffected on dilution. It is thus inferred that there is intramolecular hydrogen bonding in *p*-TBHA, and hence that the nitrogen atom is protonated in acid medium.

determination of the extraction coefficients of its metal chelates.

INTERFERENCE IN THE KINETIC DETERMINATION OF ASCORBIC ACID BY SULPHIDE AND SULPHITE

CONSTANTINA N. KONIDARI and MILTIADES I. KARAYANNIS*

Department of Chemistry, University of Ioannina, 451 10 Ioannina, Greece

(Received 12 November 1990 Revised 8 February 1991 Accepted 5 April 1991)

Summary—The reduction of 2,6-dichlorophenolindophenol (DCPI) by sulphides and sulphites has been studied kinetically by the stopped-flow technique. The reaction is first-order with respect to each of the reactants. From the distribution diagrams for the species DH_2^+ , DH and D^- for DCPI and H_2Q , HQ^- and Q^{2-} for sulphides or sulphites, a mechanism is proposed which suggests partial reactions of all possible combinations of the reacting species at any pH. An equation for calculation of the second-order reaction rate constants k at any pH is derived, which gives k as a function of $[\text{H}^+]$, the partial reaction rate constants and the dissociation constants of DCPI and H_2S or H_2SO_3 . Values of the overall reaction rate constants over a wide pH-range have been determined, together with values of k for all possible partial reactions. For particular pH-values the second-order reaction rate constant was determined by four different methods. Mean values of $k = 251 \pm 1$ and $240 \pm 11 \text{ mole}^{-1} \cdot \text{sec}^{-1}$ were obtained for pH 3.15 and 4.17, respectively, for the DCPI- Na_2S reaction and $k = 137 \pm 1$, 127 ± 1 and $136 \pm 11 \text{ mole}^{-1} \cdot \text{sec}^{-1}$ for pH 2.02, 4.25 and 5.10, respectively, for the DCPI- Na_2SO_3 reaction. From the slopes of the linear Arrhenius plots activation energies of 66 ± 0.2 and $40 \pm 0.1 \text{ kcal/mole}$ for the DCPI- Na_2S and DCPI- Na_2SO_3 reactions, respectively were calculated. The effect of ionic strength on the reactions supports the proposed mechanism.

The main chemical method for determination of ascorbic acid in biological samples is the 2,6-dichlorophenolindophenol (DCPI) method.¹ Its simplicity and the relatively close correlation with the results of biological assays have led to its extensive use. Both the equilibrium and reaction-rate procedures are widely employed.² The method works well for colourless fruit juices but has serious drawbacks when other reducing substances such as thiols, hydrogen sulphide, thiosulphates, dithionates, cysteine, homocysteine, reduced glutathione and metal ions in lower oxidation states (*e.g.*, Fe^{2+} , Sn^{2+} , Cu^+) are present.³⁻⁵

Of these interferents, hydrogen sulphide and thiols are of special interest because any dehydroascorbic acid present is measured as ascorbic acid after its reduction by hydrogen sulphide and removal of the excess of reductant. Quinols and thiols may also be formed by hydrogen sulphide reactions with the sample, and interfere with the dye reduction. Thiols reduce DCPI at a rate that depends on pH.⁶

Attempts to suppress the interference by thiols have been made,^{3,5,7} the first by formation of complexes of the interfering substances and

formaldehyde, the second by the use of *p*-chloromercuribenzoic acid, and the third by use of mercuric acetate to precipitate some of the interfering substances, but all are time-consuming and add more steps to the method. Furthermore, complete removal of hydrogen sulphide and/or thiols is not ensured.

Despite the voluminous literature on modifications of the 2,6-dichlorophenolindophenol method to avoid such interferences, many basic questions remain, some of which have already been studied⁸ or are under investigation.⁹

In this paper a kinetic and mechanistic study of the DCPI reduction by hydrogen sulphide and sulphurous acid over a wide pH-range is presented. The results are a good basis for optimization of the reaction pH, and correction of the errors due to these interferences, and the rate constants reported may be useful in other investigations.

EXPERIMENTAL

Reagents

All solutions were prepared in distilled water from analytical-reagent grade reagents without further purification.

Buffer solutions. The buffer solutions used were based on 0.2M potassium chloride and

*Author for correspondence.

hydrochloric acid for pH 1.0–2.2, 0.1M potassium hydrogen phthalate and hydrochloric acid or sodium hydroxide for pH 2.2–6.0, 0.1M potassium dihydrogen phosphate and sodium hydroxide for pH 6.0–8.0 and 0.025M borax and 0.1M hydrochloric acid or sodium hydroxide for pH 8.0–9.5.

Sodium sulphide solution. An approximately 0.05M solution was prepared daily with freshly distilled water, standardized by titration with iodine solution,¹⁰ and diluted further with the appropriate buffer as required.

Sodium sulphite solution. An approximately 0.05M solution was prepared daily with freshly distilled water, standardized by titration with potassium iodate,¹¹ and diluted further with the appropriate buffer as required.

DCPI solution. A stock solution ($\sim 7.5 \times 10^{-4}M$) was prepared in distilled water containing 210 mg/l. sodium bicarbonate, and further diluted with 210 mg/l. sodium bicarbonate solution as required. The stock solution was standardized by titration with freshly prepared ascorbic acid solution, and also spectrophotometrically at 522 nm, the isosbestic point. The molar absorptivity¹² at 522 nm is 8600 l.mole⁻¹.cm⁻¹.

Apparatus

A Durrum Model D-110 stopped-flow spectrophotometer was used; the course of the reaction was displayed on a Textronix 5103N storage oscilloscope and photographed with a Polaroid camera or recorded on a Houston Instrument Omnigraphic 2000 recorder. The path-length of the measuring cell was 2.0 cm. The experimental arrangement is described in detail elsewhere.^{2,13}

A Radiometer pH M 83 Autocal pH-meter was also used.

Procedure

The stopped-flow spectrophotometer was calibrated for 0 and 100% transmittance with the reductant solution in the observation cell. All measurements were made at 522 nm.

The concentrations given in the figures and tables are the initial concentrations in the reacting mixture.

In all experiments the analytical concentration of sulphide or sulphite was held much higher than that of DCPI in order to create pseudo first-order conditions.

Data treatment

For the generalized reaction scheme

absorbance (A) vs time (t) was recorded, with variation of parameters such as pH, reactant concentrations, temperature and ionic strength. D and Q denote DCPI and sulphide or sulphite, respectively, the subscripts ox and r representing the oxidized and reduced forms.

The Guggenheim method¹⁴ was applied to determine the observed reaction rate constants, k_{ob} . Since the reductant concentration (c_q) was always much higher than that of DCPI (c_d), the conditions were pseudo first-order and the k_{ob} was equal to kc_q . The initial slopes R_A were determined graphically from the reaction curves.

From the values of k_{ob} and the initial slopes R_A given by the equation

$$R_A = -(dA/dt)_m = \epsilon b k c_q c_d \quad (2)$$

the second-order reaction rate constants k were calculated by applying four different techniques described in detail elsewhere.⁸ The calculated constants given in the tables are symbolized as k_I , k_{II} , k_{III} and k_{IV} , corresponding to the four evaluation methods I–IV.

RESULTS

Effect of pH

Figure 1 illustrates the dependence of k on pH for the DCPI–Na₂S (a) and DCPI–Na₂SO₃ (b) reactions.

Effect of reactant concentrations

The second-order reaction rate constants at various pH-values and 25° were determined by four evaluation techniques, with one reactant at constant concentration and that of the other varied.

Table 1 gives all the elements for the calculation of the second-order reaction rate constant for the DCPI–sulphite system at pH 3.15 and pH 4.17 by the four different methods mentioned above. Table 2 gives the corresponding information for the DCPI–sulphite system at pH 2.02, 4.25 and 5.10.

The linear dependence of k_{ob} and R_A on the initial concentration of the reductant, when c_d remains constant, suggests first-order kinetics with respect to the reductant. Also, the propor-

DISCUSSION

Fig 1 Dependence of the second-order reaction rate constant on pH for the reaction of DCPI with Na_2S (a) and Na_2SO_3 (b) $[\text{DCPI}]_0 = 1.57 \times 10^{-5} M$, $[\text{Na}_2\text{S}]_0 = 6.30 \times 10^{-4} M$, $[\text{Na}_2\text{SO}_3]_0 = 5.00 \times 10^{-4} M$, temperature 25°C

tionality between R_A and the initial concentration of the dye, for constant c_q , and the observed constancy of k_{ob} within experimental error, indicate first-order kinetics with respect to DCPI.

Effect of temperature

Arrhenius plots of $-\log k_{ob}$ vs. $1/T$, and $\log R_A$ vs. $1/T$, where T is the absolute temperature, showed the activation energy to be 6.6 ± 0.2 and 4.0 ± 0.1 kcal/mole for the DCPI- Na_2S and DCPI- Na_2SO_3 reactions, respectively.

The dependence of the reaction rate constant k on pH can be explained, at least qualitatively, by assuming the following mechanism for the reduction of DCPI by Na_2S and Na_2SO_3 . At each pH value the reductant exists as a mixture of three species (H_2Q , HQ^- and Q^{2-}) with stepwise ionization constants $K_{Q1} = 1.07 \times 10^{-7}$ and $K_{Q2} = 1.26 \times 10^{-13}$ for the H_2S and $K_{Q1} = 1.3 \times 10^{-2}$ and $K_{Q2} = 6.17 \times 10^{-8}$ for H_2SO_3 .¹⁶ DCPI also exists in three states. $[\text{DH}_2^+$, DH and $\text{D}^-]$ with stepwise ionization constants $K_{D1} = 0.3$ and $K_{D2} = 2.69 \times 10^{-6}$.¹⁷ Figures 2 and 3 show the distribution diagrams of the H_2S -DCPI and H_2SO_3 -DCPI systems, respectively. From these diagrams it is evident that the overall reaction is a sum of the component reactions between the various species of reductant and DCPI, in all possible combinations whenever they co-exist.

Table 4 shows all possible combinations of the reacting species and the corresponding reaction constants according to the general scheme given in equation (1). The arrows in Figs. 2 and 3 show the different pH ranges and the reaction constants for the component reactions k_i ($i = 1-9$).

Taking these considerations into account, the overall reaction rate constant k can be derived theoretically and expressed as a function of (i) $[\text{H}^+]$, (ii) the ionization constants K_{D1} , K_{D2} , K_{Q1} , K_{Q2} , and (iii) the reaction constants of the component reactions k_i ($i = 1-9$).

For the DCPI- Na_2S reaction the overall reaction rate constant is given by equation (3), and for the DCPI- Na_2SO_3 reaction by equation (4).

$$k = \frac{k_1 \frac{[\text{H}^+]^2}{K_{Q1} K_{D1}} + k_2 \frac{[\text{H}^+]}{K_{Q1}} + k_3 \frac{K_{D2}}{K_{Q1}} + k_5 + k_6 \frac{K_{D2}}{[\text{H}^+]}}{\left[1 + \frac{[\text{H}^+]}{K_{D1}} + \frac{K_{D2}}{[\text{H}^+]}\right] \left[1 + \frac{[\text{H}^+]}{K_{Q1}} + \frac{K_{Q2}}{[\text{H}^+]}\right]} \quad (3)$$

$$k = \frac{k_1 \frac{[\text{H}^+]^2}{K_{Q1} K_{D1}} + k_2 \frac{[\text{H}^+]}{K_{Q1}} + k_4 \frac{[\text{H}^+]}{K_{D1}} + k_5 + k_6 \frac{K_{D2}}{[\text{H}^+]} + k_8 \frac{K_{Q2}}{[\text{H}^+]} + k_9 \frac{K_{Q2} K_{D2}}{[\text{H}^+]^2}}{\left[1 + \frac{[\text{H}^+]}{K_{D1}} + \frac{K_{D2}}{[\text{H}^+]}\right] \left[1 + \frac{[\text{H}^+]}{K_{Q1}} + \frac{K_{Q2}}{[\text{H}^+]}\right]} \quad (4)$$

Effect of ionic strength

The effect¹⁵ of the ionic strength I on k and R_A for the reduction of DCPI by Na_2S and Na_2SO_3 was studied by addition of known amounts of Na_2SO_4 to the reacting mixture. The results are given in Table 3 and show that a change in ionic strength has only a small effect.

Details for the derivation of equations (3) and (4) were given earlier.⁸

To calculate the values of the partial reaction rate constants, shown in Table 5, the overall reaction rate constant was measured in specific pH ranges where only one or two of the reactions take place in parallel.

* A/sec = absorbance change per second.

The theoretical curves for the dependence of the overall reaction rate constant on pH, derived from equation (3) or (4) as appropriate, and the values of k_i , are drawn as solid lines in Fig. 1 for the DCPI- Na_2S (a) and DCPI- Na_2SO_3 (b) reactions, respectively. The experimental values fit the theoretical line satisfactorily.

The type of hydrogen-ion dependence of the DCPI- Na_2S reaction is observed in reacting systems where the following conditions are met: (1) there are more than two species governed by protolytic equilibria, (2) all the species are present in comparable concentrations, (3) all the species are reactive and (4) the middle species is the least reactive.¹⁸ For the oxidation of H_2S with DCPI, all these conditions are satisfied, DH_2^+ , DH and D^- being present in comparable

concentrations and the rate constants ($\text{l. mole}^{-1} \text{sec}^{-1}$) are $k_1 = 9669$, $k_2 = 240$ and $k_3 = 499$. Thus the shape of the curve (a) in Fig. 1 is understandable. The minimum of this curve can be obtained by differentiation of equation (3) with respect to $[\text{H}^+]$. Omitting the term $k_6(K_{\text{D}2}/[\text{H}^+])$ as negligible in this pH range, the first derivative obtained is:

$$\frac{dk}{d[\text{H}^+]} = \frac{k_1}{K_{\text{D}1}} - \frac{1}{[\text{H}^+]^2} (k_3 K_{\text{D}2} + k_5 K_{\text{Q}1}) \quad (5)$$

Because the second derivative

$$\frac{d^2k}{d[\text{H}^+]^2} = 2k_3 \frac{K_{\text{D}2}}{[\text{H}^+]^3} + 2k_5 \frac{K_{\text{Q}1}}{[\text{H}^+]^3} \quad (6)$$

is positive, the dependence of k on pH has a minimum.

Fig. 2. Distribution diagrams for mixtures of species resulting from DCPI (DH_2^+ , DH , D^-) and sulphide (H_2Q , HQ^- , Q^{2-}), as a function of pH.

Fig 3 Distribution diagrams for mixtures of species resulting from DCPI (DH_2^+ , DH , D^-) and sulphite (H_2Q , HQ^- , Q^{2-}), as a function of pH

If the first derivative is set equal to zero, the $[\text{H}^+]$ value for the minimum of curve (a) in Fig. 1 is obtained:

$$[\text{H}^+]_{\text{min}} = \sqrt{\frac{K_{\text{D1}}(k_3 K_{\text{D2}} + k_5 K_{\text{Q1}})}{k_1}} = 2.24 \times 10^{-4} \text{M} \quad (7)$$

This value ($\text{pH} = 3.65$) is in good agreement with the experimental value of $\text{pH} = 3.50$. For this $[\text{H}^+]_{\text{min}}$, $k_{\text{min}} = 243 \text{ l. mole}^{-1} \cdot \text{sec}^{-1}$ was calculated by using equation (3).

For the DCPI- Na_2SO_3 reaction the $\log k$ vs. pH curve shows four distinct regions.

(a) pH 0–2.5. Since in this pH-range the species DH_2^+ and DH of DCPI and H_2Q and HQ^- of the reductant predominate, four partial reactions take place, with reaction rate constants k_1 , k_2 , k_4 and k_5 (Table 4). Also, because the relations $1 + [\text{H}^+]/K_{\text{Q1}} \gg K_{\text{Q2}}/[\text{H}^+]$ and $1 +$

$[\text{H}^+]/K_{\text{D1}} \gg K_{\text{D2}}/[\text{H}^+]$ are valid for this pH-range, equation (4) finally gives

$$k = \frac{k_1[\text{H}^+]^2 + (k_2 K_{\text{D1}} + k_4 K_{\text{Q1}})[\text{H}^+] + k_5 K_{\text{D1}} K_{\text{Q1}}}{[\text{H}^+]^2 + (K_{\text{D1}} + K_{\text{Q1}})[\text{H}^+] + K_{\text{D1}} K_{\text{Q1}}} \quad (8)$$

The sigmoid form of curve (b) in Fig. 1 in this pH-range indicates that there are at least two protonated forms of a reactant present and that the fully protonated form is the most reactive. Consequently, the reaction between the species DH_2^+ and H_2Q is much faster ($k_1 = 619 \text{ l. mole}^{-1} \cdot \text{sec}^{-1}$) than that between DH and H_2Q ($k_2 = 57 \text{ l. mole}^{-1} \cdot \text{sec}^{-1}$).

(b) pH 3.5–6.0. In this pH-range the species DH and D^- of DCPI and HQ^- of Na_2SO_3 co-exist. Consequently, k_5 and k_6 are the rate-determining factors. Because of the validity of the relations $1 + K_{\text{D2}}/[\text{H}^+] \gg [\text{H}^+]/K_{\text{D1}}$ and

$$1 \gg \frac{[\text{H}^+]}{K_{\text{Q1}}} + \frac{K_{\text{Q2}}}{[\text{H}^+]}$$

in this pH-range, equation (4) simplifies to

$$k = \frac{k_5[\text{H}^+] + k_6 K_{\text{D2}}}{[\text{H}^+] + K_{\text{D2}}} = k_5 \quad \text{or} \quad k_6 \quad (9)$$

Table 4 Possible combinations of reactions between species of DCPI and Na_2S or Na_2SO_3 , and the corresponding partial reaction rate constants

	Q	H_2S (H_2Q)	HS^- (HQ^-)	H_2SO_3 (H_2Q)	HSO_3^- (HQ^-)	SO_3^{2-} (Q^{2-})
DH_2^+		k_1	—	k_1	k_4	—
DH		k_2	k_5	k_2	k_5	k_8
D^-		k_3	k_6	—	k_6	k_9

Table 5 Second-order reaction rate constants k (at 25°C) for different combinations of reacting species shown in Table 4

Reaction	Partial rate constants, k_i							
	k_1	k_2	k_3	k_4	k_5	k_6	k_8	k_9
DCPI-Na ₂ S	9669	240	499	—	2348	899	—	—
DCPI-Na ₂ SO ₃	619	57	—	1800	128	131	1048	3

Table 6 Interference of sulphide and sulphite in the kinetic determination of ascorbic acid (Asc Ac) $[\text{DCPI}]_0 = 1.09 \times 10^{-5} M$, temperature 25°C

Reaction	pH	$[\text{Q}]_0$, $10^{-4} M$	$[\text{Asc Ac}]_0$, $10^{-4} M$			k_{obs} , sec^{-1}	
			Taken	Found*	Corrected†	Theor.	Exptl
DCPI-Na ₂ S	1.50	5.00	1.25	1.36	1.25	6.968	6.960
	5.70	5.00	1.00	1.41	1.00	0.786	0.783
DCPI-Na ₂ SO ₃	5.60	5.00	1.00	1.12	1.00	0.626	0.626
	5.86	2.51	2.50	2.62	2.51	0.790	0.794

*Without correction for the interference of sulphide or sulphite

†Corrected for the interference of sulphide or sulphites, by using the values of k given in this work

Because k_5 and k_6 have almost the same value (Table 5), the reaction rate constant of the overall reaction reduces to k_5 or k_6 .

(c) pH 6.0–9.5. In view of the partial reactions which take place in this pH-range and the validity of the relations $1 + K_{D2}/[\text{H}^+] \gg [\text{H}^+]/K_{D1}$ and $1 + K_{Q2}/[\text{H}^+] \gg [\text{H}^+]/K_{Q1}$ in this pH-range, equation (4) gives

$$k = \frac{k_5[\text{H}^+]^2 + (k_6K_{D2} + k_8K_{Q2})[\text{H}^+] + k_9K_{D2}K_{Q2}}{[\text{H}^+]^2 + (K_{D2} + K_{Q2})[\text{H}^+] + K_{D2}K_{Q2}} \quad (10)$$

As already explained for the range pH 0–2.5, the most reactive species in this case is DH.

(d) $pH > 9.5$. At pH -values higher than 9.5 only the species D^- and SO_3^{2-} predominate, and owing to the validity of the $K_{Q2}/[\text{H}^+] \gg 1 + [\text{H}^+]/K_{Q1}$ and $K_{D2}/[\text{H}^+] \gg 1 + [\text{H}^+]/K_{D1}$, for this pH , equation (4) gives $k = k_9$.

The simplifications above were applied by taking into account the inequalities $K_{Q1} \gg K_{Q2}$ and $K_{D1} \gg K_{D2}$.

Assay of ascorbic acid in the presence of sulphide

On the basis of the known dependence of the reaction rate constants of the ascorbic acid–DCPI reaction on pH ,^{19,20} and taking into account the results above, a kinetic determination of ascorbic acid (Asc.Ac) in artificial mixtures containing known concentrations of sulphide was undertaken at different pH -values. The theoretically predicted reaction rate constants were calculated and compared with the experimentally determined values for the mixtures. The results are shown in Table 6.

From the rate constant $k_{\text{asc ac}} = 4 \times 10^4$ l.mole⁻¹.sec⁻¹ reported earlier,^{19,20} and $k_{\text{H}_2\text{S}} = 243$ l.mole⁻¹.sec⁻¹ found in this work for $pH_{\text{min}} = 3.50$, it can be estimated that for equimolar concentrations the error due to the hydrogen sulphide interference is less than 0.6%.

Assay of ascorbic acid in the presence of sulphite

At low pH -values (pH 1–2) no interference by sulphites is observed, because the ascorbic acid reacts much faster than sulphite does with the DCPI. At higher pH -values, because the reaction rate constant of sulphite is comparable to that of ascorbic acid, the interference is serious, especially at high concentrations of sulphite and low concentrations of vitamin C. The experimental results are shown in Table 6.

All the results shown in Table 6 reveal that pH -control is very important for minimizing the interfering effect of sulphide or sulphite in the kinetic determination of vitamin C. As can also be seen from Table 6, correction of the observed rate constants for the contribution of the sulphide or sulphite by use of the values of k given in this work, reduced the error in the determination of ascorbic acid at very low levels.

THE RAMESES ALGORITHM FOR MULTIPLE EQUILIBRIA—V. ERROR STATEMENTS

B. W. DARVELL and V. W.-H. LEUNG

Dental Materials Science Unit, University of Hong Kong, Prince Philip Dental Hospital,
34 Hospital Road, Hong Kong

(Received 9 November 1990 Revised 28 January 1991 Accepted 6 February 1991)

Summary—The equations of multiple equilibria systems can be expressed succinctly in matrix algebra terms. This is the basis of the RAMESES algorithm for the solution of those equations. This matrix algebra leads directly to the differential equations for the interdependence of the vector variables of species concentration, component concentration and equilibrium constants, with or without certain constraints. The laws of propagation of errors then give an immediate expression of the covariance matrix for the dependent vector.

In view of the fact that any set of equations representing an equilibrium is a model, and one which is necessarily only as good as its assumptions, the calculation of the errors associated with results is of immediate interest. This is not an easy proposition for anything other than the simplest of systems, due to the non-linearity, non-homogeneity and interdependence of the set of equations which then require elaborate iterative methods of solution to be employed.¹

The RAMESES algorithm¹⁻⁴ arises from a statement of the problem in matrix algebra terms, and it is this expression of the equations that permits direct statements of all relevant errors. The present purpose is to set out the method of the derivation of these error statements, to tabulate a number of results and to give an example. In referring to the original reports, equation numbers will be identified by prefix. *e.g.*, 1.5 refers to equation (5) in Ref. 1.

Errors can arise in source data, predetermined quantities, or in experimental measurements. Whenever speciation is either the focus of a study or crucial to an interpretation, the significance or reliability of the results should be assessed by reference to the errors of the estimates. It is therefore somewhat surprising that, given the large amount of work that has been done on solving the equations of equilibrium, recognition of the value of the calculation of errors has arisen only once.⁵ (It is important to distinguish between errors in the values of variables and those of the solution in the

sense of tolerance. The latter can, in principle, be reduced to near zero, limited only by the precision of the machine/language, by sufficient iterations.) Thus, in addition to those reports previously discussed (with the exception of the two mentioned below),¹⁻⁴ accounts of COMPLEX,⁶ MINEQL,⁷ ITERAT,⁸ COM-PLX,⁹ CHEMEQUIL-2,¹⁰ IONPRODUCT,¹¹ and algorithms from Dudley and Coray¹² and Park,¹³ all failed to consider errors. Similarly, three substantial reviews of such programs¹⁴⁻¹⁶ failed to recognise this omission and made no mention of the effect of any errors or of their calculation.

The question seems first to have been mentioned in the context of the program ES4EC as a practical requirement of such calculations,⁵ and expressions were given for the error (variance) in each solution species concentrations due to errors in both 'analytical' concentrations and formation constants. A later implementation¹⁷ only mentions the derivatives of 'free' (independent species, in our terminology^{1,3}) and analytical concentrations with respect to formation constants and analytical concentrations. These derivatives were expressed in terms of summations of individual derivatives, obtained one by one, and as such they were unable to incorporate the covariance terms of the input error data.⁵ This limitation may be serious, but even so, the notation used does not lend itself to a clear visualization of the underlying algebra. It is the present intention to allow clear and full error statements and to provide the basis for more flexible calculations.

NUMERICAL METHOD

There are just three sources of error to be considered in such systems of equations: (1) most obviously in the values of the logarithmic equilibrium constants themselves, L ; (2) in the ('analytical') component totals, T , whether they are errors of analysis, weighing, or dilution; and (3) in the experimentally determined concentrations of species, X_A , as by a specific ion electrode (pH in particular) or any spectroscopic technique (such as n.m.r.). We may thus enquire about $\partial X/\partial L$, $\partial X/\partial T$, $\partial T/\partial X_A|_L$, $\partial X_B/\partial X_A|_T$ and so on, as well as the log(concentration) equivalents where ∂X is replaced by ∂P in the foregoing. We proceed by first introducing the notation to be used.

The vector partial differentiation operator, ∇ , differentiates one vector, $A(a \times 1)$, with respect to another, $B(b \times 1)$, and is to be understood as implying the following form:

$$\nabla(A, B) = \frac{\partial A}{\partial B} = \begin{bmatrix} \frac{\partial A_1}{\partial B_1} & \dots & \frac{\partial A_1}{\partial B_b} \\ \vdots & \ddots & \vdots \\ \frac{\partial A_a}{\partial B_1} & \dots & \frac{\partial A_a}{\partial B_b} \end{bmatrix} \quad (1)$$

where the resulting partial differential matrix is $(a \times b)$. The generalised inverse or matrix reciprocal operator rec is defined by:^{18,19}

$$\text{rec}(A) = (A^T A)^{-1} A^T \quad (2)$$

where A is $(r \times c)$, $r \geq c$, and superscript T means 'transpose' so that

$$\text{rec}(A)A = I \quad (3)$$

Otherwise, with $A(r \times c)$ but $r \leq c$,

$$\text{rec}(A) = A^T(A \cdot A^T)^{-1} \quad (4)$$

$$A \text{rec}(A) = I \quad (5)$$

The rec operator is convenient because, while $\nabla(A, B)$ may be directly obtainable, $\nabla(B, A)$ may not be. It is to be expected that

$$\nabla(A, B)\nabla(B, A) = \frac{\partial A}{\partial B} \frac{\partial B}{\partial A} = I \quad (6)$$

where $\nabla(B, A)$ is $(b \times a)$. This product is defined when $a \leq b$. If $a = b$

$$\nabla(B, A) = \text{rec}(\nabla(A, B)) = \nabla(A, B)^{-1} \quad (7)$$

For convenience, we define the matrix exponential operator \exp such that for A

and B , both $(a \times b)$, $B = \exp(A)$ is to be read as

$$B_{ij} = \exp(A_{ij}), \quad \text{for all } i, j \quad (8)$$

Thus, the vectors of interest now are related, for concentrations, X , by

$$X = \exp(P) \quad (9)$$

and for equilibrium constants, K , by

$$K = \exp(L) \quad (10)$$

[*c.f.* equations (1.5) and (1.4)]. We also use the 'diagonalised vector' matrix, $A^D(a \times a)$, as before,⁴ where

$$A^D = \text{diag}(A) \quad (11)$$

[see equation (4.3)]. Use is then made of identities of the form

$$\begin{aligned} \partial X_i &= \partial \exp(P_i) \\ &= \exp(P_i) \partial P_i \\ &= X_i \partial P_i \end{aligned}$$

so that we may write

$$\partial X = X^D \partial P \quad (12)$$

where the use of the diag operator preserves the element by element multiplication. Similarly, we obtain

$$\partial P = (X^D)^{-1} \partial X \quad (13)$$

The inverses of equations (12) and (13) are also valid, for example allowing us to write

$$\frac{1}{\partial K} = \frac{1}{\partial L} (K^D)^{-1} \quad (14)$$

We give an example of the method by first noting the basic equations. The fundamental expression of the equilibria and the partition which permits solution¹ is:

$$L = CP \quad (15)$$

$$= C_A P_A + C_B P_B \quad (16)$$

where C is the matrix of coefficients.¹ The component sums, S , are obtained from

$$S = M^T X \quad (17)$$

$$= M_A^T X_A + M_B^T X_B \quad (18)$$

where $S \equiv T$ at the exact solution of the entire system of equations, when the charge error $\Delta = 0$ [equation (2.13)], and where M_A , M_B and M are defined at equations (3.9)–(3.11). [S is now written as a vector, for uniformity of style, see equation (1.12)].

We have immediately from equation (15)

$$\frac{\partial \mathbf{L}}{\partial \mathbf{P}} = \mathbf{C} \frac{\partial \mathbf{P}}{\partial \mathbf{P}} = \mathbf{C} \quad (19)$$

as $\partial \mathbf{P} / \partial \mathbf{P} = \mathbf{I}$ by definition. It then follows by virtue of equation (4) that

$$\frac{\partial \mathbf{P}}{\partial \mathbf{L}} = \text{rec}(\mathbf{C}) \quad (20)$$

This is a result of some interest in that the full effects of errors in all equilibrium constants may be determined directly, and including their interactions, although without regard to maintaining sums. Equally, from equation (17) we have

$$\frac{\partial \mathbf{X}}{\partial \mathbf{S}} = \text{rec}(\mathbf{M}^T) \quad (21)$$

which shows the effect of component concentration changes, albeit without maintaining equilibrium through \mathbf{L} .

The partition of equation (16) yields

$$\frac{\partial \mathbf{L}}{\partial \mathbf{P}_A} = \mathbf{C}_A \frac{\partial \mathbf{P}_A}{\partial \mathbf{P}_A} + \mathbf{C}_B \frac{\partial \mathbf{P}_B}{\partial \mathbf{P}_A} \quad (22)$$

so that fixing \mathbf{P}_B we get

$$\left. \frac{\partial \mathbf{L}}{\partial \mathbf{P}_A} \right|_{\mathbf{P}_B} = \mathbf{C}_A \quad (23)$$

and likewise

$$\left. \frac{\partial \mathbf{P}_A}{\partial \mathbf{L}} \right|_{\mathbf{P}_B} = \text{rec}(\mathbf{C}_A) \quad (24)$$

This approach may be followed for the remaining differentials derived, as appropriate, from either equation (16) or (18). Indeed, it follows that any other partition of equation (15) or (17) may be used as needed; the particular advantage of the generalized inverse is then apparent. However, care must be taken in algebraic manipulation since only one of equations (2) and (4) can be valid if $r \neq c$, and no valid direct inversion of an expression may be possible, hence, another route must be sought.

To take the process a stage further, it must be recognised that there are effectively four vector variables: \mathbf{L} , \mathbf{S} , \mathbf{P}_A , \mathbf{P}_B (or their cognate non-logarithmic equivalents). The purpose now is to construct a set of partial differential equations which take one such vector as being fixed and require information from equations (15) and (17). It may be noted that fixing two such vectors, equivalent to the constraint of charge balance [equation (1.10) or (2.13)],

sets all $\nabla(\mathbf{A}, \mathbf{B})|_{c,d} = 0$, as the system is then fully defined. In a sense, charge balance is the one degree of freedom which is allowed in developing the following results, and this operates in the one unreferenced concentration vector.

Then, equation (18) can be rearranged and expressed as:

$$\exp(\mathbf{P}_A) = \mathbf{S} - \mathbf{M}_B^T \exp(\mathbf{P}_B) \quad (25)$$

dropping $\mathbf{M}_A^T = \mathbf{I}$ [equation (3.11)]. Then

$$\frac{\partial \exp(\mathbf{P}_A)}{\partial \mathbf{L}} = \frac{\partial \mathbf{S}}{\partial \mathbf{L}} - \mathbf{M}_B^T \frac{\partial \exp(\mathbf{P}_B)}{\partial \mathbf{L}} \quad (26)$$

Holding \mathbf{S} constant and expanding [equation (12)]:

$$\mathbf{X}_A^D \left. \frac{\partial \mathbf{P}_A}{\partial \mathbf{L}} \right|_S = -\mathbf{M}_B^T \mathbf{X}_B^D \left. \frac{\partial \mathbf{P}_B}{\partial \mathbf{L}} \right|_S \quad (27)$$

$$\left. \frac{\partial \mathbf{P}_A}{\partial \mathbf{L}} \right|_S = -(\mathbf{X}_A^D)^{-1} \mathbf{M}_B^T \mathbf{X}_B^D \left. \frac{\partial \mathbf{P}_B}{\partial \mathbf{L}} \right|_S \quad (28)$$

From equation (16)

$$\frac{\partial \mathbf{P}_B}{\partial \mathbf{L}} = \mathbf{C}_B^{-1} \left(\frac{\partial \mathbf{L}}{\partial \mathbf{L}} - \mathbf{C}_A \frac{\partial \mathbf{P}_A}{\partial \mathbf{L}} \right) \quad (29)$$

so that substitution from equation (28) gives

$$\left. \frac{\partial \mathbf{P}_B}{\partial \mathbf{L}} \right|_S = \mathbf{C}_B^{-1} \mathbf{I} + \mathbf{C}_B^{-1} \mathbf{C}_A (\mathbf{X}_A^D)^{-1} \mathbf{M}_B^T \mathbf{X}_B^D \left. \frac{\partial \mathbf{P}_B}{\partial \mathbf{L}} \right|_S \quad (30)$$

$$= \mathbf{C}_B^{-1} - \mathbf{M}_B (\mathbf{X}_A^D)^{-1} \mathbf{M}_B^T \mathbf{X}_B^D \left. \frac{\partial \mathbf{P}_B}{\partial \mathbf{L}} \right|_S \quad (31)$$

$$= \mathbf{C}_B^{-1} [\mathbf{I} + \mathbf{M}_B (\mathbf{X}_A^D)^{-1} \mathbf{M}_B^T \mathbf{X}_B^D]^{-1} \quad (32)$$

Then, using the results of identities (12) and (14), the following related result can be written down immediately:

$$\left. \frac{\partial \mathbf{X}_B}{\partial \mathbf{K}} \right|_S = \mathbf{X}_B^D \mathbf{C}_B^{-1} [\mathbf{I} + \mathbf{M}_B (\mathbf{X}_A^D)^{-1} \mathbf{M}_B^T \mathbf{X}_B^D]^{-1} (\mathbf{K}^D)^{-1} \quad (33)$$

In view of the ease of writing down any of the non-logarithmic forms, as exemplified by equation (33), and as the reciprocal differentials are obtained directly by the use of the *rec* operator given at equations (2) and (4), only the basic twelve results of Table 1 need be tabulated for any other result to be readily obtained. Even so, care is required in applying the transformations since the *rec* operator is subject to rules

Table 1. Summary of principal results. Equations (1) and (2) are derived from text equations (15) and (17) respectively, (3)–(5) from text equation (16), (6)–(8) from text equation (18); and (9)–(14) from text equations (16) and (18) combined. For explanation of the notation, see text

$\nabla(\mathbf{P}, \mathbf{L}) = \text{rec}(\mathbf{C})$	(1)
$\nabla(\mathbf{P}, \mathbf{S}) = \text{rec}(\mathbf{M}^T \mathbf{X}^D)$	(2)
$\nabla(\mathbf{P}_A, \mathbf{L}) _{\mathbf{P}_B} = \text{rec}(\mathbf{C}_A)$	(3)
$\nabla(\mathbf{P}_B, \mathbf{L}) _{\mathbf{P}_A} = \mathbf{C}_B^{-1}$	(4)
$\nabla(\mathbf{P}_B, \mathbf{P}_A) _{\mathbf{L}} = \mathbf{M}_B$	(5)
$\nabla(\mathbf{P}_A, \mathbf{S}) _{\mathbf{P}_B} = (\mathbf{X}_A^D)^{-1}$	(6)
$\nabla(\mathbf{P}_B, \mathbf{S}) _{\mathbf{P}_A} = \text{rec}(\mathbf{M}_B^T \mathbf{X}_B^D)$	(7)
$\nabla(\mathbf{P}_A, \mathbf{P}_B) _{\mathbf{S}} = -(\mathbf{X}_A^D)^{-1} \mathbf{M}_B^T \mathbf{X}_B^D$	(8)
$\nabla(\mathbf{P}_A, \mathbf{L}) _{\mathbf{S}} = -(\mathbf{M}^T \mathbf{X}^D \mathbf{M})^{-1} \mathbf{M}_B^T \mathbf{X}_B^D \mathbf{C}_B^{-1}$	(9)
$\nabla(\mathbf{P}_B, \mathbf{L}) _{\mathbf{S}} = [\mathbf{I} + \mathbf{M}_B (\mathbf{X}_A^D)^{-1} \mathbf{M}_B^T \mathbf{X}_B^D]^{-1} \mathbf{C}_B^{-1}$	(10)
$\nabla(\mathbf{S}, \mathbf{L}) _{\mathbf{P}_A} = \mathbf{M}_B^T \mathbf{X}_B^D \mathbf{C}_B^{-1}$	(11)
$\nabla(\mathbf{S}, \mathbf{L}) _{\mathbf{P}_B} = \mathbf{X}_A^D \text{rec}(\mathbf{C}_A)$	(12)
$\nabla(\mathbf{S}, \mathbf{P}_A) _{\mathbf{L}} = \mathbf{M}^T \mathbf{X}^D \mathbf{M}$	(13)
$\nabla(\mathbf{S}, \mathbf{P}_B) _{\mathbf{L}} = -\mathbf{X}_A^D \text{rec}(\mathbf{C}_A) \mathbf{C}_B + \mathbf{M}_B^T \mathbf{X}_B^D$	(14)

of precedence. Thus, for $\mathbf{A}(r \times c)$, $\mathbf{B}(c \times c)$, the following is valid:

$$\text{rec}(\mathbf{AB}) = \mathbf{B}^{-1} \text{rec}(\mathbf{A}), \quad r \geq c \quad (34)$$

and for $\mathbf{A}(r \times c)$, $\mathbf{B}(r \times r)$,

$$\text{rec}(\mathbf{BA}) = \text{rec}(\mathbf{A})\mathbf{B}^{-1}, \quad r \leq c \quad (35)$$

whereas the left hand side of neither equation (34) with $r \leq c$, nor equation (35) with $r \geq c$, has a valid simple equivalent. It is necessary therefore to apply the logarithmic/exponential transformation before the overall inverse is taken.

The results of Table 1 may be converted to the corresponding forms in \mathbf{L}' and \mathbf{C}'_A [equations (3.4)–(3.9)] simply by symbol substitution, noting only that $\mathbf{C}'_B = \mathbf{I}$.

In passing, it may be noted that equation (13) of Table 1, and its non-logarithmic equivalent, are the bases of the Newton–Raphson approaches to the solution of an equilibrium system discussed at equations (4.1) and (4.2).

It only remains to apply the above results to the determination of errors. If we are given the errors in the vector with respect to which the differentiation has been done in the form of the covariance matrix $\sigma^2(\mathbf{B})$, which is $(b \times b)$, the errors in the dependent vector $\sigma^2(\mathbf{A})$, $(a \times a)$, are given directly by the following law of propagation of errors:¹⁹

$$\sigma^2(\mathbf{A}) = \nabla(\mathbf{A}, \mathbf{B})\sigma^2(\mathbf{B})\nabla(\mathbf{A}, \mathbf{B})^T \quad (36)$$

The additivity of variance is also valid for error propagation:

$$\sigma^2(\mathbf{A}) = \sigma^2(\mathbf{B}) + \sigma^2(\mathbf{C}) + \sigma^2(\mathbf{D}) \dots \quad (37)$$

so long as all σ^2 are of the same size and those on the right hand side are mutually independent. We can therefore construct an augmented differential matrix, for example

$$\frac{\partial \mathbf{P}}{\partial (\mathbf{L}|\mathbf{S})} = [\nabla(\mathbf{P}, \mathbf{L})|\nabla(\mathbf{P}, \mathbf{S})] \quad (38)$$

and use this with the augmented error matrix

$$\sigma^2(\mathbf{L}, \mathbf{S}) = \begin{bmatrix} \sigma^2(\mathbf{L}) & \phi \\ \phi & \sigma^2(\mathbf{S}) \end{bmatrix} \quad (39)$$

But combining equations (38) and (39) according to equation (36) is equivalent to writing

$$\sigma^2(\mathbf{P}) = \nabla(\mathbf{P}, \mathbf{L})\sigma^2(\mathbf{L})\nabla(\mathbf{P}, \mathbf{L})^T + \nabla(\mathbf{P}, \mathbf{S})\sigma^2(\mathbf{S})\nabla(\mathbf{P}, \mathbf{S})^T \quad (40)$$

Thus, in computational terms, the augmented matrices at equations (38) and (39) do not actually need to be constructed in computer memory as such so long as the off-diagonal submatrices are null.

EXAMPLE

A simple example will suffice to illustrate the implementation of the above results: phosphoric acid in water. The non-logarithmic equivalent of equation (38) will be solved. The basic data for this system has already been given,³ but we now have to choose to consider a concentration of $10^{-5}M$ $[\text{PO}_4]$ which is almost pH 5. So, given

$$\mathbf{X} = \begin{bmatrix} \text{PO}_4^{3-} \\ \text{H}^+ \\ \text{OH}^- \\ \text{H}_2\text{PO}_4^- \\ \text{HPO}_4^{2-} \\ \text{H}_3\text{PO}_4 \end{bmatrix} = \begin{bmatrix} 2.93\text{E}-15 \\ 1.00\text{E}-5 \\ 1.01\text{E}-9 \\ 9.92\text{E}-6 \\ 6.23\text{E}-8 \\ 1.41\text{E}-8 \end{bmatrix}$$

$$\mathbf{K} = \begin{bmatrix} 4.73\text{E}-13 \\ 6.31\text{E}-8 \\ 1.012\text{E}-14 \\ 7.10\text{E}-3 \end{bmatrix}$$

$$\mathbf{C} = \begin{bmatrix} 1 & 1 & 0 & 0 & -1 & 0 \\ 0 & 1 & 0 & -1 & 1 & 0 \\ 0 & 1 & 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 1 & 0 & -1 \end{bmatrix}$$

we obtain the following results:

$$\mathbf{V}(\mathbf{X}, \mathbf{K}) = \text{rec}[\mathbf{K}^D \mathbf{C}(\mathbf{X}^D)^{-1}] = \begin{bmatrix} 6.20\text{E}-3 & 4.65\text{E}-8 & -5.82\text{E}-9 & -7.93\text{E}-19 \\ 3.62\text{E}-12 & 6.12\text{E}-3 & 9.97\text{E}+0 & 2.79\text{E}-9 \\ -3.62\text{E}-16 & -6.13\text{E}-7 & 9.95\text{E}+4 & -2.79\text{E}-13 \\ -1.83\text{E}-12 & -6.20\text{E}-3 & 3.68\text{E}-4 & 2.82\text{E}-9 \\ -3.39\text{E}-14 & 9.87\text{E}-1 & -6.18\text{E}-2 & 4.41\text{E}-13 \\ 2.47\text{E}-15 & -2.19\text{E}-7 & 1.40\text{E}-2 & -1.99\text{E}-6 \end{bmatrix}$$

$$\mathbf{V}(\mathbf{X}, \mathbf{S}) = \text{rec}(\mathbf{M}^T) = \begin{bmatrix} 5.71\text{E}-1 & -2.14\text{E}-1 \\ -2.14\text{E}-1 & 1.43\text{E}-1 \\ 2.14\text{E}-1 & -1.43\text{E}-1 \\ 1.43\text{E}-1 & 7.14\text{E}-2 \\ 3.57\text{E}-1 & -7.14\text{E}-2 \\ -7.14\text{E}-2 & 2.14\text{E}-1 \end{bmatrix}$$

Then

$$\mathbf{V}(\mathbf{X}, \mathbf{L} | \mathbf{S}) = [\mathbf{V}(\mathbf{X}, \mathbf{K}) | \mathbf{V}(\mathbf{X}, \mathbf{S})]$$

In the absence of actual data, only guesses can be made at error values. So taking the standard deviations of the values of \mathbf{K} to be ± 1 least significant digit, and arbitrary correlations between them with $r = \pm 0.75$; standard deviations of \mathbf{S} are assumed to be 1% of the total, and the correlations $r = -0.20$. The input covariance matrix is then:

$$\sigma^2(\mathbf{L}, \mathbf{S}) =$$

$$\begin{bmatrix} 1.00\text{E}-30 & -7.50\text{E}-26 & 7.50\text{E}-33 & -7.50\text{E}-21 & 0 & 0 \\ -7.50\text{E}-26 & 1.00\text{E}-20 & -7.50\text{E}-28 & 7.50\text{E}-16 & 0 & 0 \\ 7.50\text{E}-33 & -7.50\text{E}-28 & 1.00\text{E}-34 & -7.5\text{E}-45 & 0 & 0 \\ -7.50\text{E}-21 & -7.50\text{E}-16 & -7.50\text{E}-45 & 1.00\text{E}-10 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1.00\text{E}-14 & -2.00\text{E}-15 \\ 0 & 0 & 0 & 0 & -2.00\text{E}-15 & 1.00\text{E}-14 \end{bmatrix}$$

So that

$$\sigma^2(\mathbf{X}) = \mathbf{V}(\mathbf{X}, \mathbf{L} | \mathbf{S}) \sigma^2(\mathbf{L}, \mathbf{S}) \mathbf{V}(\mathbf{X}, \mathbf{L} | \mathbf{S})^T =$$

$$\begin{bmatrix} 4.21\text{E}-15 & -1.79\text{E}-15 & 1.79\text{E}-15 & 6.43\text{E}-16 & 2.43\text{E}-15 & -1.14\text{E}-15 \\ -1.79\text{E}-15 & 7.86\text{E}-16 & -7.86\text{E}-16 & -2.14\text{E}-16 & -1.10\text{E}-15 & 5.71\text{E}-16 \\ 1.79\text{E}-15 & -7.86\text{E}-16 & 7.86\text{E}-16 & 2.14\text{E}-16 & 1.10\text{E}-15 & -5.71\text{E}-16 \\ 6.43\text{E}-16 & -2.14\text{E}-16 & 2.14\text{E}-16 & 2.14\text{E}-16 & 4.29\text{E}-16 & 8.69\text{E}-24 \\ 2.43\text{E}-15 & -1.10\text{E}-15 & 1.10\text{E}-15 & 4.29\text{E}-16 & 1.43\text{E}-15 & -5.71\text{E}-16 \\ -1.14\text{E}-15 & 5.71\text{E}-16 & -5.71\text{E}-16 & 8.69\text{E}-24 & -5.71\text{E}-16 & 5.71\text{E}-16 \end{bmatrix}$$

DISCUSSION

Although the example given above is artificial, in that the errors in S were deliberately large, it illustrates a point which may, in the absence of such a calculation, pass unnoticed. The calculated standard error of the concentration of the ion PO_4^{3-} is, from the first element of $\sigma^2(\mathbf{X})$, about $6.5\text{E}-8$, rather larger than the calculated concentration itself, the first value of \mathbf{X} . Essentially, the interpretation must be that the sensitivity of the concentration of PO_4^{3-} is so great that nothing can usefully be said about its value in the face of the input uncertainties. The interpretation would perhaps be easier if the calculation were of errors in $\log(\text{concentration})$, when potentially negative concentrations would not be implied, but rather, a large range in the power of ten multiplier. Nevertheless, the danger in basing conclusions on such a calculated concentration is plain: the input data is simply too imprecise.

The relative errors in the means, $\sigma(\mathbf{X}_i)/\mathbf{X}_i$, should therefore be inspected as a matter of course for those species of primary interest in order to determine whether or not confidence can be placed in the results of the speciation calculation. In the reverse sense, such calculations can be used to estimate the precision necessary in analytical concentrations S or in equilibrium constants, \mathbf{K} or \mathbf{L} , to achieve the desired accuracy in a calculated concentration. Indeed, this would enable the feasibility or cost of such knowledge to be calculated. The economic implications of this in areas such as toxicology or pollution control have yet to be considered.

One other point to which attention should be drawn is that even if errors in the input variables are Normally distributed (Gaussian), in general those in the dependent variables will not be. This does not in any way affect the validity of the errors so calculated, but it must be taken as a warning that statistical tests or the calculation of confidence intervals (which rely on the tails of assumed distributions) must be approached with extreme caution. The effects of curvature in the functions being differentiated may be serious if the errors are large but, equally, small errors will tend to approach normality.

The identification of the procedure for the expression of the differential equations of equilibrium systems has made possible more rigorous error statements in respect of any of the quantities of interest. It has not been the pur-

pose here to be exhaustive in the treatment as the number of possibilities is very large indeed and error statements must be tailored to the particular task in hand. For example, second (and higher) differentials, where they exist, can clearly be derived in analogous fashion. It is the particular power of the matrix notation that such statements are possible in succinct and computationally convenient form. They can be used no matter which speciation program was employed.

It can be anticipated that the routine calculation of covariance matrices for calculated values in experimental systems will lead to new insights into the influence of some variables and the avoidance of spurious precision in reported results.

SIMULTANEOUS FLOW-INJECTION ANALYSIS OF THREE COMPONENTS WITH ON-LINE DIALYZERS IN SERIES. DETERMINATION OF SODIUM, POTASSIUM AND CHLORIDE IN BLOOD SERUM

JACOBUS F. VAN STADEN

Department of Chemistry, University of Pretoria, Pretoria 0002, South Africa

(Received 15 September 1990 Revised 22 February 1991 Accepted 6 March 1991)

Summary—A fast and reliable fully automated three-component flow-injection procedure for the simultaneous determination of sodium, potassium and chloride in blood serum is described. A single sample injection (100- μ l blood serum) is directed to two different channels by using two dialyzers in series. To avoid interferences and blocking of the fine jet of the atomizer, sodium and potassium are dialyzed by the first dialyzer before measurement by AES with a flame photometer. A second dialyzer in series is used to eliminate interferences and for automated dilution before the dialyzed chloride is measured by UV/VIS spectrophotometry at 485 nm. The results obtained for the sodium, potassium and chloride in blood serum at a sampling rate of 106 samples per hour compared well with data obtained by standard methods.

The large number of electrolyte determinations carried out in the clinical laboratory necessitated an efficient procedure which would reduce the time taken for these determinations. To supply needed data effectively and quickly, it would be an advantage to have a rapid, accurate and reliable method available for the simultaneous determination of sodium, potassium and chloride in blood serum. Conventional automated segmented continuous-flow analysis utilizes sampling rates of up to 60 samples per hour.

The concept of flow-injection analysis (FIA) is now a well defined analytical technique¹⁻⁴ which is suitable to increase the output in some laboratories. Most FIA procedures are however based on the measurement of a single signal of a product formed from a single sample injection which usually involves the determination of a single element or compound carried out on a batch of samples. It is however possible to carry out several measurements from a single sample injection in a FIA system. Simultaneous (or multicomponent) FIA determinations where two or more species are determined in the same sample with a single FIA system, is a relatively unexplored area.² This novel methodology has, however, a great potential in fields such as clinical laboratories where limited numbers of samples are involved.

The concept of mass transfer in on-line analytical dialyzers has been applied in continuous flow systems with suitable membranes for many

years especially in the area of clinical analysis. The use of on-line dialysis in segmented continuous flow systems was probably first described by Skeggs⁵ in his pioneering famous paper in 1957 on automated analysis. Continuous flow dialysis without air segmentation for the determination of glucose was reported in the mid-1960s by Kadish and Hall⁶ and Brown *et al.*⁷ Hansen and Růžička⁸ were the first to exploit this principle in flow-injection analysis in the mid-seventies when applying the technique to the determination of phosphate and chloride in blood serum. The incorporation of flow-through dialyzers as part of the manifold in FIA systems is, however, extremely useful for on-line determination of analytes in biological systems, for example blood serum. van Staden and van Rensburg⁹ studied and compared a number of variables for different semi-permeable dialysis membranes and dialyzers with different dimensions for the determination of inorganic species (Ca^{2+} and Cl^-). A dialyzer as part of the manifold system not only facilitates automated dilution, but the main aim of dialysis so far was to remove interferences like suspended solids, unwanted macromolecules (for example protein) *etc.*, present in the sample channel, by separation from a detector channel where the analyte was detected. To date, dialysis has mainly been used for determination of a single element or compound from a single sample injection. However, it is possible to use dialysis for the simultaneous determination of more than one

component. The main aim is to enable multi-component analysis of a limited amount of blood serum sample with a single sample injection rapidly, accurately and precisely with an on-line dialysis procedure which is also in the working concentration range of all the components involved.

This paper deals with the development of a FIA procedure for the simultaneous determination of sodium, potassium and chloride in blood serum on a single sample injection where two dialyzers were used in series and the dialyzed components were detected with a flame photometer and UV/VIS spectrophotometer.

EXPERIMENTAL

Apparatus

A Carle micro-volume two-position sampling valve with two identical sample loops, each having a volume of 100 μ l, was used with the FIA system together with a Cenco sampler. The valve was operated as follows: samples were aspirated through the valve on a 34-sec cycle. In the first of the two valve positions, the sample was aspirated through loop A to waste, whilst loop B was connected to the carrier stream. On switching to the second position (which was done after 32 sec of the 34-sec cycle) the carrier stream was interrupted and the contents of loop A placed into the carrier stream with loop B now being filled with the next sample from the sample

unit and so on. In this way 100- μ l samples were injected at a rate of one every 34 sec giving an optimum sampling rate of 106 samples per hour. The valve system was synchronized with the operation of the sampler unit, the sampling valve being actuated 32 sec after movement of the sampler probe to the next sample. Carrier, recipient and reagent streams were supplied at constant flow rates with a peristaltic pump operating at 10 rpm. Sodium and potassium were detected with an IL143 flame photometer. Chloride was detected by using UV/VIS spectrophotometric detection with a colour reagent solution, containing mercury(II) thiocyanate and iron(III) nitrate in an aqueous methanolic nitric acid solution, measuring the complex formed at 485 nm. A Bausch and Lomb Spectronic 21 (Rochester, New York) spectrophotometer with a 10-mm Hellma type flow-through cell (volume 80 μ l) was used. The outputs from the different detectors were recorded by a Hitachi Model QPD 53 for sodium, Hitachi Model QPD 54 for potassium and Mettler GA 12 for chloride. Transmission tubing with inner diameters of 0.38 and 0.50 mm (Fig. 1) were used in the flow system. Two slightly modified versions of 12 and 6-inch Technicon AutoAnalyzer II dialyzer units with different dimensions were used. The first dialyzer A consisted of a 160 \times 30 \times 25 module (home-made as a modified version of a 12" Technicon dialyzer) and the second dialyzer B of a 90 \times 30 \times 25 module (home-made as a

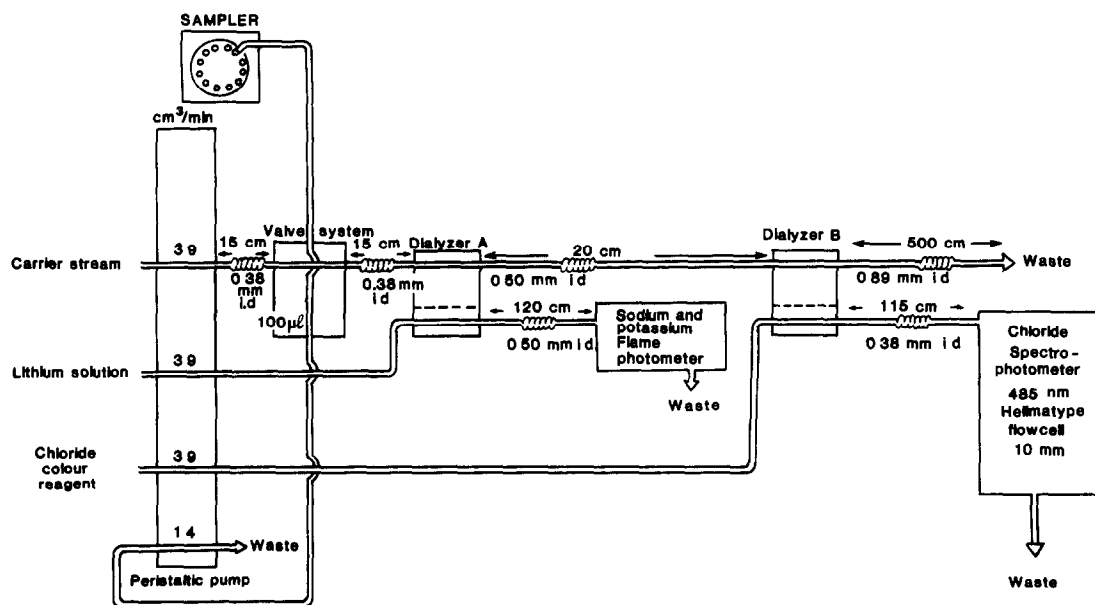

Fig. 1. Flow diagram of the FIA-system for the simultaneous determination of sodium, potassium and chloride. Valve loop size = 100 μ l; sampler = 34 sec; wash = 0 sec; valve actuation at 32 sec; sampling rate = 106 samples per hour. Tube length and i.d. are given in cm and mm respectively

modified version of a 6" Technicon dialyzer). The donor and acceptor channels of both dialyzers consisted of straight semi-tubular grooves with an i.d. of 0.5 mm (*i.e.*, 0.5 mm wide and 0.5 mm deep) and with a distance (width) of 15 mm between the entrance and exit sides of a channel. The path lengths of dialyzer A were 300 mm and of dialyzer B were 150 mm for the donor and acceptor channels of both units respectively. Both dialysis units were equipped with Technicon Pre-mount Dialysis Membranes Type "C".

Reagents

All solutions were prepared from analytical reagent grade chemicals unless otherwise specified. Doubly distilled, demineralized water was used throughout. The water was tested beforehand for traces of chloride. All reagents were degassed before measurement with a vacuum pump.

Carrier stream. Concentrated nitric acid (20 ml, specific gravity = 1.42) (Merck, Darmstadt, Germany) was diluted to 1 litre with water.

Lithium solution. A working solution of 15mM lithium was prepared by dilution of an appropriate aliquot of 1.5M lithium standard stock solution (Instrumentation Laboratory Inc. reagent, Lexington, Massachusetts) with water.

Chloride colour reagent. Mercury(II) thiocyanate (2.4 g) (Merck) was dissolved in 1 litre of distilled water to give a saturated solution which was then filtered. Iron(III) nitrate (7.6 g) (Merck) was dissolved in 5 ml of concentrated nitric acid (Merck, specific gravity = 1.42), 37.5 ml of methanol (Merck) and 0.21–0.22 ml of a solution [containing 68.5 g of mercury(II) nitrate and 10 ml of concentrated nitric acid (specific gravity = 1.42) per litre of water] were added into 250 ml of the saturated filtered mercury(II) thiocyanate solution. This solution should be left overnight to stabilize.

Standard stock solutions

Dried sodium chloride (58.5000 g) (Merck, Darmstadt, Germany) was dissolved in 1 litre of distilled water. Dried potassium chloride (7.4600 g) (Merck, Darmstadt, Germany) was dissolved in 1 litre of distilled water. Anhydrous sodium carbonate (21.2000) (Merck, Darmstadt, Germany) was dissolved in 1 litre of distilled water. Ammonium chloride (53.5000 g) (Merck, Darmstadt, Germany) was dissolved in 1 litre of distilled water.

Standard working solutions

Standard working solutions (each solution containing sodium, potassium and chloride) were prepared by dilution of appropriate aliquots of the standard stock solutions to 100 ml with distilled water to cover the ranges 110–160mM Na⁺, 2–7mM K⁺ and 82–122mM Cl⁻.

RESULTS AND DISCUSSION

A schematic flow diagram of the system used for the simultaneous determination of sodium, potassium and chloride is shown in Fig. 1. As can be seen, the manifold consists of Tygon tubing with tube lengths and inside diameters. The tubing was cut into the required lengths and wound around glass tubes of length 10 cm and width 1 cm. Two on-line dialyzers were incorporated in series into the FIA manifold, separating and channeling the sample plug from a single sample injection via two different channels to the different detectors. The sample plug from the single sample injection was transported to the donor channel of the first dialyzer A where the sodium and potassium were dialyzed to the detector channel for measurement of sodium and potassium by AES with a flame photometer. In this way any interferences as well as blocking of the fine jet of the atomizer were avoided and the sample plug was automatically diluted. The undialyzed plug moved to the second dialyzer B where chloride was dialyzed to eliminate interferences and for automated dilution before detection by UV/VIS spectrophotometry at 485 nm.

With two-cell instruments like the IL143 flame photometer internal standards are often used as a diluting fluid. The diluting fluid contains a suitable metal which is not present in the specimen; lithium is usually chosen. Collected radiation from the flame is directed to photo-sensitive detectors. One detector monitors the sample line (Na or K) and the other the internal Li standard. The photoconductive cells are matched to give proportionally the same change in response to variations in illumination as well as minor variations in gas pressure and spraying. In the proposed flow-injection system the dialysed diluted sample was mixed with standard Li solution from the acceptor stream for Na and K from where it served as an internal standard for the assay of these two species. Univariant optimization indicated that an amount of 15mM lithium at a flow-rate of 3.9 ml/min in the

acceptor stream of dialyzer A was sufficient enough to give a steady photometer output with the required sensitivity for both Na and K in the concentration ranges wanted.

The main aim of this paper was to develop a multicomponent FIA-procedure for the simultaneous determination of sodium, potassium and chloride in blood plasma where a limited amount of sample was available for a single sample injection. To achieve this goal the on-line dialysis FIA-procedure should be applicable in the normal working concentration range of all three species involved to obviate any manual dilution steps. The plasma of normal persons contains about 137–148mM sodium, about 3.9–5.0mM potassium and about 99–108mM chloride. These concentration ranges of sodium, potassium and chloride in blood plasma limited the working range of some of the different operational parameters, such as sample volume, in a multicomponent FIA-serum assay to a certain extent. These factors had to be kept in mind when the actual optimization was performed. Of the various methods of optimization: the univariate, multivariate or simplex optimization, the univariate search (where each variable was optimized, while the others were kept constant) was used because it was more convenient to vary some of the variables in fixed increments. In the proposed multicomponent FIA-procedure it was preferable to distinguish between sample volume optimization and optimization of dialysis efficiency although these two parameters seemed to be mutually interdependent to a certain extent.

The efficiency of on-line continuous dialysis between different dialyzer dimensions and of the different membrane types have been evaluated previously.⁹ van Staden and van Rensburg⁹ studied various factors including flow-injection analysis and continuous flow; the use of concurrent and countercurrent flows between the donor and acceptor streams; concentration of analyte in the donor stream; membrane surface; membrane line-length (dialysis area); membrane porosity; membrane thickness; flow-rate dependence of dialysis (same flow-rates of donor and acceptor streams); flow-rate dependence of dialysis (differences in flow-rates of donor and acceptor streams) and temperature.

The required concentration ranges for sodium, potassium and chloride in the simultaneous determination of all three species placed a restriction in the percentage dialysis necessary for the proposed FIA-system. Keeping this in mind the results obtained in this study revealed that

the Technicon type C membranes were the best suitable for the proposed multicomponent FIA-procedure. Investigation in the present work with the FIA-manifold system shown in Fig. 1, proved that the dialysis efficiency in the present case differed only slightly from the results previously⁹ reported. A percentage dialysis of 2.8% for dialyzer A (membrane pathlength, 300 mm) and 1.4% for dialyzer B (membrane pathlength, 150 mm) were obtained with flow-rates of 3.9 ml/min in the donor and acceptor streams.

A smaller dispersion,⁵ shorter equilibrium time⁹ and higher precision⁹ in a long dialyzer were reported with concurrent flow than with countercurrent flow and as this was confirmed in this study, concurrent flow was preferred in the proposed system.

It was also clear from the results obtained that optimum precise mass transfer of sodium and potassium for the first dialyzer and chloride for the second dialyzer through the semi-permeable Technicon Type C membranes were possible when the same carrier and recipient flow-rates were used in both cases. This ensured that the dialysis process did not alter the geometry of the sample injected, but that the dialysates form identical diluted protein free plugs on the recipient sides of the membranes. Flow-rates of 3.9 ml/min were used for the donor and recipient streams to ensure that an optimum sample

throughput of about 106 samples per hour per determination (that is about 318 measurements for all three components) was still possible and that the correct amounts of sodium, potassium and chloride were dialyzed for determination. The above-mentioned experimental flow-rate conditions used, also tended to equalize diffusion

rates between samples and standards. This is all confirmed by the results shown in Tables 1-3.

The chloride colour reagent used in the recipient stream was prepared in nitric acid as part of the reagent because in an univariant search it was found that a concentration of 0.3M nitric acid in the carrier stream gave the best results (accuracy and precision) for chloride.

In the optimization of sample volume with the univariant search method, peak height (as sensitivity measurement) and linearity of all three species (sodium, potassium and chloride) within the normal concentration range in serum were chosen as factors to be maximized. The results revealed that a sample volume of 100 μ l gave optimum performance when both sensitivity and linearity of all three species were considered. After completing the whole optimization procedure, it was clear that the main objectives were achieved and Figs. 2, 3 and 4 show that the proposed FIA-procedure is applicable in the normal working concentration range of all three species involved.

No fouling problems were experienced with any of the dialyses used which is possibly due to the nature of the samples. This was also attributed to the small amount of blood serum samples injected and the procedure of pumping doubly distilled water for about 15 min through both channels of the two membranes during the shutdown period of the FIA system used.

Figures 2, 3 and 4 show representative recorder outputs at an optimum sampling rate of about 106 samples per hour for sodium, potassium and chloride, respectively. Carry-over from one sample to another is less than 1% for every one of the three components measured. Each standard was injected four times followed by single injections of samples and completed by four injections of each standard to control drift. Baseline drift was virtually negligible for sodium, potassium and chloride. The calibration curves (Figs. 2 and 3) for sodium and potassium were linear over the whole working concentration range which indicated that the procedure is also applicable for the determination of concentrations of both species outside the normal concentration range especially in the case of serum sodium values which could fall due to chronic diseases. This is indicated in Fig. 2 by some peaks which lie below the indicated standard sodium value of 120mM. The chloride calibration curve tended to deviate from linearity at the chloride value of 114mM which is the normal case for high chloride concentrations where the

Concentrations of standard chloride solutions given as mM above peaks.

spectrophotometric procedure with mercury(II) thiocyanate and iron(III) nitrate as reagents is used. At lower chloride concentrations, however, the curve becomes more linear and could be used where the chloride concentration range falls below the normal range. This is indicated in Fig. 4 where some peaks lie very well below the indicated chloride value of $82mM$.

The performance of the proposed flow-injection analysis method is shown in Tables 1, 2 and 3 for sodium, potassium and chloride respectively. The values obtained for the three species by the proposed FIA system were also compared with standard methods. The proposed FIA-method compares favourably with a standard automated flame photometric procedure¹⁰ for sodium and potassium and also with a standard chloridometer method¹¹ for chloride as seen from the Tables. Standard control blood serum samples were also used to evaluate the accuracy of the proposed FIA-system. The control samples were interposed at random between the blood serum samples. The results obtained in Tables 1, 2 and 3 for sodium, potassium and chloride compares favourably with the certified values of the control samples. The precision of the proposed method was evaluated by 15 tests on each sample where each sample was analyzed respectively for sodium, potassium and chloride by the proposed FIA-system. With $100\text{-}\mu\text{l}$ samples the relative standard deviation for blood serum samples having different concentrations of sodium ($125\text{--}150mM$), potassium ($2.0\text{--}6.0mM$) and chloride ($80\text{--}110mM$) were better than 1.0% for sodium, 1.0% for potassium and 0.7% for chloride respectively.

CONCLUSION

It seems that the incorporation of flow-through dialyzers as part of the manifold in FIA-systems is extremely useful for on-line simultaneous determination of sodium, potassium and chloride in blood serum. The flow-injection analysis system described here is suitable to carry out simultaneous analysis of sodium, potassium and chloride at a rate of approximately 106 samples per hour. The proposed method should be particularly attractive to small clinical laboratories where a fast and reliable fully automated procedure is needed.

(Received 4 April 1989 Revised 19 November 1990 Accepted 5 February 1991)

Summary—Catechol and *o*-nitrophenol have been determined successfully in the solid state by means of their solid-state reaction with soda-lime. The glass-wool plug modification has been used with advantage in the determination of *o*-nitrophenol. The reaction mechanism is postulated on the basis of the reflectance electronic spectra. Some solid–solid kinetic parameters have also been studied.

Phenols are important compounds both chemically and biologically, and numerous methods are available for their detection, determination and separation, but few of these are specific for individual members of this class, and none so far has been based on a solid-state reaction.

Qureshi and co-workers¹⁻³ have developed simple solid-state analytical methods on the basis of the work of Voskresenskii⁴ and Rastogi.⁵ Here we report the application of the technique for specific detection of catechol and *o*-nitrophenol.

EXPERIMENTAL

Reagents

o-Nitrophenol and catechol (Sigma) were recrystallized until their melting points were constant and in agreement with reported values. Non-deliquescent soda-lime and sodium chloride (B.D.H.) were used as received.

Procedure

Solid-state detection. *o*-Nitrophenol or catechol (10 mg) was thoroughly ground with 1 g of sodium chloride, and a 200-mg portion of the mixture was similarly mixed thoroughly with 800 mg of sodium chloride. Then 1 mg of this mixture was placed on a spot plate and mixed with a few mg of well powdered soda-lime by

stirring with a glass rod. The colour produced was observed.

Capillary solid-state detection. Well powdered (mesh size 200) test substance and soda-lime were packed in a capillary, one from each end, with two iron rods, with as uniform pressure as possible. The capillary was then heated in an oven at the desired temperature and the colour produced at the junction was noted.

Semiquantitative determination. Fifty mg of a mixture of 8 mg of catechol with 1 g of sodium chloride were tightly packed in a capillary from one end and 500 mg of soda-lime from the other. The capillary was heated for 5 hr in an oven at 80° and the length of the coloured boundary was measured at 1-hr intervals. This procedure was repeated with other mixtures.

For *o*-nitrophenol a glass-wool plug 2 mm in length was placed between the test substance and the reagent and the capillary was heated at $30 \pm 1^\circ$ (*o*-nitrophenol melts at 44°).

Kinetic investigation. Well powdered (mesh size 200) test substance and soda-lime were packed in a capillary as before, and heated at the desired temperature. The length of the coloured boundary was measured as a function of time.

RESULTS

o-Nitrophenol gives a deep red colour with soda-lime and this colour is not given by any other phenol tested. However, since many

*Author for correspondence

phenols give a brown colour, it was thought that they might interfere in detection of low levels of *o*-nitrophenol. However, introduction of a 2-mm long glass-wool plug between the sample and reagent prevents this, as *o*-nitrophenol is the only one of the phenols tested that has a sufficiently high vapour pressure to give a colour reaction at the other side of the glass-wool plug. The limit of detection is 4 μ g, which is comparable to that of solution spot-tests.

Catechol gives a very specific green-blue colour and the limit of detection is 2 μ g.

In the semiquantitative determination catechol gives a length of coloured zone that is linearly related to weight of catechol in the range 0.4–1.2 mg. The slope of the calibration plot increases with the heating time used, but the response is adequate even with heating for 1 hr. An attempt to determine catechol in the presence of phloroglucinol (which does not give any colour with the reagent) was unsuccessful, but it was interesting that when phloroglucinol was present the sharpness and the intensity of the colour given by catechol increased. Hence, either sodium chloride or phloroglucinol can be used as the diluent for the sample, and where conditions permit the latter should be preferred. In either case linear calibration plots are obtained (see Fig. 1).

o-Nitrophenol in the range 0.1–0.5 mg can be determined specifically by the glass-wool plug modification.

Though the sensitivity of determination is not comparable to that of solution methods, it is much higher than that with the capillary method described earlier.^{1,2}

Fig 1 Calibration curves for catechol diluted with phloroglucinol.

Interferences

The following organic compounds do not give any colour with soda-lime.

Amines. Methylamine, dimethylamine, trimethylamine, triethylamine, diethylamine, *o*-, *m*- and *p*-phenylenediamine, α -naphthylamine, β -naphthylamine, diphenylamine, *N*-phenyl-1-naphthylamine, methylaniline, *o*-nitroaniline, *m*-nitroaniline and *p*-nitroaniline.

Ketones. Acetophenone, benzophenone, ethyl methyl ketone, butyrophenone and cyclohexanone.

Aldehydes. Formaldehyde, acetaldehyde, benzaldehyde, *o*-, *m*- and *p*-nitrobenzaldehyde, *p*-chlorobenzaldehyde, *p*-dimethylaminobenzaldehyde, *p*-dimethylaminocinnamaldehyde, salicylaldehyde, paraformaldehyde and paraldehyde.

Ureas. Urea, thiourea, *N*-methylurea, phenylurea, phenylthiourea and allylthiourea.

Carbohydrates. Maltose, glucose, arabinose, rhamnose, sucrose, fructose, lactose, galactose, xylose and starch.

Amino-acids. Adenine, cystine, glycine, β -alanine, sarcosine, glutamine, glutamic acid, L-histidine, L-proline, DL-phenylalanine and L-tryptophan.

Acids. Formic, uric, gallic, malonic, cinnamic, malic, fumaric, phthalic, oxalic, benzoic, barbituric, α -picolinic, *m*- and *p*-nitrobenzoic, nicotinic, monochloroacetic, indolyl-3-acetic, ethylenediaminetetra-acetic and chromotropic (disodium salt).

Amides. Benzamide, salicylamide and acetanilide.

Hydrochlorides. Hydrazine, 2,4-dinitrophenylhydrazine, benzidine and diethylamine hydrochlorides.

Hydrocarbons and their derivatives. Benzene, petroleum ether, nitrobenzene, carbon tetrachloride, chloroform, 2,4-dinitrochlorobenzene, azobenzene and *m*-dinitrobenzene.

Ethers. Diethyl ether and dioxan.

Indoles. Indole and indolyl-3-acetic acid.

Tryptamines. 5-Hydroxytryptamine, 5-methoxytryptamine, 5-benzyloxytryptamine and α -methyltryptamine.

Alkaloids. Brucine, caffeine, quinine and cinchonine.

Miscellaneous. Uracil, 1-nitronaphthalene, urea nitrate, 2,4-dinitrotoluol, dithizone, ammonium purpurate, 1,10-phenanthroline, 4-dimethylaminobenzylidene, rhodanine, diphenylcarbazide, amitrol, ethanoxymercarbide,

saccharin, 8-hydroxyquinoline, galloyanine and safranin.

The reactions of various phenols with anhydrous soda-lime give the following results: phenol (no colour), quinol (light brown), resorcinol (yellow), orcinol (light brown), *o*-methylresorcinol (brown), (+)-catechin (no colour), *m*-nitrophenol (brown), *p*-nitrophenol (yellow), pyrogallol (light brown), phloroglucinol (no colour), α -naphthol (no colour), β -naphthol (no colour), vanillin (no colour) and *o*-vanillin (no colour).

It is therefore apparent that the green-blue colour for catechol and the red colour for *o*-nitrophenol (by the glass-wool modification) are specific for these compounds among those tested, but these colours would be modified by the presence of certain other phenols.

The rate law followed by the reaction of catechol with soda-lime is

$$\xi = kt + c \quad (1)$$

where ξ is the length of the coloured boundary, t is time and k and c are constants. The rate increases with temperature.

A plot of $\log k$ vs. $1/T$ (a standard method for evaluating the activation energy) was linear. The value of E_{act} obtained from it was +8 kcal/mole.

The rate law for the *o*-nitrophenol reaction with soda-lime, with and without a glass-wool plug,

$$\xi = k \log t + c \quad (2)$$

An Arrhenius plot could not be obtained in this case, as *o*-nitrophenol melts at 44°.

DISCUSSION

It is difficult to propose rational mechanisms, owing to the complexity of the systems. However, certain features point to two different mechanisms for *o*-nitrophenol and catechol.

o-Nitrophenol

The reflectance spectrum of *o*-nitrophenol has two maxima, at 300 and 360 nm (Fig. 2). The spectrum of *o*-nitrophenol in the presence of an excess of soda-lime gives a sharp increase in the intensity of both bands and a red shift of the 360-nm band to 430 nm. These electronic spectrum features are consistent with formation of a weak charge-transfer complex. The mechanism probably involves the transformation of

Fig 2 Ultraviolet-visible reflectance spectra of *o*-nitrophenol, catechol and their reaction products with soda-lime: ●, *o*-nitrophenol + soda-lime, *, soda-lime; △, *o*-nitrophenol, ▲, catechol + soda-lime; ○, catechol

o-nitrophenol (I) into the quinoid structure (II) in the highly basic medium. Form II then complexes with form I to give a charge-transfer complex, probably of 1:1 stoichiometry. The shift of the 360-nm band to 430 nm can be rationalized as follows. According to Mulliken's now widely accepted charge-transfer theory the complex can be described by a wave function as follows:

$$\psi(AD) = a\psi_0(A, D) + b\psi_1(A^-D^+)$$

where A is an acceptor and D is a donor, ψ_0 is the non-bonding function, which is mainly due to the dispersion, dipole-dipole, dipole-induced dipole and van der Waals forces, with very little contribution from the dative structure, and ψ_1 is the dative function which signifies transfer of one electron from the donor to the acceptor in such a way that the spin multiplicity is maintained; a and b are constants; A^-D^+ is often called a semipolar double bond.

In the ground state of the complex $a \gg b$, and in the excited state $a \ll b$, and therefore the excited state is usually more ionic than the ground state. Hence, a polar medium will lower (stabilize) the excited state and raise

(destabilize) the ground state, as shown schematically below.

Therefore, $h\nu_{CT}^1 > h\nu_{CT}^2$ and $\lambda_2 > \lambda_1$.

Catechol

The reflectance spectrum (Fig. 2) of catechol shows a single peak at 300 nm, whereas the spectrum of catechol in the presence of excess of soda-lime has two maxima, one at 300 nm and the other at 700 nm, the intensity of the former being higher than that for catechol alone. The

long-wave band at 700 nm should be due to the result of chemical reaction between catechol and soda lime, and presumably arises from increased conjugation. Formation of such a product is best explained by aerial oxidation of catechol in the presence of base, by a free radical pathway.⁶ To verify this hypothesis, the reaction was performed with rigorous exclusion of air. Both solids were stored under vacuum in a desiccator, with periodic flushing with nitrogen. They were then packed in the capillary in an atmosphere of nitrogen. Under these conditions appearance of the green-blue colour was minimal and even then only on prolonged heating. Reaction scheme 1 can therefore be postulated.

Structure III is a comparatively large conjugated system which seems to be responsible for the green-blue colour. Another fact in support of III is that the increase in intensity of the 300-nm band is much less than that for the

(III)

(IV)

corresponding absorption for *o*-nitrophenol and it may be due to intramolecular hydrogen-bonding within III, as shown in IV.

SPECTROPHOTOMETRIC DETERMINATION OF PALLADIUM WITH 5,6-DIMETHYL-1,3-INDANEDIONE-2-OXIME

D MALLIKARJUNA RAO, K. HUSSAIN REDDY and D. VENKATA REDDY

Department of Chemistry, Sri Krishnadevaraya University, Anantapur 515003, India

(Received 1 March 1989 Revised 17 January 1990 Accepted 14 March 1991)

Summary—A rapid, sensitive and selective method has been developed for the determination of palladium with 5,6-dimethyl-1,3-indanedione-2-oxime in acetate buffer (pH 5.5). Beer's law is obeyed over the range 0.15–4.17 $\mu\text{g/ml}$ palladium(II). The molar absorptivity at 370 nm is $2.98 \times 10^4 \text{ l mole}^{-1} \text{ cm}^{-1}$. The method has been applied for the determination of palladium in synthetic mixtures corresponding to Pt–Ir and Oakay alloys. An interesting feature of the system is the abnormal shape of the Job and molar-ratio plots obtained.

Compounds containing a keto group *ortho* to an azomethine nitrogen atom are potential complexing agents. The reactivity of the oxime is dependent, however, on the structural characteristics of the parent aldehyde or ketone.¹ In the work presented here, 5,6-dimethyl-1,3-indanedione-2-oxime was examined as a colorimetric reagent for palladium.

EXPERIMENTAL

Reagents

5,6-Dimethyl-1,3-indanedione-2-oxime (DIDO) was obtained from Beecham Pharmaceuticals Biosciences Research Centre, Epsom, England. Its purity (99%) was checked by elemental and mass spectral analysis. Its infrared spectrum was consistent with the structure I. A 0.005M stock solution was made by dissolving 0.203 g of the reagent in 200 ml of dimethylformamide.

Stock solution of palladium(II). A 0.01M stock solution was prepared by dissolving 177.4 mg of palladium chloride (Johnson Matthey) in a few drops of concentrated hydrochloric acid and diluting to 100 ml. The stock solution was standardized.²

Acetate buffer. Sodium acetate and acetic acid solutions, both 0.2M, were mixed in suitable proportions to give buffers covering the pH-range 3.0–6.5.

All other reagents were of analytical grade and doubly distilled water was used throughout.

Apparatus

Absorption spectra and absorbance measurements were obtained with a Beckman DU-2 spectrophotometer equipped with 1.0-cm fused-silica cells.

Procedure

To a sample solution containing 15–100 μg of Pd(II) add 12 ml of 0.2M acetate buffer (pH 5.5), 2.5 ml of dimethylformamide (DMF) and 1 ml of 0.005M DIDO, in a 25-ml standard flask. Dilute to volume with doubly distilled water and measure the absorbance at 370 nm against a reagent blank in 1.0-cm path-length cells. Prepare a calibration graph similarly.

RESULTS AND DISCUSSION

The reaction is instantaneous and the final product is stable for 12 hr under optimum conditions. The order of addition of the reagents has no effect on the absorbance. In aqueous medium the final complex is precipitated; this is prevented by the presence of at least 10% v/v DMF.

The final complex has two absorption maxima, at 310 and 370 nm (Fig. 1), and latter is used for analytical purposes.

Fig 1 Absorption spectra of (A) reagent solution ($2 \times 10^{-4}M$) vs water blank, (B) Pd-DIDO complex vs DIDO blank, $[DIDO] 2 \times 10^{-4}M$, $[Pd] 2.24 \times 10^{-5}M$, pH 5.5, (C) Pd-DIDO complex vs DIDO blank, $[DIDO] 2 \times 10^{-4}M$, $[Pd] 1 \times 10^{-3}M$, pH 5.5

Maximal and constant absorbance is observed in the pH range 5.0–6.5. Hence the use of a pH-5.5 acetate buffer is recommended. A five-fold molar excess of DIDO is sufficient to develop maximum absorbance of the final complex, so 1.0 ml of 0.005M DIDO is adequate under the recommended conditions.

The absorbance is unaffected by temperature in the range 10–70°, but gradually decreases at temperatures higher than 70°.

Stoichiometry and stability constant of the final complex

The most interesting feature of the system is that the Job plot (Fig. 2) indicates the formation

Fig 2 Job plots. A and B, $[Pd] = [DIDO] = 5 \times 10^{-4}M$, C and D, $[Pd] = [DIDO] = 2.5 \times 10^{-4}M$; wavelength = 370 nm (A and C) 310 nm (B and D).

Fig 3 Molar-ratio plot. $[Pd] 4 \times 10^{-5}M$; pH 5.5, $\lambda = 370$ nm

of 1:1 and 1:2 Pd:DIDO complexes, with a marked decrease in absorbance between the two maxima. A similar phenomenon has been reported for the palladium complexes with isonitrosoacetylacetone,³ isonitrosoacetophenone,⁴ isonitrosobenzoylacetone⁵ and *o*-hydroxyacetophenone thiosemicarbazone.⁶ The mole-ratio plot (Fig. 3) is also anomalous, and it may be noted from it that conversion from the 1:1 into the 1:2 complex begins before the 1:1 complex is completely formed. Presumably some sort of rearrangement in the bonding takes place. One possibility is shown in Fig. 4. It is known that $\log k_4$ for formation of $PdCl_4^{2-}$ is only about 2, and from the Job plot it can be estimated that $\log \beta_1$ for the Pd-DIDO system is about 5. As $\log \beta_1$ for the ammine complexes of Pd(II) is 9.6, it seems feasible that an S_N1 reaction (step 1) could be followed by an intramolecular isomerization (step 2) (which could be due to the *trans*-effect or to increased stability caused by charge neutralization, or both), and finally by step 3. The stability constant for the 1:2 complex was estimated as $\log \beta_2 = 9.3$, and pK_a for DIDO was found to be 6.5.

Analytical characteristics

A linear calibration graph for the 1:2 complex was obtained over the concentration range 0.15–3.9 $\mu\text{g/ml}$ palladium, at 370 nm. The molar absorptivity was $2.98 \times 10^4 \text{ l. mole}^{-1} \text{ cm}^{-1}$. Ten replicate analyses of a solution containing 1.50 $\mu\text{g/ml}$ palladium gave a

Fig 4 Suggested reaction mechanism

mean absorbance of 0.424 with a standard deviation of 0.005.

Interferences

Various ions were examined for their effect on the determination of 1.5 $\mu\text{g/ml}$ palladium. The tolerance limit was taken as the concentration of foreign ion required to cause $\pm 2\%$ error in the absorbance. The tolerance limit for most of the noble and platinum-group metal ions is fairly high. Larger amounts of platinum(IV) and iron(III) could be masked with oxalate (280 $\mu\text{g/ml}$) and fluoride (1500 $\mu\text{g/ml}$) respectively. The results of the interference and masking studies are summarized in Table 1. EDTA and thiosulphate interfere seriously.

Applications

The method has been applied to the determination of palladium in synthetic mixtures having compositions that correspond to a Pt-Ir alloy and Oakay alloy. Fluoride (1500 $\mu\text{g/ml}$) and oxalate (280 $\mu\text{g/ml}$) were added to mask iron(III) and Pt(IV) respectively. The results are given in Table 2.

Several spectrophotometric methods using oximes have been reported.^{1,7} Most of them

involve an extraction step. The present method is rapid, sensitive and selective and requires no extraction. By comparison with recently

reported spectrophotometric methods for palladium, DIDO is seen to rank among the more sensitive reagents (Table 3). Moreover the colour reaction between palladium(II) and DIDO is fairly selective and free from interferences (Table 1). The colour reaction can be used to provide a rapid, sensitive and specific test for palladium.

Acknowledgements—The authors are thankful to the CSIR, New Delhi, for the award of a Senior Research Fellowship to one of them (DMR), and to Dr P. C. Buxton, Beecham Pharmaceuticals, Great Burgh, for a generous supply of DIDO.

SIMULTANEOUS SPECTROPHOTOMETRIC DETERMINATION OF THORIUM AND RARE EARTH METALS WITH *m*-CARBOXYCHLOROPHOSPHONAZO (CPAmK) AND CETYLPYRIDINIUM CHLORIDE

CHUNG-GIN HSU,* XI-MAN LIAN and JIAO-MAI PAN

Department of Chemistry, East China Normal University, 3663, Zhong Shan Road (N), Shanghai 200062, People's Republic of China

(Received 12 September 1990 Revised 20 February 1991 Accepted 26 February 1991)

Summary—Th and rare earth elements (REE) react with *m*-carboxychlorophosphonazo (CPAmK) in the absence of cetylpyridinium chloride (CPC) to form colour complexes. The molar absorptivities for Th and Ce are 1.03×10^5 and 1.06×10^5 l. mole⁻¹ cm⁻¹ respectively. In the presence of CPC, REE-complexes are not formed because of micellar masking, while Th gives a more sensitive reaction with CPAmK ($\epsilon = 1.50 \times 10^5$). Most of the foreign ions are tolerated in considerable amounts; 360–1000-fold amounts of rare earths do not interfere with the determination of Th. The optimum conditions of the complex-formation reactions and the compositions of Th–CPAmK complexes are described. A simple method is proposed for simultaneous determination of Th and rare earths without previous separation.

Thorium and rare earths often coexist in their minerals, products and even in waste water. Because of their similar behaviour, determination of thorium and/or rare earths is a problem in analytical chemistry. Although strong claims are made for the specificity and sensitivity of NAA, ICP–AES and ICP–MS, some of the interferences to which these methods are subject are poorly understood and continue to cause problems.¹

Therefore, spectrophotometric methods for thorium and rare earths continue to be of interest.¹ *m*-Carboxychlorophosphonazo (CPAmK, I), an asymmetric derivative of chromotropic acid with one *o*-phosphono-*o*'-hydroxyazo functional group synthesized in this

laboratory has been used for the determination of cerium subgroup rare earths^{2,3} and thorium,⁴ but they interfere with each other when they are present simultaneously.

In this paper, we described the spectrophotometric behaviour of the CPAmK-complexes of

Th and Ce (as well as other rare earths) in the presence and absence of cetylpyridinium chloride (CPC), and a rapid method is proposed for the simultaneous determination of thorium and rare earths without their previous separation.

EXPERIMENTAL

Reagents

All solutions were prepared with distilled, demineralized water.

The standard stock solution of thorium was prepared by dissolving thorium nitrate in a given volume of water, and the solution was standardized by EDTA titration. The working standard solution (10 μ g/ml) was prepared by dilution.

The standard stock solutions of rare earths were prepared by dissolving the oxides of rare earths (Specpure, Johnson Matthey) in hydrochloric acid and the cerium oxide (99.99%, Shanghai Chemicals Factory) in a mixture of sulphuric acid and hydrogen peroxide, evaporating the excess of acid and diluting with hydrochloric acid (1 + 100) to a given volume. The solutions were standardized by EDTA titration with Xylenol Orange as indicator. The working standard solutions were prepared by diluting as required with hydrochloric acid (1 + 100).

*Author for correspondence.

The standard solution of total rare earths (5.0 $\mu\text{g/ml}$) was prepared by mixing the rare earth solutions in the following proportions: $\text{La}_2\text{O}_3:\text{CeO}_2:\text{Nd}_2\text{O}_3:\text{Y}_2\text{O}_3 = 30:40:20:10$.⁵

m-Carboxychlorophosphonazo (CPAmK) solution (0.04%) was prepared by dissolving 0.04 g of CPAmK in 100 ml of water. CPAmK was synthesized as described previously.²

Cetylpyridinium chloride solution (0.2%) was prepared by dissolving 0.2 g of CPC (Fluka) in 100 ml of water.

Apparatus

Absorption spectra and absorbances were recorded and measured with a Beckman DU-7HS spectrophotometer, using 1.0-cm cells.

General procedure

(A). To the mixed solution of Th and Ce (or other REE) in a 25-ml calibrated flask, add 4.0 ml of 2M hydrochloric acid, 2.0 ml of 0.2% CPC and 1.0 ml of 0.04% CPAmK solution successively. Dilute to the mark with water and stand for 20 min. Measure the Th absorbance (A_1) at 685 nm in a 1.0-cm cell against a reagent blank.

(B). To the mixed solution of Th and Ce (or other REE) in a 25-ml calibrated flask, add 2.0 ml of 2M hydrochloric acid, *ca.* 10 ml of water and then 3.0 ml of 0.04% CPAmK solution. Dilute to the mark with water. Measure the absorbance (A_2) for the sum of Th and Ce (or

Fig 2 Absorption spectra in the presence of CPC 1 CPAmK ($6.0 \times 10^{-6}M$); reference, water, 2 Th-CPAmK; reference, reagent blank, $1.7 \times 10^{-6}M$ Th, $1.5 \times 10^{-5}M$ CPAmK, 0.32M HCl, $4.5 \times 10^{-4}M$ CPC

other REE), at 669 nm in a 1.0-cm cell against the reagent blank.

RESULTS AND DISCUSSION

Absorption spectra

In the absence of CPC, CPAmK exhibits a maximum absorption at 545 nm (Fig. 1), whereas cerium- and thorium-complexes have maximum absorption peaks at 669 nm and 676 nm, respectively, in hydrochloric acid solution. On addition of CPC, the absorption peak of CPAmK is shifted to 565 nm (Fig. 2); micellar masking⁶ prevents the formation of a Ce-complex, while the thorium complex gives a more sensitive peak at 685 nm.

Optimum conditions for complex formation

In the absence of CPC, 0.04–0.72M hydrochloric acid and $3.0\text{--}7.5 \times 10^{-5}M$ CPAmK gave the highest and most constant absorbance values of cerium- and thorium-complexes. Higher acidity led to the precipitation of CPAmK, and addition of more CPAmK would make the background absorbance too high. Both the complexes of cerium and thorium were formed instantly and their absorbances were stable for at least 24 hr.

In the presence of CPC, the optimum conditions for thorium were 0.28–0.80M hydrochloric acid, $1.13\text{--}3.0 \times 10^{-5}M$ CPAmK and $2.24\text{--}11.2 \times 10^{-4}M$ CPC. Below $2.24 \times 10^{-4}M$ CPC, the solution became turbid, and the absorbance decreased gradually as the concentration of CPC exceeded $11.2 \times 10^{-4}M$. The

Fig. 3. Absorbances of CPAmK complexes of rare earths at 669 nm 10 μg of rare earth, $3.8 \times 10^{-5}M$ CPAmK, 0.16M HCl

order of addition of CPC (before or after complex formation) did not influence the result. The Th-CPAmK complex formation was completed within 20 min and it remained stable for at least 2 hr. All solutions became turbid after standing for longer periods.

Behaviour of other rare earth elements

The absorbances of the CPAmK complexes of the other rare earths (10 μg each) were also measured at 669 nm against a reagent blank in the absence of CPC. Figure 3 shows that the complexes of cerium sub-group rare earths and yttrium (the major constituents in rare earth mixtures) give higher absorbances. The absorbances from gadolinium to lutetium (the minor constituents) decrease with an increase in atomic number. In the presence of CPC, cerium as well as other rare earths are completely masked. This behaviour enables other rare earths to be determined along with cerium.

Compositions of the complexes

The molar composition of the Th-CPAmK complex formed in the absence of CPC was ascertained by Job's method of continuous variations, slope-ratio and equilibrium shift methods. All three methods indicated that the metal-to-ligand ratio was 1:2. This ratio differs from the value (1:3) found by us in sulphuric acid medium.⁴

In the presence of CPC, the molar composition of the complex was found by the same methods to be 1:5 (Th:CPAmK). It is because

more of the negative-charged CPAmK ions are adsorbed and concentrated on the positive-charged surface of CPC micelle that the formation of a higher order complex is favoured.⁷

The stoichiometry of the Ce-CPAmK complex in the absence of CPC is 1:3, which has been previously estimated.² After addition of CPC, the complex was completely dissociated due to micellar masking.

The characteristics of the complexes mentioned above are listed in Table 1.

Analytical characteristics of the method

Under the conditions employed in procedure (A), cerium as well as other rare earths are completely masked in the presence of CPC, while the absorption of Th-CPAmK is greatly enhanced. Under the conditions for procedure (B), the absorbances of thorium and cerium (as well as other rare earths) are additive. This property can be utilized to create a method for the simultaneous determination of thorium and rare earths. Their amounts were obtained by the following expressions:⁶

$$C_{\text{Th}} = A_1/\epsilon'_{\text{Th}} \quad (1)$$

$$C_{\text{REE}} = (A_2 - A_1\epsilon_{\text{Th}}/\epsilon'_{\text{Th}})/\epsilon_{\text{REE}} \quad (2)$$

Where A_1 and A_2 are the absorbances read [at 685 nm (procedure A) and 669 nm (procedure B) respectively] and ϵ'_{Th} and ϵ_{Th} are the molar absorptivities of thorium found in the presence and absence of CPC. ϵ_{REE} is the molar absorptivity of rare earths found in the absence of CPC.

In the presence of CPC, the calibration graph for thorium was constructed according to procedure (A). Beer's law was obeyed for 0–10 μg of thorium in a 25-ml solution at 685 nm. The apparent molar absorptivity and Sandell sensitivity were found to be 1.50×10^5 l.mole⁻¹.cm⁻¹ and 1.55 ng/cm², respectively. Ten replicate analyses of a test solution containing 10.0 μg of Th gave a coefficient of variation of 1.2%.

Table 1. Characteristics of CPAmK complexes of Th and Ce

Complex	Medium HCl, M	CPC	Composition M CPAmK	λ_{max} , nm	ϵ ($\times 10^{-4}$) l.mole ⁻¹ cm ⁻¹

*Total rare earth elements

†A is absorbance, C is μg in 25-ml solution

In the absence of CPC, calibration graphs of cerium, total rare earths and thorium were constructed according to procedure (B). Beer's law was obeyed for 0–24 μg of cerium, 0–20 μg of total rare earths or 0–28 μg of thorium in 25 ml of solution at 669 nm. The apparent molar absorptivities of cerium and thorium at 669 nm were 1.06×10^5 and 8.06×10^4 $\text{l. mole}^{-1} \cdot \text{cm}^{-1}$, respectively ($\epsilon_{676}^{\text{Th}} = 1.03 \times 10^5$ $\text{l. mole}^{-1} \cdot \text{cm}^{-1}$). The Sandell sensitivities were 1.32 ng/cm^2 and 2.90 ng/cm^2 . The coefficients of variation for the determination of 10.0 μg of cerium or thorium (10 determinations each) were 1.2 and 0.8% respectively. The straight-line equations of the calibration graphs obtained by a least-squares treatment are listed in Table 2.

The difference in absorbance, obtained for equal weights of metals, between the calibration graph for cerium and that for total rare earth

†Add 3 ml of 5% oxalic acid.

elements is usually not more than 5%, hence the former can be employed for the determination of total rare earths.

Effect of foreign ions

Solutions containing 5.0 μg of thorium or 5.0 μg of cerium, and various amounts of foreign ions were prepared and determined by procedure (A) and procedure (B), respectively. The tolerance limits (5% error maximum) are listed in Tables 3 and 4. As shown in Table 3, 360-fold amounts of cerium, 440-fold amounts of europium and 1000-fold amounts of ytterbium do not interfere with the determination of 5.0 μg of thorium, which is an advantage over the published methods.⁸⁻¹² In the absence of CPC, Table 4 shows that 150 mg of oxalic acid are tolerated, which can be used to mask Fe(III), Zr(IV), U(VI) and Ti(IV), and raise the limits to which they can be tolerated.

Simultaneous determination of thorium and rare earths in waste water

The proposed method was applied to the determination of thorium and rare earths (expressed as cerium) in six industrial waste-water samples taken from chemical works. Place two appropriate aliquots of the sample in 25-ml calibrated flasks, add 6M hydrochloric acid or sodium hydroxide to adjust the solutions to pH ca. 3, then follow the general procedure (A) and

(B)* for the determinations. Thorium values were in the range 0.243–2.21 ppm and cerium values in the range of 0.258–3.92 ppm. The coefficients of variation ranged from 0.6 to 1.8% for thorium and from 0.4 to 2.9% for cerium. The recoveries of thorium and cerium found by standard addition of 2.00 μg of thorium or cerium to each determination averaged 99.4% and 97.3%, respectively, with ranges of 96.0–102% for thorium and 95.0–101.5% for cerium.

SPECTROPHOTOMETRIC DETERMINATION OF NICOUMALONE, ACEBUTOLOL HYDROCHLORIDE AND PROCAINAMIDE HYDROCHLORIDE

C. S. P. SASTRY*, T THIRUPATHI RAO and A SAILAJA

Foods and Drugs Laboratories, School of Chemistry, Andhra University, Visakhapatnam 530 003, India

(Received 5 September 1990 Revised 1 January 1991 Accepted 26 February 1991)

Summary—A sensitive spectrophotometric method is described for the determination of nicoumalone (NIC), acebutolol hydrochloride (ACBH) or procainamide hydrochloride (PAH) either in pure form or in pharmaceutical formulations. The method is based on the oxidative coupling reaction through the involvement of an aromatic primary amino group (released through reduction in NIC or hydrolysis in ACBH or existing free in PAH) in the drug with 3-methyl-2-benzothiazolinone hydrazone hydrochloride (MBTH) in the presence of ferric chloride [Fe(III)]. The resulting chromophores are measured at 620 nm for NIC and ACBH and 580 nm for PAH. The concentration measurements are reproducible within a relative standard deviation of 1%.

Nicoumalone (NIC)^{1,2} is extensively used as an anticoagulant while acebutolol hydrochloride (ACBH) and procainamide hydrochloride (PAH)^{1,2,3} are two widely used anti-arrhythmic agents. They have been officially determined by titrimetry with sodium nitrite (PAH)^{1,2} or ultraviolet spectrophotometry (NIC).^{1,2} Acebutolol hydrochloride is not yet official in any pharmacopoeia. Most of the methods for spectrophotometric determination of NIC,⁴ ACBH⁵⁻⁷ and PAH⁸⁻¹⁰ in the visible region suffer from lack of sensitivity or specificity. After oxidation with Fe(III), MBTH has been used as a chromogenic agent in the estimation of aromatic primary amines.^{11,12} In this paper we report its application to the determination of NIC, ACBH and PAH in bulk samples and pharmaceutical preparations.

EXPERIMENTAL

Apparatus

A Systronics model 106 digital spectrophotometer with 1-cm matched glass cells was used for all the absorbance measurements. An Elico LI-120 digital pH meter was used for pH measurements.

Reagents

Pharmacopoeial grade NIC, ACBH and PAH were obtained as gift samples from Sarabhai

Chemicals, May & Baker (India) Ltd. and Natco-Fine Pharmaceuticals Pvt. Ltd. They were used as working standards without further treatment. All other reagents and solvents were of analytical grade. Commercial dosage forms were purchased from local pharmacies.

MBTH solution (Fluka). Freshly prepared 0.2% solution in distilled water.

Ferric chloride hexahydrate solution (Wilson). Freshly prepared 0.8% solution in 0.01M hydrochloric acid.

Standard solution of nicoumalone (300 µg/ml). An accurately weighed 30 mg sample of NIC was treated with 10 ml of 1M methanolic hydrochloric acid and 0.3 g of zinc dust added in portions. After standing for 45 min at room temperature, the solution was filtered through cotton wool, the residue was washed with 3 × 5-ml portions of methanol (Qualigens, Excellar) and the filtrate was made up to 100 ml with methanol after bringing the pH to 5.5–6.5 with sodium hydroxide.

Standard solution of acebutolol hydrochloride (400 µg/ml). About 40 mg of accurately weighed ACBH in 15 ml of water was treated with 4 ml of concentrated hydrochloric acid and refluxed for 45 min in a waterbath, cooled and the excess of hydrochloric acid removed under vacuum and the remaining mixture diluted to 100 ml with distilled water.

Procainamide hydrochloride solution (500 µg/ml). Prepared by dissolving 50 mg of the drug in 100 ml of distilled water.

*Author for correspondence.

Procedure

Bulk samples. Volumes of the standard solutions of reduced NIC (0.25–2.25 ml, 300 $\mu\text{g/ml}$) or hydrolysed ACBH (0.25–2.0 ml, 400 $\mu\text{g/ml}$) or PAH (0.4–2.8 ml, 500 $\mu\text{g/ml}$) were placed in a series of 25-ml calibrated tubes. Iron(III) chloride (3.0 ml) and MBTH (4.0 ml for NIC, 3.0 ml for ACBH or PAH) were added successively with appropriate time intervals (1 min to ACBH and NIC; 5 min to PAH) to each tube, allowed to stand for 20 min (NIC or PAH) or 25 min (ACBH) and diluted to volume with distilled water. After colour development and final dilution the absorbances were measured at 620 nm (NIC or ACBH) or 580 nm (PAH) against a reagent blank during the stability period (1 min–5 hr for NIC, 1 min–3 hr for ACBH or 1 min–15 hr for PAH). The drug concentration was read from the appropriate calibration graphs prepared under identical conditions

Pharmaceutical preparations. Tablet powder equivalent to 30 mg of NIC was extracted with

3 \times 5-ml portions of acetone, the combined acetone extract was evaporated on a steam bath and the residue was treated as in preparation of the standard drug solution and analysed as in the procedure for bulk samples. For ACBH and PAH, tablet powder equivalent to 40 mg of ACBH or 50 mg of PAH was extracted with 3 \times 5-ml portions of distilled water and filtered. The filtrate was treated as in the preparation of the standard drug solution and analysed as in the procedure for bulk samples.

RESULTS AND DISCUSSION

Nature of the coloured species

The coloured species obtained in this reaction can be considered to be an oxidative coupling product between the drug and MBTH analogous to the products obtained by reaction of MBTH with amines.^{11,12} Under the experimental conditions, MBTH (I) loses two electrons and one proton on oxidation forming the electrophilic

†Six replicate samples

intermediate (II) which has been postulated to be the active coupling species (Scheme 1). The intermediate (II) undergoes electrophilic substitution with amine to form the coloured product (III). Aromatic primary amines react in the *para* position, or the *ortho* position if the *para* position is blocked, to the amino group, which is quite usual in such oxidative coupling reactions. The compounds mentioned above do not possess a free *para* position and so coupling takes place in the less sterically hindered *ortho* position. The variation in λ_{\max} and ϵ_{\max} in the case of oxidative coupling products resulting from NIC, ACBH and PAH appear to be due to the inductive and mesomeric effects of the other substituents (R, R') existing on the aromatic nucleus besides the primary amino group.

Reaction parameters

Since the drugs under investigation have either a free (PAH) or potential (released by reduction of NIC or hydrolytic cleavage of ACBH) aromatic primary amino group, the suitability of MBTH for their estimation was examined. The applicability of MBTH reagent in conjunction with different oxidants [Fe(III) , Ce(IV) , IO_4^- , CAT , $\text{Cr}_2\text{O}_7^{2-}$, $\text{S}_2\text{O}_8^{2-}$, OCl^- or Fe(CN)_6^{3-}] for the determination of each drug was examined, with respect to λ_{\max} and ϵ_{\max} values and stability of the coloured species formed, and the MBTH- Fe(III) combination was preferred for the high sensitivity obtained. Beer's law was found to be valid over the concentration ranges given in Table 1 at appropriate λ_{\max} (Fig. 1). To ascertain the optimum conditions for complete hydrolysis, ACBH was hydrolysed with different concentrations (1-10M) of hydrochloric acid and various time intervals (5-120 min) in a boiling water bath. Concentrations in the range 2.0-3.0M hydrochloric acid and a 45-min hydrolysis time are sufficient to yield maximum absorbance. For the reduction of NIC, use of 0.5-2.0M hydro-

chloric acid and 0.2-1.0 g of zinc dust was found to be optimal. The reduction time was established by increasing it by 5-min intervals. A 45-min period was found to yield maximum absorbance.

For 450 μg of NIC or 600 μg of ACBH or PAH, 3.0 ml (ACBH or PAH) or 4.0 ml (NIC) of 0.2% MBTH solution and 3.0 ml of 0.8% Fe(III) solution were found to be sufficient to give maximum colour intensity. Higher concentrations of reagent and oxidant did not affect the absorption intensity in PAH and NIC, but in the case of ACBH an increase in the volume of both reagent and oxidant decreases the absorbance of the chromophore. Heating the reaction mixture

Fig. 1. Absorption spectra of nicoumalone (A), acebutolol hydrochloride (B) and procainamide hydrochloride (C)-MBTH- Fe(III) systems. Concentration of nicoumalone $6.793 \times 10^{-5}M$; acebutolol hydrochloride $8.58 \times 10^{-5}M$, procainamide hydrochloride $2.061 \times 10^{-4}M$; MBTH $1.369 \times 10^{-3}M$ (for NIC), $1.027 \times 10^{-3}M$ (for ACBH and PAH) and ferric chloride $3.552 \times 10^{-3}M$ reagent blank vs distilled water (D)

†Reported method for ACBH (5), B P method for NIC (2) and PAH (2) HCT = Hydrochlorothiazide, SYFCF = Sunset Yellow FCF

for PAH causes a marked decrease in absorbance. In the case of NIC and ACBH, heating the reaction mixture at 80° for 5–10 min which looks much less critical, gives absorbances that are unstable and less precise. It was observed that when 0.1 and 1.0M hydrochloric acid are added, the absorbance of the solution gradually decreases (due to protonation of the amine group decreasing the oxidative coupling reaction) and hence the addition of hydrochloric acid was discontinued.

The coloured products developed rapidly after addition of the reagents and attained maximum intensity after about 20 min for NIC or PAH and 25 min for ACBH prior to final dilution at room temperature. They were stable for 5 (NIC), 3 (ACBH) or 15 hr (PAH). The solvents studied were water, methanol, ethanol, propan-1-ol, propan-2-ol, acetonitrile, chloroform, butan-1-ol and benzene. Water proved to be the most efficient.

Analytical data. The optical characteristics and figures of merit are given in Table 1. Commercial tablets containing each drug were successfully analysed by the proposed method. The values obtained by the proposed and reference methods for pharmaceutical preparations (Table 2) were compared statistically by the *t*- and *F*-tests and found not to differ significantly. The results of the recovery experiments by the proposed method are also listed in Table 2. Recovery experiments indicated the absence of interference from the commonly encountered pharmaceutical additives and excipients such as lactose, glucose,

starch, gum acacia, magnesium stearate and talc. Hydrochlorothiazide, which is co-formulated with ACBH, also had no effect. The colouring agent Sunset yellow FCF which was added to NIC did not interfere. The proposed method had advantages over other reported methods (including the MBTH-Ce(IV) method⁷ for direct determination of ACBH) in terms of sensitivity and freedom from interferences.

NEW REAGENT FOR SPECTROPHOTOMETRIC DETERMINATION OF SALICYLIC ACID

YI-BIN QU

Institute of Precious Metals, China National Nonferrous Metals Industry Corporation, Kunming,
People's Republic of China

(Received 14 August 1990 Revised 15 January 1991. Accepted 6 February 1991)

Summary—In 6M hydrochloric acid solution, salicylic acid reacts with pentachloronitrosyliridate $[\text{Ir}(\text{NO})\text{Cl}_5]^-$ to form a new 1:1 complex giving two absorption maxima at 369 and 446 nm with molar absorptivities both of $1.1 \times 10^4 \text{ l mole}^{-1} \text{ cm}^{-1}$. The reaction is second order with apparent energy, E_a , of 16.8 kJ/mole. At constant temperature, the apparent rate constant k increases to a maximum when the concentration of hydrogen ion is decreased to 4–5M and the concentration of chloride ion is kept at ~6M. The mechanism of the reaction is also discussed. In alkaline solution, the absorption maxima shift to 381 and 506 nm with molar absorptivities of 6.0×10^3 and $2.4 \times 10^4 \text{ l mole}^{-1} \text{ cm}^{-1}$, respectively. Salicylic acid can be determined spectrophotometrically with high sensitivity and precision. Benzoic and boric acids do not interfere.

Salicylic acid is an important antifungal agent and is widely used in pharmaceutical preparations. Although several photometric methods¹⁻⁴ have been developed for its determination, the commonly used method is alkalimetry;⁵ however, this method suffers from interference by benzoic acid. The officially approved photometric method for determination of salicylic acid in pharmaceutical preparation uses ferric nitrate as reagent,⁵ but its application is restricted because of a strict pH value of 2.45 being required for colour development. Recently, a simple spectrophotometric method has been established for the determination of salicylic acid,⁶ but the interference of benzoic acid cannot be eliminated.

Pentachloronitrosyliridate, abbreviated here as PCNI, is a versatile transition metal nitrosyl complex.⁷⁻⁹ We have studied its reaction with diphenylamine¹⁰ and sodium diphenylamine-sulphonate^{11,12} and experimental tests have also indicated that it undergoes a series of reactions with organic and pharmaceutical compounds. Its reaction with salicylic acid is sensitive and selective. Developing a spectrophotometric method for determination of salicylic acid seems to be theoretically and practically promising.

EXPERIMENTAL

Apparatus

A Pye-Unicam PU8800 spectrophotometer with 1-cm cells and a PHS-3 pH meter

equipped with glass-calomel electrodes were used.

Reagents

All chemicals were of analytical-reagent grade.

Standard salicylic acid solution, $1.04 \times 10^{-3}\text{M}$. Prepared by dissolving pure salicylic acid in distilled water, assisted by the addition of a minimum amount of 6M sodium hydroxide.

Standard PCNI solution, $1.0 \times 10^{-3}\text{M}$ in 6M hydrochloric acid. Prepared as described previously¹¹ and kept under dark conditions.

Ascorbic acid solution, 20 mg/ml. Prepared by dissolving colourless ascorbic acid in distilled water and used within 3 days.

Procedures

Procedure 1. To a 10-ml calibrated flask, add 0.2 g of sodium chloride, 0.5 ml of standard or sample solution containing up to 70 μg of salicylic acid, 1.0 ml of $1.0 \times 10^{-3}\text{M}$ PCNI solution and mix thoroughly. Keep in the dark for at least 1 hr. Add 0.2 ml of ascorbic acid and dilute to the mark with 4M hydrochloric acid. Measure the absorbance at 446 nm against a blank prepared under the same conditions.

Procedure 2. Prepare colour development as above. Add 6M sodium hydroxide solution until the colour changes from greenish yellow to red and then add an excess of 0.2 ml. Heat on a water bath for 1.0 min. Immediately cool the flask and its contents to room temperature by

placing in water. Dilute to the mark with water and measure the absorbance at 506 nm against a blank or water.

Kinetic experiments. Use a special glass flask with ground stopper and three side tubes¹³ for mixing solutions. Transfer various amounts of PCNI and salicylic acid solutions respectively into two of the side tubes. Adjust the concentrations of hydrogen ion and chloride ion of the two solutions respectively by adding hydrochloric acid, sodium (or calcium) chloride and water so that their concentrations in the two solutions are identical. Place the glass flask in a thermostat at constant temperature. After 30 min, mix the contents of the flask thoroughly and transfer immediately to a stoppered cell kept at the same temperature. Measure the absorbance at 446 nm against water at regular time intervals.

RESULTS AND DISCUSSION

Absorption spectra

In 6M hydrochloric acid solution, salicylic acid reacted with PCNI forming a colour species exhibiting two absorption maxima at 369 and 446 nm, both with molar absorptivities of 1.1×10^4 l.mole⁻¹ cm⁻¹ as shown in Fig. 1, curve 1.

Fig 1 Absorption spectra of 1, salicylic acid-PCNI complex ($4.05 \times 10^{-5}M$) in 6M HCl; 2, salicylic acid-PCNI complex ($4.05 \times 10^{-5}M$) in 0.1M NaOH; 3, salicylic acid ($4.05 \times 10^{-5}M$) in 6M HCl; 4, PCNI ($4.05 \times 10^{-5}M$) and ascorbic acid in excess.

Fig 2. Effect of concentration of HCl on the absorbance of salicylic acid-PCNI complex ($5.2 \times 10^{-5}M$) 1, 446 nm, 2, 369 nm

When the solution was diluted to various concentrations of hydrochloric acid after colour development the absorbance at 446 nm decreased slightly with the decreasing concentration of hydrochloric acid while the absorbance at 369 nm remained nearly constant as shown in Fig. 2. The absorbance at 446 nm varied also with the concentration of sodium chloride and the extent of variation was similar to that with hydrochloric acid.

When the solution was made alkaline after colour development, the colour changed from greenish yellow to red. The absorption spectrum changed gradually over a long time period at room temperature, but quickly became constant on heating. The absorption peak at 446 nm showed an increase and a slight red shift on increasing the solution pH over the range 1-5, and then decreased with a slight hypsochromic shift when the pH of the solution was further increased. This peak disappeared at pH ~ 10 . A new absorption peak occurred at ~ 480 nm when the pH of the solution reached ~ 8 and increased with increasing pH accompanied by a red shift. This peak shifted to 506 nm and its absorptivity reached a constant value when the pH of the solution exceeded 12.7. The absorption peak at 369 nm decreased with increasing pH and shifted to 381 nm when the pH of the solution was greater than ~ 10 . The absorption spectrum in alkaline solution is shown in Fig. 1, curve 2, with molar absorptivities of 0.6×10^4 and 2.4×10^4 l.mole⁻¹ cm⁻¹ at 381 and 506 nm respectively. The effect of pH on the absorbance at 446 and 506 nm is shown in Fig. 3. With a heating time of 1 min, the absorbance at 506 nm remained constant over the pH range 12.7-13.7

Fig. 3 Effect of pH on the absorbance of salicylic acid-PCNI complex ($2.6 \times 10^{-5}M$, heating, 1 min). 1, 446 nm, 2, 506 nm.

(corresponding to 0.05–0.5M in sodium hydroxide). When the alkalinity of the solution was 0.1M in sodium hydroxide, the optimum heating time was 0.5–2 min as shown in Fig. 4.

Composition and nature of the coloured species

The molar ratio of salicylic acid to PCNI in the coloured species was studied by the continuous variations method and the molar ratio method and found to be 1:1 in each case.

When the solution of the coloured species was passed through ion exchange resins, the greenish yellow species was retained by the anion exchange resin and not by the cation exchange resin, indicating that the species is anionic in nature.

According to Bottomley,^{9,14} a metal nitrosyl complex with $\nu_{NO} \geq 1890 \text{ cm}^{-1}$ may react as an electrophile. The electrophilic substitution reaction products of nitrosyl complexes of ruthenium with phenol and secondary or tertiary

Fig. 4. Effect of heating time on the absorbance of salicylic acid-PCNI complex ($2.6 \times 10^{-5}M$) in 0.1M NaOH. 506 nm.

aromatic amines are nitrosoarene complexes.^{15,16} In our previous work,¹⁰ it was shown that PCNI with a ν_{NO} of 1992 cm^{-1} has electrophilic substitution reactions with diphenylamine and sodium diphenylaminesulphonate and nitrosoarene complexes are also formed. These nitrosoarene complexes are all formed by the electrophilic attack of NO^+ of the nitrosyl complexes on the *para*-position to the amino-group or OH-group of aromatic compounds. It is assumed that the reaction of PCNI with salicylic acid is also an electrophilic substitution reaction which occurs mainly on the *para*-position to the OH-group of salicylic acid. It may be represented by the following equation.

The product formed may also be a nitrosoarene complex.

Origin of the absorption bands in the visible region

Bowden assigned the absorption bands of ruthenium nitrosoarene complexes in the visible region as $d\pi \rightarrow \pi^*$ charge transfer transitions. Because of the similarity between the nitrosoarene complexes of iridium and ruthenium, the absorption band of salicylic acid-PCNI complex at 446 nm may also be a $d\pi \rightarrow \pi^*$ charge transfer transition. When the pH of the solution is changed, the first colour change of the complex over the pH range 1–5 may be due to the dissociation of the carboxyl group and the second colour change over the pH range 8–11 may originate from the loss of hydrogen ion from the hydroxyl group. Both carboxyl group and hydroxyl group are auxochromes.^{17,18} The lone pair of electrons of the hydroxyl group are in conjugation with the π electron system of the aromatic ring. The loss of hydrogen ion from this group will increase its strength of conjugation and lower the energy of the π^* orbital, thus giving a red shift of the $d\pi \rightarrow \pi^*$ band. The carboxyl group operates as an auxochrome through its induction effect and also forms a hydrogen bond with the adjacent hydroxyl

group.¹⁸ The dissociation of this group will affect its inducing strength and the auxochromic ability of the hydroxyl group. The resulting effect of these two factors is reflected in the change of the $d\pi \rightarrow \pi^*$ band.

Kinetics of the reaction

From the preliminary calculation of the kinetic data, the reaction between salicylic acid and PCNI was found to be second order. The absorbance of salicylic acid was zero at 446 nm while that of PCNI was very low but could not be neglected. The precise calculation was carried out as follows.

From the standard equation for a second order reaction,

$$k = \frac{1}{t(a-b)} \ln \frac{b(a-x)}{a(b-x)} \quad (2)$$

let a = initial concentration of salicylic acid and b = initial concentration of PCNI. When $t = 0$, let the absorbance of $a = A_i = 0$ and the absorbance of $b = A_h$. At any intermediate time t , let the total absorbance of the solution = A_d and the absorbance of the product = A_p . When the reaction is completed, let the total absorbance of the solution = A_f and the absorbance of the product = A_m . Then:
When $a > b$,

$$x = b \cdot A_p / A_m. \quad (3)$$

Substitute equation (3) into equation (2):

$$k = \frac{1}{t(a-b)} \ln \frac{a \cdot A_m - b \cdot A_p}{a(A_m - A_p)} \quad (4)$$

where

$$A_m = A_f$$

$$A_p = A_d - A_h(1 - A_p/A_m)$$

$$\approx A_d - A_h(1 - A_d/A_f).$$

Table 1 The apparent rate constant, k , and energy, E_a , of the reaction between salicylic acid and PCNI in 6M HCl

	Temperature, K			Energy, E_a kJ/mole
	303	313	323	
k , $l \text{ mole}^{-1} \text{ sec}^{-1}$	11.8	14.7	17.6	
	11.8	14.7	18.3	
		12.1	14.8	
Mean	11.9	14.7	18.0	16.8

When

$$a < b,$$

$$x = a \cdot A_p / A_m. \quad (5)$$

Substitute equation (5) into equation (2):

$$k = \frac{1}{t(a-b)} \ln \frac{b(A_m - A_p)}{b \cdot A_m - a \cdot A_p} \quad (6)$$

where

$$A_m = A_f - A_h(b - a)/b$$

$$A_p = A_d - A_h[1 - (a \cdot A_p)/(b \cdot A_m)]$$

$$\approx A_d - A_h[1 - (a \cdot A_d)/(b \cdot A_f)].$$

The kinetic experiments were carried out first in 6M hydrochloric acid and the results obtained are summarized in Table 1. The rate of reaction increased slowly with an increase in temperature. The apparent energy was found to be 16.8 kJ/mole.

If the concentration of hydrochloric acid of the solution is decreased, the rate of reaction may be affected in two opposite ways. From equation (1), it is clear that the reaction rate may increase with decreasing concentration of hydrogen ion which is one of the products of the reaction. On the other hand, PCNI is mainly present in $\geq 6M$ hydrochloric acid solution and its concentration decreases rapidly with the

†Maintained with HCl and CaCl₂

‡Maintained with HCl and NaCl

decreasing concentration of hydrochloric acid according to the following equation,¹⁹

which causes the reaction rate to decrease. The apparent rate constant k will increase or decrease depending on which factor dominates. Thus the data in column 1 of Table 2 can be reasonably explained.

If calcium chloride or sodium chloride is added to the solution to maintain the chloride ion at relatively high levels while the concentration of hydrogen ion is decreased by decreasing the concentration of hydrochloric acid, the concentration of PCNI will be higher than that in solutions of the same acidity without adding salts, and the apparent rate constant, k , will increase. Comparison of the data in columns 2 and 3 of Table 2 with that in column 1 shows that experimental data conform well with theoretical prediction.

Stability of the complex and the optimum conditions for colour development and measurement

It is suitable to develop colour in solutions of 4–5M hydrochloric acid, saturated with sodium chloride. Calcium is not recommended for increasing the reaction rate at lower acidity since it sometimes causes irregular results. The reason is unknown at present.

The complex was stable for at least 72 hr even in 6M hydrochloric acid. Both 369 and 446 nm may be used for measurement, but 446 nm is preferable as there is less interference. Ascorbic acid was added to reduce irregular absorbance caused by a small amount of H_2IrCl_6 in PCNI solution. It also reacted with PCNI and the resulting product gave a small absorbance in

$\geq 4M$ hydrochloric acid solution and larger absorbance in solutions with lower acidity. It is acceptable to adjust the final acidity of the solution to any value between 4 and 6M.

The sensitivity was doubled when measurements were made in alkaline solution with procedure 2. The absorbance at 506 nm was stable for at least 3 hr and the reagent itself gave no absorbance.

Calibration and precision

A calibration graph was constructed by plotting known concentrations of salicylic acid against the corresponding absorbance obtained by using procedure 1 (using longer time for full colour development when the amount of salicylic acid exceeded 70 μg). The resulting graph was linear and passed through the origin. Beer's law was obeyed over the concentration range 0.5–13 $\mu\text{g}/\text{ml}$. To study the precision, a series of determinations was made for 70 μg of salicylic acid and the relative standard deviation was found to be 0.64%.

Interferences

For determination of 69.6 μg of salicylic acid, 500 μg of boric acid, 500 μg of phenacetine, 5000 μg of benzoic acid and 5000 μg of caffeine did not interfere. Wool fat or vaseline was dissolved in ethyl ether and extracted with sodium hydroxide solution. The extract did not interfere with the determination of salicylic acid.

Applications

Results obtained by applying the following procedure to the determination of salicylic acid in synthetic samples of compound benzoic ointment are shown in Table 3.

Dissolve 0.2 g of ointment in 10 ml of diethyl ether. Transfer into a 60-ml separating funnel. Extract the salicylic acid content

BOOK REVIEWS

Continuous-Flow Fast Atom Bombardment Mass Spectrometry: R. M. CAPRIOLI (editor), Wiley, Chichester, 1990 Pages x + 189 £27.50

This book is based on transcripts of papers presented at a workshop on CF-FAB in Annapolis, Maryland in 1989. The papers have been expanded and edited into this small volume detailing recent advances in CF-FAB. It is written very much at a "hands-on" level and provides a valuable reference work for the practical mass spectroscopist.

The first chapter explains the principle of operation and the necessary conditions needed to obtain the best results. The chapters are written by users of different instruments and discuss the practicalities and idiosyncrasies of using CF-FAB with their particular make of instrument. The book covers many uses of the technique, including quantitative and trace analysis, direct monitoring of biological processes, liquid chromatography/mass spectrometry and capillary-zone electrophoresis/mass spectrometry.

This is an excellent book and a new user of CF-FAB, or anyone considering taking it up, will find a wealth of valuable information contained within it. This is definitely a book to be kept handily placed in the laboratory and referred to frequently, not tucked away on a library shelf collecting dust.

M. E. HARRISON

Treatise on Analytical Chemistry, Part 1, Theory and Practice: J. D. WINEFORDER, M. M. BURSEY and I. M. KOLTHOFF (editors), 2nd Ed., Vol. 11, Wiley, New York, 1989 Pages xvii + 311 £59.00

This book is devoted to the practice of analysis by the manipulation of gaseous ions and very properly the most substantial chapter is that devoted to conventional mass spectrometry. Indeed, the mass spectrometer may be considered to be the ideal analytical instrument, providing as it does the molecular weight, atomic constitution and isotopic composition of unknown compounds, the qualitative and quantitative analysis of complex mixtures and structural information on organic molecules, and all this with sample sizes of a few micrograms or less. These aspects of the technique are fully covered in the chapter which examines in detail both instrumental aspects and the interpretation of spectra. Information is also included on the examination of mixtures by tandem and multiple unit spectrometers.

The inclusion of a separate chapter dealing with ion cyclotron resonance and the application of Fourier transform methods in a text devoted to analytical chemistry seems unjustified and the authors have very properly compared it to a stone-age tool. Despite its great potentialities it is of more interest to the physical chemist concerned with the problems of ion dissociation.

If FT-ICR may be considered to be at the very beginning of its development, then Spark Source Mass Spectrometry is at its end. Although the great sensitivity and dynamic range, and its ability to cope with the most refractory materials, are unique, the numbers of analytical problems requiring these abilities are decreasing, and so are the number of operating instruments. The authors describe in detail the theory, construction and operation of spark-source instruments and give an account of their application in geology, forensic studies and environmental science.

The great attractions of Plasma Chromatography are operation at atmospheric pressure and a sensitivity which compares with and sometimes surpasses that of the electron capture detector. The text gives a critical review of the possibilities of the technique and lists its more recent achievements.

The final chapter is concerned with the examination of solid surfaces by the energy analysis of scattered incident noble gas ions. As such the technique competes with Auger spectroscopy and ESCA. It has, however, the additional advantage that both surface layers and interior structure may be examined by the aid of sputtering. The characterization of typical surfaces of conductors, insulators and catalysts is described.

J. R. MAJER

Basic Chemical Thermodynamics: E. B. SMITH, 4th Ed., OUP, Oxford, 1990 Pages xvi + 166 £9.95 (softback), £20.00 (hardback)

Chemical thermodynamics is not the most exciting of subjects for science students, who now, as a group, appear to have even greater difficulty in understanding, and handling, equations. The new edition of this popular book will therefore be greatly welcomed, with its larger format and clearer presentation making it much more pleasant to read. The contents remain essentially as before, with the achieved objective of providing a clear description of the basic concepts of thermodynamics. A discussion of mechanical equilibrium helps the reader to understand the factors involved in chemical equilibrium, and the results are applied to a range of situations. A section is now included on Ellingham diagrams, though this could usefully be expanded to emphasize the industrial relevance of these diagrams.

BOOK REVIEWS

Continuous-Flow Fast Atom Bombardment Mass Spectrometry: R. M. CAPRIOLI (editor), Wiley, Chichester, 1990. Pages x + 189. £27.50

This book is based on transcripts of papers presented at a workshop on CF-FAB in Annapolis, Maryland in 1989. The papers have been expanded and edited into this small volume detailing recent advances in CF-FAB. It is written very much at a "hands-on" level and provides a valuable reference work for the practical mass spectroscopist.

The first chapter explains the principle of operation and the necessary conditions needed to obtain the best results. The chapters are written by users of different instruments and discuss the practicalities and idiosyncrasies of using CF-FAB with their particular make of instrument. The book covers many uses of the technique, including quantitative and trace analysis, direct monitoring of biological processes, liquid chromatography/mass spectrometry and capillary-zone electrophoresis/mass spectrometry.

This is an excellent book and a new user of CF-FAB, or anyone considering taking it up, will find a wealth of valuable information contained within it. This is definitely a book to be kept handily placed in the laboratory and referred to frequently, not tucked away on a library shelf collecting dust.

Basic Chemical Thermodynamics: E. B. SMITH, 4th Ed., OUP, Oxford, 1990. Pages xvi + 166. £9.95 (softback), £20.00 (hardback)

Chemical thermodynamics is not the most exciting of subjects for science students, who now, as a group, appear to have even greater difficulty in understanding, and handling, equations. The new edition of this popular book will therefore be greatly welcomed, with its larger format and clearer presentation making it much more pleasant to read. The contents remain essentially as before, with the achieved objective of providing a clear description of the basic concepts of thermodynamics. A discussion of mechanical equilibrium helps the reader to understand the factors involved in chemical equilibrium, and the results are applied to a range of situations. A section is now included on Ellingham diagrams, though this could usefully be expanded to emphasize the industrial relevance of these diagrams.

One important point that should be made at an early stage is the necessity to define exactly what change is being considered. The physical states of reactants and products should appear as part of every chemical equation, from the first one onwards, together with a note of the temperature and pressure. It is unfortunate that the recommendations of IUPAC have not been followed, whereby the subscript used to denote a chemical process should be written as a subscript to the Δ symbol and also the standard pressure should be taken as 10^5 N/m². This latter factor could easily have been accommodated in equations by use of a symbol to represent the standard-state pressure.

It is disappointing to find that several errors have crept into this edition, with changes in notation only partly implemented, and references to other sections now incorrect because of alterations that have been made. In addition, there are a number of mistakes in the equations and in the examples given.

Nevertheless, this is still a book to be recommended for the student seeking a sound introduction to the subject.

J. H. DYMOND

Problem Solving with Microbeam Analysis: K. KISS, Elsevier, Amsterdam, 1988. Pages 410. Dfl 255.00

This book attempts to review a whole gamut of analytical techniques, in the fields of optical and laser microscopy and spectroscopy, X-ray spectroscopy, electron diffraction and spectroscopy and heavy-ion probes. It is perhaps inevitable, as the author indicates in the foreword, that the depth to which each technique is covered is not always satisfactory.

Part I of the book is perhaps misleadingly entitled "Theory and Techniques"—the limited coverage of the mathematical background cannot realistically be construed as Theory. For example, I am unconvinced the non-expert reader could understand the principles of electron diffraction from the details given. The Techniques, on the other hand, are comprehensively surveyed, though again a little sketchily. I particularly enjoyed the historical introduction, leading me through the early development of each technique. This theme, repeated in several places, helped place into perspective the logical progression of analytical technique development to its present, profuse nature. The treatment of the techniques, as the author concedes, is reliant on a substantial use of the bibliography for a full appreciation of the details. While accepting the need for conciseness in the context of such a wide-ranging treatment, it is possible to be a touch too concise—some more depth in this section would have been appreciated. I would describe the treatment very much as a practical, non-rigorous guide to the range of analysis techniques available.

In Part II we are treated to a whole series of case studies illustrating the use of the techniques discussed. This again was impressive in its coverage of the range of applications, but as a non-analyst I felt that closer examination of somewhat fewer examples would have benefited the understanding. Apart from a few cases, the presentation was all too brief to give a real flavour of the problem, its solution and importance. This having been said, however, the availability of such a comprehensive case-book is likely to be of use to the practising analyst searching for a clue towards a temporarily intractable problem. Again combination of the sketchy information available in the book with use of the extensive bibliography could well lead, in practice, to a satisfying conclusion and a successful analysis.

In summary, this reviewer was both intimidated and impressed by the range of analysis techniques available and covered in this book. The summaries concluding each section, on the advantages and limitations of each technique, helped clear a path through this veritable forest of alternatives, leading to an awareness of the flexibility available. However, for all but the practising analyst at whom the book is directed, real satisfaction would require a significant amount of further reading.

C. C. WILSON

Gas chromatography—Biochemical, Biomedical and Clinical Applications: R. E. CLEMENT (editor), Wiley Interscience, New York, 1990, Pages x + 393. £70.50

Although it often seems that high-performance liquid chromatography dominates analytical separation methods, over the last 10 years there have been an important series of improvements in the application of gas chromatography (GC) to biomedical and biochemical samples. These developments, primarily in the use of open-tubular columns and coupled mass spectrometric detection, have frequently given gas chromatography a distinct advantage in column efficiency and for qualitative identifications, making it ideal for the examination of complex biological matrices.

These advantages are emphasized in this edited work. The most valuable chapters will be those on the applications of GC. These include GC profiling in biomedical investigations by Rosenfeld, fatty acids and lipids analysis by Muskiet and Van Doormaal, amino-acid separations by MacKenzie and the application of GC-MS to human plasma by Taguchi. More specialized aspects are the role of GC in the identification of micro-organisms by Eiceman, Windig, and Snyder, forensic and clinical toxicology by Beaumier and Leavitt and sport drug testings by Viau. The final chapter covers the analysis of organometallic compounds.

These applications chapters are preceded by a series of introductory chapters on open-tubular columns, modern instrumentation, multidimensional gas chromatography, coupled GC-mass spectrometry, derivatization and methods for qualitative and quantitative analysis. However, these are the weakest part of the book, often being over-simplified, with a number of topics repeated by different contributors. The first chapter in particular contains a number of typographical errors.

R. M. SMITH

Principles of Environmental Sampling: L. W. KEITH (editor) ACS, Washington, 1988 Pages xxiv + 458 \$39.95 (softback), \$64.95 (hardback).

Quality Assurance and Quality Control are concepts which have exploded into the day to day affairs of the majority of analysts within the last couple of years, as evidenced by the enormous interest at Euroanalysis 1990 in the QA/QC session. Methodology and laboratory management are being tackled energetically, with good examples to follow and plentiful advice to be had. But what of the most crucial step in any analysis—the sampling?

The ACS Symposium on Environmental Sampling attempted to summarize thinking not only on *how* to sample, but on *what* to consider when planning the sampling. So this book can be divided into those chapters on the philosophy and logic, definitions and interpretation of QA/QC as applied to sampling (perhaps also including the statistics of sampling), on the one hand, and those on the experience of workers who have struggled with the sampling of inhomogeneous “real” situations such as polluted natural waters, soils, sediments, stack gases, biota, sludges and so on. I feel that the first group of chapters could, with skilful editing, and without loss of information, have been condensed considerably, as there is much repetition and generalization which tires the reader and buries the message under a profusion of words. The second group of chapters, in contrast, constitutes fascinating reading from which much benefit can be extracted by the reader, learning from the difficulties encountered, though not always overcome, by many analysts experienced in handling environmental samples. As the good points far outweigh the minor criticisms the book can be strongly recommended for all practising analysts—and the price is very reasonable.

I. L. MARR

Carbon, Nitrogen and Sulphur Pollutants and their Determination in Air and Water: J. GREYSON, Dekker, New York, 1980 Pages xi + 376, \$99.75, (\$119.50 outside North America)

There are several puzzling features of this book. First, the title and contents are totally mismatched, with very few pages devoted to actual determinations, and very many to an attempt to cover all other aspects of chemistry remotely associated with these three elements. Thus over 50 pages take us through the chemistry of these elements, including lengthy yet sketchy accounts of various biochemical pathways, and a further 40 deal with reactions taking place in aqueous and atmospheric environments. Then there are inadequate chapters on various analytical techniques, with brief summaries of applications to environmental samples: 19 pages on theory of titrations and 3 on actual methods, 8 pages on thermodynamics of electrochemical cells and half a page on the silver sulphide electrode, with not a mention of the other kinds of ISEs, and so on.

The second puzzle is simply “who is the book written for?” The author suggests that it is for the engineer or chemist who finds himself having to do some analyses. Such a reader will need real help which he will not find in this book. While the cover note says “this practical reference details procedures available” the contents certainly do not. The book might have been written as a general text for introductory environmental chemistry students, but it repeats too much material which is presented much more clearly in other texts, and the price at \$100 is anyway far beyond the student’s pocket.

The third puzzle is the large number of mistakes: *n*-octane as a GC stationary phase¹, fluorescence emission at shorter wavelengths than the excitation¹, TLC with the spots *descending*¹, $\text{CO}_2 + \text{HCO}_3^- + \text{CO}_3^{2-}$ summing to 120% at pH 8¹, BOD determinations requiring solutions to be *oxygen-saturated*¹, spectrophotometry possible *only between 30% and 60%T* when most modern instruments easily measure 1%T¹, “practically all modern spectrophotometers make use of *photomultipliers*” except all those (very many) which use silicon diodes¹, *p-rosaniline* instead of *pararosaniline* (there is no group to be *para*), and so on.

A puzzling book indeed, but not one that I can recommend, for any class of reader.

I. L. MARR

Chemical Demonstrations—A Sourcebook for Teachers, Volume 1, 2nd Edition: L. R. SUMMERLIN and J. L. EALY JR (editors), ACS, Washington, DC, 1988. Pages xii + 198 \$19.95 (US and Canada), \$23.95 (elsewhere)

Chemical Demonstrations—A Sourcebook for Teachers, Volume 2, 2nd Edition: L. R. SUMMERLIN, C. L. BORGFORD and J. B. EALY (editors), ACS, Washington, DC, 1988. Pages xii + 233 \$19.95 (US and Canada), \$23.95 (elsewhere)

How did *you* become interested in Chemistry? Almost certainly because you had the best kind of teacher—one who aroused your enthusiasm by showing you interesting and exciting chemical changes. Colours! Bright lights! Explosions!!! Remember? The authors of the two volumes of “Chemical Demonstrations” fit nicely into this category themselves. They have chosen over two hundred demonstrations which are designed to be *enjoyed* by students as well as providing subjects for discussion. The experiments cover a wide range of topics—gases, solubility and solution, kinetics and equilibria, oxidation and reduction, colloids, polymers, physical changes, reactions of elements, transition metals and complex ions, and chemical bonding. They range from the very simple proof that air is a substance (Empedocles, 440 BC) to the highly intricate oscillating reactions (which follow chaotic dynamics under certain conditions). For each demonstration the procedure is described in detail, there follows an explanation together with teaching tips and questions. Many perennial favorites, e.g., the starch-iodine clock reaction, are included but for safety reasons the authors have (clearly regretfully) had to exclude several of the more dramatic classical experiments. The few obvious errors intrigue rather than confuse. One ponders over the likelihood of the “light red solution of NH_4^+ (aq)” (Vol. 1, p. 95) and over the electron-deficient

O. C. MUSGRAVE

DNA in Forensic Science—Theory, Techniques and Applications: J ROBERTSON, A. M. ROSS and L. M. BURGOYNE (editors), Ellis Horwood, Chichester, 1990 Pages xiii + 197 £39.95

DNA analysis of blood or tissues to identify a donor is of interest to forensic scientists and lawyers. Many, however, may feel that their knowledge of the scientific principles and techniques is inadequate or out of date. If so then this volume should be of considerable help.

The first two chapters describe the nature and occurrence of DNA in tissues and the way information is stored and used in the cell. This section is particularly good at describing the scale of the human genome and putting the various components into context. There are some errors in Table 1.2 in the CU* and AU* amino-acid allocations in the genetic code table and in the descriptions of the different regions of the genes represented in Figs. 1.9 and 1.11.

Having covered the groundwork the next chapters deal more specifically with forensic aspects such as the effects of the environment on, and the means of recovering useful DNA from, various types of forensic sample. The various steps in the DNA analyses are described and the bases of the variations between different individuals are explained. Although the polymerase chain reaction is cited frequently as an important alternative method of analysis and is described in the glossary and in part in various places throughout the book, a more detailed description of the process would be welcome. The application of DNA analysis to paternity testing is considered in a separate chapter.

The final chapter explores the use of this new technology in the courts and some of the legal implications.

The book is clearly written with many illustrations, a glossary, an index and is well supported with references. It should be useful to lawyers and others with an interest in DNA "fingerprinting" as well as to scientists wishing to update their knowledge.

BROMIDE DETERMINATION AT NANOGRAM LEVELS BY LASER-EXCITED MOLECULAR FLUORESCENCE SPECTROSCOPY IN A GRAPHITE FURNACE*

JAMIL ANWAR,† JESÚS M. ANZANO‡ and JAMES D. WINEFORDNER§

Department of Chemistry, University of Florida, Gainesville, Florida 32611, U.S.A.

(Received 5 March 1991. Accepted 22 April 1991)

Summary—Bromide was determined at nanogram levels by introducing the sample with excess aluminum into a graphite furnace and measuring the laser-excited molecular fluorescence of aluminum bromide. Experimental parameters including excitation and fluorescence wavelengths, thermal conditions and aluminum concentration were optimized. Effects of concomitant ions and of barium hydroxide concentration, as a matrix modifier, have also been checked. The analytical reliability of the described procedure was checked by determining the bromide content in a standard reference material.

Laser-excited fluorescence spectroscopy (LEFS) is one of the most sensitive techniques for ultra-trace element determinations. Detection limits in the femtogram range have been achieved for a number of elements when the technique was employed with high temperature atomizers.¹⁻³ However, LEFS has not been fully exploited for the determination of non-metals mainly because their resonance lines lie in the vacuum UV region and intense laser sources are not yet available in this spectral region. This limitation in the case of non-metals has not only restricted the use of fluorescence methods but has also been considered a serious obstacle in absorption techniques. As an alternative, to achieve good detection limits, research workers developed a number of indirect methods based on molecular emission and absorption of non-metals.⁴

Halogens, an important group of non-metals, have been determined at trace levels by using such molecular emission and absorption methods.^{5,6} Preliminary investigations concerning the quantitative determination of halogens by molecular emission in cool flames were carried out by using copper and indium halide compounds.^{7,8} Later, the use of molecular emission cavity analysis (MECA) improved their detection limits significantly.⁹ Molecular emis-

sion of halogen-containing diatomic molecules in high temperature arcs¹⁰ and microwave-induced plasmas¹¹ were also employed for the determination of halogens. Molecular absorption spectroscopy (MAS) has also been used for the determination of halogens; hence, absorption of halogen-containing diatomic molecules, formed in a graphite furnace, was measured. Different research groups achieved detection limits in the nanogram range for various halogens by MAS.^{12,13}

Molecular emission of halogen-containing molecules¹⁴ in flames and plasmas, and molecular fluorescence of alkaline-earth halides¹⁵ and heavy metal fluorides¹⁶ have been the subject of several physical studies. Recently, fluorescence of such diatomic molecules as indium chloride, magnesium fluoride and aluminum bromide for the analytical determination of halides has been reported.¹⁷ Dittrich and coworkers¹⁸ used a modified graphite furnace for measuring the laser-excited fluorescence of the diatomic molecules of halides with Al, In and Mg.

In the present work, bromide is measured by introducing the sample with an excess of aluminum into a standard graphite furnace tube and measuring the laser-excited non-resonance fluorescence of aluminum bromide. Experimental parameters including excitation and fluorescence wavelengths, thermal conditions and concentration of added aluminum are optimized. The use of barium hydroxide as a matrix modifier and the presence of other concomitant ions have also been evaluated. The analytical usefulness of the described method is evaluated

Table 1. Experimental conditions used for measuring the fluorescence of aluminum bromide

Maximum energy obtained from the dye laser after doubling	20 μ J
Dye-laser wavelength used (based on best signal/noise)	278.85 nm
Fluorescence wavelength (at which maximum signal obtained)	284.50 nm
Monochromator slitwidth (based on best signal/noise)	500 μ m (band width = 1 nm)
Photomultiplier tube voltage	-1000 V
Sample drying conditions	150°, 20 sec, Ar flow = 1.5 l./min
Sample ashing conditions	600°, 15 sec, Ar flow = 1.5 l./min
Sample vaporizing conditions	2600°, 2 sec, Ar flow = 0

by determining bromide content in standard samples of wheat flour.

EXPERIMENTAL

Reagents

A $1 \times 10^{-2}M$ solution of Coumarin 540 dye (Exciton Inc. Dayton, 45431) in ethanol was used in the dye laser. Standard solutions of bromide and aluminum were prepared from sodium bromide and aluminum nitrate of 99.99% purity (Aldrich Chemical Co. Wis. 53233) respectively. A $1 \times 10^{-2}M$ solution of barium hydroxide (98+ %, Aldrich Chemical Co.) was used as matrix modifier.

Instrumentation

The dye laser was pumped by a nitrogen laser (7 mJ, 337.13 nm). The laser beam from the dye laser was doubled by a doubling crystal "KDP", passed through the UV filter and then focused into a graphite furnace tube via a pierced mirror.¹⁹ The molecular fluorescence produced after vaporization of the sample in the graphite furnace was collected by the pierced mirror and focused into the entrance slit of the monochromator. The signal from the PMT photomultiplier tube was processed by a boxcar integrator and recorded on a strip chart recorder. A schematic set up of the apparatus used has been described in earlier work.²⁰

Procedure

A 10- μ l aliquot of bromide sample containing bromide and aluminum (in w/w ratio of 2×10^2) was injected into the graphite furnace with a micro syringe. This was followed by the injection of 10 μ l of a $1 \times 10^{-2}M$ solution of barium hydroxide. After introducing the sample and matrix modifier, a controlled heating program of drying, ashing and vaporizing was employed. The experimental conditions used in this work are given in Table 1.

RESULTS AND DISCUSSION

Wavelengths and slitwidth

In previous work,¹⁸ the fluorescence of aluminum bromide was measured at the resonance wavelength *i.e.*, 278.91 nm, but in our system due to severe scattering problems the measurement of resonance fluorescence was not possible; therefore, measurements were made at the non-resonant wavelength. As the literature reveals,²¹ a number of excitation schemes in both the visible and ultra violet regions of the spectrum are possible for measuring the molecular fluorescence of aluminum bromide. The strongest molecular bands representing various transitions of aluminum bromide are closely spaced in the region 279–286 nm.²¹ In the present work, the maximum fluorescence intensity was found by exciting the sample with a laser beam tuned at 278.85 nm (the 0,0 transition) and measuring the fluorescence at 284.5 nm. A number of attempts were made to measure the fluorescence at other possible wavelengths, including 422.5 nm (the 0,0 transition in visible region), after exciting the sample at 278.5 nm, but the fluorescence intensity was far less in all cases than that obtained at 284.5 nm. Hence, all the fluorescence measurements were made at this wavelength.

The effect of spectrometer slitwidth on the signal to noise ratio was evaluated over a range of slitwidths from 100–1000 μ m. The best signal to noise ratio was obtained at 500 μ m slitwidth (=1 nm band width). Greater slitwidths did not improve the signal to noise ratio and so all of the present work was done at a 500- μ m slitwidth.

Thermal conditions

After introducing the sample (10 μ l) and matrix modifier (10 μ l) into the graphite furnace tube, the contents were dried at 150° for 20 sec

Fig. 1. Effect of vaporization temperature. [10 ng Br/10 μ l; 2 μ g Al; 17 μ g Ba(OH)₂.]

and then ashed at 600° for 15 sec. Drying and ashing time intervals were critical but for the samples larger than 10 μ l an additional 5 sec of drying and ashing at the respective temperatures yielded better results. There was an argon flow of 1.5 l./min during drying and ashing. Higher temperatures and variation in gas flow-rate during drying and ashing did not cause any effect on the signal. Finally, the contents were vaporized at 2600° for 2 sec without any argon flow. The vaporization temperature was optimized by varying it from 1500–3000°. As shown in Fig. 1, the fluorescence intensity increased at about 2000° and reached its maximum at 2600°. A further increase in vaporization temperature did not give any significant increase in the signal. Similarly no noticeable effect resulted by increasing the vaporization time from 2 to 3 sec; rather it increased the noise level after recording the fluorescence signal. After every five sample runs, the graphite furnace was heated to 3000° to eliminate memory effects.

Effects of barium hydroxide

Use of barium hydroxide as a matrix modifier in the determination of bromide by measuring the fluorescence¹⁸ or absorption¹³ of aluminum bromide has already been evaluated by others. It has been suggested¹⁸ that barium ions reduce the loss of bromide as hydrogen bromide during drying and ashing stages and assist the formation of aluminum bromide in the gaseous phase. In our studies a problem arose with the addition of barium hydroxide to a bromide sample which already contained excess aluminum nitrate; precipitation of aluminum hydroxide resulted which not only reduced the

aluminum concentration in the sample but also posed problems in sample injection due to heterogeneity of the solution. To overcome this problem, the barium hydroxide aliquot was directly introduced into the furnace after the sample injection. The influences of the amount of barium hydroxide on the aluminum bromide and in the blank signals are shown in Fig. 2. The best fluorescence sensitivity was achieved by using a bromide to barium hydroxide (w/w) ratio of 1:1700. Further increase in the quantity of barium hydroxide depressed the fluorescence signal significantly probably due to the formation of aluminum hydroxide; therefore, this ratio of bromide to barium hydroxide was used throughout.

Effect of aluminum concentration

The effect of aluminum was studied by adding different quantities of aluminum to a fixed quantity of bromide and barium hydroxide. As can be seen in Fig. 3, the fluorescence intensity of aluminum bromide reached a plateau for the ratio of the amount of aluminum to amount of bromide which exceeded about 200-fold. Aluminum had no appreciable effect on the blank signals.

Effect of concomitant ions

The effect of the number of concomitant ions on the determination of bromide by the described procedure was evaluated. These ions were added in a ten-fold excess of bromide as their sodium salts except iodide and nitrate which were added as their potassium salt. As shown in Table 2 among the halogens, only

Fig. 2. Effect of Ba(OH)₂ concentration. 10 ng Br/10 μ l; 2 μ g Al. (---- = blank).

Fig. 3. Effect of Al concentration. 10 ng Br/10 μ l; 17 μ g Ba(OH)₂. (---- = blank).

fluoride increased the fluorescence signal to a considerable extent (10%) which may be due to either bromide contamination in the fluoride salt or more probably to a transition of fluoride in the observation region.²¹ The other ions which depressed the signal of aluminum bromide to a noticeable extent were phosphates and carbonate. This was probably because aluminum and barium also form stable compounds with these ions. An increase in the amount of barium and aluminum ions did not show any significant effect on the interferences due to carbonate and phosphate. Nitrate, acetate, thio-sulfate, sulfite and sulfate did not cause much variation in the fluorescence signal.

Blank signals

Extra large blank signals were seen to appear occasionally. These were mainly due to contamination in reagents, water, glassware and the

Fig. 4. Calibration curve for bromide. λ_{ex} = 278.5 nm; λ_{fl} = 284.5 nm.

graphite tube. Higher quantities of aluminum and barium hydroxide also contributed blank signals probably due to the formation of stable solid particles in the graphite furnace. However, to minimize the blank signals, doubly-demineralized distilled water and ultra-pure reagents were used. The blank signals were significantly controlled by using adequate quantities of barium and aluminum ions (see Figs. 2 and 3). The graphite tube was replaced after every fifty bromide samples.

Calibration

Under optimum conditions, a linear calibration graph in the range 0.4–2.0 ng of bromide, shown in Fig. 4, with a correlation value of 0.996, was obtained. The relative standard deviation, calculated for nine blank signals, was 5.6%; a detection limit (defined as a signal equal to three times the standard deviation) of 45 pg of bromide was obtained. The calibration graph remained linear up to 100 ng of bromide.

Bromide in standard material

Analytical applicability of the described procedure was evaluated by analyzing the standard sample of wheat flour (from NIST, USA). A known weight of the sample (\approx 200 mg) was decomposed by slow digestion with nitric acid. The desired quantity of aluminum was added and the contents were diluted to a known volume. Aliquots of the sample solution (10 μ l) were injected into the graphite furnace and the fluorescence of aluminum bromide was measured. The bromide content was calculated by comparing the signal with the calibration graph. The average analytical result was in good agreement with the reported value (Br found: 8.85 μ g; reported: 9.00 μ g/g).

Table 2. Effect of concomitant ions on the fluorescence of aluminum bromide

Concomitant ion	Added as	% Recovery
chloride	sodium	102
fluoride	sodium	110
iodide	potassium	101
carbonate	sodium	94
sulphate	sodium	102
phosphate	sodium	92
sulphite	sodium	92
acetate	sodium	98
nitrate	potassium	100
hyd. phosphate	sodium	93
thiosulfate	sodium	97

Signal from 10 ng Br/10 μ g was considered 100%.

Each ion was added in ten fold excess of Br in weight.

CONCLUSION

Bromide at nanogram levels, was determined by using laser-induced molecular fluorescence of aluminum bromide in the graphite furnace. Barium hydroxide was used as a matrix modifier in this work. The parameters, including quantities of aluminum and barium, thermal conditions, excitation and fluorescence wavelengths, and slitwidth, were optimized. A detection limit of 45 pg was obtained under optimum conditions. Among the concomitant ions, only fluoride and phosphate slightly interfered with the determination. The utility of the method was evaluated by determining the bromide content in a standard sample of wheat flour. The analytical results obtained were in good agreement with reported values.

(Received 1 March 1991. Revised 19 April 1991. Accepted 25 April 1991)

Summary—Cobalt-phthalocyanine modified carbon-paste electrodes are shown to catalyze the electro-oxidation of organic peroxides. Cyclic voltammetry offers useful insights into the catalytic behavior. Such behavior is exploited for developing an effective amperometric detection scheme for butanone peroxide, cumene hydroperoxide and tert-butyl hydroperoxide with optimum response at a potential of +0.70 V (*vs.* Ag/AgCl). Highly sensitive and stable flow injection measurements, with detection limits of 2.4–8.3 ng and relative standard deviations of 1.7–1.8% ($n = 30$), are reported. Applicability to measurements in drinking water is illustrated.

The determination of low levels of organic peroxides is of considerable importance due to their widespread use in various industries. In addition, there is growing environmental interest in the identification and quantitation of organic peroxides in drinking water in connection with ozonation disinfection processes.¹ Organic peroxides and hydroperoxides may be formed in water when ozone reacts with natural organic substances and may exhibit adverse health effects. The D.C. polarographic behavior of organic peroxides was explored during the 1960s,^{2,3} and was used to quantitate millimolar concentrations of these compounds. However, methods based on solid electrodes (that are not susceptible to oxygen interferences) may be more desirable for on-line monitoring and other sensing applications. Unfortunately, the anodic oxidation of organic peroxides suffers from high overvoltages.

This paper describes an electrocatalytic chemically modified electrode (CME) system for the voltammetric and amperometric quantitation of organic peroxides. Chemically modified electrodes, containing a surface-bound mediator, can be used to substantially lower the overvoltage for the redox processes of numerous

compounds.^{4,5} In particular, the well-known catalytic activity of metallophthalocyanines has been exploited for facilitating the detection of a wide variety of redox systems.^{6–8} Baldwin and coworkers have incorporated cobalt phthalocyanine (CoPC) into carbon paste electrode (CPEs) for catalyzing the electrooxidation of hydrazines,⁶ keto acids⁷ or sulfhydryl compounds.⁸ Similarly, the faster rates of electron transfer of hydrogen peroxide at CoPC-CMEs,^{9,10} may indicate electrocatalytic activity toward other (organic) compounds containing the peroxide bond. The following sections explore this possibility and its utility for sensitive amperometric detection of organic peroxides.

EXPERIMENTAL

Apparatus

Cyclic voltammetry was performed with a PAR EG&G Model 264A voltammetric analyzer, in conjunction with a Houston Omniscrite X-Y recorder. A Bioanalytical Systems (BAS) Model VC-2 electrochemical cell (10 ml) was employed in these experiments. The working electrode, the reference electrode (Ag/AgCl, Model RE-1, BAS), and the platinum wire auxiliary electrode were inserted into the cell through holes in its Teflon cover.

*Author for correspondence.

Fig. 1. Cyclic voltamperograms recorded at the ordinary CPE [(a) and (b)] and 1% CoPC-CPE [(c) and (d)], in the absence [(a) and (c)] and presence [(b) and (d)] of 2.8 mM butanone peroxide. Supporting electrolyte, 0.05M potassium nitrate; scan rate, 50 mV/sec.

The flow injection system consisted of the carrier reservoir, a Rainin Model 5041 sample injection valve (20 μ l loop), interconnecting Teflon tubing and a thin-layer amperometric detector (Model TL-4, BAS). A gravity feed of the carrier was used. A PAR EG&G Model 173 Potentiostat/Galvanostat and a Houston Omniscrite chart recorder were used in the flow injection experiments.

Cobalt-phthalocyanine modified carbon paste electrodes were prepared by thoroughly hand mixing CoPC with a slurry of graphite powder (Acheson 38) and mineral oil (Aldrich) (60:40% w/w graphite: oil). Electrodes containing 1 and 10% (w/w) CoPC were used in the batch and flow experiments, respectively. Fresh surfaces were smoothed on a computer card.

Reagents

All solutions were prepared from doubly distilled water. Most of the organic peroxides were purchased from Aldrich, with the exception of tert-butyl peroxyacetate (Atochem, Buffalo). Acetonitrile (LC grade, Aldrich) was used to facilitate the dissolution of some water-insoluble peroxides. All measurements were performed with a 0.05M potassium nitrate (Mallinckrodt) supporting electrolyte. Tap waters were collected in the NMSU laboratory.

RESULTS AND DISCUSSION

Cyclic voltammetry

Figures 1 and 2 show typical cyclic voltamperograms for butanone peroxide and cumene hydroperoxide, respectively, at both plain (b)

and CoPC-containing (d) CPEs. Also shown [curves (a) and (c)] are the corresponding response of the blank (0.05M potassium nitrate) solution. At the conventional CPE, these organic peroxides are not oxidized under the experimental conditions used. The CoPC modifier, in contrast, catalyzes the oxidation of butanone peroxide and cumene hydroperoxide, as is evident from the defined anodic peaks at +0.55 and +0.35 V, respectively. The oxidation process is irreversible. Similar to other CoPC-CMEs,⁶ the background currents are similar to those of the plain surface [(c) vs. (a)], although the Co(II)/Co(III) oxidation process is known to occur around +0.4 V. The catalytic cycle appears to involve a chemical reduction of the cobalt(III) by the peroxides, with subsequent electrochemical oxidation of the cobalt(II) to cobalt(III). In order to obtain and maintain the catalytic current at the level shown in Figs. 1 and 2, the CoPC-CME needed to be exposed to cathodic conditions. A similar requirement was reported for other CoPC-CMEs;^{11,12} it is not clear whether such cathodic activation involves only a change in the oxidation state of the cobalt. (Redox processes of the phthalocyanine ring have also been claimed to affect the catalytic cycle¹¹) The data of Figs. 1 and 2 were thus obtained after holding the electrode at -0.2 V for 30 sec. The use of longer periods (initially) resulted in even larger catalytic currents. Continued cycling of the CoPC-CME in the peroxide solutions resulted in a slow decrease of the peak (down to 60% of its original value over the first eight cycles), followed by a stable response. However, highly stable and large catalytic peaks were obtained for the same peroxides over a

Fig. 2. Cyclic voltamperograms recorded at the ordinary CPE [(a) and (b)] and CoPC-CPE [(c) and (d)] in the absence [(a) and (c)] and presence [(b) and (d)] of 2.7 mM cumene hydroperoxide. Other conditions as in Fig. 1.

Fig. 3. Hydrodynamic voltammograms for $4 \times 10^{-5} M$ cumene hydroperoxide (\blacktriangle), $2.8 \times 10^{-4} M$ butanone hydroperoxide (\bullet), and $4.5 \times 10^{-4} M$ tert-butyl hydroperoxide (\blacksquare). Flow rate, 1.6 ml/min, electrolyte and carrier, $0.05 M$ KNO_3 .

prolonged period (2 hr) of continued scanning at a slower (10 mV/sec) scan rate and with a more negative (-0.35 V) potential limit (to allow cathodic regeneration of the catalyst). The catalytic activity was also not affected by the solution pH over a wide pH range. Unlike the catalytic detection of other compounds (e.g., 11,12), alkaline media is not required for obtaining the electrocatalytic response. For example, no change in the peak current and potential of cumene hydroperoxide was observed by changing the solution pH between 3.5 and 9. However, the catalytic response disappeared under more acidic conditions.

Similar CV experiments were performed with other organic peroxides. A large catalytic current was observed for the tert-butyl hydroperoxide ($E_p = 0.52$ V), with no response at the plain CPE. Benzoyl peroxide, in contrast, yielded anodic peaks at both CoPC- and plain CPEs, while these electrodes exhibited no response for tertbutyl peroxyacetate (not shown). Apparently, the catalytic activity is not universal toward all compounds containing the peroxide bond. Such differences in the behavior among classes of peroxides can offer improved selectivity.

Flow analysis

The electrocatalytic behavior can be exploited for developing a highly sensitive flow detection scheme for organic peroxides. Such amperometric scheme should benefit the monitoring of chromatographic effluents, the automated flow-injection analysis (FIA) of discrete samples, or on-line assays of environmental matrices.

Anodic detection should be particularly suitable for this task, as it eliminates oxygen interferences and the need for deaeration associated with reductive flow measurements of peroxides.¹¹ Figure 3 shows hydrodynamic voltammograms (HDVs), obtained under flow injection conditions, for the oxidation of butanone peroxide, cumene hydroperoxide and tert-butyl hydroperoxide. For all three compounds, the oxidation starts in the vicinity of $+0.5$ V, with a maximum response around $+0.7$ V. Note also the peak-shaped HDV in the case of butanone peroxide. Such a peak-shaped response was reported previously for CoPC-based flow detectors. Based on the data of Fig. 3, an operating potential of $+0.7$ V was used in all subsequent work. In addition to the operating potential, the amperometric response of the CoPC-detector is influenced by the flow-rate. A gradual (25%) decrease of the FIA response for $2.8 \times 10^{-3} M$ butanone peroxide was observed on increasing the flow-rate from 0.4 to 3.1 ml/min (not shown).

Figure 4 illustrates FIA peaks for increasing (micromolar) levels of different peroxides. The CoP-CPE detector responds very rapidly to

Fig. 4. Detection peaks at 10% CoPC-CPE for successive increments of organic peroxides concentration: [A (a)-(e)] $1.35 \times 10^{-5} M$ steps of cumene hydroperoxide; [B (a)-(f)] $7 \times 10^{-5} M$ steps of butanone peroxide; [C (a)-(f)] $2.25 \times 10^{-5} M$ steps of tert-butyl hydroperoxide. Applied potential, $+0.7$ V; flow rate, 1.2 ml/min. Other conditions are as in Fig. 3.

Fig. 5. Detection peaks for $1.3 \times 10^{-5} M$ (A) cumene hydroperoxide and (B) butanone peroxide. Flow rate, 1.4 ml/min. Other conditions are as in Fig. 4.

such dynamic changes in the peroxide concentration. The peak widths are about 5 sec allowing high injection rates (of *ca.* 240 samples/hour). Calibration plots, constructed from these injections, were linear over these entire ranges with slopes of 318, 61.8, 85 nA/mM for cumene hydroperoxide, butanone peroxide and tert-butyl hydroperoxide, respectively (correlation coefficients = 0.996, 0.999 and 0.999).

Amperometric peaks for injections of solutions of $1.3 \times 10^{-5} M$ of cumene hydroperoxide and butanone peroxide were used to estimate the detection limits (Fig. 5). Favorable signal-to-noise (S/N) ratios of 48 and 10 were observed at this level. Based on a S/N of 3, these data correspond to detection limits of $8 \times 10^{-7} M$ (2.4 ng) and $4 \times 10^{-6} M$ (8.3 ng), respectively.

The CoPC-CPE flow detector also offers a high degree of reproducibility. Fig. 6(b) shows 30 repetitive injections (within 10 min) of tert butyl-hydroperoxide (A) and butanone-peroxide (B) solutions. Also shown (for comparison) are analogous measurements at the plain CPE (Fig. 6(a)). The significantly larger FIA response of the CME remained unchanged during this prolonged series (with the last injection producing more than 96–99% of the current exhibited by the first one). The relative standard deviations of these 30 successive runs

Fig. 6. Detection peaks for repetitive injections of $4.5 \times 10^{-3} M$ tert-butyl hydroperoxide (A) and $2.8 \times 10^{-3} M$ butanone peroxide (B), at ordinary (a) and CoPC (b) CPEs. Conditions, as in Fig. 4.

were 1.7(A) and 1.8 (B)%. As expected for CoPC-CME detectors,⁶⁻⁹ such high reproducibility is obtained only after an initial (3–5 min) exposure of the fresh surface to the flowing solution, during which 10–15 analyte injections are made and a gradual current decrease and stabilization is observed. While no cathodic activation (of the catalyst) was required under the present FIA conditions, operation at higher potentials may lead to passivation of the catalyst.

Reliable measurements of organic peroxides in drinking water supplies are receiving considerable attention in connection with the growing interest in ozonation treatment processes. The suitability of the CoPC-CME for flow measurements of peroxides in drinking water is illustrated in Fig. 7. Only small FIA peaks are observed for the original (unspiked) water (A), indicating a low level of oxidizable constituents. (Since the sample did not undergo ozonation treatment, these peaks are not due to peroxides.)

Fig. 7. Measurements of organic peroxides in drinking water: detection peaks for the unspiked sample (A), and upon spiking this sample with 2.7mM butanone peroxide (B), 4.0mM tert-butyl hydroperoxide (C) and 2.6mM cumene hydroperoxide (D). Applied potential: +0.6 V; flow rate: 1.2 ml/min; carrier and sample electrolyte: 0.05M KNO_3 .

In contrast, large and sharp peaks are observed upon spiking this sample with butanone peroxide (B), tert-butyl hydroperoxide (C) and cumene hydroperoxide (D).

In conclusion, the utility of CoPC-modified CPEs for amperometric detection of organic peroxides has been demonstrated. The electrocatalytic surfaces offer marked decreases in overpotentials for the organic-peroxide oxidation. The use of these electrodes in liquid chromatography with electrochemical detection (LCEC) should be attractive for highly selective and sensitive assays of peroxide mixtures. Reverse-phase chromatographic columns have been useful for separating closely-related peroxides.¹³ Such LCEC application should benefit from the recently introduced polymeric CoPC-CMEs,¹⁴ that offer higher stability and compatibility in organic phases (compared to CoPC-CMEs). FIA procedures, in contrast, should be attractive for rapid screening of drinking water. Besides analytical schemes, the diagnostic power of cyclic voltammetry may be useful for gaining insights into ozonation processes leading to the formation of organic peroxides. The nature of these processes and the identity of the resulting peroxides are currently

not clear. The CoPC-containing pastes can be easily adapted to ultramicroelectrode configurations,¹⁵ capable of characterizing and analyzing resistive media such as low-ionic strength drinking water. In addition, the ultrafast scanning capability of such electrodes should be useful for following the fate of peroxide species following ozonation. Cobalt phthalocyanine may mimic the enzymatic activity of horseradish peroxidase, HRP (which is a heme-containing glycoprotein). Work in these laboratories is progressing toward the development of bio-sensing assays for organic peroxides at HRP-based electrodes.

DETERMINATION OF BARIUM, STRONTIUM AND NINE MINOR AND TRACE ELEMENTS IN IMPURE BARITE AND STRONTIANITE BY INDUCTIVELY-COUPLED PLASMA ATOMIC-EMISSION SPECTROMETRY AFTER DISSOLUTION IN DISODIUM ETHYLENEDIAMINETETRAACETATE*

J. G. SEN GUPTA

Geological Survey of Canada, Ottawa, Ontario, Canada

(Received 26 December 1990. Revised 18 March 1991. Accepted 29 March 1991)

Summary—A new method has been developed for the determination of barium, strontium, silicon and nine minor and trace elements of barite and strontianite associated with gangue materials. It involves dissolution of the sample by boiling under reflux with a concentrated solution of disodium ethylenediaminetetraacetate (EDTA-2Na) in the presence of ammonium hydroxide. Barite and strontianite dissolve quantitatively under this condition, and any associated silicate and sulphide mineral impurities, remaining insoluble, are filtered off and ignited to constant weight in a platinum crucible. Silica is determined gravimetrically by heating the residue with concentrated sulphuric and hydrofluoric acids, followed by ignition to oxides. The residue is fused with sodium bisulphate and dissolved in dilute sulphuric acid. After suitable dilution of the EDTA-2Na solution, Ba, Sr, Be, Co, Cr, Cu, La, Ni, V, Yb and Zn are determined by inductively-coupled plasma atomic-emission spectrometry (ICP-AES). The bisulphate fusion product is separately analysed by ICP-AES, and the elements found are combined with those obtained from the EDTA-2Na solution. The replicate values of this work compare well with each other and with other values obtained by independent methods.

Recently it has been necessary at the Geological Survey of Canada to analyse a large number of samples of impure barite and strontianite where barium and strontium contents may vary from 0.1 to 40%. Although it is not hard to attack samples containing low amounts of barium or strontium as sulphate by fusion methods,^{1,2} samples containing high barium or strontium as sulphate present difficulties. In these cases, the normal procedure for attack of the sample by fusion with sodium carbonate or lithium metaborate fails because of incomplete decomposition in the case of the former³ and reprecipitation of barium sulphate in solution in the case of the latter.⁴ It was therefore necessary to look for an alternative method for dissolution of these materials.

In previous work,³ an ammoniacal solution of the disodium salt of ethylenediaminetetraacetate has been used for quantitative dissol-

ution of pure barite prior to determination of barium and strontium by flame atomic-absorption and rubidium by graphite-furnace atomic-absorption spectrometry. In the present work, the same procedure with some modification was used for decomposition of impure barite or strontianite, and from the resulting solutions barium, strontium and several minor and trace elements were determined simultaneously by the application of ICP-AES.

EXPERIMENTAL

Apparatus, operating parameters and standards

The instrument used for ICP-AES measurements, and the operating parameters, plasma conditions and the nature of the calibration standards employed are given in Table 1.

Reagents

A.C.S. grade ethylenediaminetetraacetate (disodium salt, dihydrate) was used for sample dissolution, and a blank solution of the reagent was prepared by dissolving 3 g in 25 ml of water.

Freshly prepared ammonia solution was obtained by passing ammonia gas into 500 ml of

*Invited paper presented at 73rd Canadian Chemical Conference and Exhibition, July 15-20, 1990, Halifax, Nova Scotia. Government of Canada copyrights reserved. Geological Survey of Canada Contribution No. 45890.

water, contained in a 1-litre polyethylene bottle and chilled in ice-cold water, until the volume rose to ~750 ml. The bottle was then tightly closed until used.

Ultrapure water, prepared by reverse osmosis with a Millipore apparatus, was used throughout this work.

Analytical procedure

Accurately weigh 0.1 g of sample into a 150-ml borosilicate beaker, add 60 ml of freshly prepared ammonia solution and 3 g of EDTA-2Na (dihydrate), mix with a glass rod and cover with a watch glass. Place the covered beaker on a hot plate containing an asbestos sheet on its top for even distribution of heat, and boil the solution for 3–4 hr with occasional stirring. Add ammonia solution from time to time to make up losses due to evaporation. Place the covered beaker on a steam bath and allow to stand until the turbidity clears.

Filter through a 5.5-cm Whatman # 40 filter paper and wash with 5% hot ammonia solution.

*Determined gravimetrically from the residue after EDTA-2Na dissolution.

†GSC-XRF (wavelength dispersive analysis of fused disk).

‡Not found.

Evaporate the filtrate to ~20 ml and dilute to 25 ml in a standard flask (solution A). Transfer the residue to a 10-ml platinum crucible, ignite the paper at 450° in a muffle furnace, and finally heat at 1000° to constant weight. Determine silica gravimetrically by volatilization with hy-

drofluoric and sulphuric acids on the sand bath, followed by ignition of the residue in a muffle furnace at 1000° to constant weight. Fuse the residue with 1.5 g of sodium bisulphate, cool and dissolve the salts in 10 ml of water (standard flask) adding 1 or 2 drops of 1:1 sulphuric acid, if necessary, to clear the turbidity (solution B).

Determine barium, strontium and other minor and trace elements (Be, Co, Cr, Cu, La, Ni, V, Yb and Zn) from solutions A (after necessary dilution for high Ba and Sr) and B (without dilution) by ICP-AES with suitable standards for calibration and simultaneous measurement of these elements. Wash the nebulizer with plenty of 5% ammonia solution in between aspiration of sample solutions to avoid internal deposition of salts and clogging.

RESULTS AND DISCUSSION

The results for barium and strontium in 14 impure barite and strontianite samples, as obtained by ICP-AES measurements of the EDTA-2Na fraction (solution A) and the bisulphate fusion product (solution B) are combined and the total values for replicate determinations are given in Table 2. Other values on these two elements obtained by independent methods are

also quoted in Table 2 for comparison. For most samples containing low barium and strontium, reasonably good agreement is noted between replicate ICP-AES values of this work and with other values. Greater scatter of values occurs when the concentration of barium or strontium is high. For ICP-AES measurement, this involved up to 100-times dilution of the original solution to be within the scale of calibration standards. This might have caused some dilution errors. There is also significant difference in other values for these samples containing high barium and strontium. However, the average values of this work for high barium and strontium (range ~28–42%) are generally within 2% of the mean values of those obtained by other methods.

Gravimetric values for silica as found in this work are given in Table 3 and are compared with independent X-ray fluorescence values obtained by wavelength dispersive analysis of fused disks. The agreement between replicate values is found to be excellent. Although there is an agreement between gravimetric and X-ray fluorescence values in most cases, the latter values are higher for some samples.

The results for minor and trace elements (Be, Co, Cr, Cu, La, Ni, V, Yb and Zn) in the

EDTA-2Na fraction (solution A) and the residual fraction (solution B) for the same fourteen samples of Tables 2 and 3 are given in Tables 4–6. In the absence of any reference sample of similar nature or trace element data on these samples by other methods, duplicate values of this work are found to compare well with each other in most cases.

APPLICATION OF CHEMICALLY MODIFIED PROBE-ATOMIC ABSORPTION SPECTROMETRY (CMPAAS)—I. DETERMINATION OF Bi IN COPPER ALLOY AND LEAD BY TRIOCTYLPHOSPHINE OXIDE-COATED TUNGSTEN PROBE-AAS

XU BO-XING, SHENG MING-NENG, HUANG CHAO-BIAO* and FANG YU-ZHI
Department of Chemistry, East China Normal University, Shanghai, 200062, China

(Received 4 October 1990. Revised 26 December 1990. Accepted 24 January 1991)

Summary—A trioctylphosphine oxide (TOPO) coated tungsten probe has been prepared and used for the determination of Bi and the $\mu\text{g/g}$ level in copper alloy and lead. Bismuth is preconcentrated on the probe which is placed in a graphite-cup furnace for AA determination of bismuth. The method has good sensitivity and minimises analysis time. Microgram per gram levels of Bi can be determined with good precision and accuracy.

Trioctylphosphine oxide (TOPO) is a typical organic complexant which has been studied intensively as a chemical modification reagent for modified electrodes.¹⁻³ The TOPO-coated electrodes were used widely for determination of electroactive species by electrochemical stripping analysis, because the TOPO film on the surface of the electrode could selectively accumulate different ions, such as Bi(III), Au(III), U(VI), Cr(VI), *etc.*^{2,4-6} In this paper, we attempt to combine the chemical modification technique with AAS to create a new microanalysis technique. We coated TOPO film onto a tungsten wire probe by adsorption, then directly determined the Bi on the probe by GFAAS after preconcentration by soaking the probe in the test solution for a certain period. Since Bi was preconcentrated under optimal conditions, this method can be used for analysis of different samples having complicated matrices. Also, the W wire probe has the behaviour of a L'vov platform in a graphite cup during atomization. For the determination of Bi, the results show that the detection limit (concentration giving an absorbance equal to three times the standard deviation of the background absorbance) is 0.3 ng/ml and the linear range covers 0.5 ng/ml–20 ng/ml. The RSD for 15 determinations of 4 ng/ml Bi is 6.9%.

EXPERIMENTAL

Apparatus

A Hitachi 180-80 Zeeman AAS with programmable heating unit and printer (Hitachi Co., Japan), and an electromagnetic stirrer (Shanghai analytical instrumentation factory) were used.

Chemicals

Hydrochloric acid, TOPO and ethanol were analytical reagent grade and used as received. Demineralized water was used throughout.

Bismuth stock solution. Dissolve pure Bi metal in nitric acid and dilute it with dilute nitric acid solution. A bismuth working solution ($\mu\text{g/ml}$ level) is prepared by diluting the stock solution with 1M hydrochloric acid.

Preparation of TOPO coated tungsten probes

Several researchers reported that preparation of a TOPO modified film was very simple and easy, either by covalent attachment or by adsorption.^{3,5,6} We prepared the modified probe by adsorption. The tungsten probe was made by twisting a W wire of 0.5-mm diameter into a coil (Fig. 1). The W probe was held on the arm of an automatic sampler (Fig. 2) and immersed into 0.1M TOPO-ethanol solution for 5 sec. Then the W probe was raised from the TOPO solution and moved into the graphite cup atomizer by turning the arm towards the cup. The

Fig. 1. Tungsten probe. 1. Probe coil. 2. Metallic sleeve.

probe was heated at 120° for 18 sec to evaporate the solvent and make a thin film on the surface of the W probe coil.

Procedure

Add 20 ml of hydrochloric acid acidified test solution to a 50-ml plastic beaker and stir the solution at about 300 rpm. Immerse the TOPO coated probe into the test solution for 1 min to extract trace Bi. Replace the test solution with a 0.1M hydrochloric acid solution containing $20 \mu\text{g/ml Ni}^{2+}$ and allow the probe to soak for 5 sec to wash away the test solution drop which stuck onto the coil during the previous immersion. Turn the arm and move the probe directly into the graphite cup atomizer. Determine the Bi preconcentrated in the TOPO layer under the following conditions:

Dry	120°	20 sec
Ash	600°	25 sec
Atomize	2200°	7 sec (stop gas flow)
Clean	2600°	3 sec
Ar gas flow rate		100 ml/min

RESULTS AND DISCUSSION

Effect of hydrochloric acid concentration

The HCl concentration in the test solution has a significant effect on the preconcentration of Bi, because the interaction of metal ions with TOPO is based on the formation of TOPO

Fig. 2. Schematic diagram of the probe system. 1. W probe. 2. Metallic sleeve. 3. Sampler arm.

Fig. 3. The effect of HCl concentration on the extraction of Bi.

solvates of salts.² The effect of hydrochloric acid concentration on the extraction of Bi is shown in Fig. 3. We chose 1M hydrochloric acid for an optimal acidity for Bi preconcentration.

Concentration of TOPO-ethanol solution

The thickness of the TOPO film on the probe is a very important parameter during extraction of Bi. However, formation of the TOPO-film on the surface is based on immersing the probe into the TOPO solution followed by other procedures that include evaporation and finally atomization. Therefore, discussion of the thickness of TOPO film is rather complicated. The concentration of the TOPO-ethanol solution is the most important factor. Experimental results indicated (Fig. 4) that the highest Bi extraction efficiency was given when 0.01–0.1M TOPO solution was used. We used 0.1M TOPO solution throughout.

Accumulation time

Lexa and Štulík noted that Bi was accumulated into the TOPO layer very quickly without connection to a potentiostat.⁴ Our experiments show that a period of 60 sec is practical and sufficient for enrichment of Bi at the ng/ml level

Fig. 4. The effect of TOPO concentration on the extraction of Bi.

Fig. 5. The effect of preconcentration time on the extraction of Bi. Bi: 4 ng/ml, HCl: 1M, TOPO in ethanol: 0.1M.

(Fig. 5). At more than 3 min, the accumulation rate will be decreased under the experimental conditions.

Charring temperature

To avoid interference of smoke during the AAS measurement of Bi absorbance, the TOPO film on the probe coil must be destroyed by charring and needs to be swept out with Ar flow before atomization. The data show that the optimal charring temperature is 500–600° for 25 sec. Under this charring temperature, the highest absorbance and lowest background were obtained (Fig. 6) and at a temperature over 700°, Bi is seriously lost before atomization. In order to protect Bi from evaporation during the charring step, we used an acidic solution, in which 20 µg/ml Ni²⁺ was contained, as a washing liquid. The probe was soaked in the liquid for 5 sec before the AAS measurement to wash

Fig. 6. Effect of temperature. 1. Background signal. 2. Bi absorbance.

Table 1. Effect of foreign ions on determination of 0.125 µg of Bi in 1M HCl solution

Foreign ion	Added, µg	Bi found, µg	Error, %
Pb ²⁺	125.0	0.127	+1.6
Cd ²⁺	28.1	0.128	+2.4
Co ²⁺	67.1	0.123	-1.6
	25.0	0.124	-0.8
Mn ²⁺	50.0	0.116	-7.2
	25.0	0.125	0
	50.0	0.128	+2.4
Fe ²⁺	50.0	0.123	-1.6
Cu ²⁺	31.3	0.117	-6.4
Fe ³⁺	13.0	0.123	-1.6
	62.5	0.114	-8.8
Al ³⁺	25.0	0.118	-5.8
Sn ²⁺	13.0	0.108	-13.6

off the adsorbed test solution drop, at the same time Ni²⁺ is absorbed on the surface of the probe, which allows a higher charring temperature without loss of Bi.

Effect of foreign ions

The effect of several ions on the determination of Bi was examined by the addition method (Table 1). The foreign ions do not affect the signal appreciably at the levels studied, as the errors all seem to be within the precision of the method, with the possible exception of tin and iron(III).

Determination of Bi in samples and their recoveries

To test the accuracy and precision of this method, we analysed two reference standards of copper alloy and a lead sample. The compositions of the two copper references were for BY-1914-2: Cu 57.91%, Bi 0.00290%, Mn 1.41%, Sb 0.0041%, Fe 0.86%, P 0.0093% and Pb 0.079% and for BY-1902-3: Cu 61.34%, Bi 0.0013%, Sb 0.0043%, Fe 0.14%, P 0.0062% and Pb 0.066%. The procedure is as follows: Weigh a certain amount of copper alloy and lead sample. Dissolve the samples with 1:1 nitric acid solution, evaporate to a small volume, transfer to a standard flask and dilute to the mark with water (BY-1914-2: 5.684 mg/ml, BY-1902-3: 5.139 mg/ml, lead sample: 5.430 mg/ml).

In hydrochloric acid solution, Cu²⁺ can be extracted into the TOPO layer and hence interferes with the extraction of Bi. However, the amount of Cu ion extracted and retained in the TOPO layer can be controlled by changing the HCl concentration. In 0.1–0.3M hydrochloric acid, up to 0.3 mg/ml Cu²⁺ did not interfere

Fig. 7. Effect of HCl concentration on the determination of Bi in copper alloy and lead sample. Curve 1. Copper test solution containing 0.3 mg/ml Cu and 6.0 ng/ml Bi. Curve 2. Lead test solution containing 0.25 mg/ml Pb and 15 ng/ml Bi.

with the recovery of 120 ng of Bi (Fig. 7, Curve 1). It seems that, at low hydrochloric acid concentration, the capability of Cu^{2+} to form a solvate with TOPO is lower than that of Bi. For lead, in 1M hydrochloric acid containing 0.25 mg/ml Pb^{2+} , the highest recovery of 300 ng Bi was obtained (Fig. 7, Curve 2). In order to obtain accurate results in the determination of Bi in real samples, we kept the Cu^{2+} and Pb^{2+} concentrations in the sample solution low. A 1-ml volume of the above copper test solution was taken into a 50-ml plastic beaker and diluted with 0.1M hydrochloric acid to 20 ml, and the trace Bi in the solution was determined by using the standard addition method. In the case of the lead sample, 1 ml of the sample solution was diluted by 1M hydrochloric acid and analysed by the same procedure, because

in 1M hydrochloric acid coexisting Pb^{2+} had minimal interference in the determination of Bi.

The results of Bi determinations are shown in Table 2 and are compared with the results from an ICP method. The addition recoveries of Bi in both copper and lead samples are shown in Table 3.

DETERMINATION OF URANIUM IN TECHNOLOGICAL WATERS BY ION-PAIR LIQUID CHROMATOGRAPHY

IRENA JANČÁŘOVÁ, HANA KŘÍŽOVÁ and VLASTIMIL KUBÁŇ*

Department of Analytical Chemistry, Masaryk University, CS-61137 Brno, Czechoslovakia

(Received 19 November 1990. Revised 11 April 1991. Accepted 16 April 1991)

Summary—U(VI) can be efficiently determined in the range 0.3–10mM after its separation from Th(IV), Zr(IV), Al(III), Fe(III), lanthanides and other ions by ion-pair liquid chromatography on a 3 × 150 mm glass column packed with Separon SGX C18 modified with sorbed ammonium dodecyl sulphate. Traces of uranium can be preconcentrated directly on the analytical column from acidified water solutions and separated from Th, Zr, Al, Fe, lanthanides and other elements, with an enrichment factor of ~100 and recovery of 98 ± 8%, by isocratic or pH or concentration gradient elution with ammonium 2-hydroxy-2-methylpropionate or ammonium citrate solution. Post-column derivatization with 25μM Arsenazo III in 0.1M formate buffer at pH 2.7 is used for detection and quantification.

The need for analytical methods capable of determining uranium at trace and ultratrace levels (from μg to mg per litre) has been steadily growing. Increased awareness of the risks associated with low-level emissions from uranium-handling operations or the storage of spent fuel from nuclear power stations has put increasing demands on uranium determination.

Numerous spectrophotometric and fluorimetric methods based on a wide variety of organic analytical reagents have been developed for the purpose.^{1–6} Only some of these, in particular those using hydroxytriphenylmethane dyes together with cationic surfactants as sensitizing agents,^{2–5} offer the sensitivity needed but their selectivity is usually poor. The low uranium concentrations and large amounts of other dissolved species make existing direct procedures unsuitable for these types of samples.

Better selectivity can be attained by using masking agents or a step such as liquid–liquid extractions^{2,3} or ion-exchange⁷ to separate uranium from interferents and in some cases also to preconcentrate it. However, incomplete separation causes at least a significant impoverishment of the limits of determination and often gives false results.

For these reasons, liquid chromatographic methods^{8–16} have become attractive for the purpose. Metal ions can be separated with either bonded-phase ion-exchangers or dynamically modified reverse-phase (RP) sorbent systems. Among these techniques, ion-pair chromatography with dynamically modified alkylated silica gels has found use for the separation and quantification of a number of metal ions.

U(VI), Th(IV), Zr(IV) and lanthanides can be efficiently separated on C₁₈ alkylated RP silica gel modified by octanesulphonate, pentanesulphonate or butanesulphonate.^{8,9} Slight modification to the standard lanthanides procedure would allow quantification of uranium.^{9–16} Similar systems have also been used for determination of uranium in natural ground waters after its preconcentration on a small (30 mm) C₁₈ RP silica gel enrichment cartridge.¹² The uranium is back-flushed onto an analytical column where it is separated by elution with the ammonium salt of α-hydroxyisobutyric acid (HIBA). Arsenazo III has been used as a sensitive and selective post-column spectrophotometric reagent because the presence of HIBA in the eluent has little effect on the reaction, which can be performed in acidic solution.^{8–16}

During our studies of the ion-pair (IP) HPLC determination of lanthanides, we have found that U, Zr, Th and lanthanides can be efficiently determined in this way after preconcentration on an analytical column, U and Th giving very wide peaks in the region of the peaks for

Yb–Ho^{15,16} under the same experimental conditions. In the present paper, a modified procedure for preconcentration and direct determination of uranium in technological waters from uranium ore processing is presented.

EXPERIMENTAL

Reagents

A stock solution of uranium (0.1734M) was prepared by dissolving analytical grade $\text{UO}_2(\text{NO}_3)_2 \cdot \text{H}_2\text{O}$ in approximately 0.1M nitric acid. Stock solutions of lanthanides and yttrium ($\sim 0.01M$) in *ca.* 0.1M nitric acid were prepared from the nitrates (La, Ce, Pr, Nd, Tb, Ho), oxides (Sm, Er, Tm, Lu, Y) or carbonates (Eu, Gd, Dy, Yb) of reagent grade purity, supplied by Reakhim, Moscow, (except the Tm and Lu oxides, which were from Fluka). Stock solutions of the other metal ions were prepared by dissolving their analytical grade nitrates in approximately 0.1M nitric acid. The solutions were standardized gravimetrically or by chelometric titration. Working solutions (0.01–1mM) were prepared by diluting the stock solutions with 0.1M nitric acid.

A 1mM Arsenazo III (AA3) solution was prepared by dissolving the chromatographically pure chemical in water. Working solutions of AA3 were obtained by diluting 5 ml of this solution and 20 ml of 1M formate buffer (pH 2.7) to 200 ml.

A 1.0M solution of HIBA was prepared from the reagent grade chemical (m.p. 79.0° Lachema, Brno, Czechoslovakia) and purified by passing it through a 10 × 200 mm column of Dowex 50W × 8 cation-exchanger (50–100 mesh) in the H⁺ form, at a flow-rate of 1 ml/min. A 1M stock solution of reagent grade citric acid was prepared. Working solutions of the ammonium salt of HIBA (0.090 or 0.180M) or citric acid (0.060 or 0.090M) were obtained by neutralization of the stock solutions to the required pH with concentrated ammonia solution, followed by dilution with water.

A 0.1M solution of ammonium dodecyl sulphate (ADS) was obtained by passing an appropriate sodium dodecyl sulphate solution (SDS, from BDH) at 1 ml/min through a 10 × 200 mm column of the Dowex 50W × 8 cation-exchanger in the NH₄⁺ form. The cation-exchanger columns were regenerated by passage of 200 ml of 1M hydrochloric acid (HIBA column) or 2M ammonium nitrate (ADS column) at the same flow-rate.

Fig. 1. A block scheme of the chromatographic apparatus. Apparatus

The chromatographic apparatus (Fig. 1) consists of a VCM 300 high-pressure chromatographic pump (Development Workshop of Czechoslovak Academy of Sciences, Prague), a 3 × 50 mm glass pre-column packed with Silpearl silica gel sorbent for TLC (Lachema, Brno), a Rheodyne 7125 six-port chromatographic valve (Rheodyne, Cotati, USA) with a 20- μ l sample loop, a 3 × 150 mm glass analytical CGC column, a home-made post-column reactor and a flow-through spectrophotometric detector. A six-way chromatographic switching valve with six inlet ports and a single central outlet port (Mikrotechna, Prague) was placed in front of the VCM 300 pump to create the stepwise concentration or acidity gradients in the low-pressure part of the system.

A CGC glass chromatographic column (3 × 150 mm) packed with Separon SGX C18 RP sorbent (5 μ m particle size, Tessek, Prague) was washed with 10% v/v methanol–water mixture at a flow-rate of 0.01 ml/min for 1 hr and then with 0.005M ADS at a flow-rate of 0.1 ml/min for 2–3 hr. After two weeks of use (or if unused for a period of a week), the column was regenerated by a shortened procedure, the same solutions being passed through it for 30 and 60 min, respectively, especially when the samples had very complex matrices. At the start of each day's work the column was equilibrated with an HIBA solution of appropriate concentration at a flow-rate of 0.4 ml/min for 30–40 min. The precolumn served to trap impurities from the mobile phase before it entered the injection valve and analytical column. The use of this precolumn also prolongs the life-time of the analytical column.

The post-column reactor consisted of a PTFE tee-screen type mixing chamber with a volume of $\sim 0.6 \mu$ l, to which eluate and derivatizing reagent were both fed through Teflon capillaries (0.6 mm i.d.) at a flow-rate of 0.5 ml/min. The homogeneous reaction mixture then flowed

through a reaction coil (0.3×400 mm) to an $18 \mu\text{l}$ flow-cell in the Zeiss Spekol 21 single-beam spectrophotometric detector, connected to a Zeiss K201 recorder. The analytical signal was measured at an absorption maximum of the AA3 chelates with the metal ions of interest, as either peak area or peak height.

RESULTS AND DISCUSSION

Chromatographic separation

The two distinct absorption maxima at 660 and 610 nm attained maximum intensity at pH 2.7 in aqueous mixtures of AAS and U(VI) (each $25 \mu\text{M}$) and their position and amplitude were not affected by the presence of 50mM HIBA or citric acid. The absorption band at $660 \mu\text{m}$ was chosen for the determination because of the higher sensitivity.¹

The quality of the chromatographic separation of uranium(VI) from the other elements depends primarily on the concentration of complexing agent in the mobile phase and on the pH, because of the effect of the latter on the conditional stability constants of the metal chelates formed with the eluting agent in the mobile phase (*cf.* Fig. 2). Under otherwise identical experimental conditions, the retention times increase with increasing acidity of the mobile phase and decreasing concentration of citric acid, over the pH range from 2.4 to 3, and remain constant at higher pH values because of the strong chelates formed with citric acid. The retention times increase with decreasing concentration of HIBA in the mobile phase and reach a minimum at $\sim\text{pH}$ 3.5–3.8. In general, the uranium can be quantitatively separated from other elements under suitable experimental conditions by isocratic elution with either HIBA or citric acid.

Sharper chromatographic peaks, and better and faster separation, were obtained by eluting with 0.090M HIBA at pH 3.5 or with 0.090M citric acid at pH 3.0, than with higher concen-

Fig. 2. Dependence of the retention time of U(VI) on the concentration of eluting agent in the mobile phase and the pH of the latter. [U] 0.5mM ; [AA3] $25 \mu\text{M}$. [HIBA]: \square 0.090mM , \blacksquare 0.180mM ; [cit]: \blacktriangle 0.060mM , \square 0.090mM .

trations of these elements (at the same pH). The repeatability of the retention time and peak area (see Table 1 for the statistical parameters)¹⁷ for two different concentrations of U(VI) were satisfactory ($s_r \leq 3\%$). Slightly better repeatability was obtained with HIBA as eluent, than with citric acid. Calibration graphs were linear for 0.3 – 10mM uranium, with detection limits of 0.16 and 0.18mM for elution with HIBA and citric acid respectively (the detection limit being the concentration corresponding to a signal 10 times the noise of the blank signal).

Interferences

Although only Th(IV), Fe(III) and lanthanides [besides U(VI)] gave measurable peaks in the AA3 derivatization reaction,^{1,15,16} possible interference from all elements giving a colour reaction with AA3 was studied. The retention times for uranium and the other elements varied only slightly with changes in the concentration ratios of the individual elements to uranium and with column aging. The separation of U(VI) from the other elements was complete in all cases and no interference was observed over a wide concentration range of the elements (see Table 2).

Table 1. Repeatability¹⁷ of determination of a retention time and a peak area after elution of U(VI) by 0.090M HIBA at pH 3.5 or 0.090M citric acid at pH 3.0: [AA3] = $25 \mu\text{M}$; $n = 10$

Table 2. Chromatographic separation of U(VI) from interfering ions (M) by eluting with 0.090M HIBA or citric acid at pH 3.5 and 2.5, respectively

Ion	[M], mM	t_r (HIBA), min	t_r (cit), min	Ion	[M], mM	t_r (HIBA), min	t_r (CIT), min
U(VI)	0.5	12.4	9.3	Lu(III)	0.3	11.6	—
Th(IV)	0.5	15.8	3.8	Lu(III) ^a	5.0	24.0	15.4
Th(IV)	1.0	16.4	3.6	Yb(III)	0.3	13.8	—
Th(IV)	5.0	25.1 ^b	4.3 ^c	Tm(III)	0.3	19.8	—
Th(IV)	10.0	28.8 ^b	— ^d	Fe(III)	2.0	6.2	4.3
Ba(II)	100	—	29.6	Fe(III)	10.0	8.8	—
U(VI) ^e	0.52	15.1	9.7				
Th(IV) ^e	0.1	—	5.0				
Fe(III) ^f	96	10.8	—				

^a t_r (U) = 15.1 for HIBA at pH 3.3 and 9.4 min for citric acid at pH 2.5, ^b t_r (U) = 15.9 and 16.1 min at pH 3.3, ^c t_r (U) = 9.4 min at pH 2.4, ^dno separation, ^e t_r at pH 3.3 for HIBA and 2.5 for citric acid, for separation of an artificial sample solution [composition (mM): U(VI) 0.52, Th(IV) 0.1, Fe(III) 96, Cu(II) 0.39, Ni(II), 0.49, Cr(III) 0.5, Zr(IV) 0.27, Be(II) 2.8, Mn(II) 0.01, Al(III) 9.3, Ti(IV) 0.52, Cl⁻ 270, NO₃⁻ 31, SO₄²⁻ 3.8].

Al(III) and Cr(III) are eluted at shorter retention times and do not interfere with the elution when present in up to 1000-fold concentration ratio to U(VI). Bivalent species such as Ca(II), Sr(II), Ba(II), Mg(II), also do not interfere at 1000-fold concentration ratio. Pb(II) in equimolar ratio does not interfere, and Cu(II), Ti(IV) and Zr(IV) ions do not interfere when present in up to 2-fold (Cu) or 4-fold (Ti, Zr) concentration ratio.

Th(IV), Lu(III) and Yb(III), which have retention times closest to that for U(VI), are efficiently separated from it when present in 1:1, 20:1 or 10:1 concentration ratio to it, respectively. Other lanthanides do not affect the determination of uranium unless they have a longer retention time than Lu(III), Yb(III) and Tm(III) and are present in >1000-fold ratio to U(VI), because they are eluted after Tm(III) (the retention times increase with decreasing atomic number of the element.^{15,16} If required, the complete group of lanthanides can be efficiently separated from uranium by acidity gradient elution and determination simultaneously.¹⁵

Uranium(VI) can be easily preconcentrated directly on the CGC Separon SGX C18 analytical column from sample solutions at pH 3.5–4.5, with an enrichment factor of up to 100. It is quantitatively sorbed on the analytical column from volumes of 0.1–12.5 ml. The sample solution (at pH 4) is introduced directly into the analytical column by time-controlled pumping (the precolumn and loop injector are not used) via a four-way stopcock. Before and after sorption of the analyte, the column is washed with 10% v/v methanol–water mixture for 10 min to remove the mobile phase and to fill the column with a solvent that does not affect

the sorption or desorption of uranium, and/or to wash out the rest of the sample solution with matrix before the chromatographic separation. The uranium is then eluted and effectively separated from the other elements by isocratic or pH-gradient elution (depending on the matrix composition of the sample and the purpose of the analysis, see above). The repeatability of the method was found to be better than 5%, and the recovery 90–106% for 0.01–0.1mM uranium.

Determination of U(VI) in water samples

Before determination of U(VI) in real samples, the procedure was tested and optimized for an artificial sample containing a selection of elements, at the most probable concentrations (see footnote to Table 2). The best results were obtained by eluting the sample with 0.090M HIBA or citric acid at pH 3.3 and 2.5, respectively. All the peaks appearing in the chromatograms were identified by the standard addition method. Only the lanthanides, Fe(III) and Th(IV) are potential interferents, giving measurable chromatographic peaks under the experimental conditions used, and only their peaks were found when eluting with HIBA or citric acid. None of the above-mentioned elements affects the determination of U(VI) when present at the given concentrations. A U(VI) concentration of 0.53mM (126 mg/l.) with $s_r = 1.9\%$ was found by the standard addition method with linear regression of the function $A_p = f(c)$, for peak area (A_p) vs. U(VI) concentration (c) for successive 1mM additions over the range 1–8mM U(VI), with 5 replicates for each data-point.

Two real samples were analyzed by a similar procedure, and values of 93 and 75 mg/l. with $s_r = 2.2$ and 2.5% were found by the standard addition method. These concentrations agree very well with those obtained by the spectrophotometric method with liquid-liquid extraction,² 99 and 72 mg/l. A very simple in-line preconcentration on the analytical column has to be applied for samples with U(VI) concentrations below the determination limit (35 mg/l.). For 1–20 mg/l. uranium the reproducibility was better than 5% and the results were in good agreement with radiometric analysis (maximum difference 89°).

The proposed method gives precise and correct results. It is relatively fast (around 20 min per analysis) compared to the liquid-liquid extractions,^{2,3,10} ion-exchanger⁷ and other methods. The advantage of the procedure over the extraction-photometric method is its simplicity and the quantitative separation of all interfering elements.

Acknowledgements—The authors wish to thank Dr. M. Radil of the Institute of Nuclear Fuels in Prague-Zbraslav for supplying them with a sample of chromatographically pure Arsenazo III.

INTERACTION OF SERUM ALBUMIN WITH A SULPHONATED AZO DYE IN ACIDIC SOLUTION

MARIA PESAVENTO and ANTONELLA PROFUMO

Dipartimento di Chimica Generale, Università di Pavia, Viale Taramelli 12, 27100 Pavia, Italy

(Received 1 October 1990. Revised 14 February 1991. Accepted 25 February 1991)

Summary—The uptake of the sulphonated azo dye [1-(tetrazolylazo)-2-hydroxynaphthalene 3,6-disulphonic acid, or T-azo-R] by bovine serum albumin (BSA) in the pH range 1–4 was investigated by a spectrophotometric method, based on the fact that the absorption spectra of the free and bound dye are different. The effect of increasing concentration of sodium chloride and sodium perchlorate was considered, as well as the influence of the BSA on the protonation equilibria of the dye. The Scatchard model, which has been widely used previously to describe the interaction between small substances and proteins, was not helpful in the treatment of data obtained in the acidity range considered here. Instead a phase distribution model allowed a good quantitative treatment of the experimental findings. The distribution constant of the monoprotonated T-azo-R between aqueous solution and the albumin microphase was found to be $\log K_{d(HL)}/\gamma'_{HL} = 6.3$, while the biprotonated form does not bind to BSA. As a consequence, the protonation constant of T-azo-R is decreased in the presence of BSA, particularly at low salt concentrations in aqueous solution. An equation relating the observed protonation constant to the protonation constant of the dye in solution and to the ionic strength is proposed. It has been found that the effect of salts on the uptake of T-azo-R by BSA can be explained simply by considering the variation of the activity coefficients of the ionic species involved in aqueous solution.

Among the many methods proposed for the quantitative determination of serum albumin, those based on dye binding, and spectrophotometric determination, are commonly used when large numbers of specimens are to be analyzed. The most widely utilized reagents are probably Bromocresol Green (BCG) at pH = 4,¹ or 3.8,² and HABA [2-(4-hydroxyphenylazo) benzoic acid] at pH = 3.2.³ However, no systematic investigation on the interaction between dyes and serum albumin at these acidities has been found in the literature. A study of the albumin-anionic dyes combination at these conditions should be interesting to improve the existing methods or to design new dyes with better performances.

As a first approach, the pH range 1–4 is interesting to investigate, because serum albumin is completely protonated⁴ and is in its expanded conformation.⁵ According to Pinnell and Northam⁶ the best dyes for serum albumin determination are those having protonation constants around the working pH. So the sulphonated azo dye T-azo-R [1-(tetrazolylazo)-2-hydroxynaphthalene-3,6-disulphonic acid]⁷ seemed particularly suitable for this investigation, because its second protonation reaction is as follows:

and its protonation constant is $\log K_a = 2.90$ (in 0.1M sodium perchlorate).

Therefore, this protonation takes place in the acidity range 2–4, which is that investigated in the present study. (In the text ion charges will be omitted for simplicity).

The observations by Pinnell and Northam seem to indicate that the spectrum of the free dye and that of the dye bound to albumin are better differentiated at pH values at which the protonation reaction is at equilibrium. The absorption spectra of T-azo-R bound to BSA at two different pH levels, registered against a solution of T-azo-R at the same conditions, are reported in Fig. 1. It is evident that it is

Fig. 1. Absorption spectrum of T-azo-R bound to albumin against free T-azo-R. $c_{\text{T-azo-R}} = 2.16 \times 10^{-5}$ moles/kg; $c_{\text{BSA}} = 1.54 \times 10^{-5}$ moles/kg. Curve 1: 0.0050 moles/kg HCl (pH = 2.30). Curve 2: 0.0050 moles/kg NaCl (pH = 4.10).

much higher at pH = 2.30, when reaction 1 is at equilibrium, than at pH = 4.50 when the deprotonation is complete.

In the present paper it will be shown that this is because the monoprotinated form is bound to albumin much more strongly than the biprotinated one, which shifts the protonation equilibrium (1) to the left in the presence of albumin.

Scatchard *et al.*⁸ treated the reaction of small ions with albumin as a true combination of the ligand with specific sites on the macromolecule. Since then, this model has been widely employed to describe the combination of small ions or molecules with proteins.^{9,10} However, this model doesn't seem appropriate for describing the combination of T-azo-R with BSA in the acidic solutions considered here, because the Scatchard plot $[(n/[L])e^{2.303pZL}]$ vs. n obtained here is completely different from that expected, as will be discussed later on.

Moreover, some previous observations showed that the effects of BSA on the spectrum and protonation constant of T-azo-R were similar to that of cationic surfactant micelles,¹¹ in which evidently specific interaction sites could hardly be detected. Similar behaviour was observed in the case of sulphophthaleinic dyes.¹² Based on this similarity, an attempt was made to interpret the experimental findings with a model based on the assumption that BSA can be considered as a microphase distinct from the aqueous solution in which it is dispersed. Thus, a substance X is distributed between the two phases, according to the equilibrium:

$$K_{d(X)} = \frac{a_{X'}}{a_X} = \frac{n\gamma_{X'}}{[X]\gamma_X} \quad (2)$$

where a_X and γ_X are respectively the activity

(moles/kg) and the activity coefficient of X. Primed symbols refer to species bound to albumin. Concentrations in albumin microphase are in mmoles per mmole of BSA (n).

$K_{d(X)}$ is expected to have a constant value only if the protonation and the conformation of serum albumin are constant, as it is in the pH range 1–4 investigated in the present work. The combination of T-azo-R with albumin was studied by a spectrophotometric method which is more rapid than the usual methods based on dialysis or ultracentrifugation and takes advantage of the fact that the spectra of the free and bound dye are quite different in the acidic solutions considered here, as can be seen from Figs 1 and 2.

EXPERIMENTAL

Reagents

All reagents were of analytical reagent grade. Bovine Serum Albumin (BSA) 98–99%, virtually free from fatty acids (0.005%), was obtained from Sigma Chemical Co. and used without further purification. All calculations reported for BSA are in terms of a molecular weight of 65,000. Concentrations of albumin ranging from 3.0×10^{-7} to 5.0×10^{-5} moles/kg were considered. At higher concentration, a turbidity was formed in the presence of T-azo-R. T-azo-R was synthesized as previously described⁷ and standard solutions were prepared by direct weighing of the solid. In the test solutions its concentration was in the range $1-10 \times 10^{-5}$ moles/kg.

Apparatus

A DMS 100 Varian spectrophotometer with 1-cm quartz cells was used throughout. An Orion 901 potentiometer with a combined Ross

Fig. 2. Absorption spectrum of T-azo-R in HCl 0.0050 moles/kg in the presence of albumin (broken curve: $c_{\text{BSA}} = 1.54 \times 10^{-5}$ moles/kg), and in its absence (continuous line). $c_{\text{T-azo-R}} = 2.16 \times 10^{-5}$ moles/kg.

glass electrode (Orion) was used for pH measurements. The potentiometric cell was standardized by Gran's method, as described previously.¹³ The presence of BSA doesn't change the standard potential or the liquid junction potential of the cell.

Spectrophotometric method

The concentration of the bound and free ligand ($[L']$ and $[L]$ respectively, moles/kg) was calculated on the basis of the following relationships

$$A = \epsilon'_L [L'] + \epsilon_L [L] \quad (3)$$

$$c_L = [L] + [L'] \quad (4)$$

so that

$$[L'] = \frac{A - \epsilon_L c_L}{\epsilon'_L - \epsilon_L} \quad (5)$$

where

$$[L'] = [H_2L'] + [HL']$$

and

$$[L] = [H_2L] + [HL] \quad (6)$$

and A is the absorbance measured at a fixed wavelength ($\lambda = 510$ nm, where T-azo-R combined with albumin absorbs more than the free dye), ϵ'_L is the mean molar absorptivity of the dye bound to albumin ($\text{moles}^{-1} \text{ kg cm}^{-1}$), and ϵ_L is the mean molar absorptivity of the free dye ($\text{moles}^{-1} \text{ kg cm}^{-1}$).

The mean molar absorptivities of the bound and free T-azo-R were determined from the absorbance of solutions containing known amounts of T-azo-R, in the presence of an

excess of BSA, and with no BSA. They can be evaluated from the spectra reported in Fig. 2. In the considered acidity range, T-azo-R can be monoprotonated or diprotonated, depending on the acidity. The two forms absorb differently, so that the mean molar absorptivities also depend on the acidity of the solution. In 0.0050 moles/kg hydrochloric acid, an acidity at which many determinations of the present research were done, the two mean molar absorptivities are respectively $\epsilon'_L = 6.1 \times 10^3$ and $\epsilon_L = 7.5 \times 10^2$ $\text{mole}^{-1} \text{ kg cm}^{-1}$ (standard deviation: 2×10^2 $\text{mole}^{-1} \text{ kg cm}^{-1}$).

RESULTS AND DISCUSSION

Combination of T-azo-R with BSA at constant ionic strength and test of the Scatchard model

A set of experiments was performed, keeping the T-azo-R concentration constant and increasing the BSA concentration. As an example, Fig. 3, reports the absorbance, at 510 nm, of solutions with different concentrations of T-azo-R, with increasing BSA concentration at a pH of 2.5. The absorbance increases linearly with the albumin concentration, according to the Beer-Lambert law, up to $c_{\text{BSA}} < c_{\text{T-azo-R}}/30$. At T-azo-R concentration higher than about 10×10^{-5} moles/kg a turbidity was observed at the considered conditions, so that only lower concentrations can be used for spectrophotometric determinations. As a consequence, the linear range is extended only up to 2.7×10^{-6} moles/kg.

At sufficiently high albumin concentration the absorbance reaches a steady value indicating that the dye is completely bound. ϵ'_L can be

Fig. 3. Absorbance of solutions containing increasing concentration of BSA, $\lambda = 510$ nm. Curve 1: $c_{\text{T-azo-R}} = 3.36 \times 10^{-5}$ moles/kg; 0.0030 moles/kg HCl. Curve 2: $c_{\text{T-azo-R}} = 7.38 \times 10^{-6}$ moles/kg; 0.0030 moles/kg HCl. Curve 3: $c_{\text{T-azo-R}} = 3.36 \times 10^{-5}$ moles/kg; 0.0018 moles/kg H_2SO_4 . Curve 4: $c_{\text{T-azo-R}} = 1.80 \times 10^{-5}$ moles/kg; 0.0018 moles/kg H_2SO_4 .

obtained from this absorbance and ϵ_L from the absorbance at the same wavelength in the absence of BSA. Thus, $[L']$ and $[L]$ are calculated from equations (4) and (5).

At first, an attempt was made to treat these data according to the Scatchard model.⁸ It states that if there were only binding sites of one kind for T-azo-R on serum albumin, with the same intrinsic constant K_L^0 , but electrostatically influenced by other ions already linked to BSA, the observed binding coefficient K_L should not be constant as the combination proceeds, but should depend on the total charge which is actually present on the protein molecule (z_p), according to the relationship.

$$K_L = K_L^0 e^{-2 w z_p z_L} \quad (7)$$

where $z_p = 93 - 3n$, and 93 is the protonation degree of albumin at the considered pH. The term $2 w z_p z_L kT$ is the electrostatic work of

bringing the ion L with charge z_L to the surface of the protein molecule. At the considered acidity, 80% T-azo-R is in the biprotonated form H_2L , which bears a charge of -2 ($z_L = -2$). However, in the presence of albumin the deprotonation is enhanced as will be shown later. In this case, T-azo-R is almost completely deprotonated, so that $z_L = -3$.

According to Scatchard, w in a solution at I ionic strength can be evaluated at 25° according to the relationship

$$w/2.303 = 0.0517 - 0.5085 I^{1/2}/(1 + 10.663 I^{1/2})$$

From equation (7) the following relationship can be derived

$$\frac{n}{[L]} e^{2 w z_p z_L} = K_L \gamma_L N - K_L \gamma_L n \quad (8)$$

where N is the maximum number of interaction sites on serum albumin. Thus by plotting $n e^{2 w z_p z_L}/[L]$ vs. n a straight line with negative slope should be obtained. If more than one kind of interaction site were present on serum albumin, the function should be a curve with negative slope.⁹

As an example, the values obtained for n and $n e^{2 w z_p z_L}/[L]$ in one experiment are reported in Table 1. In contrast to what is expected on the basis of equation (8) when n decreases, $n e^{2 w z_p z_L}/[L]$ decreases too. This could be attributed to an incorrect evaluation of the ionic radius of albumin in the expanded form which prevails in the acidity range considered here. However, even by assuming a radius 20 times higher for albumin, the trend of the curve $n e^{2 w z_p z_L}/[L]$ vs. n is opposite to that expected on the basis of the Scatchard model. For this reason, it is impossible to make use of the Scatchard model in the present case.

Table 1. Effect of increasing concentration of BSA on the absorbance of T-azo-R at 510 nm, in 0.0050 moles/kg hydrochloric acid. T-azo-R: 1.08×10^{-5} moles/kg; $V = 25.0$ cm³. $e = e^{2 w z_p z_L}$; $w = 0.0718$; $z_p = 93 - 3n$; $z_{\text{HL}} = -3$

Fig. 4. Effect of increasing concentration of sodium chloride on binding of T-azo-R to BSA in 0.0050 moles/kg HCl. $c_{\text{T-azo-R}} = 5.00 \times 10^{-5}$ moles/kg. Curve 1: $c_{\text{BSA}} = 4.62 \times 10^{-5}$ moles/kg. Curve 2: $c_{\text{BSA}} = 1.54 \times 10^{-5}$ moles/kg. Curve 3: $c_{\text{BSA}} = 1.54 \times 10^{-6}$ moles/kg. Curve 4: $c_{\text{BSA}} = 3.69 \times 10^{-7}$ moles/kg.

However, it can be seen from Table 1 that the ratio $n/[L]$ is practically constant, as predicted by the phase distribution model, according to equation (2) at constant acidity and ionic strength of the solution and if γ_{HL} is constant.

Indeed the following relationships hold:

$$[L] = [\text{H}_2\text{L}] + [\text{HL}] = [\text{HL}] (1 + K_a[\text{H}])$$

$$[L'] = [\text{H}_2\text{L}'] + [\text{HL}'] = [\text{HL}'] (1 + K'_a[\text{H}])$$

$$K_{d(\text{HL})} = \frac{a_{\text{HL}'}}{a_{\text{HL}}} = \frac{n\gamma_{\text{HL}'}}{[L]\gamma_{\text{HL}}} \frac{1 + K_a[\text{H}]}{1 + K'_a[\text{H}]}$$

$$= K_{\text{dc}} \frac{1 + K_a[\text{H}]}{1 + K'_a[\text{H}]} \frac{\gamma_{\text{HL}'}}{\gamma_{\text{HL}}} \quad (9)$$

where $K_{d(\text{HL})}$ is the distribution constant of the dye in the monoprotonated form, and K_{dc} is the global distribution coefficient ($K_{\text{dc}} = n/[L]$). K_a and K'_a are the protonation constants of T-azo-

R in aqueous solution and T-azo-R bound to albumin, respectively, defined as:

$$K_a = \frac{[\text{H}_2\text{L}]}{[\text{HL}][\text{H}]} \quad (9(a))$$

$$K'_a = \frac{[\text{H}_2\text{L}']}{[\text{HL}'][\text{H}]} \quad (9(b))$$

The average value of the distribution coefficient of T-azo-R at the conditions considered here is $\log K_{\text{dc}} = 5.61$.

Influence of the salt composition of the solution

Some experiments were carried out by adding increasing concentrations of sodium chloride to solutions with different BSA and T-azo-R concentrations at constant acidity (5×10^{-3} moles/kg hydrochloric acid, equal to that investigated above).

The absorbance of the solution at $\lambda = 510$ nm was recorded. Some results are reported in Fig. 4. Increasing salt concentration causes a diminution of the absorbance at 510 nm. This is due to a partial release of T-azo-R from BSA, as demonstrated by a few dialysis experiments (Table 2). The concentration of free dye is greatly increased in 0.5 moles/kg sodium chloride.

This effect was also observed in the case of sulphophthaleinic dyes at acidities around neutrality⁹ and was interpreted as competition between anions and dyes for the same binding sites on serum albumin. The ionic strength variations were not taken into account but are, however, important and can justify the observed behaviour according to the phase distribution model.

Table 2. Dialysis of T-azo-R in the presence of BSA at 0.0050 moles/kg HCl and different sodium chloride concentration. HCl and NaCl are at the same concentration inside and outside the bag. $T = 25^\circ$. Dialysis time: 48 hr; bag: SPECTRA/POR molecular membrane; tubing: 18 mm \times 50 ft; Vol: 1.0 cm³; m.w. cut-off: 3500. Concentrations are in moles/kg

0.50	6.15×10^{-6} (V = 15.2 cm ³)	1.17×10^{-4}	2.25×10^{-4} (V = 43 cm ³)	1.66×10^{-4}	5.42	6.05	

From equation (9), and by estimating the activity coefficient in the aqueous phase on the basis of the specific interaction theory,¹⁴ the following relationship is obtained

$$\log \frac{n}{[L]} = \log K_d' - \frac{0.51 z_{HL}^2 I^{1/2}}{1 + 1.5 I^{1/2}} + b(L, Na)m_{Na} \quad (10)$$

where z_{HL} is the charge of the dye (-3 in the case of the monoprotonated T-azo-R), and $K_d' = K_{d(HL)}(1 + K_a[H]) / (\gamma_{HL}(1 + K_a[H]))$ includes all the terms of equation (9) which are practically independent of the ionic strength of the aqueous solution. The term $b(L, Na)$ is the coefficient of specific interaction of the monoprotonated dye with sodium which is present at a concentration of m_{Na} (moles/kg).

The parameters of equation (10) can be estimated by a least square procedure. Good values for R^2 were obtained. The interaction coefficient is not significantly different from 0, and a mean $\log K_d'$ value of 6.10 ± 0.17 was obtained, in agreement with the value of $\log K_d' = \log K_{d(HL)} / \gamma_{HL} + \log \gamma_{HL}$ which can be calculated from the experiments reported above where the solution was 5×10^{-3} moles/kg hydrochloric acid so that $\log \gamma_L = -0.29$, and $\log K_d' = 5.90$.

The coefficient of the independent variable $I^{1/2}/(1 + I^{1/2})$ has an average value of $-5.0 (\pm 1.2)$, in fair agreement with -4.5 , corresponding to the charge (-3) of the monoprotonated species HL. It is interesting to notice that the $\log K_d'$ values obtained from the dialysis experiments, shown in Table 2, are in agreement with the values found spectrophotometrically. Thus, the effects of the increasing salt concentration can be well explained on the basis of the phase distribution model, without any

hypothesis on competition of different anions for the same binding sites.

To test the dependance of the conditional distribution constants K_d' on the acidity, an experiment was carried out in more dilute hydrochloric acid 1×10^{-3} moles/kg, by adding increasing concentrations of sodium chloride. The results are reported in Table 3. A higher value of K_d' is obtained, showing that $K_a > K_a'$. An evaluation of $K_{d(HL)} / \gamma_{HL}$ can be made by assuming that $K_d'[H] \ll 1$. A value of 5.7×10^6 is obtained at this acidity, in good agreement with the value in 0.0050 moles/kg hydrochloric acid (6.3×10^6).

According to equation (10), a different anion must have the same effect on T-azo-R binding to BSA. Some results at increasing concentrations of sodium perchlorate are reported in Table 4. The data, treated according to the phase distribution model, gave the same results as in the case of sodium chloride: $\log K_d' = 6.06$, and $0.51z_L^2 = -5.71$ ($R^2 = 0.991$). Perchlorate was chosen to test the effect of an anion having a much higher lipophilic character than chloride, hence supposedly competing with the dye more than chloride for binding to a hydrophobic environment.

Protonation of T-azo-R in presence of BSA

It is well known that macromolecular particles have an influence on the protonation equilibria of indicator dyes.⁶ The same is observed in the BSA/T-azo-R system. This point was investigated here by considering solutions with fixed concentrations of T-azo-R and BSA, at a ligand to albumin molar ratio of 3.25, and by changing the acidity by small additions of concentrated acid or base. The free proton concentration was measured with the glass elec-

trode standardized as described previously.¹³ The pH range 1–4 was studied and absorbances recorded at 510 nm (Fig. 5). Curve 1 corresponds to the deprotonation of T-azo-R in 0.1 moles/kg sodium chloride without albumin. The molar absorptivities of the species H_2L and HL at 510 nm are 4.2×10^2 and 3.9×10^3 moles⁻¹ kg cm⁻¹, respectively. In the presence of BSA and at sodium chloride concentrations lower than 0.05 moles/kg the molar absorptivity of the monoprotonated form is much higher, 7.0×10^3 moles⁻¹ kg cm⁻¹. A large effect of increasing salt

concentration is observed, which agrees with the effect reported above of inorganic salts on dye binding.

The data were treated on the basis of the following relationship:

$$\begin{aligned}
 A &= \epsilon_{\text{H}_2\text{L}'}[\text{H}_2\text{L}'] + \epsilon_{\text{HL}'}[\text{HL}'] \\
 &+ \epsilon_{\text{H}_2\text{L}}[\text{H}_2\text{L}] + \epsilon_{\text{HL}}[\text{HL}] \\
 &= \epsilon_{\text{H}_2\text{L}}([\text{H}_2\text{L}'] + [\text{H}_2\text{L}]) \\
 &+ \epsilon_{\text{HL}}([\text{HL}'] + [\text{HL}]) \quad (11)
 \end{aligned}$$

where $\epsilon_{\text{H}_2\text{L}}$ and ϵ_{HL} are the mean molar absorptivities of the free and bound dye, respectively in the biprotonated and monoprotonated form.

Thus the observed protonation constant of T-azo-R in the presence of albumin is

$$K_{\text{ao}} = \frac{([\text{H}_2\text{L}'] + [\text{H}_2\text{L}])}{([\text{HL}'] + [\text{HL}]) [\text{H}]} = \frac{(c_L \epsilon_{\text{HL}} - A)}{(A - \epsilon_{\text{H}_2\text{L}} c_L) [\text{H}]} \quad (12)$$

K_{ao} , ϵ_{HL} and $\epsilon_{\text{H}_2\text{L}}$ have been determined by a least square procedure and the results are reported in Table 5, for the solution of Fig. 5.

According to the phase distribution model, the following relationship should correlate the protonation constant observed in the presence of albumin K_{ao} with the protonation constant in aqueous solution K_a :

$$K_{\text{ao}} = K_a \frac{1 + K_{\text{d}(\text{H}_2\text{L})} \gamma_{\text{H}_2\text{L}} c_{\text{-BSA}} / \gamma_{\text{H}_2\text{L}'}}{1 + K_{\text{d}(\text{HL})} \gamma_{\text{HL}} c_{\text{BSA}} / \gamma_{\text{HL}'}} \quad (13)$$

The activity coefficients in albumin microphase were assumed to be constant and those in aqueous solution were evaluated by the specific interaction theory.¹⁴ The parameters in equation (13) can be transformed into a linear equation and their best values can be found by a multiple linear regression.

Fig. 5. Protonation of T-azo-R in aqueous solution without BSA (curve 1), and in the presence of BSA. Abscissa: pH; Ordinate: A/c_L ($\lambda = 510 \text{ nm}$). $c_{\text{T-azo-R}} = 5.00 \times 10^{-5}$ moles/kg; $c_{\text{BSA}} = 1.54 \times 10^{-5}$ moles/kg; conc. of HCl initially present. Curve 2: 0.50 moles/kg; Curve 3: 0.10 moles/kg; Curve 4: 0.050 moles/kg; Curve 5: 0.010 moles/kg; Curve 6: 0.0010 moles/kg.

Table 5. Apparent protonation constants of T-azo-R in the presence of BSA at different sodium chloride concentrations. T-azo-R: 5.00×10^{-5} moles/kg, BSA: 1.54×10^{-5} moles/kg. ϵ_{H_2L} : mean molar absorbance of the biprotonated T-azo-R; ϵ_{HL} : mean molar absorbance of the mono-protonated T-azo-R

c_{NaCl}	ϵ_{H_2L}	ϵ_{HL}	K_{a0}	n. obser.	R^2
0.01	410	7138	39	3	
0.05	208	5792	87	7	0.982
0.1	490	5636	146	8	0.999
0.5	327	4219	298	14	0.986

The following results were obtained:

number of observations = 10; $R^2 = 0.878$; $\log K_a = 2.72$; $\log K_{d(HL)}c_{BSA}/\gamma_{HL} = 1.41$, and $\log K_{d(HL)}/\gamma_{HL} = 6.22$. $K_{d(H_2L)}$ is not significantly different from 0. Thus the biprotonated form H_2L does not seem to be significantly distributed in the albumin microphase. K_a is in acceptable agreement with the value found in aqueous solution. Also $\log K_{d(HL)}/\gamma_{HL}$ agrees with the values found in the two completely independent experiments described above.

CONCLUSIONS

The uptake of T-azo-R by BSA in the pH range 1–4 cannot be described with the Scatchard model. Instead it has been demonstrated that a phase distribution model is able to describe the dye/BSA combination under different conditions. This does not require any hypothesis about the nature of the interaction of T-azo-R with albumin (for instance hydrophobic, electrostatic, at a specific site).

The proposed model seems to be useful in practice, because it describes the interaction on the basis of only one parameter, the distribution constant. It allows the prediction of the effects of the ionic strength on the uptake of the ligand by BSA [equation (10)], and the effect of serum albumin on the protonation equilibrium of

the indicator dye under different conditions [equation (13)]. An important point of the phase distribution model is that it is implicitly assumed that the global structure of albumin does not sensibly change when T-azo-R combines. This is supported by the observation that the electrokinetic potentials of albumin and of albumin in the presence of T-azo-R, at a dye to albumin molar ratio equal to 30:1 at pH = 2.3, and in 0.1 moles/kg sodium chloride are $+38(\pm 6)$ mV and $+35(\pm 2)$ mV, respectively (practically identical).

MICRO-DETERMINATION OF WARFARIN SODIUM, NICOUMALONE AND ACEBUTOLOL HYDROCHLORIDE IN PHARMACEUTICAL PREPARATIONS

C. S. P. SASTRY,* T. THIRUPATHI RAO, A. SAILAJA and J. VENKATESWARA RAO

(Received 19 February 1991. Revised 15 April 1991. Accepted 25 April 1991)

Summary—A simple, selective and sensitive spectrophotometric method has been developed for the determination of microgram quantities of warfarin sodium (WS), nicoumalone (NIC) and acebutolol hydrochloride (ACBH), either in pure form or in pharmaceutical preparations. This method is based on the haloform reaction with a known and excess of standard iodine solution under alkaline conditions. The excess of iodine is determined at pH 3.0 with metol—INH. The absorbance of the resulting *p*-*N*-methylbenzoquinonemonoimine—INH charge-transfer complex is measured at 620 nm.

Coumarin derivatives such as warfarin sodium (WS) and nicoumalone (NIC) are extensively used as anticoagulants and the butanamide derivative acebutolol hydrochloride (ACBH) is widely used as an anti-arrhythmic agent. They have been officially determined by U.V. spectrophotometry.^{1,2} Acebutolol hydrochloride is not yet official in any pharmacopoeia. A study of the literature revealed that visible spectrophotometric methods for their determination are scarce. There are none for WS, one for NIC³ and three for ACBH.⁴⁻⁶ Even these methods require some preliminary treatment (reduction or hydrolysis) and are time consuming, tedious and have low sensitive. The methylketone group existing in all three drugs has not been exploited so far. It is well known that methylketones react with iodine under alkaline conditions leading to the formation of iodoform.⁷ Sastry *et al.*^{8,9} suggested a coloured charge-transfer complex (λ_{\max} 620–630 nm) formation at pH 3.0 involving two molecules of *p*-*N*-methylbenzoquinonemonoimine (formed *in situ* from metol and iodine) and one molecule of isonicotinic acid hydrazide (INH). The drug (WS, NIC or ACBH) is treated with standard iodine in excess under alkaline conditions. The consumed iodine corresponding to the drug content in the sample is obtained by estimating the excess of iodine spectrophotometrically at pH 3.0 with metol and INH as the chromogenic agent.

EXPERIMENTAL

Apparatus

A Systronics model 106 digital spectrophotometer with 1-cm matched glass cells was used for absorbance measurements. An Elico model LI-120 digital pH meter was used for pH measurements.

Reagents

All the reagents were of analytical or pharmacopoeial grade and all solutions were freshly prepared in doubly distilled water.

Aqueous solutions of iodine [0.0035*M* I₂ (E. Merck) in 0.05*M* potassium iodide (Loba)], metol (BDH, 0.3%), INH (Wilson, 0.15%), sodium hydroxide (E. Merck, 1*M*), hydrochloric acid (Sarabhai, 1*M*) and potassium hydrogen phthalate—hydrochloric acid buffer (pH 3.0)¹⁰ were prepared.

Standard drug solutions

Standard stock solutions of WS and ACBH were prepared by dissolving 20 mg of drug in 100 ml of distilled water. A stock solution of NIC was prepared by dissolving 20 mg of drug in 30 ml of 0.01*M* sodium hydroxide and diluting to 100 ml with distilled water. The working standard solutions were prepared by suitable dilution of the stock solution with distilled water.

Procedure for bulk samples

Aliquots of standard solution of WS or NIC (0.25–3.0 ml; 100 μ g/ml) or ACBH (0.25–2.0 ml;

*Author for correspondence.

200 $\mu\text{g/ml}$) were transferred into a series of 25-ml graduated test tubes. Then 1.5 ml of iodine and 1 ml of sodium hydroxide were added and the volume was adjusted to 6 ml with distilled water. The mixture was set aside for a designated period at 25–30° (15 min for WS or NIC and 60 min for ACBH) or 45–50° (2 min for WS or NIC and 5 min for ACBH) for completion of reaction. Later 1 ml of hydrochloric acid, 15 ml of pH 3.0 buffer and 2.0 ml of metol solution were added. After 2 min, 1 ml of INH solution was added. The absorbances were measured at 620 nm after 5 min and before 20 min against distilled water. In the same way a corresponding reference solution was prepared simultaneously, containing the sample, but with 1.0 ml of distilled water instead of 1.0 ml of sodium hydroxide solution. The absorbance of the sample solution was subtracted from that of the reference. The difference in absorbance corresponds to the iodine consumed by the drug. The amount of drug present in each pharmaceutical preparation was computed from the corresponding calibration graph or regression equation.

Analysis of pharmaceutical preparations

Tablet powder equivalent to 10 mg of drug was treated with 20 ml of water (ACBH) or 0.01M sodium hydroxide (WS or NIC) and filtered. The filtrate was neutralised with alkali (ACBH) or acid (WS or NIC) and extracted with 3 \times 10-ml portions of chloroform. The combined chloroform layers were extracted with 3 \times 10-ml portions of 0.01M hydrochloric acid (ACBH) or sodium hydroxide (WS or NIC) and diluted to 100 ml with distilled water. These solutions were analysed as described under the procedure for bulk samples.

RESULTS AND DISCUSSION

Since the drugs under investigation have a methyl ketone group, the suitability of the haloform reaction has been examined. In the proposed method, the iodine consumed during the haloform reaction is indirectly determined spectrophotometrically with metol and INH. The experimental conditions have been established through control experiments. The Beer's law limits, molar absorptivity, regression equation, correlation coefficient obtained for each drug by a linear least-squares treatment of the results are given in Table 1. The precision of the method was tested by measuring six replicate samples of the drug within Beer's law limits (2 ml, 100 $\mu\text{g/ml}$ for WS and NIC; 1.5 ml, 200 $\mu\text{g/ml}$ for ACBH). The relative standard deviation and range of error at 95% confidence level are also given in Table 1.

Commercial tablets containing each drug were successfully analysed by the proposed method. The values obtained by the proposed method and reference (WS or NIC)² or reported (ACBH)⁴ method for pharmaceutical preparations are listed in Table 2. In the *t*- and *F* tests, there were no significant differences between the calculated and theoretical values (95% confidence limit) for comparison of the proposed and reference methods, indicating their similar accuracy and precision (Table 2). Recovery experiments indicated the absence of interference from the active ingredient hydrochlorothiazide.

The excipients such as magnesium stearate, talc, gumacacia and sodium phosphate do not interfere. Carbohydrates such as glucose, lactose and starch which are usually present in combination with the drug in pharmaceutical preparations interfere with the determinations of the latter by the proposed procedure. This interference was avoided by extracting the drug

*Average ± standard deviation of 6 determinations.

†B.P. method for WS² and NIC², reported method for ACBH.⁴

TY = Tartrazine Yellow; SYFCF: Sunset yellow FCF.

into chloroform from aqueous solution either in slightly acid (WS or NIC) or alkaline (ACBH) conditions. Further, the potential interference of other chloroform soluble reducing compounds, if any, in the determination of the drugs mentioned can be avoided by subtracting the amount of iodine consumed by the drug under neutral or acidic conditions from that consumed under alkaline conditions.

The proposed method is simpler, more accurate and highly sensitive when compared to reported visible spectrophotometric methods for the assay of WS, NIC or ACBH in bulk samples and its dosage forms. It is selective to compounds containing a methyl ketone portion in their molecules.

(Received 26 November 1990. Revised 18 March 1991. Accepted 9 April 1991)

Summary—The influence of nutrient level, hours of light and the flux of air by volume of solution on uptake of lead has been examined from batch growth experiments carried out with the alga *Selenastrum capricornutum* Printz. The organic matter released by the alga has been characterized in terms of absorbance at 285 nm, dissolved organic carbon and maximum intensity of fluorescence at the excitation peak. The lability of lead complexes formed with the alga exudates has been investigated in terms of differential pulse anodic stripping voltammetry (DPASV). It has been noticed that lead inhibits the division of the cells which become bigger in size but with less pigment per cell.

The unicellular green alga *Selenastrum capricornutum* Printz, a chlorophyceas of the order of chlorococcales, has been used because it is a non-mobile, quite resistant species, which allows easy enumeration in the tests. Although the behaviour of the algae in laboratory cultures can be slightly different from that of the natural phytoplankton,¹ cultures normally serve as good models. *Selenastrum capricornutum* has been chosen because it is considered by the U.S. Environmental Agency to be a standard for assaying algae growth potential in natural water samples.

The absorption of heavy metals by unicellular alga is of great importance because they are a primary link in food chains contaminating the organisms that depend directly or indirectly on them, and also are useful in terms of treatment of polluted water.

Following our work about the toxicity of cadmium to the alga *Selenastrum capricornutum* Printz² a study has been undertaken on the influence of nutrients, light and flux of air by volume of solution on the toxicity of lead at different levels. The effect on the growth rate, percentage of pigments and uptake of lead has been analysed.

In order to have a better insight into the type of organics released by the alga at different

experimental conditions, dissolved organic carbon (DOC), absorbance at 285 nm and maximum intensity of fluorescence at the excitation peak (F) have been determined and compared with those obtained in natural freshwaters.^{3,4}

The lability of formation of lead complexes with the exudates in terms of differential pulse anodic stripping voltammetry (DPASV) for different conditions has also been analysed. The results have been interpreted in terms of a possible mechanism to decrease toxicity; this type of mechanism has already been proposed by Williams.⁵

EXPERIMENTAL

Chemicals and solutions

The reagents used were of analytical grade and the content of heavy metals was tested by differential pulse anodic stripping voltammetry (DPASV) and found to be negligible. The standard solution of lead nitrate was prepared from Merck p.a. salt and checked with a standard solution of EDTA.

The distilled and demineralized water used had conductivity values $\leq 0.1 \mu\text{sec}$. In the voltammetric experiments the pH was adjusted with acetate buffer to pH between 4 and 5.

Procedure

The alga *Selenastrum Capricornutum* was isolated from fish ponds at Azambuja, Portugal. The stock monoculture for the experiment is maintained at "Instituto Nacional de Investigação das Pescas". (Fisheries Institute), according to our previous paper.² The average cellular volume was determined by measuring twenty cells from each experiment and considering them to have the form of two cones.

For the biological cultures, flasks of pyrex were used with distilled and demineralized water with concentrations of essential nutrients of 26.5 ppm potassium nitrate (3.67 ppm N) and 2.65 ppm sodium dihydrogen phosphate ($\text{NaH}_2\text{PO}_4 \cdot \text{H}_2\text{O}$) (0.60 ppm P) for the cultures with "more nutrients" and with 5.65 ppm potassium nitrate (0.78 ppm N) and 0.56 ppm $\text{NaH}_2\text{PO}_4 \cdot \text{H}_2\text{O}$ (0.13 ppm P) for those with "less nutrients".

The concentration of iron(III) was always $\sim 10^{-6}M$ and pH ~ 6 . The flasks with the medium were sterilized at 125° for 30 min before inoculation with the alga from a stock culture containing a final value of $\sim 8 \times 10^9$ cells/l. The air bubbled through the flasks was previously passed through activated charcoal. Lead was added two days before inoculation of the algae. Cultures were incubated in a Lab-Line chamber with days and nights simulated. During daytime the temperature was 20° and at night 15° . In the set of experiments with "more light" there were 11 hours of daylight and for those with "less light" the cells were subjected to 8 hours of daylight. The growth curves (number of cells per litre of solution *vs.* time) were determined from counts of cells under the microscope in Burkler Chamber Resistance L/W, Tiefe 0.100 mm, 0.0025/0.04 mm². Aliquots for counting were sampled at intervals of one day until the stationary phase was obtained, generally within 7–8 days.

All the samples of the solution of the growth media were passed through a $0.45\text{-}\mu\text{m}$ filter. For determination of dissolved organic carbon (DOC), absorbance at 285 nm (A_{285}), maximum intensity of fluorescence at maximum excitation of 340 nm (F) (calibrated at 100% for a concentration of 0.2 mg/l. salicylic acid solution according to Buffle and co-workers^{3,4}) and lead concentration without decomposition of the organic matter by DPASV, the samples were kept in the refrigerator at $\sim 4^\circ$ between 1 and 5 days. For the determination of the pigments the pro-

cedure indicated by Simões Gonçalves *et al.*² was followed.

Instruments

The voltammetric experiments were done with a PAR 174 A polarograph under potentiostatic control, with three electrodes: hanging mercury drop electrode, platinum electrode and saturated calomel electrode. A deposition potential of -0.5 V has been used.

The spectrophotometric experiments were done in a Lambda 5 Perkin-Elmer spectrophotometer. The determination of molecular fluorescence was performed with a Perkin-Elmer MPF-3 fluorimeter with a xenon lamp. DOC was determined with a Dohrmann carbon analyser DC-85 A.

The whole procedure was similar to that of our previous work.²

RESULTS AND DISCUSSION

From Fig. 1 it can be seen that the growth curves of the uncontaminated cells are not significantly influenced by the number of hours of exposure to light between 11 and 8 hr (curves B and D).

However, from curves A and C it is apparent that in the presence of a concentration of lead

Fig. 1. Growing curves of the alga *Selenastrum capricornutum* with time. Curves B, D without lead with more nutrients and more or less light. Curve G—with lead $3 \times 10^{-8}M$, more light and less nutrients. Curve F— $1 \times 10^{-6}M$ lead, more light and less nutrients. Curve C— $9 \times 10^{-7}M$ lead, more light and more nutrients. Curve A—lead $1 \times 10^{-6}M$, more nutrients, less light. Curve E—lead $2.5 \times 10^{-6}M$, more nutrients, more light. The flux of air by volume of solution was always 1.9×10^{-3} /sec. For more details see Experimental.

of $\sim 10^{-6}M$ the light has influence, the number of cells per litre in the stationary phase being significantly smaller when there is a shorter time of exposure to light. In this situation the increase of lead from 1×10^{-6} to $2.5 \times 10^{-6}M$ in the cultures with 11 hr of exposure to light (by day), causes an effect similar to that which is caused by the decrease of hours of light (by day) from 11 to 8 hr for lead concentrations of $1 \times 10^{-6}M$.

Experiments with 11 hours of light by day and "less nutrients" have also been done and it can be seen from curve G that even with a small concentration of lead ($2.7 \times 10^{-8}M$) the growing curve decreases significantly, which may indicate that for cells not too much affected, or even without lead, the decrease of the concentration of the nutrients from 3.67 ppm N and 0.60 ppm P to 0.78 ppm N and 0.13 ppm P has more influence than the reduction of hours of light (by day) from 11 to 8 hr.

However this effect is not so clear in the presence of $1 \times 10^{-6}M$ lead (curves F and C).

Figure 2 shows the influence of the flux of air (Q) divided by the volume of the culture (V) on the growing curve of the cells. In fact, it can be seen for both cultures, not contaminated (curve A) and contaminated with $\sim 2 \times 10^{-6}M$ (curve B), that after attaining the plateau a new exponential phase can occur after an increase of the ratio Q/V and the response is not instantaneous. As the solution is always saturated with oxygen

Fig. 2. Influence of the ratio of the flux of air by volume of solution in the growing curve of *Selenastrum capricornutum*. Curve A without lead, "more nutrients" and "more light". Curve B $2 \times 10^{-6}M$ lead, "more nutrients" and "more light". Q/V changed on the 3rd day from $2.5 \times 10^{-3}/\text{sec}$ to $3.5 \times 10^{-3}/\text{sec}$. For more details see Experimental.

Table 1. Influence of nutrients, lead concentration, light and the ratio of flux of the air by the volume Q/V in the growth rate of the alga *Selenastrum capricornutum* ($\ln N_{\text{cel}} = a + \mu t$)

Experimental conditions	C_{Pb}	$\mu \text{ hr}^{-1}$
more nutrients more or less light $Q/V = 1.9 \times 10^{-3}/\text{sec}$	—	$(12 \pm 1) \times 10^{-3}$
more nutrients less light $Q/V = 1.9 \times 10^{-3}/\text{sec}$	1×10^{-6}	$(3.8 \pm 0.5) \times 10^{-3}$
more nutrients more light $Q/V = 1.9 \times 10^{-3}/\text{sec}$	1×10^{-6}	$(8 \pm 1) \times 10^{-3}$
more nutrients more light $Q/V = 3.2 \times 10^{-3}/\text{sec}$	1×10^{-6}	$(14 \pm 1) \times 10^{-3}$

and carbon dioxide from the air, this is probably due to the fact that highly stirred cells are more exposed to light and nutrients. In fact CO_2 is generally not a limiting step in well aerated cultures according to Goldman *et al.*⁶

If we linearize the exponential growth phase in the form $\ln N = a + \mu t$, it can be seen from Table 1 that for the cells contaminated with lead $\sim 1 \times 10^{-6}M$ the ratio Q/V induces a change of the rate constant μ from 8×10^{-3} to $14 \times 10^{-3} \text{ hr}^{-1}$. For the smaller value of Q/V the decrease of hours of light by day from 11 hr to 8 hr leads to a change of μ from $8 \times 10^{-3} \text{ hr}^{-1}$. The increase of Q/V causes a significant increase in μ , even in the presence of lead.

Table 2 summarizes the total values of lead in the alga and in the water together with the labile lead in terms of DPASV, *i.e.*, lead determined directly in samples without the destruction of organic matter (complexes dissociated within a time scale of a few milliseconds⁷). From this table it can be seen that for the experimental conditions of "more nutrients", "more light" and flux of air by volume of solution $Q/V = 3.2 \times 10^{-3} \text{ sec}^{-1}$, the percentage of labile lead is about 70% for the concentration of lead $8 \times 10^{-7}M$ and about 80% for $C_{\text{Pb}} = 2.5 \times 10^{-6}M$ from the beginning until the last day of the experiment (9th day). This means that in the presence of less lead the cation is complexed with the exudates in the form of more inert complexes in terms of DPASV. These species can be physically (due to the size of the molecule) and chemically inert. So in an environment with less lead the alga may have the possibility of releasing organics that can act as a protection.

This has been checked from the results of the last day of the experiment (last column of

Table 2. Influence of the nutrients, light, concentration of lead and the ratio of flux of air by the volume (Q/V) in the uptake of lead by the alga *Selenastrum capricornutum* and lead speciation in the medium

more light more nutrients Q/V = 1.9 × 10 ⁻³ sec ⁻¹	9 × 10 ⁻⁷							1.47 × 10 ⁻⁷	1.40 × 10 ⁻⁷ 95%	7.46 × 10 ⁻⁷ 83%			
less light more nutrients Q/V = 1.9 × 10 ⁻³ sec ⁻¹	1 × 10 ⁻⁶							4.2 × 10 ⁻⁷	4.0 × 10 ⁻⁷ 95%	0.84 × 10 ⁻⁶ 84%			
more light more nutrients Q/V = 3.2 × 10 ⁻³ sec ⁻¹	8 × 10 ⁻⁷				3.7 × 10 ⁻⁷	2.51 × 10 ⁻⁷ 68%		2.34 × 10 ⁻⁷	1.66 × 10 ⁻⁷ 71%	5.59 × 10 ⁻⁷ 70%			
more light more nutrients Q/V = 3.2 × 10 ⁻³ sec ⁻¹	2.5 × 10 ⁻⁶	4.33 × 10 ⁻⁷	3.22 × 10 ⁻⁷ 74%	1.5 × 10 ⁻⁶ 60%	3.16 × 10 ⁻⁷	2.30 × 10 ⁻⁷ 73%		3.63 × 10 ⁻⁷	3.23 × 10 ⁻⁷ 89%	1.93 × 10 ⁻⁶ 77%			
more light less nutrients Q/V = 4.7 × 10 ⁻³ sec ⁻¹	1 × 10 ⁻⁶	2.2 × 10 ⁻⁷	1.6 × 10 ⁻⁷ 73%	0.8 × 10 ⁻⁶ 80%	3.65 × 10 ⁻⁷	2.2 × 10 ⁻⁷ 60%		2.86 × 10 ⁻⁷	1.9 × 10 ⁻⁷ 66%	0.8 × 10 ⁻⁶ 80%			

Table 2) where it can be seen that for the same experimental conditions the percentage of uptake of lead by the cells increases with the level of contamination.

In the experiment with "less nutrients" and higher flux of air by volume $Q/V = 4.7 \text{ sec}^{-1}$ with $C_{Pb} = 10^{-6} M$ the percentage of labile lead between the first and the 9th day is about 70%, which means that the level of nutrients and the charge of Q/V probably compensate each other in terms of a detoxification mechanism, which is checked by the percentage of lead uptake by the alga.

For the concentration of lead $\sim 10^{-6} M$, "more nutrients" and "more or less light" but with a smaller flux of air by volume $Q/V = 1.9 \times 10^{-3} / \text{sec}$ it can be seen that on the last day $\%Pb_{lab} = 95\%$ for both cases. So this probably means that the mechanism of detoxification is less efficient in this case when the value Q/V is smaller. The protection of algae by organics has already been noticed in experiments with the alga *Selenastrum capricornutum* with natural waters contaminated with heavy metals, where it is apparent that the sensitivity of the organism increases with the dilution of the growth medium with distilled water.⁸

We have already noticed in similar experiments with cadmium that the alga *Selenastrum capricornutum* takes more heavy metal and releases a higher percentage of organics forming inert complexes when in more adequate conditions of nutrients, light and temperature.²

In Fig. 3 the evolution of total lead in the culture medium divided by the number of cells *vs.* time is presented for experiments with different concentrations of nutrients, lead and flux of air by volume of solution. From these plots it can be seen that the evolution of the curves is of the same type, the concentration of lead by cell in the medium decreases exponentially with time. It can also be noticed that for the same order of contamination of lead the effect of the decrease of nutrients from 3.67 ppm N and 0.66 ppm P to 0.78 ppm N and 0.13 ppm P is similar to the decrease of Q/V from $4.7 \times 10^{-3} \text{ sec}^{-1}$ to $3.2 \times 10^{-3} \text{ sec}^{-1}$.

The peaks obtained in DPASV generally have potentials that are slightly more negative in the presence of organics than in their absence with a positive shift during the addition of lead. This probably means that the complexes are labile (in terms of formation) within the time scale of the technique.

Fig. 3. Plot of the concentration of lead dissolved in the water versus time. ●—experiments with "more nutrients", "more light", $C_{Pb} = 8 \times 10^{-7} M$, $Q/V = 1.9 \times 10^{-3}/sec$. ○—experiments with more nutrients, more light, $C_{Pb} = 2.5 \times 10^{-6} M$, $Q/V = 3.2 \times 10^{-3}/sec$. *—experiments with less nutrients, more light, $C_{Pb} = 1 \times 10^{-6} M$, $Q/V = 4.7 \times 10^{-3}/sec^{-1}$. For more details see Experimental.

It was checked that the peak current (i_p) was proportional to the deposition time between 1 and 15 min, indicating that there was no distortion of the peak due to possible surface effects.⁹

For all experiments it was noticed that both chlorophyll *a* and *b* as well as vegetal carotenoids decrease with the increase in lead concentration on the last day of the experiment (8th–9th day).

On the other hand from Fig. 4 it can be seen that the concentration of pigments divided by the number of cells decreases with the level of lead in the alga, which means that lead accumulated in each cell influences the level of pigments existing in each unit. Once more it can be noticed that the effect of the decrease of nutrients from 3.67 ppm N and 0.60 ppm P to 0.78 ppm N and 0.13 ppm P was compensated by the increase of the value of Q/V from $3.2 \times 10^{-3} sec^{-1}$ to $4.7 \times 10^{-3} sec^{-1}$.

From the results obtained with the experiments with cadmium,² it is also apparent that a decrease of 1/3 of nutrients is roughly compensated (in terms of pigments in the cells) by an increase of 6° of temperature and 4 hr of light.

From the experiments with the highest value of Q/V ($4.7 \times 10^{-3} sec^{-1}$) and in the presence of lead (conc. $\sim 10^{-6}$), it was very clear that the cells, although small in number, had a much higher volume ($V = 31.68 \mu m^3$) than those in

the absence of lead ($V = 19.95 \mu m^3$) (as can be seen in the photograph in Fig. 5). So, in fact, this heavy metal inhibits the division of the cells but increases their size, as already noticed by Christensen *et al.*¹⁰ However, the level of pigments per cell decreases in the presence of lead, which probably means that although bigger, the cells are not so healthy.

In Table 3 the influence of nutrients, light, concentration of lead in the contaminated medium and flux of air by volume of solution has been analysed in terms of DOC, intensity of fluorescence at 400–440 nm at the excitation maximum of 340 nm and intensity of absorbance at 285 nm. This has been done to give a better insight into the organics released by the alga contaminated or not with lead and to compare with the values obtained in natural waters.^{3,4}

From this table it is apparent that the DOC is about ~ 20 mg/l. and the effect of the change of concentration of lead, Q/V , nutrients or number of hours of light is not clear.

The values of A_{285}/DOC and F/DOC are always within 1–2, of the same order as for cadmium,² and as expected, since the concentration of benzenecarboxylic and phenolic compounds for the same DOC is generally smaller

organics are low-absorbing aliphatic organic compounds such as carbohydrates, organic acids such as glycollic acid, aminoacids, polypeptides, lipids and organic phosphates.

However, from Fig. 6 it is clear that the fluorescence of the organics released by the non-contaminated cells during the several days is higher than for the alga with lead. Therefore, as noticed with cadmium,² it seems that the organics released by the cells in healthier conditions have a higher fluorescence.

Fig. 6. Plots of the fluorescence intensity of the solution at 400–440 nm (after excitation at 340 nm) divided by the number of cells versus time. ●—experiments with less nutrients, more light, without lead and $Q/V = 4.7 \times 10^{-3} \text{ s}^{-1}$. ○—experiments with less nutrients, more light $1 \times 10^{-6} M$ in lead and $Q/V = 4.7 \times 10^{-3} \text{ s}^{-1}$. For more details see Experimental.

CONCLUSIONS

As a result of the investigations the following conclusions were drawn:

(a) The reduction of the number of hours of light from 11 hr to 8 hr has little influence on the growth curves without lead but clearly affects the cultures with lead.

(b) An increase of the ratio of flux of air by volume of solution (Q/V) at the stationary phase may produce another exponential phase.

(c) The increase of the ratio of Q/V and of nutrients and the decrease of contamination with Pb^{2+} led to a release of exudates by the alga that form more inert complexes in terms of DPASV, with a smaller relative uptake of this heavy metal by the alga.

(d) Although lead inhibits the division of the cells, the average cell volume increases considerably, which is clearer at higher Q/V values. However, the number of pigments by unit decreases in the presence of lead.

The organics released by the alga not contaminated with lead have more fluorescent groups.

FLOW ANALYSIS OF SILICATE ROCKS FOR ZIRCONIUM

R. KURODA, K. OGUMA, K. KITADA and S. KOZUKA

Laboratory for Analytical Chemistry, Faculty of Engineering, University of Chiba, Yayoi-cho,
Chiba 260, Japan

(Received 20 February 1991. Revised 28 March 1991. Accepted 3 April 1991)

Summary—A flow analysis system involving the on-line configuration of an anion-exchange column has been examined to enrich and determine trace concentrations of zirconium of several ppm to hundred ppm levels in silicate rocks and minerals. About 100 mg of sample is decomposed by fusion with a mixture of boric acid and lithium carbonate and taken up with 1M hydrochloric acid to a total of 100 ml. Depending upon the concentration of zirconium, either a 1- or 4-ml aliquot is introduced into an aqueous carrier stream, merged with sulphuric acid and passed through a small volume anion-exchange column. The enriched zirconium is then back eluted with hydrochloric acid, colour-developed with Arsenazo III, and detected spectrophotometrically at 665 nm.

Flow-injection analysis of silicate rocks for major, minor and trace constituents has been reported. For major elements specific spectrophotometric or atomic-absorption spectrometric methods^{1–5} are used for detection. For minor^{6,7} and trace^{8,9} determination, off-line and on-line enrichment techniques have been used. On-line separations are preferable to off-line techniques in view of the obvious advantages of rapidity, reproducibility and elimination of involved manipulation. Continuous on-line precipitation–dissolution techniques coupled with conventional atomic-absorption spectrometric instruments have been developed for preconcentration and determination of trace cobalt⁸ and copper⁹ in silicate rocks. Scant information is available for other trace and minor elements in silicate rocks.

Many spectrophotometric methods for zirconium have been reported in combination with time-consuming ion-exchange chromatographic techniques^{10–17} or with use of masking agents and sample-simulated standard solutions.¹⁸ In this work, a flow analysis method for on-line anion-exchange preconcentration and determination of a few $\mu\text{g/g}$ to hundreds of $\mu\text{g/g}$ quantities of zirconium in silicates has been developed in conjunction with selective spectrophotometry with Arsenazo III. Though the decomposition step is the most labour-intensive and has the lowest throughput, the flow analysis preconcentration/measurement developed in this work for the treated samples takes 17–34 min, depending on the concentration level of zirconium.

EXPERIMENTAL

Reagents

The stock solution of zirconium (1.004 mg Zr per ml of 1M nitric acid) was obtained from Kanto Chemical Co., Tokyo. A working stock solution (100.4 μg Zr per ml of 3M hydrochloric acid) was prepared from this solution. The working standards were made by serial dilution of the working stock solution with 1M hydrochloric acid. Arsenazo III [2,7-bis(2-arsonophenylazo)-1,8-dihydroxynaphthalene-3,6-disulphonic acid] of notified reagent grade (Notification no. 850004) was purchased from Dojindo Laboratories, Kumamoto, Japan) and was used as received. From an Arsenazo III stock solution (0.25% aqueous solution), the working reagent solution was prepared by dilution with 4M hydrochloric acid to yield 0.005% solution. All other chemicals used were of reagent grade.

Apparatus

A schematic of the flow system is shown in Fig. 1. A Shimadzu Model UV-180 double beam spectrophotometer with a 20-mm flow cell (62.8 μl) was used as the detector, the output being fed to a Hitachi Model 561 strip chart recorder.

The ion-exchange column (IC) for on-line use was prepared by packing a strongly basic anion-exchange resin Bio-Rad AG1-X8 (100–200 mesh in the chloride form), into a 9-cm length of 1-mm bore Teflon tube and was plugged with polyester fibre at both ends. The flow channel

Fig. 1. Block diagram of FIA system. C: carrier (water, 0.2 ml/min); R1: 0.1M sulphuric acid (2.0 ml/min); S: sample (0.945 or 4.13 ml); Cm1 and Cm2: mixing coil (200 cm and 100 cm, respectively); IC: ion-exchange column; W: waste; P1 and P2: double plunger type pump; R2: 4M hydrochloric acid, R3: Arsenazo III solution (see the text for the flow rates of R2 and R3); D: damper coil (1 mm \times 500 cm); B: bypass (0.25 mm \times 100 cm); SP: spectrophotometer; Cb: back pressure coil (200 cm).

was assembled from 0.5-mm bore Teflon tubing and Daiflon connectors except for the ion-exchange column, damper and bypass tubings. Six-way loop injection valves were used for sample injections and switching of the flow path. A reciprocating pump of the double plunger type (Kyowa Seimitsu Model KHU-W-104) (P1) was used for pumping the carrier (C) and 0.1M sulphuric acid solutions (R1). The ion-exchange column eluent (R2) and chromogenic solution (Arsenazo III solution, R3) were propelled by a Sanuki Kogyo Model DM3M-2044 double plunger pump (P2). The ion-exchange column (IC), eluent (R2) and Arsenazo III solution (R3) were heated to 60° in a thermostat to accelerate the elution and indicator reaction.

Procedure

Preparation of sample solution. Place a 100-mg powdered sample in a platinum crucible, add 600 mg of 1:1 lithium carbonate-boric acid mixture and mix. Fuse the mixture for 15 min at 1000°. Dissolve the cooled melt in 1M hydrochloric acid and dilute accurately to 100 ml with the same acid. Subject the solution to FIA measurements within 24 hr.

Flow analysis measurement. Introduce the sample solution into the carrier (C), at point S with the six-way rotary injection valve. Use a sample aliquot of 1 ml (0.945 ml in the valve used) for usual silicate rocks ($> 50 \mu\text{g Zr/g}$) and of 4 ml (4.13 ml in the valve used) for low zirconium minerals. Allow the sample slug to merge with (R1) to form the sulphatocomplex of zirconium. Then, pass through the ion-exchange column (IC), where it is sorbed. By switching the valve at 6 (or 23) min from the start of 1 (or 4) ml sample introduction, place the column

into the eluent flow path (R2) to strip the zirconium in the reverse direction. Merge the stripped zirconium with the chromogenic solution (R3) to develop the colour. Read the absorbance in the flow-through cell at 665 nm. Take measurements three times for each sample. Use the peak height or peak height times band width at the half peak height as a measure of the signal.

RESULTS AND DISCUSSION

In order to separate the zirconium from the complicated matrix in silicate rock and mineral samples, the anion-exchange was carried out in sulphuric acid media because of the high sorption and high selectivity for zirconium of this medium.^{19,20} Major elements in silicate rocks do not exhibit any tendency to sorb on the resin over a wide concentration range of sulphuric acid. The sorbed zirconium can be eluted by 4M hydrochloric acid, which leaves uranium on a conventional anion-exchange resin column as chlorocomplexes.²⁰

Recorded signals for zirconium in the flow system are illustrated in Fig. 2 as a function of sulphuric acid concentration in the on-line anion-exchange column. In these runs the flow-rate of carrier (C) and sulphuric acid (R1) was kept at 0.2 and 2.0 ml/min, respectively, and the concentration of the acid was varied in the range 0.05–0.25M. The sharp peak to the left is a refractive index peak and the subsequent skewed peak is due to the zirconium-Arsenazo III complex. As can be seen, the peak height of the complex increases with decreasing concentration of sulphuric acid, not reaching a plateau under the conditions tested. Owing to a small volume of the ion-exchange column used (0.0707 ml), the retention (elution) volume for the column is low, being calculated to be approximately 9.7 ml for the eluent 0.25M sulphuric acid and 32 ml for 0.1M sulphuric acid by assuming K_D ¹⁹ of 211 (k-prime *ca.* 390) and of 704 (k-prime *ca.* 1309), respectively. (See note for the calculation of elution volume at the end of this section.)

During the 6-min sample loading period, 13 ml of sample/the reagent stream R1 (sulphuric acid solution of varying concentration) is forced to pass through the column. Therefore, the zirconium sorbed at the earlier stage of the sample loading period may be removed from the column partially or to a significant extent, depending on the concentration of sulphuric acid

Fig. 2. Signals as a function of concentration of H_2SO_4 (M) in reagent stream R1. Zr concentration: $0.10 \mu\text{g Zr/ml}$. Concentration of H_2SO_4 : (a) $0.25M$, (b) $0.15M$, (c) $0.10M$, (d) $0.05M$. Sample loading: 0.945 ml .

solution (R2), yielding insufficient recoveries, as reflected by the varying peak height (Fig. 2). However, neither homogeneous mixing during chemical reaction nor attainment of chemical equilibrium are essential conditions for flow-injection analysis to be performed successfully. In the present ion-exchange enrichment, the reproducible quantitation of zirconium is possible with production of a coloured complex. We used $0.1M$ sulphuric acid as the reagent stream (R1). Stripping of zirconium is feasible by elution with $4M$ hydrochloric acid (R2) in the opposite direction to reduce band broadening. The temperature of the column, the eluent (R2) and the chromogenic solution (R3) was kept at 60° to avoid the occurrence of ghost peaks and to enhance the sensitivity of detection; in actual fact, heating resulted in a signal with twice the peak area as that obtained at room temperature.

Since the flow-rate of the eluent (R2) affects the detection sensitivity of zirconium with Arsenazo III, we examined the effect of flow-rates of the eluent and chromogenic solution on the peak height, keeping both rates the same, over the range $1.45\text{--}2.50 \text{ ml/min}$ [0.90 to 1.70 ml/min] in the case of 1 ml [4 ml] sample loading. The peak height decreased a little with increasing flow-rate, reaching a constant level at 1.95

ml/min for the 1-ml loading. A similar trend was observed for the 4-ml loading, but the peak height decreased rather rapidly with increasing flow-rate. From the aspect of sensitivity and avoidance of the presence of a neighbouring ghost peak, the flow-rate of 1.70 ml/min and 0.90 ml/min were chosen for 1 and 4 ml sample loadings, respectively.

The effects of other metal ions in the present system is given in Table 1. Actinides and lanthanides are known to interfere seriously with the determination of zirconium with Arsenazo III. However, lanthanides do not sorb on the anion-exchange resin from sulphuric acid media. The distribution coefficients¹⁹ of uranium and thorium on Bio-Rad AG1 at $0.1M$ sulphuric acid are 248 and 21, respectively, but their sorptions are not always quantitative, particularly for thorium during the loading of a large volume of sample + reagent solution (R1) relative to the column volume in the present anion-exchange system. The low sensitivity of Arsenazo III reaction with uranium(VI) also helps to reduce the interference from uranium(VI).

Zirconium becomes hydrolysed at low acid concentrations. The time dependence of stability of the ion-exchangeable zirconium in $1M$ hydrochloric acid of the boric acid-lithium

Table 1. Effect of foreign ions

Ion	Added as	Amount present		Zr amount, $\mu\text{g/ml}$	
		$\mu\text{g/ml}$	Added	Found (peak area)	Found (peak height)

Mg(II)	chloride	40	0.120	0.121	0.117

Conditions: sample (0.945 ml) and sulphuric acid were passed through the column for 6 min at a flow rate of 2.2 ml/min (see Procedure).

carbonate fusion case was studied. The measurable zirconium decreased relatively rapidly with time (0.5, 2 and 8% decrease after 1, 2 and 8 days respectively), so that the prompt determination of zirconium after the decomposition of sample is of importance. We subjected the sample solution to flow analysis measurements within 24 hr.

The proposed procedure was applied to the analysis of practical silicate samples. The results of two independent determinations for a number of different types of reference rocks and minerals of the Geological Survey of Japan are given in Table 2. As indicated, *ca.* 4–140 ppm of zirconium in these samples can be determined. Comparison with data for the reference samples that have been assigned working values²¹ shows that there is reasonable agreement. At the present time, no recommended values are given to these reference samples, partially because of lack of adequate data for these rocks. Users of

geostandards are solicited to contribute more data, particularly on trace elements.²¹ The reproducibility obtained for the individual sample solutions (RSD, $n = 3$) ranges from 0.27 to 9.6%, averaging at 3.4%.

Note: Calculation of the retention (elution) volume of a column

For any ion-exchanger, k' -prime is defined by the ratio of the amount of material in the exchanger phase to the amount of material in the solution (mobile) phase. The k' -prime value is related to the distribution coefficient K_D by the equation:

$$k' = K_D V_R / V_S \quad (1)$$

where V_R and V_S refer to the volumes of the resin and solution phases in the column. For a column packed with spherical resins, the stationary phase occupies roughly 65% of the column volume, so that the ratio V_R/V_S is about 1.86 (65/35).

$$k' = 1.86 K_D \quad (2)$$

The retention volume V of the sorbed species is related to k' -prime by the equation

$$V = V_S(1 + k') \quad (3)$$

where V_S of the present column is 0.0247 ml. Knowing K_D for a species under the conditions used, we can estimate roughly the retention (elution) volume, where the sorbed species elutes at a maximum concentration.

SUPERCRITICAL FLUID EXTRACTION OF HIGH SULFUR SOILS, WITH USE OF A COPPER SCAVENGER

STEVEN M. PYLE* and MATTHEW M. SETTY

U. S. Environmental Protection Agency, Las Vegas, NV 89119, U.S.A.

(Received 26 October 1990. Revised 28 February 1991. Accepted 5 March 1991)

Summary—Supercritical fluid extraction (SFE) of sulfur-containing soils and sediments was hindered by deposition of elemental sulfur in the restrictor stopping the flow of carbon dioxide. It was found that a copper scavenger column placed after the sample cell removed the elemental sulfur, making SF extraction and quantification possible. Conditions are described for SFE and analysis of two standard reference materials (SRM), with use of a copper scavenger column. Quantification was performed by gas chromatography with mass spectrometric detection and the results were compared with the certified SRM values.

Supercritical fluid extraction (SFE) is a promising method for removing organic chemicals from solid matrices without the use of toxic solvents. Past environmental applications of SFE have used carbon dioxide, which exhibits a viscosity and density intermediate between those of a gas and liquid when at above its critical temperature (31.0°) and pressure (73 atm).¹⁻⁸ Off-line SFE is accomplished by placing a solid matrix (*e.g.*, fly-ash, soil, sludge) in a high-pressure cell and then passing carbon dioxide, pressurized to above its critical point, through the sample with a syringe pump. A post-cell fused-silica restrictor maintains the supercritical pressure within the cell and leads the carbon dioxide containing dissolved organics into an appropriate solvent or cryogenic trap for subsequent analysis by gas chromatography. SFE has been shown to be cheaper and faster than classical methods of extraction (ultrasonication and Soxhlet extraction) for small samples (*ca.* 1 g).

Because the solubility of dissolved materials decreases at lower fluid pressure, the fused-silica restrictor may become plugged with extracted material as the supercritical carbon dioxide is decompressed along the length of the restrictor. Lowering the carbon dioxide pressure reduces the plugging but reduces the extraction rate and the solubility of organics in the supercritical fluid. Heating the restrictor reduces precipitation, thus minimizing obstruction of the restrictor. Unfortunately, neither technique is appropriate when the sample contains appreciable amounts

of elemental sulfur (S_8). Two recent studies^{9,10} have dealt with the presence of elemental sulfur. The more recent⁹ analyzed the cyclohexane-soluble extracts of three sediments and found that 10–20% of the elemental content was sulfur. Restrictor clogging by sulfur is therefore a potential limitation of the use of SFE for environmental applications.

In this note, we describe a technique for using granular copper to remove elemental sulfur from supercritical carbon dioxide extracts of soils. The results of the analysis of a standard reference material (SRM) are compared with the certified value. The use of an SFE scavenger column was developed from a concept by Muragaverl and Vorhees.¹ This paper is intended to inform the scientific community of a potentially useful solution to the problem of extracting samples containing sulfur. It is by no means a complete validation of the technique.

EXPERIMENTAL

Supercritical fluid extraction was performed with a Suprex (Pittsburgh, PA) Model 50 Supercritical Fluid Extractor. SFE-grade carbon dioxide was obtained from Scott Specialty Gases (Plumstead, NY) and passed through a sample cell at 400 atm pressure and 60° for 10 min. The CO₂ flow was estimated to be 3.3 ml/min during extraction, from measurement of the flow of gaseous CO₂ (with a bubble meter) as it left the restrictor at the temperature and pressure of the extraction. This flow-rate was converted into ml/min for liquid CO₂ by dividing it by the

*Author for correspondence.

ratio of the density of liquid CO₂ (0.849 g/ml) to that of gaseous CO₂ (0.00198 g/ml). The sample cell, consisting of an empty 10 cm × 4.6 mm i.d. stainless-steel tube, was made from an HPLC column cartridge (Brownlee, Santa Clara, CA) by removing the inlet frit and column packing. The scavenger column consisted of 2.0 g of granular copper in a 3 cm × 4.6 mm i.d. Brownlee HPLC guard column with the inlet frit removed. The extraction and scavenger cartridge columns were fitted into the Brownlee holders for easy installation and removal. A 0.5 μm by ¼-in. o.d. frit was placed in the inlet of the cell holder to prevent the cell contents from leaving the cell during depressurization. The 50 μm i.d. × 10 cm fused-silica restrictor was connected to the exit of the scavenger column and passed through a Valco Tee into a length of stainless-steel tubing so that the restrictor remained entirely within the oven. As the CO₂ expanded at the end of the restrictor, the Joule-Thompson effect cooled the stainless-steel (SS) tubing and empty 7.4-ml sample vial and cold-trapped the eluted organics. A piece of 0.53 μm i.d. fused-silica tubing carried the spent gaseous carbon dioxide to a molecular sieve/activated charcoal trap, which ensured that no toxic volatiles were released into the laboratory. Figure 1 shows the SFE apparatus.

The sediment used in this work was a commercially available certified standard. SRM 1941 is a marine sediment from the National Institute of Standards and Testing (NIST), Gaithersburg, MD, which contains a high concentration of sulfur and less than 1 μg/g of several polynuclear

aromatics (PNAs). Non-oxidized granular copper was purchased from Mallinckrodt.

A 1-g portion of sediment was placed in the cell and extracted for 10 min. Organic compounds extracted were deposited on the inside of the stainless-steel tubing and the empty 7.4-ml sample vial as the CO₂ was decompressed inside the SS tubing during the extraction. Organics were washed into the sample vial by replacing the plug in the Valco Tee (Valco part # ZT1) with an HPLC injector fitting (Valco screw hub nut; part # ZN1) and injecting 250 μl of hexane through the injector fitting. The vial was removed and capped for subsequent mass spectrometric analysis.

Gas chromatographic/mass spectrometric analysis was performed with an HP 5890 gas chromatograph equipped with an on-column injector and a 30 m × 0.25 μm DB-5 fused silica capillary column (J and W Scientific, Folsom, CA). The initial linear velocity of the helium carrier gas was 45 cm/sec; the linear temperature program started at 60° and ended at 300°, with a total run time of 29 min. A 1 m × 0.53 μm fused-silica retention gap was connected to the head of the analytical column to facilitate injection and to protect the analytical column. The gas chromatograph was connected to a Finnigan Incos 50 mass spectrometer which scanned from *m/z* 64 to 650 in 0.5 sec. Quantification was by the method of external standardization, based on the average response factor for four replicate injections.

Fig. 1

RESULTS AND DISCUSSION

The SFE system shown in Fig. 1 was designed for speed and ease of use. An initial design, with a 30 cm × 50 μm restrictor, was tested by spiking the empty cell with an appropriate amount of PNA standards and performing the extraction in triplicate under the specified conditions. The resulting SF extracts were compared with PNA standards of equal concentration, and the recoveries calculated. These recoveries were poor (14–65%) for the lighter, more volatile PNAs (naphthalene–fluorene). However, for the remaining PNAs, the recoveries ranged from 68 to 100% with an average recovery of 82.5%. This demonstrated that physical trapping of the less volatile eluting organics was possible with this initial design.

For the SRM 1941 samples, which contain ~25% sulfur, the restrictor was shortened to

‡No standard available; the d12-perylene response factor was used.

4 cm to increase the flow and improve recoveries, since our experience has demonstrated a "matrix effect" when working with soil samples. That is, spiked soil samples show greater recoveries than weathered samples.

The dimensions (length and i.d.) of the restrictor determine the flow of CO_2 and, therefore, the rate of extraction of the organics in the sediment sample. If the restriction is too great (long length and/or narrow i.d.), the extraction recoveries will be low and clogging will tend to occur. However, if the restriction is too little (short length and/or wider i.d.), the pressure may be difficult to maintain and the fast flow of CO_2 , along with aerosol generation, will make trapping of the organics more difficult. Since SRM 1941 did not contain any of the more volatile PNAs, the restrictor length was reduced to 4 cm for faster flow of CO_2 and, therefore, could increase recoveries in the 10 min extraction period.

The certified sediment, SRM 1941, was spiked with five deuterated PNAs (each at $410 \mu\text{g/g}$ level) and duplicate samples were extracted, with use of the copper scavenger column. The recoveries of the PNAs as a fraction of the certified or spike values are provided in Table 1. The recoveries ranged from 21 to 85% for the native PNAs and from 30 to 110% for the deuterated spikes. The recoveries of the heaviest two spikes were quantitative (110 and 96%) compared to those of the other PNAs. This is an indication that the lower PNA recovery was due to the "matrix effect" and not the copper scavenger. No extraction was possible without the copper scavenger column, since the elemental

sulfur deposited during extraction plugged the restrictor and stopped the flow of carbon dioxide. No flow-interruptions were experienced during the two extractions. After the two SF extractions the 2.0 g of copper in the scavenger column had increased in weight by 9 mg and was also totally blackened. The color change and weight gain are consistent with formation of copper sulfide.

Though the recoveries obtained in this study were not quantitative, they were in agreement with the average recoveries reported in a U.S. EPA round robin study of SFE.¹¹

CONCLUSION

The presence of elemental sulfur (S_8) in soil and sediments can degrade the performance of supercritical fluid extraction, by slowing the flow of carbon dioxide or completely plugging the restrictor. A copper scavenger column placed between the extraction column and the restrictor has been shown to effectively remove or reduce sulfur, from the supercritical carbon dioxide, apparently without adversely affecting the recoveries.

EXTRACTION OF COPPER(II) WITH THE APCD/DIBK SYSTEM FROM CONCENTRATED HYDROCHLORIC AND NITRIC ACID MEDIA: ESTIMATION OF TRUE LIMIT OF ACIDITY FOR THE EXTRACTION

MASAHIKO MURAKAMI and TAKEO TAKADA

Department of Chemistry, College of Science, Rikkyo (St. Paul's) University, Nishi-Ikebukuro, Toshima-ku, Tokyo 171, Japan

(Received 10 December 1990. Revised 26 February 1991. Accepted 6 March 1991)

Summary—The extraction of copper(II) from strongly acidic solution (0.01–8*M* hydrochloric and 0.01–5*M* nitric acid) with ammonium 1-pyrrolidinecarbodithioate in di-isobutyl ketone has been studied. Compared with the hydrochloric acid system, a considerably larger amount of the reagent is needed for complete extraction of copper chelate from nitric acid solution as the extract is more unstable in the nitric acid system. The decomposition of copper chelates extracted from nitric acid is based on the oxidation of the reagent and the chelate; the spectral change of the extract from nitric acid suggests that the copper(II) chelate is initially oxidized to copper(II) and then decomposes. The upper limit of the acidity of both acids from which the copper chelate can be quantitatively extracted strongly depends on the reagent concentration; the limit with $8 \times 10^{-2}M$ APCD (500-fold reagent: metal molar ratio) was taken as 8 and 4*M* for hydrochloric and nitric acid, respectively.

The extraction of various elements into isobutyl methyl ketone (IBMK) with ammonium 1-pyrrolidinecarbodithioate (APCD) is widely used for increasing the sensitivity of atomic-absorption spectrometry (AAS). Although it is known that APCD is relatively stable in very low pH (< 1) media and has sufficient ability for formation of the chelate with some elements even in such a media, a study of the use of the APCD/IBMK system in strongly acidic media had not been attempted. There are only two reports that suggest the possibility of using this system at very low pH (< 1) or that mention the effect of hydrogen ion concentration on the extraction of various elements,^{1,2} and neither show any positive intention to use this system in such a region.

From a practical point of view, extraction of the metal chelates from such an acidic region has significant advantages. It allows metals to be directly extracted from a sample dissolved in concentrated acid, without pH adjustment, and only requires minimum dilution of the sample solution. Such a direct extraction saves time and is free from contamination by impurities in the buffer. We have investigated the extraction of copper(II) from very acidic solution,^{3–6} based on this concept.

In preceding papers^{4,5} we studied the extraction of copper(II) from 0.01–8*M* hydrochloric acid into IBMK with APCD in order to apply this system to the extraction of some elements from very acidic solution. It was found that IBMK was less suitable for the extraction in strongly acidic media, because a considerable part of the IBMK phase was dissolved into the acidic aqueous phase, and a large amount of free acid contaminated the extract and caused decomposition of the copper chelate. We therefore studied the use of di-isobutyl ketone (DIBK) as an alternative to IBMK and found it to be a more suitable solvent for extraction of the Cu(II)–PCD chelate from strongly acidic media.⁶ In contrast to IBMK, DIBK is virtually insoluble in up to 10*M* hydrochloric acid, and the copper chelate extracted into DIBK exhibits excellent stability. Copper can be quantitatively extracted from up to 8*M* hydrochloric acid with the APCD/DIBK system.

In this paper, to estimate the optimum conditions and true limit of acidity for copper extraction, we have systematically investigated the extraction of copper(II) from 0.01–8*M* hydrochloric acid and 0.01–5*M* nitric acid. From the standpoint of practical analysis, the applicability of this extraction system to nitric acid

media is of interest. Nitric acid is often used for the decomposition of solid samples due to its oxidizing ability. In our earlier work,³ it was suggested that the chelate extracted from nitric acid solution is oxidatively decomposed. Hence, the decomposition behaviour of the copper chelate extracted from nitric acid solution with this system was also studied.

EXPERIMENTAL

Reagents

All chemicals used were of reagent grade. Water was redistilled from an all-glass apparatus. A standard copper stock solution (1000 $\mu\text{g/ml}$) was prepared from 99.99% pure metal. All solvents were used without further purification.

Procedures

Extraction. A 20-ml volume of hydrochloric or nitric acid of desired concentration and 2.5 ml of a 10- $\mu\text{g/ml}$ copper solution were transferred to a 100-ml separating funnel. DIBK (10 ml) and 2.5 ml of APCD solution were added. The mixture was vigorously mechanically shaken.

Washing of the extract. Immediately after the aqueous phase had been withdrawn a 25-ml volume of water was added to the separating funnel and the mixture was mechanically shaken for 180 sec.

Measurements. The absorbance of the DIBK phase was measured at 433.5 nm in a 10-mm silica cell against DIBK as reference. For the kinetic study, the sample was kept in the cell compartment of the spectrophotometer at a constant temperature of 25°. Timing was started when the reagent was added to the mixture.

RESULTS AND DISCUSSION

Extraction of $\text{Cu}(\text{PCD})_2$ in hydrochloric acid media

The effect of hydrochloric acid concentration on the shaking time and the reagent concentration needed for quantitative extraction were studied at 0.01–8M hydrochloric acid. The amount of copper left in the aqueous phase was also checked by using flame atomic-absorption spectrometry to estimate the degree of copper chelate extraction.

Shaking time. In the extraction of copper-PCD chelate from strongly acidic solution, use of a large excess of reagent is recommended

since the kinetic stability of the copper chelate is highly dependent on the concentration of reagent.⁴ Hence, $8 \times 10^{-2}M$ APCD (corresponding to a 500-fold reagent: metal molar ratio in this system; close to the limit of solubility of APCD) was used in this study.

Figure 1 shows that the shaking time needed for completing the extraction depends on the acidity. The minimum shaking time needed for quantitative extraction decreased as the acidity was increased: 120 sec for 0.01M, 90 sec for 1M acid, and 60 sec for 4M and 8M acid. These findings disagree with the generally accepted acidity dependence of the rate of the metal chelate formation and of its extraction; Irving and Williams⁷ reported that the rate at which the metal chelates are formed and extracted decreases as the pH is reduced. However, the same tendency as that observed in this study was also obtained in the copper extraction with the APCD/IBMK system.⁵

It can be considered that this difference in the acidity dependence of the extraction rate between these two systems and others was based on the difference in the methods of adding the reagent. In the general metal chelate extraction system, the reagent is previously dissolved in the organic phase whereas in the APCD/IBMK and APCD/DIBK systems, the reagent is added to the system as an aqueous solution since it is not very soluble in these solvents. The facts suggest that the rate of copper chelate extraction is dependent on the rate of extraction of the reagent into the organic phase. It is expected that the rate of the reagent extraction increases as the acidity is increased since only an acid form of PCD ligand can be extracted and it seems that copper is mainly extracted by the ligand extracted in the organic phase.

Fig. 1. Effect of shaking time on extraction of $\text{Cu}(\text{PCD})_2$ in DIBK from hydrochloric acid: HCl 0.01M (○), 4M (△), 6M (□), 8M (●); [Cu] $1.6 \times 10^{-5}M$; [APCD] $1.6 \times 10^{-3}M$ (HCl 0.01–6M), $8.0 \times 10^{-3}M$ (HCl 8M).

After extraction the absorbance remained constant, even after a 20-min shaking period, for all concentrations of hydrochloric acid except 8M for which the absorbance gradually decreased above 300 sec of shaking. This indicates that the copper chelate was decomposed by the contact with the acid solution during the period of shaking. Over all the acidities used, the copper chelate could be extracted quantitatively in the range 120–300 sec shaking. Hence, this range was taken as optimum.

APCD concentration. Figure 2 shows the degree of extraction of copper chelate from hydrochloric acid as a function of the reagent concentration. As the acidity is increased the minimum concentration of the reagent needed for complete extraction increases: $4.0 \times 10^{-5}M$ (2.5-fold ratio to copper) for 0.01M, $6.4 \times 10^{-5}M$ (4-fold) for 4M, $2.6 \times 10^{-4}M$ (16-fold) for 6M acid and $2.2 \times 10^{-3}M$ (140-fold) for 8M acid.

For each acidity (except 0.01M), copper chelate was not extracted at all up to a certain concentration of the reagent, and this threshold concentration of the reagent increased as the acidity was increased: $3.2 \times 10^{-5}M$ (2-fold ratio to copper) for 4M, $1.3 \times 10^{-4}M$ (8-fold) for 6M acid, and $1.6 \times 10^{-4}M$ (10-fold) for 8M acid. Both of these findings indicate that there is appreciable decomposition of the chelate during the shaking period, and it becomes more marked as the acidity is increased and the concentration of the reagent is decreased.

Kinetic stability of the extract. The kinetic stability of the chelate extracted from hydrochloric acid into DIBK was studied at various APCD concentrations. As previously reported, the $Cu(PCD)_2$ chelate extracted into IBMK or DIBK from strongly hydrochloric acid media

Fig. 2. Effect of APCD concentration on extraction of $Cu(PCD)_2$ in DIBK from hydrochloric acid solution: [HCl] 0.01M (○), 4M (△), 6M (□), 8M (●); [Cu] $1.6 \times 10^{-5}M$; shaking time 300 sec (0.01–6M), 120 sec (8M).

Fig. 3. Kinetic stability of $Cu(PCD)_2$ extracted in DIBK from 4M hydrochloric acid solution: [APCD] $7.0 \times 10^{-5}M$ (○), $1.6 \times 10^{-4}M$ (▲), $2.9 \times 10^{-4}M$ (□), $4.2 \times 10^{-4}M$ (△), $1.6 \times 10^{-3}M$ (●); [Cu] $1.6 \times 10^{-5}M$; shaking time 300 sec.

shows the characteristic behaviour of decomposition.^{5,6} Figure 3 shows the variation in absorbance of copper chelate extracted into DIBK from hydrochloric acid solution with time; the absorbance was constant for a certain time and then suddenly dropped.

Sufficient stability for the determination could be obtained by using a large amount of the reagent. Table 1 gives the time ($t_{1/2}$) needed for the absorbance of the extract to decrease to half its original value. The kinetic stability of copper chelate is strongly dependent on the concentration of the reagent added; the decomposition time ($t_{1/2}$) increases as the concentration of the reagent is increased. It was noted that when $1.6 \times 10^{-3}M$ (100-fold to copper) or more of the reagent was added, the absorbance of the extract remained constant for more than 48 hr.

When the IBMK and DIBK extracts are washed with water or are filtered with dry filter paper, the stability can be considerably increased.^{5,6} In these extraction systems, it was observed that the free hydrochloric acid transferred into the extract by dissolution and by

Table 1. Decomposition time ($t_{1/2}$) of $Cu(II)$ -PCD chelate extracted from 4M HCl

[APCD], M	$t_{1/2}$ min
7.0×10^{-5}	25.0
1.6×10^{-4}	86.0
2.9×10^{-4}	164.5
4.2×10^{-4}	244.7
1.6×10^{-3}	>48 hr
1.6×10^{-2}	>48 hr

With washing or filtration

1.6×10^{-4} >48 hr

[Cu²⁺] $1.6 \times 10^{-5}M$, shaking time 5 min.

very fine droplets of the aqueous phase causes the copper chelate to decompose. The effect of the washing is due to almost complete removal of the free acid contaminated into the extract. In the case of filtration, a large part of the free acid can be removed, and it is considered that the fine droplets of the aqueous hydrochloric acid remaining in the extract can be removed.⁶ Therefore, the free acid is effectively removed by the washing and filtering of the extract. However, in the case of DIBK extraction, the extract exhibited sufficient stability without these treatments, if a large excess of APCD (about 100-fold or more to copper) was added (Table 1).

Acidity range. To estimate the acidity range which can be used for copper extraction, the percentage extraction of copper chelate was studied as a function of concentration of hydrochloric acid, with various concentrations of the reagent. Figure 4 shows the change in the percentage extraction of copper chelate with hydrochloric acid concentration of the aqueous phase, with 1.6×10^{-3} , 3.2×10^{-3} , 8.0×10^{-3} and $8.0 \times 10^{-2}M$ of APCD solution. The acidity range depends on the concentration of the reagent added; for example, although copper chelate can be extracted from $8M$ acid with $8.0 \times 10^{-2}M$ APCD (500-fold ratio of copper), it is not extracted at all above $7M$ acid with $0.0016M$ APCD. The limiting acidities of quantitative extraction of copper chelate were taken as follows: $5M$ with $1.6 \times 10^{-3}M$ APCD (10-fold ratio to copper), $6M$ with $3.2 \times 10^{-3}M$ (20-fold) and $8.0 \times 10^{-3}M$ (50-fold) APCD, $7M$ for $1.6 \times 10^{-2}M$ APCD (100-fold) and $8M$ for $8.0 \times 10^{-2}M$ APCD (500-fold).

These findings suggest that the range of acidity which can be used for the extraction is determined by the concentration of the reagent added; however, this point has been missed in several reports which have commented on these

Fig. 4. Extraction range of Cu(II) with APCD/DIBK system in hydrochloric acid media: [APCD] $1.6 \times 10^{-3}M$ (●), $3.2 \times 10^{-3}M$ (□), $8.0 \times 10^{-3}M$ (△), $8.0 \times 10^{-2}M$ (○); [Cu] $1.6 \times 10^{-3}M$; shaking time 300 sec.

Fig. 5. Effect of shaking time on extraction of $Cu(PCD)_2$ in DIBK from nitric acid: $[HNO_3]$ $0.01M$ (□), $2M$ (○), $4M$ (△); $[Cu]$ $1.6 \times 10^{-3}M$; $[APCD]$ $8.0 \times 10^{-3}M$.

acidity ranges.^{1,2,8,9} Hence, it seems that the range of acidity for the extraction of various metals with APCD must be re-examined.

Extraction of $Cu(PCD)_2$ in nitric acid media

The extraction behaviour and the optimum conditions of copper extraction from 0.01 – $5M$ nitric acid solution were studied.

Shaking time. The shaking time needed for completing the extraction of copper chelate was studied with $8.0 \times 10^{-2}M$ APCD. Figure 5 shows the results in nitric acid media. The minimum shaking time for quantitative extraction decreases as the acidity is increased, similarly to the case in hydrochloric acid media. For 0.01 – $4M$ acid, the minimum shaking time for each acidity was the same as that for hydrochloric acid media: 120 sec for $0.01M$, and 60 sec for 2 and $4M$.

However, in $4M$ acid copper chelate was decomposed and was not extracted when the period of shaking exceeded 420 sec. It was also observed that the decomposition of copper chelate occurred during the shaking period and that the chelate was not extracted for any shaking time at concentrations above $4M$. This suggests that the kinetic stability of copper chelate in nitric acid media is lower than that in hydrochloric acid media, although the formation of the chelate is not dependent on the kind of acid. Hence, the range 120–180 sec was taken as the optimum shaking period.

APCD concentration. The concentration of reagent needed for complete extraction of copper chelate was studied at 2 and $4M$ nitric acid. Figure 6 shows the results with 120 sec of shaking. In nitric acid media, a considerably higher concentration of the reagent was needed for complete extraction compared with that for the same acidity in hydrochloric acid media. To

Fig. 6. Effect of APCD concentration on extraction of Cu(PCD)_2 in DIBK from nitric acid solution: $[\text{HNO}_3]$ $2M$ (O), $4M$ (Δ); $[\text{Cu}]$ $1.6 \times 10^{-5}M$; shaking time 120 sec.

complete the extraction, more than $3.2 \times 10^{-4}M$ (20-fold ratio to copper) and $1.3 \times 10^{-3}M$ (80-fold) reagent concentrations were needed for 2 and 4M nitric acid, respectively. In contrast to that of the hydrochloric acid system (Fig. 2), it is noted that copper chelate was not extracted at all with less than these reagent concentrations, suggesting that the decomposition of copper chelate is considerably more rapid when shaken with nitric acid than with hydrochloric acid.

The concentration of the reagent needed for completing the extraction apparently increases with increasing shaking time. When copper chelate was extracted with 300 sec of shaking, $1.6 \times 10^{-2}M$ APCD was needed. On the other hand, copper chelate could be completely extracted with $9.6 \times 10^{-4}M$ APCD, if the shaking period was reduced to 60 sec. These facts suggest that the kinetic stability of copper chelate when shaking with nitric acid solution is not so good as that with hydrochloric acid solution, due to oxidative decomposition of copper chelate and the reagent with nitric acid.

Kinetic stability. The decomposition behaviour and the kinetic stability of the chelate extracted from 2M nitric acid into DIBK were studied. Figure 7 shows the variation in the absorbance of copper chelate extracted into

Fig. 7. Kinetic stability of Cu(PCD)_2 extracted in DIBK from 2M nitric acid solution: $[\text{APCD}]$ $1.6 \times 10^{-3}M$; $[\text{Cu}]$ $1.6 \times 10^{-5}M$; shaking time 120 sec.

DIBK from 2M nitric acid solution, with time. The absorbance was constant for a certain time, similarly to the case of hydrochloric acid media; however, beyond this time the absorbance jumped to about twice as much as its original value, and then exponentially decreased with time.

The spectral changes with the decomposition of copper chelate extracted from 2M nitric acid are shown in Fig. 8. The initial absorption spectrum is the same as that of Cu(PCD)_2 chelate extracted from hydrochloric acid media in its shape, wavelength of absorption maximum and molar absorption coefficient. The initial peak at 434 nm [Fig. 8(a)] is enlarged with a shift in the peak wavelength to about 420 nm [Fig. 8(b)], with the isosbestic point at about 460 nm; then the peak gradually disappears without shift in the wavelength [Fig. 8(c)].

Such a spectral change strongly resembles that observed in the spectrophotometric monitoring of the electrochemical oxidation process of some bis-dithiocarbamate Cu(II) complexes $[\text{Cu}(\text{dtc})_2]$. Hendrickson *et al.*¹⁰ reported that $\text{Cu}(\text{dtc})_2$ underwent a single one-electron oxidation step at a platinum electrode: $\text{Cu}(\text{dtc})_2 + e^- \rightarrow [\text{Cu}(\text{dtc})_2]^+$, and the progress of this process was followed by the change in the absorbance spectrum from that of $\text{Cu}(\text{dtc})_2$ to $[\text{Cu}(\text{dtc})_2]^+$ with two isosbestic points at 464 and 328 nm. This report also noted that there

Fig. 8. Change in spectra of Cu(PCD)_2 in DIBK from 2M nitric acid solution: (a) standing time 7 min, (b) 12.5 min, (c) 13.3 min; $[\text{APCD}]$ $1.6 \times 10^{-3}M$; $[\text{Cu}]$ $1.6 \times 10^{-5}M$; shaking time 120 sec.

was an absorption maximum of $[\text{Cu}(\text{dte})_2]^+$ at about 420 nm, and its absorbance was several times larger than that of $\text{Cu}(\text{PCD})_2$. This suggests that $\text{Cu}(\text{PCD})_2$ extracted from nitric acid solution is oxidized, and a trivalent complex, $[\text{Cu}(\text{PCD})_2]^+$, is formed as an intermediate which then decomposes.

Table 2 gives the period of time when the absorbance of the extract remains constant, a so-called "decomposition time", under various conditions. The decomposition time of the chelate increased linearly with increasing concentration of the reagent up to $9.6 \times 10^{-3} M$ (60-fold); however, above this, it did not depend on the reagent concentration. In contrast to the case of the hydrochloric acid system, the kinetic stability of the chelate is not very dependent on the concentration of the reagent added in the relatively higher range of the reagent concentration, such as up to $9.6 \times 10^{-3} M$. It seems that this is due to the oxidative decomposition of copper and the reagent.

Similar to the situation in hydrochloric acid media, the washing of the extract contributed to stabilizing the copper chelate. When it was washed with water, the chelate exhibited sufficient stability for its determination; the absorbance of the extract remained constant for more than 60 min. However, the absorbance of the extract dropped within 15 min when no washing of the extract was done, even though a considerable amount of the reagent (about 500-fold ratio to copper) was added.

When the chelate was extracted from 4M nitric acid, it was observed that the absorbance of the extract increased with time due to scattering of light caused by the suspended particle in the formation of the extract with time, even if the extract had been washed with water. The absorbance of the extract could be returned

Fig. 9. Extraction range of Cu(II) with APCD/DIBK system in nitric acid media: $[\text{APCD}] 3.2 \times 10^{-3} M$ (O), $1.6 \times 10^{-2} M$ (Δ), $[\text{Cu}] 1.6 \times 10^{-5} M$; shaking time 120 sec.

to its original value by filtering it through a dry filter paper. It was observed also that the formation of suspended particles could be prevented by washing the extract twice, immediately after its extraction. This suspension is perhaps caused by decomposition of free PCD ligand in the extract due to its reaction with the free nitric acid contaminated in the extract. When the chelate was extracted from 4M nitric acid, the absorbance remained constant for over 60 min provided that the extract was washed twice. Hence, the washing of the extract is recommended for the extraction from nitric acid solution.

Acidity range. The range of nitric acid concentration which can be used for copper chelate extraction is shown in Fig. 9. Similar to the hydrochloric acid system, the acidity range depends on the concentration of the reagent, but the extent of this dependence is smaller than that observed in the hydrochloric acid system. The copper chelate could be extracted from 4M nitric acid with $1.6 \times 10^{-2} M$ APCD; however, the acidity range was not extended when the concentration of the reagent was increased to $8.0 \times 10^{-2} M$. Such a saturation of the effect of the reagent concentration on extending the acidity range in nitric acid system can be expected from the kinetic stability of copper chelate in this system.

At concentrations above 4M, it was observed that copper chelate was decomposed during a shaking period of 120 sec, even with $8.0 \times 10^{-2} M$ APCD. If the shaking period is reduced to 60 sec, copper chelate can be quantitatively extracted from up to 5M nitric acid, with $8 \times 10^{-2} M$ APCD; even in this case, provided that the extract was separated from the aqueous phase before the chelate decomposes and was washed twice with water, the absorbance was kept constant for 60 min or more.

Table 2. Decomposition time of Cu(II)-PCD chelate extracted from 2M HNO₃

$[\text{APCD}]$, M	Decomposition time,* min
3.1×10^{-4}	5.8
4.7×10^{-4}	7.4
6.3×10^{-4}	9.2
7.9×10^{-4}	10.5
9.4×10^{-4}	12.0
1.6×10^{-3}	12.8
3.1×10^{-3}	12.2
With washing 1.6×10^{-3}	>1 hr

$[\text{Cu}^{2+}] 1.6 \times 10^{-5} M$, shaking time 2 min.

*Determined by the time at which the absorbance jumps (see Fig.7).

However, such an extraction condition is too critical for practical use, and it was observed that at a concentration greater than 5M, The chelate was decomposed during a shaking period even with any extraction conditions. Hence, about 4M was taken as the practical acidity limit for copper chelate extraction in the nitric acid system.

CONCLUSIONS

With the APCD/DIBK extraction system, copper can be quantitatively extracted from up to 8M hydrochloric and 4M nitric acid. In the nitric acid system, extraction of copper chelate shows "all or nothing" behaviour. Because the decomposition of the chelate when shaken with nitric acid solution is rapid, the chelate is not extracted at all during the shaking period.

On the other hand, when the extract separates from the aqueous phase before the chelate decomposes, the chelate can be completely extracted. The kinetic stability of the chelate in the extract is also not so good as that in the hydrochloric acid system, which is thought to be due to oxidative decomposition of both reagent and copper chelate. However, sufficient kinetic stability can be obtained for its practical use, provided that the extract is washed with water.

It is worth noting that the kinetic stability of Cu(II)-PCD chelates and the acidity range are determined by the amount of the reagent added; hence, the use of a large excess of the reagent is recommended for copper extraction in strongly acidic media. Although several reports have commented on the kinetic stability and the acidity range for their extractions, it seems that they have not accurately estimated them, since they have missed this point. Therefore, in order to estimate the proper acidity range of extraction for these elements, the re-examination of the extraction conditions for each element is required.

THE EFFECT OF MOLYBDENUM(VI) ON THE PRODUCTION OF ARSINE BY THE TETRAHYDROBORATE(III) REACTION

IAN D. BRINDLE*

Chemistry Department, Brock University, St Catharines, Ontario L2S 3A1, Canada

HENGWU CHEN

(Received 30 July 1990. Revised 26 March 1991. Accepted 8 April 1991)

Summary—Molybdenum(VI) increases signals in the determination of arsenic after reduction by tetrahydroborate(III). An increase in the signal by up to two-and-a-half fold is observed when arsenic(III) is determined in the presence of sulphuric and hydrochloric acid concentrations of 0.01–0.02M. The enhancement effect disappears at higher acid concentrations and is eliminated by the presence of *L*-cysteine. Signals from other hydride-forming elements (antimony, bismuth and tin) were reduced in the presence of molybdenum(VI). Reduction of interferences in the hydride-forming reaction from nickel and cobalt is observed, so that the range of tolerance of these elements is extended by one and two orders of magnitude, respectively. The interference reducing effect is not as profound as that observed with *L*-cysteine.

A number of papers have been published over recent years which describe interferences in the determination of hydride-forming elements by various ions in solution.^{1–4} Although most papers report that interferences reduce the signal from the hydride-forming element, several describe enhancement of the signal. Thus Kirkbright and Taddia reported that the presence of copper(II) gave rise to enhanced signals from arsenic.² Tin signals have been reportedly increased by the presence of beryllium, thallium and titanium.³ We have reported that peroxodisulphate enhances recovery of germanium.⁴

Enhancement or depression of signals from ions which could be present in solution from the sample or dissolution matrix is an effect which must be taken into account when determining hydride-forming elements. The search for reagents which will eliminate these variations has led to the use of a number of compounds which have some measure of efficacy in reducing interferences. The use of iron(III) as a releasing agent in the determination of selenium by hydride generation has been reported.^{5,6} Brindle *et al.* have reported the use of *L*-cysteine and *L*-cystine to reduce interferences from various metal ions in the determination of arsenic, germanium and tin.^{7–10}

Interference from molybdenum(VI) has been reported to reduce the signal from arsenic in concentrated hydrochloric acid,^{11,12} while other authors have found the effect to be insignificant.¹ In recent investigations into the determination of arsenic, where *L*-cysteine was used to reduce As(V) to As(III)¹³ in dilute acid solution, the presence of Mo(VI) significantly increased the signal from the reduction of As(III) by sodium tetrahydroborate(III) in the absence of *L*-cysteine.

In this paper, we report on our investigations into the effect of molybdenum(VI) and other oxyanions on the enhanced production of arsine by the hydride transfer reaction and on the reduction of interferences in reaction of arsenic with tetrahydroborate(III).

EXPERIMENTAL

Instrumentation

Data were acquired with a Spectraspan V d.c. plasma atomic-emission spectrometer equipped with a Beckman hydride generator modified as described elsewhere.⁹ Signals were recorded on a Fisher Recordall Series 5000 chart recorder. A Brinckman variable volume Macro-Transferpettor was used for all analyte injections with the volume fixed at 5.0 ml.

*Author for correspondence.

The arsenic emission line at 193.7 and 228.8 nm were measured with entrance and exit slit widths of 50 and 100 μm , respectively. The slit heights were matched at 300 μm . Photomultiplier voltage and gain settings were used to provide convenient signals and to minimize noise.

Reagents

Argon of welding grade (Union Carbide, Canada) proved to be sufficiently pure for use without further treatment. All inorganic chemicals were analytical reagent grade or better. *L*-Cysteine was obtained from Sigma (Sigma grade) and BDH. Sodium tetrahydroborate(III) solutions were prepared in 0.2M sodium hydroxide and were filtered before use. Ammonium molybdate $[(\text{NH}_4)_2\text{Mo}_7\text{O}_{24}\cdot 4\text{H}_2\text{O}]$ was obtained from Fisher Scientific, Toronto. Arsenic(V) solutions (1000 $\mu\text{g}/\text{ml}$) and arsenic(III) (1000 $\mu\text{g}/\text{ml}$) solutions were prepared from $\text{Na}_2\text{HAsO}_4\cdot 7\text{H}_2\text{O}$ and As_2O_3 respectively. Since the As(V) solution was prepared from a non-standard reagent, the concentration was verified by comparison with the As(III) solution, prepared from standard arsenic(III) oxide, in the d.c. plasma spectrometer. Solutions for the determinations were subsequently prepared by dilution with the appropriate reagents.

RESULTS AND DISCUSSION

A preliminary survey of oxyanions was carried out to determine which, if any, enhance signals from arsenic(III). Ions were tested in 0.02 and 0.2M hydrochloric acid and the results are shown in Table 1. At the lower acid concentration, molybdenum(VI) at a concentration of 100 $\mu\text{g}/\text{ml}$ gave a two-and-a half fold increase in signal. This enhancement was observed at both

of the arsenic wavelengths. A small (30%) signal enhancement was observed with vanadium(V) in 0.02M hydrochloric acid, while tungsten(VI) had no observable effect on the signal. Of the strongly oxidizing ions, dichromate and peroxodisulphate gave reduced signals while permanganate eliminated the signal completely. At higher acid concentration (0.2M), the enhancement effects disappeared.

Not only acid concentration, but the acid type has a significant effect on the enhancement effect produced by molybdenum. Hydrochloric, nitric, sulphuric and phosphoric acids were investigated over the range of concentrations from 0.01 to 0.2M. Higher concentrations of acids used in the hydride generator produced instability in the plasma and were not investigated. The results of the study are shown in Fig. 1. For all acids, the enhancement effect is most significant at low concentrations and becomes insignificant at a concentration of 0.08M for hydrochloric and nitric acids, and 0.06M for sulphuric acid. The effect was most significant with hydrochloric and sulphuric acids and was somewhat reduced by the nitric acid. Phosphoric acid did not increase the signal from arsenic as much as hydrochloric acid. The most likely reason for this is the formation of the phosphomolybdate complex ion. Evidence for the formation of the ion was the formation of the characteristic blue colour when molybdenum(VI) solution was added to the solution of arsenic(III) in phosphoric acid in the reaction vessel, which retains some reducing capacity even after washing with distilled water. The colour could not be reproduced when sulphuric or hydrochloric acids were used.

Figure 2 illustrates the relationship between peak height and molybdenum(VI) concentration for the generation of arsine from

Influence of molybdenum(VI) on the arsenic signal. ●—5 ml of 200 ng/ml As(III) in 0.2M HCl, ×—5 ml of 200 ng/ml As(III) in 0.02M HCl, □—5 ml of 50 ng/ml As(III) in 0.02M HCl with 0.5% w/v *L*-cysteine (Note: the concentration of arsenic is 1/4 of the concentration compared with the other curves).

of 0.02M hydrochloric acid, the effect is quite striking. Thus the peak height increases almost linearly with molybdenum(VI) concentrations of 0–80 µg/ml, after which the signal remains constant up to a molybdenum(VI) concentration of 200 µg/ml, the limit of these experiments. Although molybdenum(VI) increased the height of the peaks from arsenic, the peak width at half maximum remained the same, suggesting that molybdenum(VI) increases the yield of arsine from the reduction process. The presence of *L*-cysteine in solution, however, served significantly to increase the signal from arsenic(III), while eliminating any effect from the presence of molybdenum(VI). The enhancement of the signal by molybdenum(VI) is only one quarter of that produced by *L*-cysteine.

The relationship between acid concentration, molybdenum(VI) and arsenic(V) is also quite significant. Thus in 0.01M hydrochloric acid, arsenic(V) gives no observable signal whereas in the presence of 20 µg/ml Mo(VI), a substantial peak was obtained. Unfortunately, Mo(VI) does not give similar recoveries for As(V) as it does for As(III). Typically, arsenic(V) gives signals

Fig. 3. The effect of tetrahydroborate(III) concentration on the molybdenum(VI) interference. \times —5 ml of 200 ng/ml As(III) in 0.02M HCl, Δ —5 ml of 200 ng/ml As(III) + 20 $\mu\text{g/ml}$ Mo(VI) in 0.02M HCl.

that are only 20–30% of the signals obtained from similar concentrations of arsenic(III).

The effect of tetrahydroborate(III) concentration is also significantly altered by the presence of molybdenum(VI) in the generation of arsine from arsenic(III). From Fig. 3, it is clear that the presence of 20 $\mu\text{g/ml}$ molybdenum(VI) created a different response as the concentration of tetrahydroborate(III) is increased. Thus, in the absence of molybdenum(VI), a relatively constant signal is obtained over the range of concentrations studied. In the presence of 20 $\mu\text{g/ml}$ molybdenum(VI), the signal increases over the same range and starts to level off at a concentration of approximately 4% w/v sodium tetrahydroborate(III).

Welz and Melcher have reported that iron(III) has a releasing effect on nickel(II) in the determination of arsenic and selenium by hydride generation.⁵ Bye has also commented on the same effect in the determination of selenium.⁶ In both cases, the releasing effect was ascribed to the reduction of iron(III) to iron(II),

prior to the reduction of nickel(II) to metallic nickel which, the authors suggest, is the agent responsible for the decomposition of the hydride, before it can be stripped from the solution. The releasing effect of molybdenum(VI) on nickel(II) and cobalt(II) was evaluated, and the results are shown in Fig. 4. It is clear that the presence of 50 $\mu\text{g/ml}$ molybdenum(VI) increased the interference-free level by one to two orders of magnitude.

Evidence for the formation of intermediate oxidation states of molybdenum is supported by the observed colour changes in the reduction reactions. Thus, when tetrahydroborate(III) solution was added to molybdenum(VI) solution in 0.02M hydrochloric acid solution, in the presence or absence of arsenic(III), the colourless solution turned yellow-brown. If the concentration of molybdenum(VI) was greater than 100 $\mu\text{g/ml}$, a small amount of brown precipitate appeared on the frit of the generator. It has been reported that molybdenum(VI) reacts with tetrahydroborate(III) in 0.001M sulphuric acid to form a blue solution of molybdenum(IV).¹⁴ It has also been reported that reduction of the colourless molybdenum(VI) solution by a strong reducing agent in dilute hydrochloric acid turned first blue, then green, and finally brown, due to the formation of molybdenum(III) chloride.¹⁵ Crouthamel and Johnson reported that molybdenum(V) is brown in dilute hydrochloric acid, and that freshly formed molybdenum(V) is unstable.¹⁶ These observations lead us to conclude that the reduction of interferences by molybdenum(VI) is most likely due to the formation of lower oxidation states of molybdenum by the tetrahydroborate(III), and that this reaction competes with

Fig. 4. The releasing effect of molybdenum(VI) on the interference from (a) Co(II) and (b) Ni(II). \times = 5 ml of 200 ng/ml As(III) in 0.04M HCl, \bullet —5 ml of 200 ng/ml As(III) + 50 $\mu\text{g/ml}$ Mo(VI) in 0.04M HCl.

the reduction of Ni(II) and Co(II) to the metals. We have argued elsewhere that intermediate hydrides may be formed that are more efficient hydride transfer reagents than tetrahydroborate(III).¹⁸ Whether this is the case with molybdenum is not clear at this point.

The generality of the method was tested on the hydride-forming elements antimony, bismuth and tin. In all cases, molybdenum(VI) has a depressing effect upon the signals from the hydrides. We have previously reported the depressing effect of molybdenum(VI) on the generation of germane.⁸

It is clear that molybdenum(VI) has an enhancing effect on arsine production at low acid concentrations, and that it reduces interferences from nickel and cobalt. The method is obviously limited in scope for analytical determinations, but may find applications in some limited areas.

ANALYTICAL APPLICATION OF A NEW THIAZOLYLAZO REAGENT, 2-(2-BENZOTHIAZOLYLAZO)-5- DIMETHYLAMINO-4-TOLYLARSONIC ACID

SPECTROPHOTOMETRIC DETERMINATION OF PALLADIUM

(Received 10 October 1989. Revised 24 February 1991. Accepted 4 March 1991)

Summary—A new thiazolyazo reagent, 2-(2-benzothiazolyazo)-5-dimethylamino-4-tolylarsonic acid, has been synthesized and found to be a good chromogenic reagent for palladium. A 1:1 blue chelate ($\lambda_{\max} = 718$ nm) is formed in a sulphuric or nitric acid medium. The molar absorptivity is 6.65×10^4 l. mole⁻¹. cm⁻¹. Beer's law is obeyed in the range 0–1.6 μ g/ml Pd. Relatively large amounts of co-existing elements, including noble metals, can be tolerated.

The selectivity and stability of the chelates of palladium with many of the thiazolyazo reagents have attracted much attention by analytical chemists. These properties are conferred by the functional group, (—NH₂, —COOH, etc.) *ortho* to the azo group.^{1,2} To improve the selectivity, introduction of an arsonic group *ortho* to the azo group is proposed, and a new compound, 2-(2-benzothiazolyazo)-5-dimethylamino-4-tolylarsonic acid (BTADMTA) has been synthesized and the photometric properties of its chelate with palladium have been studied. A blue 1:1 chelate with palladium can be formed even in strongly acidic medium. The absorption maximum is at 718 nm and the molar absorptivity is 6.65×10^4 l. mole⁻¹. cm⁻¹. Beer's law is obeyed in the concentration range 0–1.6 μ g/ml Pd. Relatively large amounts of vanadium, chromium, manganese, copper, iron, nickel, zinc, molybdenum, silicon, silver, cadmium, and even noble metals such as platinum, gold, ruthenium and iridium can be tolerated. This new reagent is comparable both in sensitivity and selectivity with thiazolyazo compounds reported earlier.³⁻¹³ A simple and rapid spectrophotometric method for determination of palladium is proposed and has been tested in the analysis of industrial samples.

EXPERIMENTAL

Apparatus

Spectra were obtained with a Hitachi Model 557 double-beam dual wavelength spectrophotometer equipped with 1-cm cells. The pH measurements were made with a Model pH-III pH-meter.

Reagents

Pd standard solution A. Pure palladium (99.9% pure, 0.1000 g) was dissolved in *aqua regia*. Sixteen ml of sulphuric acid (1 + 1) were added and the solution was heated till fuming strongly. It was cooled to room temperature, about 30 ml of water were added and the solution was cooled, transferred into a 100-ml standard flask, and diluted to volume with water.

Pd standard solution B. Prepared just before use, by transfer of 1.00 ml of Pd standard solution A into a 100-ml standard flask, addition of 1 ml of sulphuric acid (1 + 1), and dilution to volume with water. One ml of this solution contains 10 μ g of Pd.

BTADMTA solution, 0.1 mg/ml in ethyl alcohol.

Synthesis of BTADMTA

Dissolve 1.5 g (0.01 mole) of 2-aminobenzothiazol in 2 ml of formic acid and 5 ml of

Table 1. Infrared spectrum data for BTADMTA

concentrated sulphuric acid and add 8 ml of water. Add a solution of 0.72 g of sodium nitrite in 20 ml of water dropwise to this solution at 0–5°. Dissolve 2.6 g (0.01 mole) of 3-dimethylamino-4-tolylarsonic acid in 25 ml of acetic acid plus 100 ml of methyl alcohol, and cool the solution to 0–5°. Add the diazotized solution dropwise to this solution, with vigorous stirring, and let the mixture stand overnight. Adjust the pH to about 4 to precipitate crude BTADMTA and purify the red product by recrystallization from dimethylformamide (DMF) and water. Its m.p. is 214°, and the yield is about 47%. Its structure has been verified by infrared and NMR spectroscopy. (Tables 1 and 2).

Elemental analysis confirmed its purity (Table 3). The pure product is easily soluble in polar organic solvents, *e.g.*, DMF, dimethylsulphoxide, chloroform, acetone, ethanol and is also soluble in dilute acidic or alkaline solution. It is only slightly soluble in water. It is red in weakly acidic or alkaline solution, and green in strongly acidic solution.

General procedure

In a 25-ml standard flask, place 5 ml of sulphuric acid (1 + 1) and a sample containing not more than 40 μg of Pd, mix well and cool if necessary. Add successively 10 ml of 95%

ethanol and 3 ml of 0.1 mg/ml BTADMTA solution, mix, dilute to the mark with water, mix, and let stand for 10 min. Measure the absorbance at 718 nm, in a 1-cm cell, against water as reference.

RESULTS AND DISCUSSION

Effect of acidity

The colour reaction can be performed in either nitric or sulphuric acid medium. The optimum acid concentrations are 0.1–0.8 and 0.32–3.2M respectively. Perchloric acid medium can also be used but the sensitivity is lower. Since chloride forms a fairly strong complex with palladium, hydrochloric acid medium should not be used. At high nitric acid concentration, *e.g.*, 6M, the sensitivity is even higher than in sulphuric acid medium, but the blue chelate is soon destroyed. A 2M sulphuric acid medium is recommended.

Effect of organic solvents

Addition of appropriate amounts of ethanol, acetone or dimethylformamide increases the solubility of BTADMTA and thus favours the reaction with palladium, and increases the absorbance. Ethanol is the best to use, and the increase in absorbance is constant when more than 8 ml of ethanol is added. Maximum absorbance is attained after 10 min and is stable for at least 24 hr. In the absence of ethanol the reaction system achieves maximum absorbance after 5 min, but the absorbance decreases gradually upon standing. The addition of non-ionic surfactants, *e.g.*, Triton X-100, can also improve the stability but cannot increase the sensitivity (Fig. 1).

Fig. 1. Effect of organic solvent (20 μg of Pd, 3 ml of 0.1 mg/ml BTADMTA, 2M HNO₃).

Fig. 2. Absorption spectra (20 μg of Pd, 2M HNO_3 , 10 ml of ethanol, $l = 1$ cm). 1, Reagent vs. H_2O ; 2, Pd-chelate vs. H_2O ; 3, Pd-chelate vs. reagent blank.

Effect of BTADMTA concentration

For up to 40 μg of Pd, the addition of more than 0.30 mg of BTADMTA is enough for complete reaction. Hence 3 ml of 0.1-mg/ml reagent solution is specified in the general procedure. Beer's law is obeyed in the concentration range 0–1.6 $\mu\text{g}/\text{ml}$ Pd, and the apparent molar absorptivity is 6.65×10^4 l.mole⁻¹.cm⁻¹. For > 1.6 $\mu\text{g}/\text{ml}$ Pd, addition of a greater amount of BTADMTA will extend the linear range.

Absorption spectra

The absorption spectra of BTADMTA and its Pd-chelate under the optimum conditions are shown in Fig. 2. The absorption maximum of the reagent lies at 514 nm, and the chelate has two maxima, at 660 and 718 nm, the latter being chosen for measurements, as the reagent itself has no absorption.

Composition of the chelate

The mole-ratio and continuous variation methods show that a 1:1 chelate is formed, which may have the structure:

Effect of diverse ions

Under the specified optimum conditions, a 200-fold ratio of Mg(II), Al(III), Cr(III), Mn(II), Co(II), Ni(II), Cu(II), Zn(II), Cd(II), Ag(I), Zr(IV), and Si(IV) to Pd(II) does not

interfere; 100-fold ratio of V(V), Fe(III), Mo(IV), Pt(IV), Au(III), Ru, Ir can be tolerated. Fluoride, borate, citrate and a few drops of 3% hydrogen peroxide solution do not interfere. Chloride forms a stable complex with Pd(II), and ascorbic acid destroys the BTADMTA, thus causing serious interference.

Applications

The proposed method has been applied to the determination of palladium in an Ni–Al catalyst and an active carbon concentrate.

For the Ni–Al catalyst, a 50-mg sample is dissolved in a mixture of nitric acid and hydrochloric acid, 10 ml of concentrated sulphuric acid are added and the mixture is heated until fuming. For complete oxidation of organic matter in the sample, the addition of a few ml of concentrated nitric acid may be necessary during the fuming. The solution is cooled, the salts are taken up in water, and after cooling the solution is transferred to a 50-ml standard flask, and diluted to the mark with water. An appropriate aliquot is analysed as described in the general procedure.

For the active carbon concentrate, a 50-mg sample is ignited in a porcelain crucible in a muffle furnace at 850° until the carbon is completely oxidized. The residue is dissolved in 2 ml of *aqua regia* and the solution is heated to fuming after addition of 2 ml of concentrated sulphuric acid. The solution is cooled, 10 ml of water are added to dissolve the salts, and the solution is diluted to volume in a 50-ml standard flask with water. An appropriate aliquot is then analysed by the general procedure.

The results obtained for some industrial samples are consistent with those obtained by the 1-nitroso-2-naphthol photometric method¹⁴ (Table 4).

KINETIC DETERMINATION OF Hg(II) BASED ON ITS ACCELERATING EFFECT ON THE REACTION BETWEEN HEXACYANOFERRATE(II) AND 1,10-PHENANTHROLINE CATALYSED BY MICELLES

DOLORES SICILIA, SOLEDAD RUBIO and DOLORES PEREZ BENDITO

Department of Analytical Chemistry, Faculty of Sciences, University of Córdoba, Córdoba, Spain

(Received 12 September 1990. Revised 14 March 1991. Accepted 25 March 1991)

Summary—A kinetic-photometric method for the determination of Hg(II) over the range 10–80 ng/ml is proposed. It is based on the accelerating effect of this ion on the reaction between hexacyanoferrate(II) and 1,10-phenanthroline which is monitored via the ferriox complex formed. Anionic sodium dodecyl sulphate (SDS) micelles, which catalyse the reaction, allow the ferriox complex to be formed under more acidic conditions. Combination of this pH shift and the development of the reaction in the vicinity of micelles results in improved selectivity in the determination of Hg(II) compared to the reaction occurring in an aqueous medium. Some observations on the effect of SDS on the reaction are reported.

Reactions in micellar media have aroused much attention in the last two decades.^{1–3} Experiments on a variety of systems have shown that remarkable kinetic advantages can be gained upon confining a chemical reaction to a micelle and, more recently, these advantages have begun to be exploited in analytical kinetic methods.^{4–7} Two types of physico-chemical factors are responsible for the efficiency of micellar catalysis on reactions of second and higher orders, namely, the concentration of reactants inside the micellar phase and the change in the reactant reactivities on transfer from water to the micellar phase.

Micellar systems are known⁸ to have a marked effect on the acid–base equilibria of compounds with different ionization states. Changes in the apparent pK_a values can be caused and the direction in which equilibrium will displace depends essentially on electrostatic interactions between one of the species involved and the micelle surface. If both forms of the compound involved in the equilibrium have a charge of the same sign, specific factors such as hydrophobic and micro-solvent interactions and electrostatic forces will determine the displacement direction. As a result the complexes formed between these compounds and metal ions occasionally occur at lower pHs: this phenomenon has been exploited in analytical chemistry to increase the selectivity of metal ion determinations based on complexation reactions with chelometric indicators.⁹

In this work we applied the concept of micelle-induced changes in the pK_a to analytical kinetic methods in order to improve their selectivity. For this purpose, at least one reactant taking part in the reaction must have acid-base properties and one of the forms involved in the equilibrium must concentrate preferentially on the micellar surface. Thus, if a change in the pK_a value is observed and the reaction (complexation, redox or precipitation) is affected by the pH, changes in the pH region where it takes place will be produced. The reaction between hexacyanoferrate(II) and 1,10-phenanthroline, which is accelerated by mercury(II), was selected for this study.¹⁰

EXPERIMENTAL

Apparatus

Kinetic measurements were made on a Perkin–Elmer Lambda 5 spectrophotometer fitted with a Perkin–Elmer C570-0701 digital controller to keep the cell compartment at constant temperature. All measurements were recorded by using slits of 2-nm spectral band-pass. A classical stalagmometer was used for surface tension measurements in order to determine the critical micellar concentrations (cmc) of the surfactants.

Reagents

All reagents used were of analytical grade and utilized as purchased, without further purification.

A stock Hg(II) solution ($4.98 \times 10^{-3} M$) was prepared by dissolving mercury(II) oxide (Merck) in 20 ml of 1:1 hydrochloric acid and making up to one litre with doubly distilled water. Working solutions ($4.98 \times 10^{-6} M$) were prepared daily by appropriate dilution with doubly distilled water. A $5.0 \times 10^{-3} M$ aqueous solution of potassium iron cyanide [$K_4Fe(CN)_6 \cdot 3H_2O$] (Merck) was also prepared daily. A $1.0 \times 10^{-3} M$ aqueous solution of 1,10-phenanthroline was made from 1,10-phenanthroline chloride monohydrate (Merck). A sodium dodecyl sulphate (SDS) solution ($6.94 \times 10^{-2} M$) (Aldrich) was prepared by dissolving the surfactant in doubly distilled water. The other surfactants tested, *viz* sodium dioctylsulphosuccinate (Aerosol OT) (Aldrich), cetyltrimethylammonium bromide (CTAB) (Sigma), dodecyltrimethylammonium bromide (DTAB) (Sigma), cetylpyridinium chloride (CPC) (Serva), Triton X-100 (Serva), Brij-35 (Merck) and N-dodecyl-N,N-dimethylammonium-3 propane-sulphonate (SB-12, sulphobetaine) (Serva) were prepared in a similar way. Less soluble surfactants were dissolved with warming.

Procedure for the kinetic photometric determination of mercury

In a 10-ml standard flask were placed, in sequence, 1 ml of $K_4Fe(CN)_6$ ($4.997 \times 10^{-3} M$), 2 ml of 1,10 phenanthroline ($1.0 \times 10^{-3} M$), 0.7 ml of SDS ($6.94 \times 10^{-2} M$), the volume of hydrochloric acid (0.2M) required to obtain a final pH of 2.0 and appropriate volumes of mercury(II) standard solution ($4.98 \times 10^{-6} M$) to give a mercury(II) final concentration between 10 and 80 ng/ml. The stopclock was started immediately after mercury(II) was added and the solution was then diluted to the mark with doubly distilled water. An aliquot of the reaction mixture was transferred to a cell kept at $60 \pm 0.1^\circ$ and the absorbance ($\lambda = 500$ nm) was recorded as a function of time. Measurements were started exactly 3 min after the addition of mercury(II). The reaction rate was calculated by the tangent method from the absorbance-time curves and the rate corresponding to a blank solution, containing no mercury(II), was subtracted.

RESULTS AND DISCUSSION

Selection and influence of the micellar system on the mercury(II)-accelerated reaction between hexacyanoferrate(II) and 1,10-phenanthroline

The ligand-exchange reaction between hexacyanoferrate(II) and 1,10-phenanthroline, which

is accelerated by mercury(II), was used to determine this ion by measuring the rate of formation of ferriin spectrophotometrically¹¹⁻¹² according to the following system:

The 1,10-phenanthroline reagent has acid-base properties, so it yields a typical uniequivalent titration curve on titration with strong acids.¹³ The acid dissociation constant of the phenantrolium ion in aqueous solutions has been measured by several different methods and pK_a values of *ca.* 5 have been reported. Although, the UV spectra obtained from concentrated sulphuric acid solutions reveal the formation of the diprotic species, the pK_a values reported for phen.2H⁺ (about -1.6)¹⁴ indicate that the phen.2H⁺ concentration is negligible at the pH where the above reaction takes place. Therefore, only the phen.H⁺/phen. equilibrium will be considered. This can be displaced to the acid form by anionic micellar systems, which can alter the pH at which the reaction develops.

The effect of surfactants of different nature [anionic (SDS, Aerosol OT), cationic (DTAB, CTAB, CPC), nonionic (Brij 35, Triton X-100) and zwitterionic (SB-12)] on the analytical reaction was tested at three surfactant concentrations, namely, below, close to and above their cmc, and at different pH values. Micellar catalysis was found to occur in the presence of anionic and zwitterionic micelles at pH values where the aqueous reaction hardly developed. The most significant rate increase was due to SDS, which was thus chosen for subsequent experiments. Nonionic micelles had no effect on the reaction rate and the influence of cationic micelles could not be established because a precipitate was formed on addition of the cationic surfactant.

Figure 1 shows the effect of the SDS concentration on the rate of the non-catalysed hexacyanoferrate-1,10-phenanthroline system (curve a) and that catalysed by different mercury(II) concentrations (curves b and c) at pH 2. The rate was scarcely affected by surfactant concentrations below the cmc ($5 \times 10^{-4} M$, calculated under our reaction conditions), but, close to the cmc, the rates started to rise sharply to a maximum value, above which they decreased with increasing SDS concentration, the final rate decrease being the effect of dilution of the reactants over the increasing concentration of micelles in the solution. Sodium dodecyl

Fig. 1. Influence of the SDS concentration on the rate of the non-catalysed (curve a) and the mercury(II)-catalysed (curve b, c) reaction between hexacyanoferrate(II) and 1,10-phenanthroline. Mercury(II) concentration: (b) 0.05 $\mu\text{g/ml}$; (c) 0.1 $\mu\text{g/ml}$. The concentrations of the other reactants are given under Experimental.

sulphate enhances the accelerating effect of mercury, as can be inferred from Fig. 1 by comparing the reaction rate increments of the different

curves at the SDS concentrations 0 and $4 \times 10^{-3} \text{M}$. Therefore, the kinetic determination of mercury(II) in the presence of this surfactant will be more sensitive at the working pH (pH = 2).

Study of the optimum reaction conditions

The effect of different variables affecting the reaction rate was studied in the presence and absence of SDS in order to compare the behaviour of the reaction in micellar and aqueous media and optimize the conditions for the determination of mercury(II). The optimum conditions chosen were those yielding a minimum relative standard deviation for the initial rate measurement under conditions in which the reaction order was zero, or as close to zero as possible, with respect to the variable concerned.

Figure 2 shows the variation of the initial rate as a function of different variables [temperature (A); pH (B); 1,10-phenanthroline (C) and hexacyanoferrate(II) (D)] for the SDS + Hg-(curve 2) and Hg(II)-accelerated (curve 1) reactions. The initial rates yielded by the blanks [without Hg(II)] were subtracted prior to plotting.

The dependence of the initial rate of the SDS-Hg(II) accelerated reaction [Fig. 2(A),

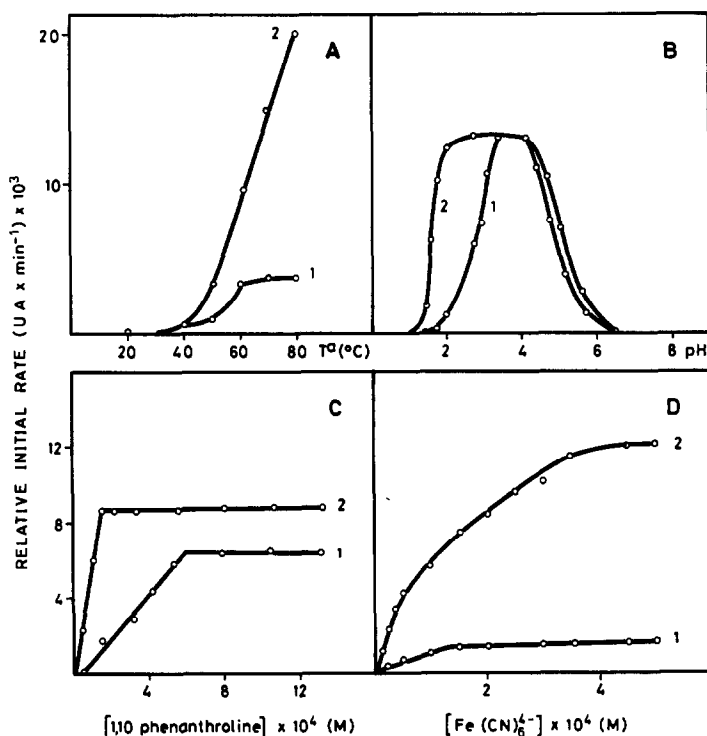

Fig. 2. Influence of (A) temperature, (B) pH, (C) 1,10-phenanthroline concentration and (D) hexacyanoferrate(II) concentration on the rate of the Hg(II)- (curve 1) and Hg(II) + SDS-accelerated (curve 2) reaction between hexacyanoferrate(II) and 1,10-phenanthroline. The concentrations of reactants are given under Experimental.

curve 2] on the temperature was exponential over the range tested (20–80°) and was greater than that corresponding to the Hg(II)-accelerated reaction. Temperatures above 60° were not advisable for the determination of mercury because of the decreased precision of the measurements.

The presence of anionic micelles of SDS allowed ferroin to be formed under more acidic conditions. As can be seen from Fig. 2(B), this complex is optimally formed at pH 2–4 and 3.5–4 in the presence and absence, respectively, of the anionic micellar system. Its analytical advantage lies in the fact that it allows the complex to be formed over a wider pH region, which increases the possibility of choosing a pH allowing the reduction or elimination of interferences. The pH selected for the determination of mercury(II) in the presence of SDS micelles was the minimum value which resulted in the maximum reaction rate in order to improve the selectivity. The optimum pH (2.0) was adjusted with hydrochloric acid; none of the buffers tested (tartrate, glycine and phthalate) was effective at this working pH.

The curves in Fig. 2(C) show the variation of the initial rate of the aqueous (curve 1) and micellar (curve 2) reaction with the phenanthroline concentration. The reaction reaches pseudozero order with respect to this variable at lower phenanthroline concentrations.

The influence of the hexacyanoferrate(II) concentration is illustrated in Fig. 2(D). The curves corresponding to the Hg(II)- and SDS + Hg-accelerated reactions show a first-order dependence on hexacyanoferrate(II) at low concentrations of this ion. As the hexacyanoferrate(II) concentration increases, this dependence tails off to zero for the Hg(II)- and SDS-Hg(II)- accelerated reactions rapidly and gradually, respectively. The concentration of hexacyanoferrate(II) corresponding to a zero-order dependence is a function of both the absolute concentrations of 1,10-phenanthroline and hexacyanoferrate(II) and of the ratio between the two (a hexacyanoferrate(II):1,10-phenanthroline ratio above 2:1 is required).

The reaction rate remained maximal on varying the order of addition of reagents and the ionic strength (adjusted with potassium chloride or potassium nitrate) at least up to $2 \times 10^{-2}M$.

Analytical features

A calibration graph for the determination of Hg(II) in the SDS micellar medium was run

Table 1. Analytical features of the determination of Hg(II) by its accelerating effect on the hexacyanoferrate(II)-1,10-phenanthroline system in the presence and absence of SDS

Parameter	With SDS	Without SDS
Sensitivity, M^{-1}/min	$(32.4 \pm 0.6) \times 10^3$	$(4.3 \pm 0.3) \times 10^3$
*Detection limit, ng/ml	4	23
†RSD, %	4.5	10.8

* 3σ .

† $n = 11$, for 40 ng/ml Hg(II).

under the optimal conditions described earlier. The determination of this ion was feasible over the range 10–80 ng/ml. Analytical features such as sensitivity, detection limit and precision (expressed as relative standard deviation) are summarized in Table 1, which also includes the same analytical features for the determination of Hg(II) in the absence of SDS at pH 2 for contrast. On the basis of these features, the determination of Hg(II) at pH 2 is more favourable in the micellar medium. At pH 3.5, and in the absence of SDS, the sensitivity and detection limit are similar to those obtained at pH 2 in the presence of SDS, as can be seen from Fig. 2(B). Only a net gain in precision in the determination of Hg(II) was observed at any pH values tested when the reaction was developed in the SDS micellar medium.

In order to elucidate whether micellar catalysis resulted in increased selectivity towards the determination of Hg(II), the effect of various ions on the hexacyanoferrate(II)-1,10-phenanthroline system in the presence and absence of SDS was studied at pH 2. The ions tested were those normally found in biological fluids, which are among the matrices most frequently used for the determination of Hg(II). Table 2 summarizes some of the results obtained. The selectivity factor, defined as the ratio between the tolerated concentrations of foreign species in the presence of SDS to that found when the surfactant was absent is also included in this table. The maximum mole ratio of ion to Hg(II) tested was 2000. The selectivity was significantly improved with respect to some cations present in biological fluids. Since the experiment was carried at the same pH values in the presence and absence of SDS, the micelles must be responsible for such an improvement. An identical experiment was done at pH 3.5 and the results obtained for the main interferents are also listed in Table 2. Logically, the selectivity decreased as pH increased for ions such as Cu(II) and Zn(II). Improved selectivity was also obtained at pH

Table 2. Effect of foreign ions on the determination of $5 \times 10^{-7} M$ Hg(II) at two pH values

Ion tested	Tolerated mole ratio of ion to Hg(II)		Selectivity factor (with SDS/without SDS)
	with SDS	without SDS	
		pH = 2	
Cu(II)	10^{-2}	10^{-3}	10
Ca(II)	≥ 2000	50	≥ 40
Fe(III)	10	1	10
Zn(II)	30	1	30
I ⁻	5	5	1
		pH = 3.5	
Cu(II)	10^{-3}	10^{-4}	10
Ca(II)	≥ 2000	50	≥ 40
Fe(III)	10	1	10
Zn(II)	10	1	10

Mg(II), K(I), Cl⁻, F⁻, HCO₃⁻, PO₄³⁻ and SO₄²⁻ ions are tolerated up to a mole ratio of ion to Hg(II) of 2000 in both methods.

3.5 in the SDS micellar medium. Therefore, micelles probably enhance the selectivity of kinetic methods, especially if they permit the reaction to occur at lower pH values than in the aqueous medium. Nevertheless, further studies must be made in this direction to determine the real applicability of micelles in analytical kinetic methods.

Some observations on the action of SDS on the reaction

In order to determine the mechanism via which SDS acts on the hexacyanoferrate(II)-1,10-phenanthroline system we must first consider the net changes that this surfactant induces on the reaction features. The observed alterations were:

- the pH over which the reaction took place [Fig. 2(B)].
- the acceleration of the reaction over a given pH range [Fig. 2(B)].

Since the hexacyanoferrate(II) ion is negatively charged and thus cannot be concentrated on the micellar surface, only 1,10-phenanthroline-micelle and ferroin-micelle interactions were investigated in order to determine the origin of the above changes.

1,10-Phenanthroline-micelle interaction. Only the phen.H⁺/phen. equilibrium was considered because the diprotic species phen.2H⁺ (pK_a about -1.6)¹⁴ was considered to be present at a negligible concentration over the pH range where the reaction took place. The pK_a of the phen.H⁺/phen. equilibrium was found to be different for the SDS micellar (6.0 ± 0.1) and aqueous (5.0 ± 0.1) media when calculated under the same conditions. Therefore, the SDS anionic micelles displace the equilibrium to the acid form and 1,10-phenanthroline becomes a

weaker acid in the micellar medium. This results in phen.H⁺ being preferentially concentrated on the micellar surface and, although hydrophobic interactions could be significant, ionic interactions are definitive.

Ferroin-micelle interaction. Micelles are known to increase the molar absorptivity of complexes, which results in apparently increased reaction rates if reaction development is monitored via the formation or disappearance of the complex. To clarify this point several experiments were done in which the potential sensitization of ferroin by SDS was investigated. The experiments were carried out by mixing Fe(II) ($4.99 \times 10^{-4} M$) with 1,10-phenanthroline ($3 \times 10^{-4} M$) at pH 2. Once the reaction was complete, the absorbance was found to decrease very slightly with time. If SDS was added to this solution 1 hr after the reaction was started, the maximum absorbance was restored, but no net increment in the absorbance was obtained under the reaction conditions. Therefore, no sensitization of ferroin by SDS micelles occurred.

In order to determine the net influence of SDS micelles on the formation of ferroin at different pH values, Fe(II) ($2.0 \times 10^{-5} M$) and 1,10-phenanthroline ($2.6 \times 10^{-4} M$) were mixed in the presence ($4.85 \times 10^{-3} M$) and absence of SDS at 60°, the temperature chosen to monitor the development of the reaction between hexacyanoferrate(II) and 1,10-phenanthroline. Figure 3 shows the maximum absorbance values obtained as a function of pH. It is clearly seen that the ferroin complex begins to be formed at lower pH values in the micellar medium compared to the aqueous medium. Therefore SDS seems to have a concomitant effect on the Fe(II)-1,10 phenanthroline and hexacyanoferrate(II)-1,10-phenanthroline systems.

Fig. 3. Influence of the pH on the final absorbance of the Fe(II)-1,10-phenanthroline system in the presence (curve A) and absence (curve B) of SDS.

Since phen.H⁺ is concentrated on the micellar surface, the effective concentration of this reactant will be increased compared to that in the aqueous medium. In addition to an increased rate of ferroin formation this increased effective concentration, may result in an increased overall concentration of the complex formed. Figure 4 shows kinetic curves for the formation of ferroin from Fe(II) and 1,10-phenanthroline at different ligand concentrations. When the ligand concentration in solution was a limiting factor for the total ferroin complex produced [Figs 4(A) and (B)], more complex was produced under the same conditions in the micellar medium. When the ligand concentration was not a limiting factor [Figure 4(C)], differences in the reaction rate of formation of ferroin only were observed in the presence and absence of SDS.

The results obtained in the above experiments allow some considerations to be made on the effect of SDS on the reaction between

hexacyanoferrate(II) and 1,10-phenanthroline. If micellar catalysis occurs when one or more reactants are concentrated on the micellar surface, at least phen.H⁺ is concentrated on SDS micelles. Since ionic interaction is the decisive factor in this association (phen.H⁺ is preferentially concentrated from the phen.H⁺/phen. equilibrium) the ionic group of the phen.H⁺ molecule must be oriented towards the micellar surface. Therefore, for ferroin to be formed, Fe(II) must approach the micellar surface. Because of the negative charge carried by hexacyanoferrate, a direct interaction between this reagent and phen.H⁺ is impossible when the reaction takes place in the micelle. As a result, a reaction intermediate with positive or null charge must be formed from hexacyanoferrate(II) or, as suggested elsewhere¹⁵ the iron-bound cyanide is released under the catalytic action of Hg(II), which forms acid-resistant cyanides, and then the free iron(II) is complexed by 1,10-phenanthroline. This could account for the similar effects of SDS on the Fe(II)-1,10-phenanthroline and hexacyanoferrate(II)-1,10-phenanthroline systems.

From Fig. 3 it is apparent that under the working conditions used the reaction between 1,10-phenanthroline and Fe(II) on the micellar surface involves phen.H⁺ since the reaction takes place at lower pH values compared to in an aqueous medium in spite of the fact that 1,10-phenanthroline is a weaker acid in the presence of SDS micelles ($pK_a = 6$). On the other hand, the reaction in the aqueous medium must involve the basic form phen since the conditional formation constant decreases with pH. Although both reactions, that on the micellar surface and that in aqueous medium, can occur concomitantly in solution the relative significance of one over the other will depend on the concentration ratio of phen.H⁺ to phen.

Fig. 4. Influence of the 1,10-phenanthroline concentration on the rate and final absorbance of the Fe(II)-1,10-phenanthroline system at pH 2 in the presence (curve 2) and absence (curve 1) of SDS. [Fe(II)] = $2 \times 10^{-5} M$ pH = 2. Ligand concentration: (A) 4×10^{-5} ; (B) 2×10^{-4} ; (C) $8 \times 10^{-4} M$.

CONCLUSIONS

The features of some analytical kinetic methods can be improved by developing the reactions involved in micellar media. Thus we have shown improved selectivity to be obtained when a reactant has acid-base properties and these are modified appropriately by the presence of surfactants. Further research is required in order to establish the advantages that micellar media can bring to kinetic methods of analysis but, in principle, improved sensitivity, selectivity and/or experimental convenience are to be expected from some reactions.

NEW SPECTROPHOTOMETRIC METHODS FOR DETERMINATION OF CAPTOPRIL BULK DRUG AND TABLETS

HASSAN F. ASKAL

University of Assiut, Department of Pharmaceutical Chemistry, Faculty of Pharmacy, Assiut, Egypt

(Received 11 February 1991. Revised 21 April 1991. Accepted 21 May 1991)

Summary—Three simple, rapid and sensitive methods for the assay of captopril which is an effective alternative to digitalis were developed. These methods are based on the oxidation reaction in aqueous solution of captopril with either ferric chloride or iodine. The indirect quantitation of the product was carried out at 523, 351 and 620 nm for ferro-bipyridyl, residual iodine and residual iodine-starch complex, respectively. All variables were studied to optimize the reaction conditions. Regression analysis of Beer's plot showed good correlation in a general concentration range of 0.25–25 µg captopril/ml. No interference was observed from hydrochlorothiazide diuretic which was recently introduced in combination with captopril or other common pharmaceutical adjuvants. The validity of the methods was tested by analysing capoten and capozide tablets. Recoveries were 99.1–102.8%.

Captopril, 1-[(2S)-3-mercapto-2-methylpropionyl]-L-proline, was made generally available for treatment of hypertensive diseases in 1981.¹ It can be used alone or in combination with thiazide diuretics or digoxin²⁻⁵ in patients with moderate heart failure. As several methods have been reported for the quantitative determination of captopril in pure form or in biological fluids, including titrimetry,⁶ amperometry,^{7,8} HPLC,⁹⁻¹⁵ gas-liquid chromatography,¹⁶⁻¹⁹ radioimmunoassay,²⁰⁻²² fluorometry²³⁻²⁵ and colourimetry.²⁶⁻²⁸ Due to the absence of chromophores and/or auxochromes in the captopril molecule, it shows no distinct absorption in the ultraviolet range above 200 nm. Therefore UV spectrophotometry is not the method of choice for the determination of this thiol compound. The reported procedures are sophisticated and time consuming, thus unsuitable for the analysis of a large number of samples.

The development of simple chemical procedures for the determination of captopril in pure and in pharmaceutical dosage forms is therefore necessary.

In the present work, three new, simple, sensitive and rapid spectrophotometric procedures were developed with Fe(III)-bipyridyl and aqueous iodine solution, alone or with starch.

EXPERIMENTAL

Apparatus

The spectrophotometer used was a Uvidex 320 (JASCO, Tokyo, Japan) with two matched 1-cm quartz cells.

Reagents

2,2'-Bipyridyl solution (0.2% w/v) (prolabo Rhone poulenc) in distilled water.

Ferric chloride solution (0.1% w/v in 0.5% hydrochloric acid).

Sodium fluoride solution (1.0% w/v) in distilled water.

Iodine solution ($1.5 \times 10^{-3}M$). Prepared by dissolving 38 mg of resublimed iodine and 80 mg of potassium iodide in 100 ml of distilled water.

Starch solution 0.5% w/v soluble starch in distilled water.

Captopril. Obtained from Squibb-Egypt and hydrochlorothiazide from Kahira Co-Egypt.

Dosage form. Capoten tablets (Squibb-Egypt) containing 25 mg captopril per tablet and capozide tablets (Squibb-Egypt) containing 50 mg captopril and 25 mg hydrochlorothiazide per tablet.

Synthetic mixtures. Captopril combined with common tablet excipients (e.g., starch, glucose, lactose, sucrose, magnesium stearate and acacia) together with hydrochlorothiazide.

Preparation of standards

Dissolve an accurately weighed amount of captopril in water and dilute quantitatively with water to obtain dilutions containing from 2.5 to 250 $\mu\text{g/ml}$.

Preparation of samples

Powdered forms. Accurately weigh *ca.* 10 mg of captopril and dissolve in 50 ml of distilled water. Dilute this solution to contain 200 μg captopril/ml.

Tablets. Weigh and finely powder 20 tablets. Accurately weigh a portion of powder, equivalent to *ca.* 10 mg of captopril, and shake with 15 ml of distilled water for 10 min. Filter the resulting mixture and dilute the filtrate and washings to 50 ml with distilled water to contain 200 μg captopril/ml.

Synthetic mixtures. Accurately weigh a portion of thoroughly mixed components of each ingredient with *ca.* 50 mg of captopril, shake with 15 ml of water for 10 min, and then complete the analysis as described under tablets, "Filter the resulting . . .".

Recovery study

Add an accurately weighed amount of captopril for each preparation in a 50-ml standard flask containing an accurately weighed quantity of mixed contents of powdered tablets. Dissolve the contents of the flask in distilled water and treat as described for tablets.

Procedure A

Pipette 1.0 ml of the standard or pharmaceutical preparations into a 10-ml standard flask and add 1.0 ml of ferric chloride solution. Mix

well and allow to stand for 5 min at $20 \pm 5^\circ$. Add 1.0 ml of sodium fluoride solution, dilute to the mark with distilled water and measure the absorbance at 523 nm against the reagent blank.

Procedure B

(i) Pipette 1.0 ml of the standard or pharmaceutical preparations into a 10-ml standard flask, add 1.0 ml of iodine solution and dilute to the mark with distilled water. Mix well and measure the absorbance at 351 nm against a reagent blank.

(ii) Repeat the same procedure, adding 1.0 ml of starch solution before diluting to the mark with distilled water. Measure the absorbance at 620 nm against the reagent blank.

RESULTS AND DISCUSSION

Of the eight closely related antihypertensive drugs (captopril, enalapril, lisinapril, ramipril, pentopril, qunapril, zofenopril and fentiapril) only captopril possesses a sulfhydryl group.²⁹

Captopril, as a reducing agent, reacts with ferric chloride and the resulting ferrous ion produces an intense colour ($\lambda_{\text{max}} = 523 \text{ nm}$) with 2,2'-bipyridyl (Fig. 1). The resulting colour is due to the formation of the stable complex cation $[\text{Fe}(2,2'\text{-bip})_3]^{2+}$.³⁰

Captopril also reacts with aqueous iodine and the excess iodine could be measured either as its triiodide ($\lambda_{\text{max}} \sim 290, 351 \text{ nm}$) or its starch complex ($\lambda_{\text{max}} = 620 \text{ nm}$) as shown in Fig. 1. The bleaching action of the thiol drug on iodine can be illustrated as follows:

Fig. 1. Absorption spectra of 1-FeIII-bipy, 2-aqueous-iodine and 3-iodine-starch with 20, 5 and 0.5 μg captopril/ml respectively.

Fig. 2. Effect of time on the colour development at 523 nm with 20 µg captopril/ml (----) with and (—) without sodium fluoride.

Although these very sensitive colour reactions are completely new for captopril, it can be postulated that the oxidation of captopril with either ferric chloride or iodine proceed via the thiol group.³¹

Investigations were carried out to establish the most favourable conditions for the assay procedure. The absorbance readings of the resulting solutions were found to increase with increasing ferric chloride and 2,2'-bipyridyl concentrations up to 1.0 ml of 0.1 and 0.2 g% respectively for procedure A. The use of 1.0 ml of $1.5 \times 10^{-3}M$ iodine solution was considered satisfactory for the proposed concentration levels of captopril in procedure B.

The reaction between the drug and ferric ion goes rapidly at 20–25° within 5 min and then proceeds very slowly; therefore, the use of sodium fluoride is necessary after 5 min for quenching the interaction and obtain stable absorbance readings (Fig. 2). The best diluting solvent among the solvents studied was water (methanol, ethanol and isopropanol).

A linear correlation was found between absorbance and concentration of captopril (Table 1). Regression analysis of Beer's plot gave the following linear regression equations:

$$A_{523} = -0.0331 + 0.0432C$$

$$\Delta A_{351} = -0.0005 + 0.0237C$$

$$\Delta A_{620} = 0.1256 + 0.2365C$$

Table 2. Replicate analysis of captopril standard solutions by different methods

*10 µg/ml.

†15 µg/ml.

‡2.5 µg/ml.

These equations can be used to calculate the concentration of an unknown sample. The use of starch makes the iodine method about eleven times more sensitive than that of the triiodide, as seen from its higher molar absorptivities.

To examine the precision of the procedures, replicate determinations were made on the same solution containing the specified amount of captopril stated in Table 2, by different procedures. The percentage coefficients of variation at these concentration levels ranged between 0.7–1.57.

We investigated the influence of frequently encountered excipients and additives on the assay of captopril. No interference was observed from the presence of hydrochlorothiazide, starch, sucrose, glucose, lactose, acacia and magnesium stearate (Table 3). Under the specified reaction conditions, reducing sugars and starch do not interfere, since iodine reacts with reducing sugars only in alkaline medium.

The suggested methods were applied to the quantitative determination of captopril in bulk and in capotin or capozide tablets (Table 4).

Table 1. Comparative statistical evaluation for captopril analysis by the suggested procedures

SIMULTANEOUS DETERMINATION OF IRON(III) AND VANADIUM(V) BY USE OF A KINETIC-SPECTROPHOTOMETRIC AND RAPID MIXING FLOW SYSTEM

HONG-BIN HE, YUN-XIANG CI,* WEN-BAO CHANG and WEN-LING GONG

Department of Chemistry, Peking University, Beijing 100871, People's Republic of China

(Received 1 March 1991. Revised 8 April 1991. Accepted 17 April 1991)

Summary—The quantitative spectrophotometric determination of V(V) by its catalytic effect on the oxidation of chromotropic acid [the disodium salt of 4,5-dihydroxynaphthalene-2,7-disulphonic acid (CS)] by potassium bromate has been adapted to a flow system employing a rapid sample and reagent introduction manifold, in which valves and carrier streams are omitted without decreasing the precision or increasing the sample consumption relative to flow-injection analysis (FIA). Measurements are made at 420 nm. Coexisting Fe(III) can be determined simultaneously at the same wavelength by its more rapid colour chelate formation with CS. An accurate determination of V(V) and Fe(III) in the mixture was developed with a sample throughput of about 60 hr.

The flow pulsations caused by pumps can have a dramatic effect on signal profiles in flow systems. Therefore, numerous measures have been taken to lessen pulsations and their effects.¹ Stopped-flow methods record the signal after the flow comes to a halt and, as a result, pulsation effects are eliminated. Along with other advantages, such as longer reaction time and high tolerance to background signals, stopped-flow has become an important form of flow-injection analysis (FIA).^{2,3} Removal of the sampling valve and the replacement of the peristaltic pump with a pulsed pump (a home-made syringe-like pump) lead to the formation of a new sample introduction system. According to A. Gomez-Hens and Perez-Bendito, a high flow-rate of reactants through the mixing chamber was very important in the stopped-flow technique.⁴ In our work reported here, we have found that this sample introducer not only retains most of the advantages of the stopped-flow FIA method, but also displays some others, such as simplicity and especially a much wider reaction inspection time, from as little as 0.1 sec to what a conventional stopped-flow FIA can reach. This merit is particularly useful in the measurements of differences in kinetic reactions of some metal ions.

The sodium salt of 4,5-dihydroxynaphthalene-2,7-disulphonic acids (CS) forms a coloured complex with Fe(III) at a much faster

rate than the oxidation of CS by potassium bromate under the catalysis of V(V), using the same wavelength of 420 nm for monitoring. Its reaction with Fe(III) is virtually complete by the time the V(V) catalyzed reaction is initiated. The new sample introducer was adopted in this work because the conventional FIA method cannot mix the sample with reagents within 0.2 sec, which is required to discriminate these two reactions. Satisfactory results have been obtained in the simultaneous determination of Fe(III) by its colour reaction and V(V) by its catalytic effect, using this new sample introducer.

EXPERIMENTAL

Apparatus

The schematic view of the system is shown in Fig. 1 and it consisted of the units described below.

Pump. The pump used was designed and made in our laboratory. Figure 2 shows one of the three lines of the pump. A time of 0.3 sec was needed for filling the chamber C with solution via valve V_2 while V_1 was closed, and 30 μ l of solution was pushed out of the chamber within 0.2 sec via V_1 toward the mixing point while V_2 was closed. The total average flow-rate for all of the three lines was about 11 ml/min. The space from the joint point of the three lines to the farther end of the light path in the flow cell was calculated to be less than 60 μ l,

*Author for correspondence.

Fig. 1. Schematic diagram of the sample introducer. P: pump; R₁: CS; R₂:KBrO₃; S: sample; λ_{in}, λ_{out}: light; C: controller; FC: flow cell; W: waste; PD: photo detector; R: recorder.

therefore, the solution from every pulsation of the pump (90 μl) could not only fill the flow cell but also wash away the waste in the cell. About 10–15 pulsations were needed to refresh the three lines and the flow cell with new sample solutions. Therefore, total sample consumption was about 0.4 ml, no more than that consumed in a conventional FIA apparatus including loading of the injection valve.

Tubing. Poly(tetrafluoroethylene) (PTFE) tubing (0.5 mm i.d.) was used throughout the experiment. The length from the joint point of the three lines to the beginning of the light path in the flow cell is 35 mm long and 1.0 mm in diameter.

Flow cell. The glass flow cell was made to give a path 1.0 cm long and 2.0 mm in diameter.

Photometric detector. A model 722 Spectrophotometer (No. 3 Analytical Instrument Factory, Shanghai, PR China) was used to measure reaction signals.

Chart recorder. An LKB Bromma 2212 Recorder was used to record signals.

The control diagram of this sample introducer is shown in Fig. 3. This introducer worked under the following procedure: when the push-button PB was first pressed, the pump pushed

Fig. 2. General diagram of the components of the pump. V₁, V₂: valves; C: chamber.

Fig. 3. Control diagram of the sample introducer. PB: push-button; T₁: timer₁; T₂: timer₂; SW: switch; R: recorder.

the solutions in the three channels into the flow cell. After a preset time (usually 5–7 sec for refreshing the three channels and the flow cell), timer T₁ stopped the pump, and timer T₂ started the chart recorder immediately after the last pulsation. After the preset time for T₂ had elapsed, the recorder was stopped so that the end point of the measurement could be examined easily. By closing the switch SW, the pump could be restarted, and the cycle T₁ (pump) → T₂ (recorder) → T₁ (pump) could go on automatically until SW was opened. The experiment for each sample was repeated until peak height repeatability to within 1 mm on the chart recorder was obtained (typically three experiments). Before and after experiments, hydrochloric acid (pH 1.7) was pumped through the three lines for cleaning.

The absorbance spectra were recorded on a Shimadzu UV-300 double/difference/dual-wavelength recording spectrophotometer.

Reagents

The following solutions were prepared: Fe(III) solution (2.25 × 10⁻³ g/ml, pH 1.7); V(V) solution (5.0 × 10⁻⁵ g/ml, pH 1.7); Chromotropic acid (CS) solution (0.5%, pH 1.7) which was kept in a refrigerator; potassium bromate solution (5.0%); hydrochloric acid and sodium hydroxide were used to adjust the pH. A mixed acid (67% HNO₃:70% HClO₄ = 1:1) was used to dissolve the food samples.

All reagents were of reagent grade and solutions were made up with double ion-exchanged water.

Procedure

Two of the three lines were inserted into the solutions of CS and potassium bromate, respectively, and the third into the sample solution. The absorbance at 420 nm was measured within the first 30 sec.

The food samples were prepared by the following procedure: 2.00 g of food sample was treated with 20 ml of mixed acid (67% HCO_3 :70% $\text{HClO}_4 = 1:1$) and was heated on an electric heater until almost dry. This food sample was finally diluted to 25 ml with 0.01M hydrochloric acid. Four measurements were done for each sample.

RESULTS AND DISCUSSION

Spectral characteristics

The absorbance spectra at reaction equilibrium are shown in Fig. 4. Curve (a) shows the absorbance of CS with Fe(III). Experiments showed that CS alone did not present any absorbance in the range 400–750 nm, and the mixture of CS with potassium bromate did not absorb significantly in the first 60 sec. Curve (b) is the spectrum of CS with potassium bromate recorded 20 min after the two reactants were mixed. Curve (c) shows the spectrum of CS, potassium bromate and V(V). The CS/ KBrO_3 /V(V) system has a maximum absorbance at 420 nm. The CS–Fe(III) has a peak absorbance at 740 nm, but it also presents significant absorbance at 420 nm. Considering the simplicity and the reproducibility of the system, 420 nm was selected as the optimal wavelength in the experiment to allow simultaneous measurement of Fe(III) and V(V).

Dynamic characteristics

The dynamic isotherms of the reactions are shown in Fig. 5. Since the mixture of CS and potassium bromate did not present any significant absorbance in the first 60 sec, all the

Fig. 4. Spectra for Fe(III) and V(V). (a) CS: 0.5%; Fe(III): 1.0×10^{-4} g/ml; (b) CS: 0.5%; KBrO_3 : 5.0%; (c) CS: 0.5%; KBrO_3 : 5.0%; V(V): 2.0×10^{-8} g/ml. All of the above spectra were recorded against water. Curve (b) was recorded 20 min after the two reactants were mixed.

Fig. 5. Plot of absorbance against reaction time. (a) CS: 0.5%; KBrO_3 : 5.0%; Fe(III): 7.4×10^{-6} g/ml; (b) CS: 0.5%; KBrO_3 : 5.0% (20 min after mixing); (c) CS: 0.5%; KBrO_3 : 5.0%; V(V): 2.9×10^{-7} g/ml. All of the curves were recorded against water.

measurements were done against water instead of the CS and potassium bromate solution. Curve (a) shows that the signal from Fe(III) rises steeply in the first second and then remains constant for about 30 sec, followed by another increase. The output from V(V) goes up gradually with reaction time up to 30 sec [curve (b)].

Table 2. Results of Fe(III) and V(V) Determinations in Food Samples*

Sample	Fe(III)		V(V)	
	Content	Recovery†	Content	Recovery†
Raisin	100 ± 4 ^c	99%	0.77 ± 0.04 ^c	98%
Milk Powder	76 ± 0 ^d	105%	1.15 ± 0.07	102%
Biscuit	98.4 ± 0	103%	0.65 ± 0.02	101%

*Concentrations expressed in mg/kg. †The recovery is for 9 mg/kg of Fe(III) and 0.1 mg/kg of V(V). ‡Standard deviation. §The concentration stated in the label is 90 mg/kg.

Curve (c) suggests that these two isotherms could be added linearly in the first 30 sec. The increase between the initial Fe(III) signal and the next 30 sec is not correlated to the concentration of Fe(III) but correlated to that of V(V). Therefore, the reaction time for vanadium measurement was selected to be 30 sec and used throughout the experiment. The iron(III) was measured from the height of the initial rapid rise portion of the signal (at about 2 sec).

Effects of reaction variables

In order to optimize the system, the effects of pH and concentration of CS and potassium bromate on the absorbance were studied. The optimal pH for both Fe(III) and V(V) was 1.7–2.0. The optimum concentration of CS was 0.3–0.8% for Fe(III) and 0.4–1.0% for V(V). Potassium bromate should be 5.0% for V(V) and can be 0–5.0% for Fe(III). A pH of 1.7, 0.5% CS and 5.0% KBrO₃ were selected for measurements.

Calibration graphs for Fe(III) and V(V)

Under the optimal conditions, a simple spectrophotometric method for the simultaneous determination of Fe(III) and V(V) has been developed. The method was used to determine the Fe(III) and V(V) contents of some foods. Calibration curves were constructed with standard Fe(III) and V(V) solutions. The calibration graph of Fe(III) covers two orders of magnitude, from 1.5×10^{-7} to 1.5×10^{-5} g/ml Fe(III). The correlation coefficient was $r = 0.9974$. The calibration curve of V(V) is linear over the range 3.0×10^{-9} – 7.0×10^{-7} g/ml V(V), with a correlation coefficient of 0.9975. The relative standard deviation obtained for 10 samples of

3.0×10^{-6} g/ml Fe(III) was 0.6% and 2% for 10 samples of 5.7×10^{-9} g/ml V(V).

Interferences

The selectivity was assessed by studying the effect of foreign ions on the kinetic determinations of Fe(III) and V(V). The results are summarized in Table 1.

Table 1 shows that Sn^{II}, Co^{II} and CrO₄²⁻ interfere strongly in the determination of Fe(III). However, these ions do not exceed the tolerance ratio in raisins, milk powder, biscuit and some other food samples. All of the tolerance ratios of foreign ions in the determination of V(V) are over 10. Therefore, this method can be applied to the determination of V(V) in food samples.

Application

Finally, to test the applicability of the method, some food and fruit samples were analyzed with the calibration curves. The results are presented in Table 2. Results of added Fe(III) and V(V) were excellent. The determined iron content of the milk powder agrees well with the labelled content.

MALACHITE GREEN AS A REAGENT FOR DETECTION AND SPECTROPHOTOMETRIC DETERMINATION OF CHROMIUM(VI)

RAM PARKASH, REETA BANSAL, AJIT KAUR and S. K. REHANI
Department of Chemistry, Panjab University, Chandigarh-160014, India

(Received 7 March 1991. Accepted 3 April 1991)

Summary—A sensitive and inexpensive method of spectrophotometric determination of chromium(VI), based on the absorbance of its complex with malachite green and acetic acid at pH 2.5 is reported. The complex shows a molar absorptivity of 8×10^4 l. mole⁻¹ cm⁻¹ at 560 nm, using malachite green and acetic acid as reference solution. The effect of time, temperature, pH and reagent concentration is studied and optimum operating conditions are established. Beer's law is applicable in the concentration range 2.0–22.8 µg/ml chromium(VI). The resin beads act as a catalyst and as little as 1.6 µg of chromium(VI) is detected in the resin phase as compared to 4.1 µg in the solution phase. The standard deviation in the determinations is ± 0.40 µg/ml for a 10.35 µg/ml solution.

Feigl and Anger,¹ Sandell,² and Snell and Snell³ reviewed the earlier work on the detection and determination of chromium(VI) as chromate or dichromate ions. Microamounts of chromium(VI) have also been determined spectrophotometrically with varamine blue,⁴ diphenylcarbazine,^{5,6} alizarin,⁷ 3,3'-diaminobenzidine,⁸ pyridine-2,4,6-tricarboxylic acid,⁹ triethylenetetraaminehexaacetic acid,¹⁰ *O*-toluidine,¹¹ α -naphthyl,¹² crystal violet,¹³ cesium iodide¹⁴ and 2-(5-bromo-2-pyridylazo)-5-diethylaminophenol.¹⁵ Indirect determination of chromium(VI) was achieved by using iron(II) and ferrozine.¹⁶ However, most of these methods are either time consuming or less selective than desired and are subject to interference from common ions.

Chromium(VI) is a moderate to severe toxic agent. Determination of its microquantities is of increasing interest to analytical chemists, particularly environmental scientists. We report here a rapid, sensitive and inexpensive method for detection and spectrophotometric determination of micro amounts of chromium(VI) based on its colour reaction with acetic acid and malachite green. The method is not only superior to most of the reported methods in simplicity, rapidity and selectivity but is also suitable for chromium determination in industrial waste water.

EXPERIMENTAL

Reagents

Analytical grade reagents and doubly distilled water were used throughout. Strongly acidic

cation-exchange resin Amberlite IR 120 (standard grade, B.D.H.) was used in the H⁺ form. Potassium dichromate stock solution (10⁻¹M) and acetic acid solution (10% v/v) were prepared by dissolving appropriate amounts of the reagents in demineralized water. Malachite green (0.1%) was prepared by dissolving an appropriate amount of reagent in distilled methanol. Working solutions of potassium dichromate of appropriate dilutions were stored in the dark.

Apparatus

A Hitachi model 330 double-beam recording spectrophotometer with 10-mm cells was used for absorbance measurements.

Detection

About 5–10 resin beads (H⁺ form) are placed on a white spot-plate and blotted dry with filter paper. One drop of test solution is added, followed by a drop of acetic acid and malachite green. Green colour develops on the bead surface within 10 min if the test solution contains chromium(VI).

Determination

Shake dichromate (20.0–228.4 µg), acetic acid (2.5 ml of 10% solution) and malachite green (1.0 ml 0.1% solution) for about 10 min for complete colour development. Make the volume up to 10 ml with water. Measure the absorbance at 560 nm against a blank solution at room temperature (25–30°).

RESULTS AND DISCUSSION

Malachite green (R^+X^-) and dichromate react without destroying the quinoidal structure of the dye. On the analogy of the reaction between antimony(III) and malachite green,¹⁷ the tentative mechanisms may be written as

Two types of ion-exchange resins, Amberlite IR 120 (H^+ form) and Amberlite IRA 400 (OH^- form) were added in two different microtest tubes containing, the coloured complex formed by the recommended procedure. The positively charged resin beads turn green, indicating that the complex formed is positively charged.

The plot of absorbance of the green complex as a function of wavelengths shows a plateau with a maximum absorbance ($\epsilon = 8 \times 10^4$ l. mole⁻¹ cm⁻¹) at 560 nm. Beer's law is obeyed for solutions containing 2.0–22.8 $\mu\text{g/ml}$ of chromium(VI) under the optimum conditions. The stability of the complex was studied by measuring the absorbance as a function of time. A green colour developed after 10 min, was stable for about 2 hr at room temperature (25–30°) and then started to fade. The absorbance of the solution decreases with the increase in temperature. However, the colour takes more time to develop at lower temperatures.

The effect of acetic acid or malachite green concentration and variation in pH on the absorption of the green complex was examined. It was revealed that 2.5 ml of 10% solution of acetic acid is the most suitable. Absorbance decreases if the volume of acetic acid is increased further. Similarly, 1 ml of 0.1% malachite green solution gives maximum absorbance. Further increase in the amount of malachite green has no effect on the absorbance. The absorbance was maximum and constant at pH 2.5 at 560 nm. On increasing the pH, the absorbance of the green complex decreases.

Chromium(VI) is detected in the presence of large amounts of foreign substances; no interference was given by Cu(II), Mn(II), Co(II), Ni(II), Zn(II), Ca(II), Mg(II), Cr(III), Fe(III), Ce(IV), V(V), chloride, nitrate, sulphate, acetate, phosphate, citrate, permanganate and tartarate in solution phase and in bead test even when present in 100 times excess. The identification limit of chromium(VI) at room temperature (25–30°) is 4.1 μg in solution phase (10 ml) and 1.6 μg in resin phase. Ion-exchange resin beads, thus, serve to concentrate the chromium product and act as detection medium to improve the sensitivity of the test.

The tolerance limits (mg) of the following elements in the determination of chromium(VI) for $\leq 0.80\%$ error are given in parentheses: Ag(I) (84.5), Cu(II) (74.8), Mn(II) (37.7), Co(II) (87.3), Ni(II) (116.0), Zn(II) (59.4), Cd(II) (184.8), Mg(II) (20.5), Ca(II) (98.4), Hg(II) (128.0), Cr(III) (60.0), Fe(III) (32.4), Al(III) (150.0) and Mo(VI) (163.8) in 80 $\mu\text{g}/10$ ml of dichromate solution. The standard deviation (10 replicates) was ± 0.40 $\mu\text{g/ml}$ for a 10.35 $\mu\text{g/ml}$ solution. In the absence of determinate error, the true value fell within 9.40–10.28 μg with a confidence interval of 95%.

This method is highly sensitive, selective, precise, accurate and quick. It offers certain advantages over several other methods. The colour reaction of chromium(VI) with 2-(5-bromo-2-pyridylazo)-5-diethylaminophenol occurs on heating the reactants in a boiling water bath for 45 min,¹⁵ whereas the reaction is complete in ~ 10 min at room temperature in the present case. The procedure suggested by Malik *et al.*¹³ also requires 2 hr for complete colour reaction. In the method of Bet-Pera and Jaselskis,¹⁶ permanganate and Fe(III) interfere. Low results are obtained in the presence of Co(II) and Ni(II) because these ions form ferrozine complexes. There is no such difficulty with the present procedure. Various oxidants such as permanganate, Ce(IV), V(V) and Fe(III) interfere in the

Table 1. Spectrophotometric determination of Cr(VI) in waste water samples

Sample	Cr(VI), (μg)		Mean recovery, %	Relative standard deviation, %	Found by reference procedure, ⁵ mean recovery, %
	Added	Found			
Chromium plating electrolyte	0.0	65.2	—	0.43	—
	20.0	85.6	102	1.85	103
waste water	0.0	64.4	—	0.85	—
	20.0	84.2	99.0	1.65	101

method proposed by Cheng and Goydish,⁸ but these oxidants do not interfere in the present studies.

The present procedure is suitable for detection and determination of Cr(VI) in industrial waste water and chromium plating electrolyte waste water without prior separation. The relative standard deviation calculated from six replicate analyses of the samples, is in the range 0.85–1.65% and 0.43–1.85% respectively. The mean recovery of Cr(VI) is 102% and 99%, respectively (Table 1).

The results obtained by this procedure agree satisfactorily with those obtained by the method reported in the literature.¹⁵

RAPID SPECTROPHOTOMETRIC DETERMINATION OF TRACE COPPER IMPURITY IN *N,N'*-DI(2-BUTYL)-*p*-PHENYLENEDIAMINE

J. K. GUPTA

Petrochemistry Division, Indian Institute of Petroleum, Dehradun 248005, U.P., India

(Received 18 October 1988. Revised 28 February 1991. Accepted 11 March 1991)

Summary—The trace copper is separated from the matrix by extraction of the latter (an antioxidant of *N*-alkylated *p*-phenylenediamine type) from ammoniacal medium and then determined spectrophotometrically.

For determination of trace copper contamination in organic products, the matrix can be removed by ashing or chemically.^{1,2} The latter is generally preferred, but ashing is particularly appropriate for coloured products. During synthesis of butylated *p*-phenylenediamine in our laboratory, the product was found to be contaminated with copper at ppm level, from the hydrogenation catalyst (copper chromite; CuO 46%, Cr₂O₃ 46%). It was desired to find a rapid process for determining the copper, but the existing non-ashing methods were unsuitable because of the dark colour and alkaline nature of the product. Therefore, an alternative non-ashing method has been developed for the purpose and could be used for determining copper in similar amine-type antioxidants.

EXPERIMENTAL

Reagents

All chemicals used were of analytical reagent grade.

Standard copper solution. Wash pure copper metal with petroleum ether to remove any surface grease and dry it at 100°. Prepare a 1-mg/ml solution by dissolving the metal in concentrated nitric acid, boiling off brown fumes, cooling and diluting accurately to known volume. Prepare a 10-μg/ml solution from this by accurate dilution.

Buffer (pH 10). Dissolve 39 g of ammonium chloride in 100 ml of water plus 100 ml of concentrated ammonia solution.

Sodium diethyldithiocarbamate solution. 0.1 g per 100 ml.

Citric acid solution. 5 g per 100 ml.

Procedure

Weigh accurately about 0.25 g of sample, dissolve it in 15 ml of 4*M* hydrochloric acid and transfer the solution into a 250-ml separatory funnel. Add 10 ml of concentrated ammonia solution, cool the mixture, and shake it vigorously with 25 ml of chloroform for about 1 min. Allow the layers to separate and then discard the chloroform layer. Repeat the extraction, if necessary, with another 25 ml of chloroform for complete removal of the organic compound.

Add 5 ml of citric acid solution, and then 4 drops of Thymol Blue solution as indicator to check that the pH is ~9 (which is indicated by a colour change from yellow to blue). Add 10 ml of buffer solution and 10 ml of the sodium diethyldithiocarbamate solution, mixing after each addition.

Transfer exactly 25 ml of chloroform to the funnel and shake the mixture for 2 min. Allow the layers to separate, transfer part of the chloroform layer into a clean, dry 1-cm path-length cell and measure the absorbance at 440 nm against a reagent blank similarly prepared (by the whole procedure). Read the copper content from a calibration graph covering the range up to 100 μg.

RESULTS AND DISCUSSION

Conventional non-ashing methods could not be used, because dissolving the copper-contaminated product (*N*-alkylated *p*-phenylenediamine) in hydrochloric acid resulted in an aqueous solution of the hydrochloride, from which the protonated organic base was not extractable into an organic solvent.

However, it was realized that alkalizing this solution by addition of ammonia solution would free the organic base and also convert any copper present into its tetraammine complex. Extraction with an organic solvent would remove the organic base and leave the copper in the aqueous phase, where it could be determined by any convenient method, such as the diethyldithiocarbamate method. Citric acid is added to mask any metal ions that might be co-extracted and interfere.

The method is rapid and simple; one determination takes about half an hour. It is reproducible and the results compare favourably with those obtained by an ashing method. Ten repli-

cate analyses of a product sample gave a copper content of 207 $\mu\text{g/g}$, with a standard deviation of 0.6 $\mu\text{g/g}$. The comparison method gave a value of 206 $\mu\text{g/g}$, with a standard deviation of 0.5 $\mu\text{g/g}$.

PROMOTION OF TIN OXIDE GAS SENSOR BY ALUMINUM DOPING

CHAONAN XU, JUN TAMAKI, NORIO MIURA and NOBORU YAMAZOE

Department of Materials Science and Technology, Graduate School of Engineering Sciences,
Kyushu University 39, Kasuga, Fukuoka 816, Japan

(Received 29 November 1990. Accepted 4 February 1991)

Summary—Effects of Al-doping on tin oxide based elements were investigated in the Al content range 0.001–5.000%. Gas sensitivity to H₂ and *i*-C₄H₁₀ was found to be promoted extensively when 1 or 5% Al was doped, while promotion was modest with doping up to 0.1% Al. Seebeck coefficients indicated that carrier concentration decreased with Al-doping, resulting in an increase in Debye length. At the same time, the crystallite size of tin oxide was found to decrease especially drastically when Al was doped excessively. It was concluded that the increased Debye lengths and decreased crystallite sizes were combined to produce the microstructure responsible for extremely high gas sensitivity of 1 and 5% Al-doped elements.

Gas sensors based on semiconductive oxides, represented by tin oxide, are very important devices for detecting the leakage of inflammable gases. Research on semiconductor gas sensors is being directed more and more towards their use in monitoring lower levels of gaseous components such as odours and harmful gases generated from various origins. To measure such low level components, however, the sensors need to be improved in several respects and gas sensitivity in particular should be promoted. Our recent investigation has revealed that this type of sensor is strongly influenced by the microstructure of sensor elements.^{1,2} The gas sensitivity (*S*) of SnO₂-based elements increases steeply as the grain size (*D*) of SnO₂ decreases down to *ca.* 6 nm. A simple model analysis has shown that such a grain size effect shows up when *D* decreases to be comparable with $2L$, where *L* is the depth of space charge layer. This shows the importance of controlling *D* to a size comparable with or less than $2L$. At the same time, this also suggests that control of *L* instead of *D* would give rise to a similar effect. It is known that *L* of a semiconductor can be controlled by doping impurities inside the lattice.³ In the case of SnO₂, *L* will increase with Al³⁺-doping, while it will decrease with Sb⁵⁺-doping, for example, according to the vacancy control principle. In fact, our preliminary study has confirmed that Al³⁺- or Sb⁵⁺-doping leads to a drastic change in gas sensitivity in accordance with the expectation. These findings have

prompted us to investigate the doping effects in more detail. This paper deals with the effects of Al³⁺-doping on SnO₂-based sensors. First we have examined how the gas sensitivity is modified with varying extents of Al³⁺-doping and then we carried out the measurements of Seebeck coefficients in order to estimate important parameters for understanding the doping effects.

EXPERIMENTAL

Hydrous SnO₂ powder was prepared by neutralizing a cold solution of SnCl₄ with an aqueous ammonia solution, followed by thorough washing with demineralized water, drying at 100° and grinding. It was calcined at a prescribed temperature for 1 hr in air to obtain undoped SnO₂ powder. To dope Al³⁺ into SnO₂ lattice (Al³⁺-SnO₂), an aqueous chloride mixture (SnCl₄ + AlCl₃) was treated with an aqueous ammonia solution. Aluminium content was varied in the range 0.001–5.000% in the atomic composition Al/(Al + Sn). The resulting coprecipitate was washed, dried and calcined at a temperature of 1100°. The mean size of SnO₂ crystallites was evaluated from the width of the X-ray diffraction (XRD) line of the (101) plane, based on Scherrer's equation.

To fabricate porous sensor elements, each powder sample prepared above was mixed with water, and the resulting paste was applied on an alumina tube with Pt wire electrodes and

Fig. 1. Apparatus for Seebeck effect measurements. T_H and T_L denote temperatures at the high and low temperature ends of the specimen.

sintered at 700° for 4 hr in air unless otherwise stated. The gas sensing properties of each element were examined in a heated chamber through which air or a sample gas was allowed to flow at a rate of 150 cm³/min. The gas sensitivity was defined as the ratio of electric resistance in air (R_a) to that in the sample gas (R_g).

Measurement of the Seebeck effect was carried out in an apparatus shown in Fig. 1. Each powder sample was pressed into a ribbon-shaped specimen (3 × 15 × 0.3 mm) under a pressure of 1000 kg/cm², and calcined at 800 or 1100°. The two ends of the specimen were fixed onto a quartz rod with silver paste, together with two Pt/Pt-Rh thermocouples as shown in Fig. 1. The assembly was set in a quartz chamber located inside an electric furnace. The temperature difference of the specimen was measured with the two thermocouples, while the difference in electric potential (thermoelectric motive force) was measured between the Pt

Fig. 2. Electrical resistance and gas sensitivity towards 800 ppm H₂ and 1000 ppm *i*-C₄H₁₀ correlated with the amount of Al doped into SnO₂ elements.

wire electrodes of the thermocouples in a flow of dry air.

RESULTS AND DISCUSSION

Properties of Al-doped sensors

Figure 2 shows the electric resistance (R_a) of the sensor elements at 300° in dry air as a function of Al content. R_a increased with increasing Al content up to 1% Al, above which R_a was saturated. This behaviour suggests that the solubility of Al in SnO₂ is 1% or less under these conditions. On the other hand, gas sensitivity (S) showed quite different dependence on Al content. As also shown in Fig. 2, S to both H₂ (800 ppm) and *i*-C₄H₁₀ (1000 ppm) increased only slightly up to 0.1% Al, and then increased dramatically. These properties of doped elements are summarized in Table 1, together with the data of the undoped one. The gas sensitivity could be promoted greatly when Al was doped by 1 and 5%.

We have reported that for undoped SnO₂ elements the crystallite size of SnO₂ (D) seriously affects the electric resistance and gas sensitivity. The crystallite size data for the present elements are also shown in Table 1. It is seen that D decreases with an increase in Al

Table 1. Properties of the Al-doped SnO₂

Amount of Al	Calcination conditions	Grain size D/nm	$\log R_a/\text{ohm}$ (300°)	Gas sensitivity	
				H ₂	<i>i</i> -C ₄ H ₁₀
0 (undoped)	800C·4 hr	25	5.30	30	41
0.001%	1100C·3 hr	>60	5.63	37	41
0.01%	1100C·3 hr	>60	6.34	50	45
0.1%	1100C·3 hr	60	7.74	69	48
1%	1100C·3 hr	43	8.93	118	145
5%	1100C·3 hr	19	8.84	204	201

content. This suggests that the properties of Al-doped elements are affected not only by the dissolution of Al into the lattice of SnO₂ but also by a change in D . As seen in Table 1, D was as small as 43 and 19 nm at Al contents of 1 and 5%, respectively, even under the severe calcination conditions applied. For those particular samples, the part of Al content in excess of solubility limit seems to have acted as a stabilizer of the ultrafine crystallites of SnO₂.

In order to examine the crystallite size effect in Al-doped elements, the resistance (R_a) and the gas sensitivity (S) to 800 ppm H₂ are shown as a function of D in Fig. 3 together with the data of undoped elements already reported. Only two elements doped with 1 and 5% Al were available for this correlation because the other elements had D values too large to be determined from XRD. The R_a vs. D relation for undoped elements is divided into two regions: R_a decreases steeply with increasing D in the small D region, while R_a increases slightly in the large D region. As has already been pointed out,¹ such D dependency of R_a results from whether D is smaller or larger than twice the depth of space charge layer ($2L$). From the D value bordering the two regions, L is estimated to be *ca.* 3 nm for the undoped SnO₂. For 1 and

5% Al doped elements, on the other hand, R_a was very large (10⁹ ohm) and exhibited no such dependency on D . As shown in Fig. 3(b), the gas sensitivity (S) of undoped elements increases drastically when D decreases down to 6 nm or less. When compared with these elements, the gas sensitivity of Al-doped elements was still very high at D as large as 20 nm or more. These data clearly show that both crystallite size (D) and impurity levels of SnO₂ bulk are important in determining S of Al-doped elements.

Seebeck coefficients

The valence control principle predicts that when trivalent ions (Al³⁺) are partially introduced into the lattice, the carrier concentration (n) of SnO₂ will decrease, leading to an increase in Debye length. In addition to such a change in the electronic structure in the bulk, however, actual Al-doped elements showed a change in the size of SnO₂ crystallites depending on Al content, as just mentioned. Furthermore, one cannot know *a priori* what portion of doped Al ions would in fact have entered the SnO₂ lattice. Under such conditions it seems imperative to separate the electronic structure factor from the microstructure factor for a basic understanding of the effect of Al-doping. For this purpose, we tried for the first time to evaluate the electronic structure of polycrystalline SnO₂ from the measurements of Seebeck effect.

The Seebeck effect is defined as the generation of a thermo-emf (electromotive force) between two points of a semiconductor when a temperature difference is applied between these points.⁴ The Seebeck coefficient (Q) is defined as a temperature derivative of thermoelectric potential (V). Under the condition that both electric field and temperature gradient are uniform between the two points, Q can be obtained as the ratio of emf (ΔV) to the temperature difference (ΔT).

$$Q = \frac{dV}{dT} = \frac{\Delta V}{\Delta T} \quad (1)$$

Thus Q was evaluated by measuring ΔV while applying ΔT between the two ends of the ribbon-like specimen. In all measurements, the lower temperature end was fixed to 300° and ΔT was set to be 10° or less. Prior to each measurement, the specimen was heat-treated at 500° for 30 min in dry air to eliminate possible surface contaminants like water and CO₂, and then kept at the temperature of measurement for 2 hr for stabilization.

Fig. 3. Influence of crystallite size in Al-doped and undoped elements on (a) electric resistance and (b) gas sensitivity towards 800 ppm H₂.

Table 2. Seebeck coefficients and related characteristics of Al-doped SnO₂

Amount of Al	ΔV , mV	ΔT , °C	Q , $\mu V/K$	n , cm^{-3}	L_D , nm
0 (undoped)	-2.045	10	-205	4×10^{18}	2.8
0.001%	-2.302	9	-256	2×10^{18}	4.0
0.01%	-3.052	9	-339	8×10^{17}	6.4
0.1%	-4.600	8	-575	5×10^{16}	25.0
1%	-6.400	8	-800	(4×10^{15})	(88.5)

The values of ΔV , ΔT and Seebeck coefficient, Q , obtained are listed for each specimen in Table 2. For an n -type semiconductor, Q is known to be negative in sign. All the specimens showed negative coefficients and the absolute values were larger for larger amounts of Al-doping. For 5% Al-doped specimen this measurement was not possible because of too large a noise.

It should be noted that in the above procedure the assumption of a uniform electric field is an important approximation. For a polycrystalline system, this assumption may not always be verified because of the surface barrier. This matter will be discussed later.

Carrier concentration

For an n -type semiconductor of a single carrier system, the carrier concentration (n) is assumed to obey a Boltzmann distribution, $n = N_c \cdot \exp[-(E_C - E_F)/k]$, where E_C and E_F are the electronic potentials at the conduction band edge and Fermi level, respectively, and N_c is the density of states in the conduction band. Then Q can be related with n by the following equation.^{5,6}

$$n = N_c / \exp[-(eQ/kT) - A] \quad (2)$$

Here A is a constant associated with the transport of energy and e is elementary electric charge. For a non-degenerate semiconductor, $A = 2$ and $N_c = 2(2\pi m^* kT/h^2)^{3/2}$, where m^* is the ratio of effective mass to mass of electron and *ca.* 0.2 for SnO₂.^{7,8}

In this way, one can evaluate the concentration of carriers from Q data by using equation (2). Resulting carrier concentrations (n) are shown in Table 2 and Fig. 4. It is seen that n decreases steeply with an increase in doping amount of Al³⁺, from 4×10^{18} (cm⁻³) for undoped SnO₂ to 4×10^{15} (cm⁻³) for 1% Al³⁺ doped sample. The n value of undoped SnO₂ coincides well with that reported for porous SnO₂ thin films which falls in the range of 10^{18} – 10^{19} (cm⁻³) depending on the preparation methods.^{9–11} This seems to verify the

evaluation of n from Seebeck coefficients. The decrease of n with Al-doping is in accordance with the valence control principle. When it is assumed that each Al ion introduced in the lattice of SnO₂ traps a conduction electron, the observed decreases in n suggest that all Al ions enter the SnO₂ lattice up to 0.01% Al-doping, while only small portions of Al ions do so for larger amounts of Al-doping.

Debye length and the depth of space charge layer

When an n -type semiconductor has a carrier concentration of n , the Debye length is given as follows.

$$L_D = (\epsilon kT/e^2 n)^{1/2} \quad (3)$$

Here ϵ is the dielectric constant of the semiconductor and is *ca.* 10^{-10} F/cm for SnO₂.¹² Thus L_D can be directly derived from the data of n , as shown in Table 2 and Fig. 4. An increase in Al content is seen to increase L_D drastically; while L_D was 3 nm for undoped SnO₂, it was 25 nm at 0.1% Al. The L_D value at 1% Al (88 nm) apparently far exceeded one half of the crystallite size (43 nm), but because the various assumptions used for deriving it may not always be justified under such conditions this is not definite. Nevertheless, it can be concluded clearly that L_D is rather close to $1/2 D$ at 0.1%

Fig. 4. Influence of Al content on carrier concentration and Debye length of Al-doped SnO₂.

Fig. 5. Idealized model for oxygen adsorption on an *n*-type semiconductor. (a) Charge distribution. (b) Energy band structure.

Al while it is far larger than $1/2 D$ at 1% and 5% Al.

L_D is an important parameter in determining the depth of space charge layer (L) when a semiconductor interacts with a gas. In our case, oxygen would be adsorbed on the surface of SnO_2 crystallites. Figure 5 shows carrier distribution and energy band structure schematically, in the surface region. In the simplest case where all donors are ionized and all conduction electrons in the space charge layer are depleted, to be trapped by surface states (adsorbed oxygen), L is proportional to L_D with a proportionality constant being determined by surface potential (eV_s) and thermal energy as follows.³

$$L = (2eV_s/kT)^{1/2} L_D \quad (4)$$

Thus one needs the surface potential data for estimating L , but unfortunately no reliable data are available for SnO_2 . At 300° , the proportionality constant of equation (4) is close to unity for $eV_s = 0.03$ eV and increases with the square root of increasing eV_s . Considering that the surface potentials are often of the order of 0.1 eV for other oxides,¹³⁻¹⁵ L does not seem to be much different from L_D for SnO_2 . It is noted that for undoped SnO_2 , L_D (3 nm) coincides well with the empirical value of L (3 nm) estimated from Fig. 3(a).

Polycrystalline state of SnO_2

Equation (1), used for the measurements of Seebeck coefficients, assumes the uniformity of both temperature gradient and electric field between the two measuring points. These requirements would be easily satisfied with a

single crystal or a densely sintered specimen but not with a porously sintered specimen, as used in the present study, because of the surface potential. Nevertheless, the measurements were found to bring about rather reasonable values of carrier concentration and Debye length, especially for undoped SnO_2 . This suggests that the specimens, though porous and polycrystalline, have a microstructure which somehow meets the requirements.

According to our previous study with TEM observation and other techniques,¹⁶ the microstructure of SnO_2 -based elements can be pictured as composed of three dimensional arrays of SnO_2 crystallites. Each crystallite is co-ordinated with 4 neighbours, on average, through necks of a diameter of $0.8 D$ (D = crystallite diameter), whereas a far fewer number of grain boundary contacts are also included in the array. For simplicity, such a microstructure can be reduced to a one-dimensional chain as schematically shown in Fig. 6. The connections between neighbouring crystallites are provided almost exclusively by necks and only scarcely by grain boundary contacts. If D is larger than $2L$, the space charge layer forms only in the surface region of each crystallite. The core region, undisturbed by the surface effect, can extend through necks in the chain until it terminates at the grain boundary contacts. When a temperature gradient is applied in the chain direction the resulting electric field inside the core region can be uniform as long as neck contacts are available. In this situation, therefore, the Seebeck effect can be measured without being disturbed by the surface effect if grain boundary contacts are scarce compared with neck contacts. This situation was probably achieved in the present specimens when Al contents were low. For 1 and 5% Al-doped samples which had D smaller than $2L$, however, Seebeck effects could possibly be seriously disturbed by the surface effect.

Implication of Al-doping for gas sensitivity

As mentioned above, the gas sensitivity of SnO_2 -based elements towards H_2 (and $i\text{-C}_4\text{H}_{10}$)

Fig. 6. One dimensional model for interconnection of SnO_2 crystallites in polycrystalline elements.

could be promoted with Al-doping, with best results at Al contents of 1 and 5%. Subsequent analyses revealed that Al-doping had two effects on the elements: the increase of Debye length of SnO₂ as a result of valence control and the stabilization of microcrystalline particles of SnO₂. Both effects are quite favourable from the viewpoint of gas sensitivity, since gas sensitivity has been shown to increase when the crystallite size of SnO₂ is comparable with or smaller than twice the depth of space charge layer.

It is often asserted that gas sensitivity should increase with increasing electric resistance of the element on the grounds that a change in conduction electron concentration would bring about a larger resistance change with increasing resistance. Figure 7 shows the relation between electric resistance (R_a) and gas sensitivity (S) for Al-doped SnO₂ in the present experiments. Although S tends to increase with an increase in R_a , the relation does not seem to be as simple as the above assertion. The increase of S is only gradual in the R_a range below 10⁸ ohm, while it is quite steep above it. This tendency is well coincident with whether $D > 2L$ (gradual increase) or $D < 2L$ (steep increase), in agreement with what was observed for undoped SnO₂. This strongly suggests that the observed increase of S with Al-doping should be understood on the basis of microstructure of the elements rather than R_a .

The present study indicates that the doping of impurities in semiconductive oxides can be an important method for promoting semiconductor gas sensors. As illustrated above, the doping affects not only the electronic structure but also the microstructure of the elements,

Fig. 7. Relationship between electric resistance in air and gas sensitivity to 800 ppm H₂ at 300° for Al-doped elements. Figures attached indicates Al contents.

both being critically important for gas sensing properties. There are many oxides which exhibit semiconductive properties, but very few of them have actually been used for gas sensors. As the doping method can modify the properties of oxides rather drastically, it is possible that new sensing materials are developed by this method. Although this method has hardly been applied so far, research in this direction is desired for further development of gas sensors.

CONCLUSION

The effects of Al-doping on SnO₂ elements were investigated with respect to gas sensing properties as well as electronic and physical structure of the elements. Gas sensitivity to H₂ and i-C₄H₁₀ is promoted tremendously when Al is doped by 1 and 5% although promotion remains slight up to 0.1% Al. Seebeck effect measurements indicate that Debye length increases with Al-doping, while XRD shows that SnO₂ crystallite size (D) decreases with Al-doping. As a result of these two effects, the relation $D < 2L$ (L = the depth of space charge layer) is achieved when 1% or more Al is doped and this is a reason for the high gas sensitivity of these elements.

(Received 27 June 1990. Revised 24 September 1990. Accepted 3 November 1990)

Summary—The utility of carbon-paste electrodes modified with 2,2'-bipyridyl and Nafion for the differential pulse voltammetric determination of iron(II) in aqueous medium is demonstrated. The method is based on formation of the 2,2'-bipyridyl complex of iron(II) and its accumulation by the Nafion. The differential pulse voltammetric response of the accumulated complex is used as the analytical signal. The response was evaluated with respect to carbon-paste composition, preconcentration time, pH, iron(II) concentration and other variables. A 3-min accumulation period permits measurement of iron(II) down to $10^{-8}M$, and a relative standard deviation of 3.8% for $2 \times 10^{-6}M$ iron(II). Rapid and convenient chemical renewal allows use of a single modified carbon-paste electrode in multiple analytical measurements over several days. The proposed procedure was applied to the determination of iron in certified standard reference materials and trace iron in natural waters.

The application of chemically-modified electrodes (CMEs) in analytical chemistry has attracted considerable attention in recent years. A number of CMEs have proved suitable as sensors in the electrochemical determination of metal ions¹⁻⁵ and organic and bio-organic species.⁶⁻⁸ Various methods have been demonstrated, including complexation,¹ precipitation,² electrostatic preconcentration,⁹ bio-accumulation,³ potentiometry,¹⁰ permselectivity¹¹ and others.¹²⁻¹⁶ Of these, the application that is currently the most widely developed and the closest to practical use in analytical chemistry is probably that involving analyte preconcentration. Concentrating the analyte in the modified film greatly improves the sensitivity and selectivity of voltammetric determination. This approach is analogous in some respects to traditional electrochemical stripping voltammetry in that a preconcentration step is employed to enhance the sensitivity and selectivity, but with the difference that in the CME approach these characteristics are governed by the chemical reactivity of the modifier rather than by the reduction potential of the analyte. As a result, the nature of the analytes that can be accumulated on the CME surface can be rationally

predicted for a given modifier, and electrodes can be designed for particular analytes. As CMEs utilize a chemical step for analyte accumulation, their use can often be more selective than electrochemical stripping voltammetry.

In addition, many methods have been used to immobilize chemically active species on the electrode surface. The carbon-paste electrode appears especially advantageous for modification. CME fabrication with this electrode involves only the addition of a sparingly soluble modifier to an otherwise conventional graphite powder/nujol oil mixture and has several attractive features. Chemically-modified carbon-paste electrodes (CMCPes) are very easy to make, and can readily be prepared with a variety of modifier loading levels. More importantly, fresh modified-electrode surfaces can be generated rapidly and reproducibly. The low background current is another advantage for practical analytical applications.

Various chemically active species (preconcentration reagents) have been introduced into carbon-paste electrodes to produce CMCPes. Baldwin and co-workers have described the use of carbon-paste electrodes modified with dimethylglyoxime and 2,9-dimethyl-1,10-phenanthroline² for the determination of nickel(II) and copper(I), respectively. Gardea-Torresday

*Author for correspondence.

et al. proposed a micro-organism-modified CPE for the bio-accumulation and subsequent voltammetric determination of copper(II).³ Ion-exchangers have also been used to modify CPEs.^{9,17-20} We have employed CPEs modified with chelating resins for the determination of silver(I)²¹ and gold(III).²²

There are several studies on the use of CMEs in the electrochemical determination of iron. Wang and Martinez²³ reported that carbon-paste electrodes modified with montmorillonite clay can be used for the collection of iron(III) from dilute solutions, followed by voltammetric quantification of the surface-bound iron(III) ion. This method suffers from poor sensitivity, however, having a detection limit of only $3.6 \times 10^{-6} M$. Guadalupe and Abruña²⁴ proposed an approach based on the use of functionalized polymer films for determining iron(II) with CMEs. In addition to taking advantage of the favourable aspects of CMEs, this method circumvents the difficulties associated with surface saturation and matrix effects. Modification of platinum electrodes with quaternized poly(4-vinylpyridine) cross-linked with 4,7-diphenyl-1,10-phenanthroline disulphonic acid has recently been reported by Gehron and Brajter-Toth.²⁵ The modified electrodes were applied to the determination of iron(II) in aqueous solution. The ligand-loaded CMEs generally offer low detection limits, but are often difficult to regenerate and suffer from poor reproducibility.

In this paper we describe a new concept for the accumulation/determination approach, based on complexation of the metal ion by a ligand (2,2'-bipyridyl)²⁶ and then accumulation by an ion-exchanger (Nafion) incorporated in the carbon-paste electrode. In the work described below, the CME was easily prepared by simply mixing the required amounts of the two modifiers with a carbon-paste matrix. This allows easy variation of the two modifier contents and regeneration of the modified electrode surface. For a 3-min accumulation period, the detection limit could be extended to $10^{-8} M$ and the relative standard deviation was 3.8%. In addition, rapid chemical renewal of the modified electrode surface was possible and the CME stability was such that the surface retained its performance for several days' use.

EXPERIMENTAL

Reagents

An iron(II) stock solution ($10^{-2} M$) was prepared by dissolving the required amount of

ammonium ferrous sulphate (analytical grade, Shanghai Chemicals Factory) in 0.01M sulphuric acid. Working solutions were prepared by diluting the stock solution with water just before use.

Graphite powder and nujol oil were of reagent grade (Beijing Chemicals Factory). Nafion solution (5%) was obtained from Dupont. 2,2'-Bipyridyl and all other chemicals were of certified analytical grade and used without further purification. Doubly-distilled water from a fused-silica still was used to prepare all solutions. It was unnecessary to remove dissolved oxygen from solutions.

Electrodes

Unmodified carbon paste was made by mixing 1.0 g of graphite powder and 0.60 g of nujol oil in a mortar. Modified carbon paste was prepared similarly, except that the graphite was first mixed with the desired weights of 2,2'-bipyridyl and Nafion solutions. Uniform dispersion of the modifiers was obtained by ultrasonication of a slurry of the graphite/modifier mixture in ethanol for 15–20 min, and evaporation of the alcohol under an infrared lamp. Finally, the carbon paste was packed into one end of a glass tube (4 mm i.d., 6 mm o.d.) and a copper wire (≤ 4 mm diameter) was inserted through the opposite end to establish electrical contact. The carbon paste surface was polished on smooth paper until shiny, and then conditioned by exposure to a Britton–Robinson buffer solution (pH 5.0) containing $5 \times 10^{-5} M$ iron(II) for 60 sec, then to 1.0M potassium thiocyanate for 10 min to remove accumulated iron(II) and finally to pure Britton–Robinson buffer solution (pH 5.0) for 2 min. The conditioning cycle was repeated 3–5 times. The modified electrode could easily be resurfaced by removing some carbon paste extruded by pushing down the copper contact wire, and repolishing.

Apparatus

A PAR 174A polarographic analyser was used for cyclic and differential pulse voltammetric measurements, together with an EG&G PAR Model 0089 X–Y recorder. Unless otherwise indicated, the pulse amplitude in the differential pulse voltammetric experiments was 50 mV and the scan-rate was 10 mV/sec. A three-electrode system consisting of a CMCP working electrode, a platinum wire auxiliary electrode and a saturated calomel reference electrode

(SCE) and a 1.0M potassium chloride salt bridge was used for all voltammetric measurements. All potentials are referred to the SCE. A magnetic stirrer with a 1.5-cm stirrer bar was used in the preconcentration and electrode renewal steps. The electrolytic cell was a 20-ml beaker. All experiments were performed at room temperature (22–25°).

Procedure

A preconcentration/medium-exchange/voltammetric determination/renewal scheme¹ was used in all experiments. The preconcentration was applied to 20 ml of Britton–Robinson buffer solution (pH 5.0) containing the iron(II); the voltammetric scan was performed in iron-free buffer solution (pH 5.0). After each electrochemical determination, the electrode was kept in stirred 0.5–1.0M potassium thiocyanate for several minutes and then thoroughly washed with water and pH 5.0 buffer solution. The cleaned electrode was placed in the preconcentration cell for the next cycle.

RESULTS AND DISCUSSION

Electrochemical behaviour of iron(II) on CMCPEs

CMCPEs intended for use in routine analysis ideally involve a permanently immobilized and stable species. In practice, however, the modifier need only be insoluble enough to ensure that the rate of bleeding into the solution is very low, and slow bleeding can even have a beneficial effect for surface renewal and continuous use. The solubilities²⁶ of 2,2'-bipyridyl and its iron(II) complex are not low enough, however, for a 2,2'-bipyridyl-modified carbon-paste electrode to work well. However, because the iron(II) complex is positively charged, incorporation of a cation-exchanger as an additional modifier will reduce the rate of bleeding to an acceptable level. Nafion polymers are perfluoro-sulphonate cation-exchange polymers with good selectivity for large organic cations,²⁸ Sharp²⁹ has reported that the 2,2'-bipyridyl-iron(II) complex is strongly retained in a Nafion film on a glassy-carbon electrode. The experimental results reported in the present paper are part of an effort to evaluate this type of CMCPE and its applications in analytical chemistry.

Initial experiments showed that carbon-paste electrodes incorporating 2,2'-bipyridyl alone were unstable when immersed in aqueous solution. After a few minutes exposure to water,

the polished electrode surface became noticeably rough and subsequently exhibited little or no complexing capabilities. Furthermore, when the 2,2'-bipyridyl-modified CPE was immersed in a relatively high concentration of iron(II) solution (10^{-3} – $10^{-4}M$), a reddish colour gradually developed, undoubtedly because of loss of the modifier to the aqueous medium. In contrast, the CPE modified with Nafion and 2,2'-bipyridyl was stable and remained chemically active in aqueous medium. Therefore, only this combination of modifiers was used in further experiments.

Figure 1 shows cyclic voltamperograms obtained with the bipyridyl/Nafion modified electrode in pH 5.0 Britton–Robinson buffer in the presence and absence of iron(II). With the buffer solution alone, there is a stable and fairly low residual current over a wide potential scan range (0.3–1.3 V) and no distinct redox waves are observed for either 2,2'-bipyridyl or Nafion. The voltamperogram is not significantly different from one obtained with a plain carbon-paste electrode in the same solution except that the residual current for the CMCPE is 40–50% larger.

In contrast, the cyclic voltamperogram obtained with a CMCPE that had been immersed for 3 min in buffer solution containing $1 \times 10^{-4}M$ iron(II) and then washed with water,

Fig. 1. Cyclic voltammetric response of iron(II) on the modified electrode. (a) Blank Britton–Robinson buffer solution (pH 5), and (b) potential scan following 3-min stirring in $1 \times 10^{-4}M$ iron(II) in Britton–Robinson buffer, rinsing with water and 60-sec electrolysis at 0.3 V (vs. SCE) in pure Britton–Robinson buffer solution. Potential scan rate 100 mV/sec.

before transfer into pure buffer solution in the determination cell, had a pair of well-defined redox waves with $E_m = \frac{1}{2}(E_{pa} + E_{pc})$ of ca. 0.79 V *vs.* SCE. These waves could be obtained not only by exposure of the modified electrode to iron(II) but also for iron(III) in the same buffer solution. However, when the modified electrode was briefly immersed in an iron(II) or an iron(III) solution (each at the same concentration) under the same conditions, then rinsed and placed in the determination cell as before, the voltammetric scan exhibited larger redox waves for iron(II) ($i_{pFe^{2+}}/i_{pFe^{3+}} = 1.5-2.0$), which are more suitable for practical use. The shapes of the cyclic voltamperograms and the peak potentials of the iron(II) and iron(III) redox waves were almost identical. Because the waves occurred in the same potential region as those obtained with a glassy carbon electrode coated with Nafion and 2,2'-bipyridyl-iron(II) complex in weakly acidic solution,²⁹ they were assigned to the oxidation of the surface-accumulated iron(II) complex and reduction of the oxidized form. The cyclic voltamperogram in Fig. 1(b) indicates that there is considerable diffusion of the iron(II) complex within the Nafion matrix ($\Delta E_p = 90-100$ mV). This behaviour is attributable to the mass-transfer and charge-transfer limitations within the Nafion film and at the substrate/film interface.^{30,31} Furthermore, when the CMCPE was immersed in a more concentrated iron(II) solution in the buffer solution or a longer preconcentration time was employed, a red colour appeared on the surface of the modified electrode before the voltammetric scan.

Figure 2 shows differential pulse voltamperograms obtained after immersing the plain CPE (a) and the Nafion-2,2'-bipyridyl modified CPE (b) in a buffered $2 \times 10^{-3} M$ iron(II) solution (pH 5.0) for 3 min, at open circuit, washing, and transferring into pure buffer. The iron(II) uptake from such a dilute solution is clear. The oxidation of the surface-accumulated iron(II)-2,2'-bipyridyl complex yields a well-defined differential-pulse peak current with a peak potential of 0.83 V *vs.* SCE. No such iron(II) peak current was observed with the plain CPE. Furthermore, the differential pulse voltammetric method is more suitable than cyclic voltammetry for practical analysis: the sensitivity is greatly improved, there is better discrimination, and the peak current is easier to measure. Normal linear sweep voltammetry or cyclic voltammetry can also be used, but the detection

Fig. 2. Differential pulse voltammetric response of iron(II) on different electrodes. (a) Unmodified CPE, (b) Nafion/2,2'-bipyridyl-modified CPE. Preconcentration of $2 \times 10^{-3} M$ iron(II) in Britton-Robinson buffer solution (pH 5.0), other conditions as for Fig. 1(b). Potential scan rate 10 mV/sec, pulse amplitude 50 mV, repetition time 1 sec.

limit is much higher (e.g., $5 \times 10^{-7} M$ for a 3-min accumulation).

These results show that fabrication of a CMCPE by use of 2,2'-bipyridyl and Nafion as modifiers is based on forming and accumulating the iron(II)-2,2'-bipyridyl complex on the CPE surface. The cationic iron(II) complex is then collected by an ion-association complex with the SO_3^- site of the Nafion. The uptake properties of large organic cations such as the iron(II)-2,2'-bipyridyl complex can thus be utilized for a very efficient preconcentration step prior to electrochemical measurement.

Convenient regeneration of an analyte-free surface is particularly attractive for analytical applications of CMEs. Effective renewal combines with reproducible preconcentration and a robust electrode surface to give highly reproducible results. The utility of various cleaning methods for renewal of the modified electrode surface was evaluated. It was found that renewal was easily accomplished by dipping the electrode into 0.5–1.0 M thiocyanate solution for a certain period, usually 5–10 min, depending on the amount of iron(II) accumulated on the surface. A subsequent differential pulse voltammetric scan should show no redox waves; if it does, the renewal step must be repeated. The effective cleaning and reproducible accumulation are illustrated by the precision obtained during a series of eight preconcentration/

determination/renewal cycles with $2 \times 10^{-6} M$ iron(II) during 2 hr of continuous operation. The complete series yielded a mean peak current of $0.75 \mu A$ with a relative standard deviation of 3.8% (conditions as for Fig. 2). These results indicate that the modification method described results in a stable electrode surface with very low leaching of the modifiers into the aqueous medium.

The ability of an individual electrode to perform multiple analytical determinations with highly reproducible results is an important feature of CPEs modified with complexing agents. In the present work, the same electrode could be used for several days, performing 25–35 preconcentration/determination/renewal cycles with no noticeable loss of sensitivity or stability. Different portions of the same modified carbon paste (stored at room temperature) yielded repeatable results over a period of at least 6 months.

The differential pulse voltammetric response of a virgin modified electrode during repetitive accumulation/determination/renewal cycles is shown in Fig. 3. It is obvious that virgin CME surfaces were somewhat less effective for iron(II) accumulation than surfaces that had been previously exposed to iron(II) solutions [Fig. 2(b)]. After several cycles, however, highly

reproducible responses can be obtained when the preconcentration/determination/renewal cycles are performed under identical conditions. Enhancement of the sensitivity during the initial cycles has been found by other authors in studying other CPEs modified with organic complexing agents.^{1,2,32} The reason for the enhancement might be that the surface chelating groups of the complexing agent, after complexation with the analyte, attain a certain degree of ordering and orientation that facilitates subsequent complexation.¹ As a consequence of this behaviour, to avoid a time-dependent sensitivity in subsequent determinations virgin modified-electrode surfaces require conditioning as described in the experimental section. Similar sequences have been found essential for successful operation of other CPEs modified with complexing agents.^{1,2,32}

Optimum experimental conditions for analysis

The effect of the carbon-paste composition on the differential pulse voltammetric response of the accumulated iron(II) was tested, with the results in Fig. 4. Curve (1) shows the effect of Nafion in carbon paste (containing 13% 2,2'-bipyridyl) on the electrochemical response. The reason for the non-linear relationship is not yet certain, but may either be a greater extent of intercalation at high Nafion loading, or increasing electrode resistance. Other possible reasons are mass-transfer and charge-transfer limitations within the polymer film and at the substrate/film interface.^{30,31} The considerable change in the background current at high Nafion loading made it very difficult to determine traces of iron(II), so carbon paste with

6–10% Nafion was employed in all subsequent experiments.

The effect of 2,2'-bipyridyl in carbon paste loaded with 6% Nafion was also tested. It was found that the largest differential-pulse peak current for iron(II) occurred when the carbon paste contained 5–10% w/w 2,2'-bipyridyl [Fig. 4, curve (2)].

The solution employed in the determination step has a profound effect on the differential-pulse voltammetric response. Various electrolyte and buffer solutions were tested. Britton-Robinson buffer (pH 5.0) proved to be better than the other solutions tested (0.1M KCl, 0.1M CH₃COONa, 0.1M NH₄Cl, 0.1M Na₂CO₃, 0.1M KNO₃, 0.1M HCl, 0.2M KCl-HCl, Na₂B₄O₇-NaOH buffer, CH₃COONa-CH₃COOH buffer, 0.1M NaOH, Na₂HPO₄-KH₂PO₄ buffer, 0.05M Na₂B₄O₇ and 0.1M NaH₂PO₄), yielding the largest and sharpest peak. A 0.2M acetate buffer (pH 5.0–5.8) was also suitable for accumulating iron(II). The effect of the pH of the Britton-Robinson buffer solution on the differential-pulse voltammetric response of iron(II) is shown in Fig. 4, curve (3); the optimum pH range is 4.0–5.6. As with 2,2'-bipyridyl alone, attempting accumulation from a more acidic medium caused a drastic decrease in the peak current. At the same time, the use of a preconcentration medium more alkaline than pH 8 often resulted in premature precipitation of iron(II) hydroxide when relatively high iron(II) concentrations were encountered and the accumulation efficiency decreased

Fig. 5. Dependence of differential pulse voltammetric response of CMCPE on pulse amplitude. (1) 5, (2) 10, (3) 25, (4) 50 and (5) 100 mV. Other conditions as for Fig. 2.

Fig. 6. Dependence of differential pulse voltammetric response of CMCPE on the accumulation time. Iron(II) concentrations: (1) 2×10^{-6} , (2) 1×10^{-5} , (3) 2×10^{-5} and (4) 5×10^{-5} M. Other conditions as for Fig. 2.

drastically. Hydrogen ion is not involved directly in either the complex or the ion-association. However, owing to the basicity of 2,2'-bipyridyl, protons compete with iron(II), reducing the formation of the complex and therefore the differential-pulse response of iron(II). In alkaline solution, because of hydrolysis of the analyte, the preconcentration of iron(II) on the modified electrode surface is also less effective.

The differential-pulse voltammetric waveform offered better response characteristics than did linear-sweep voltammetry and was used in practical measurements (as shown in Fig. 2). The peak current increased quasi-linearly with the pulse amplitude over the range 5–100 mV (Fig. 5). The best signal-to-background current ratio and high sensitivity can be obtained with 50-mV pulse amplitude and this was therefore used in all other measurements.

The dependence of the differential-pulse voltammetric peak current on accumulation time for different iron(II) concentrations is shown in Fig. 6. The rate of iron(II) uptake is dependent on concentration. The peak current increased rapidly at first, then gradually more slowly until a steady-state current was reached. The steady-state currents increased with the concentration of iron(II), but non-linearly. In all cases, the preconcentration process was relatively rapid, more than 80% of the final response being generated within the first few minutes of accumulation. Such profiles were observed at the different concentrations of iron(II) employed and appeared to represent the kinetics of the cation uptake by the ion-ex-

changer. This behaviour of electrodes modified with ion-exchanger is in agreement with common models for the rates of ion accumulation in ion-exchangers.³³

Under the optimum experimental conditions, the differential-pulse voltammetric peak current increased linearly with $[\text{Fe(II)}]$ from 3×10^{-7} to $2 \times 10^{-5} M$ (3-min accumulation period) and the detection limit was $8 \times 10^{-8} M$. Because of trace amounts of iron(II) in the chemicals and water used, lower detection limits could not be reached by using longer accumulation times. The linear response may be extended by the use of shorter accumulation times. At higher concentrations the response started to level off; a possible explanation for this may be saturation of the binding sites of the Nafion film. Another possibility is mass-transfer and charge-transfer limitations in the Nafion.^{30,31}

Interferences

The most significant potential advantage of using CMEs in analytical chemistry is the opportunity that the modifier-analyte interaction affords for greatly improved sensitivity and/or selectivity. If a highly selective modifier is used, the CME should allow interferences from co-existing species possessing electrochemical behaviour similar to that of the analyte to be by-passed in a straightforward fashion. It is precisely this kind of interference that poses a nearly insurmountable problem for conventional voltammetric stripping analysis. Furthermore, because of the high selectivity toward the target analyte, a number of co-existing species have little or no effect on its determination. Co-existing ions can interfere with the determination of iron(II) if they compete for surface binding sites and reaction with the modifier or yield an overlapping response. For the specific case of 2,2'-bipyridyl, Co(II), Cu(I), Cu(II), Ni(II), Ru(III), Ag(I) and Fe(III) are potential interferences. In these studies the response of the CMCPes to $5 \times 10^{-7} M$ iron(II) was investigated as a function of increasing concentrations of these ions. It was found that additions of $5 \times 10^{-6} M$ Co(II), Cu(I), Cu(II), Ni(III), Ru(III) and Ag(I) to the iron(II) solution resulted in 28, 25, 23, 18, 20 and 15% depression of the peak current for iron(II), respectively. Addition of $5 \times 10^{-7} M$ iron(III) results in 60% enhancement of the iron(II) peak current. Anions such as CN^- and SCN^- can form complexes with iron(II) and seriously interfere with the determination. Electroactive but non-

accumulated metal ions do not interfere, because of the use of the medium-exchange procedure. Reductants such as ascorbic acid, hydroxylamine hydrochloride and hydroxylamine sulphate, which may be used to reduce iron(III) in the sample solution to iron(II) for total iron determination, have no effect on the determination of iron(II). However, in practical use, thousandfold excesses of co-existing ions (such as Al^{3+} ions) could be tolerated before the iron(II) quantification began to be affected. In these cases, no new peak currents indicative of complex or co-precipitation formation and carry-over of the interferences were observed, but a gradual suppression of the iron(II) peak became evident. This implies that, in unknown samples, large excesses of such indirectly interacting interferences might produce erroneously low results. In such instances, more accurate determination would probably be achieved by using a standard-addition method instead of a calibration graph, or by use of a prior separation step. Alternatively, selective masking of the most important co-existing ions might also be useful.

Practical applications

The Nafion/2,2'-bipyridyl-modified CPE was applied to the determination of iron in certified standard reference materials and natural waters by a standard-addition method. Aluminium samples (0.1–0.3 g) were dissolved with a mixture of 6M hydrochloric acid and 30% hydrogen peroxide in a beaker; the solutions were carefully heated (under a cover) on a hot-plate until nearly dry, then treated with concentrated hydrochloric acid and evaporated to dryness. The residues were dissolved in 7M hydrochloric acid and the iron was extracted with a benzene/methyl isobutyl ketone mixture as proposed by Jackson and Philips.³⁴

Aqueous samples were acidified with hydrochloric acid and filtered through a fine filter paper.

An aliquot of the test solution was taken and iron(III) was reduced by adding 0.2–0.4 ml of 10 mg/ml hydrochloride hydroxylamine solution; the iron(II) was then determined by the procedure above. The results agreed well with the reference values and the recovery was good enough for practical use, as shown in Table 1.

CONCLUSIONS

Although this study should be considered preliminary, the results demonstrate the feasi-

Table 1. Determination of iron in samples

bility of using an ion-exchanger such as Nafion to immobilize a large and fairly soluble organic modifier such as 2,2'-bipyridyl and its complexes for performing trace analysis by preconcentration and determination. Carbon paste is shown to be a suitable matrix for the immobilization of Nafion and 2,2'-bipyridyl in a stable, reproducible and responsive form. This kind of CME is simple and inexpensive to prepare and the modified electrodes can be easily miniaturized by using the method developed by Wang and Brennstainer³⁵ and the manual batch procedure can also be easily automated with a computerized flow system as described by Thomsen *et al.*³⁶ A variety of potential analytical applications for this kind of CME exist, based on a judicious choice of the ion-exchanger and organic complexing reagent and control of the experimental conditions. The present work can thus serve as a basis for further research in this area.

POTENTIOMETRIC DETERMINATION OF TRACE SILVER BASED ON THE USE OF A CARBON PASTE ELECTRODE

JIANHONG PEI, QUAN YIN and JIAYUE ZHONG

Chemistry Department, Wuhan University, Wuhan, People's Republic of China

(Received 12 October 1990. Revised 6 February 1991. Accepted 5 March 1991)

Summary—A carbon paste electrode used as a sensor for silver has been developed and electrode response characteristics have been investigated. The electrode exhibits linear response to the logarithm of the concentration of silver from $5 \times 10^{-7}M$ to $1 \times 10^{-2}M$, with a response slope of 63 ± 2 mV. The detection limit according to IUPAC recommendations is $1 \times 10^{-7}M$. This electrode has been used to determine trace silver in fixing solutions and waste electroplate solutions with good results.

There are many electroactive materials that can be used in Ag^+ -ion selective electrodes, but the selectivity and sensitivity of Ag_2S -based electrodes are by far the best.^{1,2} Recently, many new types of crown ethers have been synthesized and involved in the field of ion selective electrodes (ISE).^{3,4} These substances form polar cavities in which certain ions can be enclosed because of ion-dipole interactions, with the formation of a charged mobile complex which is soluble in organic solvents. This process exhibits a high degree of selectivity. Some crown ethers containing thiol have been used as ion-carriers for silver determination.^{5,6}

The idea of mixing redox couples into carbon paste electrode was introduced by Kuwana and French⁷ in 1964, with subsequent further studies by several groups.^{8,9} Although the complex issue of transport of the electroactive species to the carbon-solvent interface is not satisfactorily explained, the electrode is very useful to analysts for the determination of many trace ions.¹⁰ Considerable attention has been focused on electrochemical determinations using chemically modified carbon paste electrodes, with the pre-concentration agent mixed into a carbon paste matrix in order to react with and bind the target solute.^{11,12} The electrochemical responses are very stable and the electrode can be easily renewed by removing an outer layer of the paste and resmoothing the surface. But so far, the applications of carbon paste electrodes are mainly defined in the field of voltammetric determination and very few have been used in potentiometry. A carbon paste electrode prepared from graphite powder and Aliquat 336, a

liquid quaternary ammonium chloride, was used as a chloride ion-selective electrode.¹³

In this paper, we report a carbon paste electrode prepared from carbon graphite and Nujol oil which is used as a potentiometric Ag^+ -selective electrode. This analyte was chosen because graphite powder has a tendency to absorb silver.¹⁴ The carbon paste electrode is simple to prepare and its surface is easy to renew in a reproducible manner, which makes it very useful as an electrochemical sensor. We have investigated its response to silver and the results show that the carbon paste electrode is very sensitive and selective, using suitable masking procedures, for silver determination. The potential response of the electrode is found to be linear to the logarithm of the concentration of silver from $5 \times 10^{-7}M$ to $1 \times 10^{-2}M$, with a response slope of 63 ± 2 mV per decade concentration and a detection limit of $1 \times 10^{-7}M$. Because of the good conductivity of carbon paste, this type of electrode is a promising new form of ion-electrode, with different modifiers mixed into the matrix. The small resistance and rapid response would be welcomed in clinical analysis.¹⁵

EXPERIMENTAL

Reagents and apparatus

Graphite powder (Hongxin Chemical Reagents Factory, Beijing, China) and Nujol oil (Wuhan Chemical Reagents Factory, China) were used for the preparation of the carbon paste electrode. A 0.100M Ag^+ standard stock solution was prepared by dissolving 1.6987 g of silver nitrate (analytical grade) in a standard

100-ml flask with doubly-distilled water. The solution was placed in the shade and protected against light. The working solutions were prepared daily by suitable dilution of this solution. Sodium nitrate (1M) and sodium fluoride (1M) solutions were prepared and used as supporting electrolyte and masking agent, respectively. All other solutions used in interference studies were prepared from analytical grade salts of nitrate. Doubly distilled water was used throughout.

The electromotive force (EMF) measurements were performed at 23.1° with a PHS-10A Digital Ion-pH Meter (Xiaoshan Scientific Instrumental Factory, China). A PHS-2 pH Meter (Shanghai Analytical Instrumental Factory No. 2, China) was used for pH determination. A 314 S²⁻ ion-selective electrode (Jiangsu Electro-analytical Instrumental Factory, China) was used to determine trace silver, which gave a reference value for the carbon paste electrode.

Cyclic voltamperograms were recorded with a PAR 174A polarographic analyser equipped with a Model 0089 X-Y recorder. The three electrode system was used with a carbon paste electrode, a saturated calomel reference electrode and a platinum auxiliary electrode.

Preparation and renewal of carbon paste electrode

A carbon paste electrode was prepared by mixing 5 g of graphite powder and 3 ml of Nujol oil in a mortar. Electrode bodies were made from disposable 1-ml polyethylene syringes (3 mm i.d.), the tip of which had been cut off with a razor blade. These bodies were filled with approximately 0.3 ml of carbon paste. Smooth surfaces were obtained by applying manual pressure to the piston while holding the electrode surface against a smooth, solid support. The electrode connection to the carbon paste was established via a thin copper wire.

A fresh electrode surface was obtained by dipping the electrode into dilute ammonia solution for one minute and rinsing in water several times to remove the residual ammonium; or squeezing out a small amount of paste, scraping off the excess with a glass rod and polishing the electrode on paper until the surface had a shiny appearance.

Procedure

The carbon paste electrode was used as indicator electrode. The reference electrode was a saturated calomel electrode (SCE) which was connected to the test solution with a salt bridge

of saturated potassium nitrate in agar gel. The measurement cell was as follows:

The carbon paste electrode was immersed in 30 ml of silver test solution containing 0.3M sodium nitrate and 3×10^{-2} M sodium fluoride with stirring, using a magnetic stirrer (100 rpm), for 30 sec. Potentials were measured at rest.

Sample analysis

Transfer two milliliters of photographic fixing solution or waste electroplate solution to a 50-ml beaker containing 1 ml of concentrated nitric acid, 1 ml of concentrated hydrochloric acid and several drops of 1M sulphuric acid. Heat until gas is no longer evolved. Repeat this addition and evaporation, then dissolve the residue in 0.1M nitric acid and adjust the pH value of the solution to about 6. Transfer this solution into a 100-ml standard flask and dilute to volume with water. The concentration of silver was determined by the procedure described above, with a calibration curve.

RESULTS AND DISCUSSION

The compositions of supporting electrolyte solution

Ideal potentiometric measurements, especially in analytical chemistry, require that only the composition of the analyte solution affects the potential of the indicating electrode. This would occur only if the liquid-junction potential could be neglected. Therefore, an indifferent electrolyte of much larger concentration has to be contained in the system. Sodium nitrate (0.3M) was chosen in this system to maintain the ionic strength and minimize the liquid-junction potential. Some multi-valent ions, such as Fe³⁺, Al³⁺ and Cr²⁺, interfered with the determination, and 3×10^{-2} M sodium fluoride was used to eliminate these interferences. Potentiometric measurements also require the potential of the reference electrode to be fixed and, in this system, silver can affect the potential of the SCE. Therefore, the saturated potassium nitrate agar gel salt bridge was used to connect the solution to the reference electrode (SCE).

Effect of pH

The effect of the test solution pH on the electrode response was investigated at

$1 \times 10^{-4}M$ silver solution. The experimental results are shown in Fig. 1. At the pH range of 4.5–7, the potential remains unchanged. At higher pH values, the solution becomes turbid due to silver hydrolysis and the response decreases. At lower pH, the response decreases and dramatically becomes unstable.

The electrode response curves at different pH values are shown in Fig. 2. At a value of about 6, the electrode gives good linearity and low detection limit. The electrode exhibits little or no response to silver at much lower pH. Thus, the data shown in Fig. 2(a) can be used to calculate the selectivity coefficient for the silver ion to the hydrogen ion with the constant interference concentration method.¹⁶ The value calculated, $K^{Ag^+,H^+} = 3.98 \times 10^{-4}$ (at pH = 1.1).

Response characteristics of carbon paste electrode

The response time of the carbon paste electrode is measured in the usual way. It was found that a long response time is required for attaining a constant potential in dilute solution (below $10^{-5}M$) without stirring. In order to decrease response time it is important to stir the sample solution for a period of time prior to measurement. The test solutions are magnetically stirred for 30 sec (100 rpm). It is not recommended to measure the potential while stirring because of potential instability. The response time (to 95% of steady reading) for different concentrations of silver are shown in Table 1 (including a 30 sec stirring time). The carbon paste electrode exhibits a sufficiently stable EMF response for several months and the drift of measurement is

Table 1. The response time of the carbon electrode (95% of steady reading)

C_{Ag^+} , (M)	10^{-6}	10^{-5}	10^{-3}
Response time, (sec)	100	60	40

less than 1 mV over four hours in $10^{-3}M$ silver solution.

The ISE potential depends directly on the test ionic activity. But in analytical practice concentration values are more often required than activity values. In this paper, concentrations are used rather than activities because of the supporting electrolyte ($0.3M$ $NaNO_3$) used to maintain the ionic strength.

Figure 2(b) shows the response curve of the carbon paste electrode at pH 6. The potential of the cell assembly exhibits a linear response to the logarithm of silver concentration from $5 \times 10^{-7}M$ to $1 \times 10^{-2}M$, with a response slope of 63 ± 2 mV per decade of silver concentration. A higher silver solution concentration was not tested. The regression equation is $E(mV) = (546.6 \pm 1.5) + (63 \pm 2) \log C_{Ag^+}$ and the correlation coefficient is 0.996. According to the IUPAC recommendations¹⁷ for ion-selective electrodes, the practical detection limit may be taken as the concentration corresponding to the point of intersection of two extrapolated lines as shown in Fig. 2 and hence the detection limit is $1 \times 10^{-7}M$.

Selectivity and interferences

In $0.3M$ sodium nitrate solution, Fe^{3+} , Cr^{3+} and Al^{3+} severely interfere with the determination of Ag^+ . A concentration of $3 \times 10^{-2}M$ F

is added as a masking agent to eliminate these interferences.

The selectivity coefficients of the carbon paste electrode were evaluated by the constant interference concentration method.^{17,18} The concentrations of the interference ions used were as follows: $0.1M$ Na^+ , K^+ , Ca^{2+} , Mg^{2+} , Zn^{2+} and Cd^{2+} ; $1 \times 10^{-2}M$ Li^+ , Fe^{2+} , Co^{2+} , Ni^{2+} and Sn^{2+} ; $1 \times 10^{-3}M$ Fe^{3+} , Cr^{3+} , Al^{3+} and Pb^{2+} and $1 \times 10^{-4}M$ Hg^{2+} and Cu^{2+} . After each interferent is investigated, the electrode is washed with water thoroughly and carefully dried with a fine filter paper. The experimental results are shown in Table 2.

Electrode renewal and its reproducibility

It is important to renew the electrode surface when the silver solution is changed from high concentration to a dilute solution because residual silver will still be adsorbed on the surface of the carbon paste electrode which will lead to poor reproducibility. The appropriate renewal process is described above. Renewal with ammonia water solution is recommended as the same electrode surface is utilized for a series of consecutive determinations. In this manner, the surface-to-surface variability occurring when the carbon paste is manually refreshed could be avoided and at the same time, an improvement in speed and flexibility of the procedure is achieved.

Six different carbon paste electrodes were used at the same time to determine $1 \times 10^{-4}M$ silver solution in order to test parallel results (Table 3).

To evaluate the reproducibility of emf response of the cell assembly, alternating

measurements were performed in $1 \times 10^{-5}M$ and 1×10^{-3} silver solution (ion background: $0.3M$ sodium nitrate, $3 \times 10^{-2}M$ sodium fluoride). The procedure was repeated six times and the results are shown in Table 4. (The electrode surface is renewed for each high/low concentration measurement cycle).

Practical applications

Trace silver in the fixing solution and waste electroplate solution was determined with this electrode. The treatment of samples was described above. The commercial $314 S^{2-}$ ion-selective electrode was used to give the reference values¹⁸ and the results are given in Table 5.

Possible response mechanism of carbon paste electrode to silver

The carbon paste electrode was immersed in $0.3M$ sodium nitrate and $2 \times 10^{-3}M$ Ag^+ solution, which was stirred with a magnetic stirrer. After 5 min, the electrode was removed from the solution and rinsed thoroughly with water, then dipped in $0.3M$ sodium nitrate solution (oxygen

free) and the cyclic voltamperogram was recorded. Figure 3 indicates that carbon paste has a tendency to adsorb the silver ion. This phenomenon has been noted by Cheek and Nelson.¹⁴ The phase boundary potential may originate from the adsorption of silver at the surface of the carbon paste electrode. Further evidence arises from the fact that dilute ammo-
